The corpus callosum, with at least 200 million nerve fibers, is the largest fiber tract that connects the two cerebral hemispheres. Comparison of split-brain patients with intact individuals provides a clear indication that the corpus callosum is critical to normal interhemispheric interaction, especially interaction that requires the transfer of information about the identify or name of a stimulus. Although there are no cortical landmarks that divide the corpus callosum, it is generally the case that different regions of the corpus callosum contain fibers originating in different cortical areas. That is, anterior portions of the corpus callosum contain primarily fibers that originate in premotor and frontal regions of the cortex, middle portions contain fibers that originate in motor and somatosensory, regions, and so forth. In addition, many callosal fibers are homotopic; that is, they connect homologous areas of the two hemispheres. An interesting hypothesis is that these fibers produce a type of homotopic inhibition at the computational level, thereby producing mirror-image patterns of activation and inhibition in the two hemispheres, which could be described as a kind of complementarity and that might contribute to the development of hemispheric asymmetry. However, the corpus callosum also contains fibers that originate in a specific region of one hemisphere and terminate in a completely different region of the opposite hemisphere, creating a mechanism whereby neural activity within one hemisphere could have more generalized excitatory or inhibitory effects on neural activity within the other hemisphere.

At a functional level, we have seen that the two hemispheres are often dominant for different task-relevant processing components. In such cases, each hemisphere is likely to take the lead for those components of processing that it handles best. In order for the two hemispheres to coordinate their activities effectively, the results of processing must be integrated across the two hemispheres. At the same time, many hemispheric asymmetries seem to involve complementary analyses of the sort that depend on incompatible neural computations, and it would seem useful to insulate those computations from each other in order for them to proceed efficiently at the same time.

With this in mind, it is not surprising that the corpus callosum has been hypothesized to play two important but very different roles: transferring information between the hemispheres and creating a kind of inhibitory barrier that minimizes maladaptive cross talk between the complementary processes for which each hemisphere is dominant.

Although the corpus callosum is certainly critical for certain forms of interhemispheric interaction, it is also clear that some types of information can be transferred subcortically. This includes information about the categories to which an object belongs, contextual information about an object, and certain aspects of information about spatial location. Subcortical structures can also play a role in producing unified

behavioral responses. Although the two hemispheres of the intact brain are capable of sharing many types of information, cooperation at all levels does not necessarily occur all the time. Studies of perceptual processing in normal individuals provide important insights about the factors that determine when it is more efficient for the two hemispheres to operate collaboratively than to operate independently. Laterality techniques described earlier have been modified to include trials that demand interhemispheric collaboration by presenting each hemisphere with only a portion of the total information needed to perform a task (the across-hemisphere condition) and comparing performance to conditions that present all the relevant information to one hemisphere (the within-hemisphere condition). One general conclusion suggested by this research is that distributing information across both hemispheres becomes more beneficial as the task becomes more demanding of attentional resources. That is, when the processing demands are minimal (such as indicating whether two letters are physically identical), there is often a within-hemisphere advantage. However, when the processing demands are increased (such as indicating whether two letters of different case have the same name or whether both are vowels), there is typically an across-hemisphere advantage. Dividing input between the two hemispheres is also beneficial when it permits them to engage in mutually inconsistent processes and at earlier compared to later stages of practice, although these may simply be additional ways of manipulating overall processing demand.

A somewhat different aspect of interhemispheric interaction has been studied in experiments that include bilateral redundant trials in which exactly the same information is presented simultaneously to both hemispheres. When normal observers attempt to identify printed consonant–vowel–consonant letter trigrams, there is a right visual field (left hemisphere) advantage, and the pattern of errors is different for the two visual fields (and hemispheres). On right hemisphere trials there are many more third-letter errors than first-letter errors, as if individual letters are processed in order one at a time. On left hemisphere trials this difference is reduced, even when the error types are normalized to compensate for the left hemisphere advantage. This may reflect the left hemisphere's ability to treat the trigram as a single pronounceable unit and thereby spread attention more evenly across the letters. When the same three-letter stimulus is presented simultaneously to both hemispheres, performance is even better than it is on left hemisphere-only trials, indicating the benefit of including both hemispheres in processing. In view of the very good level of performance on redundant bilateral trials, one might expect the error pattern to be like that obtained on left hemisphere-only trials. In fact, the error pattern on redundant bilateral trials is intermediate between the left and right hemisphere patterns (and often more similar to the right hemisphere pattern), again suggesting processing contributions from both hemispheres.

The processing strategy on redundant bilateral trials is not always a mixture of the different strategies used on unilateral trials. In some cases, the bilateral strategy has been identical to the strategy associated with one hemisphere or the other. Interestingly, when this happens it is not always the strategy of the more efficient hemisphere that emerges on bilateral trials. In fact, it is not always possible to derive the processing strategy on bilateral trials from knowledge of the strategies utilized on unilateral trials. For example, in experiments that required normal observers to make rhyming judgments, certain effects of letter font and case on bilateral trials could not be predicted at all from the complete absence of such effects on unilateral trials. This suggests that interhemispheric collaboration can also have emergent properties that are impossible to deduce from the sum of the parts provided by the two individual hemispheres. It will be important in future studies to identify the factors that determine which of these different types of functional interaction will be observed and the biological mechanisms that underlie the different types of interaction. Uncovering the mechanisms of interhemispheric interaction may also have more general implications for how it is that unified processing emerges from a brain consisting of highly specific, modular subsystems.

V. LATERALITY IN NONHUMAN SPECIES

Behavioral and biological laterality is also ubiquitous in many nonhuman species, with many instances of asymmetry being at least analogous to asymmetries found in humans. At least some may also be homologous, in the sense of sharing common structures and developmental origins. Here, I review some of the most well-established laterality effects in other species and note their relationship to human laterality.

Motor asymmetries have been discovered for a number of species, with individuals sometimes showing very strong left–right preferences. However, population-level biases have been much rarer and none

has matched the magnitude of right-handedness in the human population. Furthermore, preferences seem to depend on variables such as age and sex and on specific task demands. Despite these caveats, in several species of primates there tends to be a left-hand preference for reaching and maintaining postural control but a right-hand preference for manipulation and other high-level skilled activities. In addition to individual variation in paw preference, individual members of many species of mice and rats show a preference to turn in one direction or the other. Although an individual may exhibit a strong directional rotation bias, approximately equal numbers prefer each side. That is, there does not tend to be a population-level asymmetry. Individual rotation biases in rats have been related to asymmetries in distribution of the neurotransmitter dopamine, although the specific direction of the relationship differs for different populations.

There are also certain parallels between left hemisphere language dominance in humans and asymmetries in other species for the production and perception of vocalizations. In Japanese macaques, for example, the left hemisphere is dominant for the discrimination of species-specific vocalizations that are relevant for communication but not for the discrimination of other vocalizations. Also, in chimpanzees that have been trained to use certain visual symbols to communicate, there is evidence of left hemisphere dominance for processing those symbols but not for processing other, nonmeaningful symbols. There is even evidence that the ultrasonic calls emitted by rat pups are processed preferentially by the left hemisphere of their mother and it is well-known that there is left-brain dominance for the control of song in some species of song birds.

A number of asymmetries have been reported with respect to processing the identity and spatial characteristics of visual stimuli. In language-trained chimpanzees, for example, there is a right hemisphere advantage for processing the location of a line within a geometric figure and for identifying complex visual patterns that are not relevant for communication. In addition, rhesus monkeys have been reported to have right hemisphere superiority for recognizing monkey faces. In rats, there is evidence that the right hemisphere may be more involved than the left hemisphere in spatial exploration, although the asymmetry emerges only in rats that have been handled during the course of their early development. Pigeons and newly hatched chicks exhibit left hemisphere dominance for visual pattern discrimination. In chicks, this population-level bias occurs because light strikes only the right eye during a critical period of incubation during which the visual system is developing rapidly. Finding effects of such variables as handling and light stimulation suggests that functional hemispheric asymmetries are likely to be shaped by the complex interaction of both biological and environmental factors.

Research with rats and chicks has also demonstrated asymmetry for emotional behaviors. For example, in both handled rats and chicks the right hemisphere tends to produce emotional activity, whereas the left hemisphere tends to inhibit emotional activity. In addition to providing interesting instances of laterality, effects such as these also illustrate the importance of reciprocal activity between the left and right sides of the brain.

There are also indications that some of the biological asymmetries found in the human brain characterize the brains of certain primates, although the nonhuman asymmetries are smaller and less frequent than those of humans. For example, the brains of both humans and apes show the kind of counterclockwise torque described earlier and in chimpanzees as well as humans the Sylvian fissure tends to be longer on the left side than on the right side.

As noted previously, it is difficult to know which laterality effects in other species are truly homologous to the effects found in humans. Nevertheless, the presence of so many asymmetries in other species provides a useful range of animal models that can be used to learn about the development of laterality across the life span of an individual and across evolutionary time. Among other things, laterality in other species indicates that the emergence of language is not a prerequisite for the emergence of other behavioral and biological asymmetries.

VI. LATERALITY ACROSS THE LIFE SPAN

The various functional aspects of laterality correlate with each other weakly or not at all. This is inconsistent with the hypothesis that there is but one fundamental processing dimension along which the hemispheres differ and from which all laterality effects are derived. Consequently, laterality is unlikely to be determined by any single developmental influence. Instead, the relative independence of different manifestations of laterality indicates that there are probably several different biological factors that interact with several different environmental influences to determine an individual's pattern of laterality. Furthermore, the laterality patterns that are characteristic of mature

individuals are likely to be rooted in early stages of ontogenetic development. In this section, I outline several promising developmental possibilities.

As noted previously, the emergence of laterality in the domestic chicken illustrates how laterality can result from the interplay of biological and environmental factors. During the last 5 days of incubation, the head of the chick embryo is turned so that the left eye is pressed against the body and the right eye is turned out toward the egg shell. If the egg (and, therefore, only the right eye) is exposed to light stimulation during this critical period, the chick becomes left hemisphere dominant for making visual discriminations and the right hemisphere becomes dominant for attack and copulation behavior. Lesley Rogers and colleagues have shown that it is possible to eliminate these population-level asymmetries by incubating the egg in darkness and to reverse them by experimentally manipulating the embryo so that only the left eye receives light stimulation. It is instructive to consider whether similar developmental scenarios might exist for humans.

During the course of fetal development in humans, certain areas of the right hemisphere seem to develop earlier than homologous areas of the left hemisphere. Various possibilities have been suggested as to the manner in which certain functional asymmetries could arise from the interaction of these maturational asymmetries and changes in the nature of environmental stimulation. One promising idea is that the earlier developing right hemisphere is initially more influenced than the lagging left hemisphere by the impoverished information that the developing brain encounters. This might include nonlinguistic intrauterine noises, global properties of visual stimuli in newborns, and coarse sensorimotor feedback before and for a few weeks after birth. By being more responsive to these early environmental influences, the right hemisphere may become dominant for perceiving various nonphonetic sounds, for processing global properties of visual stimuli, and for maintaining postural control. In contrast, by being on a later developmental trajectory, the left hemisphere may be saved for complementary specializations that involve processing of more detailed or finer-grained information and sensorimotor feedback and control. In addition, other asymmetric growth spurts during childhood may provide a mechanism for the continuing unfolding of functional hemispheric asymmetry. For example, between 3 and 6 years of age frontal and occipital areas of the left hemisphere appear to develop more rapidly than homologous areas of the right hemisphere, coinciding with a developmental period that is also critical for the acquisition of several aspects of language for which the left hemisphere is dominant.

Psychologist Fred Previc has proposed that several additional prenatal asymmetries also influence later functional asymmetry. One hypothesis for which there is evidence is that certain craniofacial asymmetries that begin to appear as early as the first trimester of pregnancy lead to greater sensitivity of the right ear to sounds in the auditory frequency range that is critical for speech and that, as a result, the left hemisphere becomes more responsive to speech. It has even been suggested that this increased responsivity to speech may set the stage for the development of left hemisphere dominance for speech production. Asymmetries of fetal position during the last trimester of pregnancy have also been linked to later handedness. One ambitious hypothesis for which there is circumstantial evidence is that the typical position of the fetus during the last trimester favors enhanced development of the otolith on the left side, and this asymmetry in the organs of balance favors use of the left side for postural control and use of the right side for other more skilled activities. In view of the fact that there are neural connections between primary vestibular cortex and parietal areas, it has even been suggested that asymmetry in the organs of balance sets the stage for later right hemisphere dominance for spatial processing.

Additional research is needed to provide further tests of these hypotheses and others. Whatever the outcome, it is likely that asymmetries that are very small and subtle when they first appear can eventually have profound effects. As the developing organism encounters new and richer stimulation, the extent to which the brain's neural networks are responsive is likely to be influenced by how those networks have already been modified. It is reasonable to suppose that even a subtle difference can make one hemisphere more responsive than the other to some aspects of new sensorimotor information. In fact, neural network simulations illustrate the plausibility of such scenarios. As this process is repeated, laterality may snowball into the pattern characteristic of adults.

With the foregoing in mind, it is interesting that tasks and processes that are lateralized in adults seem to be lateralized from the time they can be accurately assessed. For example, there are indications that even in newborns there is a kind of left hemisphere dominance for speech perception and that activation of the left and right hemispheres is associated with positive and negative emotions, respectively. Also, in infants as young as a few months of age there appears

to be left and right hemisphere superiority, respectively, for processing local and global aspects of visual patterns.

At the other end of the life span, it has been hypothesized that performance of the right hemisphere declines more rapidly in old age than does performance of the left hemisphere. Despite a number of careful investigations, there is little or no evidence to support this right hemiaging hypothesis. Instead, it appears that lateralized processes remain so throughout the life span and that, on average, the performance of both hemispheres changes in the same way. However, there are indications of an age-related decline in the efficiency with which the two hemispheres can communicate and coordinate their activities.

VII. EVOLUTION OF LATERALITY

The seeds of laterality were sown in our distant evolutionary past and may even be related to asymmetry in the molecules and particles of which all living things are constructed. Here, I outline a plausible scenario for the evolutionary emergence of human laterality. Although accounts of evolution remain speculative and difficult to test, the following scenario is built on what has already been said about laterality across species and on more detailed discussions of evolutionary considerations that I and others, including Michael Corballis and John Bradshaw, have offered elsewhere.

In freely moving animals, there are strong evolutionary pressures for bilateral symmetry in the placement of sense organs and limbs and in those parts of the brain that are associated with them. This is so because such animals must be equally attentive to both sides of space and be able to move in a straight line. However, there is little pressure toward symmetry for other systems that are not involved in direct sensory registration or in direct motor responses to the environment. In fact, asymmetry may be favored in such cases as a way of packaging organs more efficiently into the body cavity or of packaging cognitive functions more efficiently into a brain whose size is limited. Once an organism's brain becomes functionally asymmetric, additional asymmetries are likely to arise via the same kind of snowball mechanism discussed earlier with respect to the development of laterality within an individual. That is, at least some of the additional evolutionary adaptations that are favored by the environment are likely to be implemented more effectively by one side rather than the other, with the result that those new adaptations also become asymmetric. Note that this would occur regardless of whether the environment favored hemispheric asymmetry for the new adaptations. As this process is repeated, the extent of functional brain asymmetry increases.

We have seen that at least some of the hemispheric asymmetries found in contemporary humans are matched by similar, although usually weaker, asymmetries in other contemporary species. By taking into account how long ago we shared a common ancestor with various contemporary species, we can use the asymmetries found in those species to suggest what sorts of laterality may have been present at different moments in our ancestral line. For example, the existence of a left-hand preference for visually guided reaching in present-day prosimians suggests that at least some type of motor asymmetry was present in our ancestral line by the time our line branched from the prosimian line, nearly 60 million years ago (mya). This left-hand advantage extends to some species of Old World monkeys. In addition, some species of Old World monkeys show right hemisphere dominance for processing monkey faces and left hemisphere dominance for processing communicatively relevant vocalizations. The similarity of these asymmetries to those of humans suggests that their precursors were present in our last common ancestors, approximately 40 mya. Contemporary chimpanzees show right-hand dominance for certain high-level tasks as well as left and right hemisphere dominance for processing communicatively relevant symbols and certain visuospatial tasks, respectively. Thus, it is possible that these asymmetries were present in the last common ancestors we shared with chimpanzees, approximately 5 mya.

Although it is admittedly speculative, the foregoing is sufficiently plausible to suggest that some forms of hemispheric asymmetry were already present in our ancestral line before the first hominids emerged approximately 4 mya. If so, then the initial appearance of hemispheric asymmetry was not triggered completely by either language or tool use, as some earlier evolutionary accounts maintained. To be sure, language and tool use are among the critical milestones that set us apart from other species, and along with other milestones, such as walking upright, they are likely to have played an important role in the continued evolution of brain laterality.

Hominids mastered the art of standing and walking upright in the period from 2 to 4 mya. This seems to have been a very important milestone for a number of

reasons. For example, an upright stance freed the hands from the need to provide postural support and minimized their use in locomotion. As a result, the hands were under less environmental pressure to be controlled in a symmetrical fashion. In fact, for efficient performance in activities such as the manufacture and use of tools, the two hands must be used in a complementary fashion; for example, one hand holds a stone while the other hand chips away at it to fashion the point of a spear or a scraper. The precursors of handedness in other primate species suggest that sufficient asymmetry already existed to produce a bias toward right-handedness for the more skilled aspects of movement (e.g., chipping a stone held by the left hand). In addition, prior left hemisphere dominance for vocalization may also have contributed to make the left hemisphere a more efficient neural substrate for the organization of purposeful, sequential actions in which spatial constraints imposed by the environment are minimal (i.e., for what has been termed manual praxis). In fact, an analysis of the flaking patterns on stone tools manufactured by *Homo habilis* suggests that the majority of the population was already right-handed as far back as 1.5–2 mya. Interestingly, study of casts taken from the inside of skulls indicates that certain structural asymmetries (e.g., longer left hemisphere Sylvian fissure) were also characteristic of the brains of *H. habilis*.

Tool making and language are both forms of praxis and involve properties such as recursion, embeddedness, and generativity. Both gestural communication and vocalization also require sequences of precisely timed movements. In view of these similarities, there may have been pressure for the same brain hemisphere to become dominant for those aspects of vocalization and language that are shared with tool making and gestural communication. Certainly, tool use and language seem to have interacted in a synergistic fashion to produce dramatic changes in human skill in the period from 10,000 to 30,000 years ago.

Additional factors are also likely to have contributed to the continued evolution of laterality. For example, we have seen that the corpus callosum may have evolved, in part, to reduce maladaptive cross talk between computations performed by homologous regions of the two hemispheres. With respect to brain asymmetry, this would add to the evolutionary advantage of segregating complementary or mutually inconsistent processes into opposite hemispheres. In addition, contemporary humans are characterized by a prolonged period of postnatal immaturity, a characteristic that is believed to have emerged approximately 2 mya. We have seen that homologous areas of the two hemispheres may mature at different rates. It seems likely that the consequences of such maturational gradients would be greater to the extent that the brain undergoes less of its development in the impoverished uterine environment and more of its development postnatally, especially because the sensorimotor capacities of newborns change dramatically during the first few days, weeks, and months after birth.

VIII. INDIVIDUAL VARIATION IN LATERALITY

Thus far, I have emphasized contemporary human laterality patterns that could be considered prototypical, as if we were all more or less identical. Although there is sufficient homogeneity to justify consideration of the prototype, there is also sufficiently reliable heterogeneity to warrant consideration of individual variation. Of particular interest has been the possible relationship of functional hemispheric asymmetry to a number of other between-subject factors, including handedness, sex, intellectual ability, and psychopathology.

Handedness is of particular interest because it is a behavioral manifestation of brain laterality for certain manual activities and it is also related to other, more cognitive aspects of laterality. Hand dominance is determined by a variety of genetic and environmental factors, both before and after birth. The direction and magnitude of hand dominance may even be determined by different factors, with the magnitude being more heritable and with the direction being more subject to environmental influence. Environmental influences include pre- and postnatal trauma, prenatal levels of testosterone and other hormones (higher prenatal levels of testosterone are associated with greater incidence of left-handedness), asymmetric positioning of the fetus *in utero*, as well as the biases of the postnatal world. As noted previously handedness is at least moderately related to other forms of laterality. On average, laterality for a group of left-handed individuals is in the same direction as that for a group of right-handed individuals, but the magnitude of the asymmetry is smaller. This group difference does not necessarily occur because individual left-handed people are uniformly less lateralized than individual right-handed people since more left-handers than right-handers show a laterality effect in a direction opposite that which is considered prototypical. Rather, there is a greater proportion of left-handed individuals who show a laterality effect in a direction

opposite that which is considered prototypical. It is noteworthy that even though the relationship between handedness and other forms of laterality is only of weak to moderate strength, it has been demonstrated by all the various techniques and tools that are used to study laterality. This suggests that if the relationship of laterality to other variables such as biological sex were as strong as the relationship of laterality to handedness, it would be relatively straightforward for these techniques to uncover.

There are many effects of fetal hormone levels on brain development in other species, and in humans there are clear relationships between biological sex and cognitive ability. For example, women tend to outscore men on tests of verbal fluency, and men tend to outscore women on tests of spatial ability. Thus, it is plausible that there are sex-related differences in at least some aspects of brain laterality. This possibility receives modest support from the fact that the incidence of left-handedness is slightly higher in men than in women, consistent with the hypothesis that higher levels of fetal testosterone promote development of the right hemisphere relative to the left hemisphere. When handedness is controlled, however, evidence for additional sex-related changes in other forms of laterality is equivocal. The most encouraging indications of such relationships have come from the observation of deficits in patients with unilateral brain damage, with some studies finding evidence of greater functional hemispheric asymmetry in men than in women. However, not all studies have shown such sex differences and there may be alternative explanations for some of them. For example, it has been suggested that there is a lower rate of aphasia after left hemisphere damage in women than in men because of sex-related differences in the organization of language within the left hemisphere rather than because of differential lateralization per se. Behavioral laterality studies using neurologically intact men and women provide, at best, weak support for the hypothesis of greater functional laterality in men because the results have been quite variable. Also, even when sex-related differences are found, there are sometimes alternative explanations in terms of the tendency for men and women to prefer different cognitive strategies that may bias performance toward different hemispheres. Perhaps most clear is that if the laterality differences between men and women were as large as the laterality differences between right-handed and left-handed individuals, they would be well-known by now.

There are indications that individual variations in brain laterality may be related to individual differences in cognitive ability. For example, relative performance on tests of verbal and visuospatial ability are related to handedness, but the relationship appears complex and is moderated by sex and by overall reasoning ability. There is also evidence that extreme intellectual precocity, especially for mathematical reasoning, is related to advanced development of the right hemisphere relative to the left, perhaps as a result of increased testosterone levels during fetal development. It also appears that some forms of dyslexia (impaired acquisition of reading) are related to subtle abnormalities within the language areas of the left hemisphere, perhaps leading to an overreliance on the less efficient mechanisms of the right hemisphere. Considerable additional work is needed, however, to substantiate these relationships and to discover the precise mechanisms that might account for them.

The existence of hemispheric asymmetry for emotion has led to consideration of the possible relationship of laterality to psychopathology. Among the more promising hypotheses is the idea that schizophrenia is related to dysfunction of an anterior region within the left hemisphere, an area that is believed to be important for language and for controlling parietal areas involved in attention. It has also been hypothesized that the corpus callosum, and therefore interhemispheric interaction, is dysfunctional in schizophrenics, but these hypotheses remain controversial and may apply to only a subset of schizophrenics. In a complementary way, depression has been linked to disturbances of the right hemisphere, but more work is needed to confirm this link and to understand its functional significance.

Popularized accounts of laterality have suggested that people can be classified as ''right-brained'' or ''left-brained'' depending on whether they prefer to use strategies and modes of cognition associated with one hemisphere or the other. Thus, left-brained people are said to be rational and analytic, whereas right-brained people are said to be intuitive, artistic, and creative. A few well-rounded individuals might even be lucky enough to be identified as ''whole-brain thinkers.'' Various paper-and-pencil schemes have been proposed to achieve this sort of classification or measure of ''hemisphericity,'' and exercises have been proposed to help more of us utilize whichever side of the brain we tend to neglect. To be sure, there is individual variation on the various dimensions of laterality, but there is no evidence that any neurologically intact individuals are functionally half-brained in the manner referred to as hemisphericity. Individuals do differ reliably in cognitive style, personality, creativity, and so forth. At the

same time, however, we have seen that hemispheric asymmetries are subtle, with no indication that aspects such as rationality and creativity are the exclusive product of one brain hemisphere. Instead, both hemispheres contribute to virtually everything we do.

IX. CONSCIOUSNESS, MIND, AND THE DUAL BRAIN

The dual nature of the human brain has led to interesting discussion of the implications for consciousness and mind. Among other things, the discovery that both of the disconnected hemispheres of split-brain patients have a good deal of competence with respect to perception and motor control has led to speculation about whether or not the surgery has produced a doubling of consciousness or resulted in people with two minds. The neurobiologist Roger Sperry, who won the Nobel prize for his work with these patients, believed that this was the case. In part, he based his conclusion on the fact that the disconnected right hemisphere has its own perceptions, cognitions, and memories of which the disconnected left hemisphere is completely unaware. Others, however, have questioned whether the right hemisphere can truly think and whether its limited abilities include the same level of awareness and consciousness that seems typical of the left hemisphere. Certainly, the disconnected right hemisphere is usually incapable of speech and other forms of verbal communication that are uniquely human and that some have argued, are essential for the concept of "mind." Of course, there is much debate among philosophers and cognitive scientists about the extent to which language is essential for thinking, conscious reflection, or mental life.

An interesting hypothesis, advanced by Joseph LeDoux and Michael Gazzaniga, is that an important function of an individual's verbal left hemisphere is the construction of an internal, subjective reality or ongoing narrative based on its observations of his or her own overt behavior. In this view, observation of one's own behavior is necessary because many processes that influence behavior are not open to conscious experience. LeDoux and Gazzaniga emphasize this with respect to behavior and bodily sensations produced by the right hemisphere, of which the left hemisphere would have no direct knowledge. However, even within the left hemisphere there appear to be a great many modules whose processes may influence behavior but that are not themselves open to conscious awareness. Thus, the need to create an ongoing personal narrative by making inferences about one's own behavior is likely to extend to covert processes performed by both hemispheres. More work is clearly needed, however, to test these and other hypotheses about the different roles played by the two cerebral hemispheres in the emergence of mind from brain.

Left-Handedness

STANLEY COREN
University of British Columbia

GLOSSARY

Broca's area The location in the brain, typically the left hemisphere, that controls speech production.

diffuse control system This refers to control of a function or behavior that involves a number of brain centers and pathways.

genetically fixed traits Genetically determined traits that are characteristic of a particular species.

pathological handedness Handedness that results after some pathological event, such as birth stress-related events, disturbs the natural development of right- or left-handedness.

rare trait marker theory A theoretical and statistical model that explains why relatively rare, but apparently benign, traits in a species are often associated with pathological conditions.

sidedness The preferential use of the right or left hand, foot, eye, or ear.

soft sign A behavior or symptom that may suggest the presence of an underlying neurological or physiological pathology.

Wernicke's area The location in the brain, typically the left hemisphere, that controls speech comprehension.

Handedness refers to the fact that most people consistently use the same hand for tasks in which skill and dexterity are required and only one hand can be used. Thus, a person who almost always uses his or her right hand when writing, throwing a ball, cutting with a knife, or using a hammer would be defined as being right-handed. Estimates of the number of right-handers in the population are between 88 and 92%. Given such an overwhelming bias toward the right in humans, it is not surprising that researchers have asked the following questions: If, as a species, we appear to be programmed to be right-handed, then why are there any left-handers? Do left-handers differ from right-handers in any ways other than their handedness? Are there any advantages or disadvantages in being left-handed?

I. SIDEDNESS

Although everyone probably knows about the existence of handedness, most people are unaware of the fact that it is just one aspect of a group of lateral biases. In the same way that we are handed, we are also footed. One would demonstrate footedness in tasks such as habitually using the same foot to step on a bug or to kick a ball to hit a target. In footedness, humans also show a right-sided bias, with approximately 80–82% of the population being right-footed.

In addition to showing motor biases favoring one side, we also show sidedness in the use of our bilateral sense organs. We demonstrate eyedness by consistently choosing the same eye to sight down a telescope or to peep through a small hole. We would be showing earedness by usually choosing the same ear to listen to the faint ticking of a clock or to press against a door to hear noises on the other side. These manifestations of sidedness are also biased toward the right, although

not as strongly as for hands and feet. Approximately 66–71% of the population is right-eyed, and 58–60% are right-eared.

Although it is clear that as a species we are right-sided, the specific proportions may vary from one study to another, depending on the particular definition used to define any aspect of sidedness. Thus, most researchers define the dominant hand as being the hand that people prefer to use for skilled tasks. Others may use the skill or strength of the hand as a measure. In addition, some researchers require consistent right-sided preference in all tasks for an individual to be classified as right–sided for that index, whereas others only require that a majority of responses show the dextral bias. One can usually tell when this latter definition is being used since the labels given for a particular aspect of sidedness might be "right-sided" versus "non-right-sided" as opposed to "right-sided" versus "left-sided"; however, regardless of the definitions or scoring procedures used, the predominance of right–sidedness in human populations is clear.

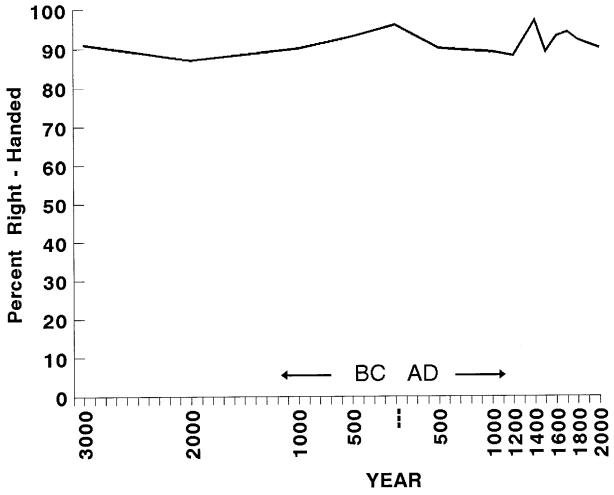

Figure 1 Analysis of handedness as shown in artworks over a period of approximately 50 centuries.

II. THE EVOLUTION OF HANDEDNESS

The nature of human handedness is unique among mammalian species. We can set up situations, analogous to handedness tests in humans, in which animals must manipulate something with only one paw. This might be a task in which a cat must reach down a relatively narrow tube to pull out a treat or in which a monkey must insert a stick into a small hole to get something to eat. When we do this, we find that most cats, rats, and monkeys are right- or left-pawed. Although individual animals show behaviors analogous to handedness, there is one major difference between these animals and humans. Whereas 9 of 10 humans are right-handed, in other species the proportion of right- and left-sided individuals is approximately 50%. In other words, there is not right-sided bias to the animal population.

It is possible to estimate the handedness of humans over history to determine if we were always right-handed. Figure 1 shows the results of a study that examined paintings and drawings, reasoning that if artists were drawing from life, then they would draw the tools and weapons held by their models in the hand that they saw the person using. Analysis of more than 50 centuries of such drawings found that the proportion of right-handedness remained at approximately 90% from the Paleolithic Era (the Old Stone Age) until the present. The date when right-handedness became dominant in our species can be pushed further back in time. Paleontologists have examined the wear patterns on stone tools and the grinding marks on devices used to grind grains. These tools and implements date back between 8000 and 35,000 BC and involve the early humanoid *Homo habilis*, one of the earliest tool makers. The wear patterns on these artifacts confirm that even at that early date, there appeared to be a consistent predominance of right-handers. Perhaps the most astounding evidence derives from more than 1.5 million years ago, involving one of our very early hominid ancestors, australopithecus. Although the australopithecines were not tool makers, they were tool users and would pick up an appropriately sized and shaped rock or stick and use it for a weapon. Examination of the skulls of baboons hunted by this early precursor to humans shows that the vast majority of these hominids were already right-handed.

III. THE GENETICS OF HANDEDNESS

Given the evidence that handedness patterns in humans extend far back into evolutionary history, it is not surprising that the vast majority of theories of handedness have included the suggestion of a genetic factor. There have been a number of studies that have examined handedness in families in order to verify this hypothesis. Unfortunately, the empirical evidence on handedness does not strongly support genetic theories.

There is a fairly consistent finding that left-handedness is more likely in children of left-handed mothers. However, when we do the fine-grain analyses needed to determine that a characteristic is inherited, the numbers relating the father's handedness to that of the offspring, the relationship between brothers and sisters, or predictions from the grandparent's handedness just do not seem to fit the patterns required by most genetic models. Some theorists are still trying to work out more sophisticated mathematical descriptions that might show that handedness is inherited; however, there is still a strong element of doubt in the data.

Perhaps the most compelling evidence against a simple, strong genetic determinant for handedness comes from the results of studies that compared the handedness of monozygotic or identical twins with those of dizygotic or fraternal twins. Twin studies are usually considered as providing the clearest indication of the presence or absence of inherited components for most behavioral traits. Monozygotic twins have an identical set of genes since they come from a single egg, fertilized by a single sperm, that later splits into two individuals in the early stages of cell division. Dizygotic twins come from two egg cells fertilized by different sperm; hence, they share only the level of genetic similarity that we would find between any pair of brothers or sisters. This means that, at a minimum, if there is a genetic component in handedness, one would at least expect that pairs of monozygotic twins would be more likely to have the same handedness than dizygotic twins. Figure 2 summarizes the results of 16 studies that compared the handedness of twins. Notice that there is no difference between monozygotic twins and dizygotic twins with regard to the likelihood that they will share the same handedness. Even more striking is that the likelihood that any form of twins will have the same handedness is no greater than if we randomly chose pairs of unrelated individuals and determined whether or not they had the same handedness.

This is not to say that genetics has no part in the determination of handedness. Certainly, genetic factors determine many human characteristics, such as the number of eyes, ears, and limbs that characterize our species. We might refer to these as genetically fixed characteristics, which are expected in all members of the species. We might contrast these characteristics to genetically variable characteristics, such as eye color, that do vary in the population, depending on the specific genes transmitted to the offspring by its parents. There is evidence that suggests that the strength or consistency of handedness is inherited from parents and, hence, is genetically variable. Children of parents with inconsistent or mixed handedness (tending toward ambidexterity) are more likely to have children with mixed handedness than are parents with consistent handedness. However, whether one is left- or right-sided seems to be a genetically fixed characteristic of species, with evolution programming humans to be right-sided. If right-handedness was meant to be a characteristic of species, then why are some people left-handed?

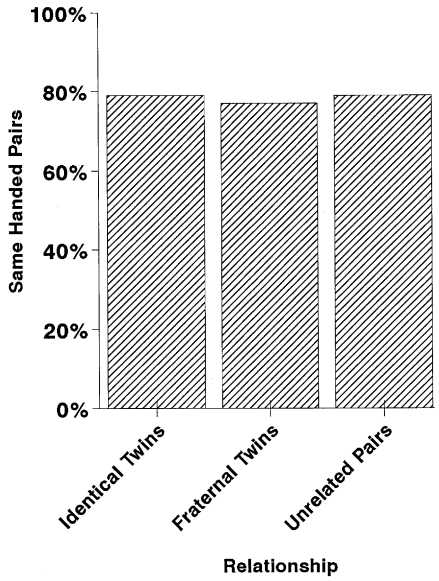

Figure 2 The number of same-handed pairs of twins does not differ among identical twins (who share identical gene sets) and fraternal twins (who are as genetically similar as any pair of siblings), and the twins are no more similar in their handedness than are unrelated pairs of individuals.

IV. THE BRAIN AND HANDEDNESS

Control of the limbs, including the hands, is contralaterally organized, meaning that the left hemisphere of the brain controls the right side of the body and the right hemisphere of the brain controls the left side of the body. In the 1860s, Paul Broca discovered that the major language production center in the brain is located in the left hemisphere of the brain. This center is now called Broca's area in his honor. There is another speech center called Wernicke's area that is associated with speech comprehension, and it is also located in the left hemisphere of the brain. The fact that

both the right-hand and primary speech functions are controlled by the same half of the brain has fuelled speculations attempting to link brain organization, language functions, and handedness. Broca started these speculations by introducing the notion of the "dominant hemisphere," by which he meant the hemisphere that directs not only the movements of writing, drawing, and other fine movements but also language and perhaps even major aspects of logical thought. He then suggested that left-handers might have a brain that is organized in a mirror image to that of right-handers, with language control on the right side of the brain.

The notion that handedness and language control are related in the brain has persisted and is still found in some theories today. The data, however, suggest that this relationship is unfounded. One important source of data on this issue has been the observations of people who are injured on one side of their brain or who acquire a pathology that damages one side of the brain. This often results in the development of aphasia, which is the loss of language abilities. Evidence from such conditions first led Broca to place the language control center in the left hemisphere. Other techniques also provide information on this matter. These involve procedures that effectively "turn off" one hemisphere of the brain. This can be done through the injection of certain drugs (such as sodium amytol) into one side of the brain. Alternatively, electric shock, such as that which is used in electroconvulsive therapy for severe psychological depression, can be used. Instead of applying the shock to the whole brain, however, it is applied to only one-half of the brain. If the drug treatment or the electric shock result in temporarily impaired language comprehension or production abilities, then we can conclude that we have turned off the hemisphere of the brain that contains the language control center. The composite results of 12 studies that attempted to locate the hemisphere containing the language control centers are shown in Fig. 3. Notice that although virtually all right-handers have language in their left hemisphere, we do not find the mirror-imaged brain that we expected in left-handers. The data show that the vast majority of left-handers have the same brain organization as right-handers, with their language control exclusively confined to the left hemisphere. Only about 2 of 10 left-handers have language exclusively in the right hemisphere, as had been predicted by Broca. There is also a small group of individuals who seem to have their language control split between both sides of the brain or duplicated on both sides of the brain.

The new technology associated with various brain scanning techniques, such as positron emission tomography, computerized axial tomography, and functional magnetic resonance imaging, has been used to explore the organization and functioning of the brains of left- and right-handers. The overwhelming number of studies have found that there is a remarkable similarity between brains, regardless of handedness, with the only major difference being that hand control regions are somewhat larger and more active on the side opposite the dominant hand. If there is any general pattern of results that seems to emerge, it is that right-handers seem to have brains that are slightly more asymmetrical, in terms of both their structure

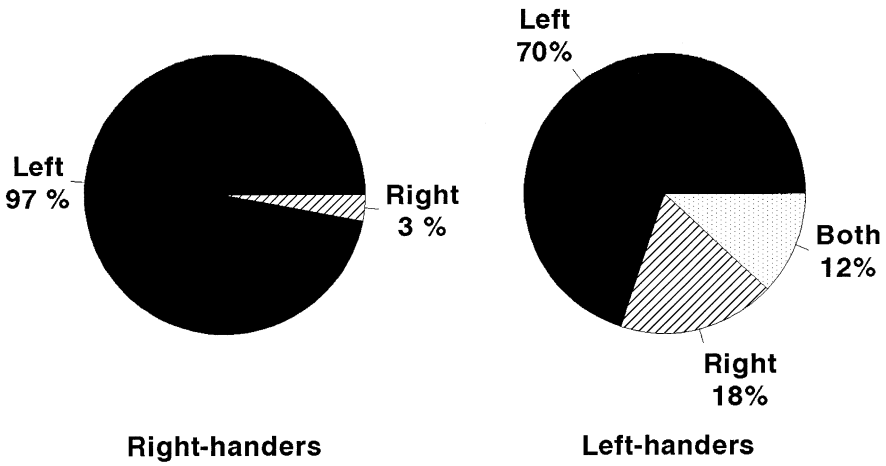

Figure 3 The side of the brain that contains the centers that control language ability for both right- and left-handers is usually the left hemisphere.

and their functional specialization. A larger proportion of left-handers seem to have more symmetrical brains and are more likely to have functions equally represented in both hemispheres. However, in most instances, a researcher presented with only data based on the structural aspects of the brain, or even the brain's function in a variety of circumstances, would be unable to determine if the brain that he or she were looking at was that of a left- or a right-hander.

V. CULTURAL AND ENVIRONMENTAL INFLUENCES ON HANDEDNESS

It should not be surprising that a technological and constructed environment created by a species in which 9 of 10 individuals are right-handed should have a bias toward use of the right hand. Most tools and equipment, furniture, traffic patterns in stores and museums, and even formal seating arrangements are structured for the convenience of the right-handed majority. Everyday implements, such as scissors, gear shifts, ice cream scoops, rulers, can openers, pencil sharpeners, and even the location of the winding stem on wrist watches, are biased toward right-handed usage. Sporting gear such as fishing reels and rifles, musical instruments such as violins, guitars, and banjos, common machinery, including voting machines, slot machines, time card punches, and also candy and soft drink dispensers are designed with a bias that facilitates right-handed operation. Even the direction in which screws are threaded favors the right-hander on the power (forward) movement, a tendency that carries the bias to other implements such as corkscrews. Given this right bias to the environment, it is apparent that left-handers are forced to learn to do many things with their right hand that a right-hander would never be expected to do with his or her left hand. If there is a learned component to handedness, this should serve to greatly reduce the number of left-handers in the world.

The presence of approximately 10% left-handers among humans is even more surprising due to direct cultural pressures to make the whole world right-handed. At some level, our society seems to intensely dislike left-handers and for proof one need go no further than our own language. The very word "left" in English comes from the Anglo-Saxon word "lyft," which means "weak" or "broken." No less an authority than the venerable Oxford English Dictionary goes on to define "left-handed" as including the meanings "crippled," "defective," "awkward," "clumsy," "inapt," "characterized by underhanded dealings," "ambiguous," "doubtful," "questionable," "ill-omened," "inauspicious," and "illegitimate."

Many common phrases in the English language demonstrate our culture's negative view of left-handedness. For instance, a left-handed compliment is actually an insult. A son from the left side of the bed is illegitimate. A left-handed marriage is no marriage at all, but refers to an unconsecrated or adulterous sexual liaison, such as in the phrase a "left-handed honeymoon with someone else's husband." Thus, a left-handed wife is actually a mistress. A left-handed diagnosis is wrong and left-handed wisdom is a collection of errors. To be about left-handed business is to be engaged in something unlawful or unsavory. Sailors speak of ships that are left-handed, meaning that they are unlucky or "wrong" in some way. It is interesting to note that there is not one positive phrase to be found in the language regarding "left" or "left-handed."

One must not suppose that speakers of the English language have a unique dislike of left-handers. The tendency appears to be universal. For example, in French the word for left is gauche, which also conveys the meanings "crooked," "ugly," "clumsy," "awkward," "uncouth," and "bashful." The German word for left-hand is links. The dictionary definition of the term linkisch is "awkward, clumsy, and maladroit." Such negative associations with left-handedness go back a long way. Even in early Latin in which the word for left was sinister, it had already taken on its alternate contemporary meaning of evil.

In many societies, use of the left hand for activities such as eating or writing is considered impolite, insulting, or the sign of ill breeding. It is therefore not surprising that perhaps between 70 and 80% of the population of left-handers report that parents or teachers made overt attempts to change them to right-handers. Some of these attempts could be quite brutal, involving punishment for using the left hand or even strapping or tying the left hand down to force right hand use.

What is most surprising about cultural pressure on handedness is that it has such a poor success rate. For females, 4 of 10 left-handers fail to change their handedness, whereas 3 of 4 males do not shift their handedness. Even for those who do change, the change appears to be only for selected actions, which society puts direct pressure on. Thus, a left-handed child may learn to eat or write with his or her right hand, but he or she will still throw a ball or brush his or her teeth with

the right hand. A good example of this can be seen in Japan, where the proportion of left-handers, measured by writing hand, is only 2 or 3%, about one-fourth of that found in North America. However, if one measures handedness by the hand used to hold a screwdriver or to use a hammer, one finds the same proportion of left-handers in Japan as in the United States.

This all leads to the conclusion that handedness is not a casual learned set of behaviors. Handedness is determined early and is quite intractable to change. If genetic factors associated with our particular species suggest that we should all be right-handed, and our culture and constructed environment bias us toward right-handedness, then why are there any left-handers?

VI. PATHOLOGICAL LEFT-HANDEDNESS

Because simple genetic explanations for the existence of left-handedness do not seem to work, an alternate theoretical position has emerged. This begins with the suggestion that, although there are some natural left-handers, right-handedness should be expected unless something unusual has occurred. Thus, although there is a genetically fixed bias toward right-handedness, and this implies some set of genes that determine handedness, in specific situations there might be partial penetrance (which simply means that the gene does not express its full set of characteristics). If the right-handed gene does not express itself, then handedness becomes a matter of chance, and a left-hander could be the result. Natural left-handedness could also occur due to nonpathological differences in the uterus during pregnancy, such as the position in which the fetus lies. For example, if a fetus comes out with the head directed to the back of the mother's right side (right occiput anterior position), the child is more likely to be left-handed than if it were born from the more common left occiput anterior position (with the head directed toward the back of the mother's left side).

Most deviations from the expected pattern of fetal development occur because something has gone wrong during pregnancy or the birth process. For this reason, researchers quickly began to focus on the relationship between handedness and birth stressors or pregnancy complications. A large body of data has accumulated that indicates that such pathological factors are associated with an increased likelihood of left-handedness. A number of particular factors have been singled out. For example, premature birth, prolonged labor, RH incompatibility, breech delivery, multiple births, and anoxia (reduced oxygen to the fetus, resulting in what is sometimes called a "blue baby") are all factors likely to result in left-handedness. Also, babies requiring resuscitation at birth, those that suffer the complications that lead to cesarian delivery, or even those that require forceps or other instruments to assist in the delivery are all more likely to become left-handed. Thus, it is not surprising that older mothers (aged 40 and older), who are prime candidates for pregnancy and birth complications, are more than twice as likely to produce left-handed children.

One of the more interesting suggestions is that certain hormonal imbalances during birth can produce an increased likelihood of left-handedness. A theory closely associated with the neuropsychologist Norman Geschwind is that while in the uterus, if the fetus is exposed to an elevated concentration of the hormone testosterone, this could also produce left-handedness by altering the relative rate at which the two hemispheres of the brain develop. Since testosterone is also the male hormone, this could also explain the observation that men are more likely to become left-handed than are women (approximately 12% left-handedness for men versus 8% for women).

The neurological reason left-handedness can arise from so many different forms of birth stress has to do with the fact that handedness may be said to have a diffuse control system. A diffuse control system simply refers to the fact that the control of handedness is neurologically complex, involving a number of brain sites and neural pathways, including at least three motor systems that originate in the cerebral cortex, several subcortical sites, several commissural systems, the pyramidal tract, the reticulospinal tract, the rubrospinal pathway, and the proprioceptive and kinaesthetic systems in the postcentral cortex. In all, at least 23 neural centers or systems have been found to be important to hand control. The notion is that anything that interferes with the normal development or functioning of any of the many sites or systems that control hand use can also alter the natural development of right-handedness. If there is any such disruption, handedness will be randomly determined, meaning that half of these birth-stressed individuals can be expected to become left-handers.

How common are pathological left-handers compared to natural left-handers? Several mathematical analyses of the distribution of handedness, birth stressors, and their interactions have led to the conclusion that left-handers are split approximately evenly between these two categories, with half having

their handedness as a result of natural, although relatively atypical, factors, and the other half obtains their left-handedness due to pathological mechanisms.

VII. LEFT-HANDEDNESS AND PHYSICAL AND PSYCHOLOGICAL FITNESS

Throughout the years there have been a large number of studies that have suggested that left-handedness may serve as a sign or a marker indicating that there may be other psychological and neurological problems present in the individual. The reasoning is as follows: To the extent that left-handedness may be caused by pathological factors, left-handedness might be a marker (at least statistically) for the possible existence of some form of neural pathology, psychological deviance, or developmental abnormality. It is suggested that, at least for the pathological left-handers, the same pathology that caused the left-handedness might have also caused some form of collateral damage that can reduce the individual's physiological or psychological fitness through direct or secondary mechanisms.

The surprising suggestion that left-handedness may be a marker for other problems is actually supported by a substantial body of research that found that left-handedness is frequently associated with a variety of symptoms or syndromes. In the vast majority of circumstances, when there are a disproportionately high number of left-handers in a group, that group is marked by some negative factor. The number of findings in which left-handedness is associated with positive outcomes in the research literature is much rarer. A review of the literature indicated at least 60 negative pathological or undesirable conditions associated with left-handedness as opposed to only 4 positive or desirable conditions. Considering associations that have been reported two or more times in the research literature, Table I provides an idea of the positive and negative conditions related to an increased proportion of left-handers.

VIII. THE RARE TRAIT MARKER MODEL

With a research literature replete with suggestions that left-handedness is predominantly associated with negative conditions, some researchers have attempted to provide theoretical models that try to explain why left-handedness may be a marker for pathology. Clinical researchers would call it a soft sign for pathology, meaning that it is not something that you can directly cut out, weigh, or subject to direct chemical or physical analysis. Handedness is merely an observable behavior that indirectly suggests a problem, rather than a hard sign, which might be actual observation of a damaged section of the nervous system. Hard signs almost always indicate pathology. Thus, a person who tests positive for HIV antibodies almost definitely has been exposed to the disease AIDS. Left-handedness is a soft sign in the sense that an individual who shows it is not definitely pathological but, rather, is more likely to have some pathological condition than a person who does not show this behavioral sign.

The linkage between handedness and these various pathological conditions occurs due to both neurological and statistical considerations. The statistical component has been mathematically explored in the form of the rare trait marker model, which indicates that a number of statistically rare traits are often found to be associated with a range of pathological conditions. Examples of rare traits include animals that are colored differently from the vast majority of their species. For instance, a "blue–marl" collie, a white dog, or an albino human often have major sensory deficits affecting their vision or hearing. These rare traits could include rare palm crease patterns, rare fingerprint patterns, or rare distributions of toe lengths, and even unusual ear shapes are often found to be associated with cognitive or physical deficits. Left-handedness, which affects only about 10% of the population, would also qualify as a rare trait.

According to theoretical considerations, if we start with a trait, such as handedness, that has a common and a rare form, we need only add the possibility that the appearance of the rare versus the common trait can be influenced by pathological factors. If we meet both of these conditions, then because of statistical considerations we have all that is needed to create a clinical soft sign for pathology.

To demonstrate the operation of the rare trait marker model, consider the situation diagrammed in Fig. 4. In this example, we suppose that we are starting with a population in which, if development proceeded naturally, 90% of the people would develop into right-handers and 10% into left-handers. Suppose that there was some disturbance in development—some aberrant condition or some birth risk factor—that caused 10% of each group to deviate from their targeted handedness. The result would be 9% of the population (10% of the 90% who would be right-handed)

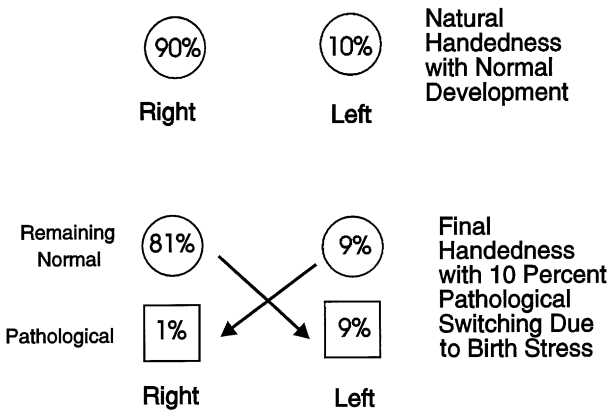

Figure 4 The rare trait marker theory is demonstrated in this diagram. The circles represent the percentages of normal individuals, whereas the squares represent the percentages of pathologically switched individuals. Notice that in the final group of left-handers, half are pathological, whereas the number of pathological right-handers is less than 2%.

"pathologically" shifting from right-handedness to left-handedness, whereas only 1% of the population (10% of the 10% originally targeted to be left-handed) shifts from left- to right-handedness. The final result is that half of the resulting population of left-handers (9% out of the total of 18% left-handers) are pathological, whereas only 1.2% (1% out of 82%) of the right-handers are pathological. This means that the relative risk of a left-hander being pathological is approximately 41% greater than that of a right-hander being pathological. How well a rare trait predicts pathology depends on its distribution in the population and the likelihood of pathological change. By chance, the approximately 10% incidence of handedness falls into the optimal predictive range of values.

The fascinating thing about the rare trait marker theory is that it really does not depend on any specific physiological, injury, or disease mechanisms. It makes no assumptions about the particular vulnerability of various parts of the nervous system. In other words, we do not have to know why or how or even when a particular injury or damage occurred. All we need to know is that there is a common and rare trait, and that some form of pathology (actually any form of pathology) can produce the rare trait.

Although the previous discussion suggests that left-handedness might be a sensitive marker for a number of pathological conditions, there is a flip side that reduces its usefulness in some ways. Given the large number of possible sites for pathology that might cause the observed left-handedness, we also must face the fact that there is little specificity. Left-handedness might be seen as a soft sign indicating increased risk for many problems; however, which specific problems an individual might suffer from, or which neural loci are involved, is not determinable. This means that given an individual about whom all one knows is that he or she is left-handed, one can list the many problems that he or she is at risk for but one cannot determine which of them this particular left-hander is most likely to have which part of the nervous system is most apt to be damaged, or what the original source of the pathology might have been. We can say with some certainty that the more diffuse the pathology that an individual has suffered, the higher the likelihood of non-right-handedness and also the higher the probability that other functions other than handedness will also be disturbed.

IX. HANDEDNESS AND LONGEVITY

The data suggest that a significant number of left-handers arrived at their left-handedness through some form of pathological event during their fetal development or associated with their birth, and that this same pathology also resulted in other physical or psychological problems. From Table I, it should be clear that a number of these problems, especially those associated with reduced immune system efficiency, might represent major health risk factors.

Since the late 1970s a number of studies have examined handedness as a function of demographic factors, such as age, sex, and race. The studies that examined handedness over the life span found something unexpected—namely, that there is a diminishing percentage of left-handers in older age groups. Although the rate of decline varies across studies, it is usually large, from about 15% left-handedness in teenagers to less than 1% in 80-year-olds. Figure 5 shows the age proportion of left-handers for various age groups based on the average values taken from seven different studies that examined this issue.

Researchers first thought that this decrease in the number of left-handers might be due to social factors since older people, educated earlier in the 20th century, are more likely to tell stories about how they were forced to use their right hands by teachers and parents than are people born later in the century. Forced switching of left-handers to right-handedness in older age groups could explain this age-related decline in the number of left-handers. However, as discussed earlier, handedness is relatively difficult to change. In addition, several analyses of the literature suggest that the proportion of adult left-handers in North American populations has not changed since the early 1900s.

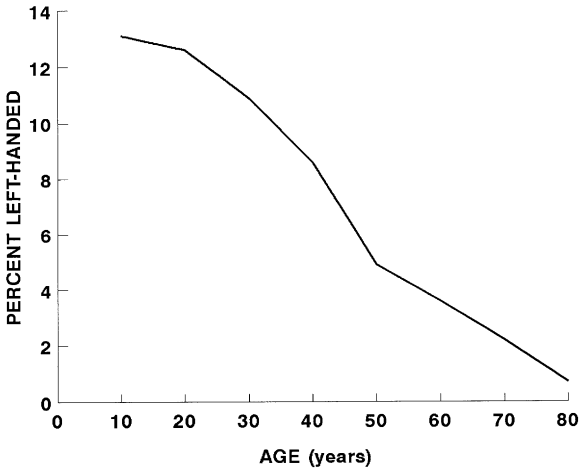

Figure 5 The percentage of left-handers diminishes with increasing age.

The alternative explanation for failing to find older left-handers might be that they are simply no longer in the population. That is, left-handers have a shorter life span, and the reason that we fail to find many older left-handers is because a large proportion of them have died early. When this hypothesis was first suggested, it evoked a lot of media attention and controversy. Recently, evidence supporting this conclusion has been obtained from several sources. For instance, a number of studies have examined the life spans of professional baseball and cricket players since records for these sports include not only birth and death dates but also information on the hand that was used in throwing. These have confirmed that left-handers seem to die younger. In other studies, researchers examined randomly selected death records and then contacted surviving next of kin to obtain handedness information. Again, the results suggest that the longevity of left-handers is less than that of right-handers. Although not all of the research that has been done on this issue has found the expected differences, whenever there is a significant relationship between handedness and life span it is always in the direction of left-handers having a poor survival rate.

Table I

Conditions That Two or More Research Reports Have Shown to Be Associated with a Disproportionately High Number of Left-Handers

	Negative conditions associated with left-handedness	
Alcoholism	Hashimoto's thyroiditis	Poor spatial ability
Allergies	Hayfever	Poor verbal ability
Asthma	High and low extremes in numerical ability	Predisposition toward aggression
Attempted suicide	Homosexuality	Psychosis
Autism	Hypopigmentation	Reading disability
Bed-wetting	Immune disorders	Reduced adult height
Brain damage	Impulsive aggression	Reduced adult weight
Chromosomal damage	Infection susceptibility	Regional ileitis
Celiac disease	Juvenile delinquency	Schizophrenia or schizotypal thinking
Crohn's disease	Juvenile-onset diabetes	School failure
Clinical depression	Language problems	Sleep difficulty
Criminality	Learning disabilities	Slow maturation
Deafness	Lower intelligence scores	Slow physical development
Depression	Manic–depressive psychosis	Strabismus
Drug abuse	Mental retardation	Stuttering
Drug hypersensitivity	Migraine headaches	Sudden heart attack death
Emotionality	Myasthenia gravis	Transsexuality
Epilepsy	Neural tube defects	Ulcerative colitis
Excessive smoking	Neuroticism	Urticaria
Eczema	Poor school performance	
	Positive conditions associated with left-handedness	
Extremely high intelligence	Good divergent thinking ability	High spatial ability
	High musical ability	

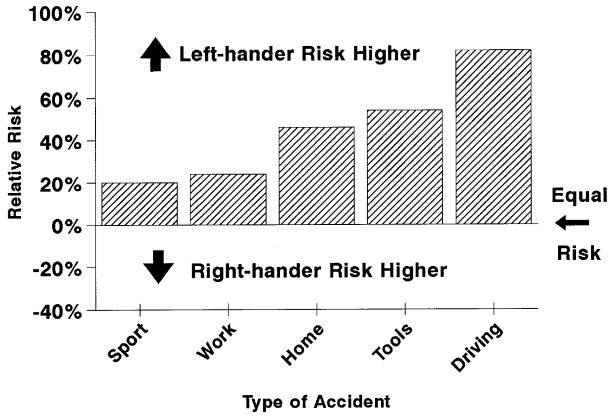

Figure 6 The relative risk of accidents is higher for left-handers in every category of accident studied.

Although many left-handers were dying of factors traceable to the problems in Table I, there was a surprise in the data: Left-handers were five times more likely to die of accident-related injuries. This brings us back to the issue that our technological world and the built environment have been designed for the safety and the convenience of the right-handed majority. There is evidence that left-handers are more likely to suffer injuries while playing sports, driving in traffic, working with tools and motorized equipment, working with kitchen and home implements and devices, and even while engaged in military activities. Figure 6 shows the relative risk of various injuries as a function of handedness based on data from four different studies. Notice that in all cases, left-handers seem to be at considerably higher risk. Obviously, these injuries are the direct result of a cultural and societal bias toward facilitating activities done with the right hand that we discussed earlier. These right-handed biases continue in today's world, even though we now know that they place the left-hander at higher risk of injury.

X. ARE LEFT-HANDERS AND RIGHT-HANDERS REALLY DIFFERENT?

When we examine all the data associated with handedness, it becomes obvious that left-handedness is not just a minor behavioral deviation shown by about 1 in every 10 humans. Handedness does not appear to be a marker for genetic differences as previously thought, neither is it necessarily a sign of difference in brain organization. The evidence indicates, however, that for about half of all left-handers, handedness does represent a sign that may indicate some level of neurological and developmental pathology. From the standpoint of behavioral medicine, we may view left-handedness as a risk factor that may well predict susceptibility to illness, physiological deficits, psychological problems, and perhaps even a shortened life span.

GLOSSARY

amygdala (from Latin "amygdale," almond or tonsil) A complex of nuclei embedded (like the meat of an almond) in the anteromedial temporal lobe.

cingulate gyrus (from Latin "cingulum or cingo," girdle, to surround) A long curved gyrus that surrounds the corpus callosum on the medial side of the cerebral hemisphere.

hippocampus (from Greek "hippocampos," seahorse) A very specialized region of the cerebral cortex, which is deeply folded into the lateral ventricle. In marsupials and rodents the hippocampus is largely situated in the dorsomedial cortex, dorsal to the thalamus, but in humans and other primates it has shifted into the medial temporal lobe.

limbic system (from Latin, "limbus," edge, border, or fringe) A system of interconnected brain structures situated around the medial edge of the cerebral hemisphere.

nucleus accumbens septi (from Latin "accumbens," leaning) The rostral, ventromedial portion of the corpus striatum, comparable to the caudate nucleus and putamen, that is immediately lateral to the septum and appears to "lean" against it.

nucleus basalis of Meynert Prominent nuclei of large cells in the basal forebrain, most of which use either acetylcholine or GABA as neurotransmitter.

orbital cortex (from Latin "orbita or orbis," wheel-track, circle) The cortex situated dorsal to the bony "orbit" that encases the eye.

prefrontal cortex Traditionally, the cortex in front of the "excitable" frontal cortex (i.e., the motor cortex, which was found in the 19th century to evoke body movements when excited with electrical stimulation).

The internal state of the body is largely controlled by the autonomic nuclei in the spinal cord and brain stem, which provide for reflex control of visceral functions, and by the hypothalamus, which provides for higher level coordination of autonomic and endocrine functions. As anyone who has checked his or her heart rate during an exciting action movie knows, however, visceral function is also modulated in relation to forebrain analysis of visual, olfactory, and other sensory stimuli. Furthermore, such visceral reactions are also modified in relation to previous experience, as you can tell if you watch the same action movie so many times that the surprises become expected. The modulations related to present and past sensory experience are both dependent on several forebrain structures that are linked together as the "limbic system." On the one hand, these structures have substantial connections to the hypothalamus and brain stem and provide an interface between forebrain sensory systems and visceral control areas. On the other hand, the limbic structures interact with the cerebral cortex, thalamus, and basal ganglia to relate visceral function to the ongoing sensory environment and to cognitive functions. In particular, these provide for the modulation of visceral and other functions across time, such that responses are altered in relation to previous experience. In humans and other primates, at least, this process is directly involved in conscious emotion and memory.

As defined by Broca (1878) and later by Papez (1937), the limbic system generally consists of a group

of structures around the medial edge of the cerebral hemisphere. (''Limbus'' means border or edge; e.g., to be ''in limbo'' is to be suspended between two states.) These structures include the amygdala, the hippocampus, the parahippocampal gyrus, and related structures, such as the orbital/medial prefrontal cortex, cingulate cortex, anterior and mediodorsal thalamic nuclei, the ventromedial corpus striatum (i.e., the accumbens nucleus and medial caudate nucleus), and the nucleus basalis of Meynert.

I. AMYGDALA

The amygdala is a complex of several nuclei in the rostromedial part of the temporal lobe (Figs. 1 and 2). There are several deep nuclei (lateral nucleus, basal nucleus, and accessory basal nucleus), which are substantially interconnected with the temporal, insular, and frontal cortex, the striatum, and the mediodorsal thalamus. On the surface are a number of modified cortical areas, many of which are interconnected with the olfactory system. In the dorsal part of the amygdala are the central nucleus and medial nucleus, which have connections with the hypothalamus and autonomic brain stem nuclei.

The amygdala receives input from all the sensory systems. In lower mammals, these are dominated by inputs from the olfactory system, although there are also inputs from the taste/visceral afferent system and the visual and somatosensory systems. In primates the most prominent inputs are derived from higher order sensory association cortex, especially from the visual areas in the inferior temporal cortex (i.e., the temporal visual processing stream, important for analysis of form and color and recognition of complex stimuli

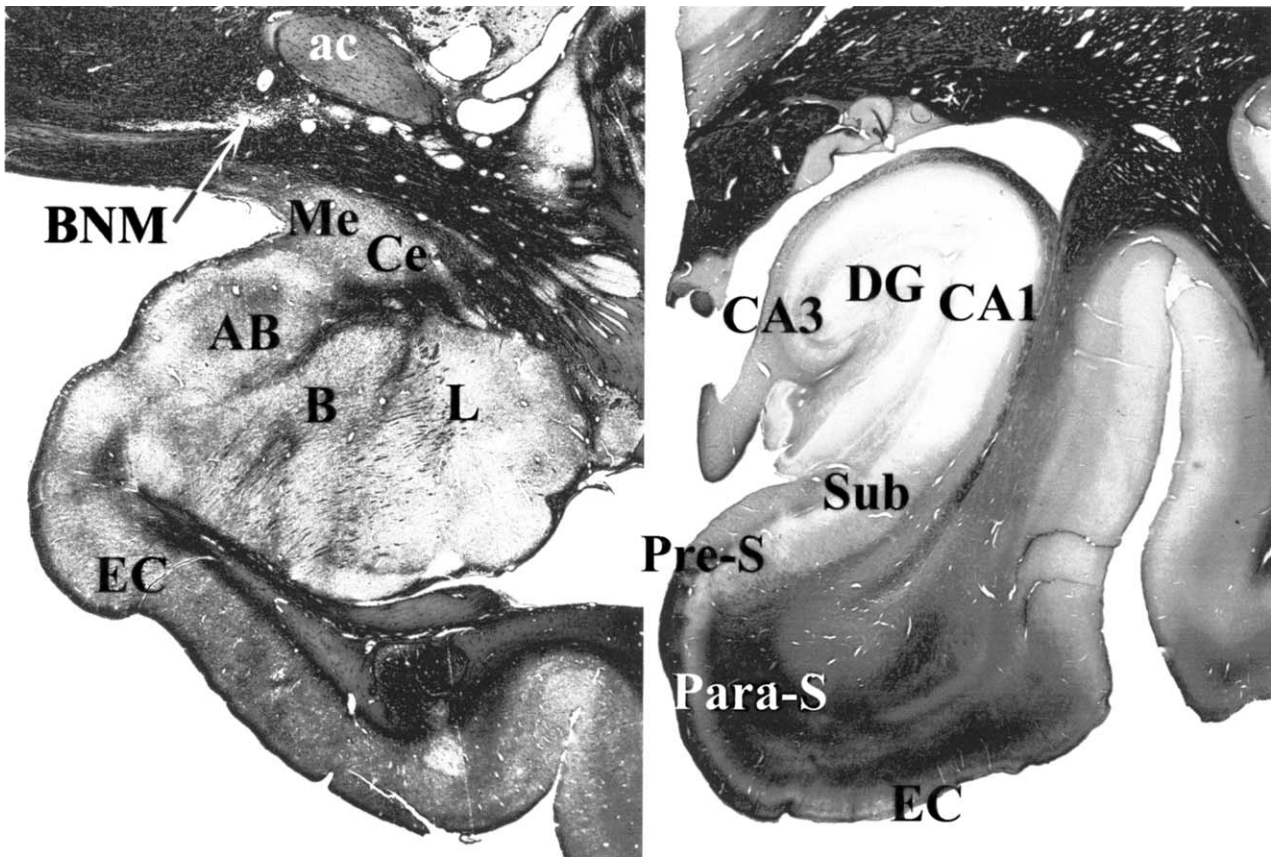

Figure 1 A photomicrograph of the amygdala, hippocampus, and parahippocampal gyrus from a human brain. BNM-basal nucleus of Meynert, ac-anterior commisure. The amygdala includes the lateral nucleus (L), basal nucleus (B), accessory basal nucleus (AB), central nucleus (Ce), and medial nucleus (Me). The hippocampus, located posterior to the amygdala in the medial temporal lobe, includes the parasubiculum (Para-S), presubiculum (Pre-S), subiculum (Sub), fields CA1 and CA3, and the dentate gyrus (DG). The entorhinal cortex (EC) occupies the parahippocampal gyrus ventral to the amygdala and hippocampus.

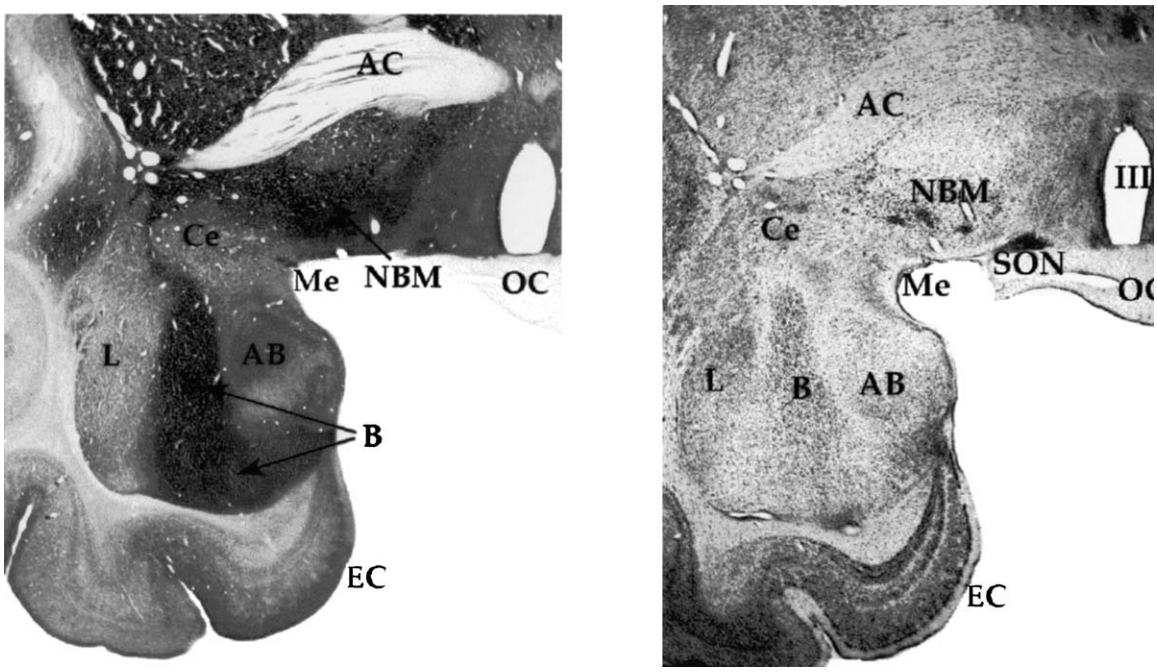

Figure 2 Photographs of the amygdala and entorhinal cortex (EC) of a macaque monkey, stained for acetylcholinesterase (left) and cells (Nissl method) (right). Note the component nuclei of the amygdala, including the basal nucleus (B), lateral nucleus (L), accessory basal nucleus (AB), central nucleus (Ce), and medial nucleus (Me). Also note the cholinergic nucleus basalis of Meynert (NBM), ventral to the anterior commissure (AC), the supraoptic nucleus (SON), the optic chiasm (OC), and the third ventricle (III).

such as faces) (Fig. 3). Recordings from the amygdala show that the neurons respond to complex sensory stimuli, including visual stimuli such as faces, as well as to other sensory modalities. In addition to the sensory aspects of the stimuli, the responses are influenced by the novelty of the stimulus or its affective sign (whether the stimulus is rewarding or aversive).

There is a complex system of intraamygdaloid connections that associate these inputs. These connect the deep amygdaloid nuclei (which interact with the cortex) with the central and medial nuclei (which connect to the hypothalamus and brain stem). There are also extensive connections to other limbic areas, including the hippocampus, parahippocampal gyrus, and the nucleus basalis of Meynert.

The outputs from the amygdala can be divided into three categories (Fig. 3):

1. Return projections back to the sensory areas that project into the amygdala: In the case of the visual system, these return projections even extend back to the primary visual cortex.

2. Descending projections to the visceral control centers of the hypothalamus and brain stem: The central amygdaloid nucleus projects to a wide variety of autonomic-related cell groups, including the lateral hypothalamus, the periaqueductal gray, the parabrachial nucleus, the nucleus of the solitary tract, the dorsal vagal nucleus, and the ventrolateral medulla. Through these projections, the amygdala can influence heart rate and blood pressure, gut and bowel function, respiratory function, bladder function, etc. For example, stimulation of the central nucleus can cause stomach ulcers as well as changes in cardiovascular function.

3. Interactions with the orbital and medial frontal cortex, both via direct amygdalocortical projections and via connections with the mediodorsal thalamic nucleus and the ventromedial parts of the basal ganglia: This circuit appears to be involved in determination of the affective "sign" of sensory stimuli (e.g., whether it is rewarding or aversive) and in setting mood.

Several additional observations may be used to illustrate the role of the amydala in the control of emotional behavior. Bilateral lesions of the amygdala and adjacent medial temporal structures in monkeys

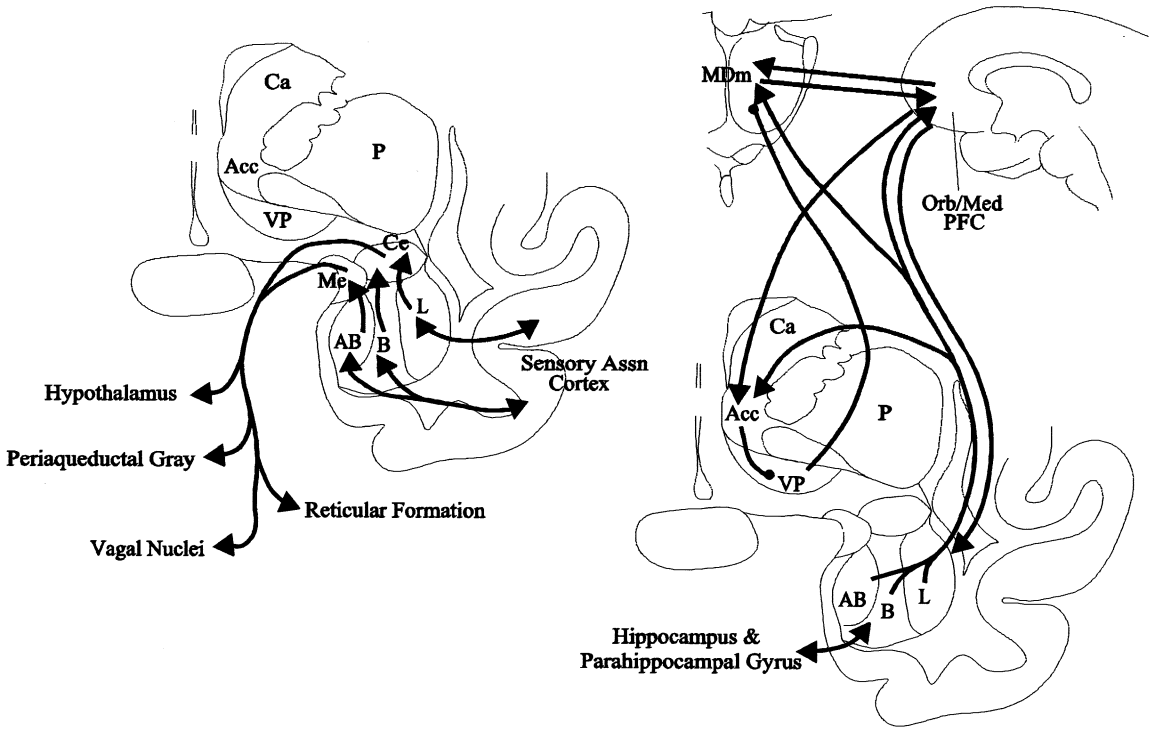

Figure 3 Schematic summary of the axonal connections of the amygdala. (Left) Inputs from sensory association cortical areas and output from the central and medial nuclei to the hypothalamus and brain stem. (Right) Connections are illustrated with the mediodorsal thalamus (MDm), the ventromedial striatum [accumbens (Acc) and caudate nuclei (Ca)], ventral pallidum (VP), and the orbital and medial prefrontal cortex (Orb/Med PFC) as well as with the hippocampal formation. The connections from Ca/Acc to VP and from VP to MDm are shown with arrowheads to indicate that they are inhibitory.

produce "psychic blindness" (Kluver–Bucy syndrome) in which the animals can see objects but are apparently unable to distinguish their significance. Such animals are not capable of appropriate social behavior, and in group settings they become isolated and solitary.

In rats, bilateral lesions of the amygdala block the acquisition of conditioned fear responses. For example, if a light is consistently coupled with a painful foot shock, the animal comes to associate the two stimuli, and the light becomes a "fearful" stimulus that can produce autonomic and behavioral responses characteristic of fear. After bilateral lesions of the amygdala, the shock produces the same response as before, but the light never becomes a fearful stimulus. Recent observations indicate that a similar deficit is present in humans who have a rare disease that results in bilateral amygdaloid destruction.

Stimulation of the amygdala in awake cats produces a defense reaction in which there are integrated behavioral and visceral changes that prepare the animal for fight or flight. Stimulation of the amgydala or hippocampus in human patients (during exploratory surgery for severe epilepsy) evokes complex sensory and experiental phenomena, often involving fear and including sensory hallucinations, feelings of deja vu, and memory-like episodes that resemble static dreams.

II. HIPPOCAMPUS

The hippocampus is a specialized part of the cerebral cortex, folded into the temporal horn of the lateral ventricle about the hippocampal fissure (Figs. 1 and 4). It is composed of several subregions, including (in order) the entorhinal cortex (in the parahippocampal gyrus), the parasubiculum, presubiculum, subiculum, fields CA1–CA3, and the dentate gyrus.

Like the amygdala, in rats the hippocampus receives strong olfactory inputs, but in primates it is dominated by multisensory inputs, mostly from higher order

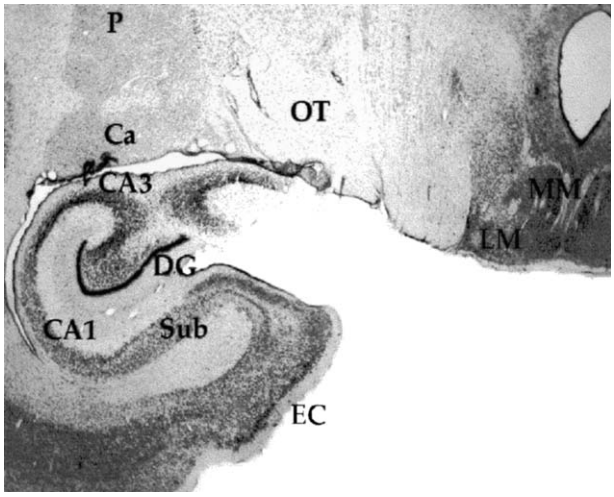

Figure 4 Photomicrograph of the hippocampal formation and the mammillary nuclei in a macaque monkey (stained with the Nissl method). Ca, caudate nucleus; EC, entorhinal cortex; DG, dentate gyrus; P, putamen; OT, optic tract; Sub, subiculum.

sensory association cortex. These inputs reach the hippocampus through a relay in the perirhinal and entorhinal cortex, which in turn receive inputs from multisensory association cortical areas. There is a relatively unidirectional set of connections through the hippocampus, beginning from the entorhinal cortex to the dentate gyrus, and then in turn to CA3, CA1, the subiculum, and back to the entorhinal cortex (Fig. 5).

Outputs to other parts of the brain mainly arise in the subiculum and entorhinal cortex. These resemble those of the amygdala:

1. Projections back to many sensory association cortical areas, including the visual and auditory areas of the inferior and superior temporal cortex.
2. Projections to the hypothalamus (but not to brain stem autonomic nuclei).
3. Connections with prefrontal and cingulate cortical areas, via direct projections and also via projections to the anterior and mediodorsal thalamic nuclei, and the mammillary nuclei, and projections to the ventral part of the basal ganglia.

The hippocampus and surrounding areas of the parahippocampal gyrus are critically involved in memory processing in general and spatial orientation in particular. Recordings in the hippocampus have demonstrated cells that fire when the animal is in a particular spatial location, as defined by characteristic sensory and other experiential stimuli. This suggests that the hippocampus provides a neural mechanism for association of different parameters that are necessary for the moment-to-moment incorporation of experience into memory. Strikingly, bilateral lesions of the hippocampus and parahippocampal cortical areas produce amnesia, an inability to form new memories (although older memories may be intact). By comparison, amygdaloid lesions that produce emotional disturbances do not produce amnesia.

III. ORBITAL AND MEDIAL PREFRONTAL CORTEX AND CINGULATE GYRUS

Cortical areas on the ventromedial surface of the frontal lobe, in the cortex dorsal to the orbit and the region rostral and ventral to the genu of the corpus callosum, are substantially interconnected with all the limbic areas discussed previously and participate in many of the same functions. These areas vary from periallocortical agranular areas with a relatively simple cortical structure in the caudal part of the region to fully developed granular cortical areas more

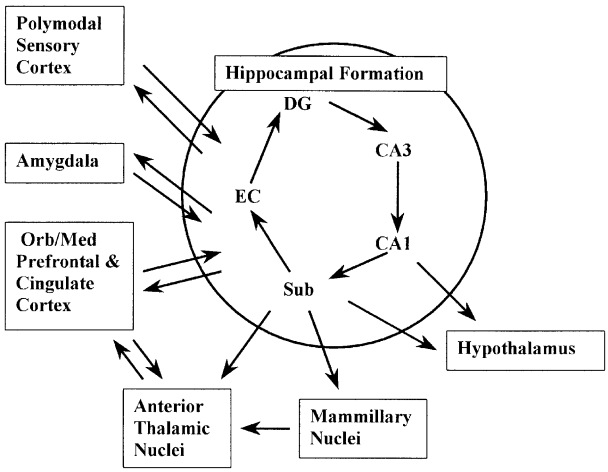

Figure 5 Schematic summary of major axonal connections of the hippocampal formation. Interactions with the polymodal sensory cortical areas occur primarily through the entorhinal cortex (EC). The amygdala, the orbital and medial prefrontal cortex, and the cingulate cortex interact with both the EC and the subiculum (Sub), whereas the Sub provides the primary output to the anterior thalamic nuclei, mammillary nuclei, and hypothalamus. Within the hippocampal formation, the principal flow of activity is from the EC to the dentate gyrus (DG), field CA3, field CA1, the Sub, and back to the EC.

rostrally. In rodents, the agranular areas dominate and the granular areas are almost nonexistent, whereas in primates and especially humans the granular areas are much larger than the agranular areas.

As a whole, the cortical areas can be divided into two relatively interconnected networks that appear to have related but distinct functions (Fig. 6). Sensory inputs from other cortical regions or the thalamus enter many of the orbital cortical areas, and these are integrated by corticocortical connections between these areas. Many of these are related to food or eating (e.g., olfaction, taste, visceral afferents, somatic sensation from the hand and mouth, and vision), and neurons in the orbital cortex respond to multisensory stimuli involving the appearance, texture, or flavor of food. In contrast, many of the areas in the medial prefrontal cortex and a few related orbital areas provide output from the cortex to visceral control centers in the hypothalamus and brain stem. Therefore, the orbital and medial prefrontal cortex appears to be adapted to evaluate feeding-related sensory information and to evoke appropriate visceral reactions.

The function of the ventromedial frontal cortex is considerably wider, however. Food is a primary reward, and many of the orbital neurons respond to rewarding or aversive aspects of stimuli beyond their sensory characteristics. In this, the cortex is closely tied to the function of the related ventromedial striatum, in which reward-related neural activity has also been found.

In addition, lesions of the ventromedial frontal lobe produce dramatic behavioral deficits, which suggests that visceral reactions evoked through this cortical

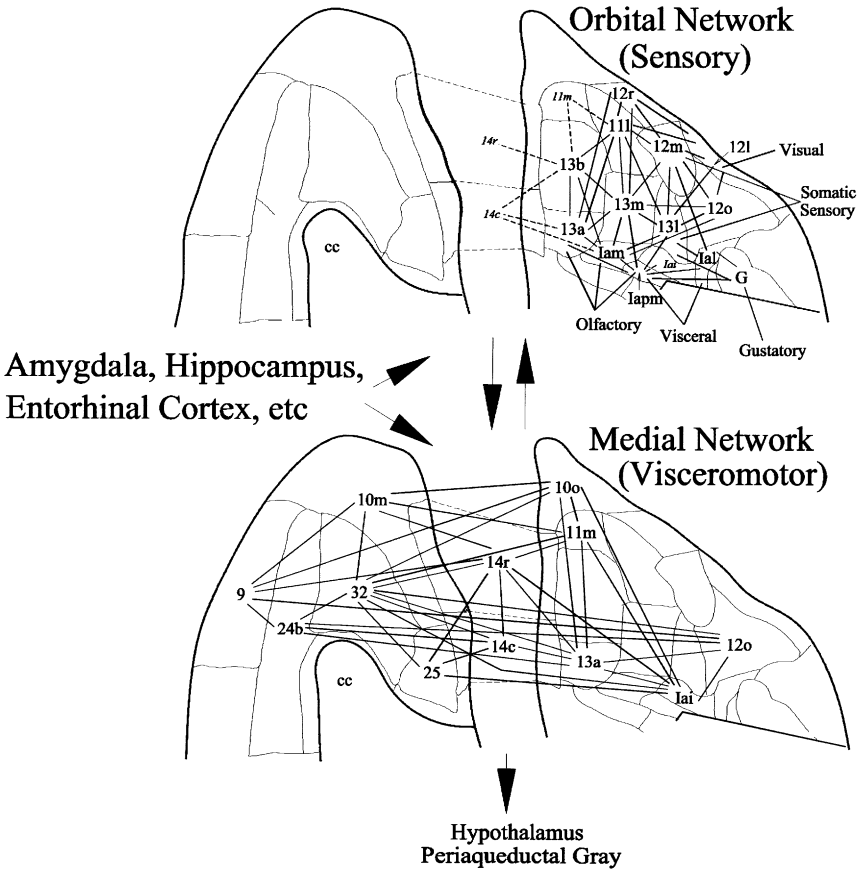

Figure 6 Diagram illustrating connections of architectonic areas in the ventromedial prefrontal cortex in macaque monkeys, drawn onto the orbital (right) and medial (left) cortical surfaces. Sensory input is particularly directed to an "orbital" network of areas (in the orbital cortex), whereas output to autonomic control centers in the hypothalamus and brain stem (especially the periaqueductal gray) arises from a "medial" network of areas (in the medial and orbital cortex). Corticocortical axonal connections between areas, which largely define the two networks, are indicated by lines connecting the areas. In addition to this sensory/visceromotor transfer, interactions with the amygdala, hippocampus, entorhinal cortex, and other limbic structure involve this cortical region in reward appreciation and affective behavior. The numbers and letters are designations of architectonic areas, modified from Brodmann; cc, corpus callosum.

area form a critical component in evaluating alternatives and making choices. As exemplified by the famous 19th-century case of Phineas Gage, individuals with damage to the ventromedial prefrontal cortex do not show deficits in motor or sensory function, or in intelligence or cognitive function, but have devastating changes in personality and choice behavior. Recent studies of such cases by Damasio and colleagues have shown that patients do not show usual visceral reactions to emotional stimuli, and this lack of response correlates closely with their difficulty in making appropriate choices. This has been explained by a somatic marker hypothesis, which postulates that visceral responses are monitored as a quick warning of choices to avoid.

In monkeys the cingulate gyrus is situated dorsal to the corpus callosum, but in humans it extends rostral and ventral to the genu of the corpus callosum and caudally around the splenium. The pre- and subgenual parts of the cingulate cortex are closely related to the medial prefrontal cortex in connections and presumably function, but more posterior cingulate regions appear to be distinct. Although the caudal pole of the cingulate gyrus is connected to the hippocampal formation, the central part of the cingulate gyrus has little relation to limbic structures.

IV. VENTROMEDIAL STRIATUM, VENTRAL PALLIDUM, AND MEDIAL THALAMUS

Although the ventromedial striatum, ventral pallidum, and medial thalamus are not part of the limbic system as traditionally defined, they have substantial connections with all the limbic structures discussed previously and are closely tied to them functionally. The amygdala, hippocampal formation, and the ventromedial prefrontal cortex all project onto the ventromedial part of the striatum, leading into a circuit that connects through the ventral pallidum to the mediodorsal thalamic nucleus (Fig. 4). Like other striato-pallidal-thalamic systems, this circuit involves two inhibitory (GABAergic) synaptic links, from the striatum to the ventral pallidum and from the ventral pallidum to the mediodorsal thalamus. In the mediodorsal nucleus, the inhibitory pallidal inputs interact with monosynaptic excitatory inputs from the amygdala, entorhinal cortex, hippocampus and other limbic structures.

Although it is usually assumed that the striatum is involved in motor functions, most of the motor-related activity is found in the dorsolateral part of the striatum, which is anatomically connected with sensorimotor areas of the cerebral cortex. In contrast, the ventromedial striatum, in keeping with its limbic associations, has been shown to be related to reward and reward-related behavior. In both cases, the role of the striatum may be to inhibit or suppress unwanted patterns of activity in order to allow other patterns to be freely expressed. Specifically, the dorsolateral striatum and related areas of the globus pallidus appear to be involved in switching between different patterns of motor behavior, whereas the ventromedial striatum and pallidum may allow changing of stimulus–reward associations when the reward status of a stimulus has changed.

V. NUCLEUS BASALIS (OF MEYNERT) AND NUCLEUS OF THE DIAGONAL BAND (OF BROCA)

These nuclei consist of scattered groups of large cells in the basal part of the cerebral hemisphere, just ventral to the anterior commissure and the globus pallidus. The nucleus basalis (Figs. 2 and 3) is most prominent at the level of the anterior commissure, but some of its cell clusters extend caudolaterally toward the amygdala and dorsally around the edges of the globus pallidus. The diagonal band nuclei extend medially and dorsally (diagonally) into the septum. Because many of the cells utilize acetylcholine as their transmitter, the nuclei stain very darkly for acetylcholinesterase. Other cells in the complex use GABA as transmitter. As a group, they project axons widely to all parts of the cerebral cortex (and the olfactory bulb and amygdala), although individual neurons within the group appear to have very restricted projections.

The principal action of acetylcholine on cortical cells is to enhance the action of other synaptic inputs. The nuclei are situated along fiber pathways that connect limbic structures such as the orbital and medial prefrontal cortex and the amygdala with the hypothalamus and brain stem, and they receive major input from all of these. The magnocellular basal forebrain nuclei are therefore well situated to modulate cortical activity in relation to limbic activity. They have been implicated in the activation (desynchronization) of the cortex that is characteristic of the waking state, and they are presumably involved in many other functions as well.

VI. THE LIMBIC SYSTEM AND PSYCHIATRIC DISORDERS

Although lesions of limbic structures do not result in apparent sensory or motor deficits, dysfunction of

these structures has been associated with a variety of psychiatric disorders, including depression, bipolar disorder, obsessive–complusive disorder, and schizophrenia. For example, structural changes have been noted in the hippocampal formation, medial thalamus, and prefrontal cortex in schizophrenic subjects. Observations from positron emission tomography indicate that the amygdala and related parts of the prefrontal cortex and medial thalamus are abnormally active in patients suffering from severe unipolar and bipolar depression. Cellular changes, especially in glial cells, have also been reported in the orbital and medial prefrontal cortex and amygdala in depressed subjects. Patients with lesions of these prefrontal areas have also been reported to have a relatively high incidence of depression. As noted previously, lesions of the ventromedial prefrontal cortex produce severe deficits in emotional reactions and in making choices.

GLOSSARY

deductive reasoning The process of establishing that a conclusion follows validly from premises (i.e., that it must be true given that the premises are true).

deontic reasoning Reasoning about actions that are obligatory, permissible, or impermissible.

formal rules of inference Rules that can be used to derive a conclusion from premises in a way that takes into account only the form, not the meaning, of the premises. Logical calculi rely on formal rules, and so do many psychological theories of reasoning.

implicit reasoning A fast, automatic, and largely unconscious process of making inferences in order to make sense of the world and of discourse (e.g., to select the appropriate sense of a word, or to establish the appropriate referent for a pronoun).

inductive reasoning The process of deriving plausible conclusions from premises.

logic The science of implications among sentences in a formalized language. Logical calculi are systems of proof based on formal rules of inference (proof theory); they have an accompanying semantics (or model theory).

mental models Representations of the world that are postulated to underlie human reasoning; each model represents what is true in a single possibility.

validity An inference is valid if its conclusion must be true given that its premises are true. A valid inference from true premises yields a true conclusion; a valid inference from false premises may yield a true or a false conclusion.

Logic captures the implications among sentences. A logical calculus consists of a precise definition of a language and a set of rules of inference that can be used to derive conclusions from premises. The rules are formal, that is, they operate on the form of sentences, not their meaning. The calculus, however, may have a semantics, which provides interpretations for all the sentences in the language. Modern logic lies at the heart of the development of computers and computer programming languages. However, logic is not easy to use in the evaluation of everyday inferences because no algorithm exists for translating such inferences into sentences in a logical calculus—a gap that the logician Bar-Hillel once referred to as the scandal of logic. Logic is also not a theory of how human beings reason. That topic is the province of psychology. Although psychologists studied deductive reasoning for almost the entire 20th century, they began to formulate theories of the process only in the past 25 years. Deductive reasoning is now under intensive investigation, and more is known about it than any other variety of thinking. The aim of this article is accordingly to outline the general principles of logic; to describe current theories of human reasoning, which owe much to logic; and to outline what is known about the role of the brain in reasoning.

I. LOGIC

From the founder of logic, Aristotle, onwards logicians have analyzed formal patterns of valid inference. A deduction is valid if its conclusion must be true given that its premises are true. The original aim of logic, as Leibniz remarked, was to replace rhetoric with calculation. Modern formal logic began during the last quarter of the 19th century, but nowadays logicians draw a sharp distinction between formal systems of

logic, which they refer to as proof theory, and semantic systems of logic, which they refer to as model theory. The distinction is clearest in the case of the sentential calculus. This calculus concerns implications that depend on sentential negation, as expressed by "not," and various sentential connectives, such as "if," "and," and "or," which are treated in an idealized way. The following inference is an example of a valid deduction that can be proved in the sentential calculus:

If the brakes are on and the switches are on then the engine is ready to start.
The brakes are on.
The switches are on.
Therefore, the engine is ready to start.

The inference is based on three atomic sentences (i.e., sentences that contain neither negation nor any connectives): the brakes are on, the switches are on, and the engine is ready to start. The inference is valid and has the form

If A and B then C.
A.
B.
Therefore, C.

where A, B, and C, are variables that can take as values any sentences including those that in turn contain connectives.

Logicians can set up the proof theory for a calculus in various ways. They can formalize the sentential calculus, for example, using just a single rule of inference and a set of axioms, which are assertions that are assumed to be true. However, a more intuitive method, known as natural deduction, dispenses with axioms in favor of formal rules of inference for negation and for each of the sentential connectives. Certain rules introduce connectives into a proof, such as the rule that introduces "and," using it to conjoin two premises:

A.
B.
Therefore, A and B.

Certain rules eliminate connectives from a proof, such as the well-known rule of modus ponens:

If A then B.
A.
Therefore, B.

These two rules suffice to prove the conclusion about starting the engine:

1. If the brakes are on and the switches are on then the engine is ready to start.
2. The brakes are on.
3. The switches are on.
4. Therefore, the brakes are on and the switches are on [The rule for introducing "and" applied to sentences 2 and 3]
5. Therefore, the engine is ready to start. [Modus ponens applied to sentences 1 and 4].

Table I presents a set of formal rules of inference for the sentential calculus. With such rules, you can construct a formal proof, as in the preceding example, with each step in the proof warranted by one of the rules of inference.

Your knowledge of the meaning of the connectives helps you to understand the validity of the rules in Table I. However, the rules do not rely on these meanings. They work in a formal way, allowing you to write patterns of symbols given other patterns of symbols. A proof in a formal calculus is accordingly like a computer program. A computer predicts the weather, for example, but it has no idea of what rain or sunshine is or of what it is doing. It slavishly shifts "bits," which are symbols made up from patterns of electricity, from one memory store to another, and

Table I
Formal Rules of Inference for the Sentential Calculus[a]

A ∴ Not (Not A)	Not (Not A) ∴ A
A B ∴ A and B	A and B ∴ A
A ∴ A or B, or both	A or B, or both. Not A ∴ B
Rule for conditional proof A (a supposition) … B (i.e., B can be derived from A) ∴ If A then B	Rule for modus ponens If A then B A ∴ B

[a]The rules in the left-hand column introduce negation and the sentential connectives into inferences; those in the right-hand column eliminate them from inferences.

displays symbols that meteorologists can interpret as maps of weather. Indeed, proofs and computer programs are intimately related, and certain programs can prove inferences in logical calculi. Likewise, certain programming languages, such as PROLOG, are akin to a logical calculus.

Formal proofs establish that inferences are valid, but validity is not a concept that is defined within proof theory. Its definition hinges on truth, which underlies the semantics of the calculus (i.e., its model theory). In the model theory of the sentential calculus, the truth or falsity of compound sentences depends only on the truth or falsity of their constituent sentences. Thus, an assertion of the form, A or B or both, is true if A is true, B is true, or both of them are true. Otherwise it is false. Logicians lay out these definitions in truth tables, as shown in Table II. Each row in a truth table is a "model" of a possibility and presents the truth value of the compound sentence—in this case, A or B or both—in that possibility. The first row in the table, for instance, presents the case in which A is true and B is true, and so the disjunction is true in this possibility.

One problematic connective is "if." Its everyday usage sometimes departs from its idealized logical meaning in the sentential calculus. An assertion such as

If that patient has malaria then she has a fever

is, in fact, compatible with three possibilities: The patient has malaria and a fever, she has no malaria and fever, and she has no malaria and no fever. It is false in only one case: She has malaria and no fever. The assertion is therefore equivalent to

If that patient has malaria then she has a fever, and if she does not have malaria then she either has or does not have a fever.

Logical license exists just as much as poetic license: Logicians make simplifying assumptions about the meanings of logical terms.

Table II

A Truth Table for the Disjunction *A or B or Both*, Which Shows Its Truth Value for the Four Possibilities Depending on the Truth or Falsity of A and of B

A	B	A or B or both
True	True	True
True	False	True
False	True	True
False	False	False

The validity of an inference in the sentential calculus can be established using the model theory of the calculus. Table III shows how premises can be used to eliminate possibilities from a truth table. When you have eliminated the impossible then, as Sherlock Holmes remarked, whatever remains, however improbable, must be the case. In other words, an inference is valid if the conjunction of its premises with the negation of its conclusion is inconsistent (i.e., not a single row in the resulting truth table contains the entry "true"). For instance, if you conjoin the negation of the conclusion in Table III, "The engine is not ready to start," to the premises, then it would eliminate the last remaining possibility in the truth table. It is therefore impossible for the premises to be true and for the conclusion to be false: The inference is a valid.

Any conclusion that can be proved using formal rules for the sentential calculus is also valid using truth tables and vice versa. There is also a decision procedure for the calculus; that is, the validity or invalidity of any inference can be established in a finite number of steps. Unfortunately, sentential inferences are computationally intractable. It is feasible to test the validity of inferences based on a small number of atomic sentences. However, as the number of atomic sentences in an inference increases, its evaluation in any system —no matter how large or how rapid—takes increasingly longer and depends on increasingly more memory, to the point that a decision will not emerge during the lifetime of the universe.

The sentential calculus has a decision procedure, but it is intractable. The predicate calculus includes the sentential calculus, but also deals with quantifiers—that is, with sentences containing such words as "any" and "some," as in "Any electrical circuit contains some source of current." The predicate calculus does not even have a decision procedure. Any valid inference can be proved in a finite number of steps, but no such guarantee exists for demonstrations of invalidity. Attempts to show that an inference is invalid may, in effect, get lost in the "space" of possible derivations. The principal discovery of 20th century logic, however, is Gödel's famous proof that no consistent calculus is powerful enough to yield derivations of all the valid theorems of arithmetic. Arithmetic is thus incomplete. This result drives a wedge between syntax (proof theory) and semantics (model theory). Any attempt to argue that semantics can be reduced to syntax is bound to fail. Semantics has to do with truth and validity, whereas syntax has to do with proofs and formal derivability.

Table III
The Validity of an Inference Is Shown Using a Truth Table[a]

1. If the brakes are on and the switches are on then the engine is ready to start.
2. The brakes are on.
3. The switches are on.

All that remains is the first possibility, and so it follows validly: Therefore, the engine is ready to start.

Brakes are on	Switches are on	The engine is ready to start	Possibilities that are eliminated
True	True	True	
True	True	False	Eliminated by 1
True	False	True	Eliminated by 3
True	False	False	Eliminated by 3
False	True	True	Eliminated by 2
False	True	False	Eliminated by 2
False	False	True	Eliminated by 2
False	False	False	Eliminated by 2

[a]The premises are used to eliminate possibilities.

II. DEDUCTIVE REASONING

Logic tells us about implications among sentences, but it is not a theory of human reasoning. This topic is a concern of psychology. In the last 25 years of the 20th century, psychologists proposed a variety of theories of reasoning—that it depends on a memory for previous cases, on rules that capture general knowledge, on "neural nets" representing concepts, or on specialized innate modules for matters that were important to our hunter–gatherer ancestors. However, humans have the ability to reason about matters for which they have no specific knowledge. Even if you know nothing about brakes, switches, and engines, you can grasp the validity of the earlier inference about them. This ability lies at the heart of the development of mathematics and logic. Hence, a critical question is whether it depends on syntactic or semantic principles. The following sections describe psychological theories of both sorts.

A. Formal Rule Theories

The first theories of human deductive ability postulated that the mind tacitly uses formal rules of inference like those of a system of natural deduction. Such theories continue to have many proponents, notably Daniel Osherson, Lance Rips, and the late Martin Braine and colleagues. Philosophers have proposed similar theories, and computer scientists have implemented formal systems for the computer generation of proofs. What these proposals have in common is the idea that reasoning depends on applying formal rules of inference to the premises of an inference in order to derive the conclusion in a sequence of steps akin to a proof.

Rips's PSYCOP theory was the first formal rule theory in psychology to cope with connectives and quantifiers and to be implemented in a computer program (written in PROLOG). The system is otherwise typical of formal rule theories. It postulates that reasoning depends on a single deterministic process, that it relies on natural deduction, and that it makes use of suppositions—sentences that are assumed provisionally for the sake of argument, and that have to be "discharged" if a proof is to yield a conclusion. There are two ways to discharge a supposition. First, it can be incorporated within a conditional conclusion (see the rule for conditional proof in Table I). Second, if a supposition leads to a contradiction, then it must be false given that the premises are true (according to the rule of "reductio ad absurdum," which is not shown in Table I). As an example, consider the proof for an inference of a form known as *modus tollens*. There are two premises, such as

1. If the switches were not on then the engine did not start.

2. The engine did start.

The proof starts with a supposition:

3. Suppose: the switches were not on.
4. Therefore: the engine did not start. [Rule for modus ponens applied to 1 and 3]

There is now a contradiction between a sentence in the domain of the premises (The engine did start) and a sentence in the subdomain of the supposition (The engine did not start). The rule of reductio ad absurdum uses such a contradiction to negate, and thereby discharge, the supposition that led to the contradiction:

5. Therefore, the switches were on.

Like other formal rule theories, PSYCOP does not contain a rule for modus tollens, because the inference is more difficult for logically untrained individuals than modus ponens. Hence, it depends on the chain of inferential steps just given. In contrast, an inference of the following form, which we encountered earlier,

If A and B then C.
A.
B.
∴ C.

could be derived in two steps, first conjoining A and B, and then using modus ponens to derive the conclusion. However, the inference is so easy that PSYCOP has a single formal rule for drawing the inference (a conjunctive form of modus ponens).

Formal rule theorists try to postulate psychologically plausible rules of inference and a mechanism for using them to construct mental proofs. One problem is that unless certain rules, such as the rule for introducing "and" (see Table I), are constrained, they can lead to futile derivations:

The brakes are on.
The switches are on.
∴ The brakes are on and the switches are on.
∴ The brakes are on and the brakes are on and the switches are on.
∴ The brakes are on and the brakes are on and the brakes are on and the switches are on.

and so on ad infinitum. One solution is to incorporate the effects of such rules within other rules. In computer programs, however, a rule of inference can be used in two ways: either to derive a step in a chain of inference leading forward from the premises to the conclusion or to derive a step in a backward chain leading from the conclusion to a subgoal of proving its required premises. PSYCOP allows the dangerous rules to be used only in such backward chains, and thereby prevents them from yielding futile steps. PSYCOP therefore has three sorts of rules: those that it uses only forwards, such as the conjunctive rule for modus ponens; those that it uses only backwards, such as the rule for conditional proof; and those that it uses in either direction, such as the rule for modus ponens. A corollary is that reasoners should make modus tollens inferences only when they are given the putative conclusion, or when they can guess the conclusion and then try to prove it.

Given an inference to evaluate, PSYCOP always halts after a finite number of steps either with a proof of the conclusion or else in a state in which it has unsuccessfully tried all its possible derivations. Hence, the theory implies that people infer that a conclusion is invalid only if they fail to prove it. They carry out an exhaustive search of all possible derivations, and only then do they judge that the conclusion does not follow from the premises. However, valid inferences exist that PSYCOP cannot prove. If its exhaustive search has failed to find a proof, then there are two possibilities. Either the inference is invalid, or it is valid but beyond the competence of PSYCOP to prove. A psychological corollary is that people should never know for certain that an inference is invalid.

Formal rule theories postulate that the difficulty of a deduction depends on the number of steps in its derivation and the availability and ease of use of the required rules of inference. Modus ponens is easy because it depends on a single rule; modus tollens is more difficult because it depends on a chain of inferences. Formal rule theorists have corroborated their theories in experiments using large batteries of deductions. They estimate post hoc the probability of the correct use of each rule of inference. When these empirical estimates are combined appropriately for each inference, they yield a satisfactory fit with the difficulty of the inferences in the battery.

B. The Mental Model Theory

The mind may not contain any formal rules of inference unless an individual has learned logic. Instead, inferences could be based on an understanding of the meaning of the premises. Consider the following inference:

From where I stand, the peak of the mountain is directly behind the steeple. The old oak is on the

right of the steeple, and there is a flag pole between them. Therefore, if I move to my right so that the flag pole is between me and the peak of the mountain, the steeple is to the left of my line of sight.

Reasoners might rely on axioms and formal rules to make this inference, but it seems more likely that they imagine the relevant spatial layout. This idea lies at the heart of the theory of mental models.

The theory postulates that mental models have three principal characteristics. First, each model represents a possibility. For example, the disjunction "The switches are on or the brakes are on, or both" calls for a separate model for each of the three possibilities (shown here on separate lines):

switches
brakes
switches *brakes*

where "switches" denotes a model of the switches being on, "brakes" denotes a model of the brakes being on, and the third model combines the two.

Second is the principle of truth: Mental models represent only what is true and not what is false, and in this way they place a minimal load on working memory. Hence, the preceding models do not represent the row in the truth table in which the disjunction as a whole is false (Table II). Likewise, the first model represents that the switches are on, but it does not represent explicitly that in this possibility it is false that the brakes are on. People make a mental "footnote" about what is false, but normally they soon forget it. If they retain such footnotes, however, then they may be able to flesh out their mental models to make them fully explicit. Table IV presents the mental models and the fully explicit models for sentences based on each of the main sentential connectives. Mental models are accordingly like truth tables in which there are no "false" entries.

Third, the structure of a model corresponds to the structure of the situation that the model represents. A model is accordingly like a biologist's model of a molecule. The previous notation for the models fails to capture their rich internal structure. Visual images can be derived from some models, but models are often not visualizable. Early formulations of the theory concerned only the logical terms in the language, but recently the theory has been extended to deal with various sorts of nonlogical terms, such as spatial and temporal relations, and general knowledge about causal relations.

Table IV
Models for the Sentential Connectives[a]

Connective	Mental models	Fully explicit models
A and B	A B	A B
A or else B	A	A ¬B
	B	A B
A or B or both	A	A ¬B
	B	¬A B
	A B	A B
If A then B	A B	A B
	…	¬A B
		¬A ¬B
If and only if A then B	A B	A B
	…	¬A ¬B

[a]The middle column shows the mental models postulated for human reasoners, and the right-hand column shows fully explicit models, which represent the false components in true possibilities using negations that are true: "¬" denotes negation and "…" denotes a wholly implicit model. The footnote on the mental models for "if" indicates that the implicit model represents the possibilities in which A is false, and the footnote on the mental models for "if and only if" indicates that the implicit model represents the possibilities in which both A and B are false.

Reasoners use all the information available to them to construct models—discourse, perception, general knowledge, memory, and imagination. They formulate a conclusion that holds in their models but that was not explicit in the starting information. If a conclusion holds in all the models of the premises, then it is necessary given the premises. If it holds in at least one model of the premises, then it is possible given the premises. The probability of a conclusion depends on the proportion of models in which it holds, granted that each model is equiprobable, which is an assumption that reasoners make in default of evidence to the contrary. The theory accordingly unifies reasoning about necessity, possibility, and probability. They all depend on a semantic process rather than a formal one. They all depend on a grasp of meaning, which is used to imagine the possibilities compatible with the premises.

To illustrate the theory, consider the following inference:

The switches are on or the brakes are on, or both.
The switches are not on.
∴ The brakes are on.

The disjunctive premise elicits the models:

switches
brakes
switches *brakes*

The second premise eliminates the models representing the possibilities in which the switches are on. The remaining model yields the conclusion that the brakes are on. This conclusion is valid because it holds in all the models—in this case, the single model—of the premises.

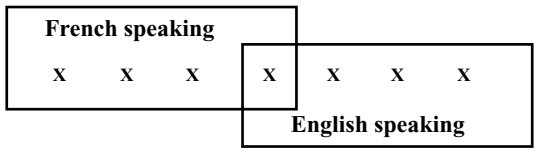

Figure 1 A counterexample used to refute an inference. Each x represents an individual: more than half of them speak French, and more than half of them speak English, but it is false that more than half speak both languages.

C. Five Empirical Phenomena

Psychological investigations have established five principal phenomena of deductive reasoning. The first phenomenon is that the more possibilities that reasoners have to envisage to draw an inference, the more difficult the inference—it takes them longer, and they are more likely to make a mistake. A simple example is that inferences based on a disjunction are more difficult when the disjunction is inclusive, as in the preceding example, than when it is exclusive and allows only two possibilities: "The switches are on or the brakes are on, but not both." The same effect of number of possibilities occurs in reasoning with other sentential connectives, in reasoning about spatial and temporal relations, and in reasoning with premises containing quantifiers, such as "all," "some," and "none."

The second phenomenon is that reasoners use counterexamples to establish invalidity. When reasoners draw conclusions for themselves, they may not consider counterexamples. However, when they reject a conclusion, they can do so by constructing a counterexample—that is, they envisage a possibility that satisfies the premises but refutes the conclusion. One experiment, for example, used problems, such as

More than half of the people in the room speak French.
More than half of the people in the room speak English.
Does it follow that more than half of the people in the room speak both French and English?

Most people responded correctly, "no," and they typically reported having envisaged a situation analogous to the one represented in Fig. 1. They drew such diagrams when they were allowed paper and pencil. They also used counterexamples when they manipulated external models—cut-out paper shapes—in order to reason with quantifiers.

The third phenomenon is that human reasoners spontaneously develop a variety of different strategies in deductive reasoning. They do not use a single deterministic strategy. For example, in reasoning based on multiple premises containing sentential connectives, some individuals develop the strategy of translating each disjunctive premise into a conditional, some base their inferences on the most informative premise, and some make use of suppositions—even when there are categorical assertions among the premises. Many distinct inferential strategies occur, but the space of possible strategies has yet to be mapped.

The fourth phenomenon is the occurrence of illusory inferences. These inferences are compelling but invalid. The following is a typical example:

Only one of the following premises is true about a particular hand of cards:
There is a king in the hand or there is an ace, or both. There is a queen in the hand or there is an ace, or both.
There is a jack in the hand or there is a 10, or both.
Is it possible that there is an ace in the hand?

Most people respond "yes." The first premise is compatible with the possibilities:

King
Ace
King *Ace*

They support the conclusion that an ace is possible. The second premise supports the same conclusion, and so reasoners are likely to respond affirmatively. However, this response overlooks the fact that when one premise is true, the others are false. Thus, if the first premise is true, the second premise is false. In which case, there cannot be an ace. Indeed, if there were an

ace in the hand, then the first two of the premises would be true, contrary to the rubric that only one of the premises is true.

The rubric "only one of the premises is true" is equivalent to an exclusive disjunction, and a compelling illusion occurs in the following inference about a particular hand of cards:

If there is a king in the hand then there is an ace in the hand, or else if there isn't a king in the hand then there is an ace in the hand.
There is a king in the hand.
What, if anything, follows?

Nearly everyone, experts and novices alike, infers that there is an ace in the hand. It follows from the possibilities that people envisage. However, given the disjunction of the two conditionals, it is an error. The disjunction implies that one or other of the conditionals could be false. If the first conditional is false, then even the presence of a king fails to guarantee that there is an ace in the hand. The fallacies arise from a failure to think about what is false. It follows that any manipulation that emphasizes falsity should alleviate them. This prediction has been corroborated experimentally.

The fifth phenomenon is that knowledge and beliefs affect both the interpretation of premises and the process of reasoning. Consider, for example, the following conditional assertion:

If she played a sport then she didn't play soccer. Conditionals are normally compatible with three possibilities (see the fully explicit models in Table IV):

sport	¬ *soccer*
¬ *sport*	¬ *soccer*
¬ *sport*	*soccer*

where ¬ denotes negation. However, the meaning of the noun soccer entails that it is a sport, and so knowledge of this meaning automatically rules out the third of these possibilities. General knowledge and knowledge of the context of an utterance can also eliminate possibilities. Individuals often know what the different possibilities are, and such knowledge modulates the interpretation of assertions. As an illustration, consider the following conditional:

If you strike a match properly then it lights.

Its interpretation includes the salient possibility:

strike	*lights*

As often happens in discourse, however, the antecedent of the conditional fails to describe in complete detail the context in which the consequent holds. There are many circumstances in which a match will not light even if you strike it properly. You know, for instance, that if it is soaking wet it will not light. In fact, you have knowledge of the following explicit possibilities:

soak	¬*lights*
¬ *soak*	¬*lights*
soak	*lights*

Now, suppose you soak a match in water and then strike it. What happens? The conditional implies that it lights. Your knowledge implies that it does not light. Your knowledge, however, takes precedence over the possibilities that the conditional asserts.

Given the following premises in a form known as a syllogism,

All the Frenchmen are wine drinkers.
Some of the wine drinkers are gourmets.

the majority of reasoners draw the plausible conclusion:

Some of the Frenchmen are gourmets.

However, with the next premises, which are identical in form,

All the Frenchmen are wine drinkers.
Some of the wine drinkers are Spanish.

few reasoners draw the conclusion

Some of the Frenchmen are Spanish.

They envisage the possibility in which the wine drinkers are of both nationalities, but they search more assiduously—and successfully—for a counterexample because this conclusion is preposterous. Hence, the main effect of beliefs on the process of reasoning is that they influence invalid inferences far more than valid inferences: People refrain from drawing unbelievable invalid conclusions.

The difficulty of coping with falsity and the effects of content come together in a well-known reasoning problem, Wason's selection task, which has been studied experimentally more than any other paradigm of reasoning. Table V presents two versions of the task, one with a neutral conditional and one with a deontic conditional concerning what is permissible. The difficulty of the version with the neutral conditional, "If a card has an 'A' on one side then it has a '2' on its other

Table V
Two Examples of Wason's Selection Task

A	B	2	3

1. The participants know that each card above has a letter on one side and a number on the other side. Their task is to select those cards that they need to turn over to discover whether the following conditional is true or false about the four cards:

If a card has an "A" on one side then it has a "2" on its other side.

Most people correctly select the "A" card, and some select the innocuous "2" card too. They fail to select the 3 card. However, if it has an A on its other side, the conditional is false.

Drinking	Not drinking	21 years	16 years

2. The participants know that each card above represents a person. One side states whether or not the person is drinking alcohol, and the other side states the age of the person. The task is to select those cards that need to be turned over to discover whether or not a person is violating the following conditional rule:

If persons are drinking then they are over the age of 20 years.

Most people correctly select the "Drinking" card and the "16 years" card.

side," arises from the participants' inability to base their selections on the possibility that falsifies the conditional:

$$A \quad \neg 2$$

They need to choose those cards that could be instances of this case, i.e., A and 3 (which is an instance of $\neg$ 2). With neutral conditionals, reasoners appear merely to select cards on the basis of their mental models of the conditional rather than its falsifying instance.

When the selection task concerns what is permissible or impermissible, such as breaking a social contract, then reasoners tend to make the correct selections (Table V, problem 2). Some psychologists argue that this version of the task maps onto mental schemas with a content that concerns such deontic matters. Evolutionary psychologists propose that social contracts mattered to our hunter–gatherer ancestors, and so an innate module evolved for reasoning about cheaters. What appears to be the case, however, is that any experimental manipulation that helps reasoners to envisage false instances of conditionals improves their performance in the selection task. Knowledge of cheating is just such a cue, but there are others. Experiments have shown, for example, that instructions to check for violations or to envisage counterexamples improve performance. The context of a conditional can also exert such effects. One study enhanced the participants' selections with a neutral conditional, "If A then 2." The participants were told that it was a rule followed by a machine that prints cards. The machine went wrong, and now the participants must check that it is printing out cards correctly.

Reasoners are sensitive to the likelihood of encountering potential counterexamples, and so some theorists have introduced probabilistic considerations into their analyses of the selection task. They defend a normative approach of this sort, arguing that participants rationally seek to maximize the expected gain in information from selecting a card. If they were testing in the real world, the following conditional:

If a creature is a raven then it is black.

it would make sense to examine creatures that are black because there are many fewer black than nonblack creatures. Hence, the argument goes, people are rational in selecting 2 rather than 3 to test the neutral conditional. In one study, however, participants were each paid 1000 pesetas (about $7) before carrying out the selection task with a neutral conditional. They were charged 250 pesetas for each card that they selected, but they were told that they could keep whatever money they did not spend provided that their evaluation of the conditional was correct. This incentive failed to improve performance. Likewise, individuals with higher SAT scores tend to do better on the selection task than those with lower scores.

Whatever "rational" is taken to mean, it seems inappropriate to apply it to those who lose money rather than gain it and to those who score lower on tests of cognitive ability.

The five sorts of phenomena reviewed in this section were all predicted by the model theory, although readers will need to consult the literature for the derivation of the predictions. Formal rule theories allow that knowledge and beliefs can affect the interpretation of premises; otherwise, the phenomena are difficult for these theories to accommodate.

III. IMPLICIT INFERENCES

Psychologists distinguish between the deliberative thinking that underlies deduction and the implicit, automatic, and largely unconscious inferences that help people to make sense of the world and its descriptions. Consider, for example, the following passage:

The pilot put the plane into a stall just before landing on the strip. He just got it out of it in time. It was a fluke.

Readers have no difficulty in understanding the passage, but every noun and verb in the first sentence is ambiguous. Also the search for the referents for the three occurrences of the pronoun "it" in the passage defeats even the most advanced computer programs for interpreting natural language. Humans have no difficulty with the passage because they are equipped with a powerful system that uses general knowledge to make implicit inferences. Readers should also have no difficulty in understanding the following passage:

Apart from her husband, a hairdresser, Eve was the only woman among 52 men on the tour. As a costumier, she filled a much needed gap, because when a company of actors is putting on a play in a different town each night, no damage to the costumes is too trivial not to be mended.

In fact, most people do not notice that the passage contains three deliberate mistakes. It implies that Eve's husband is a woman. It states that what is needed is a gap rather than Eve. It also asserts that no damage to the costumes is too trivial not be mended instead of what it surely means—no damage to the costumes is too trivial to be mended. The system of implicit inferences overrides the literal interpretation of the sentences and makes sense out of nonsense. The inferences resolve the senses of words and determine the references of pronouns and other such expressions. They enable individuals to construct a single model of the situation described in a passage, and the implicit system does not attempt to search for alternative models unless it encounters evidence for them. The process is therefore rapid, and it becomes as automatic as any other cognitive skill that calls for no more than a single mental representation at a time. For the same reason, implicit inferences lack the guarantee that their conclusions are valid. They are inductions rather than deductions. However, the implicit system is not isolated from the mechanisms of deduction. Normally, the two systems work together in tandem.

One consequence of implicit inferences is that people often jump to a conclusion, which later they have to withdraw. In logic, if a conclusion follows validly from premises, then no additional premises can invalidate it. Logic means never having to be sorry about a conclusion. As new premises are added to existing premises, then increasing numbers of logical conclusions follow (i.e., logic is "monotonic"). However, in daily life, conclusions are often withdrawn in the light of subsequent information. These inferences are "nonmonotonic". The original conclusion may have been based on an assumption made by default that turned out to be false. For instance, I tell you about my cat Hodge, and from your knowledge of cats you infer that Hodge has fur and a tail. You withdraw your conclusion, however, when you learn that Hodge is bald and tailless. Your knowledge contains various assumptions that you can make in default of information to the contrary. The whole purpose of these default assumptions is to allow you to make useful inferences that you can withdraw in the light of contrary evidence.

A more problematic sort of nonmonotonic reasoning is illustrated in the following example. You believe the following premises:

If Viv has gone shopping then she will be back in an hour.
Viv has gone shopping.

It follows, of course, that Viv will be back in an hour. However, suppose that Viv is not back in an hour. You are in a typical everyday situation in which there is a conflict between the consequences of your beliefs and the facts. At the very least, you have to withdraw your conclusion. You also have to modify your beliefs, but in what way? Should you cease to believe that Viv went

shopping or that if she went shopping she will be back in an hour, or both? Philosophers and students of artificial intelligence have made various proposals about these puzzles. Unfortunately, the understanding of nonmonotonicity in human reasoning lags behind.

Reasoning in daily life often calls for the generation of explanations and diagnoses. For example, in the case of Viv's failure to return, you do not merely modify your beliefs, you try to make diagnostic inferences about what happened:

Possibly, Viv met a friend and went for a coffee.
Possibly, Viv felt ill on the way to the shops.

One possibility leads in turn to further explanatory possibilities, for example,

Possibly, Viv couldn't get the car to start after shopping.
∴ Possibly, the car's battery is dead. Possibly, Viv left the headlights on.

You use your knowledge and any relevant evidence to generate possibilities. Human reasoners easily outperform any current computer program in envisaging putative explanations. Given two sentences selected at random from different stories, such as

Celia made her way to a shop that sold TV sets.
She had recently had her ears pierced.

they readily offer such explanations as Celia was getting reception in her ears and wanted the TV shop to investigate, or Celia had bought some new earrings and wanted to see how they looked on closed-circuit TV. This propensity to generate explanations underlies both science and superstition. The difference is that scientists test their explanations empirically.

Inferences in real life are often not deductively "closed"—that is, there is not enough information to draw a valid conclusion. Reasoners must therefore make inductions, that is, they use their knowledge to draw conclusions that go beyond the information given and that therefore may be false. There is no normative theory of induction and no comprehensive psychological theory of it, either. What does exist are a number of well-established heuristics, which were identified by two pioneers, Kahneman and Tversky. One heuristic is the availability of relevant knowledge. Most individuals, for example, judge that more people die in automobile accidents than as a result of stomach cancer. They are wrong, but the media publish more stories about auto accidents than about stomach cancer. Similarly, people rely on the representativeness of evidence. If you are told that Bill is intelligent but unimaginative and lifeless, then you are unlikely to judge that he plays jazz for a hobby, though you may find it more likely that he is an accountant who plays jazz for a hobby. If so, you have violated the principle that a conjunction (being an accountant and playing jazz) cannot be more probable than one of its components (playing jazz). The description of Bill, however, is more representative of an accountant than of a jazz musician. It has therefore led you to overlook a simple principle of probability.

IV. REASONING AND THE BRAIN

The famous Russian neuropsychologist Luria once remarked, "The cerebral organization of thinking has no history whatsoever." Fodor, the distinguished philosopher of mind, predicted that it has no future either because thinking depends on general processes rather than separate brain modules, such as those that underlie perception or motor control. Nevertheless, a start has been made in the study of the neuropsychology of reasoning. The results so far have been largely at the level of "these areas of the brain underlie reasoning," and their interpretations are at best tentative.

A. Logical Reasoning and Personal Reasoning

Clinical studies in the early 20th century often reported the loss of "abstract thinking" as a result of brain damage. Such accounts, however, suffered from two irremediable problems. On the one hand, they never succeeded in characterizing a principled difference between abstract and concrete thinking. On the other hand, they failed to pin down the particular effects of lesions in different parts of the brain. This shortcoming is understandable given that many regions of the brain are likely to underlie reasoning. Modern neuropsychological investigations suggest that the real distinction is between logical reasoning with neutral materials and personal reasoning that engages individuals' beliefs and knowledge (Table V). Some studies suggest that logical reasoning depends on the left cerebral hemisphere, whereas personal reasoning implicates the right hemisphere and bilateral ventromedial frontal cortex. Positron emission tomography scans show greater left hemisphere activity when individuals evaluate syllogisms, such as

All men have sisters.
Socrates was a man.
∴ Socrates had a sister.

or judge the plausibility of inductive inferences, such as

Socrates was a great man.
Socrates had a wife.
∴ All great men have wives.

The control task was to judge how many of the sentences had people as their subjects. The effects of brain damage also appear to support the dissociation between logical and personal reasoning. For example, left hemisphere lesions impair simple relational inferences, such as

Mary is taller than John.
John is taller than Anne
Is Mary taller than Anne?

People who live in nonliterate cultures are happy to carry out personal reasoning, but they balk at logical reasoning when the content is outside their experience. Analogous effects have been obtained using electroconvulsive therapy (ECT), which suppresses cortical activity for 30 min or more. Before ECT, the patients (depressives and schizophrenics) tended to justify their responses to deductive problems on logical grounds. They also did so more rapidly and confidently after ECT had suppressed their right hemispheres. However, after the suppression of their left hemispheres, they tended to respond on grounds of personal experience in ways similar to members of nonliterate cultures, often rejecting a logical task based on unfamiliar content as impossible because it was outside their knowledge. Similar effects of brain damage occurred in a study of the selection task with a neutral conditional (Table V). Patients with left hemisphere damage, like control subjects, tended to err in the characteristic way. Surprisingly, however, half the patients with right hemisphere damage made the correct selections.

Perhaps the right hemisphere impedes logical reasoning because it allows knowledge and probabilistic considerations to influence performance. Certainly, the right hemisphere seems to play a role in automatic implicit inferences. Given the passage,

Sally approached the movie star with pen and paper in hand. She was writing an article about famous people's views about nuclear power.

normal individuals are likely to infer that Sally wanted to ask the star about nuclear power. Patients with damage to the right hemisphere infer that Sally wanted the movie star's autograph. They are misled by the first sentence and cannot make the implicit inference from the second sentence to revise their interpretation. Patients who have had a right-hemisphere lobectomy are also poorer at reasoning from false premises than those with a left hemisphere lobectomy. In general, right hemisphere damage seems to impair the ability to "get the point" of a story, to make implicit inferences establishing coherence, and to grasp the force of indirect illocutions such as requests framed in the form of questions.

It is tempting, but erroneous, to conclude that the left hemisphere is the seat of logic, whereas the right hemisphere is the seat of personal reasoning. Damage to the right hemisphere can lead to semantic difficulties in the interpretation of words, and so it may also impair the comprehension of discourse. For instance, it impairs the deduction of converse relations, such as

John is taller than Bill.
Who is shorter?

A recent functional magnetic resonance imaging (fMRI) study confirmed the existence of dissociable networks for logical and personal reasoning, which share circuits in common in the basal ganglia, cerebellum, and left prefrontal cortex. However, the activation suggested that personal reasoning recruits the left hemisphere linguistic system, whereas logical reasoning—even in inferences of an identical form—recruits the parietal spatial system. Also, when reasoning elicits a conflict between logic and belief, right prefrontal cortex becomes active, perhaps to resolve the incongruency. Another recent fMRI study established that deductive reasoning activates right dorsolateral prefrontal cortex whereas mental arithmetic from the same premises does not. This study also showed that when an inference depends on a search for a counterexample then the right frontal pole is activated.

Frontal cortex plays a crucial role in decision making, as shown in a major series of studies carried out by Damasio and colleagues. They also investigated the selection task in testing the consequences of their somatic marker hypothesis. This hypothesis postulates that ventromedial frontal cortex underlies the typical "gut reaction" on which implicit everyday decisions rely. Considerable evidence supports this hypothesis: For example, individuals with frontal lesions tend to

go bankrupt in real life and in laboratory gambling tasks. Similarly, the investigators found that patients with lesions in ventromedial frontal cortex were unaffected by whether the selection task was based on familiar or unfamiliar neutral contents. However, patients with lesions in other areas, like normal individuals, showed the characteristic effects of content. Correct performance in the selection task depends on grasping what counts as a counterexample to the conditional assertion.

B. Imagery and Spatial Representations

Does deductive reasoning rely on visual imagery? Behavioral studies have produced little evidence to suggest this is the case. Readers might suppose that this lack of evidence counts against the model theory. This view, however, confuses models with images. The model theory distinguishes between the two: Mental models are structural analogs of the world, whereas visual images are the perceptual correlates of certain sorts of model from a particular point of view. Indeed, many mental models are incapable of supporting visual images because they represent properties or relations that are not visualizable, such as ownership, obligation, and possibility. Recent studies have sharpened the need to distinguish between the degree to which relations evoke spatial models as opposed to visual images. The studies examined three sorts of materials, as rated by an independent panel of judges:

1. Relations that are easy to envisage spatially and easy to visualize, such as above, below, in front of, and in back of
2. Relations that are not easy to envisage spatially but are easy to visualize, such as cleaner, dirtier, fatter, and thinner
3. Control relations that are neither easy to envisage spatially nor easy to visualize, such as better, worse, smarter, and dumber

The studies examined both conditional inferences and inferences about simple relations among entities. They showed that inferences were faster with contents that were easier to envisage spatially than with the control contents, which in turn were faster than contents that were easy to visualize but difficult to envisage spatially. It seems that a relation such as "dirtier", elicits a visual image, but one that is irrelevant to the construction of a mental model that allows reasoners to make the required inference. In contrast, a relation, such as "in front of" elicits a spatial model that helps individuals to draw the inference. An fMRI study has also examined spatial reasoning. Given spatial problems, such as

> *The red rectangle is in front of the green rectangle.*
> *The green rectangle is in front of the blue rectangle.*
> *Does it follow that the red rectangle is in front of the blue rectangle?*

significant activation occurred in regions of parietal cortex that are known to represent and to process spatial information. Moreover, there was no reliable difference in the degree of activation between the right and the left hemispheres. Clinical studies of how brain damage affects the use of imagery in reasoning have produced mixed results, perhaps because they have not separated the two sorts of contents—spatial and nonspatial—that are both easy to visualize.

In summary, clinical and imaging studies of the brain have yet to establish how reasoners make deductions. There is evidence for separate systems mediating logical inferences with neutral content and personal inferences with a content that engages knowledge and beliefs. Future studies may determine whether separate brain mechanisms underlie the control of different deductive strategies, the use of diagrams as opposed to verbal premises, and the construction and evaluation of multiple models.

V. CONCLUSIONS

Modern logic has developed both proof theory and model theory for systems powerful enough to cope with all the deductive inferences that human beings make. What is lacking is a systematic method for translating such inferences into formal logic. Psychologists continue to investigate deductive reasoning. Their two main theoretical accounts are based on rules of inference and on mental models, respectively—a distinction that parallels the one between proof theory and model theory in logic. Rule theorists emphasize the automatic nature of simple deductions and postulate rules corresponding to them. More complex inferences, they assume, call for sequences of simple deductions. In contrast, model theorists emphasize that reasoning is the continuation of comprehension by other means. The system for implicit inferences based on knowledge aids the process of constructing models of discourse. In deliberative reasoning,

individuals tend to focus on possibilities in which the premises are true. However, they can grasp the force of counterexamples. The evidence suggests that people have a modicum of deductive competence based on mental models. Rules of inference and mental models, however, are not incompatible. Advanced reasoners may construct formal rules for themselves—a process that ultimately leads to the discipline of logic.

Lyme Encephalopathy

RICHARD F. KAPLAN
University of Connecticut School of Medicine

GLOSSARY

fibromyalgia A chronic musculoskeletal rheumatological syndrome that is associated with muscular pain and fatigue. Symptoms include cognitive difficulties, mood change, and sleep disturbance. The etiology is unknown.

intrathecal antibody production Local production of specific antibody to *Borrelia burgdorferi* in cerebral spinal fluid.

Lyme disease A multisystem disorder of the skin, nervous system, heart, and joints caused by the tick-borne spirochete, *B. burgdorferi*.

neuropsychological assessment The use of procedures and tests that measure general intellectual abilities and specific cognitive functioning, such as memory, to aid in the diagnosis of brain dysfunction.

polymerase chain reaction A laboratory assay for *B. burgdorferi* DNA.

post-Lyme disease syndrome A condition characterized by fatigue, mood disturbance, and complaints of cognitive dysfunction that follow well-documented Lyme disease months to years after antimicrobial treatment.

single photon emission computed tomography A functional neuroimaging technique used to measure regional cerebral blood flow. Brain activity is recorded by externally placed gamma cameras, which detect a radiotracer such as t-HMPAO.

Lyme encephalopathy is a neuropsychiatric disorder beginning months to years after the onset of Lyme disease. The symptoms are non specific and typically include fatigue, sleep disturbance, slowed thinking, memory loss, naming problems, and depression. The etiology remains controversial. This article defines the nature of the syndrome and offers possible explanations from a neuropsychological perspective.

I. HISTORY AND BACKGROUND

Lyme disease, originally termed Lyme arthritis, was first recognized in 1975 following an outbreak of arthritis in and around the rural community of Lyme, Connecticut. The association of the illness with a unique skin lesion, erythema chronicum migrans (ECM), and the close geographic clustering of these early cases suggested the disease might be an infection transmitted by an arthropod. Subsequent investigations revealed that the disease was transmitted by a newly identified tick *Ixodes dammini* or related ixodid ticks. A few years later, Willy Burgdorfer and colleagues isolated the spirochete, *Borrelia burgdoferi*, from a tick, *I. dammini*, and it was determined that this was the infectious organism. A disease similar to Lyme disease had been previously described in Europe and is now known to be caused by the same spirochete. Lyme disease is now recognized as a multisystem disorder. A skin lesion, ECM, is typically the first sign of infection, although not all patients infected with Lyme disease manifest this symptom. This can be followed by systemic manifestations involving the joints, heart, and nervous system. The diagnosis of active Lyme disease is not straightforward because, unlike some bacterial infections, *B. burgdorferi* is not easily cultured. Currently, the method recommended by the

Centers for Disease Control (CDC) for diagnosing the disorder includes physician-documented ECM or the detection of antibodies in blood serum, which indicate exposure to *B. burgdorferi*, and at least one late objective manifestation of the disease, such as musculoskeletal pain, chronic arthritis, myocarditis, cranial neuritis, or radiculoneuropathy. However, not all people who are infected have the typical clinical symptoms of Lyme disease, and for this relatively small group the diagnosis is sometimes questionable. This has made the diagnosis of some disorders that have been attributed to Lyme disease, such as Lyme encephalopathy, controversial. For most patients, Lyme disease can be successfully treated with antibiotic therapy. However, a small percentage of patients develop a mild to moderate chronic encephalopathy, a peripheral neuropathy, or both, which may occur months to years after disease onset.

II. NEUROLOGICAL MANIFESTATIONS

The classic neurological symptoms of early disseminated Lyme disease are meningitis, cranial neuritis, and radiculoneurotis. These occur alone or in combination in approximately 15% of untreated patients. A unilateral or bilateral facial nerve palsy is also a relatively common symptom of early disseminated disease. Symptoms usually last for weeks to months but can become chronic. Chronic neurologic manifestations of the disorder, which include encephalopathy, polyneuropathy, and leukoencephalopathy, usually occur late in the illness. Although there have been reports of cases with severe cognitive impairment, including psychosis and dementia, and vasculitic lesions, such cases are rare. A mild chronic Lyme encephalopathy (LE) is the most common neurologic symptom in patients with late-stage disease. Months to years after disease onset, sometimes following long periods of latent infection, a small percentage of patients develop a mild to moderate encephalopathy. The symptoms tend to be diffuse and nonspecific and can include memory loss, naming problems, sleep disturbance, fatigue, and depression.

The diagnosis of LE is difficult. It is generally believed that those with immunity to *B. burgdorferi* and abnormal cerebral spinal fluid (CSF) are more likely to have a neurological basis to their illness. Even if a patient is seropositive, it is difficult to know whether active infection is causing encephalopathy because serologic testing only indicates exposure to the *B. burgdorferi*, not active infection. The standard neurological examination is usually normal. The CSF examination may show a positive polymerase chain reaction to *B. burgdorferi* DNA, intrathecal production of antibody to *B. burgdorferi*, or increased CSF protein. Traditional brain neurophysiological and neuroimaging techniques have also not been shown to be highly sensitive to the pathophysiology of LE. The routine electroencephalograph is typically normal. Magnetic resonance imaging (MRI) abnormalities have been described in Lyme patients, but these are nonspecific and relatively infrequent. When MRI abnormalities are present they are usually white matter lesions, suggesting the possibility of an inflammatory process. Single photon emission computed tomography (SPECT) imaging has shown some promise in identifying brain abnormalities in Lyme patients. Because the spatial resolution of SPECT is relatively poor, it can be used together with MRI to provide information about metabolic activity in specific brain regions (Fig. 1). SPECT has proved sensitive in identifying pathophysiologic abnormalities in other neurobehavioral disorders such as Alzheimer's disease and other dementias. In 1997, Logigian and colleagues studied a series of LE patients using a quantitative SPECT technique. In their analysis, 10 transaxial slices were imaged from each brain and divided into 4320 macrovoxels (Fig. 2). Quantitative SPECT has an advantage over visual image analysis because regional radiotracer uptake is analyzed statistically for each macrovoxel using an analysis of covariance. Patient scans are compared macrovoxel by macrovoxel to normal subjects to determine which brain regions are hyperperfused.

The Lyme patients showed patterns of multifocal hypoperfusion, most notably in the subcortical areas including the basal ganglia and white matter of the cerebral hemispheres, which was not apparent in normal controls. Patients with more objective evidence of LE, including CSF abnormalities, demonstrated significantly lower cerebral perfusion than Lyme patients with encephalopathic symptoms without objective evidence of central nervous system (CNS) involvement. Studies using visual ratings to assess the reduction in regional uptake of radiotracer have similarly reported decreased perfusion in Lyme patients. The reduction of metabolic activity in frontal and temporal lobe structures may provide a clue to the neuroanatomic basis of LE. That these same white matter regions form the large-scale neurocognitive networks involved in mediating memory and attention also suggests a possible explanation for the cognitive

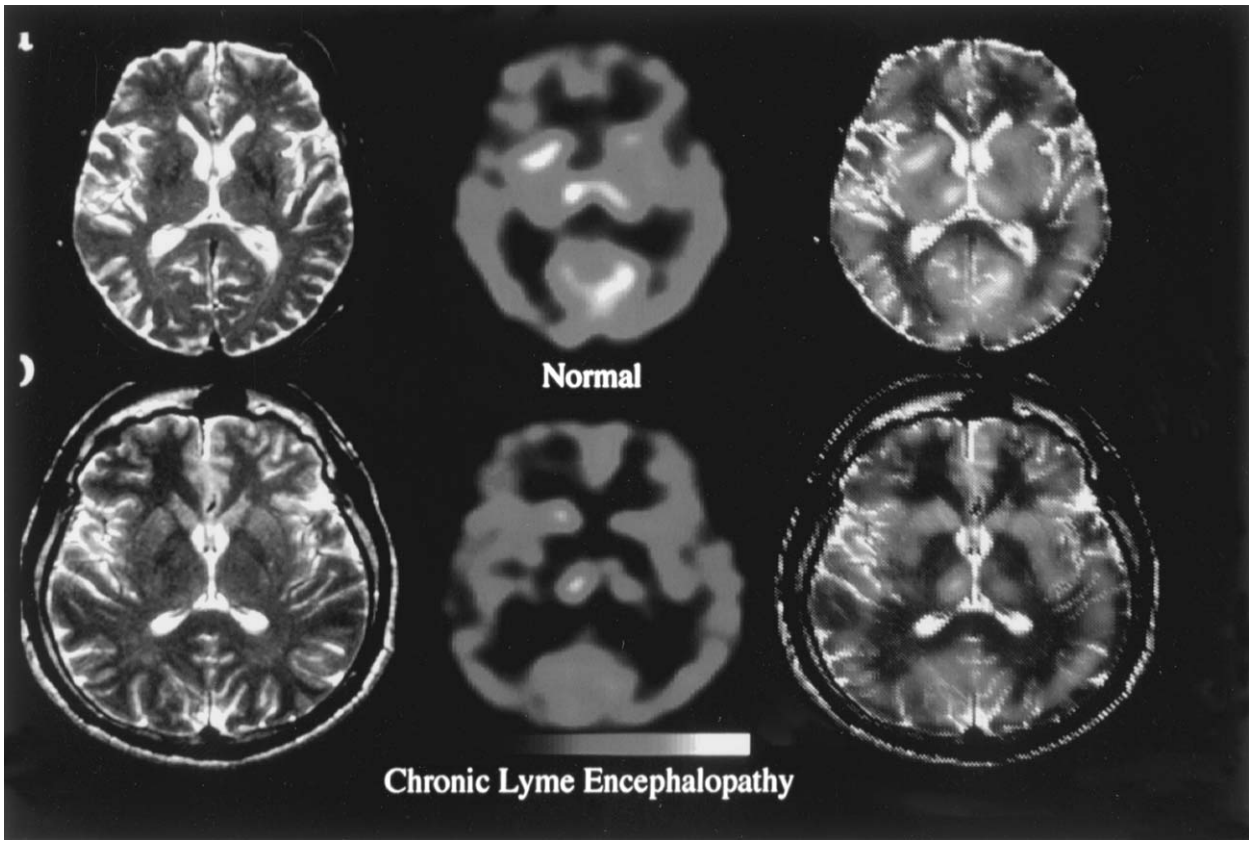

Figure 1 Representative MRI scan (left), SPECT image (center), and superimposed MRI/SPECT image (right) in a normal subject and in a patient with objective evidence of LE. The dark areas correspond to lower and the light areas to higher perfusion. (See color insert in Volume 1).

deficits described previously. Unfortunately, hypoperfusion in these brain regions is not specific to Lyme disease. Similar SPECT findings have been reported in other conditions that have symptoms similar to LE, such as depression and chronic fatigue syndrome. Although some investigators argue that the pattern of hypoperfusion in LE may differ from that seen in other disorders, current quantitative SPECT studies have not yet been done. Therefore, SPECT alone is not sufficient in diagnosing LE.

III. NEUROPSYCHOLOGICAL STUDIES

Although a number of studies that have attempted to define the relationship between positive serology, CNS infection, and cognitive dysfunction, few have used neuropsychological testing to characterize the nature of the cognitive deficits. Neuropsychological tests have an advantage over even comprehensive bedside mental status examinations in detecting cognitive dysfunction associated with LE because the deficits are often subtle. For most neuropsychological procedures, the presence or absence of functional impairment is made on a statistical basis. Ideally, performance on a given test is interpreted in comparison to normative data appropriate to the patient's age, sex, and education. Probable impairment on a specific cognitive test is inferred when performance falls below a designated cutoff score, usually two standard deviations below the normative mean. Whether or not a particular test will discriminate between normal and abnormal function for either individuals or clinical populations depends on a number of critical factors. Reliability and validity data are essential for understanding the limits of a given test. Additionally, the ability of a test to discriminate between groups depends on the purpose and population for which the test was developed. For example, tests such as the Mini-Mental State Examination that were developed to screen for dementia in elderly populations are relatively insensitive to cognitive deficits in patients with Lyme disease.

The traditional approach in neuropsychological assessment used to define cognitive deficits associated

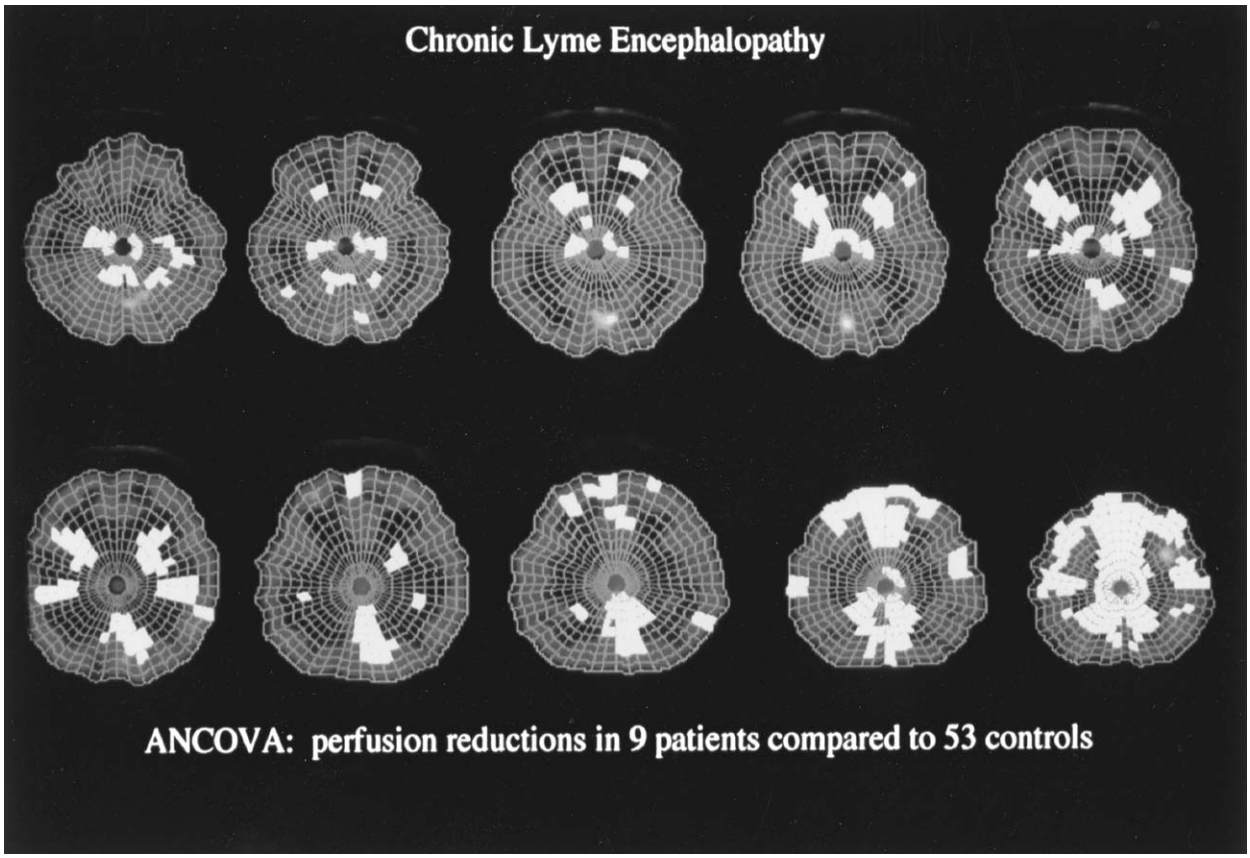

Figure 2 Quantitative SPECT analysis of nine patients with LE (mean data). Axial slices ascend from lowest (top left) to highest brain levels (bottom right). Macrovoxels whose mean perfusion is reduced at the $p < 0.001$ level below the mean of normal subjects ($n = 53$) are shown in white. The dark areas correspond to lower and the light areas to higher perfusion.

with brain disease is to administer a battery of tests. Often, differences in cognitive performance between two clinical populations, such as those with LE and those with depression alone, are best appreciated when the evaluation is based on an analysis of test score patterns. A pattern of scores not only indicates what is wrong with the patient but also what is right with the patient. The test battery usually includes both tests of general intellectual abilities, such as the Wechsler Scales, and tests developed to assess specific areas of cognitive dysfunction, such as attention, visual perception, construction, fine motor control, language, memory, and executive functioning. Test batteries also usually include measures of psychopathology in order to assess the patient's emotional state. The latter are often useful in interpreting other test results because psychological states such as anxiety and depression can impact a patient's cognitive abilities, particularly motivation and the ability to maintain and sustain attention. The importance of this cannot be overstated because although the sensitivity of neuropsychological tests in identifying brain dysfunction is quite high (between 80 and 90%), the specificity may be considerably lower. For example, a memory test that discriminates traumatic brain-injured patients from normal subjects does not indicate how important variables such as attention or affective states may impact performance. It is also incumbent upon the clinician or researcher to interpret neuropsychological test data in the context of the patients' medical and psychosocial history as well as psychiatric status. Table I provides a list of neuropsychological tests that have frequently been used in assessing cognitive deficits in Lyme disease patients.

In comparison to other more well-known brain disorders such as Alzheimer's disease, for which there are large neuropsychological databases, the number of neuropsychological studies in LE is relatively limited. The following discussion presents the neuropsychological test data in considerable detail in an attempt to

Table I
Neuropsychological Tests Frequently Used to Assess Deficits in Lyme Disease

Tested domain or function	Neuropsychological test
General cognitive abilities	Wechsler Intellignece Scales
	Shipley Institute of Living Scale
Attention/concentration	
Short-term auditory attention	Digit Span Test
Sustained attention	Stroop Test (Word and Color)
	Continuous Performance Tests
	Symbol Digit Substitution Test
Interference	Stroop Test (Color/Word)
Learning and memory	California Verbal Learning Test
	Selective Reminding Test
	Rey–Osterrieth Complex Figure Test
	Wechsler Memory Scale
Language and verbal output	
Naming	Boston Naming Test
Verbal fluency	Controlled Word Association Test
Executive functions	
Set maintenance and shifting	Trails A and B
Abstraction and set shifting	Wisconsin Card Sorting
Distractibility	Stroop Test
Problem solving	Halstead Category Test
Motor dexterity	Finger Tapping
	Grooved Peg Board
Neuropsychiatric symptoms	
Mood	Beck Depression Inventory
	Center for Epidemiologic Studies Depression Scale
	State Trait Anxiety Scale
Personality	Minnesota Multiphasic Personality Inventory
Anxiety	State Trait Anxiety Scale
Fatigue	Fatigue Severity Scale

demonstrate the nature and extent of cognitive dysfunction in LE.

In 1988, Halperin and colleagues published one of the earliest studies that included neuropsychological testing. They studied 17 Lyme patients before and after antibiotic treatment. All initially complained of memory deficits; however, only 4 had evidence of other neurological involvement and only 1 had abnormal CSF. The evaluation included tests of memory, visual spatial organization, conceptual thinking, and psychomotor and perceptual motor skills. The pretreatment results are difficult to interpret in part because these investigators failed to include a normal comparison group and also because there was no indication of the number of patients whose performance statistically fell outside the normal range. However, the authors report that there were pretreatment cognitive deficits in almost every area examined. Significant improvements following treatment were found on measures of recall memory on the California Verbal Learning Test (CVLT) as well as on tests of attention, concentration and motor speed, abstract problem solving, fine motor dexterity, and visual spatial organization. Improvement, however, was not evident on all tests. Patients' performances were unchanged on measures of tracking and sequencing, verbal fluency, auditory attention span, and recognition memory. Patients were also administered the Beck Depression Inventory (BDI), a self-administered questionnaire that measures the presence and severity of symptoms associated with depression. There was no evidence of significant depression either before or after treatment. However, the average score on the BDI, which reflects the overall severity of depression, was almost halved following treatment.

In a 1990 report, investigators at the New England Medical Center in Boston described 27 patients with chronic neurological abnormalities of at least 3 months duration following well-recognized manifestations of Lyme disease. Twenty-two of the 27 patients reported memory loss and 18 had CSF protein, evidence of intrathecal antibody to *B. burgdorferi*, or both. Each underwent a neuropsychological test battery consisting of tests of general cognitive abilities, memory, visual perception, construction, executive function, language, and fine motor dexterity. The patients were also administered the Minnesota Multiphasic Personality Inventory (MMPI) to assess emotional status. Standard scores were calculated from published, age-corrected normative data, and scores that were two standard deviations below the mean were considered as evidence of impairment on a particular test. Memory impairment was defined as two standard deviations below average on any one test or one standard deviation below average on two tests, according to a previously described system. All patients had IQ scores that were calculated or estimated to be average or above average. Twelve of the 22 patients reporting memory difficulty met the criteria for memory impairment, as did 2 patients who denied memory problems. Only 1 patient had a below average

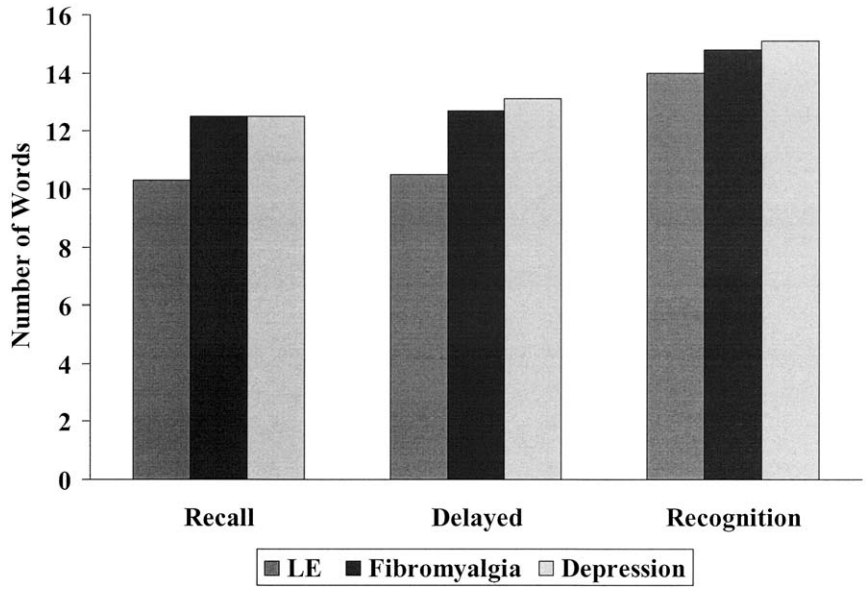

Figure 3 A comparison of memory scores for patients with LE, fibromyalgia, and depression on the CVLT.

performance on a test of abstract problem solving, the Wisconsin Card Sorting test, and 1 patient did poorly on a naming test. No patient had a below average performance on any of the other cognitive tests. Nine patients produced MMPI profiles consistent with depression. Of the 12 patients with objective evidence of memory impairment, 9 had abnormal CSF findings; however, it should be noted that 9 of 10 patients with normal memory scores also had abnormal CSF. The 4 of 24 patients with abnormal MRI scans, which were characterized as small round lesions in the periventricular white matter, all had impaired memory and 3 of the 4 had abnormal CSF.

In contrast to the earlier study by Halperin and colleagues that described a wide range of cognitive impairment, the only significant deficits in this study were in the area of memory impairment. However, unlike the patients in Halperin's study, more than half of the patients in this study had been treated with one or more courses of antibiotic treatment prior to testing. It is therefore possible that the discrepancy in results between the two studies reflects partial recovery.

Many of the symptoms of LE are similar to those reported by patients with depression. These include irritability, fatigue, emotional liability, poor concentration, impaired sleep, and memory disturbance. Depression is also common in late-stage Lyme disease. To examine the impact of psychological factors—particularly somatic concerns, depression, and anxiety—on memory impairment in LE patients, my colleagues and I compared 20 patients with well-documented Lyme disease to patients with fibromyalgia and patients with mild to moderate depression. The rationale for comparing fibromyalgia and depressed patients with LE patients was that the cognitive symptoms in these illnesses are similar. Thirteen of the 20 Lyme patients had abnormal CSF and 2 had abnormal MRI scans. Memory was assessed using the three standardized memory instruments—the CVLT, the Wechsler Memory Scale (WMS), and the Rey–Osterrieth Complex Figure. Indices of psychopathology were obtained from the MMPI and BDI. The depression and fibromyalgia groups performed significantly better than the LE group on both the CVLT (Fig. 3) and a WMS visual memory subtest, whereas recognition memory on the CVLT did not differ. The depression group also performed better than the Lyme group on the WMS Verbal Paired Associate Learning test, another verbal learning test. In contrast, both the fibromyalgia and depressed groups showed greater evidence of psychopathology. On the MMPI, the Lyme group had significantly lower scores on the scales most sensitive to depression and anxiety compared to those of the depression group and significantly lower scores on scales sensitive to the somatic concerns compared to those of the fibromyalgia group (Fig. 4). The Lyme group also had lower BDI scores, but this did not reach statistical significance. These data strongly suggest that memory impairment in LE

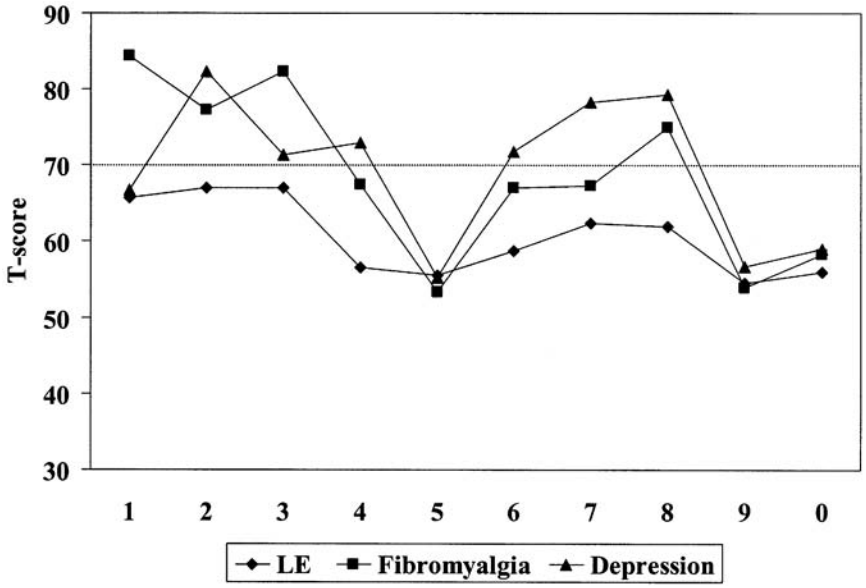

Figure 4 Composite MMPI for LE, fibromyalgia, and depression patient groups.

cannot be explained by affective symptoms alone, even though Lyme patients may report more symptoms of depression than normal controls.

If there is a pattern that emerges from the investigations outlined previously, it is that a memory disturbance appears to be the most common cognitive deficit found in LE patients. Other cognitive domains, such as attention, psychomotor performance, and executive functioning, were reported to be impaired in some but not all studies, even when observed problems in these other areas appeared to be of a lesser magnitude than the memory findings. Memory for verbal material appeared to be more affected than that for nonverbal material; however, this may be more a function of the type of test used because the verbal and nonverbal memory tests used are not of equal difficulty. The verbal list learning tests require acquisition of material over multiple trials and greater use of mnemonic strategy than the nonverbal learning tests (e.g., Rey–Osterrieth Complex Figure). It is also thought that tasks requiring sustained effort, such as the CVLT, may be more vulnerable to the effects of fatigue, and Lyme patients do report greater fatigue than controls. Furthermore, there is no anatomical reason why one would expect a material-specific memory deficit in this population. Recognition memory was spared relative to recall memory in every study. This is of interest because MRI and SPECT studies suggest that the pathophysiology of *B. burgdorferi* primarily affects CNS white matter. The pattern of memory deficits in LE parallels that of another white matter disease, multiple sclerosis (MS). On list learning tests such as the CVLT, MS patients have been shown to have lower initial acquisition rates but similar rates of learning and forgetting when compared to healthy normals. The same pattern is true for LE.

IV. POPULATION STUDIES

In the laboratory studies of the LE described previously patients were selected on the basis of neurologic complaints. Although these types of studies have been helpful in understanding the nature and severity of neurologic deficits in Lyme disease, they tell us little about the prevalence of these symptoms. Nancy Shadick and colleagues studied the prevalence of persistent neurologic symptoms in a sample of unselected patients with a history of Lyme disease in Ipswich, Massachusetts, a community endemic for Lyme disease. These investigators initially studied 38 people who met CDC criteria for previous Lyme disease and 43 people who did not. There was a slight but statistically significantly difference between groups on the CVLT, with the Lyme disease group performing more poorly. Twelve of the 38 Lyme patients scored two or more standard deviations below mean on the word list test, compared to only 5 of the 43 controls. Patients with residual symptoms, neurologic and

musculoskeletal, had longer duration of disease prior to treatment. These findings suggested that a small percentage of patients with previous Lyme disease may have permanent learning and memory deficits, albeit subtle. In a larger subsequent study on Nantucket, another community highly endemic for Lyme disease, these investigators compared 186 people with prior Lyme disease to 167 healthy controls using similar measures including the CVLT. Patients were studied an average of 6 years after infection. Although the patient group reported a higher incidence of nonspecific symptoms, including fatigue, difficulty sleeping, memory impairment, and poor concentration, there were no significant differences between groups on any of the objective tests of memory and concentration. At least two other population studies produced similar findings—namely, that the prevalence of objective measures of LE in previously infected patients who were treated for Lyme disese is very low. Thus, although patients previously infected with Lyme disease may report more neurologic symptoms than never infected controls, there is little evidence of any objective deficits. The relationship between reports of perceived memory dysfunction and performance on memory tests is discussed later.

V. LE IN CHILDREN

Although Lyme disease was first described in children, most studies of LE have involved adults. The incidence of Lyme disease is actually higher in children than in adults, but there are fewer reports of long-term problems. Even in children with Lyme arthritis, who were not treated or were treated years after the onset of infection, the incidence of encephalopathy was low. It has also been noted that children with Lyme disease almost never have the nonspecific symptoms of LE as the sole manifestation of the illness. Wayne Adams and colleagues studied 41 children, aged 6–17, with well-documented Lyme disease. All had been treated with antibiotics and the testing occurred about 2 years after disease onset. The children, 23 healthy sibling controls and 14 with subacute rheumatological diseases, were compared on a battery of standard neuropsychological tests, academic achievement tests, and parental rating scales. The neuropsychological test battery included measures of intelligence, information processing speed, fine-motor dexterity, executive functioning, and memory. The parents were also asked to complete a questionnaire rating perceived changes in their child's behavior in the areas of school, personality, family, and friends since the onset of Lyme disease. Absentee records and the results of standard academic achievement tests were obtained from the schools. No significant group differences were found on any of these measures. Moreover, among children with Lyme disease, those with early neurologic involvement did not differ on any measure from those without any neurologic symptoms. The authors concluded that although there may be individual cases of Lyme-related cognitive abnormalities, children who are properly diagnosed and properly treated are unlikely to have any long-term negative consequences from Lyme disease. Since there is evidence that LE in adults may not occur for years after the onset of the illness, these same authors reexamined 25 of the their original sample and 17 sibling controls 4 years later. Again, there was no cognitive impairment in the Lyme disease children.

VI. POST-LYME DISEASE SYNDROME

The terms post-Lyme disease syndrome and post-treatment chronic Lyme disease are used to describe patients who were previously diagnosed with Lyme disease and develop persistent encephalopathic symptoms months to years after antibiotic treatment. Not all patients with a clinical history of Lyme disease who later present with encephalopathic symptoms are seropositive or have abnormal CSF. Most patients who are seronegative do not have Lyme disease, although it is possible to be seronegative and have post-Lyme syndrome. There are also reported cases of seronegative patients with CSF evidence of Lyme infection; however, this is rare. Most patients diagnosed with post-Lyme syndrome are seropositive for Lyme disease and develop symptoms after treatment.

In 1991, Krupp and colleagues compared a group of treated Lyme disease patients who continued to report memory problems after treatment, to a group of healthy controls. All subjects received a similar neuropsychological test battery to those described previously, with the addition of a fatigue rating scale. There were no differences between patients and controls on the any of the intelligence tests, tests of tracking and sequencing, and tests of abstract problems solving. The Lyme disease group performed significantly worse on the verbal fluency and two memory measures. Patients were also more depressed than controls. Neuropsychological test scores remained lower in the Lyme group, relative to controls, even when the presence of depression was controlled

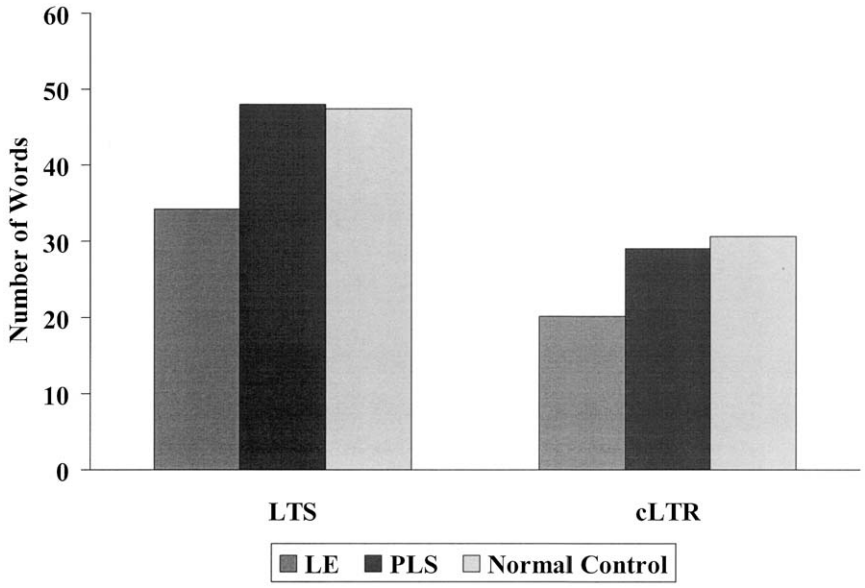

Figure 5 A comparison of memory scores for patients with LE, post-Lyme disease syndrome (PLS), and normal controls on the Selected Reminding Test. The two measures compared are total words recalled (LTS) and consistency of recall (cLTR).

statistically. Impairment was greatest for word recall on a verbal list learning test, the Selective Reminding Test (SRT). However, recognition memory did not discriminate patients and controls. The Lyme patients were also divided by the severity of neuropsychological impairment into mild, moderate, or severe categories based on the number of tests in which a patient's score fell below the published normative means (one or two standard deviations). On this basis, 9 of the 15 patients showed evidence of mild to moderate cognitive impairment, whereas 6 patients appeared normal despite complaints of memory trouble. Neither evidence of CSF infection nor MRI abnormalities correlated with the degree of cognitive impairment. However, fatigue was correlated with memory performance in the Lyme group but not the control group, with higher levels of fatigue associated with greater memory impairment. Interestingly, depressive symptoms were also correlated with memory scores. Paradoxically, however, more depressive symptoms corresponded to better memory scores.

Because it appeared that cognitive deficits exist in some Lyme patients independent of other evidence of neurological involvement, my colleagues and I studied the relationship between active infection and cognitive dysfunction. We compared 13 seropositive Lyme patients with evidence of inflammatory CSF to 20 seropositive Lyme patients without evidence of neurological disease and 14 age-matched normal controls. Most patients in both Lyme groups described memory deficits as one of their symptoms. Eleven of 13 patients with abnormal CSF and 16 of 20 with normal CSF reported memory problems, versus none of the controls. On the SRT verbal memory measure, Lyme patients with abnormal CSF recalled significantly fewer words, were less consistent in their recall, and retrieved fewer items from memory than either Lyme patients with normal CSF or normal controls, who did not differ on any of these measures (Fig. 5). On the BDI, both Lyme disease groups endorsed significantly more symptoms than the normal control group, although no group's score was sufficiently high to meet the criteria for depression. Thus, although both groups of Lyme reported memory difficulties in our study, only the group with evidence of CNS infection performed more poorly on objective memory testing. However, both Lyme groups reported more symptoms of depression and anxiety than healthy controls (Fig. 6). These data suggest that depression may be a factor in perceived memory loss.

As a group, Lyme patients report significantly more symptoms of depression and fatigue than do controls, independent of evidence of CNS disease. In several studies the average depression scores for the Lyme patients were typically higher than for healthy controls but below the suggested cutoffs for clinical depression.

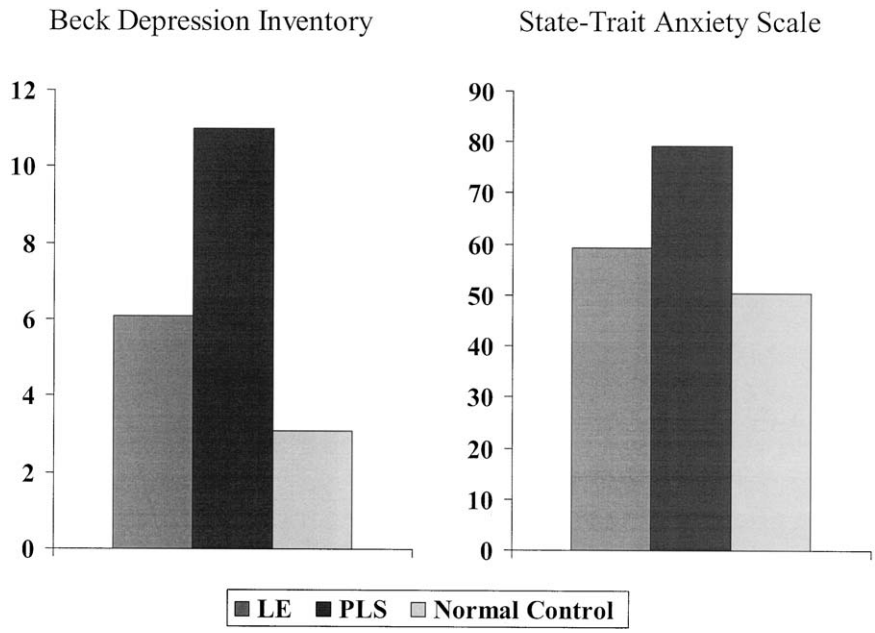

Figure 6 Depression and anxiety for LE, post-Lyme disease syndrome (PLS), and normal controls.

Moreover, although a significant proportion of Lyme patients meet the criteria for depression, depression scores and objective measures of memory loss have not been highly correlated. Fatigue, however, has been shown to be significantly correlated with poor memory in a number of studies.

In the study described previously, most Lyme patients complained of memory disturbance whether or not they had abnormal CSF. As such, the perception of memory loss was not a good predictor of objective impairment on neuropsychological testing. This finding has been replicated in several studies of Lyme disease patients. It is also not unique to Lyme disease. In most studies, self-reported poor memory is only weakly related to actual memory test performance, whereas it is strongly associated with conventional affective symptoms. Most studies have been done with elderly patients. These have shown that the relationship between subjective estimates of memory loss and objective measures of memory impairment is low. Instead, perceived memory loss tends to be related to psychological distress. As with many chronic illnesses, Lyme patients with late-stage disease often experience greater emotional distress, including depression and anxiety, than otherwise healthy people, although they do not meet the clinical criteria for psychopathology. It is therefore likely that the perceived memory disturbance in many Lyme patients may be related to the stress and affective symptoms common to many chronic diseases.

VII. CONCLUSIONS

LE was originally used to describe mild confessional state—most commonly fatigue, sleep disturbance, memory loss, and depression—in patients with active systemic Lyme disease, particularly active arthritis. However, its meaning has become more general and is often used to describe patients with similar deficits but without laboratory confirmation of active Lyme infection. This has made the diagnosis of some disorders that have been attributed to Lyme disease highly controversial. In cases in which the patient has had the characteristic clinical picture, a positive serology to *B. burgdorferi*, and abnormal CSF, the symptoms are likely due to active infection. Moreover, there is evidence, from MRI and SPECT studies, that the infection preferentially affects white matter areas of the brain, although the mechanism is not known. Neuropsychological testing in these patients typically shows mild, but statistically significant, deficits on memory testing. After adequate antimicrobial therapy, most patients show significant improvements in their cognitive functioning and return to normal. In the one quantitative SPECT study, demonstrating a

reduction of cerebral perfusion in patients with LE, there was also a partial reduction of hypoperfusion with antibiotic therapy.

The controversy regarding the diagnosis of LE stems from patients who report encephalopathic symptoms without clear evidence of an active Lyme infection, namely those with post-Lyme disease syndrome. Although some clinicians still attribute this to a subacute *B. burgdorferi* infection and recommend extended antimicrobial therapy, others question whether these symptoms are caused by active brain infection. Some neuropsychological investigations have shown these patients to perform more poorly than healthy normals, whereas others have not. Neuropsychological deficits in post-Lyme syndrome patients seem to be independent of a history of psychopathology but are correlated with concurrent fatigue. Lyme patients with independent evidence of CNS infection perform significantly worse on neuropsychological testing than post-Lyme disease syndrome patients. For patients without clear evidence of active Lyme disease, there is little efficacy to additional antimicrobial therapy. This has led some researchers to conclude that LE is probably overly diagnosed, and the lack of response to antibiotic therapy is the result of misdiagnosis. In addition to latent infection, other explanations for post-Lyme disease include the psychological consequences of chronic illness, residual deficits from past infection, and possibly an immune response. It has also been suggested that a fibromyalgia syndrome may be triggered by infection to *B. burgdorferi* after the infection is successfully treated since both disorders can result in similar cognitive complaints.

Patients with LE typically report memory problems independent of their performance on objective testing. The perception of cognitive difficulties may be common to a variety of physiological and psychological disorders. In chronic Lyme disease, patients with objective evidence of CNS infection, such as abnormal CSF, probably have a neurological basis to their reported cognitive decline. Other chronic Lyme patients are likely experiencing the stress and affective symptoms common to many chronic illnesses and similarly the perception of cognitive dysfunction.

Lastly, it is important to note that relative to the incidence of Lyme disease, the prevalence of chronic LE is quite low. Population studies have shown that only a small percentage of previously infected patients have neurological abnormalities, including objective evidence of memory impairment. Patients with residual deficits typically have had a longer duration of untreated disease prior to eventual treatment. Similarly, studies of children indicate that the chronic neurological deficits are rare when Lyme disease is adequately treated. Taken together, it is reasonable to conclude that the prognosis for returning to normal neurocognitive functioning after being infected with Lyme disease is good with adequate treatment.

Magnetic Resonance Imaging (MRI)

JEFFRY R. ALGER
University of California, Los Angeles

GLOSSARY

longitudinal (T1) relaxation The process in which the nuclear spin magnetization recovers its orientation parallel to the applied magnetic field in characteristic time, T1, following a perturbation.

magnetic resonance imaging (MRI) A biomedical procedure that utilizes the magnetic resonance signal produced by the protons of tissue water to obtain vivid depictions of the internal macroscopic anatomy of soft tissues such as the brain.

nuclear spin magnetization The magnetic properties that result from the spinning behavior of a single atomic nucleus or an ensemble of atomic nuclei when placed in a magnetic field.

spin echo pulse sequence A frequently used procedure in MRI in which, for a variety of technical reasons, the appearance of the MRI signal is caused to be delayed for a defined time period after the excitation of the magnetization away from its equilibrium orientation.

transverse (T2) relaxation The process in which the nuclear spin magnetization loses its orientation perpendicular to the applied magnetic field in characteristic time, T2, following a perturbation.

time-to-echo The time delay between MRI signal excitation and the appearance of maximal signal when a spin echo pulse sequence is employed.

time-to-repeat The time between successive MRI signal excitations.

Magnetic resonance imaging (MRI) is a procedure that utilizes the magnetic resonance signal produced by the protons of tissue water to obtain vivid depictions of the internal macroscopic anatomy of soft tissues such as the brain. It has become the method of choice for nondestructive visualization of brain anatomy. The nuclear magnetic resonance (NMR) phenomenon on which MRI is based was discovered in the 1940s. NMR has become an indispensable tool in the fields of chemistry, biochemistry, and structural biology. In the 1970s, methods of forming images from the proton NMR signal produced by the water in living tissues were developed and became known as MRI. MRI is now a routinely used clinical tool and has growing utility for investigations involving brain structure. The purpose of this article is to familiarize the neuroscientifically inclined reader with key physical principles and fundamental technological aspects that underlie MRI.

I. MRI SIGNAL GENERATION

A. The Nuclear Spin

MRI is based on the fact that collections of atomic nuclei, when placed in a strong unchanging magnetic field, interact with an externally applied oscillating magnetic field when the frequency of the oscillating magnetic field meets certain specific criteria. Many texts inaccurately summarize this by saying that atomic nuclei absorb or emit electromagnetic radiation (i.e., radio waves). It is not accurate to infer an interaction between atomic nuclei and electromagnetic radiation because electromagnetic radiation requires the concurrent presence of electric and magnetic fields with specific spatial and temporal relationships. In

MRI one avoids use of oscillating electric fields because these do not interact with the atomic nuclei. Only the oscillating magnetic field interacts with the atomic nuclei. In MRI, it is the hydrogen nucleus (^{1}H), which is often referred to as "the proton," that is responsible for generating the signal from which the images are formed. Other atomic nuclei (e.g., ^{19}F, ^{31}P, and ^{23}Na) have been used in exploratory biomedical MRI studies. However, the use of nuclei other than protons is not widespread for brain MRI. The vast majority of the protons present in biological tissue are constituents of water molecules; therefore, water protons have the greatest relevance in MRI. However, the protons in the fatty acyl components of lipid molecules of fatty tissue can also be imaged. One of the reasons that MRI is a successful neuroimaging tool is that water, which is found at high concentration in soft tissues such as the brain, generates the signal from which the images are formed. MRI is distinct from conventional radiographic and computed tomographic approaches to brain imaging. In MRI, an intrinsic tissue signal is imaged, whereas X-ray techniques are based on attenuation of an X-ray beam by the tissue.

Figure 1 illustrates the fundamental properties of the proton that lead to MRI. Any particular volume element (voxel) of brain tissue contains a very large number of water molecules, each of which has two protons. A typical MRI voxel ($1 \times 1 \times 3\,mm^3$) of brain tissue contains about 10^{20} protons. Each proton behaves as a bar magnet because it acts as if it spins about an axis. The property of spin and the associated magnetism lead to the use of the terms "spin" or "nuclear spin" as synonyms for proton or hydrogen nucleus. In the foregoing, the verb "to behave" was used to reflect the fact that the magnetic and spin properties of the atomic nucleus are governed by the laws of quantum mechanics, the science that deals with the behavior of matter and energy at very small dimensions. A detailed discussion of quantum mechanical behavior of the nuclear spin is beyond the scope of this article. Accordingly, "real-world" descriptions will be used as an approximation for the behavior of the atomic nuclei in the quantum world.

B. Interaction of the Nuclear Spin with Magnetic Fields

MRI requires that the signal-generating protons be placed in a strong static magnetic field. It is conventional to denote the applied magnetic field by a vector quantity, B_0. The typical magnetic field strength used in brain imaging is 1.5 T (approximately 30,000 times stronger than the earth's magnetic field). The spatial

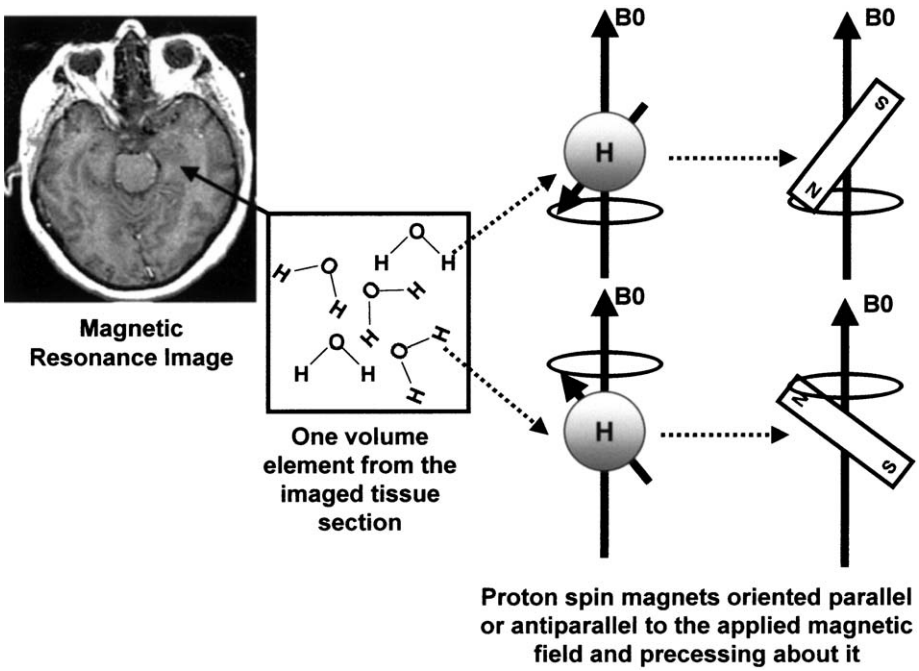

Figure 1 Key concepts related to MRI signal creation.

homogeneity of the magnetic field also plays an important role in defining feasibility of imaging. Typically, the magnetic field must vary less than 100 parts per million (ppm) over the entire brain volume and less than about 1 ppm over any particular imaging voxel. An important attribute of MRI is that the magnetic field readily penetrates bony structures, permitting MRI to "see" the brain through the bony cranium.

C. The Larmor Relationship

Figure 1 illustrates how the proton nuclear spins (equivalent to spinning bar magnets) behave in an imposed magnetic field. They tend to align parallel to (with) or antiparallel to (against) the magnetic field. Such behavior is readily appreciated when two magnets are manipulated in the macroscopic world. When a smaller magnet is placed inside a larger one, the smaller magnet's north pole tends to point toward the north pole of the larger magnet. "North to south" orientation has some stability, but a perpendicular orientation of the two magnets is highly unstable. In the quantum world, magnetic alignments are expressed in terms of their probabilities. Alignment in the parallel configuration is only slightly more probable compared to that of the antiparallel configuration. Furthermore, in the quantum world, the alignment is not perfect. The spin causes the nuclear magnet to "precess" about the applied magnetic field at a constant angle in each of the two allowed configurations. The precession frequency, v, (the number of precession cycles per second), is a linear function of the applied magnetic field

$$v = \gamma B_0$$

Precession characteristics such as these are found in everyday mechanical systems (e.g., gyroscopes). The relationship between the precession frequency and the applied magnetic field on the orbital motion of an electron was described in 1897 by Sir Joseph Larmor. Accordingly, even in the context of MRI, the expression that relates precessional frequency to magnetic field strength is known as the Larmor relationship. The Larmor relationship indicates that the precession frequency is directly proportional to the magnetic field strength, with γ (the gyromagnetic ratio) being a constant of proportionality that is a unique property of the type of nucleus. For the proton, γ is approximately 42 million cycles per second per Tesla. Therefore, the characteristic frequency at which the nuclear spins precess about the commonly used applied magnetic field strength (1.5 T) is 63.8 MHz.

D. Behavior of Large Ensembles of Nuclear Spins

A single nuclear spin would produce a signal that is far too weak to detect. Therefore, it is necessary to consider how large numbers of nuclear spins behave in a collective sense to understand how a measurable MRI signal is produced. It is the 10^{20} protons in the typical MRI voxel that produce the signal used for image formation. Some of the spins are oriented antiparallel to the applied field, whereas others are oriented parallel to the applied field (Fig. 2). Nature tends to favor the parallel configuration because this represents an energetically more stable (lower energy) state. However, the two possible configurations do not differ to a great extent in their energy stability, and there are almost equal numbers of spins in the two configurations. The magnetic field from each of the spins in the antiparallel configuration is canceled by a spin in the parallel configuration, but there are spins in the parallel configuration that not canceled by antiparallel spins. These "uncanceled" parallel spins act cohesively as an ensemble. They collectively behave as a bar magnet oriented perfectly parallel with B_0. It is common practice to refer to the magnetic properties of the ensemble as the "bulk nuclear spin magnetization" or "magnetization." The angle between the magnetization and B_0 is lost because each nuclear spin precesses about the applied field independently of the others. Nature imposes no constraints on where along

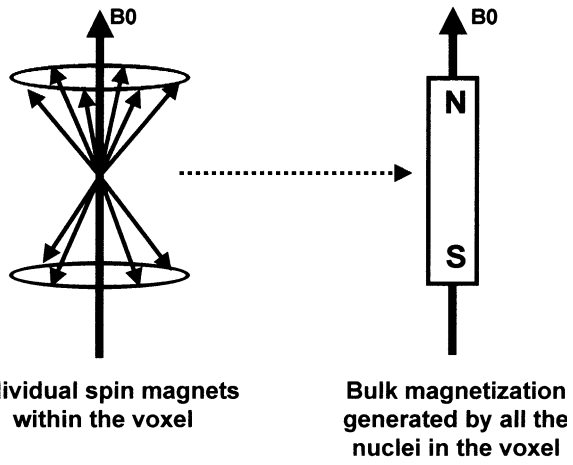

Figure 2 Ensembles of nuclear spins create a magnetization parallel to the applied magnetic field.

each precession circle each spin happens to be, and the transverse component nuclear spin magnetization perpendicular to B_0 is zero. It is important to also emphasize that the bulk magnetization produced by an ensemble of many nuclear spins behaves differently than does the spin magnetization from a single spin. The bulk magnetization from an ensemble of nuclear spins can attain any arbitrary orientation relative to B_0. Its behavior is not "quantized" as is the case for a single spin's magnetization.

E. The Magnetic Resonance Signal

In MRI, images are formed from the electrical "signals" generated by each of the volume elements in the tissue. The bulk magnetization resultant from the ensemble of spins in each of the volume elements generates the MRI signals. In order to detect the MRI signal, it is necessary to first disturb the bulk magnetization away from the equilibrium configuration shown in Figure 2. This is done using a radiofrequency (RF) transmitter pulse (Fig. 3). The working part of the RF pulse is a second magnetic field, which is usually referred to as B_1. The B_1 magnetic field differs from B_0 in that it oscillates. In order to be effective, B_1 must oscillate at a frequency that is very near to the Larmor frequency (e.g., 63.8 MHz for 1.5 T). When this is the case, there is a coupling between B_1 and the nuclear spin precessions that causes the bulk magnetization to be rotated away from its equilibrium position toward the transverse plane perpendicular to B_0. Energy from the B_1 field is used to excite the magnetization to a nonequilibrium configuration. Figure 3 shows the result of a 90° pulse in which the magnetization is twisted through an angle of 90° into the transverse plane. Coupling between the bulk magnetization and a B_1 field having the appropriate oscillatory frequency is an example of the phenomenon known in physics as resonance. The oscillatory B_1 field is created by the flow of alternating electric current through a coil of wire (i.e., the RF coil) that is placed near the tissue being imaged. The alternating electric current frequency must be very near the Larmor frequency (typically 63.8 MHz) to create the appropriate oscillation frequency for B_1. Use of RF is a central part of radio and television broadcasting; therefore, one often hears that MRI results from an interaction between "radio waves" and nuclear spins. However, as has already been stated, only oscillating magnetic fields are used in MRI, and it is not correct to state that radio waves are used in MRI.

Once the magnetization has been disturbed as shown in Fig. 3, it precesses about the transverse plane

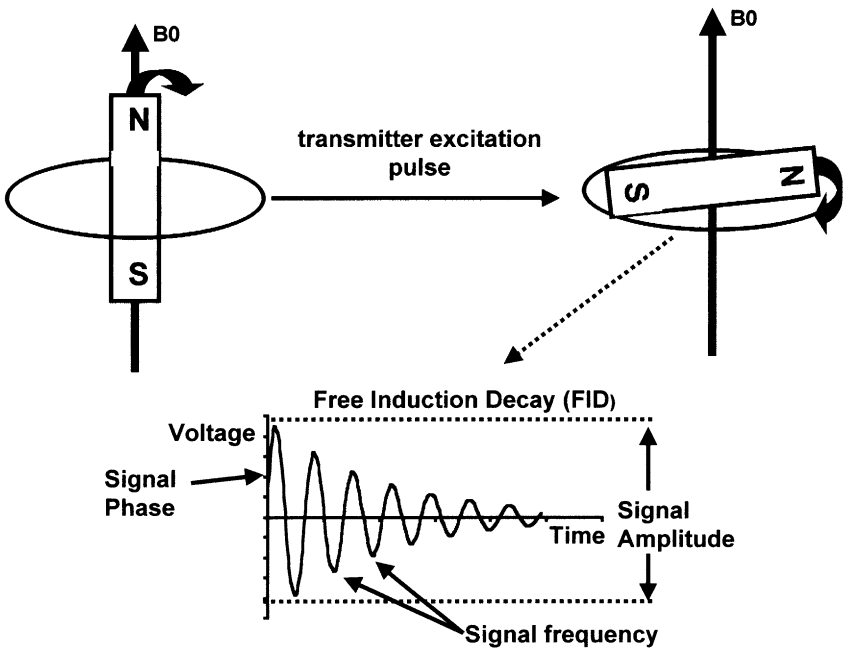

Figure 3 Perturbation of the magnetization with a radiofrequency pulse and the resultant free induction decay signal.

at the Larmor frequency. This precessional motion can be detected with a coil of wire (i.e., the RF coil) that is placed near the tissue of interest. The motion of the magnetization generates a voltage oscillating at the Larmor frequency in the coil. Therefore, one can describe the phenomenon by saying that the nuclear spins transmit a radio frequency signal on a characteristic radio "channel" that is detected by the MRI scanner. Note, however, that radio waves per se are not involved in this signal-generation process. The signal subsequently decays as illustrated in the graph shown in Fig. 3. The maximal signal amplitude (voltage) is proportional to the magnetization, which in turn is principally dependent on the number of nuclear spins in the ensemble, although other factors (described later) also play a role. The MRI signal that results immediately from a 90° pulse is known as a free induction decay (FID). It is often advantageous to cause the signal to appear sometime after the transmitter RF pulse is finished. One way of doing this is to form a spin echo. Spin echo MRI signals oscillate at the Larmor frequency just as FID signals do. However, they build up and then disappear at some defined period of time after the transmitter pulse is completed (Fig. 4). The time that elapses between the initial transmitter pulse and the formation of the echo is known as the time-to-echo (TE). The amplitude of the spin echo signal decays as the TE is progressively lengthened, as illustrated in the graph shown in Fig. 4. This will be discussed in more detail later.

Formation of a spin echo requires the use of two RF pulses given in a carefully prescribed manner. A series of pulses is referred to as a pulse sequence. In a broader sense, pulse sequences, which can be quite complicated, are frequently used in MRI to manipulate the magnetization in a defined manner so as to accentuate certain aspects of the MRI signal or for developing contrast. The spin echo pulse sequence is one of the simplest of a large and growing body of MRI pulse sequences.

II. IMAGING THE MAGNETIC RESONANCE SIGNAL

MRI visualization of structural anatomy requires measuring the MRI signal amplitude generated by each volume element within the tissue being imaged. Accomplishing this is more complicated than might be imagined. Because MRI does not use radio waves, it is not possible to focus "beams" of radio waves at suitable resolution to excite the MRI signal of only one volume element at a time and then sequentially sample all volume elements with this focused beam. Moreover, the sequential detection of the MRI signal from each volume element is highly inefficient and impractical.

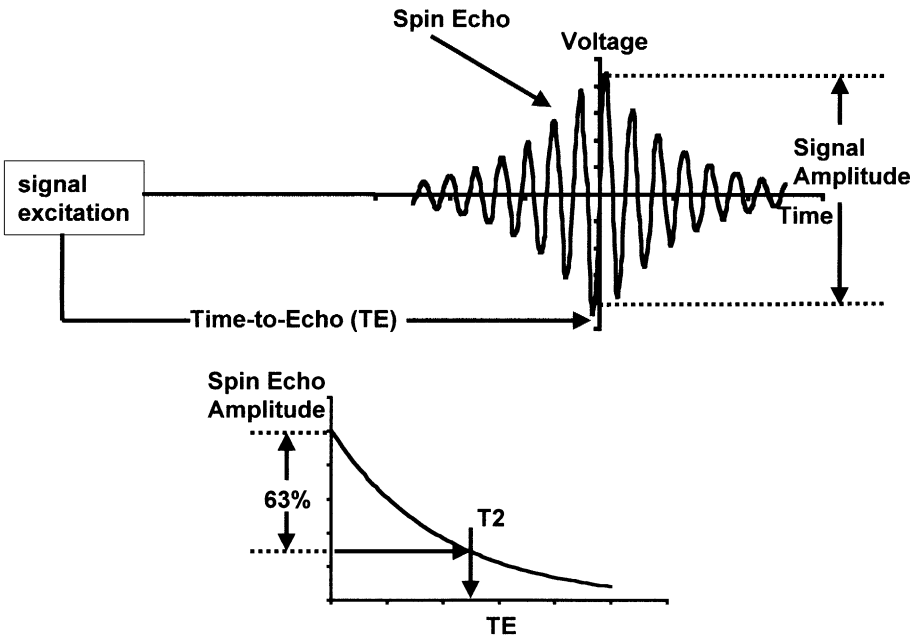

Figure 4 The spin echo signal and its dependence on TE.

Alternate ingenious methods based on the use of magnetic field gradients and precise frequency measurement are typically used for imaging entire sections or volumes of tissue.

A. Magnetic Field Gradients

A magnetic field gradient is a smooth (usually linear) variation in the static magnetic field (B_0) from one position to another position. Magnetic field gradients are purposefully applied in MRI as part of the imaging process. This is illustrated in Fig. 5. Application of a magnetic field gradient that varies smoothly in the inferior–superior direction causes B_0 in the neck to be relatively smaller compared to that in the brain. In the presence of this field gradient, the Larmor relationship ensures that there will be smooth linear dependence of the MRI signal frequency along the inferior–superior axis. Therefore, it is possible to know where along the superior–inferior axis a particular signal-generating volume element is located through precise frequency measurement. There is no strict requirement that a field gradient be oriented along any particular anatomic axis. Field gradients may be created that cause linear variation of B_0 along the left–right and the anterior–posterior axes or any arbitrary oblique axis that lies at any angle between the principal anatomic axes. Furthermore, it should be understood that magnetic field gradients can be turned on and off (i.e., switched) during the pulse sequence. This permits the application of magnetic field gradients on different axes during different parts of the pulse sequence.

B. Slice Selection

In MRI, tomographic images of tissue slices having defined orientation, thickness and location are obtained. The slice selection process is accomplished by using a frequency-selective RF pulse during the application of a magnetic field gradient. A frequency-selective RF pulse permits the highly selective excitation of MRI signals having a narrow band of Larmor frequencies. The presence of a magnetic field gradient ensures that this narrow band of Larmor frequencies will correspond with a narrow tissue section. Protons that would generate signal outside of the narrow band of Larmor frequencies (i.e., those located beyond the edges of the narrow tissue section) are unaffected and do not produce signal. Figure 5 illustrates that an axial tissue section may be selected for subsequent imaging by using a frequency-selective RF pulse in the presence of a magnetic field gradient oriented along the inferior

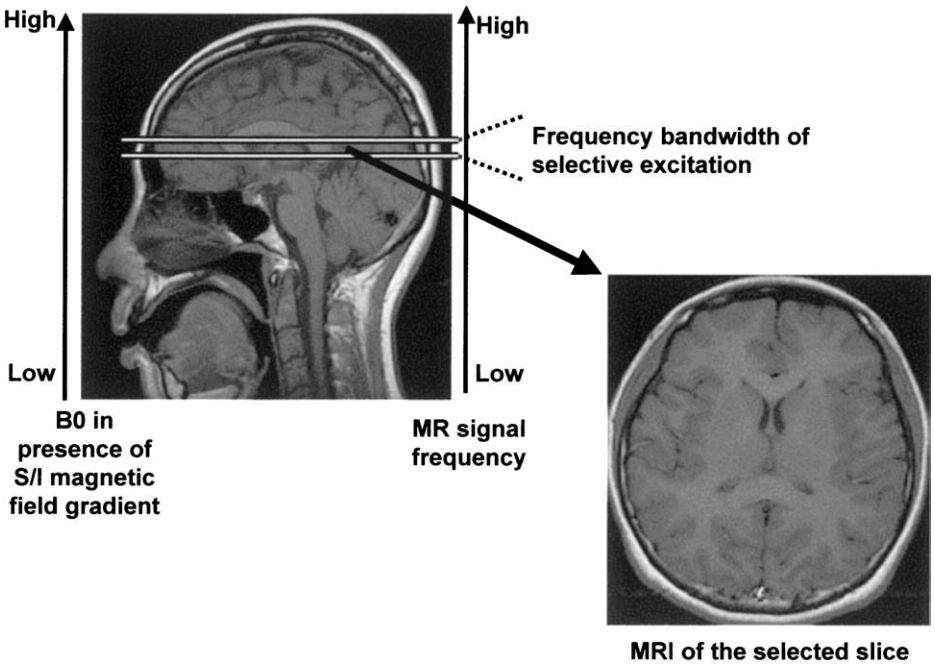

Figure 5 Slice selection in MRI.

to superior axis. Both the slice thickness and the slice location may be freely selected without physically moving the human subject or physically moving components of the scanning equipment relative to the subject. This is done by making suitable adjustments in the characteristics of magnetic field gradient or the frequency-selective RF pulse. Accordingly, the moving parts of MRI scanners tend to be limited to that needed for moving the subject into the appropriate part of the magnetic field at the beginning of the examination. Subsequently, neither the subject nor the scanning equipment moves during the image acquisition process. Furthermore, because a field gradient can be created along any arbitrary anatomic axis, it is possible to select slices in any of the three principal anatomic sectional planes (sagittal, axial, and coronal) or in any arbitrary oblique imaging plane without physically repositioning the subject or physically reorienting the imaging equipment (Fig. 6).

The obvious need to visualize anatomy in three dimensions is usually met through the use of mutlislice imaging. Figure 7 displays a series of 15 axial images that were obtained from tissue sections 3 mm thick. The conventional practice is to produce collages showing individual two-dimensional sectional images as a means of visualizing three-dimensional (3D) anatomy. If the sections can be made sufficiently thin, it is possible to create a volume rendering that displays the cortical surface anatomy. Conventional multislice MRI for human subjects is limited to a slice thickness of about 3 mm. This is relatively thick for volume rendering purposes; therefore, when volume rendering is planned, special 3D acquisition techniques are employed in which more than 100 slices having slice thickness of about 1 mm are used. Figure 8 provides an example of volume rendered images that display brain surface anatomy from a variety of perspectives. In addition to viewing surface anatomy in the manner shown, it is also possible to section the digital representation of the brain volume and produce two-dimensional images in any chosen sectional plane. This is done retrospectively using purposely designed software that sections and displays images under user control. The volumetric nature of the image data also readily lends itself to studies in which it is desired to measure the volumes of specific neuroanatomical structures that can be visualized in the images. As a result, 3D acquisition techniques are often used in research studies in which quantitative evaluation of neuroanatomic volumes are sought. The volumetric

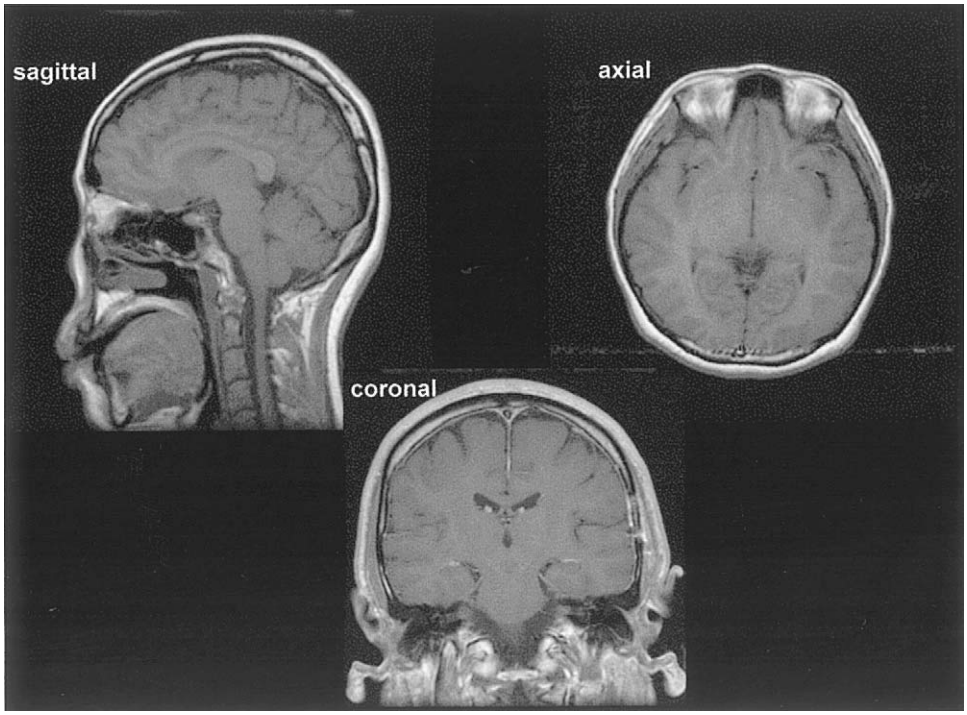

Figure 6 MRI slice selection can be in any chosen anatomic plane.

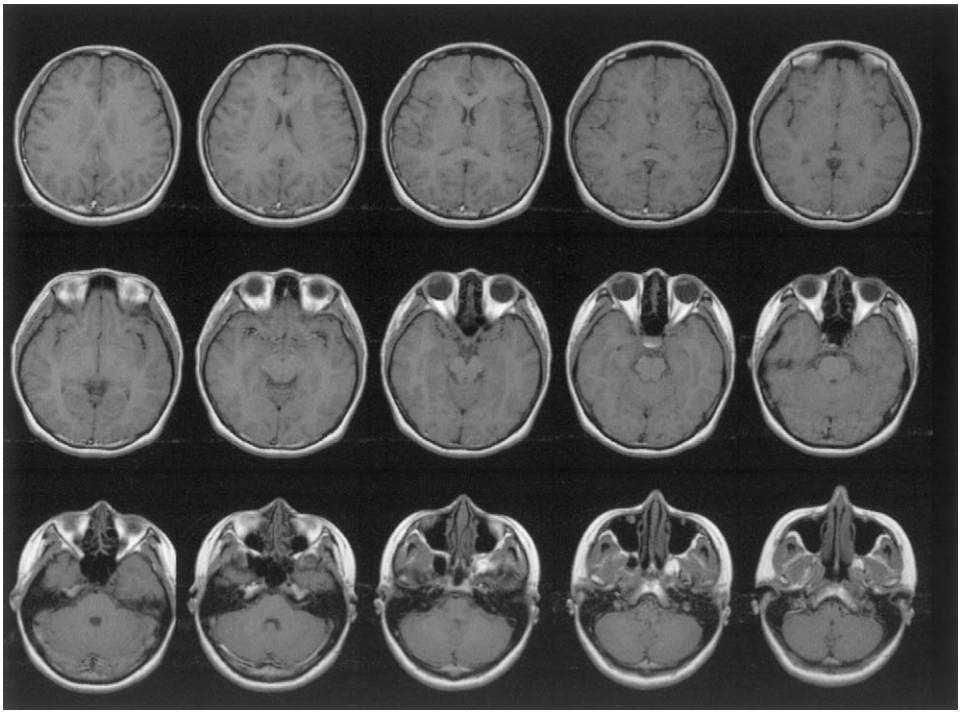

Figure 7 Multislice MRI.

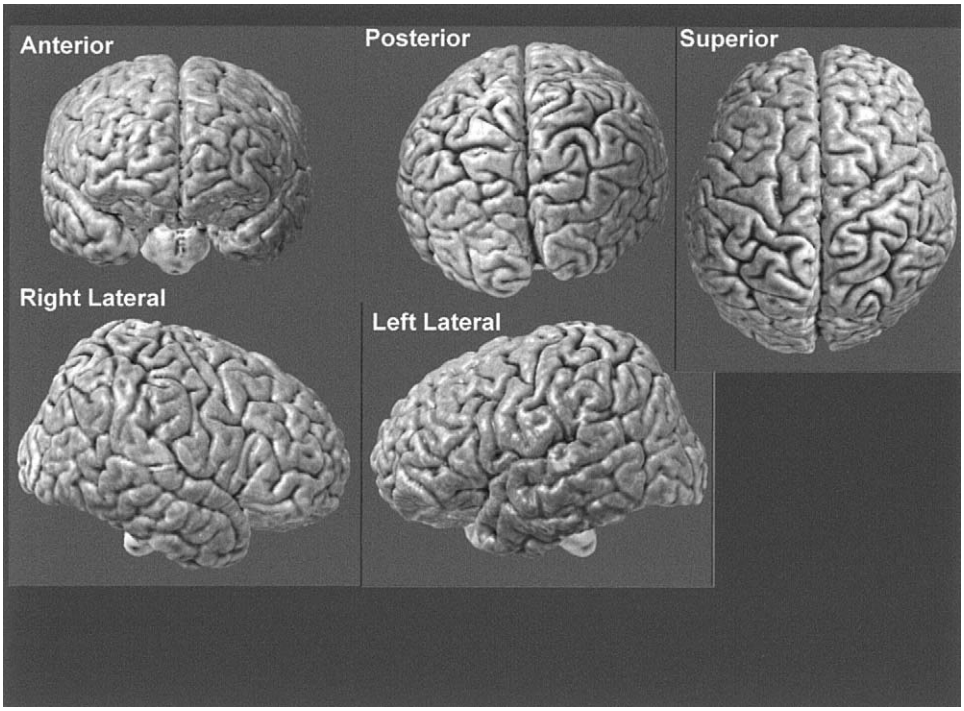

Figure 8 Volume rendering of three-dimensional MRI.

nature of the image data is also appropriate for the planning of neurosurgical procedures such as stereotactic biopsy. Accordingly, 3D volume MRI acquisition is often performed as part of the preoperative evaluation of patients for whom neurosurgical procedures are contemplated.

C. In-Plane Imaging: Frequency Encoding and Phase Encoding

Once the nuclear spins from a particular slice are excited, it is necessary to have methods of measuring how the MRI signal varies within the imaging plane. For two-dimensional imaging, two orthogonal coordinate directions are interrogated by application of magnetic field gradients that vary along these coordinate directions. Typically, frequency encoding and phase encoding gradients are used. To avoid confusing locations along the two orthogonal axes, the frequency encoding and phase encoding gradients are applied at different times during the pulse sequence. Figure 9 illustrates the general concepts. A magnetic field gradient is imposed such that the signal frequency is higher on the left compared to the right. (Note that it is customary in MRI to display the subject's left on the viewer's right.) This causes the signal frequency to depend on position along the left–right axis. A plot of signal amplitude versus frequency in the presence of this left–right frequency encoding gradient would give a one-dimensional image in which signal amplitude is projected down the columns along the anterior–posterior axis onto the left–right axis. The signal amplitude along this one-dimensional image defines the total amount of MRI signal generated by anterior–posterior columns. To obtain a two-dimensional image, a phase encoding gradient must also be used. In Fig. 9, the phase encoding gradient is applied along the anterior–posterior direction, causing the signal phase to depend on the position along the anterior–posterior direction. Phase encoding must be used because the signal frequency is already used for left–right encoding. Phase encoding is more complicated compared to frequency encoding. It is necessary to perform a number of phase-encoded signal measurements using different levels of the phase encoding to fully unravel the relationship between the position and phase. Typically, if it is desired to obtain a resolution of 256 image lines in the phase encode direction, then it is necessary to make on the order of 256 independent phase-encoded measurements.

The previous paragraph described the most commonly employed procedure for in-plane imaging. Several additional variant techniques have been

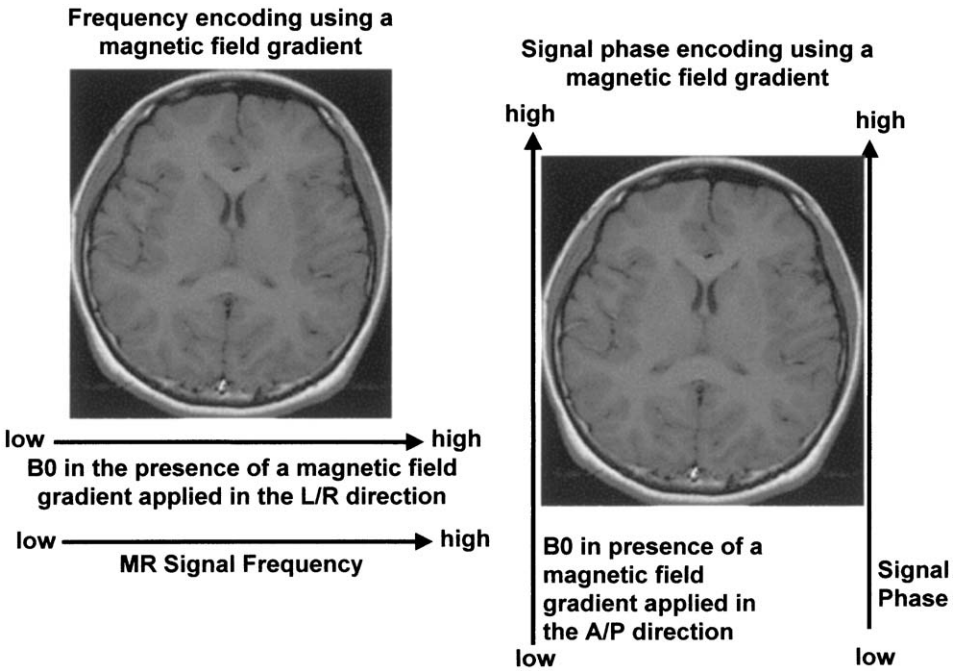

Figure 9 Frequency and phase encoding using applied magnetic field gradients with frequency measurement for in-plane imaging.

designed for specific purposes. The 3D acquisition techniques described previously use phase encoding in two dimensions and frequency encoding in one dimension without slice selection. This permits the slices to be made thinner than is typically possible when using conventional slice selection techniques. Another variant is known as echo planar imaging (EPI). In EPI, the frequency encoding and phase encoding are combined in a manner that speeds the imaging process considerably compared to conventional MRI. However, efficiency of EPI is partially offset by an increased susceptibility to artifacts arising from B_0 imperfections.

D. Resolution and Imaging Times

The typically attainable spatial resolution for brain MRI is approximately $1 \times 1 \times 3\,\text{mm}^3$. Somewhat higher resolution can be attained in special circumstances (e.g., by using magnetic field strengths greater than 1.5 T or limited field-of-view RF coils). In general, the resolution is principally dependent on the signal-to-noise ratio (SNR) of the MRI signal produced by a single voxel. MRI "noise" results from the random movement of electric currents in the detection circuitry and in the subject. The noise level can generally be assumed to be a constant and only weakly dependent on the signal detection technique. Unfortunately, the MRI signal is relatively weak compared to that detected in many other forms of spectroscopy. It is often not appreciably larger than the noise. Reducing the size of the volume element to increase spatial resolution results in a proportional decrease in the SNR and this leads to an increased level of image "graininess," complicating visualization of subtle features. SNR may be increased through signal averaging (i.e., by spending more time at image acquisition), although this provides meager returns. In general, the SNR is directly proportional to the square root of the time spent at image acquisition. Doubling the image acquisition time leads to only a $\sqrt{2}$ (about 40%) improvement in SNR. If one wishes to improve the resolution by twofold without loss of image clarity (i.e., maintain the SNR), one must increase the imaging time by fourfold.

The imaging time is also limited by the phase encoding process. A twofold increase in the resolution along the phase encoding axis requires that one spend twofold more time at phase encoding. Certain rapid imaging techniques partially circumvent this limitation. EPI and fast spin echo imaging procedures are examples. However, additional imperfections in image quality must be accepted as a consequence of more rapid imaging.

III. RELAXATION AND TISSUE CONTRAST

The process wherein the magnetization returns to its equilibrium configuration parallel to B_0 is known as nuclear spin relaxation. Typically, relaxation is conceptually separated into two separate processes: (i) relaxation of the magnetization component that is parallel to B_0 and (ii) relaxation of the magnetization component that is transverse to B_0. The former is known as longitudinal or T1 relaxation, and the latter is known as transverse or T2 relaxation.

Relaxation derives its energy from the random rotational and translational motion of the water (or lipid) molecules within the tissue. These motions are constrained by the tissue ultrastructure. It has not been possible to develop an exact theory of nuclear magnetic spin relaxation relevant to tissue due to the complex nature of the tissue ultrastructure. However, theories developed for simpler homogeneous materials can be extended to describe tissue nuclear spin relaxation. Moreover, tissue nuclear spin relaxation characteristics can be readily measured, so the absence of an exact theory is not a profound limitation. The practical utility is that different tissue types often display unique relaxation characteristics because of unique ultrastructural characteristics. Brain gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) each exhibit unique relaxation properties, and these may be used for developing image contrast between these tissue types.

A. T1 and Time-to-Repeat

T1 relaxation may be visualized as follows: At the conclusion of an excitation RF pulse, the magnetization is situated away from its equilibrium state. It takes a finite amount of time for the magnetization to recover to its equilibrium configuration. This recovery time is specified with a characteristic time constant that is known as T1. A series of image acquisitions produces signal intensity that is dependent on how rapidly the RF pulses are repeated relative to the rate at which the system is capable of relaxing. It is conventional in MRI to specify the rate of repetition with a parameter called time-to-repeat (TR). Figure 10 illustrates that repeated

acquisitions done at short TR tend to produce a relatively weak signal (compared to longer TR) because the magnetization does not have sufficient time to reattain its equilibrium configuration. A series of measurements in which signal intensity is measured as TR is increased typically leads to results illustrated in Fig. 10. Increasing signal is observed as TR is lengthened and this generally follows an exponential mathematical function. Such a mathematical function can be completely described by a single "time constant," defined as the time at which some fraction (usually 50 or 63%) of the process is complete. Therefore, the relaxation time constant, T1, is defined as the TR at which 63% of the total available signal is measured. In other words, the T1 value is determined by locating the point along the curve where 63% of the total available signal is obtained and then projecting to the TR axis.

As indicated previously, the actual value of T1 depends on the extent to which the tissue ultrastructure constrains the molecular movement. Figure 11 illustrates general features of T1 relaxation in unique brain tissues. Tissues such as CSF in which the motion of water molecules is relatively unconstrained (and therefore rapid) tend to produce relatively long T1 values. T1 values in GM or WM are smaller than in CSF because the tissue ultrastructure constrains the water movement to a greater extent. Motional constants in WM are somewhat greater than in GM due to the presence of rigid myelin structures; WM T1 values are therefore shorter compared to GM T1 values. It is indeed fortuitous that the tissue T1 values are what they are. The TR must be on the order of T1 to realize an appreciable fraction of the total available signal. Brain T1 values are such that brain MRI may be performed with TR between 500 and 2000 msec. Therefore, a typical image acquisition (128 phase encodes) requires approximately 2 min. Were the brain T1 values to be significantly greater (as is the case for distilled water) the same acquisition would take 10 times longer.

B. T1-Weighted Imaging

Figure 11 illustrates the appearance of a T1-weighted (T1w) image. By definition, a T1w image is acquired using repetitive measures (for phase encoding and signal averaging) with full excitation (90° RF pulses) and TR that is between about 300 and 1000 msec. Image acquisition at this TR maximizes signal contrast between tissue types (Fig. 11). CSF shows the lowest (nearest to black on the gray scale) signal intensity. GM shows a somewhat stronger signal intensity (closer to white on the gray scale), but this is appreciably weaker than that produced by WM. The fatty tissue (not plotted on the graph) located around the orbits and in the superficial soft tissues shows a

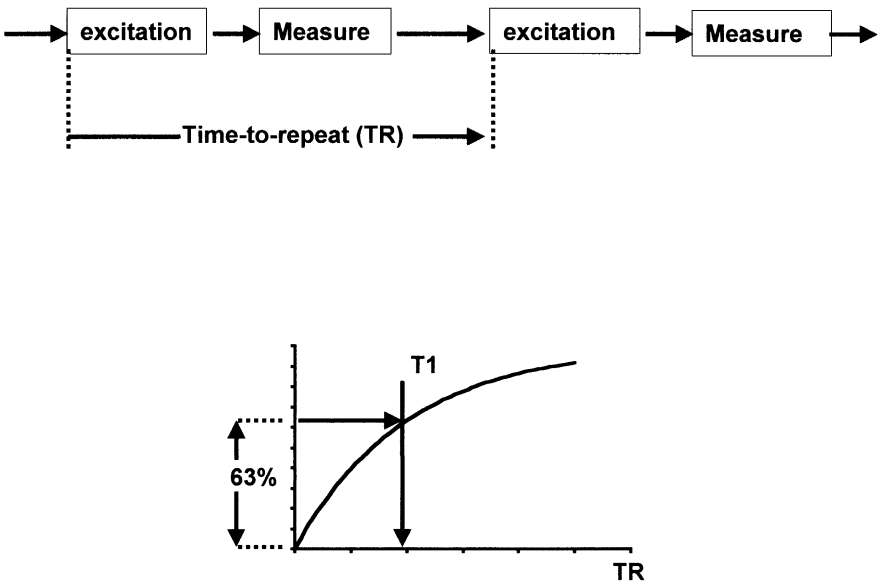

Figure 10 Longitudinal (T1) recovery and its relationship to the time-to-repeat (TR).

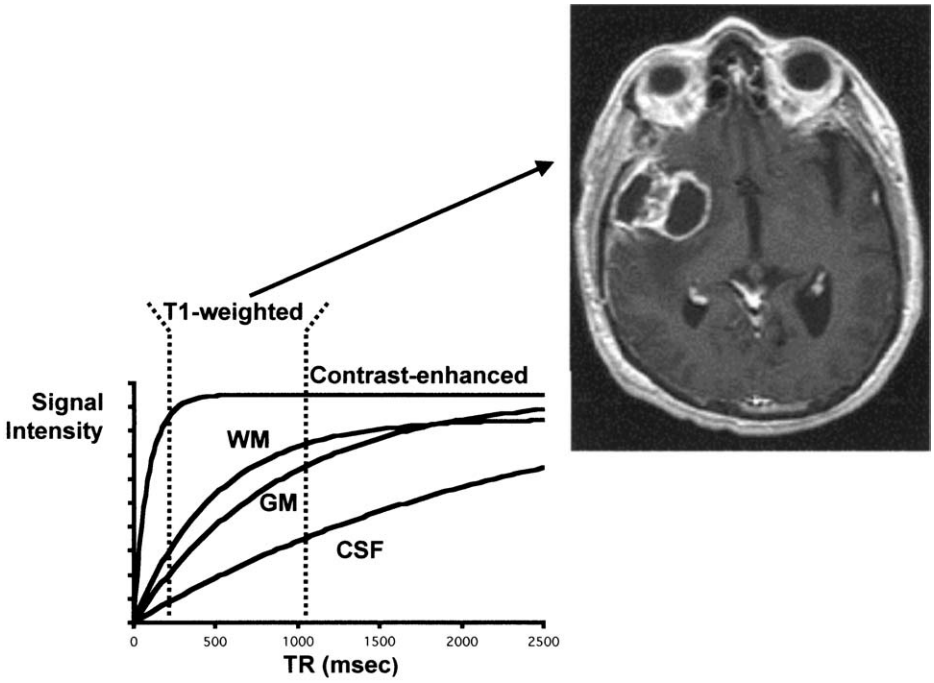

Figure 11 Contrast development through T1-weighted imaging.

very rapid T1 compared to brain tissues and this appears as intense signal in fatty tissues. The signal intensity differences in T1w imaging permit the reader to readily distinguish different tissue types and, thereby, to visualize the details of anatomic structure with great clarity.

Relaxation may be further enhanced by the use of relaxation agents, which are also called paramagnetic contrast agents. These materials have inherent magnetic properties arising from unpaired electron spins. They weakly associate with water molecules and through transient contact relax the water proton nuclear spins, making T1 very short. Intravenously infused paramagnetic contrast agents are commonly employed for clinical neuroimaging. The blood–brain barrier limits the access that such materials may have to normal brain tissue, and T1 of the normal brain tissue inside the intact blood–brain barrier is not altered. On the other hand, the agents tend to readily penetrate into tissue in which the blood–brain barrier is not intact (e.g., tumors). This leads to a relatively short T1 in tissues having a damaged blood–brain barrier and to very intense signal on T1w images. The image shown in Fig. 11 was obtained after intravenous administration of a commercially available contrast agent. It illustrates an intense double ring enhancement pattern produced by a tumor located at the right (viewer's left) frontotemporal junction. The bright "ring" is generally thought to represent highly vascular living tumor tissue that does not have an intact blood–brain barrier.

Figure 12 illustrates that T1w imaging may also be used to obtain angiographic images showing the major intracerebral vessels. This is known as magnetic resonance angiography (MRA). Blood flow tends to accentuate T1 relaxation because flow is constantly moving new water into the tissue section that is being imaged. Therefore, intravascular water tends to show full signal intensity after each excitation because it was not in the slice during previous excitations. On the other hand, the brain water needs time to relax between excitations to produce strong signal. One MRA approach is to employ very heavily T1w contrast (i.e., very short TR) so that brain signal is very weak and the intravasular water produces a much stronger signal. This is illustrated in the image shown on the left in Fig. 12. One can appreciate spots and strings of high signal intensity that depict the major vessels in this heavily T1w (flow-sensitized) image. Although single-slice views of vascular anatomy such as this are useful, display of MRA results in a manner consistent with fluoroscopic angiography is typically employed. This is illustrated in the image shown on the right in Fig. 12. To construct an angiographic projection view,

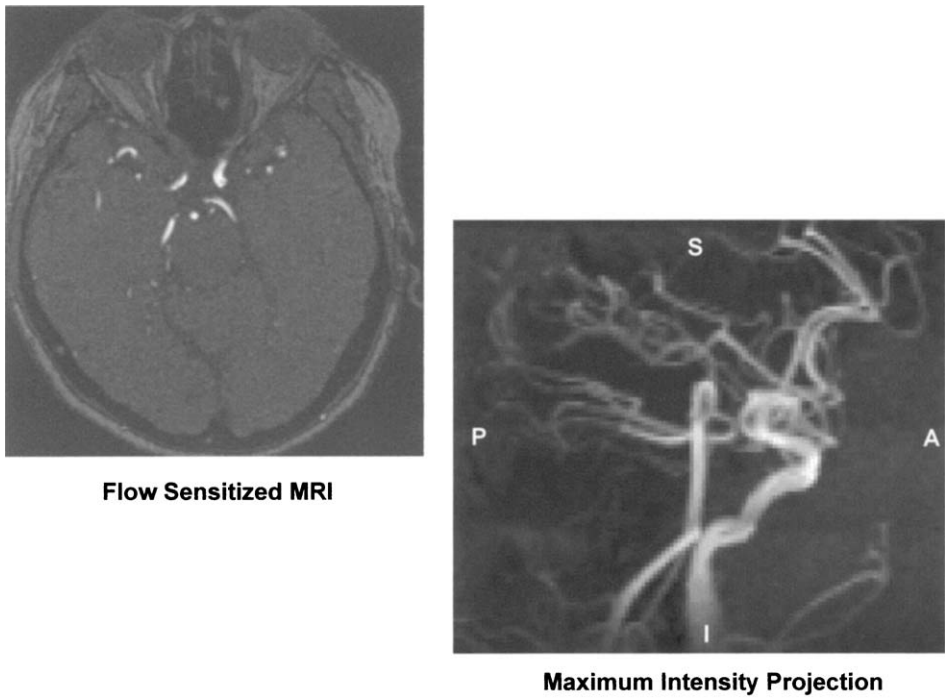

Figure 12 Magnetic resonance angiography.

flow-sensitized MRI is collected from many thin slices in a 3D format. This produces a 3D volume image in which the vessels are represented by relatively intense signal. Subsequently, the image intensities are projected onto a single viewing plane that may have any arbitrary orientation. In the example shown in Fig. 12, the angiographic information is being projected from a lateral perspective. From this perspective one can readily visualize the major feeding arteries of the corotid and basilar systems as well as many of the larger intracerebral vessels.

C. T2 and TE

Transverse (T2) relaxation is the process in which the finite components of the magnetization present in the transverse plane decay to zero (the equilibrium state). Often, T2 relaxation is discussed in terms of two separate processes. One of these is driven by molecular movements and is known as "pure" T2 relaxation. The other is the result of the presence of a magnetic field gradient within the voxel of interest and is known as T2* relaxation. To measure "pure" T2 relaxation independently of T2* relaxation, spin echo acquisitions (Fig. 4) are commonly used. The spin echo amplitude decays as the TE is lengthened, as illustrated in the graph in Fig. 4. This is generally found to be described by a decaying exponential function that has a characteristic time constant. To determine the value of the characteristic time constant for transverse relaxation (T2), one finds the point at which 63% of the signal has decayed and then projects that point onto the TE axis.

As is the case for T1, the T2 value depends on motional constraints imposed by tissue ultrastructure. However, the functional dependence of T2 relaxation differs from that for T1 relaxation. Tissues in which the water molecule motion is unhindered (e.g., CSF) tend to produce a very long T2. Increasing constraints on water movement lead to progressively shorter values for T2. WM shows a shorter T2 compared to that of GM, and both of these show a shorter T2 compared to that of CSF. The T2 relaxation characteristics of the three tissues are illustrated in the graph shown in Fig. 13. Spin echo signals produced by each of the tissues decay as TE is lengthened, with the differences becoming more pronounced as progressively longer TE values are used.

D. Proton Density-Weighted and T2-Weighted Imaging

Figure 13 illustrates that spin echo imaging can be employed to obtain two different types of tissue

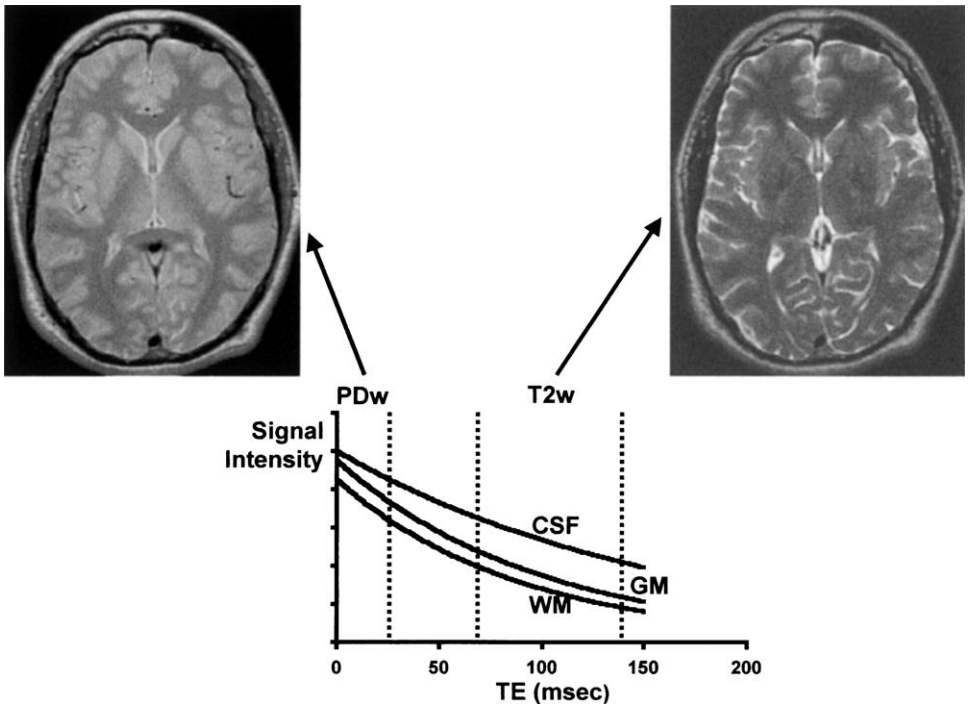

Figure 13 Contrast development through T2-weighted imaging.

contrast known as proton density contrast and T2 contrast. To obtain a proton density-weighted (PDw) image one uses a (relatively short) TE value of about 20 msec. Shorter TE values are desirable, but technical and engineering constraints usually prohibit their realization. In a PDw image the density of water protons is the predominant factor that defines what signal intensity is detected. Therefore, WM that has slightly fewer water protons per unit volume due to the presence of myelin tends to appear as lower (closer to black) signal compared to GM or CSF. CSF water density is slightly higher than in GM, causing the CSF to appear modestly more intense compared to GM. T2-weighted (T2w) images are typically obtained with TE values between 80 and 150 msec. This serves to maximize the contrast differences between the three tissue types as shown in the graph in Fig. 13. In the case of T2w images, the CSF shows the most intense signal, with GM and WM showing lower and almost equal signal intensities.

IV. MRI TECHNOLOGY

A typical MRI scanner is a complex system that utilizes advanced digital and analog electronics and expensive magnet technology. A simplified block diagram of a typical system is provided in Fig. 14. The system is centered around a computer system that interacts with a purposefully designed system controller. The system controller is responsible for coordinating each of the subsystems to produce pulse sequences and to acquire the MRI signal. The gradient system controller creates magnetic field gradient pulses by application of direct electric current to a set of gradient coils that are positioned around the subject within the magnet. The RF transmitter system is essentially a radio transmitter that is responsible for creating the RF pulses by appropriate application of alternating electric current to the RF coil. The RF receiver system is responsible for detecting the FID or spin echo signals induced in the RF coil by the movement of the magnetization.

The magnet is a relatively expensive system component. It often accounts for a large fraction of the system cost. The majority of current MRI systems use superconducting magnet technology because this provides adequate field strength, superior field homogeneity, and field stability with minimal operating costs. Despite the popularity of superconducting MRI magnets, permanent magnet technologies and conventional electromagnet technologies are also used in some commercial MRI scanners. The requirement for

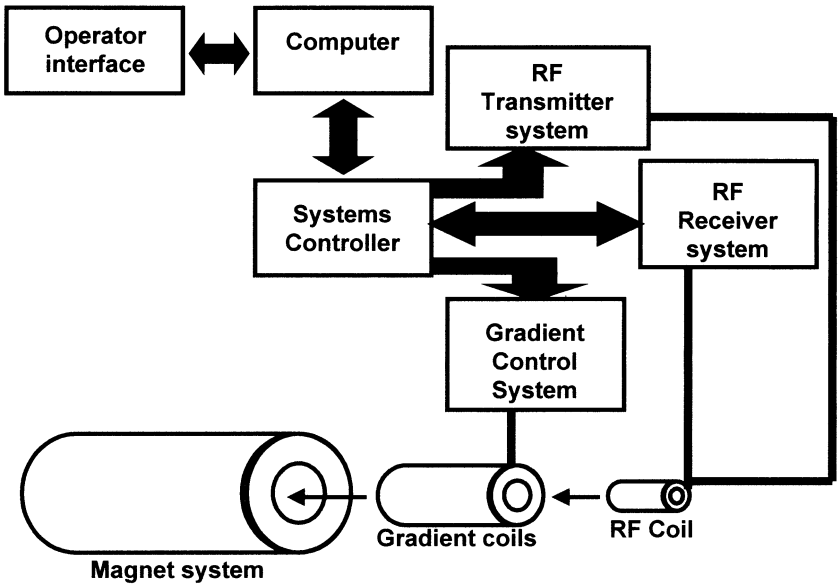

Figure 14 MRI scanner system design.

a strong magnetic field within the head necessitates that the subject be "inside" the magnet aperture (or bore). In addition, the subject's head must be placed within a RF coil, and this must be placed within a set of magnetic field gradient coils. Therefore, the RF coils and the gradient coils must also be placed within the magnet aperture (Fig. 15). In order to perform an imaging examination, the subject lies on the bed. The bed is raised to the level of the RF coil, and the RF coil is placed around the head. The subject is then moved into the magnet so the head is located approximately 1 m within the magnet bore.

V. SAFETY AND EXPOSURE

MRI is widely regarded as a safe, innocuous imaging procedure that can be repeated at virtually any desirable interval. It is generally deemed as being safe for use with normal subjects within the context of research studies. MRI is accomplished without the use of ionizing radiation (X-rays). In addition to exposing the subject to a static magnetic field of considerable strength, the imaging process also requires that the subject be exposed to magnetic fields that oscillate at a frequency used in radio and television broadcasting and also to switched magnetic field gradients. No studies have demonstrated that MRI exposure has any adverse affects on health in the short or long term. Of course, failure to detect an effect does not necessarily mean that effects do not exist. The current negative findings, however, do suggest that any possible health effects are subtle at best. Because of the possibility of unknown effects on human development, MRI is generally not used during pregnancy.

The MRI environment does present some hazards. Probably the greatest potential hazard is being struck by a magnetic object while in the MRI scanner. MRI magnets create a fringe field around them that is capable of levitating and attracting (at great speed) iron and steel objects. The majority of MRI magnets use superconducting technology and these magnets are

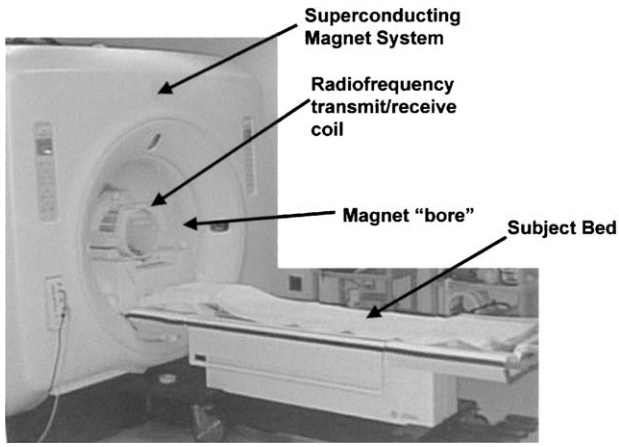

Figure 15 Photograph of a typical commercial MRI scanner.

rarely, if ever, turned off. Accordingly, the MRI scanner must be located in a controlled environment from which iron and steel objects are excluded. The magnetic field can also affect the operation of heart pacemakers and certain other electromagnetic prostheses. Individuals who rely on these devices should be excluded from the MRI environment. The magnetic field may also apply torque to certain types of aneurysm clips; therefore, subjects who have undergone vascular surgery must be carefully evaluated before being imaged with MRI. The switched magnetic field gradients used in MRI can induce electric current flow in the body and affect neuromuscular function. Accordingly, the limits of field gradient strength and gradient switching rates have been established by the appropriate regulatory authorities. Alternating RF electric currents can be induced in the body by the RF pulses used in MRI. Such currents dissipate energy in the form of heat and this can be a source of local tissue burns. This hazard becomes more probable when metallic objects (e.g., electrocardiographic electrodes) are located in or on the body in the vicinity of the RF coil. Therefore, the RF energy that can be used is regulated. With appropriate precautions, it is exceedingly rare for subjects to experience injury during MRI scanning.

Undergoing MRI is not necessarily a pleasant experience despite its innocuous health effects. MRI scanning is a relatively slow process during which the subject must remain motionless within the tight confines of the scanner hardware. Some subjects experience claustrophobia during MRI scanning. In addition, the magnetic field gradient pulses are accompanied by a high level of audio noise, which some subjects intensely dislike.

VI. SUMMARY

MRI provides exquisite images of the soft tissue structure of the brain at millimeter resolution from any viewing angle. It does this by detecting an intrinsic magnetic signal that is produced by the protons within tissue water when the body is placed in the appropriate magnetic environment. Nowhere are the uses of MRI more significant than in brain imaging. MRI is far superior to all other noninvasive brain imaging procedures because it images signal generated directly by the brain tissue and this signal is readily detected despite the presence of the bony cranium. The technology is sufficiently robust to routinely produce images at millimeter resolution with good tissue contrast. The signal detection process uses no form of ionizing radiation and is relatively innocuous. These properties permit subjects to be examined repeatedly. These attributes of MRI point to utility that extends well beyond the diagnosis and evaluation of disease. In recent years, neuroscientists have realized that MRI is a significant research tool that may be used for anatomic imaging in human and animal subjects.

Manic–Depressive Illness

EDWARD H. TAYLOR
University of Minnesota

GLOSSARY

cycle length The time from the beginning of one depressive or manic episode to the start of a new episode. As episodes increase, cycle length decreases. Individuals tend to establish rather constant and individualized cycling patterns. The term rapid cycling is used when a patient has four or more episodes of depression or mania, in any combination, during a 12-month period.

cognitive information processing (also known as social cognitive information processing) The ability to appropriately identify, classify, assess, and correctly act upon or disregard significant environmental and social cues. Processing of information requires the brain to accurately observe or attend to the environment, select important cues while disregarding less meaningful data, compare the selected cues with facts stored in memory, label partial and incomplete data, and develop a cognitive schema for action or determine that no action is required. All of the bipolar disorders reduce a person's information processing skills during periods of depression, mania, or hypomania.

depressive episode An extremely decreased mood that remains symptomatic across all or most of the person's daily activities. Depression removes the capacity for experiencing pleasure and often the ability to find meaning in endeavors or interpersonal relationships that were previously positive and enjoyable. Approximately two-thirds of people in a depressive episode think about suicide, and 10–15% kill themselves.

hypersomnia An excessive experience of sleepiness during day hours. The symptom occurs in some patients with depression and bipolar disorders but is more commonly part of a nonpsychiatric medical problem such as sleep apnea or narcolepsy.

manic episode An abnormally euphoric, elevated, or irritable mood that is associated with impulsive behaviors, poor judgment, concrete and grandiose thinking, reduced sleep, and impaired problem-solving skills. In the beginning individuals in a manic episode may express feelings of elation, energy, and increased insight. These positive perceptions, however, often evolve into feelings of anger, confusion, and fear. Obsessive thoughts of persecution, religiosity, sexuality, fame, economics, or other life events preoccupy individuals who are in a severe manic state.

neurobiological disorders Psychiatric disorders that relate to disruptions or pathological changes in the brain's structure and chemical neural messenger system. Brain abnormalities often found in neurobiological disorders include enlargement of the lateral and third ventricles, reduced frontal cortex volume, cerebellar atrophy, frontal cortex and medial temporal lobe metabolic changes, and changes in the size–shape structure of the temporal lobe and hippocampus.

spectrum disorder A term denoting psychiatric disorders that are thought to have a common pathophysiology and overlapping symptoms and often, but not always, can be treated with identical or similar psychotropic medications.

I. INTRODUCTION

Manic–depressive illness belongs to a spectrum of neurobiological diseases that today are most often called bipolar disorders. The terms are often used interchangeably in popular and scientific literature and refer to an interrelated group of illnesses rather than a

single disorder. The popular press and public speakers often use manic–depression and bipolar I disorder as synonyms for a single illness. This is understandable in that bipolar I disorder is one of the most severe forms of manic–depression illness. However, thinking of manic–depression as a cluster of similar mood disorders is more helpful. These illnesses, among other things, attack the brain, preventing individuals in varying degrees from willfully regulating their mood. Like all physiological and emotional problems, bipolar disorders can range in severity from mild to extremely disabling.

Definition of the disorders as simply shifts between high and low or depressed and manic moods misrepresents the affect, disabilities, and pain caused by these illnesses. People with bipolar disorders often report having moods and feelings that take control of their behaviors, motivations, thoughts, perceptions, and ultimately their lives. In a major depressive episode, feelings such as sadness, hopelessness, mental pain, and fatigue are amplified far beyond the normal human experience. Depression can create a pervasive and relentless sense of gloom, inadequacy, rumination, guilt, and worthlessness that the person is unable to dispel with logic, past experiences, or personal will. Mania swings an individual from an upward feeling of well-being, past exuberance, through a state of unexplained euphoria, and finally into a chaotic state of racing, incomprehensible, disconnected thoughts. Depressive and manic episodes are more than magnifications of everyday moods. They have the ability to decrease and control a person's cognitive information processing speed and accuracy, word retrieval, memory, motor speed and skills, concentration, abstract thinking and problem-solving skills, and perception of the social world. Whereas this article provides an overview of these disorders, readers should consult the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., for specific diagnostic and assessment criteria.

Most authorities believe that bipolar I and II and cyclothymic disorders represent differing types, symptoms, and severities of bipolar disorders. A growing number of researchers and clinicians also consider schizoaffective disorder as part of the bipolar spectrum. Bipolar I disorder is a severe form of manic–depressive illness and always includes the occurrence of at least one manic or mixed episode. Most individuals who have bipolar I disorder will at some point experience a major depressive episode, even though this is not a required criterion for the diagnosis. The illness can start with an episode of either mania or depression. Bipolar I disorder can cause acute, severe problems requiring hospitalization to control symptoms like psychotic episodes, extreme manic behavior, immobilizing depression, or suicidal thoughts. Bipolar II is diagnosed if the person has one or more major depressive and hypomanic episodes, but no history of manic or mixed episodes. Hypomania is a milder, less severe form of mania that seldom leads to hospitalization. Mental health professionals are sometimes unable to identify the hypomania episodes and misdiagnose the illness as severe depression or a personality disorder.

Cyclothymic disorder is the mildest form of manic–depressive illness. The disorder causes low-grade chronic mood abnormalities. For 2 or more years the person has numerous periods of hypomanic symptoms alternating with numerous bouts of mild to moderate depression. Individuals with this disorder find that, particularly during periods of depression, it becomes difficult but possible to maintain their normal activities. When hypomania occurs, the person experiences an increase in activity and at least a slight decrease in judgment and problem-solving skills. Irritability may occur in both the hypomanic and the depressed states. Many individuals with cyclothymia appear fully functional, maintain their employment, and never seek professional help. What is not seen is their internal turmoil, decreased problem-solving skills, and the amount of energy required to complete required daily work tasks.

Schizoaffective disorder represents the other end of the spectrum. It is an extremely severe form of illness that incorporates symptoms found in both manic–depressive illness and schizophrenia. Schizoaffective disorder can produce a state of persistent psychosis along with episodes of mania and depression. Normally the psychotic symptoms continue after the mood episodes dissipate. Some individuals appear to have a schizomanic condition, whereas others have more symptoms of schizophrenia and depression. The fact that mood-stabilizing medications help people with schizoaffective illness but generally are not helpful for patients with schizophrenia argues for classifying the illness as part of the bipolar spectrum.

II. HISTORICAL OVERVIEW

Throughout history scholars have described the symptoms and effects of manic–depressive illness. Ancient Greek, Persian, and biblical writers recorded

and attempted to explain the complexities of bipolar illness. In the second century AD Areteus wrote about patients who, in a state of euphoria, danced throughout the night, talked publicly, and acted overly self-confident then, for no apparent reason, shifted into a state of sorrow and despair. The fourth century BC Greek physicians lead by Hippocrates were perhaps the first to hypothesize that symptoms we now call bipolar disorder represented a neurological illness highlighted by major uncontrollable shifts in a person's mood. These early Greek scholars further taught that mental illness is caused by natural rather than spiritual forces, identified the brain as the major organ responsible for sanity and intellectual processes, attempted to classify major mental disorders, and developed crude medical treatments for mental disorders. Unfortunately, however, records from the ancient Egyptians, Greeks, Romans, Middle Ages, European Renaissance, and early American history indicate that this hypothesis gave way to assumptions of demoniacal possession, witchcraft, sinfulness, and other dehumanizing concepts. Nonetheless, traces of scientific and medical inquiries into bipolar disorders periodically appear throughout history.

The first person to identify the link between mania and melancholia or depression was Theophile Bonet. In 1686 Bonet described patients who cycled between high and low moods as having "manico-melancolicus." During the mid-1800s, French researchers Falret and Baillarger each independently observed that patients having manic and depressive episodes were not experiencing two different disorders, but rather two different presentations of the same illness. Falret described the disorder as "circular insanity" and listed the symptoms much as they appear in today's medical books and journals. He also (remarkably) hypothesized that the illness was hereditary and believed that through research a medication would be found for effectively treating the symptoms. The German psychiatrist Emil Kraepelin, building on Falret and Baillarger's work in the late 1800s and early 1900s, developed the definitive description and classification for manic–depressive illness that largely stands to this day. Kraepelin is credited with sensitizing past mood studies, clearly documenting that mania and depression are different symptoms of the same disorder, and with being the first researcher to assert that all mood disorders are neurologically related.

Kraepelin's basic concepts were challenged and widened by Eugen Bleuler in 1924. For Bleuler, mental disorders could not be classified into two major categories as Kraepelin claimed. Kraepelin believed that all mental illnesses fall into two basic, but separate groups. An illness was classified either as causing periodic recurring symptoms, such as manic–depression, or as a disorder characterized by ongoing neurological deterioration, such as schizophrenia. In his later work, Kraepelin did, however, clarify that it was impossible to neatly place everyone with mental illness into these two categories and that one cannot always discriminate among major disorders. Bleuler argued that manic–depressive illness and dementia praecox (schizophrenia) were not separate classifications, but rather a continuum. How a person was diagnosed and placed on the spectrum depended on the number of symptoms of schizophrenia that were found. More importantly, Bleuler broadened the manic–depression classification by identifying a number of subcategories and introducing the term affective illness. Between the early 1920s and mid-1980s, criteria independently developed by Kraepelin and Bleuler shaped most of the world's psychiatric diagnostic systems.

Between 1930 and 1940, mental health treatment providers largely abandoned the assumption that manic–depression and most other disorders, including schizophrenia and autism, developed from neurobiological abnormalities. Following World War II and until the early 1980s, mental health theory and treatment were mostly guided by psychoanalytic concepts proposed by Freud and his followers. Whereas psychoanalytic theory agreed that biological components played a role in affective disorders, practitioners insisted that early childhood parental or other environmental conflicts usually explained the onset and recurrence of manic–depressive episodes. As a result, it was thought that manic–depressive symptoms would resolve if individuals gained insight into their unconscious anger or other hidden emotional conflicts. Even though psychoanalysis and other forms of psychotherapy offered little help for most patients with severe manic–depressive problems, talk therapies nonetheless became the treatment of choice for decades. This preference continued for a number of years even after the introduction of lithium, the first drug found to successfully treat manic episodes.

Dr. John F. J. Cade, a doctor in the Mental Hygiene Department of Victoria, Australia, was dedicated to the belief that manic–depression was a biological, not an unconscious, psychological disorder. In the 1940s he was attempting to discover how urine toxicity levels from patients with various mental disorders differed. Cade wanted to inject guinea pigs with various concentrations of uric acid. However, uric acid is

insoluble in water and difficult to inject. To resolve this problem Cade mixed uric acid with lithium. To Cade's surprise, guinea pigs injected with the lithium solution had less toxicity in their urine. The scientist next injected the animals with lithium carbonate and observed that the animals remained conscious but less active and responsive to their environment. On the basis of these findings, Cade administered a lithium salt preparation to several highly agitated manic patients. Each of the patients had a remarkable reduction in symptoms. After Dr. Cade successfully treated 10 additional patients with the solution, European doctors started to quickly accept lithium as an important advancement in treating bipolar disorders. Because of safety concerns documented by cases of hypertension and deaths resulting from a consumer salt substitute containing lithium, the drug was not approved for use in the United States until 1970.

III. EPIDEMIOLOGY AND CAUSE

Bipolar disorders usually start in late adolescence and young adulthood. These illnesses, however, can appear any time between ages 5 and 50 and in rare cases beyond the age of 50. Research indicates that between 25 and 30% of the people who develop manic–depression as adults had one or more related symptoms before their 6th birthday. The more severe forms of bipolar illness (bipolar I disorder) are considered to be rare in prepubertal children. Only about 0.6% of adolescents are thought to have a bipolar I diagnosis, but estimates of teens with bipolar II disorder have reached as high as 10%.

Estimates of the number of people with a bipolar disorder vary. This occurs in part because of diagnostic difficulties and because of the fact that many people who have mild symptoms either do not seek or do not receive professional attention. At any given time, about 8% of America's population is at risk for developing a mood disorder. Most studies estimate that between 1 and 2.5% of the U.S. population has a bipolar disorder. A representative number of studies estimate that the prevalence of bipolar disorders is 3–6.5% of the U.S. population. Unlike unipolar depression, bipolar disorders are found equally in females and males. Between 5 and 20% of adult cases that are first diagnosed as unipolar depression over time will receive a reevaluated diagnosis of bipolar disorder.

Science has gained a large amount of information about manic–depressive illness but has been unable to identify specifically how the illness starts. There are most likely several causes for this syndrome of disorders. Studies of families, twins, and adoptions suggest that most cases of manic–depression are genetically inherited. There is general agreement among researchers that genetic components play a more significant role in transmitting bipolar I disorder than major depressive disorder, but this perspective continues to be debated. Family studies report that having a first-degree relative with bipolar I disorder increases the chances of developing manic–depressive illness by 8–18 times over families with no first-degree members having a bipolar disorder history. The likelihood of developing bipolar I disorder is 1.5–2.5 times greater if a first-degree family member has a major unipolar depressive disorder. Perhaps more illustrative of the genetic relationship to manic–depression is the fact that 50% of all people with a bipolar I disorder have at least one parent with a mood disorder. Additionally, a 25% probability exists of a child developing bipolar I disorder if one parent has this form of manic–depressive illness, and a 50–75% chance exists if both parents have bipolar I disorder. There is only a limited amount of information from adoption studies on bipolar disorders. The available data document that children adopted as infants from biological parents with a major mood disorder remain at an increased risk for developing bipolar disorders. The link between genetics and manic–depression has also been established through the study of twins. Monozygotic twins show a concordance rate for bipolar I disorder of 75%, whereas the concordance rate for bipolar I disorder in dizygotic twins drops to 20%. In addition, scientists have hypothesized that some cases of bipolar disorder may not stem from a genetic transmission. Researchers have found indications that bipolar disorders may be caused by *in utero* neuroviruses that attack the fetus' forming brain. There is currently growing interest in the role neuroviruses and immunologic abnormalities play in the formation and development of major mental disorders, including manic–depressive illness and schizophrenia.

IV. MAJOR SYMPTOMS

The type of bipolar disorder a person has is largely determined by identifying the severity, number, type, and duration of manic and depressive symptoms the

person has or is experiencing. Diagnosis of bipolar disorders is complicated by the fact that many symptoms of unipolar depression and manic–depression overlap. As an example, agitation and insomnia can occur in the depressed and in the manic state. Hypersomnia and psychomotor retardation, however, are observed more in bipolar than in unipolar depression.

Mania is one of the most dangerous of the abnormal mood states, but fortunately it is not present in all forms of bipolar disorder. Mania or manic behavior produces extreme and dramatic symptoms that can endanger the person's social and economic well-being and cause the individual to take life-threatening risks. The early stages of mania are experienced as pleasant and uplifting. The person feels energetic, creative, highly spirited, and capable. In the beginning of a manic episode, individuals are filled with a pleasant mood, ambitious thoughts, and self-confidence. They see great promise in their relationships, personal talents, skills, careers, and future. Goals are more clear, tasks seem less difficult, and life becomes magically filled with cosmic meaning and understanding. These exuberant and positive feelings, however, quickly pass and change into more pronounced psychiatric symptoms.

The person's cognitive information processing skills are disrupted by rapidly occurring thoughts that not only collide together but form incomplete and incongruent ideas. Additionally, the ability to screen and judge the appropriateness of one's thoughts, behaviors, productivity, and quality of work largely disappears. Furthermore, the previously elated mood filled with self-confidence, grandiosity, and positive symbolic meaning turns into unexplained, almost random anger and irritability. Whereas some individuals alternate between periods of elation and irritability, most slip into a state of mania dominated by dissatisfaction, frustration, intolerance, and an unsettling irritated mood. Some individuals also experience a constant internal rage that, with almost no provocation, can explode into verbal or physical violence. Mania also blunts and distorts learned social–cultural judgment while simultaneously stimulating a need for increased activity and excitement. In an attempt to alleviate these pressured feelings of desire, anxiety, anger, and grandiosity, the person behaves and makes decisions that are erratic and often dangerous. Without forethought or consideration of the consequences, individuals in a manic episode may run up large credit card debts, buy enormous quantities of a single and unusual item, engage in risky sexual activities with multiple unknown partners, drive recklessly, feel justified driving the wrong direction down a one-way street or disobeying traffic lights, indulge in large quantities of food and alcoholic drinks or go without eating and sleeping, drive aimlessly until the car runs out of gas, lose inhibitions and speak crudely or go nude in public, dress bizarrely, or verbally and physically lash out at others. Mania is always dangerous. As grandiosity is stimulated and judgment severely suppressed, the manic person can become extremely reckless and cause serious self-injury or death. The inability to foresee consequences and consider multiple solutions along with impulsive, agitated thinking and anger can induce rapid suicidal thoughts and behaviors. Depressed patients ruminate, plan, and deliberate the possibilities of suicide. For the depressed, death is often a means of ending mental anguish and hopelessness or stopping an unexplainable, but nonetheless constant drive and obsessive desire to die. In contrast, manic individuals kill themselves over poorly conceived, impulsive, almost momentary issues and feelings. Furthermore, severe mania often triggers physical violence and aggressive property destruction in people who have a more severe form of manic–depressive illness. People with a manic–depressive illness more often make death threats to presidents and other famous individuals than patients diagnosed with schizophrenia.

As the severity of a manic episode proceeds, thoughts can rush through a person's mind so fast that half-way through a sentence the beginning point is forgotten. This occurs when manic symptoms disrupt or block the brain's working memory. Under normal circumstances, working memory allows us to pull appropriate information from long-term memory, lock it in our mind, and manipulate the facts into interlinking complete thoughts and logical problem-solving models. In the most severe stages, mania can cause the person to experience psychotic hallucinations and delusions. Without medication, the person's manic hyperactivity and psychotic state will evolve into a stressful fatigue and loss of psychological orientation to time and place that causes the individual to appear completely confused, bewildered, and stupefied. In the past this was referred to as delirious mania. Fortunately today's modern medications and supportive treatment prevent most people with a manic–depressive disorder from reaching this level of severity.

Euphoria and hyperactivity that create difficulties but do not reach the level of severity of manic episodes is known as hypomania. This psychiatric condition

was first described in the late 1800s by the German psychiatrist Mendel. A hypomanic mood produces behavior that resembles the first phase of a full manic episode. The person has an elated mood, increased energy, rapid thinking and speaking, and reduced information processing skills. Though thoughts occur quickly, information is processed in a more narrow, concrete, and restricted manner. As an example, one's abilities to form alternative solutions, empathize, consider input from others, or perform problem-solving tasks requiring an exact sequential sequence are substantially reduced. Additionally, hypomania causes problems perceiving, organizing, and analyzing fragmented social information and interpreting social cues that have multiple meanings. As a result, hypomanic individuals make impulsive decisions, fail to consider behavioral consequences, and seldom perceive how others experience their actions. The symptoms may also include an inability to screen verbal communications. That is, the person feels an actual need or urge to voice almost every thought. When this symptom occurs, the individual interrupts others, talks incessantly, and has little concern if his or her words insult and upset the listener. Furthermore, hypomania, like the first phase of mania, can cause grandiose self-perceptions. During periods of grandiosity individuals overvalue their skills, status, or personal magnetism and may engage in behaviors like risky investments and business decisions, overspending and credit card debt; sexual experimentation and excess, and careless and reckless activities. A hypomanic person often displays seductive and addictive behaviors that may first appear as spontaneity or personality characteristics. A closer examination, however, will show that the individual's actions extend beyond the boundaries that are acceptable for most people within the same age and cultural group. Many times individuals with hypomania are labeled by families, schools, and community agencies as immature or delinquent and neither receive a referral nor seek mental health treatment.

Only a brief overview of depression symptoms is provided in this section. Readers are directed, however, to the complete article on the subject that is included in this volume. Depression is different from sadness, grief and bereavement, feelings of loneliness and isolation, or disappointment. Each of these situations creates a normal, but nonetheless unpleasant mood reaction to a real or perceived event. More importantly, one is able to shift away from the reaction, receive relief, and often block the feelings by engaging in nonrelated activities. That is, normal depressive feelings are mood reactions that seldom pervade every domain of our life for an extended period of time. Even when one's mood is lowered by a specific event, most individuals continue to experience a range of positive thoughts and feelings.

Unlike reactive sadness, depression is a downward spiraling or narrowing of feeling and emotional range across most major life domains for an extended period. Dulling and despondent feelings relentlessly occur from depression and prevent one from experiencing pleasure, accepting solace and praise, and finding emotional relief. Rumination over issues like regret, guilt, personal loss, shame, incompetency, disappointment, and hopelessness is often experienced as emotional stress and pain. Severe depression can also create a numbing emptiness and an inability to care about oneself, family, others, or the future. Additionally, during a depressive episode most people with a bipolar disorder experience not only a feeling of gloom but also restrictions and deficits in their cognition, information processing, motor, and perceptual skills. Concentration and working memory are always reduced by depression. Abstract thinking along with simple social cognitive information processing is greatly slowed. Other common symptoms include social withdrawal, insomnia or hypersomnia, weight loss or gain, fatigue, headaches, constipation, loss of sexual drive, and loss of interest and enjoyment in past pleasures or life skills. In severe depressive episodes a bipolar disordered person may also develop delusional thinking, hallucinations, catatonic states, or other forms of psychotic symptoms. Approximately 50% of all people with a bipolar disorder will exhibit psychotic symptoms. Additionally, even without entering a psychotic state, severe depression can usher in and maintain paranoid thinking for an extended period. To stop the emotional pain stemming from hopelessness, lost cognitive skills, and hurt from burdening others or feeling unloved or undeserving of love, far too many bipolar disordered patients during a depressive episode make serious and deadly suicidal attempts. Approximately 15% of individuals with a bipolar disorder make a serious attempt to take their life.

Another cluster of manic–depressive symptoms forms the mixed affective mood states or simply mixed episodes. A small subgroup of individuals with bipolar disorders will, for a week or more, concurrently experience the symptoms required for diagnosing a major depressive and a manic episode. This is a highly torturous state that simultaneously inflicts the rushing frenzy of mania and the restrictive negative sensations of depression. Even though the mood abnormality was

first described by a seventeenth century doctor, modern medicine continues to struggle with and debate the exact characteristics that define a mixed state. The prevailing symptoms can vary greatly for patients having a mixed episode. Some individuals, as an example, will feature psychotic symptoms, whereas others become highly irritable and yet others manifest more depressive behaviors. There is, however, growing evidence that a mixed state does not occur in all bipolar disorders. As a result, many experts believe that mixed episodes need to be thought of as a form of bipolar disorder or mixed mania that is separate from both depression and mania. Dysphoric mania is similar to mixed episodes, but the symptoms are less severe, often have a shorter duration, and do not qualify as full depressive and manic episodes. Patients who rapidly cycle between depressed and manic or hypomanic states can appear to be, but are not technically, in a mixed state.

The length of time between episodes of illness varies greatly among all patients with manic–depressive illness. For many people the cycle lengths shorten, causing more frequent episodes, then plateau at approximately 3–5 episodes per year, and finally shift to episodes that occur more or less annually. This appears to be the natural course of the illness. As the interval between psychiatric crises lengthens, most patients will have extended periods where their mood, and cognition, motor, and information processing skills return to normal. Unfortunately around 5–20% of bipolar patients have at least 4 manic or depressive episodes per year. This is known as rapid cycling, and episodes may take place in any combination and order.

Diagnostically, rapid cycling episodes do not differ in criteria from those that take place in non-rapid cycling. The symptoms must meet the criteria required for a manic, hypomanic, mixed, or major depressive episode. A smaller group of patients has ultrarapid cycling in which a depressive, manic, or a hypomanic episode may last for only a day or trigger multiple episodes within a 24-hr period. Unlike rapid and ultrarapid cycling, individuals with continuous cycling move through episodes without returning to their normal baseline or feeling normal for a significant period of time. With these individuals one depressive, manic, or hypomanic episode melts into another. Correct and prompt diagnosis of this illness is extremely important. Rapid cycling appears related to morbidity, is pharmacologically difficult to treat, and requires specific medication regimens. Studies show that these patients do not respond well to medications that are normally used with other bipolar disorders like lithium and antidepressants. Moreover, antipsychotic drugs may actually stimulate or exacerbate the cycling process.

V. CHILDHOOD ONSET

Even in the 1960s psychoanalytic theory hypothesized that children could not develop depression, let alone manic–depressive illness. This was founded on the assumption that depression results from unconscious superego conflicts. Because they thought children had not yet developed superegos, the assumption was that children also could not experience real depression. Today research documents that children, preteens, and adolescents can develop unipolar depression and bipolar disorders, but their course of illness and symptom patterns are often much different from these of adults. Manic–depression in children causes the general symptom categories found in adults but creates different patterns and behavioral problems. As an example, children have more chronic episodes distinguished by rapid and ultrarapid cycling. From the very beginning as infants many of these children behave differently from their peers. Mothers and nurseries report that the baby has long periods of crying, sleeplessness, and excessive activity.

As toddlers and preschoolers the children psychoanalytic theory destined for manic–depressive illness often are described as highly creative, bright, verbal, and intellectually ahead of most other children. Parallel to these positive developmental factors parents also recall that their children experienced severe separation anxiety and night terrors much longer than most youths. Additionally, many children who are developing manic–depressive illness have vivid, explicit dreams that typically focus on violent themes filled with blood and gore. This type of color-filled descriptive violence can also occur in the discourse of normal conversations. They may meet simple requests or instructive guidelines, such as gently requesting the child to remain in line, with an exaggerated physical threat. A parental ''no'' can send the manic–depressive child into a destructive rage for hours. During tantrums these children routinely cry, kick, hit, pull hair, bite, and attempt to punch holes in the wall or destroy other property. Discovery that the child has destroyed favorite personal items and damaged walls and furnishings when sent to a room for a time out punishment is a common experience among parents. Not only do many children rapidly cycle, often

switching from one mood state to another within hours, but additionally high degrees of agitation, unhappiness, anxiety, and anger can accompany both depressive and manic episodes. Manic episodes may include obsessive silly behaviors that grate on others, including peers. As the child's grandiosity increases, the youth may make unrealistic claims and brag about current and future fame. Mania can also cause the child to steal or hitchhike and travel in a totally unplanned and unprepared manner. Many times children in a manic episode will not know where they are going or why they are traveling. Still others will break into a house and take off all clothing for no apparent or logical reason. Impulsive behaviors highlight childhood mania and greatly increase the risk for suicide and self-injury.

The onset of a bipolar disorder during childhood usually starts with a depressive episode. Both unipolar and bipolar early onset depression may feature a distinct loss of pleasure in activities that had been pleasurable, tantrums or crying for almost no known reason, lethargy and oversleeping, an increase in self-consciousness, previously unseen or greatly increased phobic anxiety, increased agitation, arguing, and physical fighting. In almost all cases the child's school behavior and academic performance decrease, and many children develop or experience increased separation anxiety symptoms.

VI. TREATMENT ISSUES

When symptoms first start in children and adults, an extensive physical exam from a qualified physician is immediately required. Both depression and manic symptoms can stem from problems ranging from vitamin deficiencies or excess to major autoimmune, cardiovascular, gastrointestinal, endocrine, hematologic, neurological, and pulmonary diseases or malignancies. Additionally, a long list of medications and drug interactions can cause manic–depressive behaviors. Commonly, bipolar symptoms caused by medical problems other than a neuropsychiatric disorder will improve as the person recovers from the primary physical illness. Once alternative medical problems are ruled out and the person is diagnosed with a bipolar disorder, psychotropic medications become the first and fundamental treatment method.

Lithium along with the anticonvulsant medications carbamazepine and valproic acid are widely used as mood stabilizers. Lithium continues to be the most widely used drug for combating manic episodes and has also been found to relieve depressive symptoms for some individuals. Approximately 70% of bipolar patients experience significant benefits from taking lithium. This, however, is not without a cost. Lithium can cause numerous transient cognitive and physiological side effects and become life-threatening if the amount accumulating in the blood becomes toxic. When taking lithium, blood must be drawn routinely to monitor the blood's drug level and insure that toxicity does not occur.

Depression in bipolar disorders can be difficult to treat. Standard antidepressant medications, especially those known as tricyclics, can induce mania and rapid cycling in bipolar patients. This presents a particular hazard for individuals with bipolar II. These individuals often present as having recurring severe depression. The hypomania component can be hidden and difficult to diagnose. When this occurs, the person is at risk of being incorrectly diagnosed, prescribed an antidepressant, and sent into a state of mania or rapid cycling. Therefore, best practice guidelines recommend that bipolar depression be treated first with one of the mood-stabilizing medications mentioned earlier. Lithium is reported to be effective for 30–79% of bipolar depressed patients. The other antimania drugs are significantly less effective in treating depression. When the depressive episode is not reduced by lithium treatment, the psychiatrist will add either an additional mood-stabilizing medication or an antidepressant. Because tricyclic medications are known to increase mania, physicians most often put the patient on a monoamine oxidase inhibitor (MOAI) or one of the newer serotonin re-uptake inhibitor (SSRI) antidepressants. MOAI have generally been found to be the most reliable class of antidepressant medications for bipolar patients, but the drug tolerance and effectiveness, as with other psychoactive drugs, vary from patient to patient. Reports on best practice methods for treating bipolar depression consistently emphasize that antidepressants generally must be coadministered with a standard antimanic medication. Furthermore, unlike unipolar depression, there is no evidence that maintaining a patient on an antidepressant after the bipolar depression ends prevents the recurrence of future episodes.

Psychotherapy is always part of the comprehensive treatment of manic–depressive illness. During severe depressive or manic episodes, therapy anchors the person offering support, assurance, hope, and reflections of reality. As episodes lift and normal moods and thinking emerge, psychotherapy assists in logical and

systematic problem-solving, reinforcing positive behaviors and cognition, and understanding one's self and world. More specifically, psychotherapy can help individuals who have manic–depressive illness better understand their disorder, remain on prescribed medications, learn to predict and prevent or soften recurring episodes, learn to not be afraid when experiencing normal sadness, grief, or joy, how and when to let others take charge of their decision making, and how to better care for their significant others and friends. A combination of cognitive, behavioral, and supportive therapies can accomplish these goals with many individuals. An important part of psychotherapy is recording in a chart or journal how moods change over time, how they are affected by medication, and reactions in differing environments. Methods of this type are also used to identify internal thoughts or cognitive nonverbal self-talk. The messages we silently give ourselves can highlight strengths, fears, and oncoming depressive and manic episodes. By knowing that the patient's cognition and behaviors are changing dangerously, the treatment team can take steps for preventing or reducing the severity of an approaching illness. Prevention is accomplished by adjusting the person's medication, providing additional psychological support, and reducing stress in the person's home and work environment. Psychotherapy can help individuals make sense and meaning out of their physical and mental difficulties.

Families can provide important information concerning the patient's developmental history, illness onset, and current progress. Family members, however, also need support, understanding, and assistance from the treatment team. Living with an ill loved one is stressful and difficult. Psychotherapists or other treatment team members can offer families psychosocial education, guided problem-solving sessions, and methods for managing anxieties and organizing their thoughts. Psychosocial education provides the family information about the cause, treatment, care, and prognosis of bipolar disorders. Family members need to understand that manic–depression is a biological illness that can be treated. They also often need assistance in knowing how to relate with the ill family member and how to help with the on-going treatment. With the onset of illness, families not only must learn how to live together once again and redistribute work tasks but also concretely know how to respond to psychiatric emergencies. Family members, as an example, must know when and when not to call mental health professionals, police, clergy, and emergency rooms.

Treatment not only involves medication, psychotherapy, and education but also concrete support for the patient and the family. Comprehensive treatment must help patients and families gain real services and tangible resources. Bipolar disorders can greatly alter the patient's and the family's ability to earn money and provide transportation, housing, food, medication, and access to medical services. Family members and patients also need opportunities to separate and rest. Living daily with someone who is in the midst of a depressive or manic episode is extremely stressful. To prevent suicide or other hazardous behaviors, family members often remain with the patient continuously for an extended time. Other family members take on additional employment to pay for medical and rehabilitation expenses or spend countless hours coordinating services for the ill family member. Treatment teams need to not only understand the stressors experienced by families but substantially assist in the resolution of these problems.

VII. STRESS AND ONSET

Stress does not appear to be a major factor in explaining why individuals develop a bipolar disorder. Additionally, research does not support the idea that the number of depressive or manic episodes experienced by a patient relates to that individual's pre-onset stress level. There is also little or no scientific evidence that bipolar episodes are related to stress through the brain's kindling process. Kindling refers to the brain at the cellular level learning from repeated episodes to automatically trigger an event such as a seizure. Studies show that, after a number of electrically stimulated seizures, spontaneous epilepsy will occur without the introduction of electrical stimulation. The popular brain kindling and behavioral sensitization theory hypothesized that bipolar patients become highly aware of stress. Environmental and behavioral symbols for stress are then linked to repeated depressive and manic episodes. Eventually the brain will automatically trigger a relapse with only the slightest perception of a stressful stimulus. Whereas kindling has been shown to occur in laboratory animals, it has never been demonstrated in humans. No experimental or clinical research has shown that kindling occurs in the brain of individuals with a bipolar disorder.

There is some evidence that the onset of the first episode may partially be triggered by a stressful experience. This appears to be less true for depressive

and manic episodes occurring after the initial onset of the illness. Whereas stress may not explain why episodes occur, a strong relationship exists between the severity and frequency of symptoms and environmental stress. Reduction in interpersonal, community, and work stressors often increases the patient's level of functioning and decreases the manic–depressive symptoms. This is one of the immediate benefits some individuals gain from emergency hospitalizations and partial hospital programs. Stress management, however, is an adjunct therapy that serves as an enhancement to appropriate medication and psychotherapy treatment. Environmental manipulations cannot independently address and treat manic–depressive symptoms. Furthermore, people who are in the midst of an extremely severe episode may receive almost no relief from stress reduction and environmental enhancements.

VIII. NEUROCHEMISTRY

In the simplest terms, bipolar disorders occur from abnormalities in the brain's anatomy and chemistry. As a result, the brain is unable to orchestrate the dispatch and reception of chemical messages that direct, appropriately control, or modulate a person's mood. These are complex illnesses that cannot be explained by a single neurotransmitter or localized to one primary brain structure. Neurotransmitters are chemical messengers that carry electrical impulses between brain cells. Early research in the 1950s demonstrated that imipramine medication used for treating depression inhibited the re-uptake or increased levels of neurotransmitters known as neurogenicamines (neuroamines). Re-uptake is the process whereby chemicals that remain after transmission from one cell to another are either stored in the neuron's presynaptic terminal or eliminated by glial cells.

Norepinephrine and dopamine, considered the most important neurotransmitters in the neuroamine group, were thought to be the key for understanding bipolar disorders. This led scientists to hypothesize that depression developed principally as norepinephrine decreased and that mania occurred when the re-uptake system caused norepinephrine levels to increase excessively. In the 1960s this concept became known as the "catecholamine" hypothesis, because both norepinephrine and dopamine are classified as catecholamines. Dopaminergic pathways project throughout much of the brain but are highly concentrated in the nigrostriatal region. This area is most often associated with Parkinson's disease, stiffness, tremors, and other movement disorders. The nigrostriatal system ranges from the substantia nigra to the neostriatum and is responsible for controlling complex muscular movements and posture. As part of the dopamine pathway, the system also plays a role in the coordination of voluntary movement.

Individuals with manic–depressive illness can experience alterations in their coordination and movement in both depressive and manic episodes. It is also thought that dopamine located in the basal ganglia filters unwanted verbal expressions. This may explain why during periods of depression some individuals find word selection difficult, make distressed nonword sounds, walk with their head down, awkwardly swing their arms, distort their facial muscles, or fail to use complete sentences or speech structures. However, it is during manic episodes that people most often lose their verbal filtering skills. The most universal symptoms reported for manic patients are motor hyperactivity, rapid or pressured speech, and a decreased need for sleep.

An overabundance of dopamine appears to be related to psychotic episodes, whereas lower levels are associated with Parkinson's disease. Unfortunately, dopamine's complete role in manic–depressive illness is not yet understood. We do know that the neurotransmitter not only influences movement and verbal filtering but also is involved in arousal, attention, mood, reality testing, and cerebral blood flow. The reduced information processing, reality testing, and social judgment experienced during manic episodes may in part result from changes in dopamine levels. These symptoms are greatly influenced by the cerebral cortex, frontal and temporal lobes, and hippocampus and other limbic system areas. Dopaminergic pathways travel throughout and link each of these brain regions. Additionally, for some patients medication targeted at dopamine re-uptake provides greater relief from depression than drugs that impact serotonin neurotransmitters.

Early catecholamine research tended to focus on the actions and effects of a primary neurotransmitter rather than the interactions occurring among neurochemicals and brain structures. Manic–depression was often described as a chemical imbalance primarily caused by changes in a person's norepinephrine level. Today we know that a disruption or change within a single re-uptake system only partially explains why individuals uncontrollably cycle through states of

depression and mania. Additionally, not everyone is adversely affected by an increase or decrease in norepinephrine levels. There is strong evidence that bipolar disorders involve defects in complex interplays among multiple neurotransmitters and physical changes in the brain's structure. Chemically, moods appear to be controlled or destabilized by changes in the level and interaction of norepinephrine, serotonin, dopamine, and other neurochemical factors.

Although norepinephrine cannot stand alone as an explanation for manic–depressive illness, it nonetheless continues to be viewed as a major contributor to the illness. The neurotransmitter's circuitry illustrates why it is an important link in understanding bipolar disorders. Norepinephrine pathways originate in the pigmented locus ceruleus of the brain stem and project through the limbic system and other major brain areas. The limbic system includes the hypothalamus, amygdala, hippocampus, and septal regions. These cortical and subcortical areas play a significant role in the regulation and modulation of moods, emotions, memory, and how one responds to events in the external world. Research has consistently found that individuals with bipolar disorders have reduced norepinephrine levels. Catecholamine metabolites such as norepinephrine are excreted in urine and provide a proportional measurement to that of the primary brain source. Most, but not all, studies have found that urinary measurements of norepinephrine are substantially reduced in bipolar patients compared with individuals who have either unipolar depression or no mental disorder. The severity of manic episodes may be an influencing factor in urinary catecholamine levels. Norepinephrine levels often differ between bipolar I disordered individuals and unipolar depressed patients, but not between those with a milder bipolar II disorder and patients who experience unipolar depressive episodes. Additionally, post mortem brain studies show that an increased density of norepinephrine receptors is highly associated with a history of major depressive episodes. When synapses are deprived of transmitter molecules, the postsynaptic cells compensate by increasing the number of receptors and attempt to retrieve any additional neurochemical signals that are available. Furthermore, medications that block norepinephrine re-uptake and increase the neurochemical in synapses reduce depressive symptoms for some individuals.

In the late 1960s, researchers found that the neurotransmitters norepinephrine and serotonin not only contribute to shaping a person's mood but also impact upon each other. Serotonin-producing neurons project from the brain stem's raphe nuclei through the amygdala, hypothalamus, and cortical areas. These regions produce the major symptoms experienced during depressive and manic episodes. As an example, the amygdala controls mood and affective responses, whereas the hypothalamus regulates appetite, sleeping patterns, and sexual drive and the frontal cortex assists with social judgment, information processing, and concentration. A person with manic–depressive illness will experience a reduction or slowness in these functions during a depressive episode and a flooding or racing of uncontrolled mental activities when the manic episode starts. This cycling between lethargic depression and racing mania is thought to occur in part because the serotonin circuitry incorporates or interacts with neuron sites that secrete or control the release of norepinephrine. It is thought that serotonin reaches a point of depletion that triggers or actually permits the brain's norepinephrine level to significantly drop. Furthermore, because serotonin-producing cells are found in many diverse brain regions, for some individuals, depression may result from inadequate serotonin levels interacting with neurons and neurochemicals other than norepinephrine.

The idea that serotonin depletion triggers a change in norepinephrine or other neurochemical levels has become known as the permissive hypothesis and continues to receive attention among researchers. Though the exact roles of these neurotransmitters remain unclear, there is no doubt that they both play important roles in manic–depressive illness. Scientists, as an example, can measure the brain's serotonin level by the amount of a serotonin byproduct found in a person's cerebrospinal fluid. Studies of cerebrospinal fluid consistently find that the serotonin levels in the brain for depressed and suicidal individuals as a group are significantly below those found in populations with no history of mood disorders. Additionally, post mortem studies report that, compared to people with no history of a mood disorder, depressed and bipolar disordered individuals have an increased density of serotonin receptors (type 2). This, like the increase in norepinephrine receptors, suggests that the brain may be attempting to compensate for extended periods of reduced serotonin in the synaptic cleft.

IX. NEUROANATOMY

The brain's inability to control neurochemical functions may result in part from anatomic abnormalities. Individuals with bipolar disorders have specific areas

of their brain that structurally differ from the neuroanatomy of individuals with no history of mental illness. Furthermore, there is growing evidence that differences in brain structure are also found among individuals with manic–depressive illness and other major diagnostic categories such as major depression and schizophrenia. University of Michigan researchers using positron emission tomography (PET) found that individuals with bipolar illness have a higher density of monoamine-releasing cells than people who do not have an affective disorder. These specialized cells are responsible for controlling the discharge of norepinephrine, serotonin, and dopamine. Magnetic resonance imaging (MRI) studies show that individuals with bipolar disorders have significantly enlarged lateral ventricles, frontal and temporal lobe sulci, and Sylvian fissures. Studies of third ventricular enlargement in bipolar disorders are at best mixed and often contradictory. This appears to be one of the anatomical differences between manic–depressive illness and schizophrenia. That is, there is strong evidence in schizophrenia, but not bipolar disorders, that lateral and third ventricular enlargement may be caused by a neuropathological process that is independent of sulcal changes. Furthermore, lateral ventricular enlargement and sulcal prominence have been found in many, but not all, patients with manic–depressive illness. Therefore, we currently cannot use neuroanatomical measurements as a means of diagnostically determining bipolar or other mood disorders.

Our understanding of how neuroanatomy differs between psychiatric diagnoses was greatly advanced by MRI studies of monozygotic twins discordant for either bipolar I illness or schizophrenia. Although these are genetically identical twins, one of each pair developed either manic–depressive illness or schizophrenia whereas the other twin remained well. The MRI study found a strong trend for the ventricular enlargement among twins affected with either bipolar I or schizophrenia disorders to be similar. When measured just within each discordant group, differences between right lateral, left lateral, and third ventricles were much more statistically significant. There was a greater difference, however, between the twins affected with schizophrenia and their well sibling twins than in the twins discordant for bipolar illness. Significant differences were also found between the schizophrenia-affected twins and their well sibling twins in the right and left hippocampus, amygdala, and basal ganglia areas of the brain. Interestingly, these differences did not significantly occur in the twins discordant for bipolar illness. This is at odds with numerous MRI nontwin studies of manic–depression. The lack of agreement may exist because the middle and posterior portions of the twins' hippocampus are yet to be studied.

X. CONCLUSION

Manic–depression is a spectrum of neurobiological illnesses that involve abnormal changes in the brain's chemistry and cellular structures. The neurotransmitters serotonin, norepinephrine, and dopamine appear to play key roles in triggering manic–depressive episodes. Anatomical damage or changes have been documented in the lateral ventricles, frontal and temporal lobe sulci, and Sylvian fissures. How bipolar disorders specifically start is yet to be explained. Evidence from family histories, adoptions, and twins strongly indicates that the disorders are genetically transmitted. There is, however, growing evidence that some individuals may develop manic–depressive illness from an *in utero* neurovirus. Environmental stress does not appear to play a major role in the causation of bipolar disorder or the number of episodes experienced by a person. Brain kindling and behavioral learning theories have not been helpful in explaining the cause or course of these disorders. Once individuals are in the midst of an episode, the reduction of environmental stress does appear to help reduce or soften the symptoms. Nonetheless, medications remain the principal treatment for bipolar disorders. Psychotherapy, psychosocial education, and environmental manipulation therapies serve as important adjuncts or additive components to treatment but are never the primary or sole intervention. This is particularly true for bipolar I and II and schizoaffective disorders. Approximately 70% of patients with bipolar I disorder significantly improve after taking lithium. Psychotherapy alone seldom has a meaningful impact on severe manic–depressive episodes. The future is extremely hopeful for individuals with bipolar disorders. New medications are currently being studied clinically, and our knowledge of how the brain functions is rapidly growing. Researchers are also learning to identify early risk factors and minor symptoms that signal the onset of illness. Unfortunately, manic–depression is an illness that cannot yet be prevented and continues, for many people, to be misdiagnosed. However, as our knowledge of medications, brain functioning, and early symptoms grows, science will be better positioned to effectively prevent and treat manic and depressive episodes.

Memory Disorders, Organic

ANDREW R. MAYES
Liverpool University

GLOSSARY

amnesia Either a nonspecific term for any kind of memory disorder (usually one caused by brain damage rather than arising for psychological or motivational reasons) or the global amnesia syndrome in which an impairment of recall and recognition of postmorbid facts and episodes (anterograde amnesia) is accompanied by varying degrees of recall and recognition impairment for premorbidly acquired memories of facts and episodes (retrograde amnesia), together with preservation of intelligence and working memory.

declarative memory Memory for facts and personally experienced episodes that the subject is aware of remembering. As such, the memories can be declared either by verbal statements or by some non-verbal means such as drawing. It is contrasted with procedural or nondeclarative memory, in which subjects cannot typically indicate what they are remembering except in the broadest manner.

episodic memory Memory for particular incidents in personal life that have specific spatial and temporal contexts. It is often contrasted with semantic memory.

explicit memory A form of memory contrasted with implicit memory; the distinction between the two is very similar to that between procedural and declarative memory. Like declarative memory, explicit memory often involves intentional retrieval of factual or episodic information.

implicit memory A form of memory contrasted with explicit memory that corresponds closely with procedural or nondeclarative memory. The presence of memory is only indicated indirectly and the subject does not intentionally try to remember anything specific but tries to perform a task well, with changed performance indicating the presence of memory.

priming A form of information-specific implicit, procedural, or nondeclarative memory in which remembering is indicated by a change in the way that previously studied information is processed. In other words, studied information is processed faster, more accurately, or in some other way more efficiently, although subjects need have no awareness that they are remembering the information.

procedural memory Memory that is only accessible through performance in an indirect or implicit fashion and comprises skill memory, conditioning, priming, and simple forms of nonassociative memory. It is sometimes referred to as nondeclarative memory by those who wish to stress that it may be constituted of a heterogeneous collection of different kinds of memory, the only common feature of which is that they are not forms of declarative memory.

semantic memory Memory for facts or the kinds of information that can be stored in our mental dictionaries and encyclopedias. Unlike episodic memory, semantic memory contains no necessary reference to the personal context(s) in which it was acquired although some facts necessarily include reference to the non-personal contexts in which (for example, historical) events occurred. It is controversial, however, whether retrieving personal contextual information may nevertheless sometimes be important in remembering facts. Resolving this issue is difficult because a common but nonessential difference between semantic and episodic memory is that the former tends to be much more rehearsed than the latter.

working memory The temporary storage for a few seconds of information that is being processed in any of a range of cognitive tasks.

Damage to different parts of the brain impairs both short-term and long-term memory for different kinds of information often in very selective ways that leave basic processing intact. Lesions to association neocortex cause several different short-term memory

disorders in which memory for phonological, visuospatial, color, or other kinds of information is selectively disrupted within approximately 1 sec of presentation. These immediate memory disorders occur in the presence of normal processing and are associated with longer term memory deficits for the same kinds of information. Several different kinds of long-term memory disorders exist. Posterior neocortical lesions disrupt semantic memory, but the deficit also seems to include episodic memories and to affect older memories much more severely than newer ones. Frontal neocortical lesions disrupt the ability to plan and organize processing in a variety of ways, and this causes impairments of long-term and perhaps (less severely) short-term memory for episodes and facts. At least in monkeys, there is some evidence that ventromedial frontal cortex lesions cause organic amnesia. This syndrome, which is known to be caused by lesions to the medial temporal lobe, the midline diencephalon, the basal forebrain, or their connections, involves pre- and postmorbid impairments of memory for facts and episodes but leaves intelligence and short-term, overlearnt semantic, and several forms of procedural memory intact. Processing of factual and episodic information seems to be relatively preserved. Priming of information already familiar at study is preserved in amnesia, but whether priming of previously novel information is preserved remains controversial. Perceptual priming has been shown to be impaired after posterior neocortical lesions. Other forms of procedural memory are disrupted by subcortical lesions. Thus, motoric classical conditioning is impaired by cerebellar lesions and skill learning is particularly disrupted by basal ganglia lesions. The range of distinct memory disorders has led to the view that there are several different memory systems, each dealing with a specific kind of information, dependent on different brain regions, and perhaps also dependent on qualitatively distinct kinds of memory processes.

I. INTRODUCTION

It has been known for more than 100 years that brain damage can impair memory in a relatively selective fashion. In the past 50 years, it has also become clear that damage to different brain regions selectively disrupts some kinds of memory, but leaves other kinds of memory intact. Since the 1970s, it has become increasingly possible to scan the brains of living memory-impaired subjects to better identify the location of damage that causes specific kinds of memory deficit. In the 1990s, research exploring the effects of differently located brain lesions on memory was complemented by neuroimaging studies that have explored the brain regions that are activated when particular memory processes are engaged. These neuroimaging studies have helped clarify the normal role of brain structures that when damaged cause different kinds of memory disorder.

Memory depends on encoding (processing and representing) different kinds of information, which are then stored and later retrieved. The occurrence of selective memory disorders has several implications about the way in which the brain mediates these processes. First, the existence of selective memory disorders is surprising because it means that memory loss occurs although the information for which memory is impaired is still being processed (and hence encoded) relatively normally. This challenges a widely held assumption that information is stored in the same neural network that represents it during encoding because if the assumption is correct, then brain lesions that damage such networks should disturb not only storage but also the ability to process and represent the information. In other words, the assumption seems difficult to reconcile with the occurrence of selective memory deficits for particular kinds of information that are still processed normally at input. Because retrieval and encoding involve many overlapping processes, the assumption is still problematic even if it was postulated that a memory deficit was caused by a retrieval deficit. Therefore, care must be taken to determine the selectivity of memory disorders.

Second, the existence of different kinds of memory disorders is consistent with growing evidence that the whole central nervous system is, to varying degrees, plastic and thus capable of storing memories. The spinal cord, as well as the brain, should be regarded as a storer as well as a processor of information. That different kinds of memory should be disrupted by lesions in different brain areas should not be surprising because it is known that different kinds of information are processed and represented in different parts of the central nervous system.

Third, the existence of several different kinds of selective memory disorders caused by lesions in distinct brain regions has resulted in the view that there are several systems of memory organized in a hierarchical fashion. Memory systems differ from each other not only because they are mediated by distinct systems of neurons but also because they involve qualitatively distinct kinds of memory processes. Memory systems are organized hierarchically to the

extent that certain kinds of memory share more qualitatively similar kinds of processes with each other than they do with other kinds of memory.

What is known about the range of short- and long-term memory disorders caused by brain damage and the selectivity of these disorders to memory are outlined before briefly considering what this reveals about how the brain mediates memory.

II. WORKING MEMORY DISORDERS

A. Impairments of Phonological and Visuospatial Working Memory

It has long been believed that memory that lasts for only a few seconds without rehearsal depends on different storage processes than does memory that lasts for minutes or longer without rehearsal. Short-term storage may depend on continued patterned activity in the neurons that represent information during encoding, whereas longer term memory may depend on structural changes between the same neurons that represent the information during encoding and short-term memory. If brain lesions can disrupt short-term memory for specific information, then this view would lead one to expect that long-term memory for that information would also be disrupted. Impaired processing of the poorly remembered information might also be expected.

Cortical damage can impair short-term or working memory while leaving processing relatively intact. This pattern of impairment has been explored most extensively with phonological short-term memory, for which the ability to hold sequences of phonemes in mind for several seconds has been found to be disrupted by lesions to the left parietal lobe, particularly in the left posteroinferior parietal lobe where it conjoins with the left temporal lobe. A patient with such damage may only be able to repeat one or two spoken digits when tested immediately after their presentation compared to the normal level of approximately seven digits, and spoken nonword repetition ability is lost with similar rapidity. Even the ability to hold one digit in memory is lost pathologically fast if rehearsal is prevented. Despite this rapid loss of phonological information, whereas some patients may be dysphasic, others show no other cognitive deficits, clearly understanding speech and seemingly processing phonemes normally when memory load is minimized. For example, some patients have been shown to be unimpaired at making same–different judgments with spoken syllables. Therefore, impaired phonological working memory can occur in the presence of apparently normal processing of phonemes.

In his model of working memory, Baddeley postulated that there was a rehearsal loop as well as a short-term store for phonological information. There is evidence that the phonological short-term store and the rehearsal loop can be disrupted separately. Thus, although some patients have impaired phonological working memory despite normal rehearsal, there are other patients whose impaired phonological working memory is caused by deficient rehearsal. Interestingly, anarthria is not sufficient to cause an impairment of phonological working memory, which suggests that rehearsal of articulated information is mediated centrally and does not require overt speech.

Baddeley's model of working memory also postulated the existence of a visuospatial short-term memory store as well as a phonological one. There is evidence that working memory for visuospatial materials can be disrupted separately from phonological working memory. Thus, whereas some patients have impaired phonological short-term memory and intact visuospatial short-term memory, others have been found to show the reverse pattern of deficit sometimes following lesions in the region of the right Sylvian fissure. In other words, differently located cortical lesions can disrupt these two forms of working memory separately.

B. Other Kinds of Working Memory Disorder

Lesions also disrupt forms of working memory not postulated in the original working memory model of Baddeley. Thus, visual verbal short-term memory can be selectively disrupted, and there has also been a report of a patient with a selective short-term memory deficit for color information in the presence of normal processing of color when memory load was minimized. There is also evidence that relatively selective lexical semantic short-term memory deficits exist. Thus, a patient has been described who was more impaired than a second patient, who had a phonological short-term memory deficit, on tests dependent on lexical semantic short-term memory (e.g., word span tests) but performed better although not completely normally on tests primarily dependent on phonological short-term memory such as non-word span tests. This semantic short-term memory deficit was not caused by

a semantic processing impairment because the patient's semantic processing was usually normal when memory load was minimized. The patient's lesion involved the left posterolateral frontal lobe and adjacent parietal regions anterior to where damage probably causes phonological working memory deficits.

Future work will examine the possibility that each sensory system and the motor system has one or more short-term memory systems by exploring whether the corresponding selective short-term memory deficits exist. This work will be guided in part by neuroimaging studies of working memory, which have already supported the implications of the lesion studies. For example, visuospatial and visual object working memory tasks have been found to activate distinct cortical regions. This leads to the expectation that there should be lesions that separately disrupt working memory for these two kinds of visual information.

C. Effects of Working Memory Disorders on Long-Term Memory

Until recently, it was widely believed that long-term memory is preserved in patients with short-term memory deficits because patients with impaired phonological short-term memory show normal long-term memory for spoken verbal materials. This finding was interpreted to mean that short-term memory processes do not trigger long-term memory processes, and the two are mediated by separable groups of neurons. These conclusions do not hold, however, because the preserved long-term memory shown by patients is almost certainly for semantic information, whereas their short-term deficit is for phonological information. Patients are able to recode phonological inputs into a semantic code very rapidly so that the recoding can be achieved even in the presence of very fast loss of phonological information. If care is taken to ensure that the phonological information cannot be recoded, then long-term memory might well be impaired. This has been shown in a patient with very impaired phonological short-term memory who was also found to be completely unable to learn spoken Russian words transliterated into her native Italian. In other words, she was impaired at both short- and long-term memory for meaningless spoken words, which she had to represent as phonological sequences. In a similar way, it has been found that another patient not only had impaired visuospatial short-term memory but also had severely impaired long-term memory for spatial layouts and new faces. A third patient, who had a semantic short-term memory deficit, was also very impaired at long-term memory for lexical semantic information (e.g., word lists) but showed preserved long-term memory for any information for which he had normal short-term memory.

These results imply that short-term memory disorders are specific to particular kinds of information and can occur despite preserved processing of that information at input. Short-term memory for different kinds of information is mediated by distinct cortical systems of neurons, but it remains to be fully explored how these "working memory" neurons relate to the neurons that represent the information at initial coding. Short-term memory disorders are accompanied by long-term ones for the same information. This strongly implies that the same systems of neurons are involved in both short- and long-term storage for specific kinds of information such that damage to a specific system disrupts both short- and long-term memory for the information that it represents. The pattern of deficit, however, neither confirms nor refutes the view that short-term memory processes are necessary for *triggering* long-term ones.

III. DEFICITS IN PREVIOUSLY WELL-LEARNED SEMANTIC INFORMATION

A. The Relationship between Semantic and Episodic Memory Disorders

Memory for the kinds of fact that one might encounter in an encyclopedia or a dictionary (semantic memory) is often contrasted with episodic memory, which concerns personally experienced episodes. The two kinds of memory must interact closely, however, because the kinds of information they involve greatly overlap. Thus, memory for personally experienced episodes typically includes facts as well as perceptual information, and memory for facts may include memory for public episodes with their accompanying contextual markers (a key feature of episodic memory) and perceptual features. In comparing deficits of semantic and episodic memory, much attention needs to be paid to the information involved, and the amount of rehearsal that each kind of memory has received, because although this is not a defining feature, it tends to be greater for semantic memories. Semantic memory is certainly disrupted by brain lesions, but episodic memory may often be similarly disrupted when

allowance is made for contaminating factors such as the amount of rehearsal.

Neocortical lesions, particularly to the anterolateral temporal cortex, cause impaired long-term memory for previously well-established semantic memories. These semantic memory deficits are found in dementing conditions, such as Alzheimer's disease and the variant of frontotemporal dementia known as semantic dementia, as well as following closed-head injury and herpes simplex encephalitis. Semantic dementia patients are impaired at naming, identifying, and describing the properties of objects, at defining spoken and written words, and at identifying semantic commonalities between pictures, but they show preservation of perception, non-verbal intelligence, and syntactical and phonological abilities. It is important to determine how selectively these deficits affect factual memory, how selective the dissociations between different kinds of factual memory deficits are; whether the location of cortical damage determines the specific factual memories disrupted; and whether the deficits reflect access or storage breakdowns.

There is an incomplete double dissociation between semantic dementia and organic amnesia. Semantic dementia has usually been regarded as a selective disorder of semantic memory, and amnesia has been regarded as a selective disorder of episodic memory because memory for premorbidly overlearned facts is preserved. Therefore, this dissociation has often been interpreted as evidence that memory for facts and memory for episodes are mediated by partially distinct brain mechanisms. The two memory systems clearly interact, however, although the nature of these interactions is poorly understood. Such interactions have been used to explain the incompleteness of the double dissociation between semantic dementia and organic amnesia. Thus, it is argued that semantic dementia patients typically acquire episodic memories relatively normally but do not show completely preserved episodic memory because new episodes will often involve factual information that they have forgotten (so that semantic dementia patients will not be able to make full sense of an episode). Failure to interpret new episodes in a normal semantic fashion reduces episodic memory because people show worse episodic memory when semantic encoding is minimal. Conversely, it can be argued that amnesics fail to learn new facts normally because their episodic memory impairment prevents the rapid acquisition of new fact memories although these eventually become independent of episodic memory. The implication is that facts can initially only be acquired rapidly as components of episodic memories, which are selectively impaired in global amnesia.

There is evidence that suggests that "semantic dementia" is a misnomer. This is because the disorder does not seem to be selective to semantic memory; and it also involves an episodic memory deficit that is not secondary to the semantic memory impairment. It was found that semantic dementia patients have an inverted temporal gradient of deficit in which remote autobiographical memories (formed when semantic memory was normal) were more impaired than recent ones, which were sometimes preserved. Similarly, better recognition of famous faces and recall of information about them was found if these faces were encountered during the current time period rather than earlier.

These findings suggest that whether memories are semantic or episodic may not matter. Rather, the only thing that matters may be the memories' age. Thus, in semantic dementia, new facts and episodes seem to be learned as well as remaining semantic memory permits and such information is perhaps retained normally for a while. If memory depends minimally on encoding factual information, then in the short term it may be almost normal. For example, forced-choice recognition memory for recently studied real and chimeric animal pictures is relatively normal in semantic dementia patients. This kind of memory probably depends much more on perceptual than on factual information. However, very long-term storage even of information that can be mainly encoded in terms of perceptual features is very impaired in semantic dementia, because patients have damage to the neocortical structures, responsible for very long-term retention of facts and episodes, so that over a period of years both kinds of information are lost pathologically. This interpretation is consistent with the widely held hypothesis of medial temporal lobe (MTL) amnesia, which states that binding information for fact and episode memories is initially stored in the MTL but through processes such as rehearsal there is a gradual reorganization of storage that is transferred for very long-term maintenance to neocortical structures such as the anterolateral temporal cortex.

A few cases of very severe global amnesia have been reported in which very impaired episodic memory was accompanied by some ability to acquire postmorbid vocabulary and semantic facts, although memory for these things was also very impaired. Such findings can plausibly be regarded as evidence that there is a slow neocortical learning mechanism that gradually creates a long-term memory for semantic information over

many learning trials. A disproportionate deficit for episodic memory relative to memory for postmorbidly encountered facts may arise simply because facts, but not particular episodes, are repeatedly encountered. In other words, it may be an artifact of the number of learning trials that facts and episodes typically receive. This would be true if the slow neocortical learning mechanism has the ability to slowly create memories for personally experienced episodes as well as facts. Whether different neocortical lesions can cause dissociable deficits for previously well-established semantic and episodic memories is currently unresolved. Dissociation seems likely to the extent that episodic information differs from semantic information, provided one assumes that memories are stored where they are represented and that different information is represented in different neural structures. In this assumption, semantic memories for different kinds of information are likely to be disrupted by different cortical lesions, and the same may apply to episodic memories of different kinds of episode. The different effects of cortical lesions on memory for different kinds of fact and episode may be much more striking than any general differences between semantic and episodic memory. This issue remains to be systematically explored. However, there is evidence that different cortical lesions do dissociably disrupt different subtypes of semantic memory.

B. Subtypes of Semantic Memory Disorder

There is good evidence that semantic memory for different categories of information breaks down in a dissociable manner although how such dissociations should be interpreted remains controversial. There are examples of dissociations, including ones between impairments of word and object knowledge and between knowledge of abstract and concrete words, respectively. Some semantic memory deficits can be extraordinarily specific. For example, following a stroke, one patient was found to have an impaired ability to name pictures and objects from the categories of fruits and vegetables. This patient could name other food objects and all nonfood objects without difficulty, so his difficulty with name retrieval was specific to the semantic categories of fruits and vegetables. The most explored semantic memory deficits have been those for animate category and inanimate category knowledge. Memory deficits for animate and inanimate categories of knowledge have frequently been shown to dissociate from each other. It is still disputed by some whether this dissociation reflects uncontrolled differences between the categories tested in variables such as frequency, familiarity, and age of acquisition. Nevertheless, the dissociation might be expected if animate concepts primarily involve visual perceptual properties, whereas inanimate concepts primarily involve functional properties that are less visual in nature. The evidence is conflicting that this is the case. For example, this hypothesis has difficulty explaining why some patients with animate category knowledge deficits are impaired at identifying nonvisual as well as visual features of living things. One possibility that is supported by neuroimaging work is that visual information has to be retrieved even when nonvisual information about living things is retrieved (as revealed by activation of the left fusiform cortex), whereas this is not true about nonliving things. It remains to be seen whether this neuroimaging work can be reconciled with lesion evidence that suggests that more posterior temporal cortex lesions produce deficits in memory for man-made things, whereas more anterior temporal cortex lesions disrupt memory for animate things.

C. Evidence of Storage or Access Failure

In principle, deficits in semantic memory could occur because of degradation in storage, because of a disturbance in processes that access the stored information, or because both of these problems are present. In the 1980s, Shallice proposed five criteria for deciding whether a semantic memory deficit reflects a problem with keeping fact memories in store or with accessing them. The two most plausible of these criteria involve consistency of success or failure of retrieval and the presence or absence of priming or information-specific implicit (unaware) memory. Shallice argued that consistently unsuccessful retrieval of particular items on different occasions implies that storage has been degraded, whereas retrieval should be relatively consistently successful across occasions if storage is still intact. Conversely, if information is not recognized or recalled but is associated with normal priming, then the explicit memory deficit reflects an access problem selective to aware memory. This is because the same information is still available to unaware memory through the presumably distinct access mechanisms required for retrieving memories without awareness (priming). Minimally, Shallice's argument requires that consistent failure should not be found with intact implicit memory. The criteria

currently lack a strong theoretical base, so it remains unclear whether they cover the effects of partial storage damage or even whether, for example, consistent failure might sometimes reflect access rather than storage deficits. Nevertheless, there is evidence that, in semantic dementia, when previously retrievable memories become inaccessible, they remain so consistently, so there is a reliable pattern of semantic memory breakdown that requires interpretation.

IV. ORGANIC AMNESIA AND FRONTAL LOBE DAMAGE: EPISODIC AND SEMANTIC MEMORY

A. Organic Amnesia

The most intensively studied of the organic memory disorders is the global organic amnesia syndrome, which was first characterized in the 19th century. In this syndrome, there is impaired recall and recognition of facts and episodes encountered both postmorbidly (anterograde amnesia) and (more variably) premorbidly (retrograde amnesia). These deficits often occur even when intelligence and shortterm memory are preserved. There is also preservation of overlearned semantic memories, of various forms of motor, perceptual, and cognitive skill learning and memory, and of at least some kinds of unaware memory for specific information (priming). The deficits can be produced by lesions to structures in the MTL, midline diencephalon, basal forebrain, and possibly ventromedial frontal cortex as well as to structures that link these regions, such as the fornix.

There is growing evidence that the syndrome is functionally heterogeneous. First, it has been claimed that retrograde amnesia can be produced relatively independently of anterograde amnesia. Several studies have found poor correlations in patients between severity of anterograde amnesia and deficits in more remote premorbid memory. There have also been several reports of relatively selective or focal retrograde amnesia in which patients had a severe and enduring deficit in premorbid memory but a relatively preserved ability to acquire new memories (so that old memories could be ''relearned'' to some extent). The location of lesions that cause this condition remains to be accurately resolved, but damage often includes the anterolateral temporal neocortex, particularly on the left. There have also been reports of patients with focal retrograde amnesia who had damage to their temporopolar and frontal cortices, mainly on the left. These patients showed extensive retrograde amnesia, but their new learning abilities were relatively intact. The results suggest that old memories about autobiographical and public information may be disrupted by lesions to parts of the temporal cortex. Damage to prefrontal cortex can also disturb these memories, but it is unproved that such lesions alone can disrupt premorbid memory relatively selectively. It needs to be determined more precisely which temporal (and possibly parietal) lesions disrupt remote premorbid memories and how these relate to the damage underlying semantic dementia. There is also a particular difficulty with these focal retrograde amnesia patients in proving that they are not malingering or suffering from a psychogenic deficit. In such cases, the premorbid memory deficit is not directly caused by brain damage but may reflect the patient's conscious wish to achieve financial gain or avoid something unpleasant or the patient's unconscious avoidance of something traumatic. These cases can appear very similar to those arising from brain damage.

Second, it has been argued that amnesia is heterogeneous because lesions to different MTL structures impair memory in distinct ways. It is generally agreed that amygdala damage does not usually cause anterograde amnesia, in contrast to other MTL lesions. However, the amygdala probably plays a role in emotional memory by modulating the effectiveness with which other MTL structures store memories when emotionally evocative information is encoded. This role of the amygdala would explain why events associated with marked emotional arousal are so well remembered (flashbulb memory). The effects of amygdala lesions on memory have been very little explored in humans because of the rarity of selective amygdala lesions.

Some researchers believe that lesions of either hippocampus or perirhinal cortex within the MTL disrupt memory in the same way, but that hippocampal lesions may have a lesser effect. This view implies that free recall and item recognition are equivalently disrupted after MTL lesions. In contrast, it has been argued that hippocampal and perirhinal cortex lesions cause dissociable deficits. This view is based on animal and human evidence. First, animals with perirhinal lesions have shown item recognition impairments but intact spatial memory, whereas the reverse effect has been found with hippocampal lesions. Second, meta-analysis of human recognition data has suggested that there is a single dissociation in which patients with damage to the hippocampus or other parts of Papez circuit, such as the fornix, mammillary bodies, or

anterior thalamus, are relatively unimpaired on item recognition but as impaired as more generally lesioned global amnesics (who are also impaired at item recognition) on tests of free recall.

Several patients with apparently selective hippocampal damage were found to be clearly impaired on item recognition when an extensive battery of tests was given. However, patients with selective hippocampal sclerosis related to temporal lobe epilepsy were reported not to show impaired item recognition, and other patients with probable hippocampal damage caused by hypoxia showed a similar preservation. In addition, three patients with evidence of early selective hippocampal damage were shown to have completely selective free recall deficits because their item recognition was normal on a range of tests. Similar patterns of memory performance with relatively preserved item recognition have been found in patients with selective hippocampal damage acquired in adulthood, so it is unlikely that the pattern of selective free recall deficits reflects reorganizational processes following early brain damage.

Apparently selective hippocampal damage, sometimes causes severe item recognition deficits and sometimes leaves item recognition relatively or completely intact. Animal studies have shown that cerebral ischemia often produces damage that extends beyond the hippocampus. Because such damage may be both highly variable and difficult to identify either by structural imaging or by postmortem analysis, it is likely that those patients with more severe recognition deficits have damage extending into other brain regions important for item recognition, such as the perirhinal cortex. There is even evidence that extrahippocampal damage is exacerbated by abnormal processes in the hippocampus that are triggered by ischemia. Extrahippocampal damage is probably best detected by measuring whether blood flow is abnormal in nonhippocampal brain regions so that it can be determined whether such abnormalities are more striking in patients with severe item recognition deficits. This kind of abnormality, invisible to structural magnetic resonance imaging, has been identified using positron emission tomography in patients who suffered hypoxia following heart attacks. These patients showed reduced blood flow in regions that appeared normal in structural magnetic resonance imaging (MRI). It is possible, however, that less used and more sophisticated structural MRI procedures would identify abnormalities in these regions.

Selective damage to other parts of the Papez circuit has also been found to cause little or no disruption of item recognition. Thus, relatively selective free recall deficits have been reported after fornix lesions caused by colloid cyst surgery and also following relatively selective mammillary body lesions. Lesions that affect only the anterior thalamic nucleus within the thalamus are very rare, but one patient has been described whose thalamic damage was confined to the left anterior thalamic nucleus, although she also had damage to the head of the left caudate nucleus and the left fornix. This patient had completely normal recognition for items and a free recall deficit for verbal materials.

Some animal research supports the existence of another memory system that comprises the perirhinal cortex, the dorsomedial nucleus of the thalamus to which it is reciprocally connected, and possibly the orbitofrontal cortex to which the thalamic nucleus links. The interconnections of this system with the Papez circuit system are illustratred in Fig. 1. As indicated previously, in animals, selective perirhinal cortex lesions disrupt item recognition but not some kinds of spatial memory. They also disrupt associations between similar kinds of items. Little relevant work has been done in humans mainly because selective perirhinal cortex lesions are probably nonexistent and selective dorsomedial thalamic lesions are extremely rare.

However, total bilateral destruction of the perirhinal cortex (and other regions) in humans has been reported to show more severe impairments of recognition for complex patterns at delays of a few seconds compared to those of global amnesics without perirhinal cortex lesions. Interestingly, these patients performed normally at delays of 0 and 2 sec as well as when making judgments regarding when the stimulus was still present. This could mean that perirhinal cortex lesions selectively disrupt long-term memory because they leave short-term memory and visual perception intact. This interpretation is not undisputed because it has been argued, on the basis of animal research, that perirhinal cortex lesions disrupt the ability to represent complex conjunctions of stimulus features in perception, and that memory deficits may be secondary to these high-level perceptual deficits. If this argument is correct, then amnesia that is caused by perirhinal cortex damage does not constitute a pure memory deficit. In principle, the argument can also be extended to hippocampal lesions that might be causing disruption of the ability to represent other kinds of complex conjunctions (such as those between objects and locations or between faces and voices). Such high-level perceptual deficits would secondarily cause memory impairment, and they

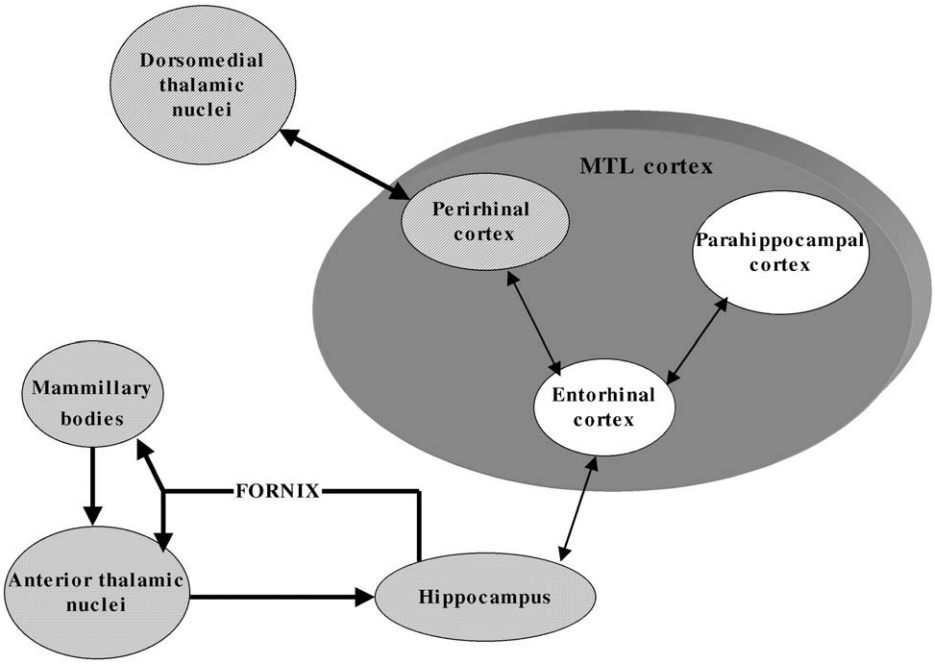

Figure 1 The connections between the structures that may constitute the two memory systems as well as interconnections between the systems and between the systems and neocortical regions. Shading with lines indicates structures that may form the perirhinal cortex–dorsomedial thalamic memory system, whereas pale gray shading indicates structures that may form part of the Papez circuit memory system. Arrows indicate that there is evidence that connections exist. Thick solid lines indicate connections that can confidently be related to the memory systems. Thin solid lines indicate connections that are known to link the two memory systems. Both systems connect to prefrontal association cortex, but it is uncertain what role this cortex plays in memory and it is also unclear whether the two memory systems interact in the prefrontal association cortex.

would be very difficult to detect because of the likelihood that affected patients would use compensatory strategies. It cannot therefore be confidently claimed that major forms of amnesia are unrelated to very specific forms of encoding failure.

The very severe long-term memory deficits that have been reported following perirhinal cortex lesions may be dependent on this damage being nearly total. Support for this possibility is provided by a subgroup of epileptic patients with selective damage that includes only part of the perirhinal cortex who show normal performance on standard tests of anterograde amnesia but accelerated forgetting over delays of weeks. By these delays, their memory is badly impaired. Partial perirhinal cortex damage may therefore cause a much less severe and much delayed item recognition deficit than does total damage to this cortex. The mnemonic effects of dorsomedial thalamic lesions may also critically depend on the extent of damage. Thus, patients with marked destruction of this nucleus show impaired item recognition as well as free recall, whereas patients with only a small portion of the nucleus damaged show little evidence of memory deficits.

Papez circuit lesions and perirhinal cortex system lesions both cause retrograde as well as anterograde amnesia. Although severe retrograde amnesia can extend back to memories acquired decades before the causative brain damage, there often appears to be a temporal gradient in which earlier acquired memories are less disrupted. Considerable evidence suggests that Papez circuit lesions cause a less severe, more steeply temporally graded retrograde amnesia than do larger lesions that involve the whole of the MTL. This would be consistent with the hypothesis that the hippocampus (and perhaps other MTL regions) only stores facts and episodes for a limited time until reorganization results in neocortical storage in the sites that presumably represent the stored information. An alternative view that challenges this claim is that there is no reorganization of the location of long-term memories as a result of processes such as rehearsal, at least for some kinds of information (such as spatial). The simplest interpretation of this view is that it should predict no temporal

gradient, although more complex interpretations are also possible that make it more difficult to distinguish between the predictions of the no change and the change views of what happens to long-term memory as it ages. Therefore, additional work is needed to determine whether memories cease to depend on the MTL as they age. Future work must also explore whether selective Papez circuit lesions minimally disrupt premorbid item recognition memory.

Exactly what processes are disrupted in patients with the amnesia syndrome? If the syndrome is heterogeneous, there must be several such processes. It is widely believed that many global amnesia patients process facts and episodes normally because their intelligence is preserved and normal kinds of information are available to them at input when memory load is minimized. As discussed previously, however, it has not been shown conclusively that subtle high-level perceptual processes may not be disrupted following MTL lesions. Evidence from transient global amnesia (TGA) indicates that it is unlikely that retrieval is impaired in global anterograde amnesia. TGA is a form of global amnesia that lasts for only a few hours and is usually caused by a reversible abnormality in the MTL, which has been revealed by showing that blood flow to the MTL (and sometimes other brain regions) is reduced during a TGA attack but usually returns to normal when tested later. Upon recovery, although all premorbid memories apart from those acquired in the few minutes or hours prior to the incident typically return, as does the ability to lay down new memories, no memories for the incident return. Because these memories do not return even when retrieval must be normal, global anterograde amnesia is probably caused by a failure to consolidate facts and episodes into long-term memory in the minutes following input.

If Papez circuit lesions do cause a selective amnesia, they will disrupt the consolidation of different kinds of information from those disrupted by perirhinal cortex lesions. The available evidence suggests that patients with selective hippocampal lesions can be relatively normal not only for recognition memory for single items (e.g., words or faces) but also for associations between the same kind of items (e.g., word–word or face–face associations). However, they are severely impaired at recognizing associations between components that would probably be processed in different cortical regions (e.g., object–location and face–voice). Similar and possibly more severe spatial memory deficits have also been reported following parahippocampal cortex lesions. The evidence is more conflicting about whether patients with selective hippocampal lesions show relatively preserved remote memory for overlearned facts. Patients are unquestionably impaired at the initial acquisition of new facts (such as vocabulary) but it remains to be shown that their impairment does not occur because their factual memory cannot be facilitated by the retrieval of associated contextual information (which involves episodic memory and is disrupted). Also, some patients may learn to compensate for their learning deficit by rehearsing factual information much more frequently than people with normal memory. Probably, hippocampal and Papez circuit lesions disrupt consolidation of both factual and episodic associations, the components of which are represented in different cortical regions.

Although lesions that include the perirhinal cortex drastically impair item recognition, little is known about the effect of selective lesions of this structure in humans. Animal studies indicate that selective damage to this cortex disrupts recognition of items and associations between similar components but not memory for some kinds of spatial information. It is uncertain in humans whether perirhinal cortex lesions disrupt memory for all the kinds of information affected by hippocampal lesions and memory for some other kinds of information as well, or whether there are some kinds of memory (such as some forms of spatial memory) that are only disrupted by hippocampal lesions.

B. The Role of the Prefrontal Cortex in Memory

Prefrontal cortex damage sometimes disrupts long-term memory for post- as well as premorbidly experienced facts and episodes. Commonly, the deficits are of free recall, with item recognition being relatively normal. The ability to remember the temporal order in which items have been presented is also often impaired, as is the ability to remember the source (who said something or whether it was encountered via TV, the radio, or newspaper) of information. Prefrontal cortex lesions have also been found to disrupt various kinds of metamemory, such as being able to predict whether one will be able to recognize information one has failed to recall when it is presented later. However, recognition deficits have also been reported in the presence of free recall that is relatively good apart from the production of a pathological level of false positives.

Such memory impairments are probably secondary to the effect of frontal cortex damage on executive processes and perhaps working memory. If sophisticated encoding processes cannot be properly

orchestrated, then memory will suffer, and the effect is likely (as is often found) to disrupt free recall, which is more dependent than item recognition on the storage of rich interitem associations. Similarly, if the organization of searching and checking operations during retrieval is disrupted, then free recall will probably be affected more than item recognition. Whether this kind of explanation accounts for the disruption of temporal and source memory in frontally damaged patients remains to be proved, but these kinds of contextual memory are likely to require considerable amounts of organization at both encoding and retrieval. Similarly, it remains to be determined whether the abnormal recognition shown by some patients with prefrontal cortex lesions is caused by the disruption of different executive processes from those affected in cases of free recall deficit or contextual memory deficit. Finally, it is believed by some that damage to the ventromedial prefrontal projections of the MTL causes a syndrome very similar, if not identical, to global amnesia.

Neuroimaging evidence indicates that the left and right prefrontal cortices are activated when verbal and difficult to verbalize information respectively are encoded into memory. This suggests that left and right prefrontal cortex lesions may respectively disrupt verbal and nonverbal memory. There is evidence that lateralized lesions do have this kind of material-specific effect, although it has been noted that laterality effects are weaker than with more posterior cortical lesions, and that verbal learning deficits are much more common after bilateral than after left prefrontal cortex lesions. Evidence for other kinds of dissociation between left and right prefrontal cortex lesions is weak. Although there may be a weak relationship between right frontal damage and retrograde amnesia for episodes, there is little evidence that right frontal cortex lesions disrupt retrieval for recently experienced episodes. However, a pathological tendency to make false alarms during recognition testing has been noted in some patients after both left- and right-sided frontal cortex damage. The manipulations that improve performance, however, are variable and include the use of a semantic orienting task at encoding and using foils that were in a different semantic category from all target items.

Long-term memory for episodes and facts involves a large network of neural structures interacting with each other. The network includes several frontal cortex regions interacting with both temporal and parietal cortices as well as subcortical structures. The precise characteristics of the memory impairments caused by lesions to specific parts of the network need further specification so as to test the functional deficit hypotheses more rigorously. Neuroimaging has provided evidence that the roles of the prefrontal and MTL cortices in memory are complementary. Thus, patients with amnesia caused by MTL lesions can show normal frontal activation patterns during encoding despite their impaired memory. If the frontal and MTL contributions to memory are complementary, then one would expect that temporal order memory deficits arise for different reasons in amnesia and following frontal cortex lesions. The impaired process is presumably different in the two cases, involving consolidation in the former and some kind of difficulty in executing effortful encoding and/or retrieval processes in the latter. It has been shown that the frontal deficit mainly occurs following intentional encoding, which indicates that the source of the problem is probably impoverished effortful encoding. If the deficit relates to poor consolidation in amnesia, amnesics should be impaired following both intentional and incidental encoding. This likely possibility remains to be tested.

V. PRIMING DEFICITS

Priming involves memory for specific information that people are typically unaware they are remembering. This kind of unaware memory is indicated by the enhanced fluency with which the remembered information is reactivated when cues that form part of the memory are encoded. Enhanced reactivation fluency of the remembered representation probably depends on storage changes at the synapses within the representing region so that the components of the memory are bound more tightly together. These changes should occur in different neocortical regions, depending not only on whether semantic or perceptual information is being implicitly remembered but also on precisely what kinds of such information are involved. Consistent with this, functional imaging has shown that whereas visual object priming produces reduced activation of visual cortex regions where the visual object information should be represented at encoding, semantic priming produces less activation in the left inferior frontal cortex where semantic information may be partially represented. This implies that perceptual and semantic kinds of priming occur in different cortical regions, although perceptual priming may not always be based in posterior cortex or semantic priming in frontal cortex regions. Lesions in these regions would be expected to disrupt the appropriate kinds of priming.

Amnesics, who do not have damage in these neocortical regions, might be expected to show preserved priming. However, if the priming involves retrieval of the kinds of association that amnesics fail to store normally, then deficits might be expected. The evidence is still incomplete. There is good evidence that amnesics show preserved priming for information that was already in memory prior to study (such as words or famous faces), but they are often impaired at priming for various kinds of information that were novel prior to study. Meta-analysis of available studies that involve priming of both novel and already familiar information reveals that although amnesic patients show completely normal priming for information that was already in memory at study, they are significantly impaired across studies at priming various kinds of novel information. One interpretation of such results is that normal people may effortfully be using explicit memory in those priming tasks at which amnesics are impaired, whereas the patients cannot do this. This interpretation, however, does not provide a principled explanation of why control subjects use or do not use explicit memory with similar priming tasks that differ merely with respect to whether studied information is novel or already familiar.

If perceptual information is processed in the posterior association cortex, then one might expect that lesions in this region will disrupt perceptual priming. This is consistent with evidence that Alzheimer patients typically show preservation of perceptual priming but impairment in more semantic kinds of priming. These patients have relative preservation of primary sensory processing regions in the posterior cortex but marked atrophy in the temporal association cortex, which together with the left frontal region plays a key role in processing semantic information. Thus, Alzheimer patients show preservation of priming for previously novel patterns but are impaired at a more semantic verbal free association priming task. There is disagreement about whether these patients are impaired at stem completion priming, which some argue may relate to this being a partially semantic priming task. A key requirement for preserved stem completion priming that may explain the inconsistent results is that patients have to explicitly process the words phonologically during study if they are to prime normally.

Alzheimer's patients are impaired not only at certain kinds of priming but also at explicit memory for facts and episodes, so they do not show evidence of impaired priming in the face of intact recognition and/or recall. However, selective impairment of perceptual priming has been shown in a patient with a right posterior neocortical lesion. This patient was impaired at certain kinds of visual repetition priming. In contrast, he was relatively normal not only at semantic priming but also at recognition of visually presented words for which visual repetition priming was impaired. A double dissociation was noted between this patient and amnesics who have disrupted recognition memory but normal visual priming of premorbidly familiar materials. A similar patient was found to be unimpaired in the familiarity component as well as in the recollection component of recognition.

Such a dissociation between perceptual priming of words and recognition of words might arise because visual word recognition usually involves familiarity as well as recollection for primarily semantic information rather than the kinds of visual information retrieved in the perceptual priming at which patients with right-sided visual cortex damage were impaired. However, it has been shown that recognition of modality and font of word presentation can also be preserved in the presence of impaired visual priming. If the perceptual information retrieved in the intact recognition and impaired priming tasks was truly matched, and the priming deficit was caused by a storage deficit, this finding would show that the perceptual fluency that underlies perceptual priming does not contribute to the familiarity component of perceptual recognition.

There has been little exploration of whether priming deficits can occur without accompanying, if subtle, processing deficits, so this remains an open issue. The priming deficits shown in the patients just described, however, are associated with some visual processing problems, so it remains possible that priming deficits are always accompanied by corresponding processing deficits. It could even be that a visual processing deficit produces the false appearance of a priming impairment, and that the memory underlying priming is preserved.

VI. DEFICITS IN OTHER KINDS OF PROCEDURAL/IMPLICIT MEMORY

Procedural memory comprises not only priming but also various forms of conditioning, various forms of skill memory, and nonassociative forms of memory such as habituation. The core feature of all these forms of memory is that remembering is not accompanied by a feeling of memory. They are probably much more functionally heterogeneous than semantic and episodic memory, but less is known about them. It is believed that they are mainly dependent on subcortical

mechanisms, but neuroimaging evidence suggests that frontal and motor cortex regions are important in the early stages of skill acquisition.

Amnesics perform normally on nonpriming kinds of procedural memory such as classical conditioning as well as skill learning and memory. For example, they show preserved delay eye blink classical conditioning. Amnesics have also been shown to acquire normally the motor skill of mirror drawing, the perceptual skill of reading mirror reversed words, and the cognitive skill of intuitively grasping the relationship between variables to achieve a target value. Furthermore, amnesic performance has been shown to be preserved in the acquisition of adaptation-level effects with weights and in the acquisition of the ability to perceive depth using random-dot stereograms. This indicates that the forebrain regions critical for episodic and semantic memory play little or no role in these forms of procedural memory.

In contrast to amnesics, patients with Huntington's disease (HD), who have neostriatal damage, have been found to show impaired acquisition and retention of skills such as reading mirror-reversed words and relatively normal performance at verbal recognition tests. Similarly, Parkinson's patients, whose substantia nigra pathology also disrupts neostriatal function, have shown impaired acquisition of cognitive skills despite being normal at some explicit memory tasks.

With respect to motor skills, and unlike amnesics, patients with HD fail to show normal adaptation-level effects with weights. This is particularly interesting because although no correlation between motor dysfunction and motor skill acquisition dysfunction has been found in these patients, there is still uncertainty about what functional deficits underlie the motor skill acquisition deficit in HD. Because the adaptation-level task is much less dependent on overt movement than motor skill acquisition, it is likely that neostriatal damage disrupts the development of motor programs vital for both normal motor skill acquisition and adaptation-level effects. The neostriatum may be particularly involved in developing motor programs for sequences of motor acts because neurodegenerative diseases affecting the neostriatum disrupt serial reaction time performance. Cerebellar atrophy disrupts performance on the serial reaction time task, which suggests that the cerebellum is also involved in developing motor programs, perhaps because it indexes the temporal order of sensorimotor events.

The involvement of the striatum in perceptual and cognitive skills is supported by several reports of deficits in the development of such skills in patients with degenerative damage in the region. However, impairments are not always found because preserved acquisition of mirror-reading skill has been found in Parkinson's disease patients. Whether cerebellar damage impairs perceptual and cognitive skill acquisition is uncertain because although deficits have been reported, there is strong evidence that patients with selective cerebellar degeneration do not show deficits in learning to read mirror-reversed text or solving the tower of Hanoi difficulty. The difficulty is that many studies have included patients with degeneration that extended beyond the cerebellum.

Cerebellar lesions have, however, have been shown convincingly to disrupt the development of delay eye blink classical conditioning while leaving explicit memory intact. However, the same patients show unimpaired autonomic or emotional conditioning. Studies with animals indicate that fear conditioning, which typically involves autonomic as well as behavioral conditioning, is disrupted both by amygdala lesions and by lesions that disrupt sensory input to the amygdala. Therefore, the neural bases of motoric and emotional classical conditioning, appear to be very different, so it needs to be shown what these two forms of conditioning share apart from the name.

Whereas delay conditioning in which the conditioned stimulus is still present when the unconditioned stimulus appears is preserved in amnesics, more complex forms of conditioning may not be. Thus, amnesics are impaired at reversal discrimination conditioning (in which a response is first conditioned to one discriminative stimulus and inhibited to the other, after which the process is reversed) perhaps because normal performance depends partly on the use of aware (explicit) memory, which is impaired in amnesics. There is conflicting evidence about whether amnesics are impaired at trace motor conditioning (in which the conditioned stimulus ends before the unconditioned stimulus appears) although a growing body of evidence suggests that patients are unpaired. This conflict probably arises because measuring conditioned responses in the trace conditioning paradigm is difficult partly because fine grained features of the response's timing may indicate whether it is an automatic conditioned response or a voluntarily produced anticipation of the unconditioned stimulus. This difficulty may also relate to the dispute about whether trace conditioning depends on explicit memory for the contingencies between conditioned and unconditioned stimuli or is automatic and independent of explicit memory, as one would expect if it is a pure form of procedural memory.

VII. CONCLUSION

Differently located brain damage disrupts memory for different kinds of information despite often having little obvious effect on the processing of the poorly remembered information. Processing may not always be unaffected (as perhaps is the case with selective priming deficits) and it is sometimes difficult to show convincingly that it is not (as with skill memory and conditioning); however, insofar as it is unaffected, the view that information is stored in the same neurons that process and represent it is challenged. At least four explanations of this apparent challenge are possible. First, the damaged region may merely modulate storage in the neural system that represents the poorly remembered information. Basal forebrain structures may play this modulatory role. Second, partial damage to the representing neural system may be sufficient to disrupt its storage abilities while having a minimal effect on its representational processing abilities. This may apply to the short-term memory disorders. Third, there may be multiple representational–storage neural systems for the same information. In other words, the same information may be represented and stored in several different neural sites. Fourth, information is not stored exactly where it is represented.

The existence of multiple memory deficits has been used as evidence to support the claim that there are different memory systems for different kinds of information, each with its own neural system that may mediate memory through the use of qualitatively distinct processes. Two comments about such memory system views are warranted. First, if memory is organized as a set of systems, then these should be arranged hierarchically. This is true of the influential taxonomy that discriminates between declarative and nondeclarative memory, where the former involves all aware forms of memory and the latter all nonaware forms. If correct, all aware forms of memory should have more in common with each other than they do with any form of nonaware memory and vice versa. This would be untrue if amnesics have impaired priming for the same novel information for which they show impaired aware memory, as the available evidence suggests, and also if they are impaired at forms of conditioning that can be shown not to depend on aware memory, as some believe to be the case. The issue is very important and currently unresolved. Either memory systems are mainly organized around whether or not they produce aware memory or the kinds of information they store is more fundamental to their organization. Resolution will involve determining the relationship between unaware and aware memory and how aware memory is produced.

Second, memory may be mediated by different brain systems, but they may work in the same way. Anatomical differences should not be regarded as equivalent to qualitative differences in processing. Although such qualitatively different memory processes may operate for memory of different kinds of information, the methods for showing this remain to be properly established. Indeed, one cannot even be sure for most organic memory disorders whether they are caused by encoding, storage, or retrieval failures. Thus, it is currently unknown whether radically different kinds of memory processing are mediated by distinct brain regions.

GLOSSARY

event-based memory system This system provides for temporary representations of incoming data concerning the present, with an emphasis on data and events that are usually personal or egocentric and that occur within specific external and internal contexts.

knowledge-based memory system This system provides for more permanent representations of previously stored information in long-term memory and can be thought of as one's general knowledge of the world.

language attribute This attribute involves memory representations of phonological, lexical, morphological, syntactical, and semantic information.

response attribute This attribute involves memory representations based on feedback from motor responses (often based on kinesthetic and vestibular cues) that occur in specific situations as well as memory representations of stimulus–response associations.

reward value (affect) attribute This attribute involves memory representations of reward value, positive or negative emotional experiences, and the associations between stimuli and rewards.

rule-based memory system This system receives information from the event-based and knowledge-based systems and integrates the information by applying rules and strategies for subsequent action.

sensory-perceptual attribute This attribute involves memory representations of a set of sensory stimuli that are organized in the form of cues as part of a specific experience.

spatial (space) attribute This attribute involves memory representations of places or relationships between places.

temporal (time) attribute This attribute involves memory representations of the duration of a stimulus and the succession or temporal order of temporally separated events or stimuli.

Memory neurobiology is defined as the organization of memory systems in terms of the kind of information to be represented, the processes associated with the operation of each system, and the neurobiological substrates including neural structures and mechanisms that subserve each system.

I. INTRODUCTION

Memory neurobiology is defined as the organization of memory systems in terms of the kind of information to be represented, the processes associated with the operation of each system, and the neurobiological substrates including neural structures and mechanisms that subserve each system. Because it is assumed that memory is highly complex and distributed across many neural systems, the overall organization of memory systems can take many forms, with different emphases on the nature of memory representation and different operations associated with processing of mnemonic information.

For example, the most widely accepted view of memory is based on the idea that memory can be divided into a declarative component based on conscious recollection of facts and events and mediated by the hippocampus and interconnected neural regions, such as the entorhinal cortex and parahippocampal and perirhinal cortex, and a nondeclarative

component based on memory without conscious access for skills, habits, priming, simple classical conditioning, and nonassociative learning mediated by a variety of brain regions, including the striatum for skills and habits, the neocortex for priming, the amygdala for simple classical conditioning of emotional responses, the cerebellum for simple classical conditioning of skeletal musculature, and reflex pathways for nonassociative learning. Others have used different terms to reflect the same type of distinction, including a hippocampal-dependent explicit memory vs a nonhippocampal-dependent implicit memory and a hippocampal-dependent declarative memory based on the representation of relationships among stimuli vs a nonhippocampal-dependent procedural memory based on the representation of a single stimulus or configuration of stimuli.

According to these models, the key difference in memory representation across different brain regions is based on conscious access to the information to be processed or stored. Support for this distinction comes from studies with human amnesic patients. For example, Korsakoff patients, with presumably diencephalic damage, and patients receiving electroconvulsive shock treatments, which presumably produce major disruptive effects in the temporal lobe, can acquire and retain (for at least 3 months) a mirror reading skill as easily as normal subjects (nondeclarative memory). However, when asked to remember the words they read in this task, they were severely impaired (declarative memory). Patient H.M. with bilateral medial temporal lobe damage, including hippocampus and amygdala, can learn and remember a set of complicated skills associated with solving the Tower of Hanoi problem, but this patient cannot recall any contextual aspect of the task or the strategies involved in solving the task. Thus, it appears that amnesic patients can acquire skills necessary for correct mirror reading performance but cannot remember the specific facts or events associated with the experiment. Further support for a problem with conscious awareness associated with declarative information is based on a patient with bilateral damage to the hippocampus who was impaired in learning which stimuli were paired with an unconditioned response but learned very readily a conditioned autonomic response to the critical visual and auditory stimuli. In contrast, a different patient with a bilateral lesion of the amygdala was impaired in learning a conditioned autonomic response to visual or auditory stimuli but learned very readily which stimuli were paired with the unconditioned response. Also, amnesic subjects with damage to the hippocampus are not impaired on a variety of tests that measure implicit memory for a number of stimulus patterns using the nondeclarative memory system, but they are impaired in explicitly remembering the same stimulus patterns using the declarative memory system. Finally, amnesic subjects can learn a complex probability classification task, but they perform poorly on multiple-choice tests that attempt to measure the training experience.

Others have suggested that memory can be divided into a short-term, working or episodic memory system defined as memory for the specific, personal and temporal context of a situation and mediated by the hippocampus and a reference or semantic memory defined as memory for rules and procedures (general knowledge) of specific situations mediated by nonhippocampal brain regions, such as the neocortex. According to these models the key difference in memory representation across different brain regions is not necessarily based on conscious access to the information to be processed or stored but rather on differential processing of short-term vs long-term memory representations.

A more comprehensive view of memory organization based on multiple processes and multiple forms of memory representation is based on the neurobiology of a multiple attribute, multiple process, tripartite system model of memory that will be presented later. The tripartite attribute model of memory is organized into event-based, knowledge-based, and rule-based memory systems. Each system is composed of the same set of multiple attributes or forms of memory, characterized by a set of process-oriented operating characteristics and mapped onto multiple neural regions and interconnected neural circuits.

II. TRIPARTITE MEMORY SYSTEM

On a psychological level, the event-based memory system provides for temporary representations of incoming data concerning the present, with an emphasis on data and events that are usually personal or egocentric and that occur within specific external and internal contexts. The emphasis is on the processing of new and current information. During initial learning, great emphasis is placed on the event-based memory system, which will continue to be of importance even after initial learning in situations in which unique or novel trial information needs to be remembered.

The knowledge-based memory system provides for more permanent representations of previously stored

information in long-term memory and can be thought of as one's general knowledge of the world. The knowledge-based memory system would tend to be of greater importance after a task has been learned given that the situation is invariant and familiar. The organization of these attributes within the knowledge-based memory system can take many forms and they are organized as a set of attribute-dependent cognitive maps and their interactions that are unique for each memory.

The rule-based memory system receives information from the event-based and knowledge-based systems and integrates the information by applying rules and strategies for subsequent action. In most situations, however, one would expect a contribution of all three systems with a varying proportion of involvement of one relative to the other.

The three memory systems are composed of the same forms, domains, or attributes of memory. Even though there could be many attributes, the most important attributes include space, time, response, sensory perception, and reward value (affect). In humans, a language attribute is also added. A spatial (space) attribute within this framework involves memory representations of places or relationships between places. It is exemplified by the ability to encode and remember spatial maps and to localize stimuli in external space. Memory representations of the spatial attribute can be further subdivided into specific spatial features, including allocentric spatial distance, egocentric spatial distance, allocentric direction, egocentric head direction, and spatial location. A temporal (time) attribute within this framework involves memory representations of the duration of a stimulus and the succession or temporal order of temporally separated events or stimuli. A response attribute within this framework involves memory representations based on feedback from motor responses (often based on kinesthetic and vestibular cues) that occur in specific situations as well as memory representations of stimulus–response associations. A reward value (affect) attribute within this framework involves memory representations of reward value, positive or negative emotional experiences, and the associations between stimuli and rewards. A sensory-perceptual attribute within this framework involves memory representations of a set of sensory stimuli that are organized in the form of cues as part of a specific experience. Each sensory modality (olfaction, auditory, vision, somatosensory, and taste) has its own memory representations and can be considered to be part of the sensory-perceptual attribute component of memory. A language attribute within this framework involves memory representations of phonological, lexical, morphological, syntactical, and semantic information. The attributes within each memory system can be organized in many different ways and are likely to interact extensively with each other even though it can be demonstrated that in many cases these attributes operate independent of each other.

Within each system attribute information is processed in different ways based on different operational characteristics. For the event-based memory system, specific processes involve (i) selective filtering or attenuation of interference of temporary memory representations of new information, labeled pattern separation; (ii) short-term memory or working memory of new information that is partly based on pattern associations; (iii) consolidation or elaborative rehearsal of new information; and (iv) retrieval of new information based on flexibility, action, and pattern completion.

For the knowledge-based memory system, specific processes include (i) selective attention and selective filtering associated with permanent memory representations of familiar information, (ii) perceptual memory and long-term memory storage based on pattern associations, and (iii) retrieval of familiar information based on flexibility and action. For the rule-based memory system, the major process includes the selection of strategies and rules for maintaining or manipulating information for subsequent action.

III. EVENT-BASED MEMORY SYSTEM

On a neurobiological level each attribute maps onto a set of neural regions and their interconnected neural circuits. For example, within the event-based memory system it has been demonstrated that in animals and humans the hippocampus supports memory for spatial and temporal attribute information, the caudate mediates memory for response attribute information, the amygdala subserves memory for reward value (affect) attribute information, and the perirhinal and extrastriate visual cortex support memory for visual object attribute information as an example of a sensory-perceptual attribute (Fig. 1).

Evidence supportive of the previously mentioned mapping of attributes onto specific brain regions is based in part on the use of paradigms that measure the short-term or working memory process based on performance within matching or nonmatching-to-

sample, delayed conditional discrimination or continuous recognition memory of single-item or lists of items tasks; the consolidation and retrieval process, based on learning and retention of a variety of behavioral tasks; and the pattern separation process based on performance within category memory or discrimination tasks.

A. Spatial (Place) Attribute

With respect to short-term or working memory, the data indicate that animals and humans with damage to the hippocampus are severely impaired in working memory for spatial information, including spatial features such as allocentric spatial distance, egocentric spatial distance, head direction, and spatial location. In contrast, rats, monkeys, or humans with damage to the hippocampus are not impaired in working memory for response, reward value (affect), or visual object attribute information. Similar patterns of results have been reported for the involvement of the hippocampus in mediating spatial but not response, reward value, or visual object information during new learning (consolidation).

In the context of the pattern separation process, it has been shown that the hippocampus responds to all sensory modalities, suggesting that a possible role for the hippocampus is to provide the opportunity for using sensory markers to demarcate a spatial location so that the hippocampus can more efficiently represent spatial information. It is thus possible that one of the main process functions of the hippocampus is to encode and separate spatial events from each other. This would ensure that new highly processed sensory information is organized within the hippocampus and enhances the possibility of remembering and temporarily storing one place as separate from another place. It is assumed that this is accomplished via pattern separation of event information so that spatial events can be separated from each other and spatial interference is reduced. This process is akin to the idea that the hippocampus is involved in orthogonalization of sensory input information, in representational differentiation, and indirectly in the utilization of relationships.

Since pattern separation paradigms are new and have been developed only recently, a more detailed description of the paradigms is presented. In this task, rats are required to remember a spatial location dependent on the distance between the study phase object and an identical object used as a foil. Specifically, during the study phase an object that covers a baited food well is randomly positioned in 1 of 15 possible spatial locations on a cheese board. Rats exit a start box and displace the object in order to receive a food reward and are then returned to the start box. On the ensuing test phase rats are allowed to choose between two objects that are identical to the study phase object. One object is baited and positioned in the previous study phase location (correct choice), and the

other (foil) is unbaited and placed in a different location (incorrect choice). Five distances (min = 15 cm; max = 105 cm) are randomly used to separate the foil from the correct object. Following the establishment of a criterion of 75% correct averaged across all separation distances, rats are given either large (dorsal and ventral) hippocampal or cortical control lesions dorsal to the dorsal hippocampus. Following recovery from surgery the rats are retested. The results indicate that whereas control rats match their presurgery performance for all spatial distances, hippocampal lesioned rats display impairments for short (15–37.5 cm) and medium (60 cm) spatial separations but perform as well as controls when the spatial separation is long (82.5–105 cm). The fact that the hippocampal lesioned group is able to perform the task well at large separations indicates that the deficits observed at the shorter separations are not the result of an inability to remember the rule. The results suggest that the hippocampus may serve to separate incoming spatial information into patterns or categories by temporarily storing one place as separate from another place. It can be shown that the ability to remember the long distances is not based on an egocentric response strategy because if the study phase is presented on one side of the cheese board and the test originates on the opposite side, the hippocampal lesioned rats still discriminate the long distances without difficulty. Furthermore, the hippocampal lesioned group has no difficulty discriminating between two short distances. It is clear that in this task it is necessary to separate one spatial location from another spatial location. Hippocampal lesioned rats cannot separate these spatial locations very well, so they can perform the task only when the spatial locations are far apart. Subsequent experiments have shown that lesions of the dorsal dentate gyrus result in the same spatial pattern separation problem, but lesions of the dorsal CA1 region do not produce an impairment, suggesting that pattern separation mechanisms might reside in the dentate gyrus. Similar deficits have been observed for new geographical information in patients with hippocampal damage due to an hypoxic episode.

Does spatial pattern separation play a role in the acquisition (consolidation) of a variety of hippocampal-dependent tasks? One example will suffice. Because rats are started in different locations in the standard water maze task, there is a great potential for interference among similar and overlapping spatial patterns. Thus, the observation that hippocampal lesioned rats are impaired in learning and subsequent consolidation of important spatial information in this task could be due to difficulty in separating spatial patterns, resulting in enhanced spatial interference. Evidence in favor of this idea comes from the observation that when fimbria–fornix lesioned rats are trained on the water maze task from only a single starting position (less spatial interference), there are very few learning deficits, whereas training from many different starting points results in learning difficulties. In a similar study it was shown that total hippocampal lesioned rats learned or consolidated rather readily that only one spatial location was correct on an eight-arm maze.

Response, reward value, and visual object pattern separation are not processed by the hippocampus but involve the caudate for response pattern separation, amygdala for reward value pattern separation, and perirhinal cortex for visual object pattern separation. With respect to associations, the hippocampus does not mediate all arbitrary associations, not even all stimulus–stimulus associations, but only associations that involve spatial or temporal information, such as object–place and odor–place associations or trace classical conditioning, but not, for example, odor–odor or odor–object associations or delayed classical conditioning.

B. Temporal (Time) Attribute

With respect to short-term or working memory, the data indicate that animals and humans with damage to the hippocampus are severely impaired in working memory for temporal information, including duration and temporal order. It has been suggested that trace conditioning requires memory for the duration of the conditioned stimulus. Thus, it is of importance to note that rabbits with hippocampal lesions and humans with hypoxia resulting in bilateral hippocampal damage are impaired in acquisition (consolidation) of trace but not delayed eye-blink conditioning.

Based on ample evidence that almost all sensory information is processed by hippocampal neurons, perhaps to provide for sensory markers for time, and that the hippocampus mediates temporal information, it is likely that one of the main process functions of the hippocampus is to encode the temporal order of events. This would ensure that newly highly processed sensory information is organized within the hippocampus and enhances the possibility of remembering and temporarily storing one event as separate from another event in time. On this basis, it has been shown

that the hippocampus is involved in temporal pattern separation for spatial, visual object, odor, or language information.

C. Language Attribute

With respect to language attribute information, it can be shown that with the use of the previously mentioned paradigms to measure short-term memory there are severe impairments for lists of words for humans with left hippocampal or bilateral hippocampal damage, suggesting that the hippocampus plays an important role in short-term memory representation of word information as an important feature of language attribute information. There is much evidence supporting the idea of lateralization of hippocampal function in humans, with the right hippocampus representing spatial information and the left hippocampus representing linguistic information. For example, patients who had left or right temporal lobectomies that included the hippocampus were tested on a task of recall for a visual location. In this task subjects made a mark on an 8-in line in order to reproduce as close as possible the exact position of the previously shown circle. Subjects with right temporal lobe lesions were impaired on this task, whereas subjects with left temporal lobe lesions were not significantly different from control subjects. In contrast, recall of a list of words resulted in an impairment for subjects with left, but not right, temporal lobe resections. Additional support for the idea that the right hippocampus mediates memory for temporal order for novel spatial information and the left hippocampus mediates temporal order for novel linguistic information comes from the demonstration that subjects with right temporal lobe lesions are impaired relative to controls for temporal order for novel spatial location information but not for the temporal order of novel linguistic information. In contrast, subjects with left temporal lobe lesions are impaired relative to control subjects for the temporal order of novel linguistic information but not the temporal order of novel spatial information. Even though hypoxic subjects or left temporal resected patients are impaired in remembering the order of presentation of words in nonmeaningful sentences requiring the processing of new event-based linguistic information, they are not impaired in remembering the order of presentation of words in syntactically or syntactically and semantically meaningful sentences requiring the processing of knowledge-based linguistic information.

D. Response Attribute

With respect to short-term or working memory, data indicate that animals and humans with damage to the caudate are severely impaired in working memory for response information, including memory representations based on feedback from motor responses (often based on kinesthetic and vestibular cues) that occur in specific situations as well as memory representations of stimulus–response associations. For rats with caudate lesions there are profound short-term memory deficits for a right or left turn response, for an egocentric distance response, for head direction, and for response-based sequential learning. For humans with caudate damage due to Huntington's disease, there are short-term memory deficits for reproducing a hand movement, remembering a list of hand motor movement responses, or learning the sequence of motor movements. Furthermore, rats, monkeys, and humans with caudate lesions have deficits in tasks such as delayed response, delayed alternation, and delayed matching to position. One salient feature of these tasks is the maintenance of spatial orientation to the baited food relative to the position of the subject's body often based on proprioceptive and vestibular feedback. These data suggest that the caudate plays an important role in short-term memory representation for the feedback from a motor response feature of response attribute information. The memory impairments following caudate lesions are specific to the response attribute because these same lesions in rats do not impair short-term memory performance for spatial location or visual object attribute information. Similar patterns of results have been reported for the involvement of the caudate in mediating response, but not spatial or reward value, information during new learning (consolidation) and response-based pattern separation. With respect to associations, the caudate mediates associations that involve the response attribute, thereby supporting primarily stimulus–response-type associations.

E. Reward Value (Affect) Attribute

With respect to short-term or working memory, data indicate that animals and humans with damage to the

amygdala are severely impaired in working memory for affect information including reward value (affect) associated with magnitude of reinforcement or for a liking response based on the mere exposure of a novel stimulus. The memory impairments following amygdala lesions are specific to the affect attribute because these same lesions in rats do not impair short-term memory performance for spatial location, visual object, or response attribute information. Similar results have been reported for the involvement of the amygdala in mediating affect, but not spatial, response or visual object information during new learning (consolidation) and to some extent reward-based pattern separation. With respect to associations, the amygdala mediates associations that involve the reward attribute, thereby supporting primarily stimulus–reward-type associations.

F. Sensory-Perceptual Attribute

With respect to sensory-perceptual attribute information, I concentrate on visual object information as an exemplar of memory representation of this attribute. In the context of short-term or working memory, data indicate that animals and humans with damage to the extrastriate or perirhinal cortex are severely impaired in working memory for visual object information. The memory impairments following perirhinal cortex lesions are specific to the visual object attribute because these same lesions in rats do not impair short-term memory performance for spatial location attribute information. Similar patterns of results have been reported for the involvement of the perirhinal cortex in mediating visual object information during new learning (consolidation) and visual object-based pattern separation. With respect to associations, the perirhinal cortex mediates associations that involve visual object information, thereby supporting primarily visual–visual-type associations.

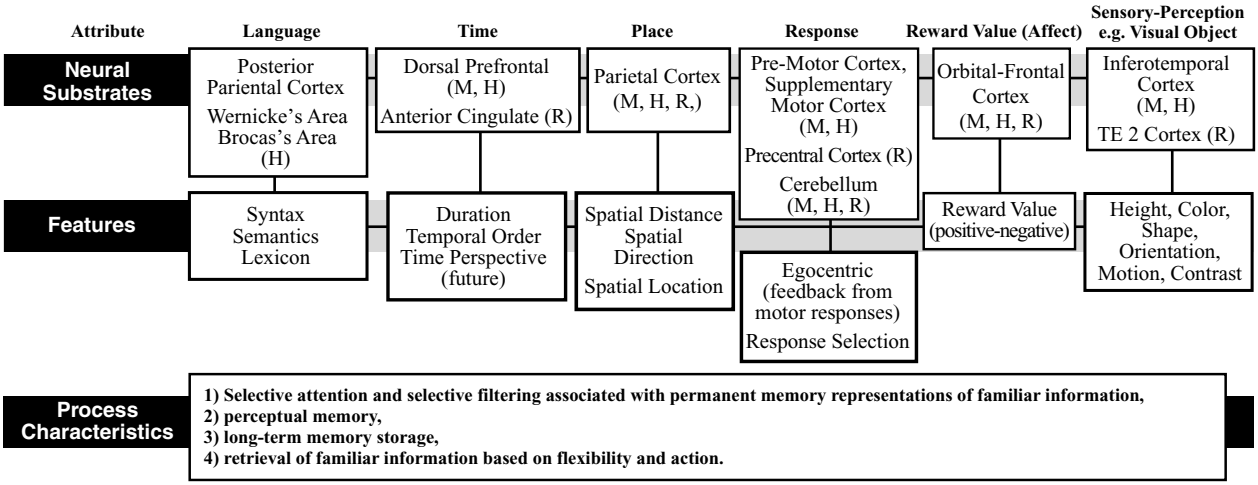
Thus, it appears that the neural systems that support different attributes within the event-based memory system can be dissociated from each other, suggesting that they can operate independent of each other. However, it is clear that many interactions can occur between the proposed brain regions (e.g., between hippocampus and amygdala, between hippocampus and perirhinal cortex, or between hippocampus and caudate nucleus). Furthermore, there are interactions that are based on convergence onto other brain regions (e.g., hippocampus and amygdala projections to the same neurons in the nucleus accumbens). Each neural system subserves a different attribute but engages the same set of processes and is therefore part of the same event-based memory system.

The event-based memory system is more akin to episodic memory; however, it also maps to some extent onto declarative memory, but without the emphasis on the need to use conscious processing and the need to require only the operation of the medial temporal cortex. Instead, the attribute model suggests that there are additional brain circuits that mediate multiple attributes or forms of memory and specifies to a much greater extent the operation of specific multiple processes. Finally, this event-based memory system incorporates rather well White's three- system model that includes the hippocampus for stimulus–stimulus associations, the caudate for stimulus–response associations, and the amygdala for stimulus–reward associations.

IV. KNOWLEDGE-BASED MEMORY SYSTEM

Within the knowledge-based memory system, it has been demonstrated that in animals and humans (i) the posterior parietal cortex supports memory for spatial attributes; (ii) the dorsal and dorsolateral prefrontal cortex and/or anterior cingulate support memory for temporal attributes; (iii) the premotor, supplementary motor, and cerebellum in monkeys and humans and precentral cortex and cerebellum in rats support memory for response attributes; (iv) the orbital prefrontal cortex supports memory for reward value (affect) attributes; and (v) the inferotemporal cortex in monkeys and humans and TE2 cortex in rats subserve memory for sensory-perceptual attributes (e.g., visual objects) (Fig. 2).

Evidence supportive of the previously mentioned mapping of attributes onto specific brain regions is based in part on the use of paradigms that measure the perceptual memory process based on performance within a repetition priming or a discrimination performance paradigm, the attention process by measuring performance within selective attention and stimulus-binding tasks, and the long-term storage and retrieval process by measuring learning and retention in a variety of behavioral tasks. Due to of space constraints, I discuss only the role of the parietal cortex in processing spatial information and that of the inferotemporal cortex in processing visual object information.



Key: M=Monkeys, **H**=Humans, **R**=Rats

Figure 2 Representation of the neural substrates, features, and process characteristics associated with the knowledge-based memory system for the language, time, place, response, reward value (affect), and sensory-perception attributes.

A. Spatial (Place) Attribute

Monkeys with lesions of the parietal cortex show deficits in place reversal, landmark reversal, distance discrimination, bent-wire route finding, pattern string finding, and maze-learning tasks. Similarly, rats with parietal cortex lesions cannot perform well in mazes. Furthermore, rats with parietal cortex lesions display deficits in both the acquisition and retention of spatial navigation tasks that are presumed to measure the operation of a spatial cognitive map within a complex environment. They also display deficits in the acquisition and retention of spatial recognition memory for a list of five spatial locations. In a complex discrimination task in which rats have to detect the change in location of an object in a scene, rats with parietal cortex lesions are profoundly impaired, but on less complex tasks involving the discrimination or short-term memory for single spatial features including spatial location and allocentric and egocentric spatial distance, there are no impairments. Similarly, there are no impairments in discriminating between visual objects in terms of either new learning or performance of a previously learned visual discrimination. When the task is more complex, involving the association of objects and places (components of a spatial cognitive map), parietal cortex plays an important role. Support for this comes from the finding that rats with parietal lesions are impaired in the acquisition and retention of a spatial location plus object discrimination (paired associate task) but show no deficits for only spatial or object discriminations.

Humans with parietal cortex lesions have difficulty in drawing maps or diagrams of familiar spatial locations. They also have problems in using information to guide them in novel or familiar routes, to discriminate near from far objects, and to solve complex mazes. There is also spatial neglect and deficits in spatial attention. There is a general loss of "topographic sense," which may involve loss of long-term geographical knowledge as well as an inability to form cognitive maps of new environments. Using positron emission tomography (PET) scan and functional magnetic resonance imaging (fMRI) data, it can be shown that complex spatial information results in activation of the parietal cortex. Thus, memory for complex spatial information appears to be processed by the parietal cortex.

The parietal cortex is probably not the only neural region that mediates long-term memory for spatial information. For example, topographical amnesia has also been reported for patients with parahippocampal lesions and spatial navigation deficits have been found following retrosplenial and entorhinal cortex lesions. Thus, other neural regions (e.g., parahippocampal cortex, entorhinal cortex, and retrosplenial cortex) may also contribute to the long-term representation of a spatial cognitive map.

B. Sensory-Perceptual Attribute

With respect to sensory-perceptual attribute information, it can be shown that lesions of the inferotemporal cortex in monkeys and humans and temporal cortex (TE2) in rats result in visual object discrimination problems, suggesting that the inferotemporal or TE2 may play an important role in mediating long-term representations of visual object information. Additional support comes from PET scan and fMRI data in humans, in whom it can be shown that visual object information results in activation of inferotemporal cortex. In a different study, it was shown that neurons within the inferotemporal cortex responded more readily after training to a complex visual stimulus that had been paired with another complex visual stimulus across a delay, suggesting the formation of long-term representations of object–object pairs within the inferotemporal cortex. Finally, it has been shown in rats that based on a repetition priming paradigm, perceptual memory for spatial location information is mediated by the parietal cortex but not the TE2 cortex, whereas perceptual memory for visual object information is mediated by TE2 cortex but not the parietal cortex, suggesting support for independent mediation of spatial location and visual object attribute information within the knowledge-based memory system.

V. INDEPENDENCE OF THE EVENT-BASED AND KNOWLEDGE-BASED MEMORY SYSTEMS

Even though the two systems are supported by neural substrates and different operating characteristics, suggesting that the systems can operate independent of each other, there are also important interactions between the two systems, especially during the consolidation of new information and retrieval of previously stored information. It is thus likely to be very difficult to separate the contribution of each system in new learning tasks since each system supports one component of the consolidation process. However, there are a few examples based on tasks in which the major consolidation processes have already taken place. Olton and Papas ran animals in a 17-arm maze with food available in 8 arms and no food available in 9 arms. In order to solve this maze, an animal should not enter unbaited arms, activating knowledge-based memory, but should enter baited arms only once utilizing event-based memory. After learning the task to criterion performance, animals were given fimbria–fornix lesions. The lesioned animals had a deficit only for the event-based memory memory component of the task. In a different study, it was shown that in an 8-arm maze parietal cortex lesions placed in rats after training on 4 unbaited and 4 baited arms resulted in a deficit in the knowledge-based but not event-based memory. If one assumes that the presentation of unbaited arms reflects the operation of the knowledge-based memory system and that the presentation of baited arms reflects the operation of the event-based memory system, then it appears that lesions of the hippocampus disrupt only the event-based memory system, whereas lesions of the parietal cortex only disrupt the knowledge-based memory system. Similarly, in humans there is evidence that patients with hippocampal damage do not have difficulty remembering knowledge-based information, whereas they have difficulty remembering event-based information. For example, hypoxic subjects or left temporal resected patients are impaired in remembering the order of presentation of words in nonmeaningful sentences requiring the processing of new event-based linguistic information, but they are not impaired in remembering the order of presentation of words in syntactically or syntactically and semantically meaningful sentences requiring the processing of knowledge-based linguistic information.

In a different series of studies a double dissociation between perceptual memory (a measure reflective of the operation of the knowledge-based memory system) and short-term memory (a measure reflective of the operation of the event-based memory system) was reported in human subjects. It was shown that patients with a right occipital cortical lesion displayed impaired performance for perceptual memory tests of visual priming for words but intact performance on short-term tests of recognition and cued recall of words. In contrast, the reverse pattern was present for amnesic subjects with hippocampal damage. Furthermore, for patients with parietal lesions resulting in spatial neglect, there was a deficit in spatial repetition priming (perceptual memory) without a loss in short-term or working memory for spatial information. In a different study, it was shown that, like humans with parietal cortex lesions, rats with such lesions are impaired in a spatial repetition priming (perceptual memory) experiment but perform without difficulty in a short-term or working spatial memory experiment, suggesting that the parietal cortex plays a role in spatial perceptual memory within the knowledge-based memory system but does not play a role in spatial memory within the event-based memory system.

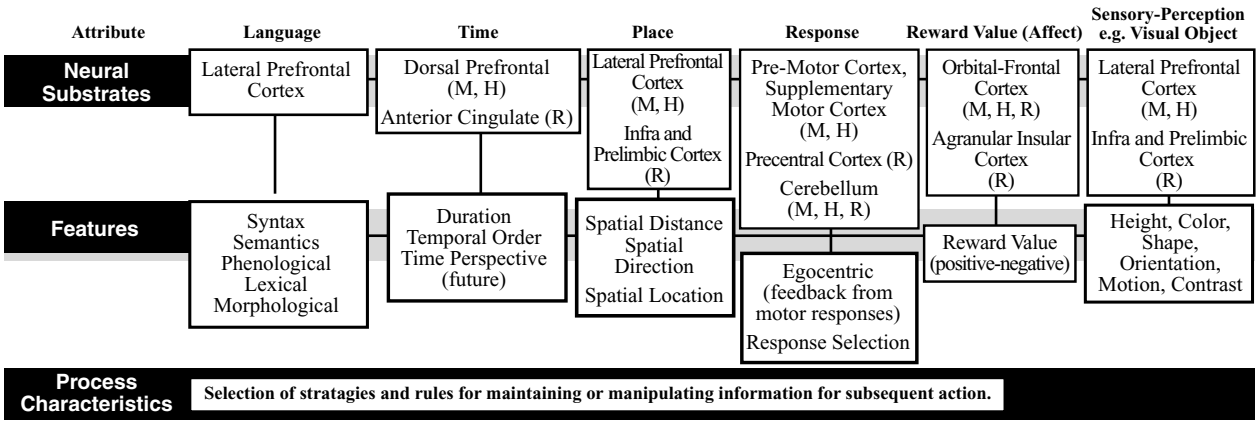
In a different set of studies it was shown that patients with temporal lobe lesions that did not involve hippocampus or perirhinal cortex had difficulty in naming familiar objects (semantic dementia) but had no difficulty in recognizing the same familiar objects, whereas amnesic subjects with hippocampal damage had no difficulty in naming objects, but were impaired in recognizing those objects. If one assumes that naming is a process that is supported by long-term memory and thus a characteristic of the knowledge-based memory system, then these data provide further support for a dissociation between the knowledge-based and event-based memory systems.

The knowledge-based memory system is akin to semantic and reference memory, but it also maps to some extent onto nondeclarative memory but without the emphasis on the need to use unconscious processing and the need to require only the operation of the medial temporal cortex. The nondeclarative memory system has a large memory representation, and compared to the tripartite attribute model it includes the knowledge-based and rule-based memory systems as well as some components of the event-based memory system. It is therefore very difficult to characterize the operations that are necessary for efficient functioning of the nondeclarative system. Instead, the tripartite attribute model suggests that for the knowledge-based memory system there are specific brain circuits that support a set of processes that differ from the brain circuits that support a different set of processes within the event-based memory system. Furthermore, it appears that the knowledge-based memory system and the event-based memory system can operate independent of each other and that information can be processed by distinct neural regions, even though there are also important interactions between the two systems, especially during the consolidation of new information and retrieval of previously stored information.

VI. RULE-BASED MEMORY SYSTEM

Within the rule-based memory system it can be shown that different subdivisions of the prefrontal cortex support different attributes. For example, the dorsolateral and ventrolateral prefrontal cortex in monkeys and humans and the infralimbic and prelimbic cortex in rats support spatial, visual object, and language attributes; the premotor and supplementary motor cortex in monkeys and humans and precentral cortex in rats support response attributes; the dorsal, dorsolateral, and mid-dorsolateral prefrontal cortex in monkeys and humans and anterior cingulate in rats mediate primarily temporal attributes; and the orbital prefrontal cortex in monkeys and humans and agranular insular cortex in rats support affect attributes. (Fig. 3).

Evidence supportive of the previously mentioned mapping of attributes onto specific brain regions is based in part on the use of paradigms that measure the use of rules within short-term or working memory based on performance within matching- or nonmatching-to-sample, delayed conditional discrimination or continuous recognition memory of single-item or lists



Key: **M**=Monkeys, **H**=Humans, **R**=Rats

Figure 3 Representation of the neural substrates, features, and process characteristics associated with the rule-based memory system for the language, time, place, response, reward value (affect), and sensory-perception attributes.

of items tasks, temporal ordering of information, and sequential learning. It is also based on paradigms that measure the use of rules in cross-modal switching, reversal learning, paired-associate, and problem-solving tasks. Here, I concentrate only on the data reported in the context of short-term memory or working memory.

A. Spatial (Place) and Sensory-Perceptual Attributes

The dorsolateral and ventrolateral prefrontal cortex in monkeys and humans and infralimbic and prelimbic cortex are involved whenever there are rules associated with working memory for spatial and visual object attribute information. Evidence for this idea comes from the finding that rats with lesions of the infralimbic and prelimbic cortex disrupt working memory for spatial information and working memory for object information. In monkeys lesions of the dorsolateral and ventrolateral regions disrupt performance on delayed response, delayed alternation, delayed occulomotor, spatial search, and visual object recognition tasks. Furthermore, in monkeys, for working memory there are delay-specific cells in the dorsolateral and ventrolateral prefrontal cortex in spatial tasks, such as delayed response, delayed alternation, and delayed occulomotor tasks, and in visual object delay tasks. In humans, based on a meta-analysis of multiple studies using neuroimaging techniques, both the dorsolateral and the ventrolateral cortex are activated during object and place working memory tasks. Thus, the data indicate that the infralimbic and prelimbic cortex in rats and dorsolateral and ventrolateral cortex in monkeys and humans play a very important role in processing visual object and spatial attribute information, suggesting a possible contribution of this region in supporting the use of working memory rules associated with object and spatial attributes. The working memory impairments following infra- and prelimbic lesions are specific to the object and place attributes because these same lesions in rats do not impair working memory performance for response or affect attribute information.

B. Temporal (Time) Attribute

The dorsal prefrontal cortex, dorsolateral prefrontal cortex, and mid-dorsolateral prefrontal cortex in monkeys and humans and anterior cingulate cortex in rats are involved whenever there are rules associated with working memory for temporal attribute information. Evidence for this idea comes from the finding that in rats, monkeys, and humans, following lesions of this region, there are deficits in working memory for temporal order information and memory for frequency information. Furthermore, using fMRI, it was shown that the dorsolateral prefrontal cortex is activated in a memory for a temporal order task. All the previously mentioned results suggest that this region plays an important role processing temporal attribute information. The working memory impairments following anterior cingulate cortex lesions in rats are specific to the temporal attribute because these lesions do not impair working memory performance for spatial, visual object, or affect attribute information.

C. Response Attribute

The premotor and supplementary motor cortex in monkeys and humans and precentral motor cortex in the rat are involved whenever there are rules associated with the processing of response attribute information. Support for this idea comes from the observation that lesions of the precentral cortex in the rat disrupt rules associated with processing of response information such as working memory for a motor (right–left turn) response. Also, in humans prefrontal cortex lesions result in a deficit for memory for a motor movement and memory for a list of motor movements, supporting a role for this region in processing response attribute information.

D. Reward Value (Affect) Attribute

The orbitofrontal cortex in monkeys and humans and agranular insular prefrontal cortex in the rat are involved whenever there are rules associated with working memory for affect attribute information, especially based on odors and tastes. Evidence for this idea comes from the findings that in both animals and humans, following lesions of this region there are deficits in working memory for taste or odor (affect attribute) information. The working memory impairments following the agranular insular prefrontal cortex lesions are specific to the affect attribute because these same lesions in rats do not impair

working memory performance for spatial attribute information.

E. Language Attribute

The lateral prefrontal cortex in humans is involved whenever there are rules associated with working memory for language attribute information. This is based on evidence demonstrating activation of the lateral prefrontal cortex in verbal learning tasks and impairments in working memory for verbal information in patients with lateral prefrontal cortex lesions.

Various subregions within the prefrontal cortex also play a role in the use of rules associated with other tasks besides working memory, such as tasks that measure the use of rules in cross-modal switching, reversal learning, paired associate, and problem solving.

It is assumed that there are important interactions between the rule-based and event-based memory systems across specific attributes. In support of this assumption, it was shown based on a disconnection experiment that there are interactions between prefrontal cortex and perirhinal cortex but not between perirhinal cortex and amygdala or hippocampus in supporting short-term memory for visual object attribute information. It should be noted that the role for the prefrontal cortex is not specified in the declarative–nondeclarative model.

VII. INTEGRATION

The overall tripartite attribute model of memory is shown in Fig. 4. Different forms of memory and its neurobiological underpinnings are represented in terms of the nature, structure, or content of information representation as a set of different attributes, including language, time, place, response, reward value (affect), and visual object as an example of sensory perception. For each attribute, information is processed in the event-based memory system through operations that involve pattern separation or orthogonalization of specific attribute information, short-term memory processing, encoding of specific pattern associations into long-term memory, and retrieval of stored information via flexibility and pattern completion. In addition, for each attribute, information is processed in the knowledge-based system through operations of long-term storage, selective attention, perceptual memory, and retrieval of pattern associations. Finally, for each attribute, information is processed in the rule-based memory system through the integration of information from the event-based and knowledge-based memory systems for the selection of strategies and rules for maintaining or

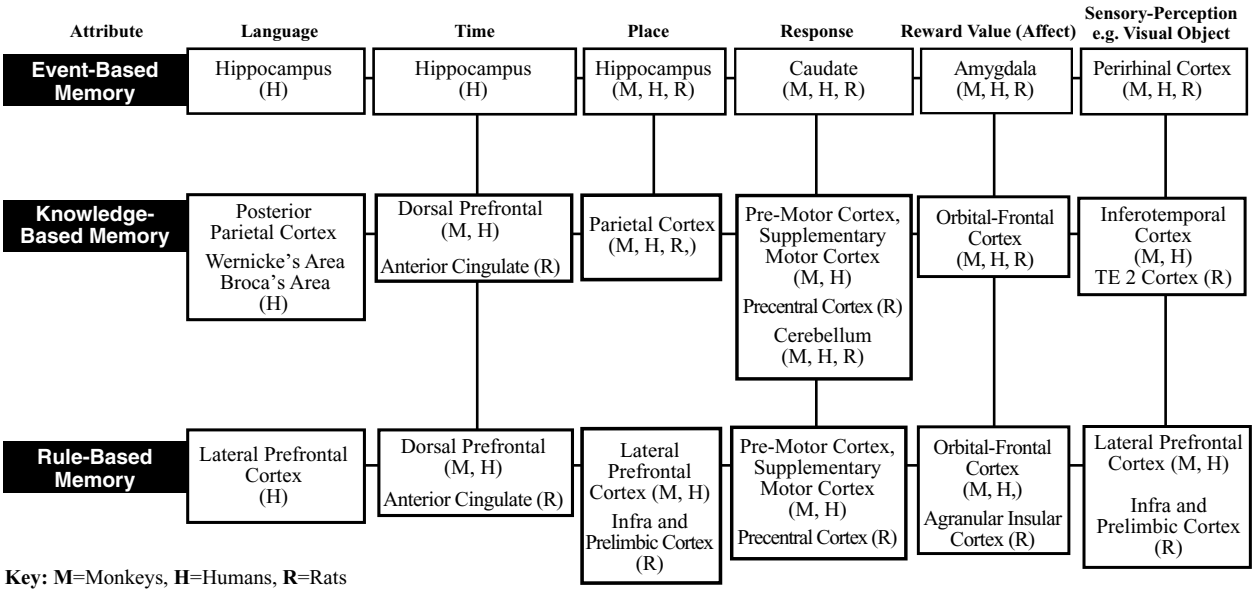


Figure 4 Representation of the neural substrates associated with the event-based, knowledge-based, and rule-based memory systems for the language, time, place, response, reward value (affect), and sensory-perception attributes.

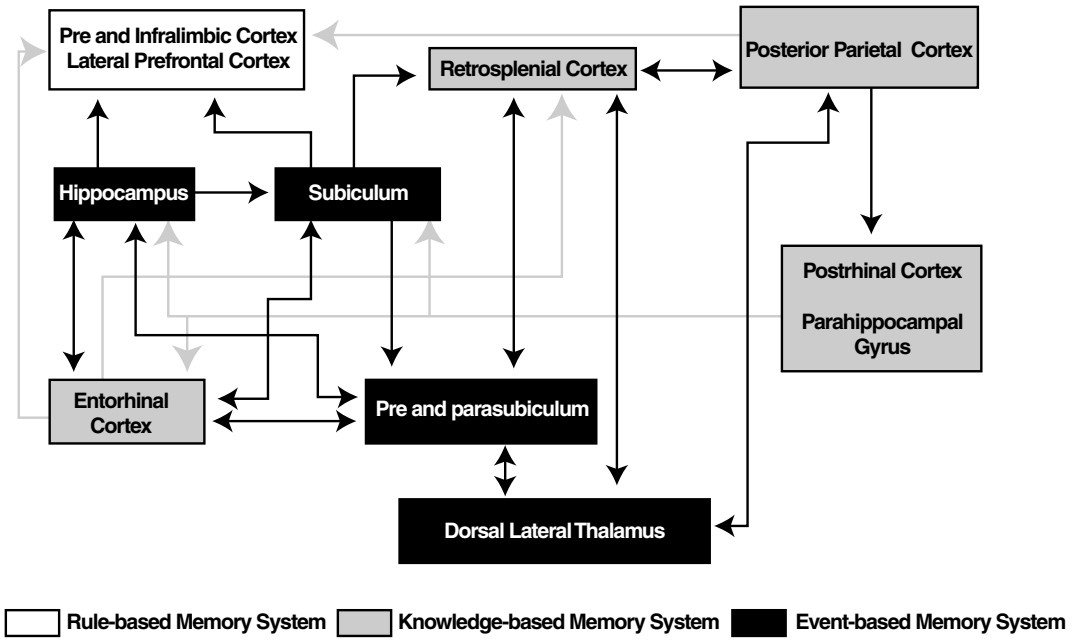

Figure 5 Representation of the spatial attribute neural circuit incorporating neural regions that mediate rule-based, knowledge-based, and event-based memory.

manipulating information for subsequent action. The neural systems that subserve specific attributes within a system can operate independent of each other, even though there are also many possibilities for interactions among the attributes. Although the event-based and knowledge-based memory systems are supported by neural substrates and different operating characteristics, suggesting that the two systems can operate independent of each other, there are also important interactions between the two systems, especially during the consolidation of new information and retrieval of previously stored information. Finally, because it is assumed that the rule-based system is influenced by the integration of event-based and knowledge-based memory information, there should be important interactions between the event-based and knowledge-based memory systems and the rule-based memory system. Thus, for each attribute there is a neural circuit that encompasses all three memory systems in representing specific attribute information. Space only allows for the presentation of one neural circuit as an example. Figure 5 depicts the neural substrates and their interconnections associated with the spatial (place) attribute across all three memory systems. Note that the dorsal lateral thalamus, pre- and parasubiculum, hippocampus, and subiculum represent neural substrates that support the event-based memory system; the entorhinal cortex, parahippocampal gyrus or postrhinal cortex, posterior parietal cortex, and retrosplenial cortex support the knowledge-based memory system; and the lateral prefrontal cortex or pre- and infralimbic cortex support the rule-based memory system. This circuit provides anatomical support for a possible independence in the operation of the hippocampus as part of the event-based memory system and posterior parietal cortex as part of the knowledge-based memory system in that spatial information that is processed via the dorsal lateral thalamus can activate both the hippocampus and the posterior parietal cortex in parallel. Also, information can reach the lateral prefrontal cortex or pre- and infralimbic cortex as part of the rule-based memory system via direct connections from the posterior parietal cortex as part of the knowledge-based memory system and hippocampus as part of the event-based memory system. Finally, spatial information can interact with other specific attributes via a series of direct connections, including an interaction with reward value attribute information via hippocampal–amygdala connections or lateral prefrontal cortex–orbital frontal cortex connections or an interaction with response attribute information via hippocampal–caudate or lateral prefrontal–premotor or supplementary motor connections. In general, the tripartite attribute memory model represents the most comprehensive memory model capable of integrating the

extant knowledge concerning the neural system representation of memory.

Memory, Explicit and Implicit

KATHLEEN B. MCDERMOTT
Washington University, St. Louis

GLOSSARY

explicit memory Intentional retrieval of the past as manifested on a test in which people are asked to recollect the past. Explicit memory is what laypeople typically mean by the term memory.

implicit memory The change in performance as a result of prior experience in the absence of intention to remember the prior event. Implicit memory is often facilitative, although it can cause interference.

generation effect The finding that requiring people to generate information (e.g., from a conceptual clue, "hot–c____") leads to a higher likelihood of remembering the generated information (e.g., "cold") on a later explicit memory test than if the to-be-remembered item is simply presented to the person (e.g., they read the word "cold" or read "hot-cold").

level-of-processing effect The finding that on most explicit memory tests, events encoded with respect to their meaning are more likely to be retrieved at a later time than those processed only to a superficial level (e.g., in terms of visual features or sound).

picture superiority effect The finding that on most explicit memory tests, items previously presented as pictures are better remembered than those previously presented as words.

priming Change in performance on a current task caused by recent prior experience in the absence of intent to use that experience on the current task. This is the measure of memory on most laboratory-based implicit memory tests.

recall A type of memory test in which the subject must produce the previously encountered items, either from minimal cues (as in free recall: "Write down as many words as you can remember seeing in the previous study list") or in response to a cue (as in cued recall: "Tell me the word previously paired with "hot").

recognition A type of memory test in which the to-be-remembered items are presented to the subject, whose task is to decide whether he or she remembers having encountered the item previously (free choice recognition) or to decide which of several items he or she remembers having encountered (forced choice recognition).

Memory researchers typically discuss memory as being a three-stage process: encoding (or the acquisition of information), storage (or the retention of information over time), and retrieval (or accessing information previously encoded). Explicit and implicit memory refer to different ways that past events can be retrieved. Specifically, one can intentionally try to retrieve the past. This is what is commonly referred to as "memory" or memory retrieval and is what experimental psychologists call explicit memory. We "search our brains" for information previously encountered. For example, remembering where you parked your car, remembering your first day of school, and remembering the last time you ate at your favorite restaurant are all examples of explicit memory. Implicit memory, in contrast, refers to the unintentional manifestation of previous experience on a current task. Psychologists generally do not use the term "remembering" when discussing implicit memory; instead, they refer to "priming." If you recently heard an unusual word such as "perspicacious," you are more likely to use that word in conversation than you otherwise would be; You are "primed" to use the word. This is an everyday example of implicit memory. As will be seen, both explicit and implicit memory are typically studied by psychologists through controlled laboratory experiments in which people are given sets of materials (e.g., pictures or words) to remember, and retention of this information is assessed by one or more types of memory test.

I. EXPLICIT MEMORY

A. Definition

Explicit memory can be thought of as intentional retrieval. That is, explicit memory is the willful process of thinking back in time for the purpose of retrieving previously encountered events. It is also sometimes referred to as *episodic memory* because explicit memory involves memory for prior episodes in one's life (as opposed to memory for general knowledge of the world, e.g., who served as the first U.S. president, which is called *semantic memory*). In psychology experiments, explicit memory is usually defined operationally in terms of test instructions. That is, if participants are asked to retrieve a previous event, then the experiment is one that taps explicit memory.

B. Measures

Explicit memory is usually measured with tests of recognition or recall. *Recognition* refers to the case in which the memory test gives an answer and the person must decide whether or not it is correct (called *free choice recognition* or yes/no recognition) or choose from among possible alternatives (*forced choice recognition*). For example, imagine that subjects in an experiment were given a list of 100 words to remember. They might then receive a free choice recognition test in which 50 of these words are presented, mixed with 50 new words (the ratio need not be 50 : 50). The job of the participant is to determine for each word whether it had been presented in the study phase. Thus, they give a yes or no answer to each word. This test is similar to true/false tests often given in school. An alternative test would be forced choice recognition, in which people would be given a set of words, with each set containing at least 1 studied word and at least 1 nonstudied word. The subject's task would be to decide which of the words had been studied. This approach is analogous to what are called multiple-choice tests in educational settings.

Recall differs from recognition in that the answer is not presented to the person. There are several types of recall as well. In *free recall* and *serial recall*, no cues are given; people are simply told to think back to the study phase (in our example here, the word list) and write down (or say) everything they remember. Free recall differs from serial recall in that order of recall does not matter in free recall; in serial recall, however, people are instructed to produce the studied items in the same order in which they were previously experienced. On a *cued recall* test, subjects are given cues to help them remember the list. For example, if the studied list contained the words "zebra," "lion," and "dog," they might be given the cue "animals" to help guide their recall. Perhaps they would be given the first few letters of the words (e.g., "ze___") to help them remember items in the list.

C. Typical Patterns of Results

As discussed previously, researchers generally conceptualize memory as having three stages (encoding, storage, and retrieval). The types of strategies that people use during the encoding (or acquisition) stage have a profound effect on what is remembered at a later time. Considered here are just a few of the classic variables shown to strongly affect performance on a later memory test.

1. Level of Processing

The *level-of-processing effect* is one of the most robust and well-known findings in the explicit memory literature. In two seminal papers on this topic in the mid-1970s, Fergus Craik, Robert Lockhart, and Endel Tulving showed that if people are encouraged to think about the meaning of words (from a list of words to be remembered later), they later recall and recognize those words with a higher probability than if they are encouraged to think about the sound (or phonology). For example, for the word "lizard", people could be asked "Is it an animal?" or "Does it rhyme with wizard?" The former question would lead to a higher probability of recall and recognition on average, across many words in the study list. Similarly, people remember words encoded with attention to sound better than words that are processed at a more superficial level (e.g., determining whether the word is in uppercase letters). This phenomenon is called *level of processing* because it was proposed that people must go through the more "shallow" levels (e.g., the letter level) to access the "deeper" levels (e.g., meaning-based processing). The level-of-processing effect is a very robust phenomenon; one of the primary principles of memory is that if one wants to remember something later, he or she will do well to think hard about its meaning and importance at the time of encoding.

2. The Generation Effect

The *generation effect* is similar to the level-of-processing effect in that it shows that the more meaningfully and effortfully items or events are processed, the better they will later be remembered on explicit memory tests (both recall and recognition). The way the effect is typically studied in the laboratory was popularized by Norman Slamecka and Peter Graf in the 1970s. People are either given antonyms to read (e.g., "hot–cold") or given the first word and asked to generate its antonym (e.g., "hot —"). Later, on recall and recognition tests, people remember "cold" better if they previously had to generate it themselves than if they simply read it. Consider the way children use flash cards to learn vocabulary words or the periodic table of the elements. Flash card techniques take advantage of the generation effect in that the information is generated by the user before looking at the answer. For example, the flash card user might see "mercury" on a card and try to generate its symbol (Hg) before checking the answer on the back of the card. Research has shown that even instances in which the generation attempt fails (e.g., the flash card user cannot successfully remember the item on the other side of the card), the generation effect occurs: Memory for the to-be-generated information can be facilitated relative to the condition of simply reading the information.

3. The Picture Superiority Effect

The *picture superiority effect* refers to the finding (made widely known through experiments by Allan Paivio in the late 1960s) that pictures are remembered better than words. This pattern occurs regardless of the type of explicit test—recall or recognition; it even occurs when the recognition test contains words (referring to pictures or words previously encoded). The source of this effect is thought to be that pictures access meaning more fully than words (and therefore are processed more "deeply" in level-of-processing terms); furthermore, pictures can often be accompanied by a verbal label. For example, if a picture of a fish is shown, people can easily think "fish" or "trout" to themselves when looking at the picture. Thus, pictures tend to access two types of codes (pictorial and verbal), whereas words tend to access only a single type of code (verbal). Of course, people could also form a mental image of a fish when given the word, in which case they would access both types of codes; indeed, when they do so, words are better remembered than when no imagery is invoked.

D. Neural Correlates

What parts of the brain contribute to our ability to remember the past? There are two primary ways of answering this question. The first and traditional way is to use unfortunate accidents of nature—naturally occurring brain lesions—to determine what cognitive processes break down when certain parts of the brain are injured due to stroke, accidents, or other insults to the brain. William Scoville and Brenda Milner described the memory impairments of a man known by his initials, H.M., who had his temporal lobes (including most of the hippocampi) surgically removed in the early 1950s in an attempt to cure intractable epilepsy (Fig. 1). The result was a profound loss of ability to remember anything that happened since the surgery (*anterograde amnesia*). However, H.M. was able to remember most things that occurred before the surgery and was able to converse somewhat normally. This pattern of results and similar outcomes exhibited by other patients with temporal lobe damage suggests that the temporal lobes (in or around the hippocampus) are necessary for the formation of new explicit memories. Interestingly, as will be discussed later, amnesic patients such as H.M. exhibit intact implicit memory (Fig. 2). The point to be taken from this study and other similar studies is that the medial temporal lobes play an important function in remembering the past; when they are removed or damaged, new explicit memories cannot be formed. One difficulty, however, lies in determining which stage(s) of the memory process (encoding, storage, or retrieval) this structure exhibits its effect. Does the information not enter the amnesic's brain properly? Is it encoded properly, with a breakdown in the storage or retrieval phase? Is it coded in one type of memory system (implicit) but not the other type (explicit)?

Recently, a new set of techniques has been developed that allows one to address these and similar questions. Specifically, *neuroimaging techniques* [e.g., *event-related potentials* (ERPs), *functional magnetic resonance imaging* (fMRI), and *positron emission tomography* (PET)] allow researchers to view the normal, living brain as it encodes and retrieves information (and while it processes information generally). By taking advantage of the fact that when specific brain regions are engaged in a task (e.g., a recognition memory test), these regions receive enhanced blood flow relative to their normal resting state (in the case of fMRI and PET) or the fact that electrical activity increases (in the case of ERP), these techniques can inform our understanding of the neural

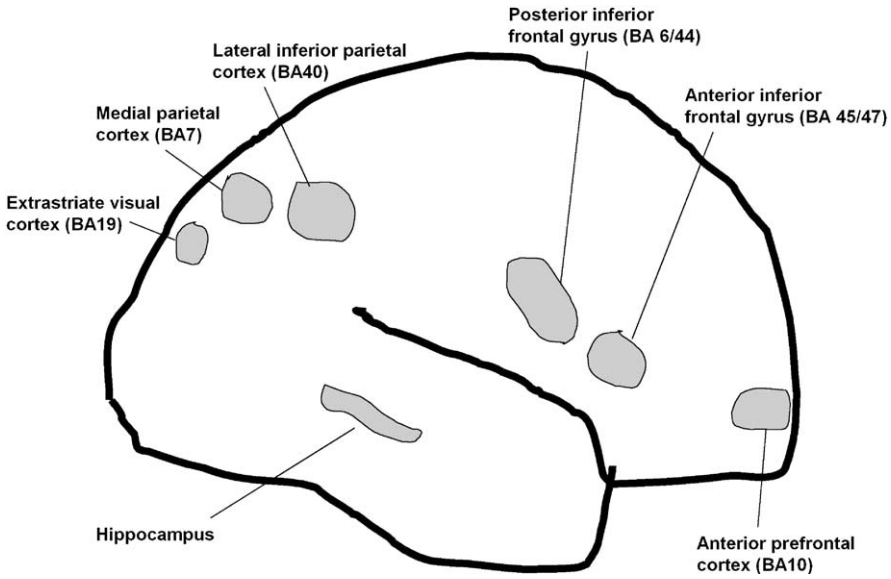

Figure 1 Schematically depicted brain regions involved in explicit and implicit human memory. The front of the brain appears on the right side of the figure. BA, approximate Brodmann's area.

underpinnings of memory. These approaches have shown that several regions are typically engaged during memory retrieval. Interestingly, although the hippocampus is sometimes shown to be active during encoding and retrieval on explicit memory tests, these techniques have pointed to other brain areas as also being important contributors to explicit memory. Some of these regions were relatively unanticipated from the literature on patients with brain lesions. Specifically, a region in the anterior portion of the frontal lobes [in or near Brodmann area (BA) 10] tends to be active when we try to think back to a previous point in time (Fig. 1). This region is sometimes active primarily on the right side and sometimes bilaterally; it is currently a topic of great interest to determine whether the two sides make different contributions and what those contributions might be. Some possibilities are that one or both sides represent the "mental set" or the fact that someone is trying to focus his or her attention to recollect an earlier point in time or that he or she performs reflective processing such as trying to recollect whether an item was seen previously as a picture or as a word. Recent findings demonstrate that these anterior prefrontal regions (in or near BA10) are more active when people successfully retrieve the past than when they try but fail to retrieve the past. A great deal of effort is currently being focused on these questions.

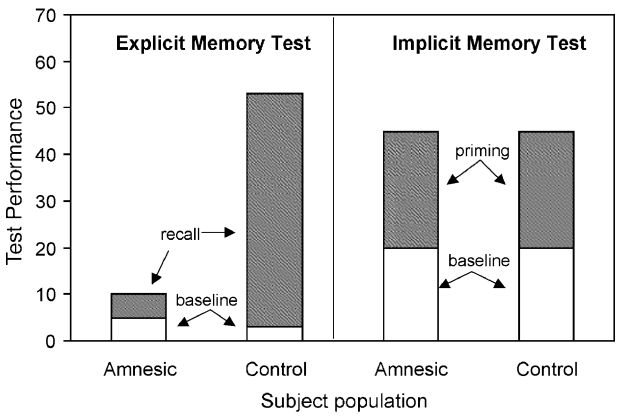

Figure 2 Explicit and implicit memory tests show different patterns of results. Data in this (and all) figures are idealized data demonstrating the general pattern observed across multiple studies. (Left) Patients with damage to the hippocampus and surrounding areas of the medial temporal lobes show profound impairments on tests of explicit memory. The baseline measure represents incorrect answers (or guessing). As shown here, amnesic patients show lower levels of recall than do normal control subjects. (Right) Patients with damage to the hippocampus and surrounding medial temporal lobes demonstrate intact priming. The baseline level represents performance in the unprimed state (e.g., completing a word fragment when the answer was not recently encountered).

A second set of regions indicated by neuroimaging lie within parietal cortex. Regions within both medial parietal cortex (BA 7) and lateral parietal cortex (BA 40) have been shown to be active during retrieval (Fig. 1). Recent studies have shown that they tend to be more active during recognition for items studied before

and correctly recognized by subjects (*hits*) than for nonstudied items correctly classified as such (*correct rejections*). These regions have thus far received less attention than the anterior frontal region, and their role in retrieval is uncertain.

Much more work needs to be done to determine the exact nature of the contribution of these memory-related regions, and such work is ongoing. The relatively new functional neuroimaging techniques will complement lesion studies in that the two techniques typically answer slightly different questions. Functional neuroimaging studies typically examine the normal human brain as it processes information. Functional neuroimaging can also be applied to patient populations, in which case patients are often compared with normal control subjects. Traditional lesion studies involve the study of people who have suffered brain damage; the goal is to determine which tasks they can no longer perform normally. Ultimately, both techniques will be important; if functional neuroimaging identifies a region implicated in performing a cognitive function, it will be important to show that this function breaks down when the region is damaged.

II. IMPLICIT MEMORY

A. Definition

As mentioned previously, explicit memory refers to intentional retrieval. In contrast, *implicit memory* can be thought of as unintentional or incidental retrieval. Implicit memory refers to the change in performance as a result of prior experience without intentionally trying to remember the prior, facilitating event. For example, if you were to read this entry a second time, you would read it faster than the first. This would happen even if you are not conscious of this difference or trying to produce it. What is important is that you are not attempting to draw on previous experience to aid you in the current task; instead, it manifests itself in the absence of your intent to use that information. As will be seen, implicit and explicit memory differ in many important ways.

B. Measures

Implicit memory is measured in terms of *priming*, or the amount of change (often facilitation) observed on an implicit memory test. In order to better understand how implicit memory works, psychologists have devised three main classes of implicit memory tests: perceptual implicit memory tests, conceptual implicit memory tests, and procedural learning.

Perceptual implicit memory tests require people to resolve a perceptually degraded object or word. For example, a word might be flashed very briefly (e.g., 30 msec) on a computer screen, and the task of the person is to try to guess the word. Accuracy in guessing the word is better if the word was recently read. Other types of tests involve completing word puzzles, such as those seen on game shows (e.g., "a _ r _ _ a r _" will be more readily recognized as "aardvark" if the intact word was recently read). Another popular test is to have people fill in the blanks to form the first word that comes to mind that begins with specified letters (e.g., "app_____"). If "apple" were previously seen, it would be primed; it would be used by subjects more often than if they had not previously seen this word. However, if "appendix" were previously seen, it would be the primed word. These tests are called word identification, word fragment completion, and word stem completion, respectively. Similar tests can be employed with pictures, unfamiliar objects, visual patterns, or sounds. For example in picture fragment identification, people are given line drawings of common objects (e.g., a lamp), but parts of the lines have been erased. Their task is to guess the name of the picture from its fragmented form.

The second type of implicit memory test, *conceptual implicit memory tests*, have received much less attention. They, too, use priming as the measure of memory, but they do so by observing how performance on a conceptual, or meaning-based task is influenced by the recent past. For example, if someone asked "What is the name of an airplane without an engine?" a person would be more likely to answer correctly with "glider" if he or she recently encountered that word. Similarly, if a person were asked to say the first word to come to mind when given "aviation", he or she would be more likely to say "glider" than he or she otherwise would if it had not recently been encountered. Peoples' thinking processes in the present are influenced by the recent past, even when there is no attempt to use that recent past to perform the task at hand.

Notice that unlike explicit memory tests, there are sometimes no correct or incorrect answers on an implicit memory test. For example, saying the first word that comes to mind when given another word (i.e., *word association*) or saying the first word that comes to mind that begins with "app____" have many "right" answers; priming, however, is measured in the enhancement of saying a word prespecified by the

experimenter and recently studied. Specifically, researchers search for enhanced probabilities of producing whatever word was recently encountered (usually called the target word or the primed word) relative to the condition in which that word was not recently encountered.

Another example of a conceptual implicit memory test is a "liking" judgment. That is, the answer to "How much do you like this?" can be affected by recent experience. A song heard several times will sometimes tend to "grow on" a person, and this, too, is a form of conceptual implicit memory.

Procedural learning is a third index of implicit memory. The previous example of reading a passage of text faster the second time than the first is an example of procedural learning. Other examples include relearning mazes and recompleting jigsaw puzzles. People can perform complex procedural tasks more quickly and efficiently if they have had recent prior experience with the same materials.

C. Typical Patterns of Results

As mentioned previously, implicit memory tests tend to show different patterns of results from those of explicit memory tests. Perhaps the most dramatic difference is that patients with amnesia (e.g., patient H.M. described previously) perform normally on these tests, despite profound impairments on explicit memory tests (Fig. 2). Indeed, this finding was the spark that produced such great interest in these tests.

With respect to independent variables, perceptual implicit memory tests show patterns markedly different from those exhibited by most explicit memory tests. Conceptual implicit tests, however, tend to exhibit patterns similar (although not always identical) to many explicit tests. The following sections discuss the three patterns of effect of encoding tasks discussed previously with respect to explicit memory (the level of processing effect, the generation effect, and the picture superiority effect), as they relate to perceptual and conceptual implicit memory.

1. Perceptual Implicit Memory Tests

Perceptual implicit memory tests tend to show no (or a very small) difference in degree of priming as a function of level of processing. The explanation is that these tests are thought to be sensitive to the degree of overlap in perceptual features between study and test, and semantic (or meaning-based) processing does not modulate performance. If one sees "aardvark," viewing the visual form of that word will facilitate later reading of the same word because the visual system has an easier time identifying the incoming information. Therefore, verbal perceptual implicit memory tests are primed by verbal stimuli; picture-based perceptual implicit memory tests are primed by picture stimuli (Fig. 3). There is little cross-form priming; that is, if one makes contact with the concept but no visual features match, little or no priming occurs (e.g., seeing a picture of a windmill does not facilitate completion of its fragmented word; similarly, seeing the word "windmill" does not facilitate identification of a fragmented picture of a windmill; Fig. 3).

Similarly, level-of-processing effects and generation effects are typically absent (or very small) in perceptual implicit memory tests. In fact, the reverse pattern is often seen with a read/generate manipulation in that generating the word from a conceptual cue leads to less priming than does reading the word (Fig. 4, left). The explanation calls on whether there is perceptual overlap from the study and test phases; this overlap exists in the read condition, but there is no overlap of visual features in the generate condition.

The picture superiority effect that is seen in explicit memory tests also differs for perceptual implicit memory tests, as alluded to previously (Fig. 3). Because these tests are sensitive to the overlap in perceptual features, whether a picture superiority

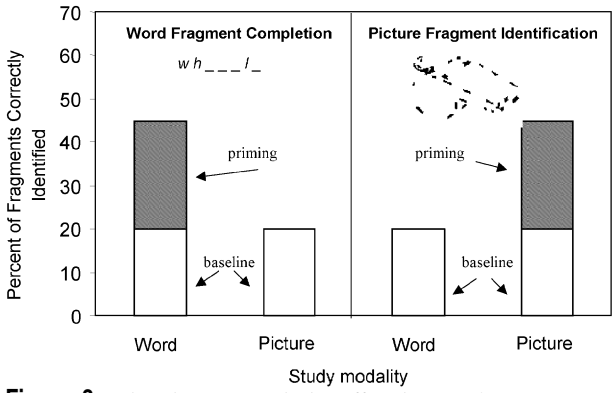

Figure 3 The picture superiority effect is not always seen on implicit memory tests. (Left) Overlap in perceptual features between the study and test phases influences priming on perceptual implicit memory tests. Robust priming occurs on a verbal perceptual implicit memory tests (e.g., word fragment completion) following visual presentation of words (e.g., seeing the word "whistle" primes solving the fragment "w h _ _ _ l _"). However, seeing a picture corresponding to the concept of interest (e.g., a picture of a whistle) does not facilitate performance on word fragment completion. (Right) The converse set of results is seen for picture fragment identification. Seeing a picture primes the identification of its later fragmented form, whereas seeing the corresponding word does not.

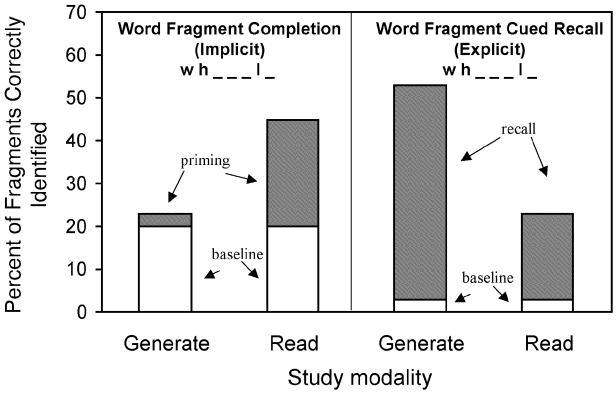

Figure 4 The retrieval intentionality criterion. The retrieval intentionality criterion is met here because the same test cues are used (word fragments) with two different sets of test instructions, and different patterns of results are observed for the implicit and explicit tests. (Left) A reverse generation effect is seen on word fragment completion. Less priming results from generating a word from a clue relative to reading the word. The explanation for this pattern is that there is transfer with respect to the visual features of the word in the read condition but not the generate condition (i.e., the word is seen in the read case, but not the generate case). (Right) The typical generation effect is seen on word fragment cued recall (an explicit test in which people are given a word fragment and asked to complete it with a word from a previously studied list).

effect is present depends on the exact type of test. If a picture-based test is given, the perceptual overlap between study and test will be enhanced for a picture study condition (relative to a word study condition). However, the opposite is true for a verbal perceptual implicit memory test: Encountering words in the study phase primes these more than pictures.

When different patterns are obtained on explicit and implicit tests, the tests are said to have been *dissociated*. The most convincing dissociation occurs when the only feature that differs between the implicit and explicit test is the instructions; when this occurs, it is said that the *retrieval intentionality criterion* is met, as described in the late 1980s by Dan Schacter, Jeffrey Bowers, and Jill Booker. For example, word stems (''whi____'') could be given either with implicit instructions (fill in the blanks with the first word that comes to mind—word stem completion) or with explicit instructions (fill in the blanks to form a word that you encountered earlier in the experiment—word stem cued recall). The only feature that differs between the two cases is instructions: One instructional set requires that people intentionally retrieve, whereas the other does not.

When different patterns of results are obtained on different memory tests, one can argue that different forms of memory underlie the different tests. For example, examine Fig. 4. People either read words during the study phase (e.g., ''whistle'') or generated the word from conceptual cues (e.g., ''blow-w____''). As discussed before, explicit tests exhibit a generation effect such that the generate condition enhances later retrieval relative to the read condition. This pattern is found for the explicit test of word fragment-cued recall in which people are given cues (e.g., ''w h _ _ _ l _'') and asked to use the cue to create a word from the study list. However, if the same cues are given with a different set of instructions, in which people are simply asked to fill in the fragment with the first word that comes to mind, the opposite pattern is observed. The read condition leads to more priming than does the generate condition. In this case, the retrieval intentionality criterion is met; the only procedural difference between the word fragment-cued recall and word fragment completion tests is instructional; Instructions for the former ask subjects to recollect the past, whereas instructions for the latter ask people simply to perform a task to the best of their ability and no mention is made of the relevance of the recent past.

2. Conceptual Implicit Memory Tests

As discussed previously, conceptual implicit memory tests show many of the same patterns exhibited by most explicit memory tests. For example, they show greater priming following meaning-based processing relative to superficial processing (a level-of-processing effect), and they also demonstrate a generation effect. One surprising finding is that a picture superiority effect is not observed on these tests, and the reasons for this unexpected finding are not well understood. In general, however, conceptual priming demonstrates the same patterns of results seen on most explicit tests.

D. Neural Correlates

As alluded to previously, damage to regions in the medial temporal lobes does not produce a general impairment on perceptual implicit memory tests. Whether general impairments occur on conceptual implicit memory tests is more controversial. The finding of intact perceptual priming in patients with damage to the hippocampus and surrounding structures within the medial temporal lobe was reported by Elizabeth Warrington and Lawrence Weiskrantz in the late 1960s. This finding spurred interest in the phenomenon of priming. Prior to this finding, it had been thought that the medial temporal lobes were globally important in memory; however, this finding demonstrated that this was not the case.

If the medial temporal lobes are not critical for producing perceptual priming, then what brain regions are? The brain mechanisms that underlie priming effects differ as a function of the type of implicit memory test. In general terms, brain regions that are critical for performing a task in the unprimed state are *less active* in the primed state. This makes sense if one thinks about priming as facilitation; the brain regions critical to performing the task have to put forth less effort in the primed (facilitated) state.

Consider first perceptual implicit memory tests. Reading a visually presented word taxes the visual system. However, regions in extrastriate visual cortex (Fig. 1) show less activity in the primed state relative to the unprimed state, consistent with the idea that less neural effort is required to perform the task; the neural pathways necessary to accomplish the goal are facilitated. Although less well studied, on the basis of this logic we would expect auditory implicit memory tests (e.g., identifying an auditory word stem) to show less activation in regions of the brain responsible for auditory processing (relative to the unprimed state).

Conceptual implicit memory tests, however, are not sensitive to the match or mismatch in perceptual features between the study and test phases; hence, the neural manifestation is not at the perceptual level. Rather, facilitation is observed at higher level regions of the brain, which are concerned with the task at hand. Consider the case of generating an associate to a presented word (e.g., given the word ''elephant,'' the person would respond with a related word, such as ''tusk''). This task calls on many brain regions, and two critically important regions lie within the left inferior frontal cortex (Fig. 1, anterior and posterior inferior frontal gyri). These regions show diminished activation in the primed condition. Again, it can be seen that regions that are important for performing the task have to put forth less effort to accomplish the task at hand in the primed condition. The brain is more efficient in the primed case.

III. IMPLICATIONS

As previously reviewed, implicit and explicit memory differ as a function of:

1. Subject populations: The finding that amnesic patients exhibit intact implicit memory despite grossly impaired explicit memory spawned a great deal of interest in characterizing implicit memory tests.

2. Independent variables: Many standard findings in explicit memory do not hold up (and often are reversed) for perceptual implicit memory tests. Explicit and implicit memory seem to be fundamentally different types of memory.

3. Neural substrates: Explicit memory tests show *increased* activity in a network of brain regions, including regions within anterior prefrontal cortex and lateral and medial parietal cortex. Implicit memory tests show *decreased* activity in regions critical for performing that task (e.g., in visual cortex as seen for word stem completion).

In the late 1980s, there was a debate over the question of whether different memory ''systems'' were responsible for performance on implicit and explicit memory. This hotly contested question was argued before the tools to observe localized brain activity relatively directly (via PET and fMRI) had become widely available. The availability of these techniques has allowed researchers to go beyond debating whether there is a system or network of regions in the brain responsible for implicit memory (or explicit memory) and instead to focus on the precise role of various specific brain regions to specific memory tasks. The general conclusion is that no single brain region is solely responsible for implicit (or explicit) memory. We do now have an emerging understanding of the network of brain regions underlying implicit memory and explicit memory tests, and there are marked differences between the two. However, differences also exist among various explicit tasks as well as among different implicit tasks. Whether one wants to refer to the networks underlying performance as brain systems is largely a matter of taste. One suggestion advocated here (in collaboration with Henry Roediger and Randy Buckner) is that it makes sense to put the question of systems aside until the individual components of the systems (i.e., individual brain regions) are better understood, with the eventual goal being to understand the entire network of brain regions contributing to implicit and explicit memory in their multiple instantiations.

IV. TERMINOLOGICAL CONSIDERATIONS

I consider here a few difficult issues involving terminology. First, implicit and explicit memory tests have been defined here according to instructions. However, consider the case in which the instructions given to subjects are for an implicit test, but people choose to ignore the instructions and decide to think back to the past in an effort to enhance performance on the test. Is

the test still implicit? Conversely, what if people decide that an explicit memory test is too difficult and therefore begin responding with whatever first comes to mind? Is the test explicit simply because the instructions asked people to think back in time? The approach advocated here is that safeguards can (and in some situations should) be built into experiments to ensure that subjects do indeed follow instructions; this is as true of explicit memory experiments as of implicit memory experiments, however. Thus, instructions to subjects define the test type to a first approximation, but it is desirable to have some behavioral evidence documenting that people did follow those instructions.

A second issue that researchers have wrestled with is the concept John Gardiner termed *involuntary conscious recollection*. This term refers to the situation in which a person vividly recollects some aspect of the past even though he or she is not trying to do so. Consider the case in which, for example, you are walking down the street when seemingly out of nowhere you recall going to the circus as a child. You did not intentionally recall that memory; it simply "popped to mind," perhaps sparked by the unconscious association to some cue in the environment. Does such an experience tend to happen on implicit memory tests—a subject recognizes a word as studied after it has been retrieved—and, if so, does it contaminate the results? Although such phenomena sometimes do occur on implicit tests, research indicates that it need not affect the implicit test results. As long as people do not alter their strategy on the implicit test (i.e., as long as they do not adopt a strategy of attempting to recollect the recent past to aid performance on the test and instead continue to follow instructions), such involuntary conscious recollection does not contaminate the results.

A third difficult issue is that implicit and explicit have been referred to here as representing test types as defined by instructions and have also been referred to as representing different manifestations of memory, which underlie performance on the two types of test. This confounding of terms is pervasive in the field but can lead to confusion. One approach (advocated here) is to apply the terms to the type of test (implicit or explicit memory test) because test type can be defined (at least approximately) by instructions, whereas "implicit memory" and "explicit memory" cannot be observed directly. However, the title of this article referred to implicit and explicit "memory," and these concepts are widely discussed in the literature; therefore, implicit and explicit are used in both senses throughout this article.

V. SUMMARY

Perceptual implicit tests of memory and traditional, explicit tests of memory demonstrate fundamentally different types of memory. The former is preserved in amnesia, sensitive to the overlap in perceptual details between the study and test phases of experiments but relatively insensitive to higher level strategies. Conversely, explicit tests of memory demonstrate profound decrements for amnesic patients. Also, they are relatively insensitive to mismatches in perceptual features between the study and test phases, but are highly sensitive to the types of study strategies invoked during the study phase. Understanding both types of memory and the brain regions contributing to them will provide a more complete understanding of the workings of human memory.

GLOSSARY

declarative memory Information stored in memory that can be retrieved explicitly.

encoding The set of processes that transform some physical event into a memory representation.

episodic information Information in memory that is tied to the time and/or place of occurrence, such as being tied to one's autobiographical past.

executive processes The set of operations that allows one to shift attention from one task to another, plan a set of operations, tie information to its context, and generally modulate the operation of other mental processes.

long-term memory The system of storage that is the large repository for information that is stored for very long periods of time.

procedural memory Information that allows one to engage in some skill, including motor and cognitive skills.

retrieval The processes responsible for extracting information from memory for some purpose. The most frequent kinds of retrieval are recall and recognition.

semantic information Information that is generic in form without being tied to some time or place of occurrence, such as knowledge of facts about the world.

storage The processes responsible for holding information in memory for some period of time.

working memory The system of storage that is responsible for small amounts of information for short periods of time.

The study of memory has been remarkably facilitated by the use of neuroimaging tools in recent years. As we now know, memory is not a unitary function or set of processes; rather there are multiple systems of memory that underlie our cognitive life. This article examines the full taxonomy of memory in humans, and reviews what we know about the brain basis of memory from neuroimaging studies. Beyond this, the purpose of the article is also to illustrate how knowledge of the brain mechanisms of memory can help inform us about a proper psychological view of how memory works functionally.

I. SOME INTRODUCTORY CONCEPTS

A. Types of Memory

One of the critical properties that makes the human mind so extraordinarily suited to understanding and dealing with the world is its ability to shift in time—to model the future and reconstruct the past. Reconstruction of the past requires memory, and memory is fundamental to nearly any cognitive skill. It is involved in complex processes such as problem-solving, and it is involved in even what seem to be the simplest skills, such as recognizing a familiar face. The role played by memory in cognition is complex enough that not just a single memory system will do. Humans and other animals have several memory systems with different characteristics and different neural implementations,

and these systems, acting in concert, contribute to the human mind's tremendous adaptability.

At the broadest level, one can distinguish between "working memory" and "long-term memory." Working memory refers to the system that stores a small amount of information for a brief span of time. Information stored in working memory is then used in the service of other cognitive tasks. For example, if we were solving an arithmetic problem such as 817 + 723 without the benefit of writing anything on paper, working memory would be used to store the problem, store the intermediate steps in the addition, and store the final solution. In addition to temporary storage, an important component of working memory is what is called "executive processing:" the set of operations that permits one to manipulate the contents of working memory. In the previous example, executive processes would be involved in switching attention from one column of addition to another and in organizing the order of steps to arrive at a final sum. Whereas there is as yet no overall agreement about a full list of executive processes, they generally can be thought of as operations that regulate the processes operating on the contents of working memory, processes such as selective attention to relevant information (more about this shortly).

In contrast to the short duration and small capacity of working memory, long-term memory is a system with very long duration memory traces and a very large storage capacity. In our previous mental arithmetic example, long-term memory would be the repository of the facts of addition that would be needed to solve the mental arithmetic problem. Of course, long-term memory stores much more than that. For example, it is the repository of all the words we know in our language, of the sensory information that we all have stored for untold numbers of events (e.g., the taste of a good chocolate), of the spatial information we have stored for navigating around our world, and so on. In addition, many pieces of information are stored that we normally do not retrieve consciously but that nevertheless guide our everyday behavior, such as the rules of language or habitual actions in which we engage every day.

Larry Squire of the University of California and Endel Tulving of the University of Toronto have proposed schemes that summarize the various forms of long-term memory. One way of synthesizing and expanding these schemes is shown in Fig. 1. The figure shows that there are two broad divisions of long-term memory: declarative and procedural. Declarative memory refers to the facts and events that we can retrieve at will, often consciously. By contrast, procedural memory refers to stored information that has an impact on our behavior but that is not willfully retrieved. Consider, for example, the concept of a bicycle. A declarative memory you might have of a bicycle is that it is blue and that it has 21 gears, mountain terrain tires, two handbrakes, and so on. These are all facts that can be willfully retrieved from memory. By contrast, you also have stored information that allows you to ride your bicycle—a task that any 6-year-old child will tell you is not easy. This information is not consciously retrievable; indeed, it is a nontrivial problem in physics and kinesiology to describe just how people are able to ride a two-wheeled bicycle without falling over. The contrast between these two sorts of memory is a contrast between declarative and procedural memory. Perhaps the most compelling evidence that procedural knowledge is different from declarative knowledge is that patients with damage to their hippocampi and surrounding medial temporal lobes can learn new procedural skills, even though they cannot encode where they learned

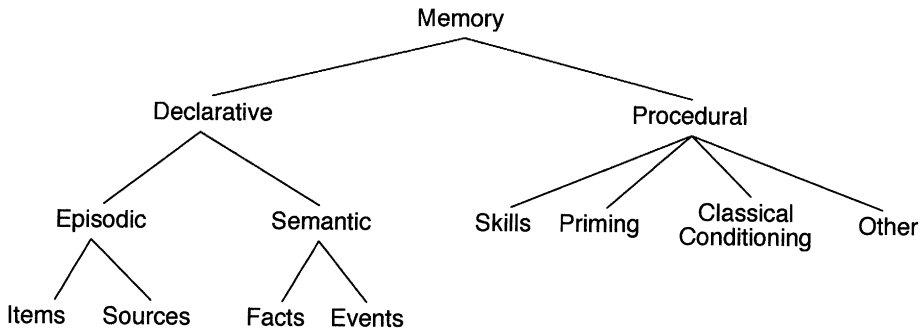

Figure 1 A taxonomy of various forms of long-term memory.

the skill or remember any details of having practiced it, even when that practice occurred very recently. Other patients with cerebellar damage can remember the practice sessions, but their skills on most motor tasks do not improve. This pattern of deficits, called a double dissociation, helps to define procedural and declarative processes as distinct types of memory.

Declarative memory itself comes in two forms. One is called episodic memory, or memory for specific events, and it consists of memory traces that are accompanied by memory for the context in which they were formed. Each piece of episodic memory has a source tag associated with it, possibly including the time and place of memory formation and other details about the context. When retrieving an episodic memory, one can retrieve either the item itself, given information about the source, or the source, given information about the item. For example, you may recall where and when you purchased your current bicycle or, given the time and place, you may recall the features of the bicycle that you purchased. The other category of declarative memory is semantic. This type of memory consists of the vast store of facts and events that you have in long-term memory, regardless of whether you can retrieve when and where you learned them. For example, you may remember the fact that bicycles can be mountain bikes, racing bikes, hybrid bikes, and so on, yet you may not be able to recall when or where you learned this semantic fact.

Procedural memories also are of various sorts. There are skills, for example, such as riding a bicycle. There are classically conditioned responses, which entail a previous pairing of an unconditioned with a conditioned stimulus to yield a conditioned response. And there are cases of priming, in which a previously learned piece of information facilitates processing of some new piece of information. Psychological measures of priming, such as decreases in response time to recognize a previously viewed word, indicate that a trace of the previously learned piece of information is affecting current cognitive processing—even if there is no conscious recollection of having seen the word before.

Another important dimension of memory, whether working or long-term, is the type of information being stored. As we shall see later, the brain circuitry involved in a memory task honors the type of information that is stored and retrieved. Perhaps the most frequently studied case of this concerns the distinction between linguistic information (such as letters, words, sentences, and stories) and visual or spatial information (such as a scene, an object, a face, or a spatial environment). By now ample evidence exists that the two hemispheres of the brain are differentially activated by these two types of information, with the left hemisphere specialized for verbal information and the right for visual or spatial information in most humans.

B. Types of Processes

Memory entails three cognitive operations: encoding, storage, and retrieval. These terms refer to the sequence in which memory processes are thought to occur. Entering information is first put into the proper internal code and a new memory trace is formed (encoding). Encoding is followed by storage of the information for some period of time. This stage may include consolidation or alteration of memory traces to make them last longer and ease retrieval. Retrieval is the process of reporting information from storage.

The nature of encoding depends on two factors: the type of material that is involved in the memory task and the task that is performed with that material. The type of material exerts a strong influence on the path of activity in the brain early in the processing sequence. The best example of this is the visual system. Spatial information about a visual stimulus is selectively routed to a dorsal stream of information processing that mainly includes the parietal lobes, whereas information about shape and other nonspatial object features of the same stimulus is processed by a ventral stream in the occipital and inferior temporal lobes. To generalize from this example, we can say that the nature of incoming information will influence the path of processing that the information takes in the brain. Beyond this, though, there is also an influence of the task with which a person is faced, as many different operations may be performed on any given type of material. For example, one can process a word by noting its meaning or by noting whether it is printed in uppercase or lowercase letters. These very different types of processing on the same stimulus yield different patterns of activation in the brain, as we shall see later.

Once encoded, information is retained for some period of time. Consistent with the fundamental distinction between working and long-term memory, the length of the retention interval in large part will determine which of these systems is most heavily involved. Retrieval after short retention intervals—up to, perhaps, intervals as long as 30 sec to 1 min—uses working memory. Retrieval of information stored for longer periods will, under most circumstances,

necessitate the involvement of long-term memory storage. Which memory system is engaged will be revealed by the circuitry that is activated. Working memory engages circuitry in frontal and parietal cortices most prominently, whereas long-term memory requires the involvement of frontal and parietal circuitry as well as hippocampal and parahippocampal mechanisms.

Just as encoding different types of material engages different mechanisms, storage of different types of material also requires different mechanisms. This has been demonstrated most handsomely in the contrast between verbal and visual material, which predominantly activate left and right hemisphere structures, respectively. This distinction has been demonstrated for both working memory and long-term memory, as we shall see later.

Once encoded and stored, information in memory can then be retrieved as needed. Suppose, for example, that we ask a person to memorize a list of words. Retrieval can be accomplished in several ways. We might simply ask the person to recall as many of the words as possible (free recall). Or we might guide recall by giving some of the words on the list as hints and asking the person to recall the others (cued recall). Or we might present the person with a longer list of words, some of which were presented on the original list and some not, and ask the person to decide which is which (recognition). Any of these procedures requires the person to access the stored information in memory and produce an explicit response that depends on that stored information. For this reason, these are often called explicit tests of memory. However, there are also implicit tests. Suppose, for example, that we presented someone with a list of words and later flashed the same words and new words, one by one, so briefly that they were difficult to identify. If the person were more accurate in identifying words that had been presented on the original list than ones that had not (which is what happens in this perceptual identification situation), then we could conclude that the original words were stored in memory even though no explicit retrieval of them was ever demanded. The process of storage and use of information without explicit memory is called priming. Evidence from positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) suggests that implicit and explicit tests of memory recruit different brain areas, as reviewed later.

With these preliminaries about memory in place, we are now in a position to review what neuroimaging evidence has contributed to understanding basic mechanisms of human memory.

II. WORKING MEMORY

The canonical model of working memory is due originally to Alan Baddeley, and it is this model that has been investigated in detail using neuroimaging methods. The model claims a fundamental distinction between short-term storage of information and the executive processes that manipulate this information. This general view is supported by the existence of patients who have intact short-term storage but deficits in executive processes; this pattern of impairments contrasts with that of other patients who have deficits in executive processing but intact short-term storage. Such a double dissociation suggests that the circuitries of storage and executive processing are separable, and imaging studies have confirmed this separability.

A. Short-Term Storage

The short-term storage of information in working memory appears to be accomplished via two mechanisms: one that retains information and another that "rehearses" that information in order to keep the memory traces active during a retention interval. This is perhaps best illustrated for verbal information. A task that has been used frequently to study the mechanisms of verbal working memory in neuroimaging experiments is the item-recognition task. In this task, participants are presented with a small number of target items, typically randomly selected letters, to store for a retention interval of several seconds. Following this interval, a single probe item is presented and participants must decide whether this item was a member of the memorized set. When participants engage in this task in PET and fMRI settings, a number of easily replicable sites of activation exist compared to a control condition that does not require memory at all or in which the memory requirement is minimal. One frequent site of activation is in the posterior parietal cortex, typically more prominently in the left hemisphere than the right. In addition, a set of activations appears in frontal areas, including the inferior frontal gyrus on the left, premotor cortex (more prominently on the left than on the right), and supplementary motor cortex. These brain regions, and all other major regions discussed throughout this article, are shown in Fig. 2.

The frontal cortical areas that are activated in this task are quite similar to those activated in a task that requires one to make judgments of rhyming, a task that

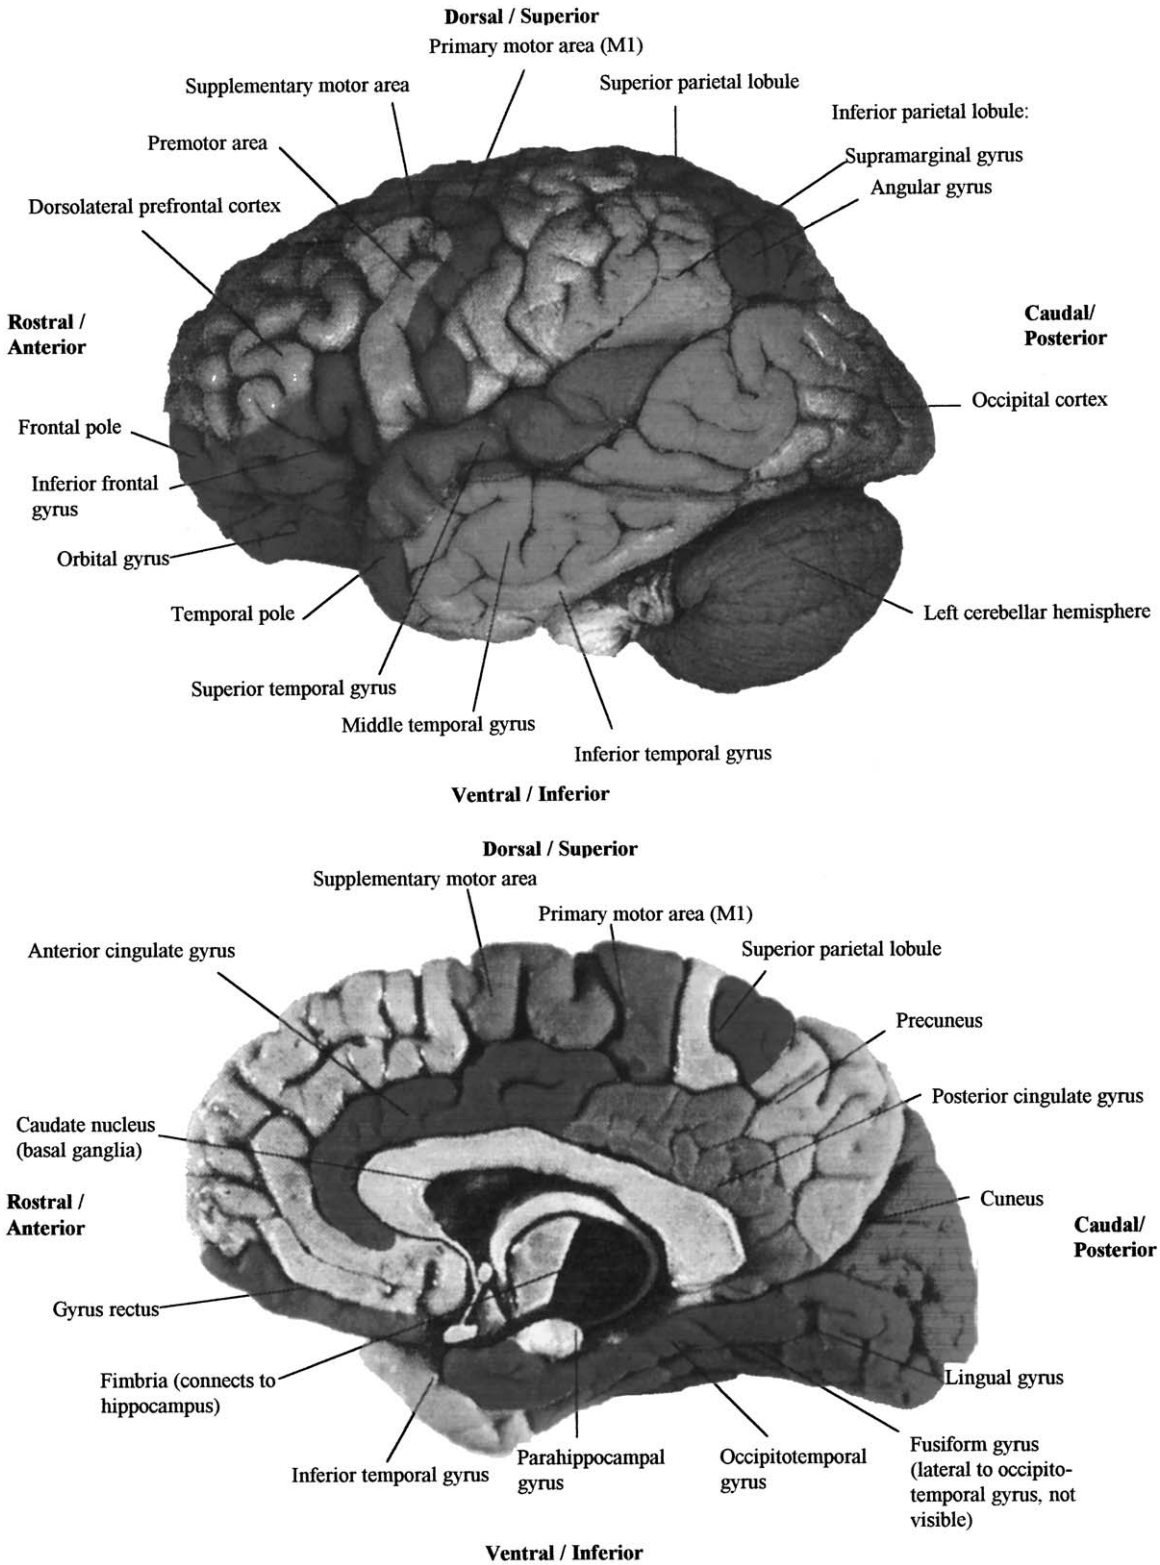

Figure 2 Brain diagrams highlighting the major structures discussed in the text. The upper figure shows a lateral view of a left hemisphere of the human brain, and the lower figure shows a view of the right hemisphere as seen from the midline of the brain. Major structures of relevance to memory are labeled.

presumably requires production of a speechlike representation. So, it is likely that these frontal areas are the ones involved in rehearsal, which involves internally generating and regenerating a speechlike code for the stored verbal material. The posterior parietal sites have been suggested as sites for the storage of verbal information as well as for switching attention between one item and another.

The purported dissociation between the frontal and parietal sites is nicely supported by a study that used a different task involving verbal working memory, the two-back task. In this task, participants see a series of letters presented at a pace of one every 2.5 sec, and they must judge whether each matches in identity the one that appeared two letters back in the series. This task clearly requires storage and rehearsal of each letter, as well as other processes that we discuss next. Compared to a task in which participants must simply judge whether each letter in the series matches a single target (say, the letter "P"), the two-back task produces activations in regions similar to those in the item-recognition task. This is as it should be if both tasks involve storage and rehearsal. Beyond this, though, the two-back task has also been compared to another condition, one in which participants had to silently rehearse letters to themselves with little storage requirement (e.g., say the letter "P" for 3 sec, followed by silently saying the letter "M," and so on). Subtraction of the activation in this rehearsal condition from that in the two-back condition revealed much lower activation in the frontal areas. The rehearsal condition is presumed to involve the explicit production of silent speech. Subtraction of the activations in this condition from those in the two-back condition reduces frontal but not parietal activation; therefore, one can conclude that the frontal activations in the two-back and other verbal working memory tasks must reflect an inner rehearsal process as part of those tasks. These same frontal regions are also activated in tasks that require a recall response, so they are not unique to the peculiarities of the item-recognition task or the two-back matching task.

Just as we can identify the frontal sites used in verbal rehearsal, we can also identify the parietal sites used in verbal storage. Evidence that the parietal sites are used in part for storage comes from a study in which subjects memorized a set of nonsense letter strings (e.g., "MAVER") and then kept these items in memory during a retention interval of some 50 sec, during which they underwent PET scanning. After the scan, they had to retrieve the items to be sure that they had been stored accurately. Scanning during just the retention interval allows one to isolate storage processes or at least to concentrate scanning on storage. One study using this procedure found posterior parietal activations, leading to the conclusion that these activations reflected storage processes and not encoding or retrieval processes.

Storage and rehearsal should not be restricted to verbal information, of course, if they are general properties of working memory as Baddeley has supposed. Indeed, many studies have investigated the storage and rehearsal circuitry used for spatial information as well. The clearest result of these studies is that the circuitry activated by spatial information in a working memory task is quite different from that activated by verbal information, even when the tasks are quite similar and only the material differs. For example, in an analog to the item-recognition task, subjects are presented with a set of dots on a screen and asked to store their locations in memory. Following a retention interval of several seconds, they are presented with a single probe dot, and their task is to decide whether it appears at the same location as one of the locations they have stored. This task has the same formal structure as the item-recognition task for letters, yet it yields activations that are quite different. In common are activations in the posterior parietal and premotor cortex, although with a tendency for greater activation in the right than the left hemisphere. However, quite different are activations in the occipital cortex, superior frontal cortex, and inferior frontal cortex, most prominently in the right hemisphere.

The common activations in parietal and premotor cortex between verbal and spatial versions of the task suggest that there are some processes in common between the tasks, possibly having to do in part with allocating attention to several items in memory. However, the differences in activations suggest that the mechanisms by which information is stored and rehearsed may be different. Indeed, there is evidence of a similarity in circuitry between processes mediating spatial working memory and those mediating shifts of attention to various locations in the visual field when stimuli are being perceived. This leads to the conclusion that spatial rehearsal may amount to a successive allocation of attention to internal representations of spatial locations, a process possibly mediated by premotor mechanisms near the frontal eye fields. This region, together with parietal cortex, may also play a role in maintaining the representations of the spatial locations as well, a conclusion that is consistent with lesion studies and electrophysiological studies of monkeys in spatial working memory tasks. So, we

can see that, although storage and rehearsal are common features of spatial and verbal working memory, they appear to be implemented in the brain in different ways.

Of course, visual information that is stored need not be spatial in nature. Features such as the shape of an object or its color are not spatial, even though they are visual. As described earlier, the brain honors this distinction in simple visual processing, and indeed neuroimaging research suggests that spatial memory and memory for other visual information are processed differently in the brain as well. One experiment that demonstrates this used pictures of three faces presented sequentially in three different spatial locations. After a retention interval, a probe picture was presented in one of the locations. When subjects were tested on their working memory for objects, they had to decide whether the probe face was the same as any of the previous three; when they were tested on spatial working memory, they had to decide whether the probe was in the same location as one of the original faces. The elegance of this design is that it involves the very same stimuli, and only the nature of the memory task changes. The results show that this change in task produces an important difference in brain activation: The object task activated regions of dorsolateral prefrontal cortex, whereas the spatial task activated a region posterior to this in the premotor cortex. Beyond this, a meta-analysis of several spatial and object working memory tasks suggests that there is also a dorsal–ventral difference in activation in the posterior cortex. Spatial working memory tasks activate more dorsal structures in the posterior cortex, whereas object working memory tasks activate more ventral structures.

B. Executive Processes

In addition to storage components, the model of working memory proposed by Baddeley includes a component due to executive processes. Although there is not yet a clear taxonomy of executive processes in hand, descriptions of them typically include the following: (a) focusing attention on relevant information and inhibiting attention from irrelevant information; (b) scheduling processes in tasks that require multiple processes; (c) planning and prioritizing a sequence of steps to meet some goal; (d) updating and checking the contents of working memory; and (e) coding internal representations for time or place of occurrence. All of these processes involve the manipulation of information that is temporarily stored in working memory. Research on executive processes using neuroimaging techniques has revealed a heavy contribution of frontal mechanisms regardless of the executive process in question.

As an example, recall the verbal item-recognition task. In that task, subjects are presented with a set of letters that they have to retain for several seconds, after which they have to decide whether a probe letter matches one of the letters in memory. Several studies have introduced an inhibitory component in this task in the following way. Trials were included in which the distractor probes (probes that did not match an item in the current memory set) were letters that did match a letter in the memory set from the previous trial. Thus, these probes were relatively familiar because they had been memorized recently. This design creates a situation in which participants have a sense of familiarity about the probe item, but they must remember that it does not match the memory set on the current trial. On such trials, subjects take longer to give a "no match" response. Both PET and fMRI studies show that there is a site in the left lateral prefrontal cortex that is activated on these trials, and the activation occurs most prominently at the time the probe is presented. Furthermore, older subjects, who show a greater interference effect on these trials, also show less activation at this left lateral site, and patients with damage to this area show a dramatically increased interference effect compared to patients with damage elsewhere in the frontal cortex. Taken together, this evidence suggests that the left lateral site is involved in resolving the conflict between familiarity and source memory that arises on these trials.

Another example of a task in which executive processes interact with storage processes is the two-back task described earlier. Recall that, in this task, single letters are presented in succession and subjects must judge whether each letter matches the one two earlier in the sequence. To succeed at this task, one not only has to store the recent stream of letters but also has to update this stored set as new letters are presented, dropping older letters and adding newer ones. This task is similar to the item-interference task in that it includes an inhibitory component, as described earlier. In addition to this executive process, the letters that are stored in memory also have to be tagged by their order of appearance so that the subject can keep in mind which one is two back, which is one back, which is three back, and so on. Thus, the two-back task must recruit an executive process responsible for temporally tagging information, a sort of

short-term episodic memory requirement. Indeed, the two-back task shows evidence of activations in the dorsolateral prefrontal cortex in addition to other sites that may well be responsible for temporal tagging. The dorsolateral prefrontal activation that arises in this task seems to be a common broad site of activation in many tasks that require manipulation of the information stored in working memory, and so this leads to the general conclusion that prefrontal mechanisms may be responsible for a wide array of executive processes.

C. Summary of Working Memory

Overall the neuroimaging research concerned with working memory has reliably revealed a set of structures that may be important for storage, rehearsal, and executive processes. Posterior parietal mechanisms have been implicated in the storage of verbal material, and prefrontal ones concerned with language processing have been implicated in the rehearsal of stored verbal material. For spatial material, the sites of storage and rehearsal are different; nonetheless, one can conclude that there are storage and rehearsal processes for nonverbal material as well, but that these may be implemented via nonlinguistic mechanisms. Finally, various sites in the prefrontal cortex, most prominently dorsolateral prefrontal areas, have been documented in the mediation of executive processes. Thus, the psychological architecture proposed by Baddeley in his model of working memory seems to be amply supported by a brain architecture that may honor the same distinctions among processes.

III. EPISODIC MEMORY

As described earlier, episodic memory can be defined as memory for information that is associated with a time and place of occurrence. Take, as an example, a semantic fact: one may know that the turn of the century French impressionist painter Claude Monet lived and worked for many years in his provincial home at Giverny. This fact is in the domain of semantic memory. However, one's memory of learning this fact in an art history course would be an episodic memory. Episodic memory is often studied in a controlled laboratory setting using recognition or recall tasks, described in the introduction to this article. These tasks require memory for a source code (e.g., time or place of occurrence) that is the essence of episodic memory. In the context of neuroimaging, the encoding and/or retrieval phases of these tasks are scanned using PET or fMRI and then compared to a control task with a diminished or absent demand on memory.

These studies have identified a set of regions underlying episodic memory. These include medial temporal structures, such as the hippocampus and parahippocampal areas, prefrontal cortex, anterior cingulate cortex, cerebellum, and parietal and superior temporal association cortices (shown in Fig. 2). Important hemispheric, regional, and functional differences exist, however, between the encoding and retrieval phases of episodic memory. In addition to exploring these differences, neuroimaging studies have also begun to examine cases in which this system performs inadequately.

A. Episodic Encoding

As discussed earlier, memory entails three important general stages: encoding, storage, and retrieval. At the encoding stage, processes must be involved that create an internal code for a piece of information and then attach a context (a place or time) to the new memory.

Several neuroimaging studies have scanned participants while they perform some task to encode a set of items. For example, participants might be asked to make a judgment about whether a word represents an animal or vegetable, an encoding task that requires access to the semantics of the word. Alternatively, a subject might simply be asked to memorize a set of items and be tested on them later. Subsequent testing of the items confirms whether subjects have effectively encoded the items. These studies show that encoding involves the left prefrontal cortex, hippocampus, parahippocampal cortex, anterior cingulate, and some superior temporal cortex. Further experimentation, including converging evidence from neuropsychology and other experimental paradigms, has begun to examine the role of each of these regions and their relationships to one another.

The hippocampus and surrounding areas have long been associated with memory. Evidence from both animal studies and studies of brain-damaged patients has shown that damage to the hippocampus can result in amnesia, one form of which is caused by damage to medial temporal structures such as the hippocampus and parahippocampal gyrus. Though amnesics typically are able to retrieve memories from their distant past, they show a profound deficit in the ability to form new memories, a phenomenon known as anterograde

amnesia. For this reason, the hippocampus is thought to be involved with the encoding and consolidation of long-term memories.

In line with this, many neuroimaging studies using the encoding paradigms described earlier have shown hippocampal activity. Neuroimaging evidence has shown, however, a selective response of the hippocampus to novelty. In one experiment, participants were shown pictures of indoor and outdoor scenes while in the MRI scanner. They were required to judge whether each scene was an indoor scene or an outdoor scene and remember the pictures for a later test. In some scans, the same two pictures were repeated many times so that participants became very familiar with them. During other scans, the scenes were entirely novel and unfamiliar. Comparison of the unfamiliar scans to the familiar scans showed activity in the parahippocampal gyrus bilaterally. Given this fact, it would seem that the medial temporal lobe is particularly responsive to novel stimuli—a finding consistent with the intuition that most episodic memory encoding occurs on the first presentation of new material.

The function of the left prefrontal cortex appears to involve processing the context (or source) in which new information is learned. An event-related fMRI experiment has studied the different functions of left prefrontal and hippocampal mechanisms in episodic memory. Event-related fMRI allows the examination of areas of the brain that are active in response to different events occurring within the context of a single cognitive task. In this experiment, participants were required to learn word pairs in which the first word served as semantic context for a second word, for example, ''athlete–boxer.'' Participants were presented with several of these word pairs during each scan. Sometimes the context for a word would change, as in ''dog–boxer.'' Other times the word would change as in ''dog–labrador.'' Both word and context could also be new or both could be old. This design permitted independent manipulation of the novelty and the context of the item to be learned during encoding. The hippocampus was active when either the context word or the related word was new, and it was most active when both were new. This corroborates the idea that the hippocampus is involved in processing novel items. The left prefrontal cortex was most active when an old context was attached to a new word or a new context attached to an old word. This finding suggests that the prefrontal cortex is involved in representing the context of the item to be remembered, a function that is critical for episodic memory.

We can test whether the effectiveness of encoding is related to the brain activations that reflect encoding by varying what is called the depth of processing participants apply to material. It is well-known that evaluation of the semantic content of material (deep encoding) leads to more elaborate processing and a longer lasting memory trace than evaluation of the physical features of material (shallow encoding). One experiment that takes advantage of this effect required subjects to judge whether a word was abstract or concrete (deep encoding) or whether it was printed in upper- or lowercase characters (shallow encoding). Deeply encoded words were remembered better than words encoded shallowly, replicating previous behavioral results. When the two conditions were compared, it was found that there was greater activity in the hippocampus and left prefrontal cortex for deep encoding, suggesting that both areas are more vigorously involved with deep than with shallow encoding.

This result by itself does not indicate that more activity in the prefrontal cortex and hippocampus produces better behavioral performance; it only indicates that depth of encoding and activation are correlated. To address the performance question, several studies have directly examined the relationship between performance on retrieving an individual item in memory and brain activation while encoding that item. After being scanned, the participants had to recognize the encoded items, and they were grouped by whether the items were retrieved correctly or incorrectly, an indication of good or poor encoding, respectively. This comparison revealed activity bilaterally in the hippocampus and in the left prefrontal cortex. Hence, it would seem that for effective encoding not only must the information be consolidated effectively by the hippocampus but the prefrontal cortex must also assist in processing the context.

To summarize, encoding recruits a set of regions that includes the left prefrontal cortex, hippocampus, parahippocampal gyrus, parietal cortex, and anterior cingulate (as shown in Fig. 2). These regions appear to be involved in transforming information into a mental code in the brain that can later be retrieved. Two processes entailed by this task are the consolidation of a novel item by the hippocampus and the processing of its context by the left prefrontal cortex. The extent to which the information being encoded can be effectively recovered at a later time is strongly dependent on the depth of encoding, which seems to have an effect on the activity of the hippocampus and left prefrontal cortex.

B. Episodic Retrieval

Retrieval of episodic memory is mediated by regions that generally are functionally and anatomically distinct from those used in encoding. Most neuroimaging studies of retrieval use a task design similar to that used in studies of encoding, in which participants must study a set of items and are subsequently tested for their memory of the items. The difference is that participants are scanned while they retrieve (recall or recognize) rather than while they encode the material. In recognition tasks, an item is shown, and it is the task of the participant to indicate whether that item was presented during the study phase. Hence, it is necessary only to access the source and not the item. In recall tests, it is necessary to generate the item as well. Neuroimaging studies of both recall and recognition typically show activity in the right prefrontal cortex, hippocampus, medial as well as inferior parietal cortex, anterior cingulate, and cerebellum. There are some important variations in this pattern, however, that are discussed next.

The hippocampus is typically considered to be involved in the consolidation of long-term memories, as discussed earlier. Although this function implies that the hippocampus should not be involved in retrieval, some studies *have* found it to be activated during retrieval tasks. To test whether the effort required for retrieval might influence activation of the hippocampus, one study varied the amount of effort required to search memory. In a ''high-recall'' condition, words were deeply encoded and, hence, less effortfully retrieved. When the recall phase was scanned, this manipulation revealed activity in the hippocampus bilaterally, supporting the view that the hippocampus is involved in effortless, conscious recall. In a ''low-recall'' condition, words were encoded more superficially and, hence, required more effortful retrieval. Scanning during this more effortful recall phase showed bilateral prefrontal but not hippocampal activation. The finding that the prefrontal cortex is involved in effortful retrieval is consistent with the view that one function of the prefrontal cortex is to implement retrieval strategies. The hippocampus, by contrast, may be involved in relatively more automatic retrieval.

Certain neuroimaging studies of episodic retrieval have found not only increased activity in the right prefrontal cortex but also decreased activity in other areas such as the left prefrontal cortex. On the basis of this effect, some have suggested that episodic retrieval is not just an active process of search and retrieval but involves the active inhibition of certain regions of the brain by other areas of the brain. By this model, the right prefrontal cortex could be actively inhibiting left frontal regions as well as inferior temporal regions, areas that sometimes show deactivations in retrieval tasks. In the case of the temporal regions, for example, this might indicate the suppression of language processes during episodic retrieval. This effect has been termed ''ensemble inhibition'' and suggests that episodic retrieval may be carried out, in part, by inhibitory processes.

Retrieval processing involves an interplay between the right prefrontal cortex and the hippocampus in the implementation of search strategies and conscious, effortless retrieval, respectively. The involvement of other areas of the brain such as the precuneus, parietal cortex, anterior cingulate, and cerebellum has yet to be fully elucidated, so much further research is required on this problem.

C. Synthesis: The HERA Model and Its Extension

Stable differences appear to exist in the activations accompanying encoding versus retrieval. The most striking pattern is in the activity of the prefrontal cortex. Most studies of encoding have shown activity in the left prefrontal cortex at a more anterior site, whereas most studies of retrieval have shown activity in the right prefrontal cortex, also at a more anterior site. This hemispheric difference in prefrontal activity in episodic memory is typically referred to as the Hemispheric Encoding–Retrieval Asymmetry model or HERA.

Other areas of the brain have also come to be included in the HERA model. For example, the left cerebellum seems to be more active during retrieval than during encoding. The cerebellum's anatomical connections are predominantly with the contralateral prefrontal cortex (via the thalamus), so that the coupling of right prefrontal and left cerebellar activations is not surprising. What function the cerebellum might be serving in the context of episodic retrieval is unclear. The cerebellum has long been associated with motor coordination and visuomotor skill learning. It is possible that the cerebellum is serving one of these general roles in effortful retrieval, but its exact role remains to be elucidated.

The association cortices have also gained some attention in regard to the HERA model. The left temporal cortex has been found to be activated in some

studies of encoding, whereas activation in the right or bilateral parietal cortex has been documented during retrieval. These findings, though not entirely uncontroversial, seem to follow the HERA pattern, with encoding being a left hemisphere function, in this case in the temporal lobe, and retrieval being a right hemisphere function, in the parietal cortex. There is a great deal of speculation as to exactly what these areas are doing. Some accounts claim that they are involved in some way in the execution of special encoding or retrieval strategies. In the case of the temporal cortex, this might be attaching some kind of mnemonic code to items to ease retrieval later on. Others suggest that the parietal cortex is involved in perceptual aspects of retrieval, such as mental imagery. Further study is necessary to fully understand the functions subserved by these regions, as well as the way that they interact with the other areas of the brain that are active during episodic encoding and retrieval.

It must be noted that there are important exceptions to the HERA model's general description of the patterns of brain activity during tasks of episodic memory. The model does not do well in predicting patterns of activation in the hippocampus. Hippocampal activation has been found unilaterally on the right and left and bilaterally in tasks of both encoding and retrieval. The pattern of activity in the hippocampus is best described as being dependent on the type of material being encoded or retrieved, not on encoding and retrieval by themselves. This is shown by systematic patterns of activation depending on whether verbal or nonverbal stimuli are used in an experiment. Most experiments using verbal information have shown predominantly left hippocampal activity. In contrast, the right hippocampus or both hippocampi may be more active in encoding visual information. For example, a study in which people retrieved information about a spatial route through a town activated bilateral hippocampi. It should be noted as well that the material specificity of activations extends to the prefrontal cortex. One area of prefrontal cortex often observed in studies of episodic memory does not follow HERA but rather depends on whether the stimulus material is verbal or visuospatial, the former producing activation on the left and the latter on the right. So, even within the prefrontal cortex, one region obeys the description given by the HERA model and another does not.

Overall, it does appear that many patterns of activity demonstrated in tasks of episodic memory follow an asymmetric hemispheric pattern in regard to encoding and retrieval. In the prefrontal cortex and in temporal and parietal association areas, activity in the left hemisphere is associated with encoding processing and activity in the right hemisphere is associated with retrieval processing. The cerebellum also shows a hemispheric asymmetry, but it is the reverse pattern with the left cerebellum engaged during retrieval. There are exceptions to this pattern, and these are seen in the hippocampus, posterior regions, and some anterior regions of prefrontal cortex as well. The patterns of activity in these regions are dependent on the modality of the information being processed—verbal information lateralized to the left hemisphere and visuospatial lateralized to the right—rather than encoding and retrieval processes.

D. False Memories

Memories of our personal experiences are extremely vulnerable because memory often is not *reconstructive* but *constructive*. When retrieving an episodic memory, we try to reproduce the event as closely as possible, constructing the most plausible approximation. Consequently, we often incorporate aspects of the event that are close to the original but not exactly it, and we can even insert information that never occurred at all. This vulnerability can even go so far as to produce elaborate situations that never actually happened, though the person might swear that they did.

Neuroimaging studies have begun to examine differences in brain activation, comparing retrieval of a true past event from false memory for an event that did not occur. Most of these studies have used a task in which participants are shown lists of words to study. After a long retention period, the participants are asked to perform a recognition task, indicating which words on a second list were present on the first list. Some of the words on the second list that were not present on the first list, called foils, are semantically related to the words on the first list. For example, the words "pajama, bed, night" might have appeared on the first list, but the word "sleep" might appear at the time of the recognition test. Semantically related foils often were falsely recognized as having appeared on the originally studied list. Furthermore, participants often rated their confidence that the words had been on the original list as highly as they rated their confidence that actual words had appeared. Thus, it appeared as if the participants had created false memories of semantically related foil words.

Neuroimaging studies have compared activations due to falsely recognized words to activations due to

correctly recognized words. One difference that emerges is activation in the frontal cortex during true recognition. This is consistent with other retrieval studies, as reviewed earlier. Another feature of activation is that words on the recognition test that had actually been presented sometimes caused activation in the primary sensory cortex of the modality in which they had appeared. For example, a word presented aurally, when tested at the time of recognition, might show activation in the superior temporal cortex. By contrast, words that did not appear showed no such sensory cortex activation. Thus, a neural signature apparently exists that permits one to distinguish actually presented words from semantically related foils, even if one does not access this signature in the recognition judgments.

IV. SEMANTIC MEMORY

Episodic memory is distinguished by the fact that it requires not only the retrieval of an item from memory but also a source or context for that item. But many times, we retrieve a fact with no knowledge of its context, as when we can identify various types of bicycles without knowing when and where we learned about the various types. Semantic memory can be defined as memory for facts about the world, naked of their source context. This kind of knowledge plays a critical role in all forms of cognition, from language to reasoning to problem-solving. Hence, semantic memory is an important topic for study. Most studies of semantic memory have focused on the retrieval of semantic information from memory because this is studied most readily and because it is more difficult, given the normal course of learning, to study encoding or storage of semantic memory.

A. Verbal Semantic Memory

Many of the concepts that make up our semantic knowledge are coded in the form of language, probably because we are such intensely linguistic creatures. These concepts come from various categories, of course, such as living things and nonliving things, distinctions that we can readily make for many concepts. Evidence from patients with focal brain injury shows that the brain seems to honor some of these categorical distinctions among concepts. For example, there are patients who appear to have lost their ability to identify living things, such an elephant or a flower, even though they are still capable of identifying nonliving things, such as tools. One interpretation of this result is that the brain's organization of semantic memory is, in part, organized by broad categories. To test whether this is so in normal adults as well as brain-injured adults, one study used PET to examine what areas of the brain are active during the retrieval of three different semantic categories. Participants were given several scans during each of which they were asked to name photographs of either famous people, animals, or tools. As predicted, different brain activations resulted from naming each kind of stimulus. Naming famous people produced activity in the most anterior part of the temporal cortex, called the temporal pole. Naming animals produced activity in a more posterior area of the temporal cortex in inferior and middle temporal gyri. Naming tools showed activity in an even more posterior portion of the inferior temporal gyrus. In general, the more specific the item that had to be named, the more anterior the activation in the temporal cortex. These findings are consistent with the notion of a visual processing stream that spreads from occipital cortex into temporal cortex, moving from general classification to more specific categorization in the anterior temporal cortex.

A related PET study of object and face naming provides corroborating evidence for these findings and further distinguishes between activations involved in the identification of specific faces versus the simple recognition of stimuli as faces. In one condition, participants were asked to make gender discrimination judgments of familiar and unfamiliar faces. Relative to a control condition, this task produced activations broadly in the extrastriate occipital cortex. Only when participants identified faces of famous people, and so had to make a specific face identification, were the temporal poles activated. Also activated were other structures in the temporal cortex (fusiform gyri, right lingual and parahippocampal gyri, and left middle temporal gyrus) as well as the orbitofrontal cortex.

Object naming in this study shared some common areas of activation with face naming, including the orbitofrontal cortex, left middle temporal gyrus, and left fusiform gyrus. Converging evidence from animal and lesion studies may shed light on the roles of these regions. Neuropsychological data suggest that the left middle temporal gyrus may be necessary for naming, but not recognizing, objects and faces. Lesions of orbitofrontal cortex have been related to visual memory impairments in animals. Finally, the fusiform

gyri appear to be involved in the recall of both faces and objects, with face recognition activating the right gyrus and object recognition the left. Interestingly, the fusiform gyrus has also been implicated in the *perception* of faces and objects, so the region responsible for semantic memory for this type of information may be similar to the region used to perceive it. This hypothesis is supported by intracortical electrode studies done on patients in preparation for possible surgery to treat epilepsy. These recordings showed that face recognition elicited electrical activity in the fusiform gyrus and that electrical stimulation in this same region resulted in an inability of the patients to name a face for the duration of stimulation.

These complementary results suggest that face perception and recognition share a common substrate and that the boundary between perception and semantic memory may be indistinct for this type of material. Studies of object naming more generally show that semantic memory about concrete objects appears to be organized, at least to some degree, in cortical modules devoted to particular types of remembered material, and these become more specific moving from posterior to anterior brain regions.

Semantic memory for words must take on more than just a simple recognition and naming function. Indeed, when faced with an object it is often more useful to know what can be done with that object rather than just its name. This type of information, as well as information about constructs that are not concrete, is within the domain of semantic memory and has been directly studied.

To examine this sort of semantic memory, a PET experiment was designed that required participants to generate an associated verb for each word in a list of nouns. For example, when shown a picture of an apple, a participant might respond "eat." This experiment revealed a preferential role of lateral and inferior frontal cortex in the generation of verbs associated with visually presented objects. It has been suggested that verbs are at the core of semantic structure, and hence activation in frontal cortical areas might be an indication of which areas are critical in mediating the generation of semantic concepts. Further study of this verb-generation situation compared a task in which participants had to name a verb for each noun presented to two control conditions—reading words and passively viewing words. Multiple subtraction conditions were used to identify areas related to the motor execution of speech (motor cortex), word reading (left insula), and verb generation (left frontal cortex, anterior cingulate, and right cerebellum). This study also revealed changes in activation with practice on this task, as reviewed later. The constellation of regions that were activated in this study probably included a complex combination of areas involved in attention, inferential reasoning, willed action, episodic encoding, and working memory, but most prominently, significant activation occurred in the left prefrontal cortex and elsewhere that could be attributed to semantic retrieval.

V. COGNITIVE SKILL LEARNING

Investigation of practice-related changes in the verb-generation task provides a convenient segue into a discussion of skill acquisition—another vital aspect of memory. After 15 min of practice on the verb-generation task, 90% of the verbs that participants generated were rote responses that had been consistently associated with the nouns. Participants no longer had to search through memory for a novel association; instead, they could quickly recall a response they gave previously. Analysis of the difference between the PET images early and late in the verb-generation task showed that, with practice, activity decreased in the anterior cingulate, left prefrontal cortex, bilateral inferior frontal gyri, left temporal cortex, and right cerebellum—the very areas that were active when verb generation was compared to word reading. In fact, after practice the PET images were indistinguishable from those of word reading. Increases in activation with practice were observed in the precuneus and cuneus on the medial wall of the posterior cerebrum and in the right superior parietal cortex. These shifts in activation could be due to decreased demand on attention and effort, decreased searching of semantic memory, or some other factor.

Without further evidence, it is hard to distinguish among these causes. Certainly evidence exists that some of these areas are involved in other cognitive processes. For example, the left prefrontal cortex is activated in verbal working memory tasks and in the encoding of long-term memories, as we reviewed earlier. The anterior cingulate is also activated in some overpracticed motor tasks, particularly when they might require attending, making inferences about a pattern, or anticipating future stimuli or feedback. One region that may have a clearer role in the practice effect seen in the verb-generation task is the insula, an area located anatomically near the region responsible for speech output and an area that showed increased activation in the verb-generation task with practice.

This activation may be an indication of increasing automaticity in producing verb associations given nouns as stimuli, a kind of stimulus–response connection that developed even over the course of relatively little practice.

Of course, one might ask whether skill in the verb-generation task is a good example of cognitive skill learning in general. The shifts in activation in this task seem to result not from an improved ability to generate *novel* verbs, but rather from the ability to call up from memory the same verb the subject gave on the last trial, a kind of automatic stimulus–response mapping. It is not yet understood how true cognitive skills, such as the ability to make inferences and manipulate abstract concepts, are learned, except that their appearance in children seems to parallel development of the frontal lobes. However, a great deal of what we normally consider to be cognitive skills, such as expertise in chess, can be explained as the formation and retrieval of ever larger and more complex sets of associations in semantic memory.

A final example of cognitive skill learning comes from a PET study of categorization. Experimental studies have shown that people learn to categorize objects in several ways: through the application of rules, learning of specific exemplars of a category, and implicit learning of an average or "prototype" of the category. Patients with medial temporal damage, who have virtually no remaining episodic memory, fail on rule- and exemplar-based categorization but learn prototype-based categorization as readily as do normal participants. In the study, people classified pictures of contrived animals based on previous practice with similar (but not identical) animals. One practice group learned to categorize animals by a rule, and the other group learned the categories by trial and error. The rule group categorized the new animals presented during scanning by applying the rule. The trial-and-error group categorized animals during PET scanning on the basis of their similarity to the animals they saw during training, an exemplar-based strategy. Only rule-based categorization activated the bilateral parietal cortex, right prefrontal cortex, and bilateral supplementary cortex, possibly reflecting greater working memory demands, attention shifting, and retrieval and application of the rule. Exemplar-based categorization activated the left extrastriate cortex and left cerebellum. The extrastriate activation may reflect greater use of a perceptually based memory trace in the exemplar-based strategy, consistent with the involvement of extrastriate visual cortex in studies of implicit memory. This study suggests that different learning regimens may have a profoundly different effect on the brain circuitry recruited to the task, at least for a task requiring categorization processes.

VI. LEARNING PROCEDURAL SKILLS

Procedural knowledge, as described earlier, consists of knowledge of how to do something. It includes all the behaviors shown as examples of procedural knowledge in Fig. 1, common to all of which is the fact that they do not require explicit retrieval of information; rather, they require the person to tap memory in the service of some other task, such as riding a bike taps memory to coordinate the muscles in various ways so that balance can be maintained. This is often called "implicit" memory. Viewed this way, it is clear that a vast number of motor skills are mediated by procedural memory. Of course, procedural memory must develop over the course of practice, and the changes that occur with practice are often highly specific, improving performance on precisely those tasks we practice. Although this may seem to limit our behavioral repertoire, in fact, once we have learned a sequence of motor movements, we can quickly learn to adapt these movements to similar situations.

Skill learning occurs when a new movement or sequence of movements is acquired, and performance becomes both faster and more accurate with training. Sometimes this learning might involve the acquisition of new sensory–motor mappings. Studies of motor skill learning have focused on either the acquisition of some new sequence of motor movements, such as a sequence of finger taps, or the acquisition of some sensory–motor mapping, such as guiding a visual cursor with joystick movements.

A note: it is often difficult to separate the brain areas involved in learning a skill from those involved in other aspects of processing that change along with skill learning. As people learn a skill, for example, they devote less attention to the task, so that neural circuitry responsible for focusing attention is less involved. At the same time, the incidence of errors decreases, so the brain activity related to error detection and correction will decrease. The brain regions responsible for mediating task performance may also change as skills become automatic. All of these changes obscure the interpretation of neuroimaging studies of the learning process by making it difficult to determine which activations are due to skill learning per se and which are due to other processes.

A. Motor Skill Learning

Execution of motor tasks such as tapping fingers in a particular sequence or maintaining contact between a target moving in a circular pattern and a hand-held marker activates large regions of cerebral cortex and subcortical structures, including sensory motor cortex (primarily the primary motor cortex), supplementary motor area (SMA), premotor area (PMA), putamen, cerebellum, and sensorimotor thalamus (see Fig. 2). Traditionally, and consistent with data on the anatomical layout of the motor system, neuroimaging studies have found activations in these areas on the side contralateral to hand movement (with ipsilateral activation of the cerebellum because of its crossed connections to the cortex). However, evidence indicates that complex movement of even one hand can activate motor areas bilaterally. For example, in one experiment, participants rotated two metal balls at a constant rate in either their right or left hand. These complex movements activated the regions mentioned previously, including significant bilateral activations in the postcentral gyrus, traditionally considered primary somatosensory cortex, and intraparietal sulcus. Notably missing from this list of activations is the basal ganglia, which appear to be preferentially activated during the performance of learned sequences of movements.

Areas involved in the learning of motor skills are largely the same areas as those used during task performance. However, some regions become active only during initial 1earning or only after performance has become automatic and requires little effort. These changes are specific to the type of task—they vary depending on whether automatic performance involves increased or decreased use of sensory cues and whether the task involves learning a new movement, a sequence of movements, or a sensory–motor association.

B. Sequence Learning

Among the first motor learning tasks studied is the sequential tapping task, in which participants must tap the fingers of their dominant hand (all studies reviewed here used right-handed subjects) in a prespecified sequence. An early study scanned participants doing sequential finger tapping at three stages in the learning process. The three levels corresponded to an initial learning phase when a skill is first being learned, the phase when a skill becomes automatic after significant practice, and skilled performance after performance level has reached its asymptote. The ipsilateral (right) cerebellum was activated in all three conditions, and the activation per movement in the cerebellum decreased as training progressed. The striatum was also activated during advanced practice, suggesting a role for the basal ganglia in the development of automaticity.

Subsequent studies of sequential finger tapping have examined the role of the cerebellum and other structures, including changes in primary motor cortex, in more depth. Unpracticed performance activated a network of areas often associated with the planning and execution of movements: contralateral primary motor cortex and putamen, bilateral PMA and SMA (with more activity on the contralateral side), and cerebellum. With practice, activity decreased in the lateral portion and deep nuclei of the cerebellum, supporting the view that the cerebellum is important in sequence learning and may be less important in the execution of highly learned sequences.

Subsequent studies examined activations during a sequential finger-tapping task in which participants had to learn the correct sequence by trial and error. The first study compared activations between new sequences, learned sequences, and a resting control. Similar to the earlier studies, the performance of learned sequences with some degree of automaticity activated the contralateral (left) primary motor cortex, PMA, SMA, putamen, bilateral cerebellar hemispheres, vermis, deep cerebellar nuclei, anterior cingulate, parietal cortex, and ventrolateral thalamus. Of course, because sequence performance was compared with a resting condition, this network includes areas responsible for processes irrelevant to sequence learning. When compared to rest, the performance of new sequences showed, in addition to these areas, increases in prefrontal cortex and more extensive activation of the cerebellum. When compared to the practiced sequence directly, learning of a new sequence produced activations in the bilateral PMA, cerebellum, anterior cingulate, prefrontal cortex, and medial thalamus. It seems likely that the requirement that the participant infer the correct sequence on the basis of feedback was responsible for the activation of the anatomically interconnected prefrontal–anterior cingulate–medial thalamus network. However, as we will see later, it is possible that the cerebellum also contributes to error detection and correction.

In another revealing manipulation, participants were asked to pay attention to their finger movements while performing a highly learned sequence. Attention

resulted in the reactivation of the anterior cingulate and prefrontal cortex. By comparing learning of a new sequence with a control condition that required a similar level of attention and similar decision and motor processes, the researchers found activation of the caudate nucleus and cerebellum. This result indicates that these two structures may be important in learning a new sequence, as opposed to other task-related processes. Together, these studies suggest that the basal ganglia and cerebellum, and possibly the PMA, are involved in skill learning, whereas anterior cingulate and prefrontal areas are involved in attention and higher level control processes.

A more controlled version of the tapping task is the Repeated Sequence Task. In this task, participants see a cue appear above one of four squares, and they must touch that square as quickly as possible. As a particular sequence appears more frequently, participants become faster in pressing the appropriate squares. The faster responses for the learned sequence indicate that implicit learning of the sequence has occurred, even though participants have no explicit, declarative memory for the sequence.

Doyon and co-workers, using this paradigm, compared PET activation among several conditions, including different amounts of learning, and included a condition in which subjects were given explicit knowledge of the sequence prior to scanning. Performance on highly learned versus random sequences resulted in increased activation in the right (ipsilateral) ventral striatum, right cerebellum, bilateral anterior cingulate, right medial parietal cortex, and right extrastriate cortex. Decreases were found in the ventrolateral frontal, frontopolar, and lateral parietal cortices, all on the right side. As with previous studies, basal ganglia activity increased when performance was highly learned. These changes are consistent with animal models suggesting a role for the basal ganglia in the performance of movement sequences.

When compared with newly learned sequences, highly learned sequences showed increased activity in the cerebellum, suggesting a role for the cerebellum in sequence performance or in the development of automaticity. This finding contrasts with previous sequence learning studies, which found that cerebellar activity decreases as performance becomes automatic. Thus, further research is necessary to investigate the role of the cerebellum. It is possible that the cerebellum has multiple roles and plays a part both in initial learning and in later retrieval of sequences. An alternative explanation for cerebellar activity in the learned–unlearned comparisons in these studies is that the cerebellum is required for speeding up movements while maintaining a criterion level of accuracy. In the early stages of training, it may be difficult to keep movements speedy, resulting in cerebellar activation that decreases as it becomes easier to perform the task at the requisite speed. This hypothesis highlights the fact that neuroimaging results may be interpreted in multiple ways.

Newly and highly learned sequences in the Repeated Sequence Test were also examined before and after participants were given explicit knowledge of the sequence. Explicit knowledge of highly learned sequences relative to implicit performance decreased activation in the right (ipsilateral) cerebellum and increased activation in the right ventrolateral frontal cortex. Explicit versus implicit knowledge of newly learned sequences resulted in increased activation of the right cerebellum and left ventrolateral frontal cortex.

The sequence learning studies reviewed here implicate the cerebellum and basal ganglia in initial learning and automatization of new skills. Three studies found significant activity in the basal ganglia with practiced, but not novel, sequences. Two other studies found basal ganglia activity in newly learned sequences, one relative to a resting control and the other relative to a free-selection tapping task. The cerebellum appears to be involved in early learning of the sequence, but it is also active during skilled performance relative to rest. Its activity may increase as participants gain skill, if that skill involves making speeded responses to visual cues.

Notably, none of these PET studies showed changes in the primary motor cortex as a function of practice. However, some researchers have shown that skill learning produces nonmonotonic changes in the strength and spread of activation within the primary motor cortex. These researchers scanned participants learning one of two similar finger-tapping sequences using fMRI. Initially, a habituation effect to sequence performance was found: activity in the primary motor cortex was lower when it was performed later in the scanning block. After 30 min of practice, activity in the primary motor cortex was higher when it was performed later in the scanning block, but only for practiced sequences, possibly reflecting fast learning processes that set up later consolidation of a new motor sequence. After 4 weeks of daily practice, more areas in the primary motor cortex were recruited during performance of the learned sequence, showing that practice resulted in a true expansion of the cortical area recruited in the primary motor cortex.

C. Learning Sensory–Motor Associations

What are strikingly missing from analyses of sequence learning, but apparent in other motor learning tasks, are changes in activation of the premotor and supplementary motor cortices. Studies of sequential finger tapping primarily require the learning of associations between movements that form a sequence. This kind of learning may be fundamentally different from learning that requires improvement in coordination or learning an altogether new motor movement. In addition, the finger-tapping task requires a series of internally generated movements rather than movements elicited by sensory cues. We have already seen that learning in the Repeated Sequence Test, which involves visuomotor associative learning, may produce a different pattern of cerebellar activity than learning of internally generated movement sequences. Perhaps examination of nonsequence motor learning, including studies of rotor pursuit, trajectory movements, joystick movements, and maze tracing, may help resolve discrepancies.

Rotor pursuit involves maintaining contact between a hand-held stylus and a target moving in a circular pattern. Several studies have compared rotor pursuit with visual tracking of the stylus, identifying changes due to skill learning of the appropriate hand movement. An initial study showed increases with practice in the primary motor cortex, SMA, and pulvinar nucleus. In a later study, PET scans over 2 days of learning revealed a similar pattern of activation on day 1, this time including practice-related changes in the ipsilateral cerebellum, cingulate, and inferior parietal cortex. On day 2, after an extensive practice period, the rotor pursuit–visual tracking subtraction revealed changes in the putamen and parietal cortex bilaterally and the left (contralateral) PMA. Improvement on the task was correlated with increased activity in the premotor, prefrontal, and cingulate areas and decreased activity in visual processing areas.

An opposite pattern of changes in the PMA and SMA were observed in a series of studies of maze tracing. In the maze-tracing task, participants practiced tracing cutout maze patterns with their eyes closed. Tracing a novel maze with the right hand in a clockwise pattern (relative to a control) resulted in increases in the right PMA and left cerebellum. Practice diminished both of these loci of activity: PET scanning after 10 min of practice produced increases in SMA and decreases in the right PMA and left cerebellum. Contrary to expectations, training affected activity in the ipsilateral cerebrum and contralateral cerebellum. A follow-up study examined maze tracing with the left hand in a counter-clockwise pattern and, strikingly, produced the same results. A third study confirmed that only the primary motor cortex and anterior cerebellum showed activation depending on which hand was used, suggesting that learning and performance in the maze-tracing task require an abstract representation of movements and patterns not directly tied to motor activity.

Contradictory effects of practice in similar tasks, such as that found in PMA and SMA in the studies reviewed earlier, may reflect something of the underlying functions of premotor brain regions. It has been suggested that the SMA is active in the internal generation of responses, and PMA is preferentially active when responses are contingent upon sensory cues. That distinction can be applied to neuroimaging studies of human skill learning. In the rotor pursuit studies, learning of a new motor skill resulted in increased activity in SMA. After the movement was automatic, PMA and basal ganglia were activated in adapting the movement to the motion of the stylus. In the maze studies, initial performance relied heavily on somatosensory feedback from the cutout maze, and so the PMA was heavily recruited. After the maze was well-learned, a coordinated, internally generated movement could be used to trace the maze successfully without reliance on sensory feedback. This type of internally generated movement appears to be the domain of the SMA. Consistent with this view, neuropsychological evidence shows that patients with PMA damage are impaired in sensory-cued motor learning.

A study in which participants had to write the letter "R" found increases in the right PMA and right parietal cortex, possibly indicating enhanced attention to sensory feedback. Again, the activation was unexpectedly ipsilateral to the hand used. When participants wrote the letter as quickly as possible, a network including the left primary motor, PMA, SMA, and right putamen was activated. These experiments also compared writing novel ideograms with the right hand to a baseline in which participants watched the figures being drawn. Novel ideograms, as compared to baseline, activated the left primary motor cortex and right cerebellum. Practiced ideograms minus baseline activated the right PMA, left SMA, and right cerebellum. Once again, cerebellar activity appeared during the initial learning and automatization phases of new visuomotor patterns, but was not apparent when writing the letter "R," a highly practiced ideogram.

These studies show increases in PMA when sensory feedback or external cues are critical for task performance. Right PMA increases appear to be modulated by task demands, e.g., asking participants to be accurate, and independent of the hand used. In the study of unilateral two-ball rotation mentioned earlier, positive correlations were found between unilateral PMA activity during movements of either hand and skill improvement for the ipsilateral hand. Skill improvement was measured during nonscanning intervals by comparing the maximum rotation speed of the balls just after the first scan and just before the last scan. The strongest correlation was between right PMA activity and skill improvement for the right hand. Correlations between left PMA and skill improvement for the left hand were also positive and significant.

The cerebellum appears to play a particular role in the learning of new visuomotor associations. In a classic study, participants made joystick movements to align a cursor with a visual target in one of three joystick–cursor mappings: normal mapping, reversed mapping in which joystick movements caused the cursor to move in the opposite direction, and random mapping with no relationship between joystick and cursor movement. The PET camera in this study was centered on the cerebellum to allow maximum sensitivity to changes in this structure. When the mapping between joystick movements and cursor movements was reversed, cerebellar activity was high during initial learning and decreased as performance improved. When the mapping between joystick movements and cursor movements was random, no learning occurred and cerebellar activity remained high. The authors concluded that the cerebellum contributes to visuomotor skill learning by participating in the detection and correction of errors. It should be noted, in closing, that the cerebellar contribution to skill learning may be primarily in sensory–motor association tasks. Patients with cerebellar atrophy can improve on some motor skill tasks, but they fail to coordinate and adapt movements to environmental contexts.

D. Learning Perceptual Skills

Research on the psychophysics of perceptual learning suggests that long-term learning of skills is not limited to motor areas. This research suggests three striking findings: learning to detect a visual stimulus is specific to a retinal location, it only occurs if the stimulus is behaviorally relevant, and effects of learning remain robust after nearly 3 years without practice.

Although there has been relatively little neuroimaging research on perceptual learning, the research that has been conducted is illuminating. Perhaps the first study was an fMRI experiment of mirror reading. Participants viewed words and matched nonwords printed backward and decided whether the stimulus was a real word. Improvement in mirror reading is still detectable after 2 months of practice, and changes in performance are evident after 1 year without practice. The researchers compared mirror reading with normal reading and practiced, mirror words with unpracticed ones. Mirror reading compared to normal reading produced increases in blood flow in a number of areas, including the medial and lateral occipital cortex, right superior parietal cortex, bilateral fusiform gyrus, pulvinar, and cerebellum, particularly on the right side. Decreases were found in nearby regions of some of the same areas, including the medial occipital and right superior parietal cortices, as well as in the precuneus and bilateral middle–superior temporal gyrus. The occipital, fusiform, and pulvinar areas form an anatomically interconnected network associated with visual processing, object recognition, and visual attention. The authors suggested that these activations were due to visual transformation of the letters in unpracticed mirror reading.

With practice, mirror reading activation increased in the precuneus, left superior parietal cortex and fusiform, and right cerebellum and superior temporal gyrus. Decreases were found in a number of areas, including left lingual gyrus, bilateral occipital cortex, right cerebellum, superior and inferior parietal, inferior temporal, and pulvinar. The deactivation of right superior parietal cortex and occipital cortex could reflect decreased involvement of attention, which is associated with right parietal activation in a number of studies, or it could result from a decreased need to rely on visuospatial transformations. Increases in the left fusiform gyrus, activated in at least one other letter recognition study and in studies of object recognition, could reflect a shift to direct letter recognition processes. Overall, the results are consistent with a shift in strategy from sensory transformation to direct recognition of mirror words.

E. Implicit Memory

All of the studies of skill learning discussed earlier involved both explicit and implicit memory for motor

activity. Although procedural in nature, in most of the tasks participants were allowed to develop conscious recognition of the sequences and movements to be learned. In one study, explicit awareness of a sequence was associated with changes in the cerebellum, ventrolateral frontal cortex, and medial frontal cortex. The remainder of the changes with skill learning, found prominently in parts of the cerebellum, primary motor cortex, SMA, PMA, and basal ganglia, presumably reflect changes in procedural motor processes: the kind you can do, but cannot describe—and, if you are amnesiac, may not remember that you ever learned.

Implicit memory is not limited to motor and perceptual learning, however. Exposure to words, pictures, faces, and other stimuli influences later processing of this information, even though subjects may not remember any of the trained items. This unconscious memory is independent of explicit recollection, meaning that the amount of explicit memory one has for a stimulus does not predict the amount of implicit memory. Also, implicit memory is not affected by depth of encoding as is explicit memory. The two forms of memory appear to be separate species that operate independently of one another. Neuroimaging results support the conclusion that explicit memory and implicit memory are mediated by separate circuits in the brain—explicit memory by the hippocampus, prefrontal cortex, and related circuitry, and implicit memory by perceptual areas similar to those discussed in the previous section.

One of the most common ways to study implicit retrieval is the word stem completion task. In the encoding phase of the task, participants are given a list of words and asked to make some judgment, semantic or otherwise, about the words. Subsequently, the participants are given a list of incomplete words, such as the first three letters, and asked to complete the fragments with whatever word comes to mind. If the fragments match words that they viewed before, participants are more likely to complete the stem with the previously viewed word, whether or not they consciously remember it.

Daniel Schacter and co-workers predicted that, when only implicit memory is involved in a task, stem completion will not activate the hippocampus, the structure critical to explicit episodic memory. They asked participants to count the number of "T" junctions in a list of words and compared activation during stem completion of words from the list with novel words. Participants did not explicitly remember the words, but their performance showed priming effects. Their PET scans revealed no hippocampal activation, but did show decreases in extrastriate (visual) cortex. In another study, Schacter *et al.* compared stem completion when participants had encoded words deeply (when they were required to make semantic judgments) or superficially (when they counted T junctions). Explicit memory and hippocampal activation during stem completion were greater for the deeply processed words. Other studies have replicated this basic finding with object naming and categorization tasks. Taken together, these results indicate a dissociation between explicit and implicit memory; explicit memory involves the activation of hippocampal structures, whereas implicit memory involves the deactivation of posterior neocortex.

Studies in other domains of semantic knowledge, such as object categorization and object naming, show similar priming-related reductions in activation. One explanation of the decrease in activation is that repeated presentations lead to more efficient perceptual processing and lower levels of activation. However, in an auditory word stem completion task studied by Schacter and colleagues, auditory presentation of words and auditory stem completion produced the same regional cerebral blood flow (rCBF) decreases in bilateral extrastriate cortex, as well as decreases in the right anterior medial prefrontal cortex, right angular gyrus, and precuneus. Thus, priming effects on the extrastriate cortex appear to be modality-independent.

VII. SOME CONCLUDING REMARKS

There has been remarkable progress in the study of memory during the last half of the twentieth century. The development of neuroimaging techniques has contributed in no small part to this progress. These techniques have provided a source of evidence about the relationship between brain structure and psychological function that complements evidence from the study of human patients with brain injury, behavioral evidence from normal human subjects, and evidence from animal models. Taken together, these sources of evidence have sketched the outlines of complex memory systems. These systems, in their interaction, form a seamless whole capable of dealing with a variety of cognitive problems. Our memory apparatus has multiple components (working memory, long-term memory), multiple representations of information in different formats (e.g., verbal versus spatial), multiple retrieval schemes (explicit versus implicit), multiple circuitries, and multiple processes (encoding, retention, and retrieval). We are far from getting our arms

around a complete description of this system, but continued use of the full array of investigative tools promises much new progress in the current millenium.

Memory, Overview

JOHN A. LUCAS
Mayo Clinic

GLOSSARY

Alzheimer's disease A gradually progressive degenerative dementia of insidious onset that is characterized by early, prominent memory dysfunction and loss of the ability to perform activities of daily living.

amnesia Loss of memory.

dementia A behavioral description of any acquired disorder that involves amnesia plus impairment of at least one other cognitive ability, such as language, visuospatial function, attention, or problem solving. The degree of cognitive impairment must be severe enough to interfere with social functioning, occupational functioning, or activities of daily living.

Korsakoff syndrome An amnesic disorder resulting from severe thiamine deficiency, most often seen in patients with chronic alcoholism.

neocortex In evolutionary terms, the newest, most highly evolved region of the brain, containing six neuronal layers and forming the outer surface of the brain.

Memory is the ability to maintain previously learned information within an internal storage system so that it may be accessed and used at a later time. Memory may be observed in overt behavior, such as when a student recalls information from previous readings in order to answer questions on a test, or in less readily observable events, such as neuronal development and change. This article reviews the behavioral components of memory as well as the neurobiological bases and underlying neuroanatomical substrates believed to be important to memory functioning.

I. CLASSIFICATION OF MEMORY

Memory is not a unitary construct but instead reflects a number of distinct cognitive abilities that can be categorized along a number of different dimensions. For example, one can characterize memory based on the amount of time that elapses between presentation and recall of information (e.g., short- vs long-term memory) or the nature of the information that is remembered (e.g., visual vs verbal). Memory behaviors can also be characterized by task demands (e.g., recall vs recognition) or by the cognitive processes that underlie these demands (e.g., retrieval vs retention). These and other conceptual divisions of memory are reviewed in this section.

A. Short- and Long-Term Memory

In 1890, William James distinguished between memory that endured for a very brief time and memory that lasted after the experience had been "dropped from consciousness." The former, known as short-term (or primary) memory, refers to one's ability to recall material immediately after it is presented or following uninterrupted rehearsal. The latter, known as long-term (or secondary) memory, refers to the ability to remember information at a later time without the need for intervening rehearsal.

Short-term memory is of limited capacity, holding an average of seven pieces of information at any one time. This information can be maintained for up to several minutes, but it is lost or replaced by new information if not sustained by active rehearsal. A common example of short-term memory is the act of

looking up an unknown telephone number in a directory and dialing that number. The number is held briefly in short-term memory as one looks away from the directory and dials the number. If the telephone is across the room, one can maintain the number in short-term memory by repeating it continuously until it is dialed. Soon after dialing, however, the number is usually forgotten.

In contrast, long-term memory has an extraordinarily large capacity, with the potential for holding information indefinitely without the need for continued rehearsal. For example, one can recall his or her own telephone number, as well as a myriad of other facts, experiences, and personal information, without needing to reference an external source or rehearse the information continuously.

The clinical significance of the distinction between short- and long-term memory has been exemplified in patients with amnesic disorders. One of the most famous case studies in the neuropsychological literature describes a patient (H.M.) who became amnesic following surgical treatment for epilepsy. After surgery, H.M. was unable to retain any new information that he learned, such as the names of new staff in his doctor's office or information that he read each day in the newspaper. His ability to repeat information immediately following presentation or hold onto new information with active rehearsal, however, was normal. This dissociation underscores the distinct nature of the processes required to create new short- and long-term memories.

A second notable dissociation of memory functions demonstrated by H.M. was that although he was unable to form new long-term memories, he could recall previously learned information normally. This discrepancy suggests that the cognitive processes required to retain and access stored information differ from those required to encode new information.

B. Encoding, Retention, and Retrieval

Encoding, retention, and retrieval refer, respectively, to the processes by which information is acquired and transformed into a stored mental representation, maintained over time without active rehearsal, and brought back into consciousness from storage. Successful encoding occurs when an individual demonstrates acquisition of more information than would normally be possible to hold in short-term memory alone. For example, if someone is presented a list of 16 words, he or she might be able to recall only 6 or 7 of those words after seeing the list for the first time (e.g., a normal amount of information that can be held in short-term memory). If the list is repeated, however, a neurologically intact individual will remember increasingly more words with each subsequent repetition. The ability to remember more words than could normally be held in short-term storage indicates that the information has been encoded into a more permanent, long-term storage.

Once information is encoded, it must be retained for later use and accessed when needed. Failure to remember encoded information may indicate a problem with either retention or retrieval mechanisms. These are distinct memory processes that can be distinguished by examining the relationship between free recall and recognition. Free recall of information places maximum demands on retrieval processes because an individual must actively search memory to find and access the information. Recognizing the correct answer among multiple choices, however, is a less difficult memory task because it minimizes search and retrieval demands. If information is retained successfully but cannot be retrieved, free recall will be impaired but recognition of the correct information will be disproportionately better. In contrast, if information is not retained in long-term storage, both recall and recognition of information will be equally poor. The differences in memory performances among individuals with selective deficits in encoding, retention, and retrieval are presented in Fig. 1.

C. Retroactive and Proactive Interference

Memory can be disrupted by events or information encountered at approximately the time of encoding. This disruption is known as an "interference effect."

1. Retroactive Interference

Retroactive interference (RI) refers to the disrupting effect that new learning has on the ability to recall previously learned information. For example, a student studying several text chapters for an exam will be able to recall a greater amount of information from a chapter that he or she has just finished reading than from a chapter that was read earlier in the evening. In this example, information read in the most recent chapter interferes with memory for information from previous chapters.

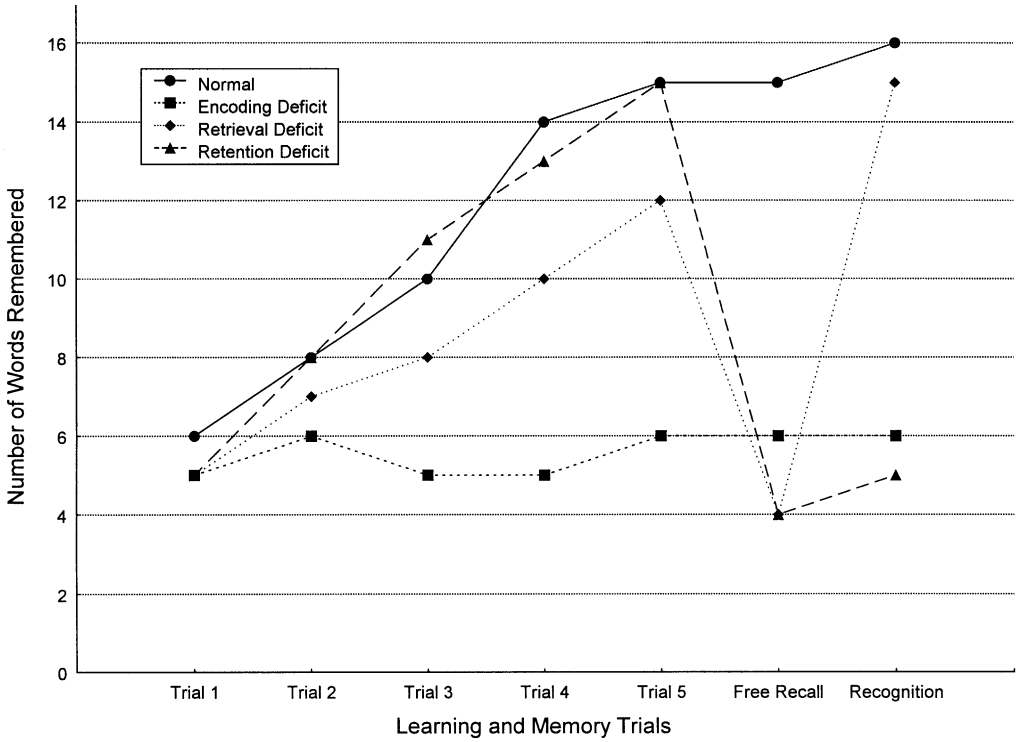

Figure 1 Memory test profiles expected in neurologically intact individuals and patients with primary deficits of encoding, retrieval, or retention. A list of 16 words is presented over five learning trials, with memory for the list assessed immediately after each trial. Memory for the word list is again assessed after a 20-min delay by means of free recall and recognition. Compared to individuals with no memory disorder, patients with encoding problems do not recall more words with repeated exposure to information. Patients with retrieval problems show poor delayed memory when assessed by free recall but normal memory when assessed by recognition. Patients with retention problems do not benefit from recognition testing.

The effect of RI is a function of the amount of new information encountered and the degree to which the interfering information and target information are similar. If a large amount of similar material is presented between initial learning and eventual recall of target information, recall will be poorer than if small amounts of dissimilar information had been presented during the intervening time.

2. Proactive Interference

Proactive interference (PI) occurs when information presented at an earlier time interferes with one's ability to learn and recall new information. For example, suppose one is asked to learn several lists of different words. After the first list is presented and memory for the words is assessed, a new list of words is presented and memory for the new words is assessed. As more lists are presented, memory for the new words declines because previously learned words produce interference.

As with RI, the effect of PI on recall also increases with the amount of interfering information and the degree of similarity to the target information. If one were presented five successive word lists, the effect of PI would be greater after the fifth list was presented than after the second list was presented. In addition, if the lists all contain similar words, such as animal names, memory for each new list will be worse than if each list contained a variety of different words.

One interesting aspect of PI is that presenting dissimilar interfering information can facilitate memory. Using the previous example, suppose a group of individuals are asked to learn four successive word lists, all of which contain different animal names. Now suppose a fifth trial is given. Half of the individuals are presented another list of animal names, whereas the other half are presented a list of words belonging to an unrelated category (e.g., clothing). Results of such an experiment are presented in Fig. 2. Individuals who are presented more animal names on trial 5 continue to demonstrate PI, whereas those presented with a

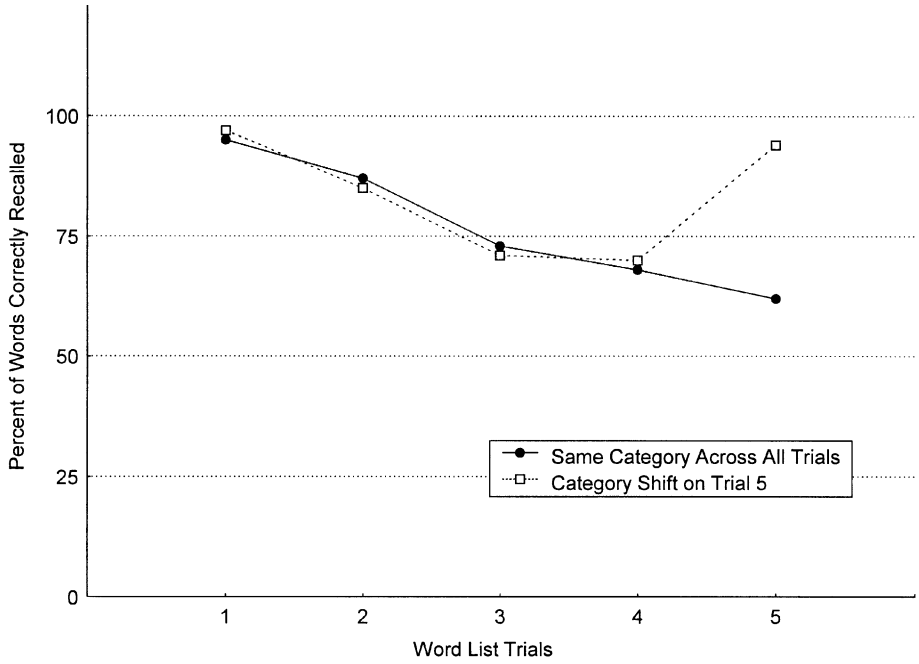

Figure 2 An illustration of proactive interference (PI). On four consecutive trials, study participants are asked to recall different lists of words from the same semantic category (e.g., animals). The effect of PI can be seen in the decline in performance over these trials. On the fifth trial, participants who are asked to recall another set of words from the same category continue to demonstrate PI, whereas those who are asked to recall words from a new semantic category (e.g., clothing) show improvement, known as "release" from PI.

dissimilar list of words demonstrate improved recall. This phenomenon is commonly known as "release" from PI.

D. Anterograde and Retrograde Memory

Anterograde memory is the ability to learn new information and to form new memories from a given moment forward. In contrast, retrograde memory is the ability to recall or recognize information or events that occurred prior to a specific moment in time.

Anterograde and retrograde amnesias are often seen in patients with brain injuries. Patients who are injured in motor vehicle accidents, for example, may not recall the events leading up to the accident (i.e., a retrograde deficit) or the events that occurred immediately following the accident (i.e., an anterograde deficit). The degree of anterograde and retrograde amnesia following a head injury is highly correlated with the severity of brain damage sustained. Anterograde and retrograde amnesias can also occur independently. It is common for patients with certain disorders to have intact memory for past events but poor ability to lay down new memories. The reverse pattern, however, is rare. Individuals who present with complete loss of past memories, personal history, and personal identity typically are found to have psychological rather than neurological disorders.

1. Recent and Remote Memory

The temporal dimension of retrograde memory is often divided into recent versus remote time frames. Recent memory typically refers to information that has been acquired within a relatively short period of time prior to an event (i.e., injury or time of evaluation), whereas remote memory refers to information about events or experiences that occurred years or decades before.

Patients with retrograde amnesia often demonstrate a temporal gradient in which memory for more recent events is disrupted to a greater extent than memory for remote events. This gradient is illustrated by the case of patient P.Z., a distinguished scientist who became amnesic secondary to alcoholic Korsakoff syndrome. Several years prior to the onset of his amnesic syndrome, P.Z. completed an autobiography. Investigators used this information to assess P.Z.'s memory for his own past life events. A temporally graded retrograde amnesic disorder is illustrated in Fig. 3, as this patient demonstrated significantly greater

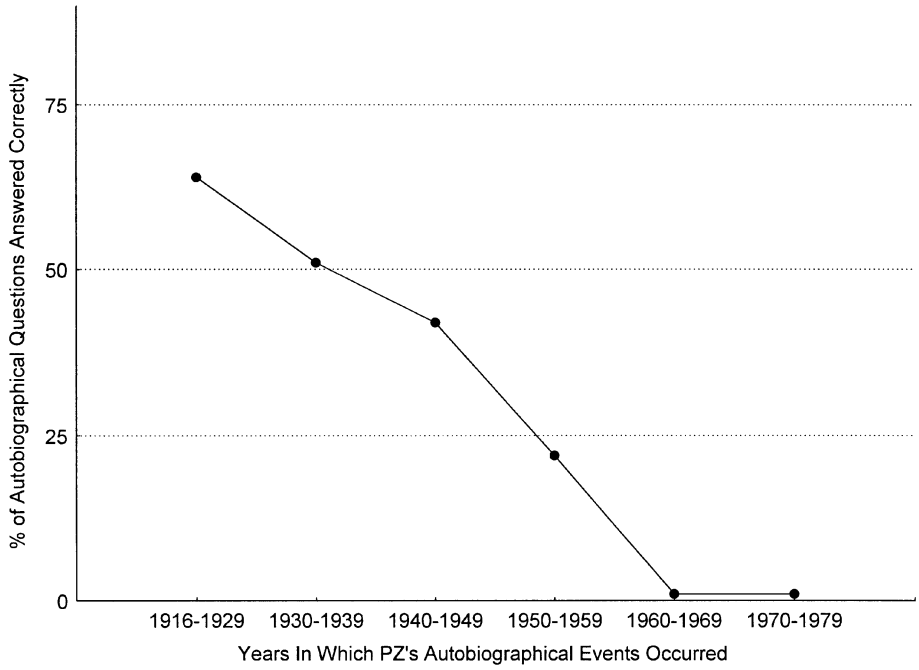

Figure 3 Temporally graded retrograde amnesia for autobiographical information as seen in patient PZ. Information from earlier decades in PZ's life was recalled better than information from recent decades.

impairment of memory for recent experiences and events compared to his memory for events from his early life.

E. Declarative versus Nondeclarative Memory

Declarative memory (also called explicit memory) refers to the acquisition of facts, experiences, and information about events. It is memory that is directly accessible to conscious awareness and thus can be "declared." In contrast, nondeclarative memory (also called implicit memory) refers to various forms of memory that are not directly accessible to consciousness. These include skill and habit learning, classical conditioning, priming, and other situations in which memory is expressed through performance or skill rather than through conscious recollection.

1. Types of Declarative Memory

a. Episodic Memory Episodic memory refers to information that is linked to a particular place and time. The ability to answer questions regarding what you ordered at a restaurant the night before or what information was presented at a meeting you attended are examples of episodic memory. That is, in order to recall the target information correctly, the individual must access information regarding the time and place the information was acquired.

b. Semantic Memory Semantic memory refers to general knowledge that is not linked to a particular temporal or spatial context. For example, defining the word "restaurant" or reciting the alphabet do not require knowledge of where or when that information was originally learned. Both episodic and semantic memories are declarative, however, in that retrieval of information is carried out explicitly, on a conscious level.

2. Types of Nondeclarative Memory

a. Procedural Memory Procedural memory is the process of retrieving information necessary to perform learned skills. These skills may be movement based, such as tying a shoe or riding a bicycle, or they may be perceptual in nature, such as learning to read mirror-reversed text. Although some aspects of skills can be declared, the skills are most often performed automatically, without conscious retrieval of information regarding the procedure. Amnesic patients such as H.M. can learn how to perform several complex tasks

and will demonstrate normal retention of these new skills despite not being able to remember having ever learned how to do the tasks.

b. Conditioning Classical conditioning is one of the most basic forms of learning. A stimulus that naturally produces a certain response is paired with a neutral stimulus. After repeated pairings, the neutral stimulus alone will elicit the response. For example, a dog will naturally begin to salivate when presented food but not when presented with the sound of a bell ringing. If, however, a bell is rung repeatedly along with presentation of food, bell ringing alone will eventually produce salivation. As with procedural memory, patients with very poor declarative memory can demonstrate normal conditioning despite being unable to recall any of the training sessions that led to the conditioned response.

c. Priming Priming is the phenomenon by which prior exposure to information influences performance on later tasks even without conscious awareness. Priming effects are demonstrated by presenting a stimulus on one occasion and measuring its influence on performance on a subsequent occasion. Depending on the level of processing, priming can be perceptual or conceptual in nature. Perceptual priming occurs when exposure to the *form* of a stimulus influences later behavior. Two examples of perceptual processing are priming for picture identification and verbal information. In picture identification tasks, an individual looks at pictures or line drawings of different objects. Later, the individual is presented a series of ''degraded'' pictures (i.e., pictures in which much of the visual information is masked or missing) and asked to identify them. Identification of degraded pictures is faster and more accurate if the individual had previously seen the complete picture than when a novel picture is presented, indicating some form of memory for the information.

Perceptual priming for verbal information is commonly demonstrated in word-stem completion paradigms. During the first phase of the paradigm, individuals perform tasks designed to expose them to different words. For example, they may be shown a series of words and asked to judge whether each word has a ''pleasant'' or ''unpleasant'' connotation. Later, during the test phase, a new task is introduced in which the first three letters of words (i.e., word stems) are presented and the individuals are asked to complete each stem with the first word that comes to mind. Study participants are more likely to complete word stems with words seen during the exposure phase of the study, even if they are less commonly used words. For example, individuals who participate in the exposure task and see the word ''motel'' will be more likely to use that word to complete the word stem ''mot__'' than individuals who did not participate in the exposure task. When not previously exposed to the word ''motel,'' the more common completion of this stem is the more frequently used word, ''mother.''

Although the previous example involves verbal stimuli, it is the perceptual aspect and not the meaning of those stimuli that is primed. When processing the meaning of a stimulus influences later behavior, *conceptual* priming has occurred. The exposure phase of conceptual priming experiments is similar to that of the word-stem completion paradigm. During the test phase, however, participants engage in word-association tasks or other activities that require the processing of word meanings. Suppose, for example, the word ''crown'' is presented during an exposure task. Individuals who were primed by exposure are more likely to respond with the word ''crown'' when asked for the first word that comes to mind in response to the word ''king,'' whereas naive (i.e., ''unprimed'') study participants more often respond with the word ''queen.''

Patients with impaired episodic memory typically perform normally on perceptual priming tasks even though they have no memory of having previously seen the words or pictures that have been primed. Conceptual priming, however, may be reduced in patients with declarative memory dysfunction.

II. NEUROBIOLOGICAL BASES OF MEMORY

Early investigators hypothesized that learning and memory might occur through growth of new neurons in the brain, much in the same way that strength is increased through growth of muscle tissue. It soon became clear, however, that the central nervous system was limited in its ability to generate new cells. Investigators eventually showed that existing neurons possessed the ability to form new processes and connections, and that learning and memory reflected modification of neuronal signal processing, interneuronal communication, and functional relationships among brain systems. There is now a rapidly growing and exciting literature suggesting that generation of new neurons may indeed be possible in adulthood. Although this avenue of exploration holds much promise, to date evidence suggests that neuronal

modification remains the primary mechanism underlying memory formation.

A. Memory as Change of Synaptic Structure and Efficacy

A complete discussion of neuronal function and synaptic transmission of information is beyond the scope of this article. Briefly, a synapse is a functional juxtaposition of two or more neurons (Fig. 4). When a neuron is stimulated to a sufficient degree, chemicals known as neurotransmitters are released from its axon terminal into the microscopic space that separates it from its neighboring neuron. The presence of neurotransmitters within this region produces characteristic changes in the membranes of neighboring neurons.

Each neuron in the brain interconnects with many other neurons in this fashion, forming a series of networks and feedback loops. In the first half of the 20th century, D. O. Hebb proposed that psychologically important events such as memory were manifestations of the flow of activity within a given network of neurons that were acting together as a single unit. He suggested that when an event or experience caused a set of neurons to be excited together, the synapses involved in that pathway became functionally connected.

Although some of the specific neuronal mechanisms that Hebb proposed were not supported by subsequent research, the basic hypothesis of memory as structural

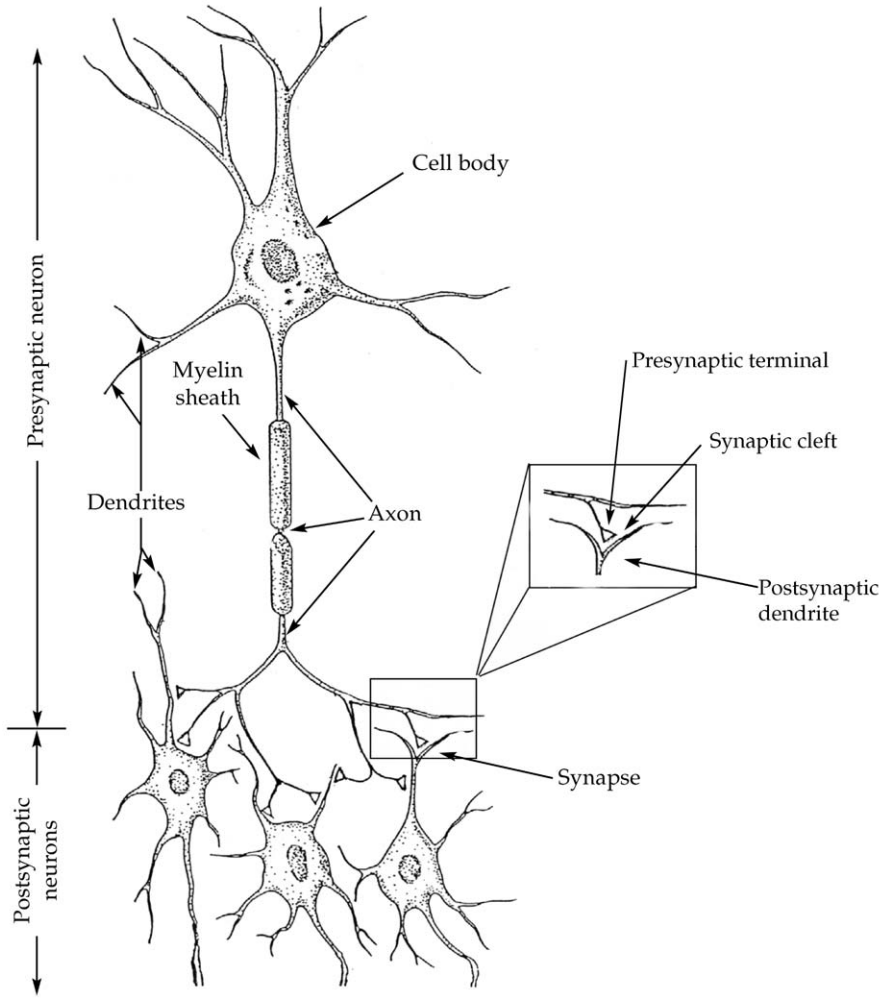

Figure 4 Illustration of the basic structure of neurons and neuronal synapses. Modified from Kandel, E. "Principles of Neural Science," 3rd ed. (1992), The McGraw-Hill Companies. Reproduced with permission of The McGraw-Hill Companies.

and functional change involving neuronal activity and synaptic transmission has endured. Research has shown that when animals are trained to perform specific tasks or are exposed to enriched environments, new synapses grow and preexisting synaptic connections become better developed. Synaptic change in response to new learning is observed in both young and adult animals and can occur subsequent to a single learning experience.

B. Neuronal Processes Underlying Short- and Long-Term Memory

A distinction can be made between the neuronal processes underlying short- versus long-term memory. Although temporary changes in the dynamics of neuronal functioning can maintain information for up to several minutes, more permanent structural changes are believed to be necessary to retain information for days or longer.

1. Neuronal Processes Underlying Short-Term Memory

Studies show that a neuron's function can be modified by intense activity. High-frequency stimulation by a presynaptic neuron, for example, tends to increase the responsiveness and efficiency of postsynaptic membranes, a phenomenon known as potentiation. Some neurons can demonstrate increased responsiveness lasting for several minutes to more than 1 hr after active stimulation has ceased. This temporary increase in synaptic effectiveness is known as posttetanic potentiation (PTP) and reflects one possible way that recently learned information can be remembered. PTP may cause neurons activated during learning to remain active for a brief time after learning has ceased, thus allowing that information to remain available.

Another possible mechanism by which neuronal activity associated with recently learned information may be maintained for a brief period of time is by means of a feedback loop. Specifically, excitatory input from exposure to information could theoretically be maintained after active input ceases if neurons within a closed loop excite each other (Fig. 5). Excitatory neuronal feedback systems such as these are known as reverberatory circuits.

The amount of time that elapses before information in short-term memory degrades is believed to be a function of PTP strength and/or the level of neuronal excitement in reverberatory circuits caused by the learning experience. More intense changes in these neuronal dynamics are typically associated with more persistent memory, whereas weaker changes are associated with more rapid forgetting. Are short- and long-term memories, then, different ends of a single graded continuum of neuronal dynamics, with long term-memory reflecting a chronic state of persisting neuronal activity?

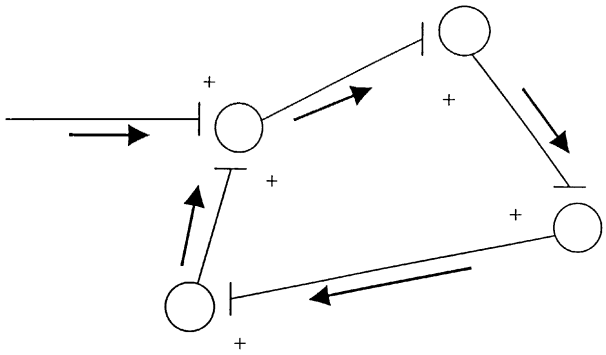

Figure 5 Schematic of a reverberatory circuit. Neuronal responses are prolonged by reexcitation of excitatory neurons.

If both types of memory relied on dynamic mechanisms such as PTP and reverberatory circuits, then interrupting those dynamics should interfere with both short- and long-term memory. Studies of patients undergoing electroconvulsive therapy (ECT), however, show that this is not the case. ECT is a treatment for medically refractory depression that works by delivering low-voltage electric current to the brain. Neuronal activity in the brain is briefly "short-circuited" by this procedure, thus interfering with all electrical activity, including PTP and activity within reverberatory circuits. Following recovery from ECT, patients demonstrate memory loss for information immediately preceding treatment; however, memories in long-term storage remain intact.

2. Neuronal Processes Underlying Long-Term Memory

The ability to encode information into a more permanent long-term storage system is believed to be a function of long-term potentiation (LTP). LTP is similar to PTP in that high-intensity stimulation increases the effectiveness of the neuronal synapse. LTP is much more powerful and longer lasting than PTP, however, and it cannot be produced by activation of only a single presynaptic neuron in a single pathway. Instead, a minimum number of inputs must be present to produce an effect.

Another difference between LTP and PTP is that LTP is associated with the activation of genes that direct the growth and structure of synapses. These neuronal changes are believed to underlie long-term memory formation and are not observed in short-term memory.

It is unlikely that every neuronal synapse is modified by each learned experience, nor is it likely that each memory corresponds to changes in a single neuron in a one-to-one fashion. So where in the brain are long-term memories formed and stored? The first neurons to be discovered that were capable of LTP were found in the hippocampus and surrounding structures, although it has since been recognized that neurons in other brain areas also demonstrate LTP. Similarly, behavioral studies of memory function and dysfunction in humans and animals indicate that a number of different brain regions are important for memory.

III. NEUROANATOMY OF MEMORY

The cumulative literature of learning and memory in humans and nonhuman animals provides a broad outline of the major neuroanatomical structures and connections believed to be important for memory functioning. In the following sections, the neuroanatomical substrates of declarative and nondeclarative memory are reviewed.

A. Neuroanatomical Correlates of Declarative Memory

Several brain regions are believed to be important to encoding and storage of long-term declarative memories. These include structures in the medial temporal lobes, medial diencephalon, basal forebrain, and prefrontal cortex. In addition, certain subcortical nuclei and white matter pathways are important for retrieving acquired information from storage. The gross anatomy of the lateral and medial surfaces of the brain is illustrated in Figs. 6 and 7, whereas some of the more important structures related to memory are illustrated in Fig. 8.

1. The Temporal Lobes

Recall from the beginning of this article the case of H.M., who suffered a profound long-term memory

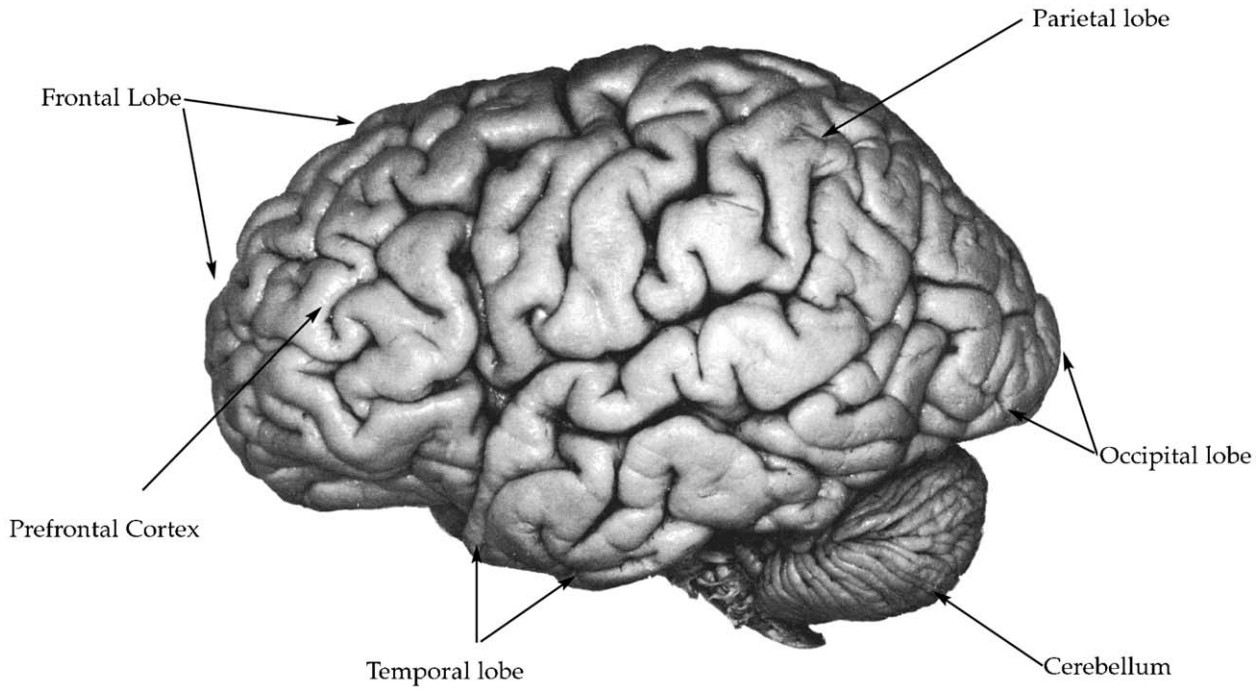

Figure 6 Lateral surface of the brain. From "Structure of the Human Brain: A Photographic Atlas," 3rd ed. by S. J. DeArmond, M. M. Fusco, and M. M. Dewey, copyright 1974, 1976, 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

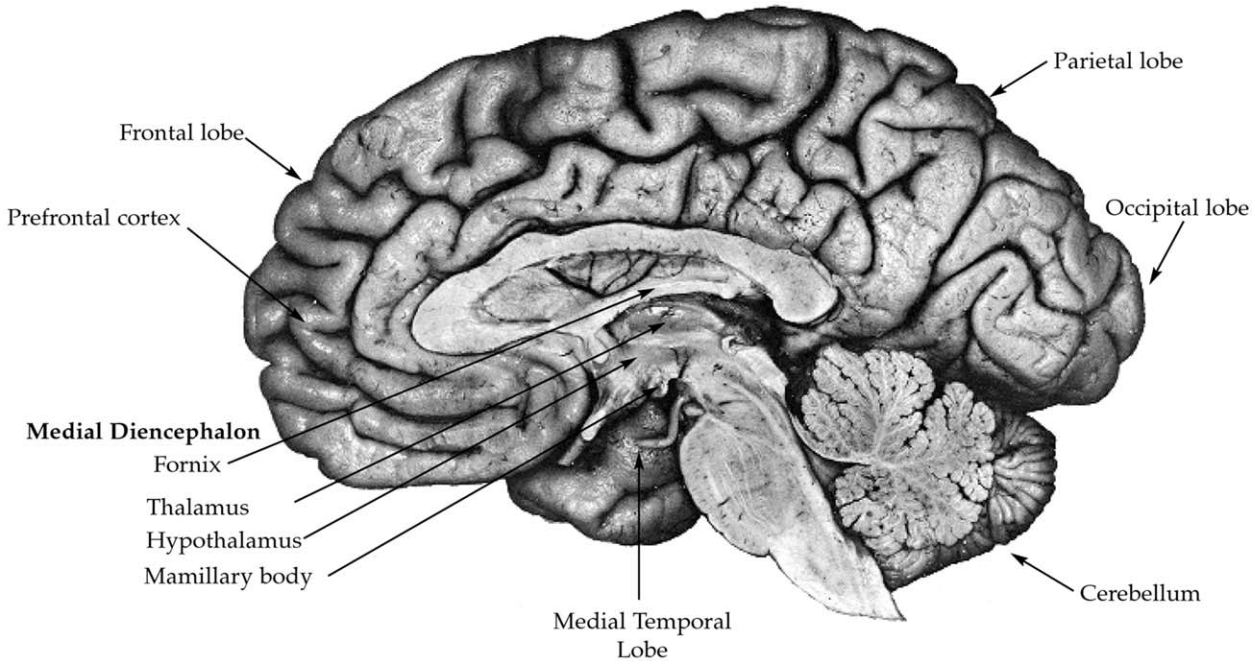

Figure 7 Medial surface of the brain. From "Structure of the Human Brain: A Photographic Atlas," 3rd ed. by S. J. DeArmond, M. M. Fusco, and M. M. Dewey, copyright 1974, 1976, 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

disorder following brain surgery. H.M.'s surgery involved the removal of the medial portion of both temporal lobes, thus demonstrating the importance of this region to long-term memory functioning. Patients with bilateral medial temporal lobe dysfunction typically demonstrate a global anterograde memory deficit. Although short-term memory for newly presented information may be unaffected, these patients cannot encode information into long-term storage. On memory tests, they demonstrate poor recall and poor recognition of previously presented information. Patients with medial temporal lobe damage, however, demonstrate intact memory for information that had been acquired prior to their injury, semantic knowledge, and previously learned skills. They also demonstrate normal priming effects.

Patients with bilateral medial temporal lobe dysfunction demonstrate global declarative memory deficits. The most common cause of this type of brain dysfunction is Alzheimer's disease, a progressive degenerative disorder in which neuropathological changes are first observed in the hippocampus. Other brain regions are affected as dementia progresses; however, the ability to form new episodic memories tends to remain the most significant behavioral symptom.

Patients with focal brain diseases such as stroke or tumors may demonstrate unilateral temporal lobe dysfunction. In such cases, material-specific memory deficits may be observed. Patients with left temporal lobe damage typically have more difficulty learning and remembering verbal material, such as stories or word lists, than nonverbal material, such as abstract geometric patterns, faces, tonal patterns, or the spatial location of objects. Patients with right temporal lobe damage tend to demonstrate the opposite pattern of memory impairment.

The temporal lobe is a relatively large brain region with several anatomically distinct areas. Most investigators agree, however, that the structures in the medial portion of the temporal lobes—specifically the hippocampus, its surrounding cortex, and the amygdala—are most important for memory (Figs. 8–10).

a. The Hippocampus and Related Structures The human hippocampus and associated cortices are located bilaterally in the cerebral hemispheres, forming a ridge that extends along the temporal horn of each lateral ventricle. As illustrated in Fig. 9, these structures are convoluted in shape, with several distinct regions defined by differences in cellular structure and organization. Proceeding from the collateral sulcus, the parahippocampal gyrus curves dorsally, transitioning into the subiculum, which curves medially and transitions into the hippocampus

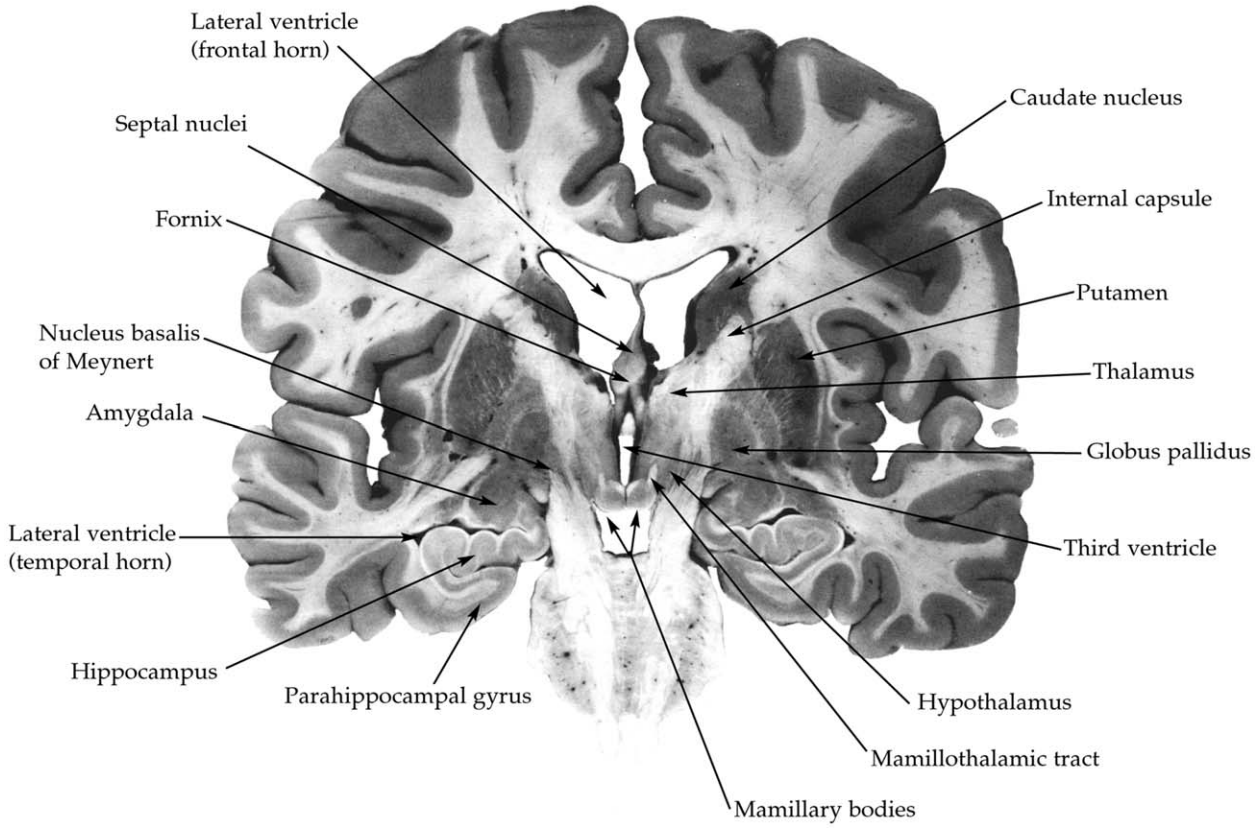

Figure 8 Coronal section of the brain at the level of the anterior portion of the temporal lobes illustrating many of the structures believed to be important to memory. From "Structure of the Human Brain: A Photographic Atlas," 3rd ed. by S. J. DeArmond, M. M. Fusco, and M. M. Dewey, copyright 1974, 1976, 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

proper. The hippocampus curves inward again, forming the hippocampal fissure. When the hippocampal fissure is opened, a narrow layer of cortex can be observed, known as the dentate gyrus. Axons arise from neurons comprising the hippocampus proper, converge to form the fimbria, and continue into the fornix, which is the major white matter tract out of the hippocampal formation.

b. The Amygdala The amygdala is a collection of nuclei and specialized cortical areas situated in the dorsomedial portion of the temporal lobe rostral and dorsal to the tip of the temporal horn of the lateral ventricle (Fig. 8). Although early investigators believed the amygdala was primarily an olfactory structure, later studies revealed substantial inputs from brain regions responsible for processing many different types of sensory information, including visual, auditory, somatosensory, and autonomic stimuli. Outputs from the amygdala project to many brain regions believed to be important to memory, including the hippocampal formation, thalamus, hypothalamus, prefrontal cortex, basal forebrain, and corpus striatum.

The amygdala is important to emotional, autonomic, reproductive, and feeding behaviors. Electrical stimulation of the amygdala in animals typically results in a constellation of aggressive and fear-related responses. Bilateral lesions to the amygdala in humans result in Klüver–Bucy syndrome, a disorder characterized by excessive docility, lack of fear response, hypersexuality, hyperorality, and changes in dietary habits.

c. Relative Contributions of the Hippocampus and Amygdala to Memory Given the close proximity of the hippocampus to the amygdala, both structures are typically damaged in clinical cases of amnesia, thus leading to the question of which structure is more important to memory. The preponderance of case studies reported in the literature suggest that when damage is restricted to the hippocampus proper,

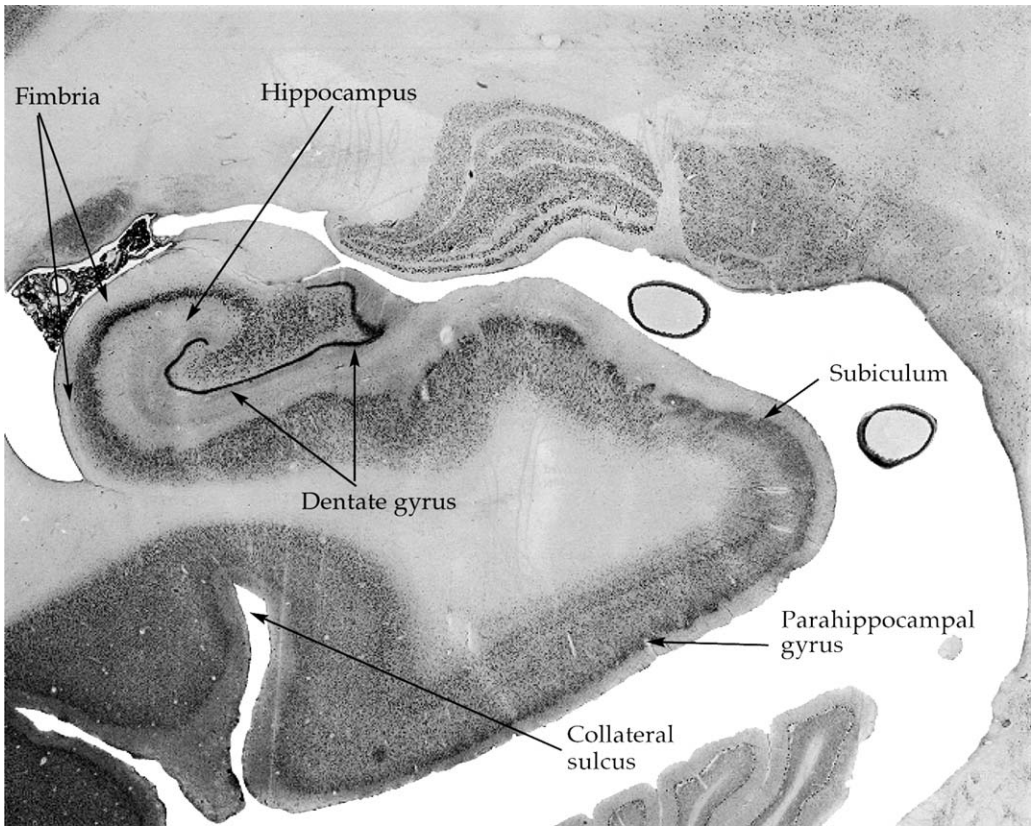

Figure 9 Illustration of a transverse section through the human hippocampal formation and parahippocampal gyrus. From "Structure of the Human Brain: A Photographic Atlas," 3rd ed. by S. J. DeArmond, M. M. Fusco, and M. M. Dewey, copyright 1974, 1976, 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

fimbria, dentate gyrus, and subiculum, declarative memory impairment is less severe than when there is more radical loss of tissue.

Similar findings have been observed in nonhuman primates. When the hippocampal formation and its adjacent cortical region are lesioned, less severe declarative memory disturbance is observed than when the amygdala and its adjacent cortices are also involved. The most severe deficit is observed when the hippocampus, its adjacent cortical region, and the cortical region adjacent to the amygdala (i.e., the entorhinal and perirhinal cortices) are damaged. Damage to the amygdala, however, does not create any greater declarative memory deficit beyond what is caused by damage to the other three brain regions.

As discussed earlier, the amygdala is known to be important for processing sensory stimuli and information related to emotions. Studies show that the amygdala is important for remembering the emotional context of information. It is also implicated in certain types of nondeclarative memory, such as conditioning and evoking fear-related behaviors.

2. The Medial Diencephalon

The diencephalon is a region of several important nuclei located at the rostral part of the brain stem (Figs. 7 and 8). This region can be divided into four major areas: the epithalamus, thalamus, hypothalamus, and subthalamus. The divisions important to memory functioning include portions of the thalamus and hypothalamus. The thalamus is the largest subdivision of the diencephalon and is composed of several histopathologically distinct nuclei (Fig. 10). The hypothalamus lies below the thalamus and creates the floor of the third ventricle. It controls many autonomic, endocrine, and somatic functions and is composed of several distinct anatomical structures, including the mamillary bodies.

Severe amnesia results from damage to regions along the midline of the thalamus and hypothalamus.

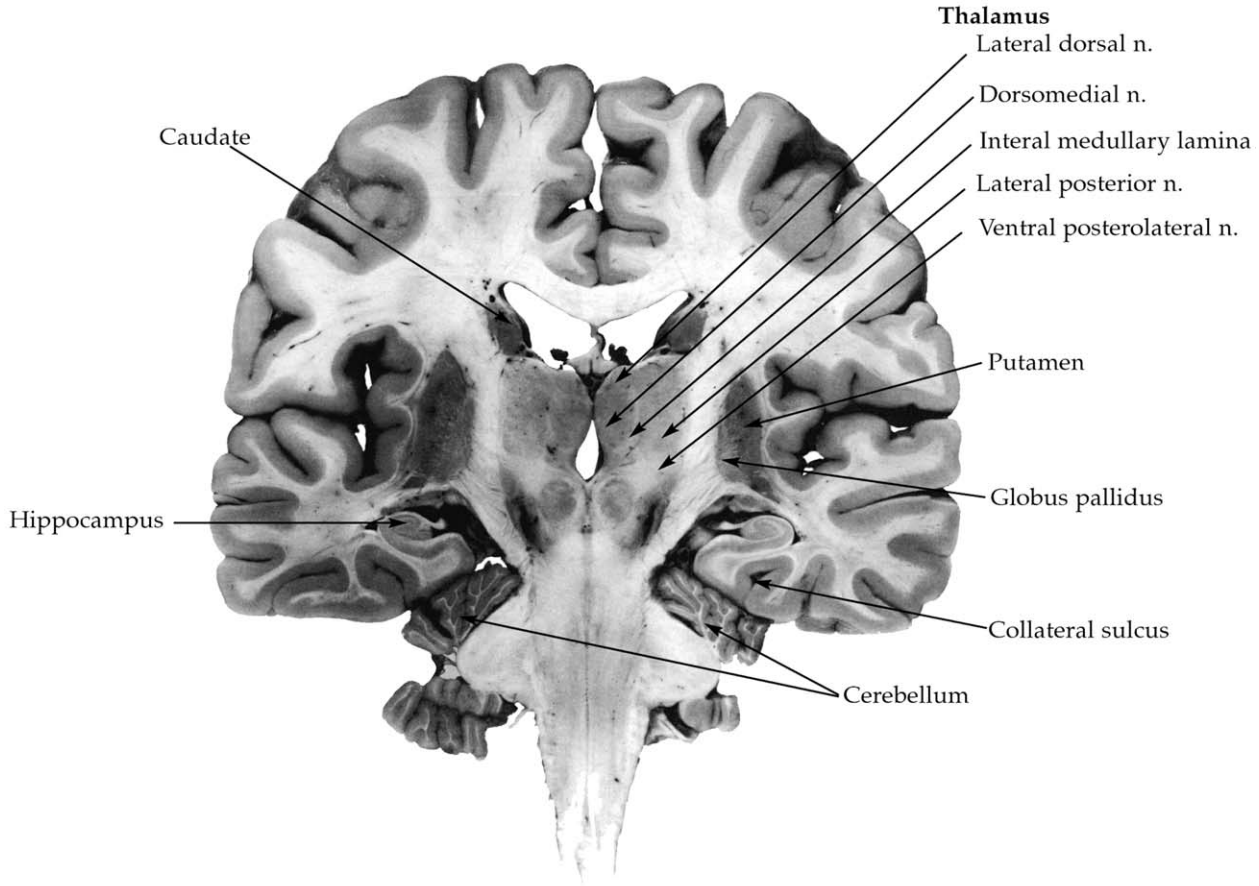

Figure 10 Coronal section of the brain at the level of the midbrain illustrating the thalamic nuclei. From "Structure of the Human Brain: A Photographic Atlas," 3rd ed. by S. J. DeArmond, M. M. Fusco, and M. M. Dewey, copyright 1974, 1976, 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

There has been considerable controversy, however, concerning which of the many neuroanatomical structures and connections in this region must be damaged to cause memory dysfunction. The structures that have most often been implicated in diencephalic amnesia are the dorsomedial nucleus of the thalamus, the mamillary bodies of the hypothalamus, and the white matter (mamillothalamic) tract connecting these structures.

Patients who most commonly demonstrate diencephalic amnesia are individuals with Wernicke–Korsakoff syndrome. This disorder is caused by severe thiamine deficiency, often associated with chronic severe alcoholism. The first stage of this disorder involves an acute, global confusional state, oculomotor abnormalities, ataxia, and peripheral polyneuropathy. This stage is known as Wernicke's encephalopathy, during which the patient is in danger of suffering a potentially fatal midbrain hemorrhage unless treated immediately with thiamine. Approximately one-fourth of successfully treated patients regain the majority of their premorbid cognitive abilities. The remaining 75%, however, demonstrate severe, persistent anterograde and retrograde memory deficits.

a. The Mamillary Bodies and Dorsomedial Nucleus The mamillary bodies and dorsomedial nucleus of the thalamus are both frequently damaged in Korsakoff syndrome. The few case studies in the literature of patients with naturally occurring lesions suggest that damage restricted to either the dorsomedial nucleus or the mamillary bodies is capable of interfering with memory.

In monkeys, lesions involving both the mamillary bodies and the dorsomedial thalamic nucleus result in memory deficits that are substantially more severe than those caused by lesions to either structure separately. Moreover, lesions to any single

diencephalic structure appear to produce less memory impairment than lesions to the hippocampal formation.

b. The Internal Medullary Lamina A series of studies using an animal model of alcoholic Korsakoff syndrome in rats suggested that damage to the internal medullary lamina may also be critical in diencephalic amnesia. Diencephalic damage induced in rats via an experimentally controlled thiamine deficiency caused bilateral lesions in the mamillary bodies, dorsomedial nucleus of the thalamus, and internal medullary lamina of the thalamus. Rats with radio frequency-induced lesions to the internal medullary lamina demonstrated more similarities to rats with thiamine deficiency on measures of spatial memory than to rats with lesions to the mamillary bodies or midline thalamic nuclei.

3. The Basal Forebrain

Significant memory dysfunction has been associated with damage to the basal forebrain. The basal forebrain is a loose term used to describe the area of the brain superior to the optic chiasm. It includes the medial septal nuclei, nucleus accumbens, anterior hypothalamus, diagonal band of Broca, nucleus basalis of Meynert, and part of the prefrontal cortex (i.e., Brodmann's area 13). The structures within the basal forebrain project widely throughout the rest of the brain. The septal nuclei and nucleus basalis of Meynert (Fig. 8), for example, have extensive connections to and from the hippocampal formation, amygdala, and neocortex and are believed to be important to memory functioning.

Basal forebrain involvement in memory functioning is implicated primarily from the study of two patient groups: patients with ruptured aneurysm of the anterior communicating artery and patients with dementia due to Alzheimer's disease. The basal forebrain is perfused primarily by branches of the anterior communicating artery; thus, disturbances within this flow of circulation result in infarction and necrosis of basal forebrain tissue. Patients with stroke, hemorrhage, or damage to this area subsequent to aneurysm surgery often demonstrate declarative memory deficits.

Patients with Alzheimer's disease demonstrate marked degeneration within the basal forebrain as well as in the medial temporal lobes, as discussed earlier. The region of the basal forebrain most affected by Alzheimer's disease is the nucleus basalis of Meynert, a complex of neurons that produce the neurotransmitter acetylcholine. Recall that the ability to learn and remember new information reflects enhanced communication among neurons due to the development and growth of synapses. This growth occurs when neurotransmitters are in adequate supply. The primary neurotransmitter associated with the ability to encode and retain new declarative memories is acetylcholine. Thus, the depletion of acetylcholine in the brain caused by degeneration of neurons in the nucleus basalis of Meynert is believed to underlie part of the memory disorder associated with Alzheimer's disease.

In monkeys, combined lesions to the nucleus basalis of Meynert, medial septal nuclei, and diagonal band of Broca result in significant memory impairment. No significant memory impairment is noted, however, if each structure is lesioned separately. Thus, it appears that extensive damage to the basal forebrain, rather than specific damage to any given structure, is necessary to produce memory impairment. In light of these findings and the presence of extensive anatomical connections between the basal forebrain and medial temporal lobe structures, some have suggested that the basal forebrain most likely modulates medial temporal lobe memory processing but is not in and of itself a memory center.

4. The Prefrontal Cortex

Functional neuroimaging studies have found that activity in the anterior region of the prefrontal cortex (Figs. 6 and 7) increases when one attempts to retrieve previously learned information. Specifically, the prefrontal cortex is believed to play an important role in directing the attentional and organizational processes necessary for both encoding and retrieval of information. Disruption of these cognitive processes is associated with characteristic memory impairments, including source memory deficits, impaired temporal ordering, and confabulation.

Source memory and temporal ordering refer to the ability to recall the spatial and temporal contexts within which information was originally acquired. Patients with prefrontal cortical damage may recall factual information correctly, but they often have difficulty recalling where they learned the information. If they learned several pieces of information over a period of time, they may recall all the information adequately but be unable to report which information was learned first.

Another interesting behavioral consequence of prefrontal damage is the tendency to confabulate.

When patients with prefrontal damage cannot recall factual information, they often fabricate false information rather than indicate that they do not remember the correct information. This is different from lying because these patients have no desire or intent to deceive. Confabulation is believed to be a manifestation of source memory and temporal ordering deficits, coupled with poor self-monitoring abilities. When spatial and temporal contexts of information are missing it becomes very difficult to select accurate recollections from all the possible information that can be retrieved in a memory search. Patients with prefrontal damage, it is argued, simply choose one of the many alternatives retrieved from memory.

5. Subcortical Nuclei and White Matter

As illustrated in Figs. 8–10, two kinds of substances can be appreciated when the brain is cut—one light and one dark. The dark substance is known as gray matter and contains neuronal bodies, dendrites, and synapses. Gray matter covers the external surface of the brain (i.e., the cortex) and forms several discrete nuclei within the central portion of the brain (i.e., subcortical nuclei). The light substance separating the cortical and subcortical gray matter is known as white matter. White matter is made up of neuronal axons, the majority of which are covered in fatty sheaths known as myelin. It is the myelin that is responsible for the white appearance of these regions.

Information is processed and encoded in gray matter, whereas the white matter pathways provide the means by which information is transferred and communicated throughout the brain. Research suggests that the ability to search and retrieve information from long-term memory stores is a function of subcortical nuclei and white matter systems. These data derive primarily from studies of patients with basal ganglia diseases, such as Parkinson's disease and Huntington's disease, and from studies of patients with white matter diseases, such as multiple sclerosis. These patients tend to be slower when processing and learning information, and they demonstrate poor free recall. Their recognition memory, however, is usually equivalent to that of healthy controls, indicating a primary retrieval deficit.

B. A Model of Encoding and Memory Storage

Memory researchers believe that after sensory information is processed by the neocortex, it is sent along parallel pathways to the hippocampal cortices and medial diencephalon for memory processing. During encoding, associations are created among stimulus features. These associations serve as indices to the cortical sites where the information was originally processed. Input from the basal forebrain and prefrontal cortex modulates memory processing and tags the newly learned information with temporal and spatial information.

Once memories are formed, they must be stored in such a way as to be searched and accessed at a later time when the information is needed. One possibility is that long-term memories are stored in the same brain structures in which new memories are formed. Research on amnesic patients, however, suggests that this is unlikely. Patient H.M., for example, lost the ability to form new memories following bilateral removal of medial temporal lobe structures, but he was able to recall previously learned information normally. This suggests that after new memories are formed they are transferred elsewhere for long-term storage. Researchers believe that permanent memory storage develops in the neocortex; however, the exact nature of the stored information is not known. It remains unclear, for example, whether information is stored regionally or more diffusely throughout the brain and whether memories are stored as basic elemental forms or in more complex formats.

C. Neuroanatomical Correlates of Nondeclarative Memory

Nondeclarative memory is performance based and comprised of phenomena such as skill learning, conditioning, and priming. Unlike declarative memory, the formation of nondeclarative memories is not reliant on the medial temporal lobe/medial diencephalic system. Instead, memories underlying acquired skills or conditioned or primed responses are a function of the sensory and motor systems inherent in the involved behaviors.

1. Skill Learning and Memory

The ability to learn new motor skills and procedures is a function of the corticostriatal system and the cerebellum. The coroticostriatal system includes the basal ganglia and its projections from the neocortex. The basal ganglia are large subcortical nuclei that include the caudate nucleus, putamen, and globus

pallidus (Figs. 8 and 10). The basal ganglia have extensive connections with the thalamus, subthalamic nucleus, amygdala, substantia nigra, and broad regions of the neocortex.

The basal ganglia are important for motor planning and programming. Patients with diseases causing dysfunction of the basal ganglia, such as Parkinson's disease and Huntington's disease, typically demonstrate impaired motor skill learning. Learning a new skill requires development and modification of accurate motor programs. As the skill is learned, appropriate movements are performed in the correct serial order and the correct temporal pattern within that order. A feedback system detects errors and generates new, more accurate movements as a result. Dysfunction of the basal ganglia interrupts complex motor and sensory circuits and thus interferes with the ability to generate and/or modify motor programs.

Skill learning that depends on integrating visual and motor information or that requires visual feedback to develop and refine the skill is believed to be a function of the cerebellum. Lesions to the cerebellum are associated with impairments of abilities such as learning and demonstrating the skill of tracing objects when looking at them in a mirror.

Learning visual perceptual skills that do not require motor responses, such as the ability to read text that is presented in reverse mirror-image, depends on the integrity of posterior cortical regions. During learning, the right parietal region becomes activated, presumably because of the need to process the visuospatial aspects of the information. Once the skill is acquired, however, this region becomes less active while activity in the left temporooccipital region increases. The left temporooccipital region is important to normal reading, suggesting that once the skill is learned, the need to decode the visuospatial aspects of the words diminishes and skilled reading occurs.

2. Conditioning

Animal studies indicate that the cerebellum is responsible for most types of conditioned learning. Electrophysiologic changes are observed in the cerebellum during conditioned learning, whereas lesions to the cerebellum disrupt learning. Electrophysiologic changes are also noted in the hippocampus during classical conditioning. Lesions to the hippocampus, however, do not inhibit conditioned learning, suggesting that the hippocampus reflects a parallel information processing system during conditioning but does not in and of itself mediate conditioned learning. In humans, naturally occurring cerebellar lesions have been shown to interfere with conditioning, whereas lesions to the medial temporal lobes, medial diencephalon, or basal ganglia have no effect on conditioned learning.

The ability to condition a fear response by pairing a neutral stimulus, such as a light or tone, with an aversive unconditioned stimulus, such as electric shock, is a special case of classical conditioning and is a function of the amygdala. Ablation of the amygdala in a variety of mammalian species interferes with the animal's innate fear response and its ability to learn new fear responses. The site of storage for long-term fear-related memory, however, is believed to be outside the amygdala. When the amygdala is lesioned shortly after a new fear response is conditioned, the animal will not demonstrate the response; however, lesioning the amygdala several days after successful conditioning causes no disruption in the conditioned response. Brain areas that have been implicated as possible storage sites for fear memories include the insular cortex and the vermis of the cerebellum.

3. Priming

Patients with dysfunction of the medial temporal lobe, medial diencephalon, and basal ganglia demonstrate intact perceptual priming despite impaired declarative memory or skill learning. Therefore, perceptual priming does not appear to be dependent on these brain regions. Instead, perceptual priming is a function of the cortical regions necessary to process whatever information is primed. Brain imaging studies, for example, show that the right posterior cortex (i.e., the brain region responsible for processing physical features of visual stimuli) is necessary for perceptual priming of words. Patients with damage to this region do not demonstrate visual word priming despite the ability to remember the words on explicit recall tasks. Brain regions required for other forms of perceptual priming likely include cortical regions involved in processing the stimulus qualities and external demands inherent to the individual priming task. Conceptual priming, on the other hand, is believed to be a function of the left frontal cortex.

IV. SUMMARY

The past several decades have witnessed great progress in our understanding of cognitive, biological, and

neuroanatomical processes underlying memory functioning. We have learned, for example, that there are two dissociable memory systems—one that is conscious and declarative in nature and another that is unconscious and expressed through performance rather than through conscious recollection. Each of these broad categories of memory is composed of several qualitatively different functions that can be defined along a variety of dimensions.

We have also learned that encoding and memory reflect changes in neuronal function in different brain structures. The medial temporal lobe structures and medial diencephalon, for example, are critical for the formation of new declarative memories but have little impact on memory for previously learned information or nondeclarative forms of learning and memory. On the other hand, basal ganglia dysfunction can disrupt some aspects of nondeclarative memory (i.e., skill learning) while sparing declarative memory. The cerebellum is essential to most forms of classical conditioning, whereas the amygdala plays a key role in conditioned learning of fear responses and emotional modulation of memory.

Despite our advances in knowledge, we still know relatively little about where and how memories are preserved in long-term storage. We know that this information is not stored in the brain structures in which they are created and we presume instead that they are stored in the neocortex. The exact location and format in which memories are preserved over long periods of time remain unclear.

GLOSSARY

akathisia Involuntary motor restlessness with increased fidgety behaviors.

brachycephaly The physical feature of having a broad or tall head.

dyskinesia Involuntary nonrhythmic motor movements that can be slow or fast and usually involve movements of the mouth.

epicanthic folds Folds of skins at the inside corner of the eye, common in persons with Down's syndrome.

hypogonadism Decreased function of the sex glands.

idiopathic Relating to or designating a disease having no known cause.

incidence The number of new cases of disease occurring in a period of time divided by the number of people at risk during that period.

macroorchidism Enlarged testes.

nystagmus Involuntary rapid movements of the eyes.

philtrum The groove in the midline of the lips.

prevalence The total number of cases of a disorder existing within a population at a given time or in a given area.

strabismus Deviation of one or both of the eyes during forward gaze.

Mental retardation refers to substantial limitations in a person's level of present functioning. It is characterized by significantly subaverage intellectual functioning, existing concurrently with related limitations in two or more of the following applicable adaptive skill areas, communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. Mental retardation manifests before age 18.

I. INTRODUCTION

The term mental retardation represents divergent meanings to different persons. It is a general label that incorporates a heterogeneous group of persons, including those with variable cognitive aptitudes, emotional functioning and adjustment, and social development. It can be described as a concept, condition, symptom, or syndrome. The purpose of this article is to elucidate the

facets of mental retardation by focusing on its history, definitional issues, legal implications, etiology and prevention, prevalence, characteristics within specific syndromes, comorbid psychopathology, and treatment.

II. HISTORY OF MENTAL RETARDATION

There is a long history of persons with mental retardation that dates back to antiquity. In general, the view of persons with mental retardation varied based on accompanying social, political, and religious beliefs. Earliest recordings of mental retardation are found at approximately 1500 BC from ancient Egypt. These recordings refer to those whom we would distinguish as persons with mental retardation as being inferior, needing to be separate from society, and having the real possibility of being put to death because of their unusual presentation and limitations. In the Greco-Roman period (1300 BC to AD 476), persons with handicaps were not regarded as being fully human. They were placed alongside slaves and women, who could not take part in public life. They were described as the "private people" or "the idiots." Neglect, infanticide, cruelty, and abuse were common.

The Middle Ages, Renaissance, and Reformation (476 to the 16th century) began with the fall of Rome and the subsequent heightened status of Christianity. This resulted in a period of time in which the church, through foundling homes and orphanages, provided for those whom they believed were mentally deficient. These individuals came to be known as children of innocence and of God who were to be protected. Later in this period, Martin Luther proposed that "feeble-minded children" were a result of sin and the Devil, and that they and their mothers should be burned at the stake. Luther's view was one that influenced society in a pervasive manner. Throughout all the foregoing years of the Middle Ages, there was little true understanding of mental retardation and limited acknowledgment that mental retardation was separate from other disorders. Instances of formal recognition of mental retardation as a general disorder were sparse.

During the 17th and 18th centuries, the Enlightenment period, advances in medicine as well as the philosophical thought of that time played important roles in the conceptualization of mental retardation. In the medical field, many physicians wrote about mental retardation, epilepsy, hydrocephalus, and cretinism. Locke was the first to distinguish between "idiocy" and "insanity," and he and Rousseau advocated for the influences of the environment on impacting the outcome of human capacity. This cultural enlightenment served as a catalyst to the scientific study of mental retardation and the development of more humane treatment programs.

The Age of Progress (1800–1899), championed by the leadership of French physicians and educators, brought the formal emergence of the construct that today we refer to as mental retardation. It was during this era that the variability in cognitive functioning began to be appreciated, and this increased understanding contributed to the development of treatment programs. The National Institutes for Deaf-Mutes in France hired Jean-Marc Gaspard Itard in 1800 to work with Victor, a feral child found in the woods. Itard developed a broad educational program that focused on Victor's senses, intellect, and emotions. Itard believed that Victor, who by today's standards would most likely be classified as moderately or severely retarded, had not been born in his present mental state, but that his intellectual deficiencies were a consequence of the absence of sensory experiences in a socialized environment. Itard worked diligently with Victor for 5 years but considered himself a failure since Victor was not fully remediable. However, the benefits of his work, such as the thorough recounting of Victor's mental processes and the specifications of the education program, advanced the scientific study and humane treatment of persons with mental retardation.

During this time period (circa 1830) another Frenchman, Esquirol, provided the first classification scheme. He identified two levels of mental retardation that were distinguished by the extent of both cognitive deficiencies and coping impairments: idiot and imbecile. These terms are approximately synonymous with the more current terminology of moderate and severe mental retardation, respectively.

Edward Seguin, a French physician and educator, also had a significant impact on the field by his endeavoring to aggrandize treatment efforts and education programs. He was convinced all persons deserved to be educated and that this was a universal right. Seguin believed that society had an obligation to improve the circumstances of all its members, and those individuals with mental retardation were among the most needy. As such, Sequin developed gradated care based on one's level of need: full supportive care for the most severe and protective care coupled with training for the others. Seguin was later appointed head of the Pennsylvania Training School for Idiotic and Feeble-Minded Children (later renamed Pennsylvania Training School, Elwyn School, and then the Elwyn Institute). By 1857 the population at the

Pennsylvania Training School was 175 students, and less than 50 years later the Pennsylvania Training School served 1041 children and adults and had 165 staff members. By the late 19th century, public school classes for what we would call mild mental retardation were established in all major cities in the United States.

Considerable understanding in the identification of clinical conditions associated with mental retardation was gained in the 1900s. Among the new disabilities that were identified and classified were von Recklinghausen's disease, Tay–Sachs disease, Sturge–Weber syndrome, and Down syndrome (mongoloidism). J. Langston Down made a significant contribution to the field by being the first to provide a separate classification and description of mongoloidism. He proposed that idiocy could be classified into three categories: congenital (idiots), accidental (feeble-minded and idiots), and developmental (feeble-minded). In addition, the Association of Medical Officers of American Institutions for Idiotic and Feeble Minded Persons, a forerunner to the current American Association on Mental Retardation, was established.

The 1900s also brought significant changes in the care of persons with mental retardation. In the early 1900s, Binet's method of assessing intelligence was widely used in the evaluation of persons with mental retardation. Clearly, this had an immense impact on the conceptualization and operationalization of mental retardation via redefining the definitional criteria and related diagnostic procedures. However, the prevailing view in the early 1900s quickly changed to a belief that society needed to be protected from those with mental retardation. This resulted in decisions pertaining to the need for sterilization and the reluctance to accept immigrants with mental retardation. Despite this belief, a number of definitional changes occurred during this time. Edgar Doll advocated one significant change. Doll notably impacted the field with his discernment of social competence and its need to be included in the definition of mental retardation. Another notable change challenged the belief that an institutional setting was the only appropriate setting for treatment. This challenge contributed to the deinstitutionalization movement and furthered discussions regarding the need for increased community-based treatments.

III. DEFINITION OF MENTAL RETARDATION

The definition of mental retardation has been modified several times throughout the years. For the sake of brevity, the numerous reconceptualizations and recapitulations of the definition of mental retardation are not discussed in full. Despite variability in definition, the definitions have held constant with the inclusion of impairments in cognitive and adaptive abilities. One of the major changes in definition occurred in the 1950s when a limitation in adaptive behavior was included as a necessary criterion for the diagnosis. Prior to this change, having a low IQ was sufficient for a diagnosis of mental retardation. Earlier definitions included varying levels of mental retardation, mostly based on the IQ score. For example, a person with an IQ ranging from 35–40 to 50–55 was considered moderately retarded.

In 1992, the American Association on Mental Retardation (AAMR) defined mental retardation as referring to substantial limitations in present functioning. It is characterized by significantly subaverage intellectual functioning, existing concurrently with related limitations in two or more of the following applicable adaptive skill areas: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. An age limit criterion (e.g., mental retardation manifesting before age 18) also was included in this definition.

In applying the definition, the AAMR asserted four assumptions that are essential to the application of the definition. First, a valid assessment is critical and should consider cultural, communication, behavioral, and linguistic diversity. Second, the adaptive skill limitations should occur within community environments typical of the individual's age peers (e.g., work setting and school environment) and be part of determining the individual's service needs and supports. Third, specific adaptive limitations may be present concurrently with areas of strengths in other adaptive areas. Fourth, appropriate supports provided over a sustained period will most often lead to improvements in the life functioning of a person with mental retardation. This definition was designed to reduce professionals' reliance on the IQ score for measuring the severity of the disability, and it focused on using associated adaptive skills as a means of determining appropriate services and supports necessary to maximize functioning.

When compared to the 1983 definition of mental retardation, several changes are evident. Previously, adaptive behavior had only been roughly defined; however, with the 1992 definition, 10 specific areas of adaptive skills were identified and well-defined. Second, the new definition was to be more functional in its

nature. This definition emphasized the interplay between three dimensions: one's capabilities (e.g., intelligence and adaptive behaviors), the environments in which the person functions (e.g., home, work, school, and community), and the need for varying levels of support that may change over the life span. The 1992 definition provided for a means to classify individuals in terms of level of necessary support (e.g., intermittent, limited, extensive, or pervasive) rather than only in terms of level of severity, such a mild, moderate, severe, or profound. It was hoped that the use of the categorical levels of mental retardation would be discontinued; however, to date these levels of support have not been widely acknowledged or applied. Finally, this definition allowed professionals a means to develop a profile of needed supports based on intellectual functioning and adaptive skills, psychological considerations, health factors, and environmental circumstances. Overall, the 1992 definition has been groundbreaking in its nature and theoretical underpinnings; however, it has not been without its critics, with most of the criticism focused on the discontinuation of the use of the levels of severity (e.g., intellectual levels).

In an effort to continually advance the field of mental retardation, the AAMR has prepared a new definition of mental retardation. This new definition was not formally published at the time of publication of this article; however, a proposed definition has been presented [AAMR (2001)] and is reviewed here. As a whole this proposed 2002 definition builds on the 1992 definition. This proposed definition states that mental retardation is a disability characterized by significant limitations in both intellectual functioning and conceptual, social, and practical adaptive skills. This disability originates before age 18.

There are several noted similarities between the 1992 definition and the proposed 2002 definition including: (a) the use of a functional orientation, (b) intellectual functioning, adaptive behavior, and age of the onset as diagnostic domains, and (c) a dedication to the notion that the level of needed supports for an individual should be the primary focus of a classification system.

The central differences in the proposed 2002 definition as compared to the 1992 definition include: (a) an additional standard deviation criterion within the intellectual domain, (b) the additional dimension of participation, interaction, and social roles as a means of adding to the multidimensional approach to mental retardation, (c) clarification of adaptive behavior which is encompassed in conceptual, social and practical skills that representing one's typical performance, and (d) reconfiguration of assessment of support and determination of intensity of need.

At the risk of perpetuating the earlier definition of mental retardation, this article uses the 1983 nomenclature. The reasons for the continued use of the earlier definition of mental retardation are threefold. First, the nomenclature of the 1992 definition that emphasizes level of support has not been widely used in clinical and research practices. As such, discussion of the levels of retardation is inherently found in the literature describing this population, and it continues to be the most familiar to researchers, clinicians, and other professionals. Second, the proposed levels of support do not clearly align with the accepted nosology often used in practice (e.g., *DSM-IV* and *ICD-10*). Finally, for the purposes of this article, using the more commonly accepted and understood levels of retardation will aid in the ease of interpretation and the conveying of information. Despite our choice to lean toward communicative ease, those professionals working with individuals with mental retardation should become familiar with the most recent definition and its intended clinical use.

IV. FEDERAL LAWS AND MENTAL RETARDATION

Although there are several federal and state laws that directly or indirectly address the rights of persons with mental retardation and other disabilities, three will be highlighted here. Each of these has one main focus: to protect persons with disabilities, including those with mental retardation, from discrimination due to their disability. These laws apply to different institutions that are affected by each statue; however, their overall goal is the same. Landmark legislation to be reviewed include Public Law 94-142, the Education for All Handicapped Children Act, renamed and reauthorized as the Individuals with Disabilities Education Act (IDEA) of 1997; Section 504 of the Rehabilitation Act; and the Americans with Disabilities Act.

A. Individuals with Disabilities Education Act

In 1975 Congress passed the Education for All Handicapped Children Act (PL 94-142). PL 94-142 was revised in 1990 and renamed the Individuals with Disabilities Education Act. It was reauthorized in 1997. This legislation provides for the rights of all

children (ages 3–21) to be educated, despite their disabilities, and for this education to be done in a way that addresses children's specific needs. The main thrust of IDEA is a mandate to states to provide a "free and appropriate public education" in the "least restrictive environment" while protecting a child's rights. To determine eligibility, a student must be evaluated, typically by his or her school district, to determine if he or she is eligible to receive special education and related services. If a child is deemed eligible, the next step is for an Individualized Education Plan (IEP) to be written, which in effect becomes a contract for services between the parents and the school system. This statute provided for nondiscriminatory testing and required parent participation.

In addition to mandating services for children over the age of 3, Part C of IDEA makes available services for children from birth up to age 3. Infant–toddler services within IDEA recognized the need to augment the development of children with disabilities, minimize the need for later special education via early intervention, capitalize on one's ability to live independently, and to improve the capacity of a family to meet the needs of their child.

The reauthorization in 1997 addressed several issues, including regular education teachers as IEP team members, graduation, discipline, children with attention problems, reevaluation practices, public charter schools, parentally placed children in private schools, and use of the "developmental delay" category. The latter change has specific implications as related to mental retardation. The new legislation mandated that a child could receive a diagnosis of developmentally delayed through age 9. Previously, the age limit was 5 years. This change in the legislation may serve to shift the pattern of identification of mental retardation. That is, it may be that numerous children with mental retardation may be labeled with the possibly less stigmatizing label of developmentally delayed, thus decreasing the reported prevalence of mental retardation before age 9.

B. Section 504 of the Rehabilitation Act of 1973

Section 504 of the Rehabilitation Act of 1973 applies to beneficiaries of any kind who receive federal funding, such as schools (elementary, secondary, and universities) and hospitals. Section 504 provides for prohibition of denying persons with disabilities goods, services, facilities, privileges, advantages, or accommodations that are available to those without disabilities. In addition, agencies or groups subject to Section 504 must adjust their work requirements and eligibility standards to accommodate the needs of persons with disabilities. However, Section 504 only protects an individual if the individual is deemed to be otherwise qualified and able to meet the essential eligibility requirements for the job, program, or activity. For individuals with mental retardation, Section 504 undoubtedly has created educational and vocational opportunities that would not have been possible without this legislation.

C. The Americans with Disabilities Act of 1990

The scope of the Americans with Disabilities Act of 1990 (ADA) is more expansive than either of the previously discussed landmark legislative decisions and has been called by some an "emancipation proclamation" for persons with various disabilities. The ADA borrowed heavily from the Rehabilitation Act of 1973 and built on the rights described in the earlier act. The groups of persons protected are virtually the same since both acts share the same definition of disability, but the ADA provides a broader scope of privileges because it is not limited to the purview of agencies that are funded by the federal government. The ADA mandates nondiscrimination in the areas of public entities, public accommodations, employment, architecture, transportation, and communication barriers. As with other legislative acts, the ADA likely has contributed to improving the quality of life and increased the number of opportunities for individuals with mental retardation.

V. CAUSES OF MENTAL RETARDATION AND PREVENTION EFFORTS

The etiology of mental retardation is variable and complex. In fact, there are more than 350 known disorders and conditions, both genetic and acquired, that can result in mental retardation at different developmental stages. To understand the etiology of mental retardation, it is helpful to consider biological and environmental events that may occur prenatally, perinatally, or postnatally.

Before we examine specific causative agents, it is important to note that in general the estimates of the etiology vary based on the level of severity. Mild

retardation is most commonly of idiopathic origins, whereas severe mental retardation most often results from prenatal or genetic factors such as chromosomal abnormalities. For example, for persons with mild retardation, approximately 45–60% of these cases are due to unknown reasons; approximately 10–25% are due to some prenatal, nonchromosomal cause; 4–8% are due to a chromosomal disorder; and 20% of cases can be traced to a perinatal or postnatal cause. When we consider severe mental retardation, as many as 40–70% of cases are due to chromosomal disorders or other prenatal factors. Less than 20% of cases are due to perinatal (e.g., prolonged birth anoxia) or postnatal factors, whereas 25–40% of etiologies are unknown.

A. Prenatal Etiology

Genetic factors have been shown to be one of the most common causes of mental retardation. Chromosomal abnormalities are either heritable mutations or variations of genetic material. Advances in medical technology have furthered our knowledge of the role of genetic transmission of many conditions, including mental retardation. Chromosomal abnormalities may involve either single gene disorders (autosomal-dominant syndromes or autosomal-recessive syndromes) or disorders of the sex chromosomes. Chromosomal disorders that can lead to varying degrees of mental retardation and other cognitive and behavioral characteristics include phenylketonuria (PKU), Turner's syndrome, Lesch–Nylan syndrome, Tay–Sachs disease, maple syrup urine disease, *cri du chat* syndrome, and Klinefelter syndrome.

Numerous agents can have significant deleterious effects on the fragile central nervous system of a child *in utero*. Such teratogens are nongenetic, nonchromosomal agents that are major causes of mental subnormality. These include poor nutrition, toxic substances, maternal disease or infection, blood incompatibility, drugs and alcohol exposure, and cigarettes.

For example, maternal alcohol abuse during pregnancy can result in fetal alcohol syndrome (FAS) or fetal alcohol effects (FAE). The dangers of ingestion of alcohol during pregnancy have been well-known for years. The teratogenic effects of alcohol and other illicit substances impact the developing, vulnerable brain and cause an interruption in the developmental stages of the body organs, most often the central nervous system. If a child meets all diagnostic criteria, as discussed later, he or she is said to have FAS. A child whose mother drank with some moderation during pregnancy, however, may have a typical physical appearance and milder cognitive impairments with accompanied learning and behavioral problems. Such a child would be noted to have FAE.

The prevalence of FAS is not known; however, it is clearly one of the major causes of mental retardation in the United States. It is estimated that 5000 children are born in the United States with FAS each year, with rates of 1–3 cases of FAS per 1000 births. As a whole, alcohol ingestion while a woman is pregnant has been associated with a spectrum of physical and neurodevelopmental effects on the developing child. The criteria for a diagnosis of FAS include pre- and postnatal growth retardation (e.g., low birth weight), central nervous system abnormalities (e.g., mental retardation), and craniofacial malformations (e.g., microcephaly).

Specifically, 80% of children with FAS are born low birth weight, 70% have feeding problems as infants, and most of the children are thin and short in stature. Characteristic physical features include microcephaly, widely space eyes with narrow eyelids, short and upturned noses, thin upper lips, large low-set ears, and a flattened philtrum. Vision problems, such as strabismus or nystagmus, also may be present. In addition to the noted physical and cognitive abnormalities, about two-thirds of children with FAS manifest significant behavioral and emotional problems, including oppositional and defiant behaviors, inappropriate response to social cues, social withdrawal, mood instability, and other overt (e.g., aggression) and covert (e.g., lying and stealing) psychopathology.

B. Perinatal Etiology

The perinatal stage defines the time period surrounding the birth process (e.g., time of birth ± 7 days). During this period, several obstetric complications may occur that can place a child at increased risk of having mental retardation. Perinatal factors account for approximately 20% of cases of mental retardation. These include prematurity and low birth weight. Prematurity and low birth weight are factors highly correlated with the presence of mental retardation; however, prematurity may not be the specific casual agent in and of itself. Rather, prematurity may be the outcome of several other risk factors that contribute to the manifestation of mental retardation. That is, the premature infant is born with more biological and environmental risk factors and likely will have more

risks across time. Other possible perinatal complications include anoxia, breech or other atypical presentation for delivery, birth injury, or difficulty with delivery (e.g., umbilical cord entanglement).

C. Postnatal Etiology

Overall, postnatal etiology of mental retardation is implicated less often than prenatal and perinatal conditions. Nonetheless, many conditions in these early years can lead to mental retardation. In fact, it has been estimated that between 5 and 20% of cases of mental retardation are a result of trauma or neglect. Postnatal causes include traumatic brain injury, cerebral infections (e.g., meningitis and encephalitis), child abuse (e.g., shaken baby syndrome), lead poisoning, and nutritional deficiencies. Childhood head injuries can be a result of various agents (e.g., falls, motor vehicle accidents, bicycle accidents, gunshot wounds, and sports-related injuries). Those at highest risk of a brain injury are boys between the ages of 15 and 18 years and children younger than 5 years of age.

Environmental etiologies are most often related to the presence of mild mental retardation. A large percentage of persons with mental retardation are affected by psychosocial retardation due to economic disadvantage such as poverty. This group includes those who have a diagnosis of mental retardation that did not result from a distinctive, identifiable organic or genetic anomaly.

Environmental risk factors work in combination to impact outcomes of children who do not have any identifiable biological risk but for whom early life experiences are sufficiently limiting that they impart a high probability for delayed development. Poverty has pervasive effects on a child, the family, and the environment. Poverty does not equate to defining a certain cultural group, but poverty is pervasive across cultures. However, not all characteristics described will be present in each economically disadvantaged home situation. In addition, it is important to note that many children reared in impoverished homes function within normal intellectual levels.

Many years of study have enabled researchers to identify causative factors within the impoverished environments that may directly or indirectly impact developmental outcomes. Intergenerational patterns of dysfunction can affect the cognitive development of children. In the case of poverty, the environment may be analogous to poor nutrition, health care, self-esteem, limited parenting skills due to young maternal age or lack of education of the parents, and limited educational and vocational opportunities. The home environment may be overcrowded, understimulating, unpredictable, or provide an excessive amount or inappropriate type of stimulation. In addition, disadvantaged families may not be able to provide basic survival necessities such as food or adequate shelter. Family economics often result in low parental education, low social status of the family, and low parental expectations, which all can negatively impact development resulting in cognitive and adaptive behavior limitations.

D. Prevention Efforts

In the past 25 years, efforts to eliminate or reduce cases of mental retardation have been marked. Prevention has occurred across all three levels: primary, secondary, and tertiary. In short, primary prevention involves efforts to intervene such that one eradicates or minimizes the risk factors before a disabling condition develops. Primary prevention efforts often comprise the backbone of public health programs. Secondary prevention comprises efforts toward the early detection, diagnosis, and treatment such that the duration of the disease is shortened, secondary conditions are reduced, and discomfort is minimized. To achieve this goal, professionals must recognize the precursors of a disease or condition and intervene to limit its progression. For example, neonatal intensive care units act as an agent to limit the numerous consequences of premature births. For those who have an identified disability or disease, tertiary prevention is necessary. Tertiary prevention involves promoting maximal functioning among persons with identified disorders or diseases. The intervention efforts serve to provide for functionality or normalization within the least restrictive environment. One example is the array of community-based life skills training programs for persons with mental retardation.

The goal of prevention, despite successes, remains a daunting one due to multifactorial etiologies, competition for resources, and lack of client motivation and/or empowerment for participation. Another challenge specific to the outcome of mental retardation is the long latency period between exposure to causal factors and the diagnosis of mental retardation. This latency period presents a challenge for determining the etiology of mental retardation (and other developmental disabilities). However, developmental epidemiological studies can assist in the challenge of dealing

with the latency period between exposure to causal factors and the manifestations of a developmental outcome. This can be accomplished by using linked extant databases to examine causative and protective factors and their relation to the outcome of interest. This methodology effectively creates a longitudinal file for each individual for which all data points are available without having to wait multiple years for the outcome (e.g., mental retardation) to be manifested.

To date, prevention efforts have proven successful in eliminating congenital rubella by immunization and antibody screenings; eliminating retardation due to PKU, galactosemia, and congenital hypothyroidism by newborn screenings and dietary management; and eliminating kernicterus by the use of globulin therapy. Prevention efforts have also greatly reduced morbidity from prematurity through neonatal intensive care nurseries, the presence of measles through vaccination, and Tay–Sachs disease through early screening and prenatal diagnosis. In addition, efforts have proven effective in reducing the incidence of neural tube defects by folic acid supplementation, fetal alcohol syndrome through public awareness and education, lead poisoning by environmental improvements and lead screenings, traumatic brain injury by using child restraints in automobiles, and child abuse and neglect through family education and supports. Finally, improvements have also occurred via early identification and intervention of young children at risk for developmental delays. With such efforts, various medical, allied health, and early intervention professionals have been effective in providing earlier identification and treatment for individuals with mental retardation.

1. Early Childhood Intervention

The provision of early childhood intervention services involves systematic efforts to provide at-risk children with additional educational and developmental experiences before school age. It also includes the provision of family services. Several investigations have attempted to quantify the impact of early intervention on the cognitive development of young children from disadvantaged backgrounds (e.g., Early Training Project, Perry Preschool Project, Houston Parent Child Development Center, Milwaukee Project, Carolina Abecedarian Project, and Project Care) and those with biological risk factors (e.g., low birth weight—the Infant Health and Development Project). Although these research projects defined disadvantage in slightly different ways, initiated intervention at varying ages, and included different intervention components, their collective results provide evidence that high-quality early intervention services prevent or minimize the potentially harmful effects of various environmental and biological risk factors for young disadvantaged children. These programs provide short-term benefits in the areas of cognitive functioning and long-term effects on decreased grade retention and special education placement. In addition, evidence from a few studies suggests that programs with the greatest educational intensity and duration maintain cognitive functioning benefits until adulthood. The positive cost-benefit ratio for society should not be underestimated in this regard.

In general, programs that begin earlier and continue longer afford greater cognitive functioning benefits than those that begin later and have shorter durations. Intervention studies that begin during infancy and preschool years, before at-risk children develop increasingly depressed cognitive/developmental scores, have demonstrated the largest impact on cognitive level of functioning. These intervention programs have shown that participating children continue to score in the average range on cognitive/developmental tests, whereas children not receiving the full intervention score in the low-average range. Programs that began at later ages, approximately 4 or 5, have shown that upon entry children's cognitive scores have already begun to decline. After 1 or 2 years of intervention, children's cognitive scores are higher, whereas the scores of children who did not receive the intervention have not changed. Although these types of interventions may lessen the morbidity associated with moderate and severe levels of mental retardation, they stand to impact most significantly on individuals with mild mental retardation with idiopathic etiologies.

VI. PREVALENCE OF MENTAL RETARDATION

It is estimated that people with mental retardation comprise approximately 1–3% of the population. However, these data vary based on the method of case ascertainment, definition used, and population studied. The prevalence of mental retardation has not changed appreciably for more than 60 years as a result of the stasis between advancing health care and the emergence of new cases. For example, although neonatal diagnosis of children with phenylketonuria and subsequent management has theoretically resulted in the elimination of mental retardation caused by this metabolic disorder, there has been an increase in

prenatal exposure to toxic substances (e.g., drugs and alcohol) and an increased survival rate of very low or extremely low-birth-weight, premature infants. Therefore, this balancing effect has contributed to static prevalence rates of mental retardation throughout the years.

As noted, mental retardation comprises a heterogeneous group of persons and syndromes with dissimilar prevalence, physical manifestations, cognitive abilities, and social–emotional development. Previously, all persons with mental retardation were seen as a homogeneous group of individuals. However, we now have a significant knowledge base that allows us to understand more about selective disorders. As such, we consider relevant issues within specific syndromes that are associated with mental retardation.

VII. CHARACTERISTICS OF SYNDROMES ASSOCIATED WITH MENTAL RETARDATION

A. Down Syndrome

Down syndrome (DS) is easily recognized by the lay population and perhaps thought to be synonymous with mental retardation. It is one of the most common genetic causes of mental retardation and perhaps the best known. It is estimated that DS occurs about 1 to 1.5 times every 1000 births. However, other estimates reveal DS may occur once in every 600 births. The risk of having a child with DS increases as the age of the mother increases. It is estimated that males are affected slightly more than females (1.3 to 1.0), which may be due, in part, to a higher mortality rate in females during infancy.

The most common cause of DS involves an extra chromosome existing at the 21st position, known as nondisjunction or trisomy 21. Nondisjunction results from an inappropriate separation of chromosomes during meiotic division that results in a total of 47 chromosomes. This accounts for approximately 95% of the cases of DS. However, DS can also be caused by the chromosomal abnormalities of translocation or mosacism. Translocation (responsible for 2–4% of cases of DS) occurs when part of a chromosome is attached or translocated to another location or chromosome, often to chromosome 14. Mosaicism (responsible for 1–4% of cases of DS) occurs when there is an uneven pattern of dissimilar cells with 46 or 47 chromosomes.

DS results in a cluster of physical traits that include short stature; flat, broad face with small ears and nose; brachycephaly; short, broad hands and feet; tongue protrusion and/or fissured tongue; heart defects; hypotonia; slanted and almond-shaped eyes; epicanthic folds in the inside corners of the eyes; a wide space between the first and second toe; and a single crease that transverses the palm. These physical traits can vary from individual to individual and may become less pronounced as an individual grows and develops.

Most individuals with DS often have some degree of intellectual impairment, with mild to moderate mental retardation being most prevalent. As children with DS age, there seems to be a general decline in their developmental rate and progression, with verbal short-term memory skills being most vulnerable. Some research has suggested that individuals with mosaicism have higher average cognitive scores (10–30 points higher) than individuals with trisomy 21 on standardized measures of IQ. Children with mosaicism have also demonstrated average visual-perception skills.

The accepted stereotype of persons with DS is that they are happy, social, and friendly; however, this is not scientifically based. Instead, studies have shown that children with DS have temperament profiles that are comparable to those of typically developing children. Children with DS have difficulty in the area of social competence, perhaps due to concomitant motor, cognitive, and language delays. Individuals with DS exhibit other comorbid disorders, including attention deficit/hyperactivity disorder, conduct/oppositional disorder, aggression, phobias, stereotypic behavior and self-injurious behaviors.

B. Fragile X Syndrome

Fragile X syndrome (FXS) is the most common inherited cause of mental retardation. FXS occurs in approximately 1 in 1500 male births and 1 in 1000 female births. Subsequent studies using DNA have demonstrated a lower prevalence of FXS at approximately 1 per 4000 males in the general population. It is a single gene disorder on the X chromosome that occurs in both males and females, but males are typically affected more severely. It is an X-linked disorder and results from a pinched, restricted, or "fragile" location on the long arm of the X chromosome. In 1991, the fragile X mental retardation 1 (FMR1) gene was discovered. With the discovery of FMR1, DNA testing for the presence of fragile X was available. DNA testing provides a more effective means to detect the presence of FXS and carriers of the FMR1 gene by specifically showing the genetic

mutation at FMR1. Female carriers can pass down the disorder through generations. FXS minimizes the function of the gene responsible for producing an essential protein necessary for normal brain function.

Because of the divergent impact on males and females, there is a significant degree of phenotypic variability expressed in this disorder. In fact, early in life, there is a limited physical phenotype with a distinctive appearance developing at approximately the time of puberty. That is, males with FXS may have macrocephaly, elongated face, long protruding ears, prominent jaw, macroorchidism in adulthood, large nose, and a prominent forehead. Early in life, the one physical characteristic that may be present is the large ears. Females typically have only a slightly abnormal appearance, with approximately half presenting with protruding ears and other subtle features, such as flexible joints, low muscle tone, or flat feet.

Males and females show disparate patterns of cognitive profiles. Males most often have IQ scores in the moderate to severe range of mental retardation, with some scatter to the borderline to low-average range of intellectual functioning. Behavioral manifestations also include attentional difficulties, hyperactivity, tactile defensiveness, hand flapping, seizures, stereotypic behavior, echolalia, and gaze avoidance. Females with FXS are often carriers with little or no expression of the condition they may often be diagnosed as having a learning disability rather than mental retardation.

C. The Mucopolysaccharidoses

The mucopolysaccharidoses (MPS disorders) are a group of autosomal-recessive genetic abnormalities of mucopolysaccharide metabolism that results in variable impairment across physical, sensory, cognitive, and behavioral domains. There are six main types of MPS, many of which include specific subtypes. Prevalence estimates vary based on the subtype of MPS disorders and geographic location. Prevalence estimates range from 1 in 25,000 (Sanfilippo syndrome in the United Kingdom) to 3 in 1 million persons (Morquio syndrome).

Often, MPS disorder results in impairment of the skeletal system. Other organ systems that are impacted include the cardiovascular, respiratory, and nervous systems. Skeletal impairments include widened collarbone and ribs, progressive curvature of the lower spine, short stature, shortened neck, claw-like hands, joint contractures, enlarged head, flattened bridge of the nose, protruding tongue, and thick hair coupled with excessive body hair.

Intelligence varies within subtypes of MPS from average to progressive mental retardation. Behavioral issues also vary within subtypes of the MPS disorders. Individuals with Hurler syndrome, for example, are described as being anxious, restless, and having sleep problems but are not aggressive. Children with Hunter syndrome are overactive, aggressive/destructive, fearful, defiant, and also have sleep problems. Children with Sanfilippo syndrome manifest the most noticeable behavioral symptoms. These children often wander aimlessly, are restless, mouth clothing and objects, have sleep problems, and can be aggressive even when not provoked.

D. Noonan Syndrome

Prevalence estimates of Noonan syndrome (NS) range from 1 in 1000 births to 1 in 2500 births. Males and females are equally affected, and no racial or geographical differences have been reported. Physical manifestations of NS include craniofacial abnormalities (e.g., small jaw, low-set ears that are angled toward the posterior, a deep groove in the philtrum, and a high arched palate), congenital heart disease, skeletal abnormalities (e.g., short stature, webbed neck, and abnormalities of the thorax), and genital malformations. Intellectual functioning ranges from mild mental retardation to superior intellectual levels.

Although further research is necessary regarding the social–behavioral aspects of persons with NS, it is known that social interactions may be deficient because of other concomitant disorders (e.g., low muscle tone impacts athletic participation). Overall, children with NS seem to mature more slowly than their typically developing peers, and they often prefer to play with younger children. No evidence of behavioral or psychiatric disorders comorbid with NS has been reported.

E. Klinefelter Syndrome

Klinefelter syndrome (KS) is a sex chromosome disorder and occurs due to the presence of an extra X chromosome in males (XXY). It is estimated that 1 in 700 to 1 in 900 live male births are affected by KS. Early research linked KS with psychiatric disorders, criminal behavior, and mental retardation. These studies had methodological concerns that impacted

validity; however, many still hold to these early findings. In truth, males with KS are at risk for developmental, learning, language, and behavioral problems along with psychiatric disorders, but they are not inherently criminal.

Physical manifestations of KS result in impairment of normal genital and sexual development. Although persons with KS enter puberty at the typical age, inadequate testosterone levels prevent normal pubertal progress. Hypogonadism is present with a slowed development of or lack of secondary sexual characteristics. In addition, KS leads to smaller than normal testes that often contribute to infertility. Cognitive abilities range from mild mental retardation to above-average intelligence. In general, persons with KS have deficits in verbal abilities, whereas nonverbal abilities are typically in the average range. Behaviorally, individuals with KS may be reserved, withdrawn, and immature, and they are at risk for having poor peer relationships. Self-esteem problems also have been described. In contrast, they also have been described as being easygoing, underactive, compliant, and, consequently, well liked by teachers.

F. Lesch–Nyhan Syndrome

Lesch–Nyhan syndrome (LNS) is a rare X-linked recessive disorder that typically only impacts males, whereas females act as carriers. Research has found that approximately 1 in every 380,000 births is affected, and no ethnic groups or individuals in different geographic regions are known to be at greater risk. Individuals with LNS suffer from dystonia (including hypotonia and hypertonia), spasticity of movement, speech deficits, renal disease, gout, and mental retardation. Motor impairments are severe and often restrict an individual to use of a wheelchair with necessary physical supports. In addition, motor abilities impact the ability to produce intelligible speech and perform self-care tasks independently.

Perhaps one of the most distinguishing behaviors of LNS is that nearly all individuals with LNS demonstrate severe self-injurious/self-mutilating behaviors that can begin as early as 26 months of age. These behaviors escalate with age. The self-mutilation often begins with repeated biting of the lips, hands, and fingers. The severity of self-mutilation is such that permanent tissue loss often results (e.g., self-amputation of fingers or tongue).

Cognitive assessment of individuals with LNS is challenging due to their physical limitations and self-injurious behaviors. Findings suggest that persons with LNS have varying degrees of cognitive impairments ranging from mild to severe, but it is widely held that cognitive skills may actually be higher than measured due to assessment limitations.

G. Prader–Willie Syndrome

Prader–Willie syndrome (PWS) occurs evenly across both gender and ethnic lines. Approximately 1 individual in 10,000–15,000 births is impacted. PWS is caused by a microdeletion of chromosomal matter on chromosome 15. One unique feature of PWS is that genes are expressed in a divergent manner depending on whether one inherited them from one's mother or one's father. Physical manifestations include failure to thrive (early in development), characteristic facial features (e.g., narrow nasal bridge, downturned mouth, almond-shaped eyes, and thin upper lip), hypotonia, hypogonadism, later insatiable appetite and resulting obesity, and a specific behavioral phenotype.

The behavioral phenotype includes impulsivity, aggression, obsessive behaviors, underactivity, anxiety, daytime sleepiness, and perseverative tendencies. In addition, other maladaptive behaviors and psychopathology are present in persons with PWS, including tantrums, mood changes, argumentativeness, stubbornness, oppositional behaviors, theft, and rigidity. Clearly, managing obsessive food-seeking behaviors that occur in clever and manipulative manners poses a substantial challenge for those working with and caring for these individuals. Most persons with PWS are functioning within the mild range of mental retardation, with an average IQ score estimated to be approximately 70. Individual variation has been noted, with scatter from the average level to the profound range of mental retardation. In general, cognitive abilities seem to plateau in adolescence or early adulthood. Adaptive behavior scores are generally reported as being lower than scores for their level of cognitive functioning, with steady gains in socialization and daily livings skills as these individuals grow and develop.

H. Williams Syndrome

Approximately 1 in 20,000 live births results in a child with Williams syndrome (WS), and it is equally distributed across ethnic groups. WS is a multisystem disorder that includes impairments in cognition,

congenital heart disease, dysmorphic facial features, and connective tissue problems that impact the bowel, bladder, skin, and joints. Individuals with WS also have distinctive personality characteristics. Diagnosis in infancy most often is a result of a triad of symptoms: developmental delay, severe cardiovascular diseases, and dysmorphic facial features. In early adolescence, it is often diagnosed based on a specific cognitive profile and personality characteristics.

Characteristic facial features include a flat profile, a broad brow with bitemporal narrowing, a wide mouth with full lips, full cheeks, upturned nose with a bulbous nasal tip, asymmetry in the face, and a long philtrum. Children with WS often have chronic otitis media as well as ocular and visual abnormalities. Additionally, abnormalities in the respiratory system often lead to an idiosyncratic voice pattern. This voice pattern is described as being hoarse, low pitched, and flat. Complications of the renal, gastrointestinal, musculoskeletal, and neurological systems are present as well.

Individuals with WS function across varying levels of intellectual abilities. Overall cognitive abilities range from low average to severe mental retardation, with most persons with WS categorized in the mild range of mental retardation. Children with WS typically score better on measures of verbal abilities compared to nonverbal (visual–spatial) abilities. In fact, their visual–spatial abilities often represent extreme weaknesses in their cognitive profile. The cognitive profile for persons with WS also includes auditory rote memory skills that are slightly better what would be expected based on their overall cognitive performance, and these abilities may contribute to their apparently higher verbal abilities.

Children with WS often have attentional problems, most often due to overactivity and distractibility. Thought problems and social problems have also been reported. Research on the personality characteristics of individuals with WS has shown that these individuals are intense, anxious, curious, less reserved toward strangers, overfriendly, eager to learn, and oversensitive to sound. In addition, individuals with WS have negative moods, have a lower threshold of excitement, and have difficulty sleeping.

VIII. PSYCHOPATHOLOGY AND MENTAL RETARDATION

During the past 30 years, research studies have clearly established that persons with mental retardation are more likely to experience some form of psychopathology than are persons without disabilities. Indeed, nearly all the disorders reviewed in this article have some type of unusual or distinctive social–behavioral patterns. A complex combination and diverse array of biological, psychological, and social factors interact to contribute to mental health problems in persons with mental retardation. There is unanimous agreement among professionals that persons with mental retardation are at higher risk for developing comorbid psychiatric disorders, but there is no agreement on the actual prevalence of comorbid psychiatric disorders. The prevalence estimates vary from as low as 1% to as high as 79%.

One of the major reasons for this large disparity between these prevalence estimates is due to methodological considerations. Prevalence studies diverge based on definition issues, identification, and sampling methods. That is, the studies vary in differing interpretations regarding how to define mental retardation (e.g., historically diagnosed or IQ cut-off), diagnostic procedures in establishing a formal psychiatric diagnosis (e.g., review of case files, direct assessment of psychopathology or direct care staff or other person acting as a reporter of symptomatology), type of psychopathology being examined, the criteria for establishing psychopathology (e.g., does psychopathology include ''challenging behaviors''), and population sampled (e.g., level of severity and living arrangements of sample). Despite this variability, the fact remains that the full range of psychiatric disorders can be observed within the population of individuals with mental retardation.

Another consideration relates to the heterogeneity of persons with mental retardation. Although this may be tied to the level of function issues, it could also relate to the pattern of function and/or the type of mental retardation manifested. For example, an individual with LNS manifests with a very serious level of self-injurious behaviors, whereas individuals within other types of mental retardation display very little if any self-injurious behaviors. Similarly, even within some disorders, such as FXS, the type and severity of psychopathology can vary by gender.

The third reason for disparity in prevalence estimates relates to the measurement of psychopathology in clients with mental retardation. Because of factors inherent in most individuals with mental retardation, an accurate psychiatric diagnosis may be problematic. Clearly, intellectual limitations may impact one's ability to conceptualize and effectively communicate or describe subjective feelings or objective events. In addition, limited social skills and inflexible thinking

may impact the information provided by the client and, in turn, impact diagnostic status.

In an effort to overcome these issues and thereby obtain a more accurate diagnosis of psychopathology in individuals with mental retardation, several instruments have been developed, including the Psychopathology Instrument for Mentally Retarded Adults (PIMRA), the Reiss Screen for Maladaptive Behavior (RSMB), and the Diagnostic Assessment for the Severely Handicapped (DASH). These instruments focus on the major forms of psychopathology and have been shown to be effective in diagnosing psychopathology in persons with mental retardation. The PIMRA can be administered in a self-report format or an informant version. Direct-care staff or others who are familiar with an individual complete the RSMB. The DASH involves a comprehensive structured survey answered by a direct-care staff member or other familiar individual.

IX. TREATMENT/INTERVENTION APPROACHES

The use of the term treatment can be misleading as related to mental retardation. Treatment usually infers the presence of a cure or a complete remediation of present problems. In the discussion of treatment and mental retardation, one should not interpret treatment in its literal sense but, rather, as a means of providing specific interventions that provide considerable benefit to persons with mental retardation and often target a specific deficit or problem. The main treatment approaches discussed here have received support as empirically based approaches and include counseling services, cognitive–behavioral treatments, and behavioral treatments. However, it is important for the reader to note that there are a number of other treatment approaches available (e.g., pharmacological). Furthermore, the astute reader will recognize that it is important to individualize treatment programs to a client's particular characteristics and needs, particularly with respect to developmentally appropriate practices.

A. Counseling

Clearly, the use of individual or group counseling as a treatment modality for persons with mental retardation has limitations. Persons with mental retardation often have trouble generalizing behaviors, recognizing consistent patterns of behaviors, and generating insight-oriented understandings. However, counseling that is directive and modified has been used effectively in the treatment of educational, vocational, and nonpsychiatric behavioral problems. Modifications should include the use of simplistic language, structured and directive communication, and the use of visual aids when necessary. In general, establishing realistic and attainable goals given the developmental levels and profiles of the client is the primary motivation of the counselor. Specifically, the counselor's goals are often to assist a person in understanding and labeling his or her emotional states, teach problem-solving and decision-making skills, and help the client learn that his or her behaviors result in consequences. Efficacy studies examining the use of counseling strategies for persons with mental retardation have demonstrated positive outcomes.

B. Cognitive–Behavioral Treatments

Cognitive–behavioral treatments have been effective in increasing functioning within the educational and social domains of persons with mental retardation. It has been shown that children with mental retardation are deficient in their ability to use metacognitive skills. As a whole, children with mental retardation use fewer cognitive strategies in memory and learning situations than their peers without mental retardation. In addition, they often lack the abilities to apply learned skills in a new situation. The use of metacognitive training can enhance one's memory and learning skills by teaching self-management skills. For example, a child may be taught to determine what type of math problem is presented to him or her. Subsequently, the child is taught to choose the appropriate strategy and then to evaluate the strategy choice (metacognitive skills).

Along with educational intervention, cognitive–behavioral strategies have been used in the social realm to address peer acceptance and social competence. That is, a person with mild mental retardation who is experiencing social problems can be taught to use metacognitive skills in a given situation. In doing so, one might work toward encoding properly (e.g., think about what happened), interpreting social cues (e.g., what the other person is feeling), and evaluating the possible choices for a response and its consequences.

C. Behavioral Treatments

Behavioral treatments have been shown to be effective in reducing aggression, self-injurious behaviors, and other learned maladaptive behavioral patterns in

persons with mental retardation. In addition, behavioral treatments have improved quality of life via teaching basic living skills. For many years, behavioral strategies have been the most thoroughly researched and widely used group of interventions for persons with mental retardation. These strategies rest on the belief that behavior is regulated by its consequences, and that environmental influences can promote or diminish behaviors. Consequences can increase the probability of a future occurrence of a behavior, or they can reduce the probability of a behavior occurring.

All behavioral therapies involve several key components: operationalizing target behaviors, recognizing antecedents to behaviors, identifying an appropriate array of reinforcers, and specifying when target behaviors will be rewarded or punished. With such knowledge, one can devise appropriate environments in which a person can be reinforced for desirable and adaptive behaviors and not reinforced for maladaptive behaviors.

Behavioral treatments also involve the specification and quantification of the occurrence of the maladaptive behavior in terms of its context, function, frequency, duration, and intensity. Upon determining the specific maladaptive behavior to target and its potential reinforcers, it is the goal of the professional to determine the purpose or function that one's behavior is serving. A functional analysis attempts to determine the relationship between behavior, antecedents, and consequences, which permits the choice of an appropriate treatment. In conducting a functional analysis, information can be obtained that determines whether a behavior is maintained due to antecedents specific to the environment (e.g., interaction with peers and overstimulation) or due to consequences (e.g., desired avoidance of an event).

X. FUTURE RESEARCH

There are three main areas to be addressed as we strive to improve our commitment to providing services for persons with mental retardation. First, continual work on the definition of mental retardation is necessitated by the lack of widespread use of the most recent definition. As noted previously, many clinicians and researches have not adopted the classification put forth in 1992 by the AAMR. Achieving the goal of widespread use of this contemporary language in practice is perhaps an onerous one; which is perhaps furthered by the proposed 2002 definition. Further understanding by practitioners and clinicians regarding how the contemporary nomenclature coincides with historically established taxonomy is essential.

Second, research is needed that provides insight into the relationship between genotypic and phenotypic linkages. Biomedical technology advances, such as recently witnessed via the Human Genome Project, may serve to identify the major genetic causes of mental retardation. As such, once a genetic syndrome is identified, this lends itself to study of how this disorder is expressed phenotypically. Such information allows for more accurate and earlier identification of mental retardation, which in turn allows for the most fitting service provision and supports available (e.g., provision of early intervention services).

Third, research must continue to move away from the study of persons with mental retardation as a homogeneous group. Research must move toward providing detailed descriptions of the cognitive (e.g., neuropsychological), behavioral, and social profiles, including strengths and weaknesses, of a specific group of persons with mental retardation (e.g., persons with mental retardation due to FXS). This line of research will refine clinicians' and service providers' abilities to perform their respective tasks. Clinicians will be provided with excellent tools to diagnose persons with mental retardation accurately and efficiently, and service providers will be able to target the areas of intervention more successfully.

XI. CONCLUSIONS

The field of mental retardation is quite broad, and the full range of disorders, treatment, and related diagnostic issues (e.g., assessment) cannot be realistically addressed within the confines of a single article. We have endeavored, however, to address many of the key issues inherent in this field, with a particular focus on historical foundations, definitional issues, etiological factors, and considerations such as comorbidity and treatment approaches. We also devoted significant discussion to several specific disorders, and it is believed that much of the future work in this field should address more homogeneous groupings of individuals with mental retardation. It is likely that this approach will be more informative for educators, clinicians, therapists, caseworkers, employers, and families. Even with its rich clinical and research history, this field holds great promise for future scientific advancement and improved clinical practice.

Mental Workload

RAJA PARASURAMAN and DANIEL CAGGIANO
Catholic University of America

GLOSSARY

central executive A hypothesized control center in the brain that is involved in high-level processes, such as coordination of multiple processes, error correction, and planning.

data-limited processing Cognitive processing that is limited solely by the quality of the input to the process, whether that input is external or drawn from memory.

electroencephalography (EEG) The spontaneous electrical activity of the human brain recorded at the scalp.

endogenous driver An internal source of mental workload; reflects the individual's mental effort, task strategies, proficiency, etc.

event-related potentials (ERPs) Electrical potentials of the human brain (recorded at the scalp) evoked by stimulus and response events and present in the background EEG.

exogenous driver An external (environmental) source of mental workload.

functional magnetic resonance imaging (fMRI) A functional brain imaging technique involving a static magnetic field that is typically used to assess cerebral blood flow in humans.

mental workload A composite brain state that reflects the interaction between the environmental and task demands imposed on an individual and his or her capability to meet those demands.

positron emission tomography (PET) A functional brain imaging technique involving ionizing radiation and computed tomography that is typically used to measure cerebral blood flow and metabolism in humans.

resource-limited processing Cognitive processing whose efficiency is dependent on the amount of information-processing resources allocated to the process.

working memory A mechanism for maintaining information briefly in an active state for use in various information-processing activities.

***Mental workload* refers to a composite brain state or set of** states that mediates human performance of perceptual, cognitive, and motor tasks. Mental workload can be driven *exogenously* (or "bottom-up") by environmental sources, namely, by task load, as well as *endogenously* (or "top-down") by the voluntary application of mental effort.[1] A simple example will illustrate these two sources of mental workload. Mental multiplication of two 2-digit numbers, say 12×13, is challenging but within the capacity of most adults. If three such numbers have to be multiplied, however, say $12 \times 13 \times 14$, then mental workload rises due to the increased task load—an exogenous driver of mental workload. Another exogenous driver is time pressure, the requirement to complete the task within a specified period of time. The workload associated with mental multiplication would be relatively low if one is given unlimited time to complete the task but would be considerably increased if an answer had to be provided in only a few seconds. In addition to exogenous sources, mental workload also reflects how much effort an individual puts into the process of mental multiplication under time pressure—in lay terms, a person can work more or less hard at this task in order to meet the time deadline. More generally, and

[1]This association reveals why the term *mental effort* has been used almost synonymously with mental workload. A highly influential book by Daniel Kahneman, *Attention and Effort*, published in 1973, introduced the concept of mental effort and its physiological concomitants in human autonomic and central nervous system activity. For a variety of reasons, however, the term mental workload is currently more popular and will be used throughout this article.

in a task more complex than mental multiplication, endogenous workload will also reflect the strategies that an individual uses to solve the task. This article describes the structural and functional properties of mental workload in relation to human brain function. Neural signs of mental workload as reflected in electroencephalography (EEG), event-related potentials (ERPs), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) are described.

I. STRUCTURAL AND FUNCTIONAL CHARACTERISTICS OF MENTAL WORKLOAD

Mental workload has been variously characterized as the objective task demands imposed on an individual, the mental effort he or she exerts to meet these demands, how well the person performs the task, and his or her subjective perception of expended effort. A definition that merges these different views postulates that mental workload is an intervening construct that reflects the interaction between the environmental and task demands imposed on a person and the capabilities of that individual to meet those demands. The intensity of this interaction is reflected in brain states, whose measurement can provide for objective assessment of human mental workload.

A. Mental Work and Brain Work

The notion of mental workload as a reflection of how hard one's mind is working at any given moment is intuitively appealing. Given that the mind is a function of the brain, it follows that mental workload should be associated with brain work. How can brain work be assessed? Various candidate measures have been proposed over the years. The work of Sir Charles Sherrington, the great nineteenth century physiologist, suggested that an answer could be found in the regulation of the blood supply of the brain. Sherrington demonstrated that there is a close coupling between the electrical activity of neuronal cells, the energy demands of the associated cellular processes, and regional blood flow in the brain. His pioneering work suggested that, if mental activity results in increased neuronal response in localized regions of the brain, then in principle it should be possible to measure mental workload by assessing regional cerebral metabolism and blood flow.

Autoradiographic studies conducted in animals have confirmed Sherrington's principle for the regulation of brain blood flow and its coupling to neuronal activity and energy usage. But it would take several years before sensitive techniques were developed for measuring regional brain blood flow in humans. An early development was the invention of the xenon-133 (Xe-133) method for assessing regional cortical changes in brain blood flow and glucose metabolism. Injection of the radioactively tagged xenon gas, which passes freely across the blood–brain barrier, into human patient volunteers showed that the performance of various mental tasks (such as mental arithmetic of the type mentioned at the beginning of this article) led to increased metabolic activity in specific cortical regions.

This was the first demonstration of a link between mental work and brain work in humans. However, the Xe-133 technique was too invasive to be used routinely in normal human subjects. The development of positron emission tomography (PET) paved the way for less invasive measurement of regional cerebral metabolism and blood flow. PET is an adaptation of autoradiographic techniques originally developed for measuring blood flow in animals. Regional cerebral glucose metabolism can be determined noninvasively using PET and radioactively labeled glucose (18-fluorodeoxyglucose), whereas regional cerebral blood flow may be assessed with PET and radioactively labeled oxygen (O-15) in water. PET was also more accurate than the older methods in localizing the specific cortical regions activated by cognitive task demands. Nevertheless, the spatial resolution of PET, particularly in individual subjects, had room for improvement. Furthermore, the need for ionizing radiation, although safe when used within exposure limits, was an impediment against frequent use in studies with normal human subjects. The development of functional magnetic resonance imaging (fMRI) overcame both of these limitations. fMRI provides noninvasive, high-resolution assessment of regional cerebral blood flow. PET and fMRI studies of mental workload are discussed further later.

B. The Structure of Mental Workload: Unitary or Modular?

Brain imaging can provide for objective measurement of human mental workload. Such studies may also illuminate a fundamental issue that has been debated for several years: whether mental workload is unitary

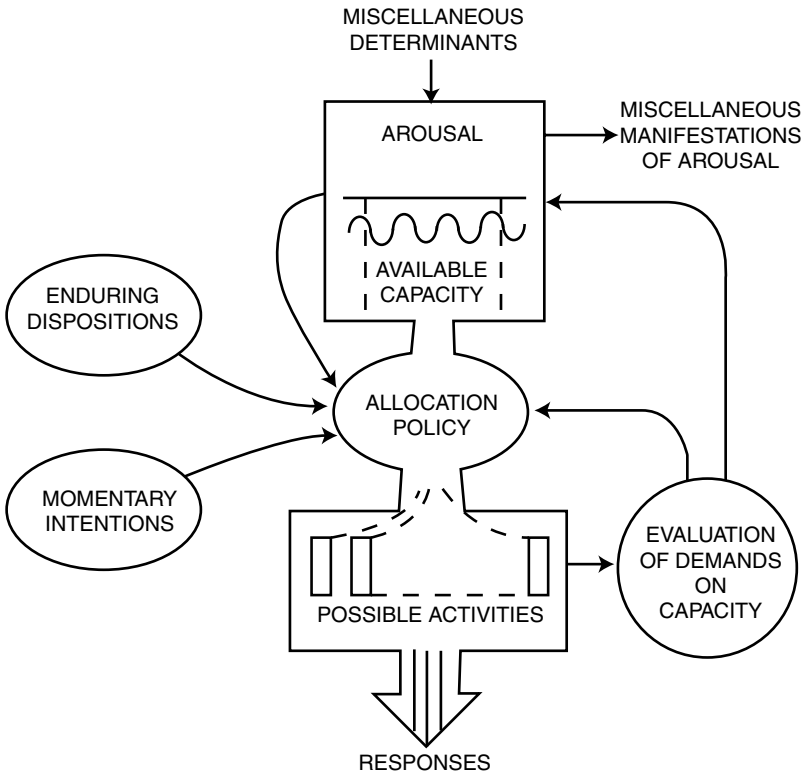

Figure 1 Unitary resource (capacity) model of Kahneman (1973). *Attention and Effort* © Daniel Kahneman. Reprinted by permission of Pearson Education Inc., Upper Saddle River, NJ.

or modular. Cognitive psychologists have addressed this question in some detail in research on human attention. Beginning with Daniel Kahneman's seminal work on attention and effort (1973), mental workload has been linked to information-processing theories of attention. These theories assume that tasks require the allocation of information-processing resources for their efficient execution (except those that can be performed automatically) and that mental workload reflects the overall demand for such resources. Kahneman's resource (or capacity) model is shown in Fig. 1. Every individual has a pool of available resources that is modulated by arousal level, with capacity being low during drowsiness and sleep and high during attentive wakefulness. The available capacity is allocated in parallel to various possible information-processing activities, according to the current behavioral goals of the person.

Some resource theories, like Kahneman's model, assume a single pool of resources that can be flexibly allocated to different processing activities. This is the unitary view. In the modular view, functionally separate resources are applied to different processing activities. Modules may be defined by such factors as sensory modality and stages of information processing, as in a model proposed by Christopher Wickens (see Fig. 2). An influential model of "working memory" by Alan Baddeley represents a hybrid view. This model proposes that modular "slave" systems for verbal and visuospatial processing are controlled by a unitary "central executive" system (see Fig. 3).

According to both the unitary and modular views, the processing resources that are applied to a task (or a component of a task) increase with the mental effort invested by the individual. Resources also increase in response to task demand. The human information-processing system, like an economic system, thus is able to adjust the supply of processing resources in response to demand. However, there is an upper bound to the amount of processing resources that can be applied: information-processing capacity is limited (see Fig. 4). Moreover, as task demand increases, the amount of "spare" capacity decreases, so that less can be allocated to other processing activities, whose efficiency may then suffer. This line of reasoning accounts for the performance decrement that can occur when two tasks are performed simultaneously and the demand of one task is increased.

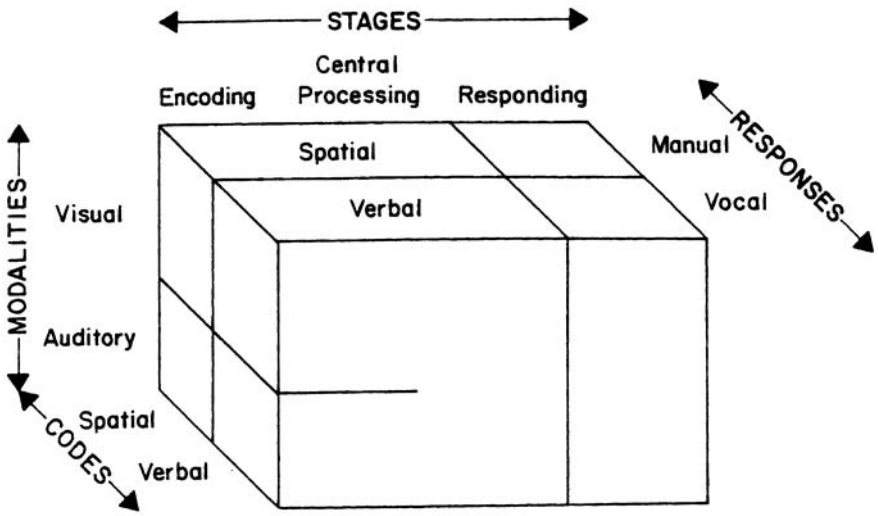

Figure 2 Multiple resource model from Wickens (1984).

Capacity limitations appear to be a fundamental property of both artificial and biological systems. Work in computer vision and robotics has shown that fully parallel processing of an entire complex visual scene is computationally inefficient in comparison to limited-capacity serial processing of parts of the scene. The large receptive fields of neurons in the higher perceptual processing areas of the primate brain are also consistent with such a computational limitation; because several objects in a visual scene fall within a neuron's receptive field, they compete for neuronal processing. Identification of an object among distracters therefore is dependent on the allocation of this limited processing resource.

Competition for limited processing resources is also a major factor in the decrement in performance that occurs when two tasks must be carried out simultaneously. According to unitary resource theories, interference between concurrent tasks occurs when

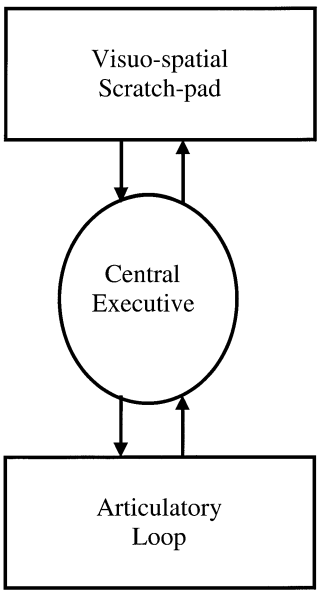

Figure 3 Baddeley (1992) model of working memory.

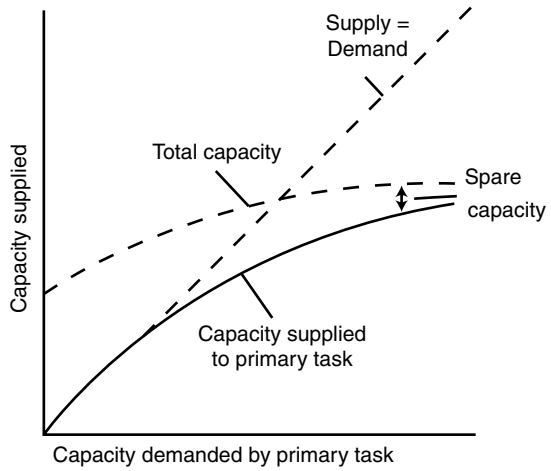

Figure 4 Relation between capacity (resources) demanded by a task and capacity supplied. From Kahneman (1973). *Attention and Effort* © Daniel Kahneman. Reprinted by permission of Pearson Education Inc., Upper Saddle River, NJ.

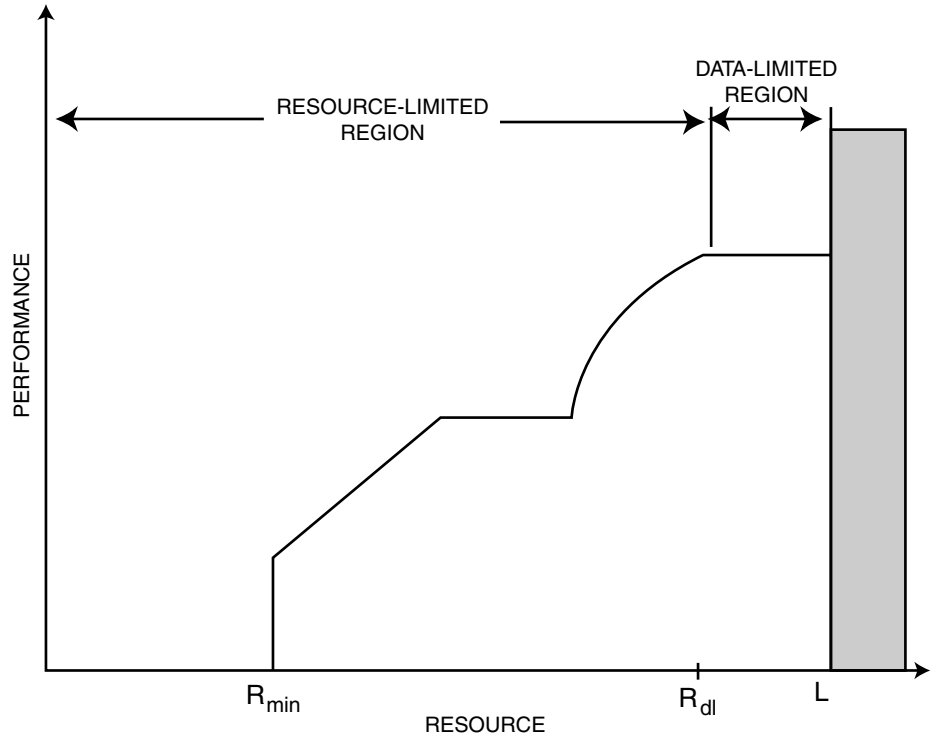

Figure 5 Relation between performance (processing efficiency) and resources for data-limited and resource-limited processes. Processing efficiency remains constant for data-limited processing but improves with further application of resources for resource-limited processing. From Norman and Bobrow (1975).

the total demand for processing resources exceeds the available supply. Modular theories predict that interference occurs only to the extent that concurrent tasks compete for the same module, e.g., two tasks that both demand visuospatial resources.

More formal resource models of mental workload distinguish between *data-limited* and *resource-limited* processes. According to this view, which assumes that resources are unitary, there are different ways in which the availability of resources can influence the functioning of simultaneously active mental processes. Once a certain minimum level of resources is allocated to activate a mental process, the application of greater resources leads to more efficient (e.g., faster, more accurate) execution of that process. Such a process is said to be resource-limited, in that the quality of its output is dependent on the allocation of resources. Subjectively, "working harder" at a task will improve its performance. As more resources are applied, however, there may come a point at which further allocation no longer improves the efficiency of the mental process. At this point, performance is said to be data-limited; efficiency is determined by the quality of the input source to the process, whether that source is sensory or drawn from memory storage (see Fig. 5). The subjective experience is that when the stimulus input is degraded, performance cannot be bettered: for example, no amount of "trying harder" will improve one's perception of a weak sound buried in loud noise.

II. CORTICAL SIGNS OF MENTAL WORKLOAD

Cognitive psychologists have deliberated on the functional structure of mental workload for a number of years. Debate has focused on the two major issues of whether resources are unitary or fractionated into modules and given the latter, how the modules are defined. There is even argument concerning the notion of resources. Some investigators question the need for this construct, arguing that many aspects of complex human behavior, e.g., concurrent performance of two or more tasks, can be explained without recourse to a resource concept. For example, it has been suggested that interference between two discrete tasks can be

explained by the postponement of the central response–selection stage of processing of one of the tasks, as in the phenomenon of the "psychological refractory period." According to this model, there is no graded sharing of resources between tasks at any stage of processing. However, this model and related structural models cannot account for all aspects of multiple-task performance, especially for continuous tasks such as tracking and reading, and other investigators have vigorously defended the need for the resource concept.

These debates have ebbed and flowed over the years but an impasse has been reached. Meanwhile, more practically oriented research on the assessment of the mental workload of human operators in real work settings has continued. Use of the traditional behavioral tools of cognitive psychology to resolve the issues may prove difficult. Like in many other fields of psychology, the advent of cognitive neuroscience has raised the hope that brain imaging studies may shed some additional light on the issues. In addition to PET and fMRI, studies using electroencephalography (EEG) and event-related potentials (ERPs) have also been reported.

A. Physiological Bases for Resources

In comparison to PET and fMRI, EEG and ERP studies of mental workload have the longer history. Of course, EEG and ERPs also assess neural activity directly (as opposed to indirectly through blood flow and metabolism with PET–fMRI), although measurement at the scalp smears and distorts the original neuroelectrical signals. Spectral power in two major frequency bands of the EEG, α (7–14 Hz) and θ (4–7 Hz) has been linked to mental workload. In fact, the reduction in the amplitude of the α rhythm during mental arithmetic was first reported in 1929 by the discoverer of human EEG, Hans Berger. Although the intracerebral generators of scalp-recorded EEG α are not known precisely, α is thought to arise in widespread cortical areas via thalamocortical interactions. Functionally, α may represent a type of cortical "idling" that is disrupted whenever attentional resources are allocated to a task. Spectral power in the α frequency band thus is inversely related to resource allocation. In contrast, more recent studies suggest that EEG θ recorded from midline sites overlying the frontal cortex increases in power with increased task difficulty and with higher memory load during working memory tasks. Frontal θ power thus varies directly with resource allocation and can be distinguished from the posterior θ waves that have traditionally been linked to drowsiness. Again, although the source of this anterior EEG rhythm is unknown, it is consistent with a generator in the medial frontal cortex, perhaps the anterior cingulate cortex (ACC).

The EEG data provide good evidence for a physiological basis for resources in the human brain. The changes in EEG α and θ may represent a relatively gross, whole-task allocation of resources, given that the associated brain electrical activity spans several seconds and is relatively invariant with the type of information processing (although hemispheric differences have been noted with different forms of processing, e.g., verbal versus spatial tasks). The processing characteristics of specific components underlying a task can be assessed by recording task-evoked ERPs, which reflect the neural activity in response to a stimulus with millisecond precision.

ERP studies of mental workload have identified two resource-sensitive components, the P300 and N100. Most of these studies have examined dual-task performance, although working memory studies have also been carried out. The amplitude of the P300 component to a secondary task of counting infrequent tones among more frequent tones (an "oddball" task) decreases when combined with a primary task such as visual discrimination or psychomotor tracking. Thus, P300 amplitude shows a dual-task decrement, i.e., it is reduced in amplitude when the eliciting task is combined with another task. Importantly, only changes in the difficulty of visual discrimination and not motor tracking affect P300 amplitude on the secondary task. Because the P300 component has been shown to be more sensitive to central stages of information processing than to the response-selection stage, this finding provides strong supporting evidence for a modular theory of resources based on stages of processing (see Fig. 2).

A strong prediction of theories that postulate sharing of scarce resources is one of *resource reciprocity*, or an inverse relationship between primary and secondary task resource allocation and performance. As resources are withdrawn from the primary task, they are simultaneously allocated to the secondary task, and vice versa. If P300 amplitude reflects the allocation of resources to a central processing stage, its amplitude should vary accordingly. Consistent with this prediction, P300 amplitude to the primary or secondary task has been found to increase or decrease appropriately as resources are applied or withdrawn. Resource allocation between two tasks can also be

manipulated endogenously (through instructions and a payoff scheme) such that resources are allocated in differing proportions between two tasks (e.g., 25–75%, 50–50%, or 75–25%). Such studies have the advantage that the stimuli and responses remain constant across conditions, as opposed to single–dual task comparisons, which confound resource allocation with stimulus and response variations. In the resource reciprocity studies, the amplitudes of both the P300 and the early-latency N100 components have been found to vary in a graded manner with resource allocation.

The significance of these results should be emphasized. The finding of a dual-task decrement in P300 or N100 amplitude is insufficient by itself to support a resource model, because factors other than resource scarcity may contribute to dual-task interference. Consequently, the demonstration that ERP components show *graded* changes between tasks as resources are dynamically traded off between each other, with invariant stimuli and response requirements, provides strong support for resource theories. The P300 data also support a modular theory based on different stages of processing.

B. Cortical Localization: Working Memory, Divided Attention, and the Central Executive

The ERP studies of mental workload have provided supporting evidence and a physiological basis for resources in relation to dual-task performance. A particularly important contribution of these studies is their support for predictions from basic cognitive theory. The ERP data also provide support for the modular view, although they do not rule out hybrid theories in which modular resources are combined with a general purpose resource that is invoked for all processing activities.

As brain electrical activity recorded from the scalp, EEG–ERP studies do not provide strong evidence for cortical localization of resources. The poor spatial resolution of EEG and ERPs can be overcome to a degree through the use of such techniques as dipole modeling and spatial deconvolution. For example, the use of these techniques has led to the view that workload-related EEG θ activity is generated in the anteromedial frontal cortex, possibly the ACC, which has also been proposed to be a high-level central executive control center on the basis of PET and lesion studies, as will be discussed further later. In general, however, brain imaging techniques offer spatial resolution superior to that of EEG–ERPs and have provided evidence on the cortical localization of resources. This line of research follows from early work on measuring cerebral blood flow and metabolism using Xe-133, as described previously.

Much of the evidence stems from PET and fMRI studies of the neural substrates of working memory. This is a type of memory involved in keeping and maintaining information "on line" so that it can be used in the service of other processing activities—in language, decision making, and problem-solving. The functional properties of working memory have been studied in the cognitive psychology literature, and a widely accepted model is that illustrated in Fig. 3. The possible neural bases of these components of working memory have been the focus of intense study. A general finding is that active maintenance of information in working memory is associated with the activation of both frontal and posterior (parietal) cortical regions, depending on the type of material encoded and the specific operation in working memory probed. For example, it is well-known that perceptual operations can be divided into object and spatial components and that these operations are mediated by cortical processing streams that activate regions in the inferior temporal (ventral stream) and parietal cortices (dorsal stream), respectively. This cortical subdivision of labor during perception has been postulated to result in similar divisions "upstream" in the frontal cortex. In support of this prediction, working memory for objects such as faces has been found to activate the lateral prefrontal cortex, whereas spatial working memory has been shown to recruit more dorsal regions of the frontal cortex in the premotor region. Brain imaging data thus support the modular resource view shown in Fig. 3 to the extent that separate frontal loci have been observed for verbal and visuospatial working memory.

PET and fMRI studies of working memory have used a variety of tasks, such as delayed match-to-sample, in which a target item (the sample) must be retained in working memory and then compared to another stimulus presented after a delay. Another task is the *n*-back task, on each trial of which the *n*th previous stimulus in a series of stimuli presented sequentially must be identified and responded to (generally $n = 1$ or 2). In such tasks, activation of the ventrolateral prefrontal cortex (VLPFC), dorsolateral prefrontal cortex (DLPFC), and posterior parietal cortex is observed. Broca's area is also activated when verbal stimuli are used, probably reflecting phonologic rehearsal of items. Such studies

have also revealed a modular distinction within the lateral prefrontal cortex. Processes associated with the maintenance of information in working memory activate VLPFC and posterior parietal cortex, whereas processes associated with the manipulation of that information activate DLPFC. DLPFC activation has also been observed for high levels of working memory load, possibly reflecting mechanisms that are needed to provide processing support when task demands exceed short-term memory capacity. It has also been suggested that the posterior parietal areas may be a more passive storage buffer of on-line information, whereas VLPFC mediates more active maintenance processes. However, other work suggests that posterior parietal areas may in fact be involved with executive processes as well. The types of manipulation processes performed in DLPFC may include monitoring, updating, scheduling, attention shifting, and inhibition. Because of the prominence of the DLPFC in manipulation and other high mental workload-related processes, it has been implicated as a possible neural basis for a central executive module.

Studies of the Stroop task have identified another frontal cortical region involved with executive control, the ACC. In this task a person is asked to name the color in which a word is written. The word itself represents the name of a color and is written in either the same color (e.g., "red" written in red: congruent condition) or a different color (e.g., "green" written in red: incongruent condition). Reaction time to color naming typically is longer in the incongruent condition: this is known as the Stroop effect. Several studies have associated the Stroop effect with the activation of both the DLPFC and the ACC. These brain regions have also been implicated specifically in response selection in divided attention tasks and more generally with executive or supervisory activity. One study showed that it is possible to functionally dissociate these two regions using fMRI. DLPFC activation was found to be associated with cognitive control or with the focusing of attention on the demands of the task. In contrast, ACC activation was related to the provision of feedback about subjects' accuracy on the task.

Divided attention (dual-task) studies have obtained results relevant to the distinction between unitary and modular theories of workload and the concept of a central executive. In these studies, brain regions activated by the concurrent execution of two tasks are compared to those activated during the execution of either task in isolation. Dual-task performance ostensibly requires the central executive because of the need for coordination (although this must be demonstrated empirically for any given pair of tasks, and not all studies have done this). Therefore, any brain region activated by dual-task but *not* by single-task performance would potentially provide evidence for a specialized central executive region, such as the DLPFC or the ACC. Two fMRI studies failed to provide support for this view. In tasks involving verbal and face working memory, no new brain area was activated for dual-task performance. Instead, activation increased with dual-task performance but in the same regions active during the performance of each task individually. Although these findings do not rule out the possibility that specific executive processes are mediated anatomically by specialized modules, they do concur with other findings and are consistent with a modular view of workload, with content-specific slave buffers but no separate central executive control "center."

C. Beyond Localization: Parametric Manipulation of and Dynamic Interactions in Working Memory

Brain imaging studies of working memory and divided attention paint a fairly consistent picture. On-line maintenance of information in support of cognitive performance, whether in specific processing domains such as verbal, object, or spatial processing or more generally as in executive processes, activates specific neural circuits in the frontal cortex. The first generation of these imaging studies was primarily concerned with localization. As such, they have value in pointing to the cortical regions putatively associated with resources and, therefore, in describing the cortical expression of mental workload. However, localization per se is only partially informative with respect to the functional aspects of the neural mechanisms underlying mental workload. Localization is only a first step in a deeper understanding of such mechanisms. More important would be evidence that shows that neural activity in specific cortical regions exhibits systematic variation with task or subject variables or, as previously discussed, with exogenous or endogenous drivers of mental workload.

An early example of such parametric manipulation of workload was reported in an fMRI study of language processing in which the computational complexity of comprehending different sentences was varied. Sentence comprehension requires working memory processing resources first to compute the comprehension operations (word integration, syntactic and semantic relations, etc.) and second to maintain

these representations actively during the period of processing, which can be considerable for a long, complex sentence. The study examined sentences that varied in structural complexity by comparing simple conjoined sentences, including subject and object clauses. Important controls were the number of words, word frequency, and the complexity of individual words, so that the sentences differed only in overall structural complexity. Left hemisphere areas associated with sentence processing were analyzed for the volume of activation in the superior temporal cortex (Wernicke's area) and inferior frontal gyrus (Broca's area). Activation volumes increased with sentence structural complexity in both cortical areas and in a graded manner. Thus, the quantitative extent of neural activity evoked by sentence processing was directly related to the associated computational demand. These findings suggest that manipulation of processing complexity unconfounded with other factors results in increased brain activation in a manner consistent with the allocation of specific processing resources.

Similar parametric studies of working memory have also been reported. Such studies have shown that, as mental workload increases with an exogeneous driver, the cortical areas associated with the type of process manipulated exhibit corresponding increases in activity. PET studies of the *n*-back task have shown monotonic increases in activity in a number of areas, including the DLPFC, VLPFC, posterior parietal cortex, and Broca's area, as the size of *n* or the amount of information retained in working memory increases. In addition, monotonic deactivation with increasing verbal working memory demands has also been reported for certain brain regions. Although no clear consensus has been reached as to the relevance of these deactivations to the functioning of working memory systems, the consistent parametric activation of process-specific "slave" modules, coupled with parametric deactivation of other brain regions, suggests a reallocation of mental resources to compensate for increased task demands.

The working memory and dual-task studies indicate first that activation of specific frontal cortical regions can be identified as cortical signs of processing resources associated with task performance. Second, activity in these regions increases, or the volume of activated tissue increases, in response to demand for greater processing resources with exogenous drivers of workload. Such increases probably also reflect endogenous sources of workload, but exogenous and endogenous effects have not yet been differentiated by brain imaging studies. An important additional question is whether such cortical signs of processing resources are *necessary* for efficient task performance. For example, is the working memory "signature" in the frontal cortex sustained across time when a target object that has to be kept in mind occurs repeatedly? Specifically, how can processing resources be deployed to sustain attention to a specific object over time in the presence of distractors? fMRI studies have shown that neural responses are changed as stimuli become more familiar or as new associations are learned. However, such alterations in activation cannot distinguish a specific object that is currently the focus of attention from equally familiar distracters that should be ignored.

The neural responses that mediate repeated target identification during working memory were examined in an fMRI study. On a given trial subjects were required to study a sample object (a face) and then to identify it repeatedly with a button press in a stream of objects containing distracters (there were a total of 13 items plus the sample in a single trial). Subjects were familiarized with every object, and a specific object was used as a target on some trials and as a distracter on other trials. Distracters were also repeated within a trial. Thus, neither familiarity nor simple repetition could be used to signal the presence of a target, but rather a representation of the target on that trial had to be kept in mind for the duration of the trial. Under these conditions, enhanced neural responses were found primarily in bilateral inferior–middle frontal and left insular cortices (see Fig. 6). These responses signaled the identification and maintenance in working memory of the currently attended target item. Targets were also responded to faster with each repetition within a trial. The neural response to targets remained constant with repetition in frontal–insular areas, whereas those to targets or distracters in posterior regions declined (see Fig. 7). Activity associated with repeated distracters in frontal regions also remained at a constant but low level throughout the trial. Thus, the enhanced frontal neural responses and the speeded response to targets signaled the maintenance of the target object in working memory, supporting a role for the active maintenance component of working memory in the selection of targets among distracters. Effective selective attention requires that the neural response to a target stimulus is enhanced and maintained during the period of time the target remains behaviorally relevant. The sustained enhancement of frontal responses across target repetitions might reflect such top-down allocation of attentional resources to target detection.

III. CONCLUSIONS

Mental workload represents a composite brain state that reflects the interaction between task demands and a person's capability to meet those demands by the voluntary application of mental effort. Unitary theories propose that mental workload is associated with a single pool of information-processing resources that can be flexibly allocated to different processing activities. In the modular view, functionally separate resources are applied to different processing activities.

Evidence from electrophysiological (EEG, ERP) and functional brain imaging (PET, fMRI) studies supports a physiological basis for processing resources in the human brain. In general, these indexes of human brain function support a modular view of mental workload, although they do not rule out hybrid theories in which modular resources are combined with a general purpose resource that is invoked for all processing activities. PET and fMRI studies of working memory and dual-task performance indicate that mental workload is associated with the activation of cortical networks, including the dorsolateral and ventrolateral prefrontal cortices and posterior parietal cortex. Parametric modulation of activation in these brain regions with increased workload has been reported in a few studies. Mental workload may reflect the dynamic recruitment of these anterior and posterior brain regions in support of task performance in response to increased task demands.

GLOSSARY

antigen presentation Presentation of processed antigens on the surface of macrophages, microglia, or dendritic cells concomitant with major histocompatibility complex class II molecules is a mandatory step for generation and activation of antigen-specific T cells.

cytokine Soluble factor regulating interactions between immune cells.

glia Nonneuronal cells of the central nervous system encompassing microglia, astrocytes, and oligodendrocytes.

major histocompatibility complex Immunological surface molecules important in antigen-recognition processes by T cells and self/nonself discrimination.

microglia A subpopulation of glia in the central nervous system.

myelin Biological membrane around nerve fibers facilitating fast nerve conduction; produced by Schwann cells in the peripheral nervous system and oligodendrocytes in the central nervous system.

nerve regeneration Regrowth of nerve fibers after injury.

synaptic stripping Active detachment of synapses from neurons by glial processes.

Wallerian degeneration Term for the complex cellular and molecular events in the distal stump after nerve injury with degeneration of nerve fibres.

Microglia are a major glial component of the central nervous system (CNS) of presumed bone marrow origin. Only the perivascular microglia, a subtype, are regularly replaced from the bone marrow in adult animals, whereas parenchymal microglia are extremely sessile. Microglia respond to virtually any, even minor, pathological events in the CNS. This article reviews basic properties of microglia and discusses their multiple functions in the CNS during neurodegeneration, ischemia, autoimmunity, and inflammation.

I. BASIC PROPERTIES OF MICROGLIA

A. Microglia in the Normal CNS

The CNS is composed of neurons and a nonneuronal population of cells, designated glia, that includes astrocytes, oligodendrocytes, and microglia. del Rio Hortega discovered microglia in 1919 when he developed the silver carbonate methology. He identified process-bearing cells in the CNS parenchyma and named these cells microglia. Microglia contribute to about 10% of the total glial cell population in the CNS of adults. In the 1960s, the existence of ramified microglia as a distinct glial population was further confirmed by electron microscopy showing lack of intracellular intermediate filaments and intercellular gap junctions that are typical ultrastructural features of astrocytes. In contrast to oligodendrocytes, the principal myelin-forming cells of the CNS, microglia do not entertain myelin sheaths. Microglia are present in all parts of the brain and spinal cord (Fig. 1) but are

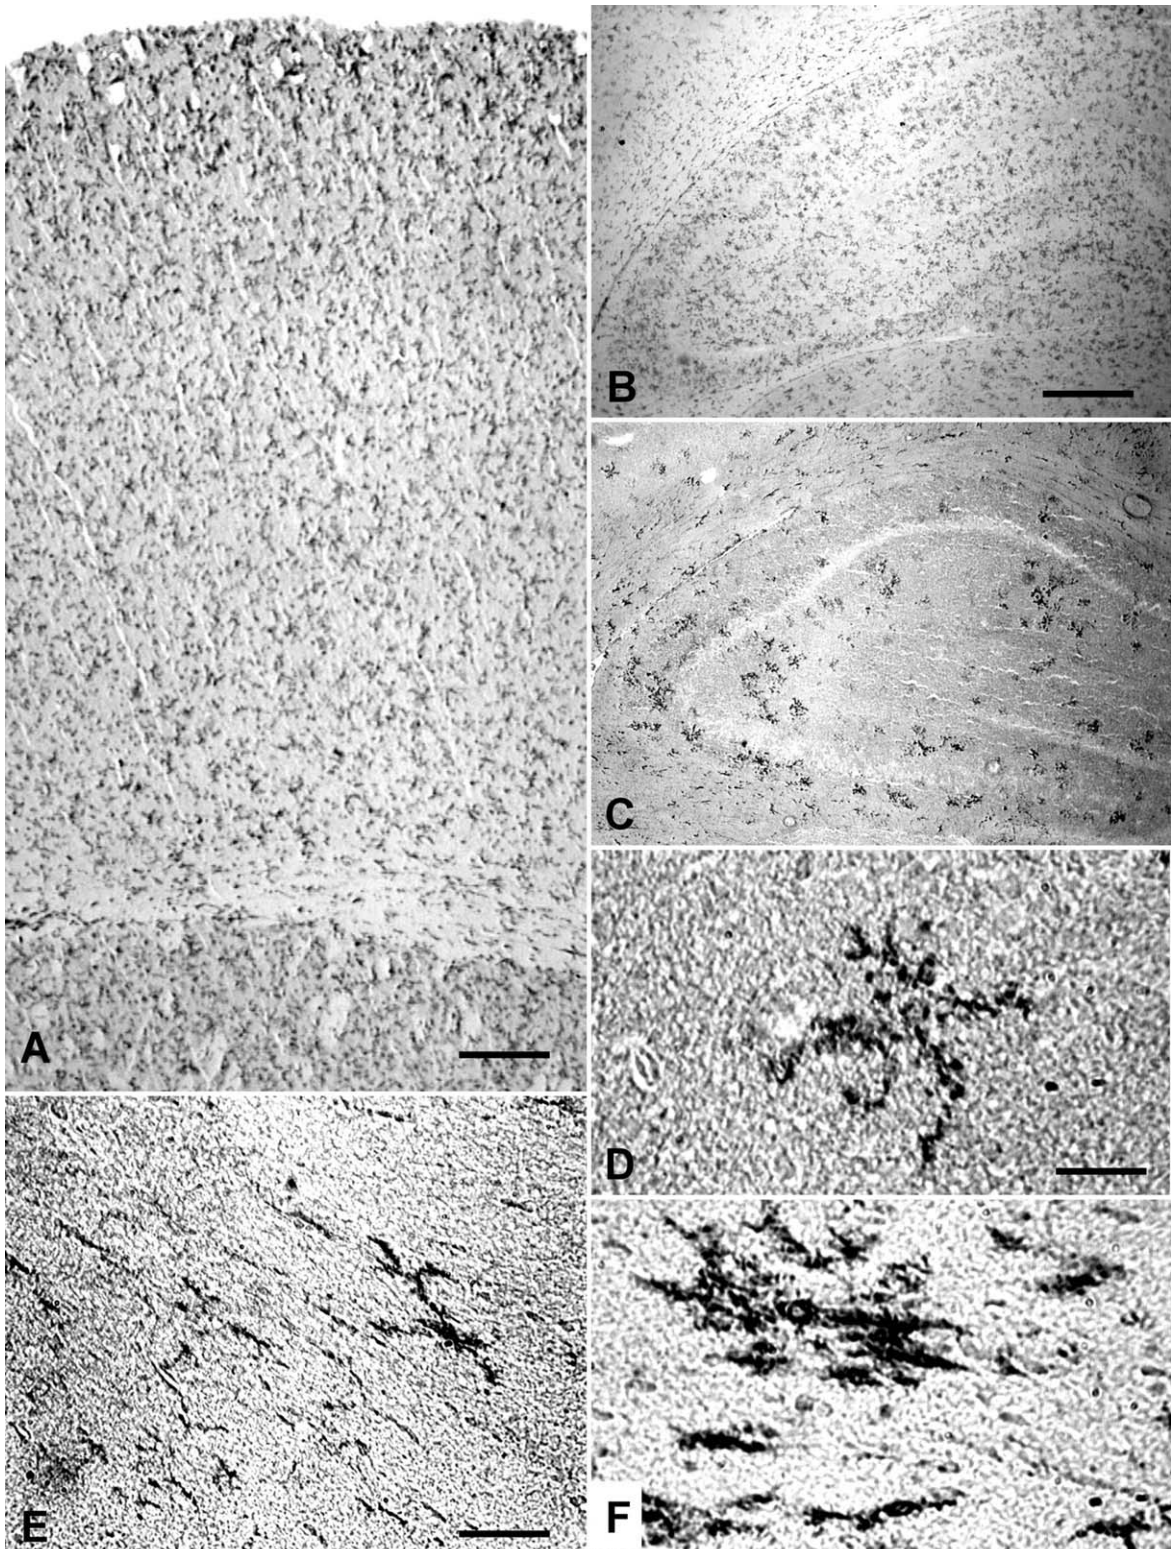

Figure 1 Parenchymal microglia in the rat brain. Sections of the sensomotor cerebral cortex (A), hippocampus (B–D), and cortical white matter (E, F) stained immunocytochemically with antibodies against the complement receptor-3 (CR-3) (A, B, E, F) and against keratan sulfate proteoglycans (KSPG) (C, D) to identify microglia. Note the widespread distribution of microglia in the cortex (A) and their typical ramified morphology (D). Microglia show a more longitidinal orientation in white matter tracts (E,F). More microglia express CR-3 (B) than KSPG (C). Scale bars = 200 μm in A, 80 μm in and B and C, 20 μm in D and F, and 40 μm in E.

not uniformly distributed. Microglia are located in close vicinity to neurons in the gray matter (Figs. 1A–1C) and between fiber tracts in the white matter of the CNS (Figs. 1E and 1F). More microglia are found in gray than in white matter. Microglia vary in morphology depending on their location. Longitudinally branched cells are found in fiber tracts (Figs. 1E and 1F). They possess long processes that are usually aligned parallel to the longitudinal axis of the nerve fibers. Radially branched cells are found throughout the gray matter (Fig. 1D). During normal aging microglia undergo morphological changes. Although in newborn brain few ramified microglia can be detected, they increase in number during postnatal development and are abundant in the middle-aged human brain. In the aged brain microglia change morphology again and show signs of activation, with enlarged longitudinally arranged processes.

Today, microglia can unequivocally be distinguished from other resident, nonneuronal cells in the CNS by immunocytochemistry. Resting microglia constitutively express the complement type-3 receptor (CR3; CD11b/CD18 complex) (Figs. 1A, 1B, and 1E), Fc receptors for binding of immunoglobulins, and galactose-containing glycoconjugates that bind isolectin B4 from Griffonia simplicifolia seeds. However, these antigens are not specific for microglia. Hematogenous macrophages that invade the CNS under certain pathological conditions also express CR3, Fc receptors, and the lectin binding site. Currently, the only antigen to our knowledge that is not shared between microglia and macrophages is a keratan sulfate proteoglycan epitope (KSPG) detected by monoclonal antibody 5D4 (Figs. 1C and 1D), which, underlies modification during immune-mediated processes in the CNS. In the gray and white matter of the normal rat CNS, a subpopulation of rat parenchymal microglia constitutively express KSPG.

Resting microglia generally express low to absent levels of major histocompatibility complex (MHC) class II molecules. These molecules are important for immune reactions. Already within a given species there are fundamental differences in the expression of microglial surface molecules. Whereas in the rat constitutive MHC class II expression of ramified microglia can be detected in Brown Norway and Dark Agouti strains, it is virtually absent in Lewis and Fischer 344 rats. Interestingly, constitutive MHC class II expression is inversely related to KSPG expression. These findings suggest a significant impact of genetic factors on the molecular differentiation of resident microglia in the normal CNS that are not yet elucidated.

Microglia respond to a variety of functional and lesional disturbances in the CNS. This response is accompanied by characteristic morphological and molecular signs of activation. Activated microglia retract processes followed by rounding of the cell body, particularly in conditions in which microglia finally act as phagocytes. This is associated with increased levels of CR3 expression on the surface. As a relatively early sign of microglial activation, MHC class I and II antigens are upregulated on the cellular surface, which enables microglia to interact directly with T cells. Except in mice, activated microglia express CD4 antigens, which are accessory molecules of T helper lymphocytes. Upon further transition into phagocytes, microglia develop intracellular phagolysosomes that can be visualized by immunocytochemistry. All these molecules indicative of microglial activation are also present on hematogenous monocytes/macrophages. This makes a distinction between the relative contribution of activated local microglia and that of invading macrophages from the blood in CNS disorders, in which both cell types are involved, difficult.

A subset of microglia, the perivascular microglia (which have also been termed perivascular cells), can be distinguished by their unique association with vessels and by immunocytochemistry using mab ED2 in the rat (Figs. 2A and 2C). These cells are spindle shaped and located around blood vessels. Perivascular microglia constitutively express the immune activation markers CD4 and MHC class II molecules (Figs. 2B, 2D, and 2E).

B. Microglia in Culture

Culture experiments have allowed the study of basic functional capacities of microglia. Most of these studies have been performed with microglia that were isolated from mixed glial cell cultures based on newborn rodent brain as starting material. In these isolated culture systems, microglia lose their characteristic ramified shape and round up to an ameboid morphology reminescent of activated microglia in areas of tissue remodeling during development and after brain injury (Fig. 3A). Compared to the normal *in vivo* situation, production of inflammatory cytokines is markedly enhanced in cultured microglia and likely further increased by the presence of serum that is routinely added to the culture medium but normally excluded from the brain parenchyma.

Treatment of cultured microglia with proinflammatory substances such as interferon-γ (IFN-γ), which is

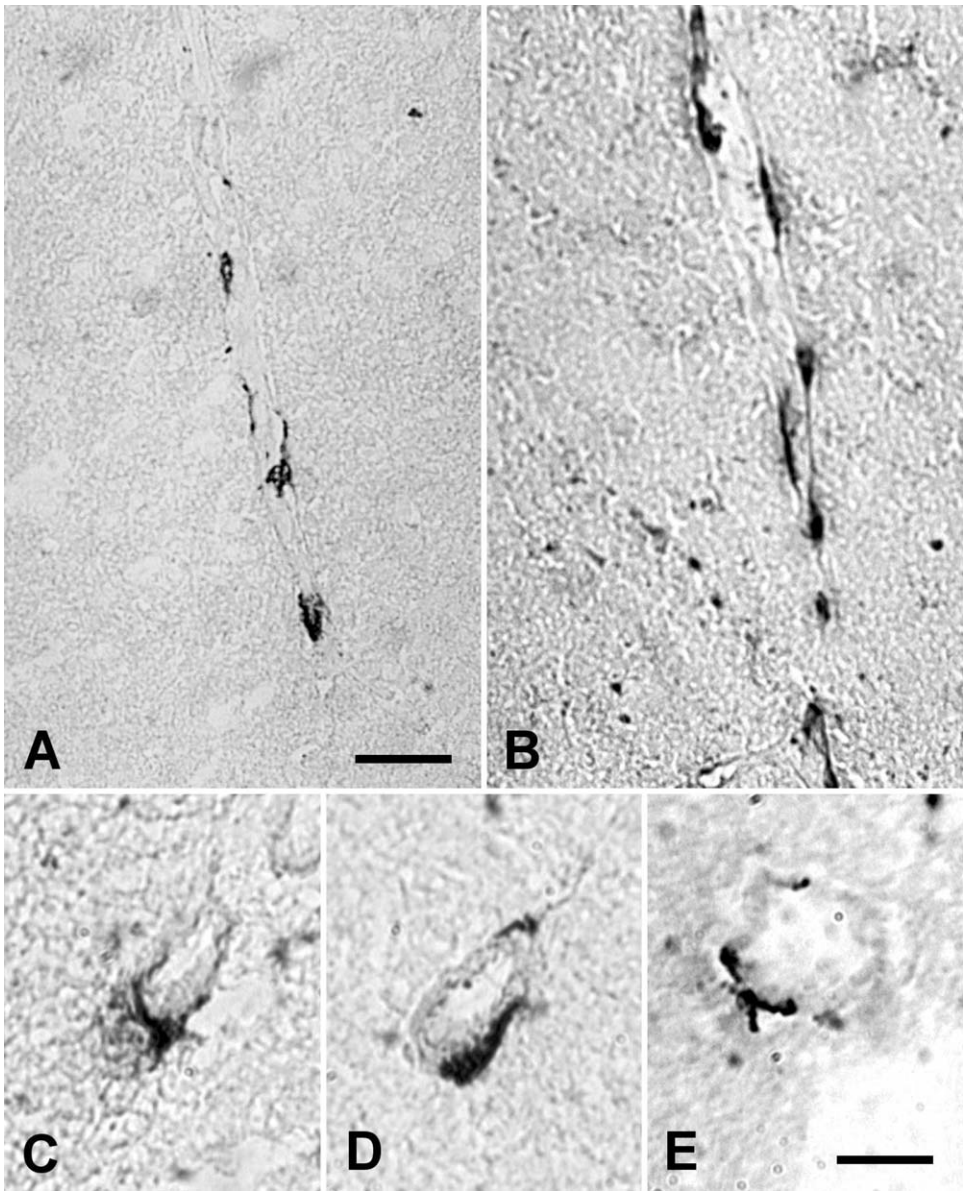

Figure 2 Perivascular microglia in the rat brain. Immunolabeling with ED2 antibody reveals a unique cell population of microglia also designated perivascular cells (A) that also express CD4 (B). Note the exclusive localization of the $ED2^+$ (A) and $CD4^+$ (B) microglia in close vicinity to cerebral blood vessels. (C–E) Perivascular microglia at higher magnification and their expression of ED2 (C), CD4 (D), and MHC class II antigens (E). Scale bars = 40 μm in A and B and 20 μm in (C–E).

secreted by T cells during inflammation, leads to induction of MHC class II antigens and a number of adhesion and costimulatory molecules, such as intercellular adhesion molecule-1 (ICAM-1), B7-1, and CD40, that are essential participants in the process of antigen-specific T cell stimulation. Accordingly, activated microglia derived from newborn rodent brain efficiently stimulated the activation and proliferation of antigen-specific T cells *in vitro*, supporting a role for microglia as the major antigen-presenting and immune-stimulatory cell type in the mammalian brain. However, this concept has been challenged by recent studies using ramified microglia isolated from the adult brain that have shown downregulatory rather than immune-stimulatory interactions of parenchymal microglia with T cells.

When microglial cells are grown on an astrocytic monolayer they develop processes similar to those of

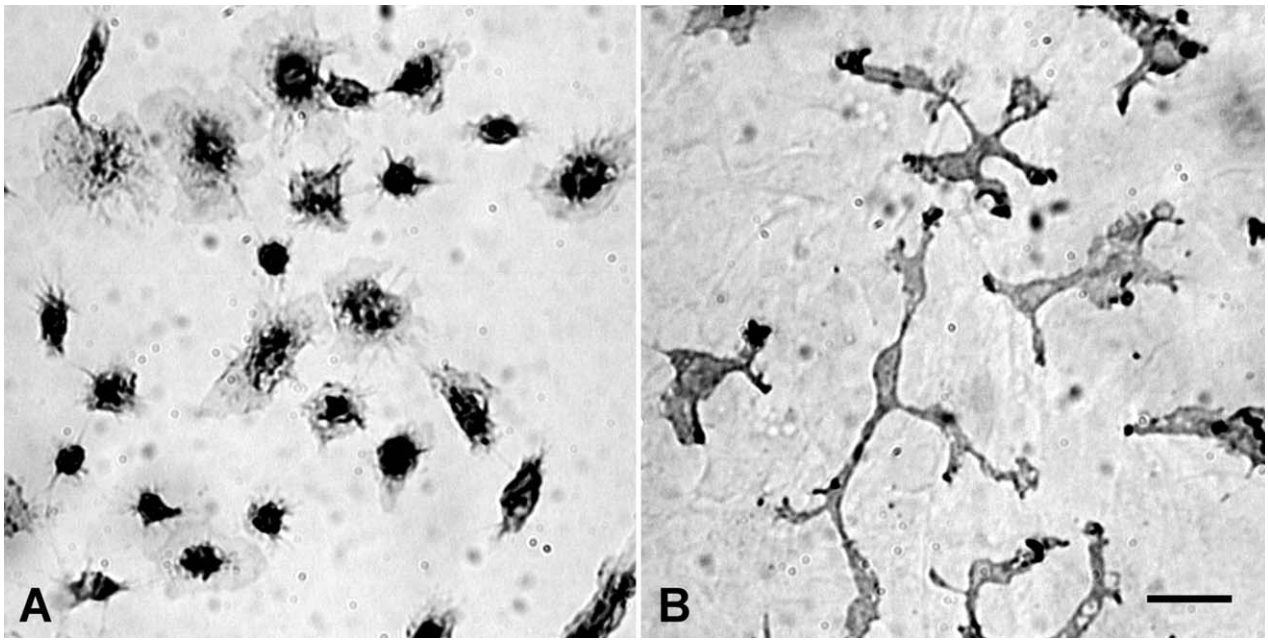

Figure 3 Rat microglia in culture dishes: immunostaining for complement receptor 3 by monoclonal antibody Ox42, a microglial marker. (A) Note the round (ameboid) morphology of isolated microglia resembling monocytes/macrophages. In the presence of astrocytes in primary mixed glial cultures (barely visible in the background), microglia develop multiple processes and acquire their distinctive morphological features (B). Scale bar = 20 μm.

ramified microglia in brain parenchyma (Fig. 3B). This points to an important influence of astroglia on microglial properties that is further substantiated by the fact that coculturing microglia with astrocytes markedly suppressed phagocytosis. Nondiffusible matrix components as well as astrocyte-derived cytokines such as the macrophage colony-stimulating factor (M-CSF) have been implicated in the induction of microglial ramification in these coculture models. In support of the proposed hematogenous origin of ramified microglia, monocytes or spleen macrophages brought into coculture with astrocytes likewise displayed a ramified morphology that was indistinguishable from that of CNS-derived microglia. Functionally, ramification was accompanied by the downregulation of immunomoleucles such as MHC class II, leukocyte function-associated antigen-1, and ICAM-1. Microglia bear a variety of receptor molecules on their surface, facilitating signaling through complement components, growth factors, cytokines, and chemokines. Antiinflammatory cytokines, such as interleukin-(IL-10) and transforming growth factor-β (TGF-β), can effectively suppress the expression of MHC class II antigens on microglia as well as neuronally produced factors such as brain-derived neurotrophic factor. *In vivo*, the cellular microenvironment of the CNS thus provides multiple autocrine as well as paracrine antiinflammatory feedback loops that tightly control the potentially harmful activation of microglia in disease states.

C. Factors Produced by Microglia

A striking feature of microglial reactivity is the ability to synthesize and secrete a large number of substances, which alone or in concert with factors derived from other brain or hematogenous cells can orchestrate immune responses and repair processes or directly cause brain damage. Factors produced by microglia include cytokines, growth factors, coagulation and complement factors, prostanoids, free radicals, extracellular matrix components, enzymes, and neurotoxins. In general, our knowledge about the circumstances in which each of these factors is produced and the regulatory factors involved is limited. This is mainly due to the complexity of possible interactions.

Microglia are an important source of the proinflammatory cytokines tumor necrosis factor-α(TNF-α), IL-1, IL-6, IL-12, and IL-18, which play an essential role in the initiation, amplification, and effector phase of T cell-mediated autoimmunity in the CNS.

Moreover, the cytokines IL1-β and TNF-α, have been inflicted in the pathophysiology of ischemic neuronal death but, on the other hand, may also exert neuroprotective effects. Interestingly, microglia also produce cytokines with antiinflammatory activities such as IL-10 and TGF-β. These cytokines provide an efficient autocrine mechanism for controlling microglial activity.

Nitric oxide (NO), whose formation is catalyzed by nitric oxide synthase (NOS), is a potent local mediator in the CNS. NO plays a major role in neural transmission, inflammation, neurotoxicity, host defense, and in the regulation of the vascular tone. Microglia derived from rodent brain are potent producers of NO upon stimulation with lipopolysaccharide (LPS) and cytokines. Contrastingly, the expression of inducible NOS and secretion of NO by human macrophages and microglia is controversial. Although low levels of NO appear to elicit protective responses, excessive NO production during autoimmunity and cerebral ischemia contributes to tissue damage. In the CNS, neurons and oligodendrocytes are most susceptible to NO cytotoxicity. Other potentially cytotoxic substances of microglia include superoxide anions, the enzymes elastase and gelatinase, excitotoxin, and quinolinic acid. However, most of the information on the cytotoxic properties of activated microglia pertains to *in vitro* observations and requires confirmation *in vivo*. On the other hand, microglia-derived neurotrophins, such as nerve growth factor, neurotrophin 3, basic fibroblast growth factor, and TGF, as well as the cellular matrix component thrombospondin likely contribute to repair processes after injury.

II. ORIGIN OF MICROGLIA

The origin of ramified microglia has been a long-standing controversial issue, although most authorities would accept that microglia are bone marrow derived and belong to the monocyte/macrophage lineage. The observation that the decline of blood-derived ameboid cells (macrophages) in the CNS during the first postnatal weeks was accompanied by a dramatic increase in the number of ramified microglia was suggestive for a transition of ameboid cells into resident ramified microglia. Based on morphological grounds, however, transitional forms between these brain macrophages and resting microglia could not be detected in the developing brain. Moreover, in an attempt to directly address the issue of transition, young mice received bone marrow transplants from transgenic mice, thereby allowing the distinction between host and donor cells in tissues. In these chimeric animals only 10% of parenchymal microglia in the CNS displayed the transgenic signal. In adult animals attempts to directly demonstrate the replacement of ramified parenchymal microglia from bone marrow-derived precursors have so far yielded inconclusive results. Ramified microglia in the adult CNS are an extremely sessile cell population exhibiting virtually no turnover from circulating monocytic precursor cells. In contrast to the parenchymal microglia, the perivascular microglia are definitely bone marrow derived and regularly replaced in the adult CNS as demonstrated by use of chimeric rats by Hickey and Kimura.

The view that parenchymal microglia are bone marrow derived has been challenged. Based on their finding that astroglial cultures initiated from newborn mouse neopallium contained bipotential progenitor cells that could give rise to both astrocytes and microglia, Fedoroff and colleagues put forward the idea that parenchymal microglia are of neuroectodermal origin, as are all other glia. This view was further supported by the observation that the majority of microglia lacked the transgenic signal after bone marrow transplantation as described previously. Despite the uncertainty about their origin, microglia share most surface molecules with bone marrow-derived monocytes/macrophages.

III. MICROGLIA AND CNS INJURY

Microglia are able to transform into large phagocytes and thereby remove debris in the CNS. Microglial responses, however, appear to be tightly controlled by environmental factors in CNS injury. This is most apparent when the phagocytic activity of microglia during Wallerian degeneration is compared to that of necrotic CNS lesions induced by stab wounds, bacterial infection, or cerebral ischemia.

A. Ineffective Phagocytic Activation of Microglia during Wallerian Degeneration

The simplest model of nerve injury is axotomy of fiber tracts. Transection or crush of a fiber tract in the nervous system leads to breakdown of axoplasm within days, loss of axonal connectivity, and to cellular and molecular changes in the distal nerve segment

referred to as Wallerian degeneration. In the peripheral nervous system (PNS) nerve fibers promptly regenerate from the proximal stump into the degenerating distal nerve segment, but no such regrowth occurs in the CNS. One of the prerequisites for axonal regeneration in the PNS is the rapid removal of growth-inhibitory myelin debris from the degenerating distal nerve segments that is facilitated by infiltration of hematogenous macrophages within the first 2 weeks. After transection of the optic nerve (a component of the CNS) and of nerve fiber tracts in the brain or spinal cord, hematogenous macrophages are largely or completely excluded, probably because the blood–brain barrier remains intact. Thus, growth-inhibitory myelin components in the distal stump persist for weeks. Only at the site of the transection where the blood–brain barrier is disrupted is a rapid macrophage infiltration observed. Although microglia could substitute hematogenous macrophages by phagocytic transformation and thereby compensate for the failure of macrophage entry into degenerating CNS fiber tracts, microglial activation is surprisingly slow and insufficient to clear myelin debris. In the PNS the complement system and lectins play a major role in myelin removal by macrophages. MAC-2 is a galactose-specific lectin mediating myelin phagocytosis by macrophages in the PNS. MAC-2 is not induced in microglia in degenerating fiber tracts in the CNS. Interestingly, the phagocytic activity of both macrophages and isolated brain-derived microglia could be enhanced upon their exposure to sciatic nerve segments but was inhibited by exposure to optic nerve segments. In conclusion, both the insufficient activation and the active suppression of microglia by unknown mechanisms in conjunction with the lack of macrophage entry may partly account for regeneration failure in the CNS. Elucidation of the different molecular signaling during Wallerian degeneration in the PNS and CNS can be expected to have important clinical implications for nerve repair.

B. The Prompt Microglial/Macrophage Response in Necrotic CNS Lesions

1. Microglial Responses to Stab Wounds and Bacterial Infection

In CNS injury leading to neuronal necrosis with breakdown of the blood–brain barrier (BBB), microglia are promptly activated and aided by infiltrating monocytes/macrophages from the circulation. As stated previously, at the stage of phagocytic transformation microglia and macrophages become indistinguishable by morphological grounds and by immunocytochemistry. Therefore, the population of phagocytes is referred to as microglia/macrophages in this article. The normal CNS appears to be relatively resistant to leukocyte diapedesis since intracerebral injections of proinflammatory cytokines such as IL-8, IL-1, and TNF-α elicit only minimal monocytic recruitment into the CNS parenchyma. However, necrotic brain lesions induce prompt inflammation. The critical role of breakdown of the BBB to macrophage recruitment into CNS lesions was demonstrated in the following experiment: Blood monocytes were prelabeled to allow follow-up of their distribution after injury. Although a mechanical CNS lesion with breakdown of the BBB led to prompt recruitment of these prelabeled peripheral monocytes, degeneration of inferior olivary neurons induced by intraperitoneal administration of 3-acetylpyridine, a neurotoxic process that respects the integrity of the BBB, led to microglial activation only.

The most simple traumatic CNS lesion with destruction of the BBB is a stab wound. A device is penetrated into the cortex. The ensuing cellular response is limited to the site of penetrating injury and the immediately surrounding tissue. Giulian and colleagues described activation of microglia at the lesion edges and infiltration of the wound site by hematogenous macrophages within hours after injury. Microglia proliferated locally with a maximum on Days 2 or 3, and mononuclear phagocytes rapidly cleared trauma-induced debris and produced IL-1, a cytokine that stimulates astrogliosis and neovascularization. Macrophages are attracted to tissues by chemokines. After penetrating mechanical CNS injury, astrocytes and endothelial cells increased mRNA levels of the chemoattractant monocyte chemoattractant protein-1 (MCP-1) and within 12 hr expressed MCP-1 protein, followed by prompt macrophage infiltration.

Microglia are involved in the formation of bacterial brain abscesses. Brain abscesses were produced experimentally in the rat by direct intracerebral injection of agarose beads laden with *Staphylococcus areus*. This approach allowed a sequential analysis of glial and inflammatory responses during different stages of abscess development. The first stage, acute cerebritis, was characterized by brain edema and diffuse infiltration of a wide rim of edematous brain parenchyma by microglia/macrophages around a necrotic center filled with granulocytes. Between Days 4 and 8 chronic cerebritis developed and microglia strongly

upregulated CD4 and MHC class II molecules. At this stage increasing numbers of hematogenous macrophages were recruited and gathered around the necrotic lesion. This finally led to capsule formation, regression of the abscess, and resolution of the edema. Interestingly, a subpopulation of macrophages recognized by the antibody ED2 in the rat preferentially infiltrated brain abscesses. Their functional properties in comparison to those of the usual population of $ED1^+/ED2^-$ macrophages in other brain lesions have not been characterized.

2. Microglia and Cerebral Ischemia

Local microglial activation and hematogenous macrophage infiltration are hallmarks of focal cerebral ischemia, which also leads to prompt breakdown of the BBB. Microglia are activated early in the border zone of infarcts, retract processes, round up, and partly transform into phagocytes (Fig. 4). In conjunction with a dramatic influx of hematogenous macrophages during the first 2 weeks after focal ischemia, microglia rapidly remove necrotic debris. Activation of microglia is accompanied by upregulation of MHC class I and II molecules. Morphological transition of microglia from normal brain tissue toward the infarct border can regularly be seen in human infarcts of recent age (Fig. 4). Macrophages are presumably attracted by chemokines released by astrocytes in the penumbra zone of infarction. The relative contribution of microglia/macrophages to the pool of phagocytes was formally assessed by depletion experiments in the model of photochemically induced focal ischemia in the rat. Macrophages can be depleted temporarily from the blood and lymphoid organs by intravenous application of dichloromethylene diphosphonate-containing liposomes, a treatment that does not affect microglia. In these macrophage-depleted rats there was no difference in the number of phagocytes on Day 3 after ischemia, but there were significantly fewer phagocytes on Day 6 compared to controls. This means that in the initial phase after focal ischemia, microglia to some extent transform into phagocytes and macrophages are recruited secondarily to aid in the removal of debris. The timing of macrophage recruitment as shown here for photothrombotic ischemic lesions may differ in other stroke models and other species.

Further phenotypical characterization revealed that besides $CD4^+$ microglia/macrophages, which are regularly seen in degenerating fiber tracts in the CNS, a novel population of microglia/macrophages appeared surrounding the infarcts predominantly between Days 3 and 6. This observation was independent of the mode of infarct induction and was a consistent finding also after permanent occlusion of the middle cerebral artery. By confocal laser microscopy and reverse transferase-polymerase chain reaction, we could show that this subpopulation of microglia/macrophages expressed the $CD8\alpha/\beta$ heterodimer, so far only described on cytotoxic/suppressor T cells. Secondarily degenerating fiber tracts and nuclei after cerebral ischemia showed the slow microglial activation and low phagocytic activity known from transected CNS fiber tracts as decribed previously and did not contain $CD8^+$ microglia/macrophages. The functional role and particular cytokine profile of this novel $CD8^+$ microglia/macrophage population in the rat CNS are unknown. Moreover, it is unclear whether this distinct microglia/macrophage population also exits in species other than the rat.

Reactive phagocytes can release neurotoxins after ischemic and traumatic injury to the CNS and thereby could aggravate tissue damage. However, neurotoxicity of microglia/macrophages in ischemic brain lesions has not been formally proven *in vivo*. The cytokine TNF-α apparently plays a key role in ischemia-induced microglial responses, although functional data are conflicting. In mice genetically deficient in TNF receptors, microglial responses were attenuated although neuronal damage increased after focal ischemia. In addition to their presumed neurotoxic actions, microglia/macrophages can also exert beneficial effects through production of neurotrophic factors.

Microglial activation is not restricted to infarcts and their immediate border zones but encompasses the entire ipsilateral, but not contralateral, hemisphere. A similar remote activation occurs in astrocytes that upregulate glial fibrillary acidic protein. This microglial and astroglial activation is transient and can partly be blocked by the NMDA receptor antagonist MK-801. This suggests that the remote glial responses are induced by periinfarct spreading depression like depolarization during the first hours after focal ischemia. The functional consequences are currently under investigation.

In contrast to the almost immediate onset of neuronal loss in permanent focal ischemia, transient global cerebral ischemia leads to delayed neuronal death in vulnerable areas. After brief periods of global ischemia (up to 15 min) damage is mainly restricted to CA1 pyramidal cells in the hippocampus. In areas of impending neuronal loss that can be delineated at 2–4

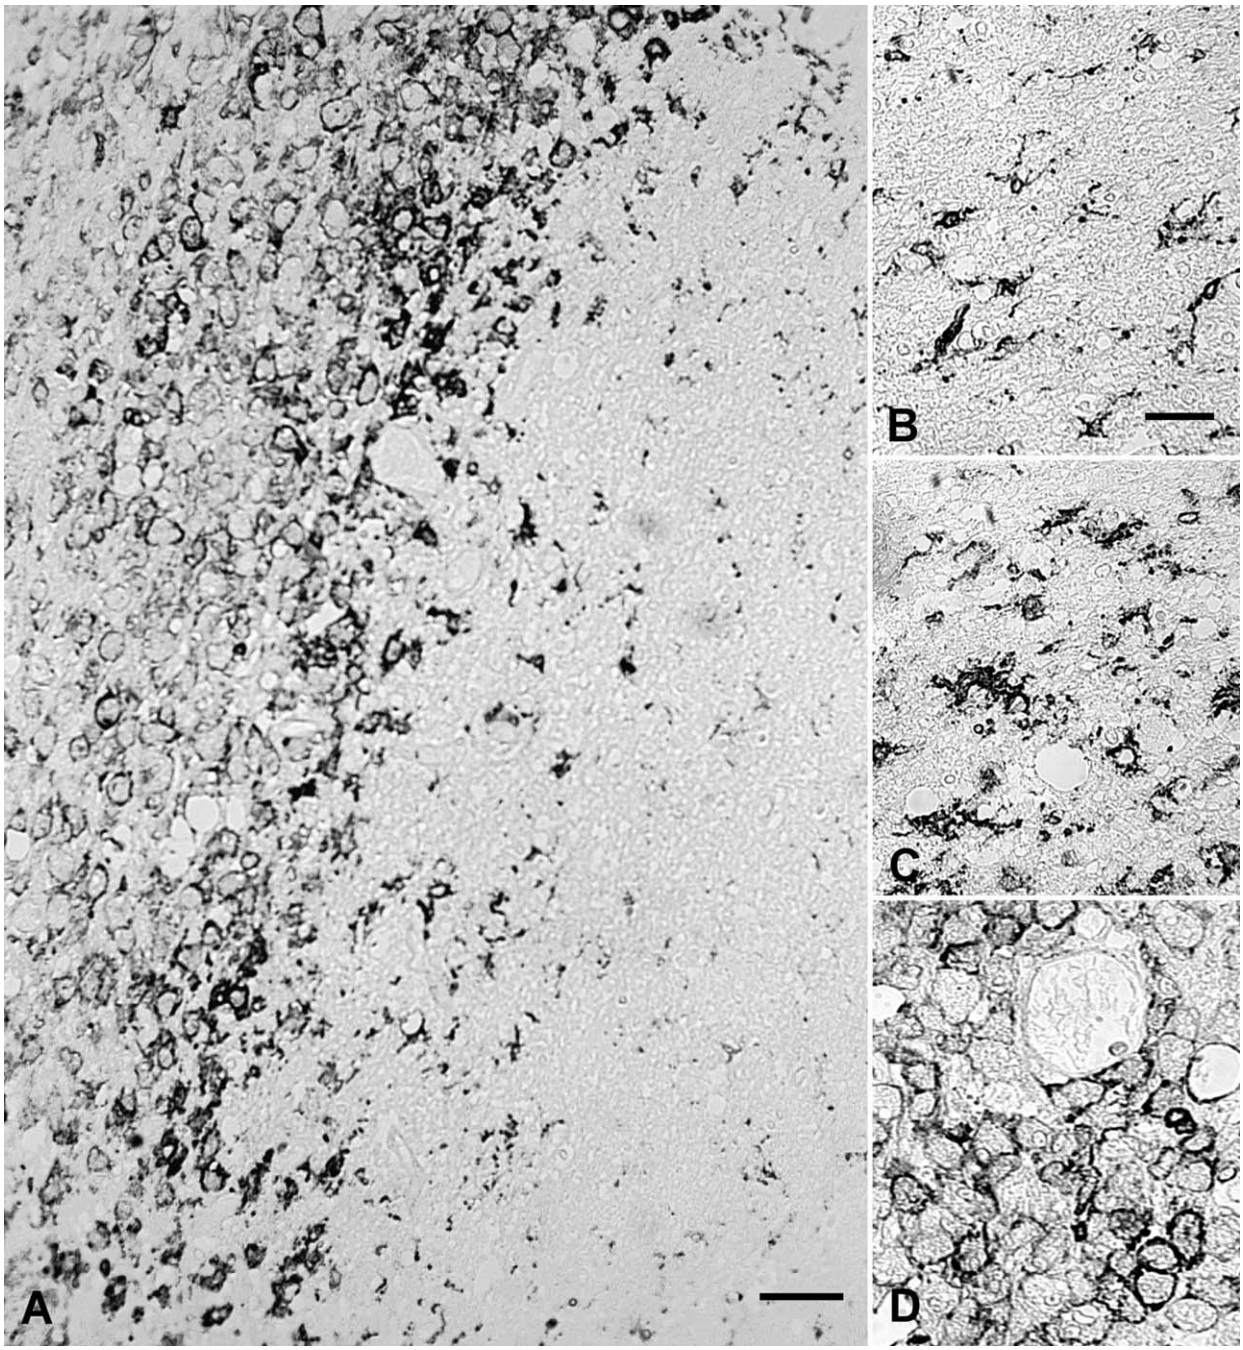

Figure 4 Microglia and macrophage responses in the human brain 5 days after cerebral ischemia (autopsy case). (A) The infarct is on the left side. Immunocytochemistry for the activation marker MHC class II reveals characteristic morphological changes in microglia from normal brain tissue (right) toward the edge of infarction (left). (B–D) Details of this morphological transformation from the typical ramified microglia (B) to ''stout'' microglia with loss of ramification (C) and finally to round phagocytes (D). At the stage of phagocytic transformation within the inner infarct border zone microglia and hematogenous macrophage are indistinguishable. Scale bars = 50 μm in A and 25 μm in B–D.

days after global ischemia, microglia show signs of activation within 24 hr after reperfusion and later cluster around degenerating neurons. In areas with a higher hypoxic resistance microglial activation is also observed, but in the absence of neuronal degeneration it occurs only transiently.

IV. MICROGLIA AND NEURODEGENERATION

A. Synaptic Stripping

Transection of the facial nerve is a useful model for studying microglial responses in the absence of infiltrating macrophages, as shown by the seminal work of Kreutzberg and colleagues. The facial nerve is cut outside the brain and the reactions of facial motoneurons and their glial environment to retrograde axonal degeneration can be studied in the brain stem, which shows no disturbance of the BBB in this lesion paradigm. After transection of the facial nerve microglia proliferated within 3 or 4 days mainly around the corresponding motoneurons and expressed long-standing activation markers (CD4, MHC class I and II, and cell adhesion molecules), amyloid precursor protein, and the cytokines TNF-α and TGF-β. TGF-β is a cytokine with a potential role in tissue repair. From Day 4 after axotomy onward, proliferating perineuronal microglia ensheathed the soma of the injured motoneurons and detached afferent synaptic terminals from the motoneuron surface, a process designated synaptic stripping. Synaptic stripping is an important process in synaptic reorganization after injury. Interestingly, microglia were activated but did not phagocytose unless the motoneurons underwent lethal injury. After selective death of motoneurons induced by retrogradly transported toxic ricin, a paradigm that also leaves the BBB intact, surrounding microglia transformed into phagocytes and removed dying neurons without the aid of hematogenous macrophages. Similarly, kainic acid-induced neuronal degeneration led to phagocytic transformation of microglia in the hippocampus.

B. Microglial Responses in Degenerative CNS Diseases

A pathogenic role of microglia has been suggested in degenerative CNS diseases, such as Alzheimer's disease (AD) and Parkinson's disease, that are characterized by selective loss of neurons in distinct regions of the brain. These conditions lack an overt inflammatory response, but microglia are activated at sites of neuronal degeneration. AD is characterized pathologically by the presence of insoluble structures in the cerebral cortex that represent either extracellular plaques consisting of amyloid-β protein (Aβ) deposits or neurofibrillary tangles within nerve cell bodies. In AD brain microglial cells accumulate in the center of plaques and in regions of perivascular deposits of Aβ. Further examination of the relation of microglial activation to different stages of plaque development revealed a preferential association of activated MHC class II-positive microglia with diffuse amyloid deposits and of enlarged phagocytic microglia with amyloid plaques. This strong association has been commonly interpretated as a beneficial microglial attempt to phagocytose and remove neurotoxic Aβ. In fact, microglia can internalize Aβ fibrills by scavenger receptors, but the rate of Aβ degradation is limited and the cells appear to be subsequently overwelmed by the amount of Aβ present. As an alternative possibility, activated microglia have been suggested to contribute to neurotoxicity. In support of this view, Aβ in culture together with the cytokine IFN-γ activated microglia to produce reactive nitrogen intermediates and TNF-α. This process led to neuronal cell injury *in vitro*. Treatment of microglia with a secreted derivate of β-amyloid precursor protein (APP) led to activation of the transcription factor NF-κB with ensuing induction of IL-1β and inducible NOS. Taken together, these findings indicate that β-APP can activate microglia and enhance their neurotoxicity.

The importance of microglial activation in degenerative CNS diseases has further been highlighted in an animal model of globoid cell leukodystrophy (GLD). GLD is a severe demyelinating disorder of the CNS. It is characterized by an increased number of MHC class II-expressing microglia/macrophages in the CNS but no T cell infiltration. Twitcher mice serve as an animal model for GLD. Mating twitcher mice with MHC class II-negative knockout mice led to a profound clinical improvement accompanied by reduced numbers of microglia/macrophages in the CNS in comparison to MHC class II-positive littermates. This points to a pathophysiological role of microglial MHC class II molecules in neurodegeneration independent of a T cell response. The underlying molecular mechanisms are unknown.

V. THE ROLE OF MICROGLIA IN CNS AUTOIMMUNITY AND INFLAMMATION

Microglia exert multiple functions in CNS autoimmunity and inflammation. Microglia can present antigens to T cells, produce cytokines and toxic radicals, and exert effector functions in CNS inflammation. Microglia are very sensitive to systemic stimuli. Intraperitoneal injections of the nonspecific immune activator

LPS led to increased IL-12 expression in parenchymal microglia and cyclooxygenase-2 activity in perivascular microglia. Moreover, microglia proliferated in response to circulating cytokines as shown for IFN-γ.

A. Antigen Presentation and Effector Functions

Experimental autoimmune encephalomyelitis (EAE) is a widely used model of autoimmune CNS disease that mimics several aspects of human multiple sclerosis (MS). It is the prototype of a T cell-mediated CNS disorder and can be induced in susceptible animals by immunization with CNS myelin components or adoptive transfer of T helper cells primed against central myelin. Clinically, the disease is characterized by weight loss, paralysis, and ataxic gait developing at the end of the second week after immunization. Depending on the immunization protocol and the species used, animals recover spontaneously and disease subsides or animals develop a relapsing–remitting course. Histopathologically, EAE is characterized by massive T cell and macrophage infiltration in the CNS and variable degrees of demyelination. The interactions between T cells and macrophages are orchestrated by cytokines. In EAE, the balance between pro- and antiinflammatory cytokines most likely determines the clinical course. In the acute phase of the disease, strong expression of proinflammatory cytokines occurs, but it subsides during the recovery phase.

Myelin-primed T cells entering the CNS in EAE have to be restimulated locally to evoke clinical disease. The fundamental role of perivascular microglia as antigen presenting cells in T cell responses in the CNS has been established in chimeric rats by Hickey and Kimura. Systemic injection of lymphocytes of the T helper phenotype ($CD4^+$) from Lewis rats directed against CNS myelin into Lewis rats elicited EAE. A transfer of the same T cells into Dark Agouti (DA) rats provoked no disease. The reason for this discrepancy lies in the fact that infiltrating T cells need to be restimulated in the CNS by local antigen presenting cells in the context of the same MHC haplotype. Lewis rats are of the MHC $RT1^1$ haplotype, and DA rats express a different $RT1^a$ MHC molecule. Hickey and Kimura created (Lewis $\times$ DA) F1 hybrid rats. Then, DA rats were lethally irradiated to remove all bone marrow-derived cells and received bone marrow from F1 hybrid rats. Two months later, 90% of lymph node cells of these bone marrow-transplanted DA rats expressed the Lewis MHC molecules ($RT1^1$), an indication that a high percentage of the immune system was repopulated with donor F1 hybrid cells. In these chimeras only bone marrow-derived cells of the F1 hybrid donor could express molecules of the Lewis MHC ($RT1^1$). When T cells of Lewis rat origin were injected into the chimeric DA animals, they developed EAE. This means that a bone marrow-derived cell of Lewis origin ($RT1^1$) must have become established in the CNS of the chimeric DA rats to restimulate the infiltrating T cells. Further immunocytochemical analysis confirmed that bone marrow-derived cells in the CNS of these chimeric DA rats corresponded in location to perivascular microglial cells previously described on morphological grounds. Moreover, these perivascular microglia expressed macrophage antigens. This important study not only clarified the origin of perivascular microglia but also established a functional role of perivascular microglia in immune responses as antigen presenting cells in the CNS. It appears that despite their extensive expression of MHC class II antigens, parenchymal microglia are not necessary for the induction of a T cell response in the CNS since these microglia were of the $RT1^a$ haplotype in Hickey and Kimura's experiments and thus they were noncompatible with the transferred Lewis rat ($RT1^1$) T cells. The concept of an immunological dichotomy of perivascular and parenychmal microglia was further supported by *in vitro* studies showing that only a minority of isolated CNS microglia/macrophages had the capacity to stimulate encephalogenic $CD4^+$ T cells, whereas the majority of ramified microglia were ineffective antigen presenting cells.

Ramified parenchymal microglia are activated and act as effector cells in the inflammatory reaction in concert with infiltrating hematogenous macrophages both in EAE and in human MS. In EAE and MS lesions, microglia/macrophages do not only respond to T cell-derived cytokines but also may undergo autocrine activation through endogenously produced IFN-γ and thereby entertain a chronic inflammatory process even at a stage in which T cells have been eliminated by apoptosis. Within and at the border of actively demyelinating MS and EAE lesions, as a sign of activation MHC class II expression on microglia is abundant. Moreover, microglia show features of transformation into phagocytes, suggesting an active role in myelin destruction. *In vitro*, TNF-α is able to destroy myelin and oligodendrocytes. Activated T cells can induce TNF-α secretion by microglia. Microglial TNF expression has been demonstrated in MS and EAE lesions. EAE could be inhibited by drugs that

selectively blocked the production of TNF-α or by soluble receptors that presumably antagonized the effects of TNF-α on the surface of responding cells. Accordingly, EAE was more severe in transgenic mice overexpressing TNF-α in the CNS. In these transgenic animals the demyelination process proceeded chronically in the absence of T cells and was accompanied by persisting microglial/macrophage activation. In TNF knockout mice, T cells and macrophages infiltrated the CNS but failed to move forward from the perivascular position into the CNS parenchyma, suggesting a pathophysiological role of TNF in the final effector phase of EAE. Experiments conducted in knockout mice, however, produced conflicting results with respect to the role of TNF. Conversely, in another study TNF knockout mice developed more severe EAE, suggesting a potent antiinflammatory action of TNF-α in autoimmune-mediated demyelination. Comparison between these studies is difficult because different animal strains, gene targeting strategies, and encephalitogenic protein antigens were used. The differential role of resident microglia versus hematogenous macrophages as sources of TNF-α in this context remains to be defined.

B. Microglia and Downregulation of Immune Responses

The CNS has a high potential for eliminating infiltrating T cells. T cell apoptosis is considered an important mechanism by which immune responses in the CNS are limited and probably accounts for spontaneous clinical recovery in EAE. Apoptosis, a form of programmed cell death, is characterized by chromatin condensation and cell shrinkage and, in contrast to necrosis, initially preserves the integrity of the cell membrane. Thus, leakage of intracellular components is avoided and inflammatory responses to dying cells are very limited. Several studies have shown that in EAE autoreactive T cells are eliminated by apoptosis. This process can be enhanced by glucocorticosteroid or high-dose antigen therapy. The precise *in vivo* mechanisms of T cell apoptosis in EAE have yet to be elucidated. There is evidence that activated ramified microglia are involved in T cell apoptosis. When tested directly *ex vivo*, purified MHC class II-positive parenchymal microglia stimulated autoreactive T cells and elicited production of the cytokines IL-2, IFN-γ and TNF-α; surprisingly, however, T cells subsequently died by apoptosis after this interaction. In contrast, perivascular microglia and meningeal macrophages led to full T cell activation and supported T cell survival. These unexpected results were confirmed by others but are in apparent contrast to results of several previous studies showing efficient stimulation of antigen-specific T cell proliferation by activated cultured microglia. The reasons for these discrepancies are unclear. Species differences or different protocols used in the generation of antigen-specific T cell lines may be responsible. The recent results raise the possibility that parenchymal microglia are more involved in downregulation than in activation of T cell responses in the CNS.

Costimulatory molecules such as B7-1 and B7-2 expressed by antigen presenting cells play an important role in T cell activation. There is evidence that B7-1 signaling shifts immune reactions toward a proinflammatory Th1 response, whereas B7-2 signaling induces an antiinflammatory Th2 phenotype on T cell populations. Interestingly, human resting microglia from brain biopsies isolated and analyzed immediately *ex vivo*, expressed the antiinflammatory costimulatory molecule B7-2, whereas the B7-1 molecule was expressed on microglia in and around active MS plaques. In the rat, *ex vivo* isolated microglia lacked significant B7-1/B7-2 expression, again indicating the importance of species differences. Currently, the molecular mechanisms underlying the presumed downregulatory role of parenchymal microglia are vague and deserve further investigation.

GLOSSARY

binaural Auditory processing that involves two ears.

binocular Visual processing that involves two eyes.

cerebral aqueduct The portion of the ventricular system in the brain connecting the third and fourth ventricles.

cuneiform nucleus Mesencephalic reticular formation.

gaze movement Combined movements of eyes and head to shift the direction of the fovea.

inferior colliculus Caudal to the superior colliculus in the tectum, involved in auditory sensory processing.

mesencephalon The midbrain. One of the five main parts of the brain.

periaqueductal gray The region of neurons that surrounds the cerebral aqueduct.

superior colliculus The most dorsal portion of the midbrain (tectum), involved in visual–motor control.

tectum The dorsal portion of the midbrain, sensory. Includes superior and inferior colliculus.

tegmentum The ventral portion of the midbrain, motor.

vergence movements Movements of the eyes toward the nose (in opposite directions).

The midbrain or mesencephalon, one of the five major subdivisions of the human brain, sits literally at the middle of the brain and forms the junction between the forebrain (thalamus and telencephalon) and the hindbrain (medulla and pons). The midbrain is divided into a dorsal *tectum* and ventral *tegmentum* by a plane that bisects the long axis of the cerebral aqueduct. The tectum forms the roof of the midbrain and includes the pretectum, superior colliculus, and inferior colliculus (Fig. 1). Together, the four colliculi (both sides of the inferior and superior colliculi) form the quadrigeminal plate, the anterior most portion of which is the superior colliculus. The tectum develops from the alar plate in the embryo. Hence, the neurons of the tectum are usually related to sensory function. In contrast, the tegmentum is the basement of the midbrain and is a basal plate derivative in the embryo. Consequently, the neurons of the tegmentum are more closely tied to motor function, and the tegmentum contains the motor nuclei of the extraocular muscles, substantia nigra, and reticular formation (Fig. 1).

This article is organized according to these major sensory and motor divisions. First, we will discuss the role of the midbrain in the auditory system where the primary focus is the inferior colliculus and sensory processing. Second, we will turn to the control of eye movements by the midbrain. This topic includes the superior colliculus as a focus of sensory–motor integration and the ventral midbrain structures used for motor control of the eyes and head. This article will conclude with discussions of pain modulation by the periaqueductal gray and the blood supply of the midbrain. A list of abbreviations is provided in Table I.

I. THE AUDITORY SYSTEM OF THE MIDBRAIN

The auditory system extends from the medulla to the telencephalon. Almost all parts of the auditory system are connected to the midbrain. The present treatment

of the auditory system emphasizes the organization from the perspective of the midbrain.

A. Components of the Auditory System in the Midbrain

1. Inferior Colliculus (IC)

As the main component of the auditory system in the midbrain, the inferior colliculus represents the posterior part of the tectum (Fig. 1A). Its major role is to receive and integrate ascending input from most of the auditory system in the hindbrain and send its output toward the auditory cortex via the medial geniculate body in the thalamus (Fig. 2). It also receives major inputs from the cortex and has descending projections. The main part of the inferior colliculus is the large and prominent central nucleus. Surrounding the central nucleus, dorsally and caudally, is a cortex, and laterally and medially the paracentral nuclei are found. For each of these regions, we will describe the cellular organization, inputs, and outputs.

a. Central Nucleus of Inferior Colliculus (CNIC) The central nucleus is the major midbrain

Table I
List of Abbreviations

BA	Basilar artery
BSC	Brachium of superior colliculus
CNIC	Central nucleus of inferior colliculus
CP	Cerebral peduncle
DC	Dorsal cortex of inferior colliculus
DNLL	Dorsal nucleus of the lateral lemniscus
EW	Edinger–Westphal nuclei
INC	Interstitial nucleus of Cajal
LC	Lateral cortex
LL	Lateral lemniscus
LR	Lateral rectus muscle
MLF	Medial longitudinal fasciculus
riMLF	Rostral interstitial nucleus of the medial longitudinal fasciculus
MGB	Medial geniculate body
MR	Medial rectus muscle
MRF	Mesencephalic reticular formation (cMRF, central part of mesencephalic reticular formation)
ND	Nucleus Darkschewitsch
NOT	Nucleus of the optic tract
NPA	Anterior pretectal nucleus
NPC	Nuclei of the posterior commissure
NPP	Posterior pretectal nucleus
OC	Oculomotor complex
OPN	Pretectal olivary nucleus
OKN	Optokinetic nystagmus
P1	Proximal segment of the posterior cerebral artery
P2	Distal segment of the posterior cerebral artery
PAG	Periaqueductal gray
PC	Pretectal complex and the accessory optic system
PCA	Posterior communicating artery
Pcom	Posterior commissure
Post Com Art	Posterior communicating artery
RED	Red nucleus
SAG	Nucleus sagulum
SAI	Stratum albican intermediale
SAP	Stratum albican profunda
SC	Superior colliculus
SGI	Stratum griseum intermediale
SGP	Stratum griseum profunda
SGS	Stratum griseum superficiale
SO	Stratum opticum
SZ	Stratum zonale
SN	Substantia nigra
TN	Trochlear nucleus
VCLL	Ventral complex of the lateral lemniscus

component of the auditory pathway. In the human midbrain and most mammalian species, the central nucleus is defined by the presence of *fibrodendritic laminae*. The fiber component represents the ascending afferent axons from virtually all parts of the auditory system in the lower brain stem. Individual laminar axons form parallel sheets, several hundred micrometers wide, that extend in a ventrolateral to dorsomedial and rostrocaudal plane. These laminae represent an anatomical substrate for the *tonotopic organization* of the inferior colliculus. Acoustic stimuli at the lowest frequencies stimulate laminae in the dorsolateral part of the central nucleus, and successively higher frequencies stimulate laminae ventromedially (Fig. 2).

In the fibrodendritic laminae, the dendrites arise from the principal neurons in the central nucleus and are defined by their morphology. Disk-shaped neurons have flat, narrow, planar dendritic fields that parallel the planes of the laminar axons. The dendritic field of the large disk-shaped cell in humans is up to 1 mm long, and small disk-shaped cells have dendritic fields 600 μm long. In contrast, the width of the dendritic field is only around one-fourth the width of the axonal lamina (50 μm). This means that the disk-shaped dendrites are usually contained within a laminar plexus. A second, less common cell type is defined by a stellate or less flat dendritic morphology. Stellate cells can be small or large and have dendritic fields whose longest axis is either parallel or perpendicular to the fibrodendritic laminae.

Cell types in the central nucleus also are defined on the basis of their neurotransmitter content and by the target of their axons. A majority of the disk-shaped neurons in the inferior colliculus probably use glutamate as the neurotransmitter; however, a significant proportion of these cells use γ-aminobutyric acid (GABA) as the neurotransmitter (about 20% in the cat). Stellate cells can also synthesize GABA. Both GABAergic and non-GABAergic neurons can send their axons to other parts of the brain to form connections in the auditory pathway.

Neurons in the central nucleus are characterized by their membrane properties. At least six types of neurons can be defined using electrophysiological and pharmacological criteria in brain slice preparations in rats. The data suggest the presence of one or more unique potassium or calcium currents in each cell type, and these are likely related to unique combinations of potassium and calcium ion channels. Most cells in the central nucleus have membrane properties that tend to modify the inputs, e.g., act like filters. For

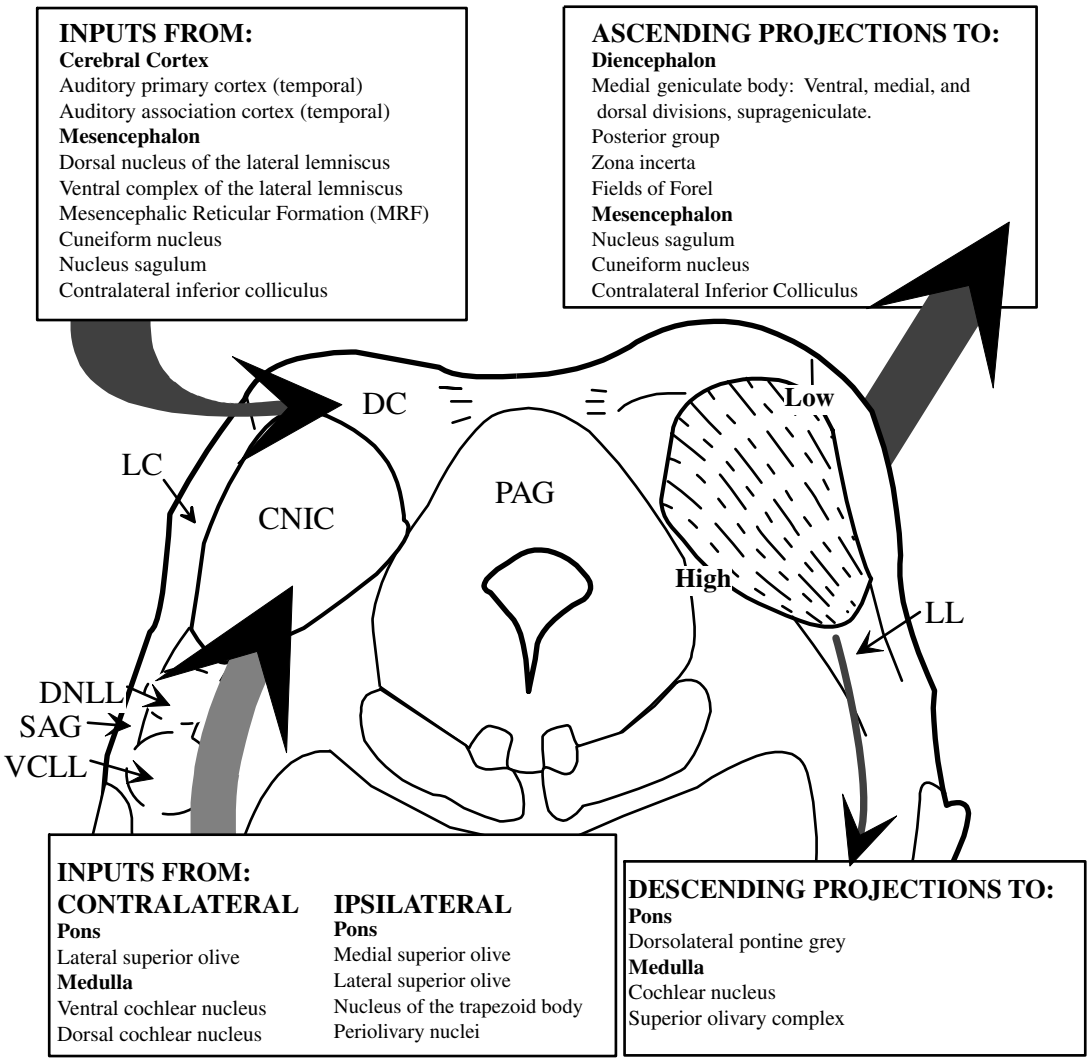

Figure 2 Inputs and outputs of the inferior colliculus. The fibrodendritic layers of the central nucleus are illustrated (right) by dashed and dotted lines. High and Low indicate high- and low-frequency laminae and the tonotopic organization. Inputs to the inferior colliculus are shown on the left side and outputs on the right side. Caudal structures are listed at the bottom, and rostral structures are listed at the top. See Table I for abbreviations.

example, in some neurons the firing rate will adapt (decrease in rate) slowly, whereas others will adapt quickly (a transient response) in response to continuous stimulation. An extreme version of the transient response is the onset response, firing once at the beginning of continuous stimulation. In contrast, some neurons in the central nucleus have responses that do not tend to modify their inputs, are not adaptive, and fire continuously in response to continuous stimulation. Thus, different membrane properties will regulate the ability of the neuron to fire and may set conditions under which it will and will not respond.

As the major midbrain component in the ascending auditory pathway, the inputs and outputs of the central nucleus include some of the main auditory pathways in the brain (Fig. 2). Ascending projections to the central nucleus arrive via the lateral lemniscus. The central nucleus receives binaural inputs from the superior olivary complex and monaural inputs from the cochlear nucleus. Of these, the largest number of synaptic inputs are excitatory inputs from the medial superior olive on the ipsilateral side. Other major excitatory inputs to the central nucleus are from the lateral superior olive, which projects to the central nucleus bilaterally, and the dorsal and ventral cochlear

nuclei on the contralateral side. The cochlear nucleus contains a variety of different cell types, but only the stellate cells from the ventral cochlear nucleus and the fusiform cells from the dorsal cochlear nucleus project to the inferior colliculus. Fine axonal inputs from the cerebral cortex to the central nucleus have been described. These are considerably fewer in number than cortical inputs to other parts of the inferior colliculus, and their influence is not well-established.

The central nucleus also receives distant projections, which are inhibitory. Much of the projection from the lateral superior olive on the ipsilateral side uses the neurotransmitter glycine and is likely to have an inhibitory influence on the cells of the central nucleus. Neurons in the dorsal nucleus of the lateral lemniscus use the neurotransmitter GABA and project primarily to the contralateral central nucleus. In contrast, the neurons in the ventral nucleus of the lateral lemniscus project to the ipsilateral central nucleus. Neurons in the ventral nucleus often contain both GABA and glycine; however, a specialized function is unclear for these colocalized neurotransmitters.

b. Cortex of Inferior Colliculus The central nucleus of the inferior colliculus is covered on its dorsal, caudal, and lateral surfaces by a cortex (Fig. 2). In most mammals including humans, a *dorsal cortex* (DC) and *caudal cortex* (CC) are easily recognized. These cortices contain stellate cells arranged in thick layers that are generally concentric and parallel to the surface of the inferior colliculus. At least four layers are found in the dorsal cortex of humans with the largest multipolar cells found in the deeper third and fourth layers. Smaller multipolar, stellate cells are found in the two superficial layers and in the caudal cortex. Disk-shaped cells are less common in cortex. Even when highly oriented dendrites are found, the neurons have local axons that are distributed widely in the dorsal cortex, unlike the disk-shaped cells of the central nucleus whose axons are confined to the same narrow lamina in which the dendrites are found. The lateral cortex of the inferior colliculus is subject to more variation between species. In humans, it is a relatively thin lateral zone. Because the lateral cortex has different connections and, possibly, a different cellular organization from the dorsal and caudal cortices, it is usually regarded as a separate part of the inferior colliculus (see later discussion).

The primary inputs to the dorsal and caudal cortices come from the telencephalon (Fig. 2). All parts of the auditory cortex project to the inferior colliculus. The heaviest inputs terminate in the dorsal cortex. Here, the axons from the telencephalon run perpendicular to the layers of the dorsal cortex, not parallel as in the central nucleus. Although all parts of the auditory cortex in the cerebrum project to the inferior colliculus, the subdivisions of the auditory cortex have different targets. Primary auditory cortex projects ventrally to the deepest layer of dorsal cortex, whereas the nonprimary auditory cortex projects to the superficial layers of the dorsal cortex. The deepest layer of the dorsal cortex, layer 4, receives inputs from both the ascending lateral lemniscus afferents and from the telencephalon. Thus, the deep dorsal cortex may have a special role to integrate ascending and descending pathways. The cortex of the inferior colliculus also receives inputs from the midbrain tegmentum and from the superior colliculus.

c. Paracentral Nuclei of Inferior Colliculus—Lateral Cortex (LC) Lateral to the central nucleus is the lateral cortex, also called external cortex (Fig. 2). The lateral cortex contains two or more cellular layers and is bounded superficially by the efferent fibers of the inferior colliculus that eventually form the brachium of the inferior colliculus. It has two parts, a superficial lateral zone (human), also called the lateral nucleus in the cat, and a *ventrolateral nucleus* at the ventral–lateral corner of the inferior colliculus. The ventrolateral nucleus may occupy a larger proportion of the lateral cortex in the rodent, whereas it is smaller and restricted to the ventrolateral corner of the colliculus in humans and cats. Despite differences in the nomenclature of this region, the structure of the lateral cortex is probably homologous in most mammalian inferior colliculi. The lateral cortex receives input from both auditory and nonauditory sources. Most of the inputs to the superficial, lateral zone are from the auditory cortex of the telencephalon and from the central nucleus. Other inputs include projections from the somatosensory system (spinal cord and dorsal column nuclei). In contrast to the lateral zone, the ventrolateral nucleus receives direct inputs from some auditory afferents that ascend to the midbrain via the lateral lemniscus. The dorsal cochlear nucleus and superior olive send important inputs to the ventrolateral nucleus.

d. Nucleus of the Rostral Pole The nucleus of the rostral pole is one of the paracentral nuclei of the inferior colliculus located rostral to the central nucleus. It contains stellate, multipolar cells organized without laminae. However, it is similar to the central nucleus in that it receives input from axons that ascend

from the lower auditory nuclei via the lateral lemniscus.

e. Commissural Nucleus The commissural nucleus of the inferior colliculus is medial to the central nucleus and dorsal cortex. It contains cells that lie among the fibers of the commissure of the inferior colliculus. Most inputs to the commissural nucleus probably originate from cells in the central nucleus and dorsal cortex of the inferior colliculus and terminate as the axons cross through the commissure.

2. Lateral Tegmental System

Ventral, medial, and rostral to the inferior colliculus are midbrain structures that have significant ascending connections with the auditory system. The lateral tegmental system includes the *superior colliculus*, *cuneiform nucleus* (see MRF), and *nucleus sagulum* (Fig. 1A). Although they do not receive direct input from the lower auditory system, they each project to the auditory part of the thalamus (the medial geniculate body). Thus, the lateral tegmental system may provide important nonauditory input to the auditory system.

3. Nuclei of the Lateral Lemniscus

The lateral lemniscus is a fiber bundle located in the lateral tegmentum of the midbrain that carries the axons from neurons in the cochlear nucleus and superior olive to the inferior colliculus. Embedded in the fibers are the nuclei of the lateral lemniscus: the dorsal nucleus and the ventral complex of nuclei.

a. Dorsal Nucleus of the Lateral Lemniscus (DNLL) The dorsal nucleus of the lateral lemniscus is situated at the top of the lateral lemniscus, just ventral to the inferior colliculus (Fig. 1A). It has many large, prominent neurons, and virtually all of the neurons contain GABA. Thus, the dorsal nucleus of the lateral lemniscus is usually thought to function as an inhibitory nucleus in the auditory pathway. The neurons in the dorsal nucleus have dendrites that are organized in horizontally oriented layers. The edges of the layers curl up in the ventral part and curl down in the dorsal part of the nucleus. Although the precise laminar arrangement has not been studied in humans, it may resemble the pattern seen in the cat rather than the more complex pattern seen in rodent species. These laminae are the substrate for a tonotopic organization with the lowest frequencies dorsally and the highest frequencies ventrally located. Most of the fibers of the lateral lemniscus penetrate the dorsal nucleus in fascicles and give off axon collaterals that contribute to the laminar organization of the dorsal nucleus.

Inputs to the dorsal nucleus arise from most of the same sources that project to the inferior colliculus (Fig. 2). These include the major input from the medial superior olivary nucleus (ipsilateral) and other projections from the lateral superior olivary nucleus (bilateral) and the ventral cochlear nucleus (contralateral). The dorsal nucleus also receives heavy inputs from the contralateral dorsal nucleus whose fibers make up the commissure of Probst. Most of these inputs are excitatory except for the input from the contralateral dorsal nucleus (GABA) and the ipsilateral projection from the lateral superior olive (glycine). Because of the major inputs from the superior olive, the dorsal nucleus of the lateral lemniscus contains neurons that are binaural and sensitive to interaural time and intensity differences.

The output of the dorsal nucleus is primarily to the inferior colliculus bilaterally and to the opposite dorsal nucleus. The projection from the dorsal nucleus to the central nucleus on the contralateral side is the major GABAergic input to the inferior colliculus. It terminates as a tonotopically organized, laminar projection whose ultrastructure and neurochemistry are characterized. Because of the large size of the dorsal nucleus neurons and axons, this inhibitory input reaches the colliculus quickly and may precede excitatory input from lower auditory structures in some cases. Inhibition in the inferior colliculus that arises from the dorsal nucleus may be important for many aspects of binaural information processing.

b. Ventral Complex of the Lateral Lemniscus (VCLL) The ventral complex of the lateral lemniscus is a collection of nuclei surrounded by the fibers of the lateral lemniscus (Fig. 1A). It extends from the rostral superior olivary complex in the pons to the ventral border of the dorsal nucleus beneath the inferior colliculus in the midbrain. The ventral complex contains at least three parts. A *ventral nucleus of the lateral lemniscus* is the main part. It is ventral and lateral and consists of many small, densely packed neurons. A majority of these neurons are immunoreactive for both GABA and glycine and are likely to release both at their axonal target. An *intermediate nucleus of the lateral lemniscus* is sometimes recognized as the region inserted between the ventral nucleus and the dorsal nucleus. It tends to have more sparsely distributed cells that are horizontally oriented.

Neurons in the intermediate nucleus are labeled with GABA and glycine less often, but they frequently have dense, glycinergic axosomatic terminals. A third region of the ventral complex is the *medial nucleus*. These are sparse neurons scattered in the fibers medial to the ventral nucleus. The ventral complex has a highly complex neuropil whose layers are suggested to resemble a helix. This complexity has delayed the comprehension of the frequency organization.

Most input to the ventral complex of the lateral lemniscus comes from the contralateral cochlear nucleus. Studies in the unanesthetized rabbit confirm that a majority of neurons of the ventral complex are monaural and respond best to sounds in the contralateral ear. However, binaural responses are seen and predominate in the medial nucleus. The binaural responses may be related to additional inputs from the ipsilateral cochlear nucleus or inputs from the superior olive.

The outputs of the ventral complex of the lateral lemniscus are primarily directed at postsynaptic targets located exclusively in the inferior colliculus on the same side of the brain. Because of the complexity of the neuropil, it had not been ascertained until relatively recently that they probably project in a topographic and tonotopic fashion. Because both GABA and glycine are found colocalized in the nucleus, it is possible that these neurons will inhibit their postsynaptic targets in the colliculus. Thus, both the dorsal nucleus and the ventral complex of the lateral lemniscus act to inhibit the activity of the inferior colliculus. Whereas the dorsal nucleus is predominantly GABAergic, binaural, and projects heavily to the contralateral colliculus, the ventral complex is predominantly glycinergic with GABA colocalization, often monaural, and projects exclusively to the ipsilateral colliculus.

B. Auditory Processing in the Midbrain

At its position at the halfway point in the auditory pathway, the inferior colliculus plays a fundamental role in the integration of information derived from the initial stages of auditory processing and transmission of this information to the auditory thalamus and, eventually, the auditory cortex. Essentially, all types of information about sound must pass through the inferior colliculus. Because the inferior colliculus is more accessible than the auditory structures of the lower brain stem, the inferior colliculus has been studied extensively with the aim of revealing the processing that occurred at previous stages of the auditory pathway as well as the processing that occurs at the midbrain. Much of the processing requires only one ear (monaural), whereas other types require the interaction of two ears (binaural).

1. Monaural Processing of Frequency, Sound Pressure Level, and Sounds with Complex Spectra or Timing

The inferior colliculus receives information about the spectrum of sound through all of its inputs, but most studies of frequency organization and spectral responses have emphasized monaural stimulation. There is only a single tonotopic map of frequency that extends across both the central nucleus and the dorsal cortex of the inferior colliculus. The characteristic frequency of single neurons in the central nucleus changes in the dorsolateral to ventromedial direction in steps of 180–200 μm, which correspond to the layers of the fibrodendritic laminae and the inputs from the auditory cortex. Characteristic frequency is defined as the frequency of sound to which the neuron responds with the lowest threshold, and it often corresponds to the frequency that drives the neuron at the highest rate at higher sound levels. There is evidence that the sharpness of tuning in the central nucleus is not uniform, and neurons with different sharpness of tuning could be mapped within the laminae.

The colliculus also participates in the processing of complex temporal signals such as speech signals, which include amplitude and frequency modulation. Neurons in the inferior colliculus have best modulation frequencies for amplitude modulation that may be mapped along the laminae of the colliculus. In some animals like the bat, there are neurons that are sensitive to the duration of a stimulus and sensitive to particular frequency modulations that are used in echo location. The role of the inferior colliculus in speech processing in the primate remains unclear. However, speech sounds are undoubtedly processed by the colliculus, and it possible that certain inputs to the colliculus are better excited by these complex signals than others.

2. Binaural Processing of Interaural Time and Intensity

The inferior colliculus receives extensive input from the superior olive that represents the initial stages for processing interaural time differences (ITD) and interaural intensity differences (IID). Both ITD and IID are necessary for the localization of sound, which is calculated neurally, unlike the localization of visual

or somatosensory stimuli, which are the result of spatially mapped receptor surfaces in the eye and skin, respectively. Inputs from the medial superior olive convey ITD information from low-frequency stimuli and are excited when coincident stimuli activate neurons. In contrast, the lateral superior olive appears to be sensitive to both IID and ITD information and covers the entire range of audible frequencies. However, the lateral superior olive tends to be inhibited when coincident stimuli arrive simultaneously. Thus, inputs from the medial and lateral superior olive have distinct properties, and the inferior colliculus appears to play an important role in preserving these properties.

3. Parallel Processing

One major question regarding the function of the inferior colliculus is the extent to which information from the different binaural and monaural pathways is transformed as opposed to relayed in an unchanged state. Both parallel processing and convergence of inputs from multiple sources appear to take place, and this conclusion is supported by both anatomical and physiological data. Parallel processing in the colliculus is supported by the continued presence of neurons with monaural responses and responses that mimic those in the medial and lateral superior olive. If all inputs were to converge onto the single frequency map in the colliculus, that preservation of response types would not occur. This principle of separation of binaural time and intensity pathways was established in avian systems (e.g., barn owl), and similar mechanisms are surely utilized by the human midbrain.

Anatomical evidence in mammals confirms that the inputs from different brain stem auditory centers do not all converge uniformly on the fibrodendritic laminae of the inferior colliculus. Instead, the laminae are probably organized into functional zones that each contain a unique set or group of laminar input axons that terminate together, in register with each other. Some inputs may terminate in one part of a lamina, whereas other inputs may terminate in another part or in a flanking lamina. The separation of parts of laminae into functional zones, called synaptic domains, may allow the basic response properties generated in the superior olive to remain intact.

4. Inhibitory Inputs to Central Nucleus Contribute to Transformations

Unlike other sensory systems, the auditory system of the midbrain contains a number of major nuclei (cell groups) that act as major inhibitory relays in the auditory network. Invariably, these inhibitory nuclei project to the central nucleus of the inferior colliculus. Thus, the functional zones of the inferior colliculus contain one or more excitatory inputs and one or more inhibitory inputs. Inhibitory inputs to the central nucleus originate primarily in the dorsal nucleus of the lateral lemniscus, the ventral complex of the lateral lemniscus, and the lateral superior olive. The binaural inputs from the dorsal nucleus of the lateral lemniscus are GABAergic and have been shown to influence or modify ITD and IID responses, especially in the contralateral central nucleus. Likewise, the binaural inputs from the lateral superior olive are glycinergic and are likely to modify binaural responses in the ipsilateral central nucleus. The frequently monaural inputs from the ventral complex are also likely to influence the ipsilateral central nucleus, but this is less well-established. Identification of the specific inputs to synaptic domains in the central nucleus of the primate is necessary before the full complexity of the auditory pathway in the midbrain can be appreciated.

C. Auditory Midbrain Outputs

1. Excitatory and Inhibitory Outputs from the Inferior Colliculus to the Thalamus

The major output of the central nucleus of the inferior colliculus is provided by a large number of neurons that project primarily to the ventral division of the medial geniculate body (ipsilateral) via the brachium of the inferior colliculus and the medial division of the medial geniculate (bilateral). These include GABAergic neurons (see later discussion). The central nucleus also has commissural projections to the contralateral inferior colliculus and descending projections to the ventromedial periolivary region of the superior olive (ipsilateral) and to the cochlear nucleus (bilateral).

The major outputs of the dorsal and lateral cortices are ascending projections to the dorsal and medial divisions of the medial geniculate body (ipsilateral). Dorsal cortex sends outputs to the dorsal and deep dorsal nuclei. Lateral cortex projections also terminate in the dorsal nucleus and in the margins surrounding the ventral division. Unlike the central nucleus, the dorsal and lateral cortices contribute few if any ascending projections to the ventral division of the medial geniculate. Thus, the dorsal and lateral cortices of the colliculus are unlikely to directly influence the projections from the thalamus to the primary auditory cortex of the telencephalon.

GABAergic projections ascend to the thalamus from the inferior colliculus in parallel with non-GABAergic projections. These parallel projections have not been confirmed in primates, but such projections would be consistent with their presence in diverse species like rats and cats. It is unusual for GABAergic cells to participate in ascending sensory projections to the thalamus, and it is not seen in the visual or somatosensory systems. Brain slice experiments in rodents have shown that short-latency, inhibitory postsynaptic potentials that use GABA-A receptors are produced in neurons of the medial geniculate after electrical stimulation of brachium axons. These short-latency potentials can precede the excitatory potentials from the central nucleus and may regulate the onset of thalamic excitation from the inferior colliculus. Many neurons in the medial geniculate receive both excitatory and inhibitory inputs from the inferior colliculus. However, some neurons in the medial geniculate receive only excitatory inputs from the midbrain.

2. Lateral Tegmental System

The superior colliculus, cuneiform nucleus, and nucleus sagulum comprise the lateral tegmental system. It may provide important nonauditory input to the medial geniculate body in the thalamus. This input to the thalamus is thought to be excitatory because few, if any, GABAergic neurons in the tegmentum or superior colliculus contribute to the thalamic projections.

The *superior colliculus* is rostral to the inferior colliculus and the other main part of the tectum (Fig. 1). It is primarily concerned with vision and the control of gaze, that is, the control of eye and head movements. However, the superior colliculus also receives inputs from the nonprimary auditory cortex and brachium of the inferior colliculus (see later discussion). Projections from the deep layers of the superior colliculus terminate in the dorsal division of the medial geniculate body, and these could provide information to the nonprimary auditory cortex about head and eye position.

The *cuneiform nucleus* (mesencephalic reticular formation, Fig. 1) is the most caudal part of the reticular formation in the mesencephalon. It is ventral to the inferior colliculus, medial to the lateral lemniscus, dorsal to the brachium conjunctivum, and lateral to the mesencephalic nucleus and tract of the trigeminal. The cuneiform nucleus receives input from the nonprimary auditory cortex among many other nonauditory sources. Outputs from the cuneiform nucleus terminate primarily in the dorsal division of the medial geniculate body, particularly in the dorsal and suprageniculate nuclei.

Nucleus sagulum is the tissue lateral to the nuclei and fibers of the lateral lemniscus (Fig. 1). It is a small-celled region of the tegmentum that is remarkably interconnected with parts of the auditory system. It receives inputs from nonprimary auditory cortex, inferior colliculus, and ventral nucleus of the lateral lemniscus and nucleus sagulum on the contralateral side. The major auditory projection of the nucleus sagulum is a projection to the dorsal division of the medial geniculate body.

3. To the Visual–Motor System: Nuclei of the Brachium of the Inferior Colliculus

Studies indicate that the brachium of the inferior colliculus may provide an important link between the auditory and the eye-movement systems of the midbrain. In mammals, there are few direct connections between the inferior and superior colliculi. Thus, the link from the auditory to visual–motor systems has not been obvious. However, such a link would be important because it would allow the location of sounds in space to be correlated with the positions of objects in space in the visual field. Sounds can initiate head and eye movements that are partially controlled by the superior colliculus. The fibers from the inferior colliculus terminate along the rostrocaudal extent of the nucleus of the brachium during their course en route to the thalamus. Neurons in the brachial nucleus project in a topographical manner to the superior colliculus, with the rostral brachium terminating rostrally and the caudal brachium terminating caudally. This rostrocaudal axis of the superior colliculus corresponds to the horizontal meridian of the visual field. Thus, the brachium projection to the superior colliculus is consistent with an auditory map of horizontal azimuth being transmitted from the auditory system to the visual system.

II. EYE MOVEMENT SYSTEMS OF THE MIDBRAIN

A. Components of Eye Movement Systems

1. Superior Colliculus (SC)

The superior colliculus forms the anterior roof of the midbrain (Fig. 1B). Its rostral border is the pretectum, and its caudal border is adjacent to the inferior

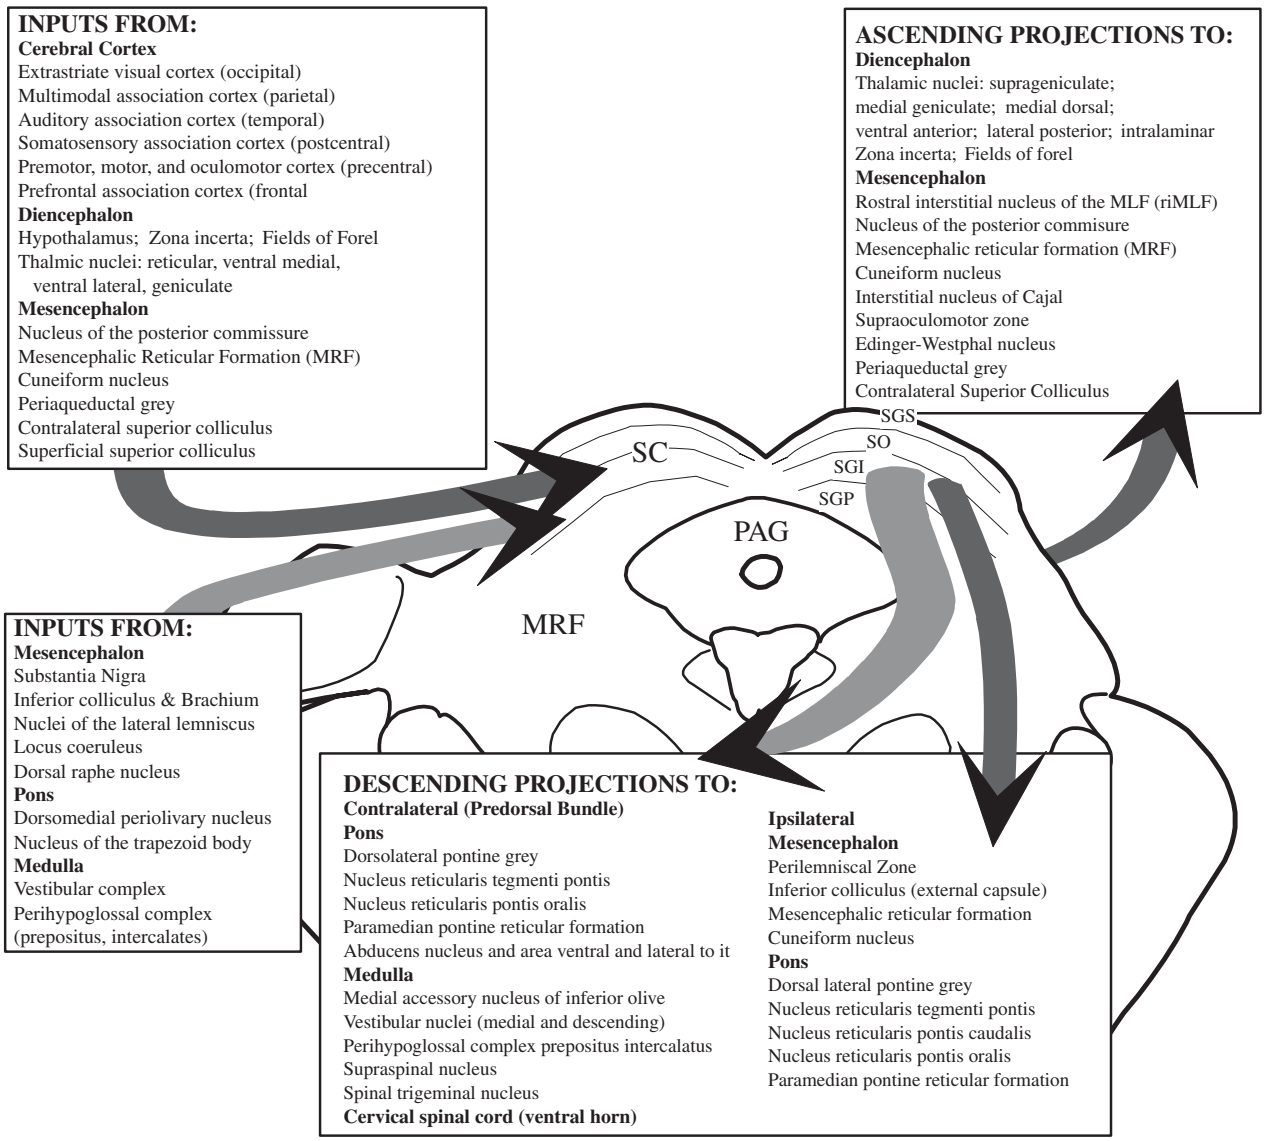

Figure 3 Inputs and outputs of the intermediate and deep layers of the superior colliculus. Layers of gray matter and optic fibers are indicated (right). Afferent connections are shown on the left side and efferent projections on the right side. Ascending projections are above the section of the superior colliculus and descending connections are below the section. See Table I for abbreviations.

colliculus. Seven alternating fiber and cellular layers make up the superior colliculus. However, the main functional divisions are a superficial visual part (three layers) and a deeper oculomotor part (four layers).

The superficial layers are composed of the stratum zonale (SZ), stratum griseum superficiale (SGS), and stratum opticum (SO) from dorsal to ventral, respectively (Fig. 3). Whereas retinal and cortical afferents innervate the SZ, SGS, and SO, the distribution of inputs to these areas is not even. Indeed, the stratum griseum superficiale can be further subdivided into three sublayers in terms of the distribution of inputs. SGS1 (25–120 μm from the surface) derives much of its input from W-type retinal ganglion cells. SGS2 occupies approximately 300 μm, and much of the input to this region is from areas 17, 18, and 19 of the visual cortex. The Y-type retinal ganglion cells synapse in SGS3. In general, the visual responses of individual superficial layer neurons are binocular, direction-selective, and have discrete retinotopically organized

receptive fields. The overall organization of retinal and visual cortical afferents to the primate superior colliculus places neurons with parafoveal receptive fields near the rostral pole, whereas neurons with peripherally located visual fields are located more caudally. The upper contralateral visual field is represented medially and the lower visual field laterally. Whereas the retinal contribution from the contralateral eye is evenly distributed across the colliculus, the input from the ipsilateral eye is densest in the central portion of the colliculus. This distribution leaves the neurons of the rostral pole of the primate colliculus driven solely by the contralateral eye (i.e., these cells are monocular). Furthermore, the contralateral retinal projection to the superficial layers is distributed to the dorsal SZ and SGS than the ipsilateral afferents that target the deeper portions of the SGS and most of the SO. Another aspect of the retinal afferents is that they tend to cluster in patches that extend across one or two of the superficial layers. Interestingly, these puffs or patches in the SZ and SGS receive predominantly contralateral, cholinergic input from the parabigeminal nucleus. Other subcortical afferents to the superficial layers arise from the ventral lateral geniculate nucleus, which primarily targets the ventral portion of the SGS and the SO. These projections are bilateral, but are predominantly ipsilateral. Last, the pretectum, especially the nucleus of the optic tract, sends a projection to the superficial layers.

The primary efferents from the superficial layers originate from the L-type neurons, small or medium-sized cells with elaborate dendritic trees. They participate in the ipsilateral descending and dorsal ascending tectofugal bundles. These cells provide synaptic input to the parent neuron through recurrent collaterals as well as more ventrally to the deeper tectal layers including the stratum griseum intermediale. The primary extratectal target of the L neurons is the parabigeminal nucleus. Other efferents arise from superficial layer neurons whose cell types have not been well-described. The stratum zonale provides efferents to the pretectal nuclei, lateral posterior pulvinar complex, and dorsal and ventral lateral geniculate nuclei. The more superficial portions of the SGS (layers 1 and 2) provide afferents to the dorsal lateral geniculate body, whereas the deeper SGS projects to the lateral posterior pulvinar.

The intermediate and deep layers of the superior colliculus (Fig. 3) are called the stratum griseum intermediale (SGI), stratum albican intermediale (SAI), stratum griseum profunda (SGP), and stratum albican profunda (SAP). These layers participate in the control of visually guided movements such as those of the eye, head, and arm. The inputs to the intermediate and deep layers include both descending cortical and subcortical contributions. Distinct from the superficial layers, the intermediate and deeper layers receive somatosensory, auditory, as well as visual inputs. The parietal (area LIP) and frontal cortices (frontal eye fields, supplementary eye fields, dorsolateral prefrontal cortex) provide much of the cortical, glutaminergic (i.e., excitatory) inputs to the intermediate and deep layers of the superior colliculus. The mesencephalic reticular formation and basal ganglia (primarily the substantia nigra pars reticulata) provide much of the GABAergic input (i.e., inhibitory) input to the superior colliculus. The afferents to the intermediate and deep layers of the superior colliculus from the pedunculopontine nucleus at the junction of the pons and midbrain are primarily acetylcholinergic (i.e., excitatory). Afferents to the intermediate and deep layers of the superior colliculus from the fastigial nucleus (deep cerebellar nuclei) and the nucleus prepositus hypoglossi are also well-described, but their transmitters have not been identified. For a listing of the afferent and efferent connections of the intermediate and deep layers of the superior colliculus, refer to Fig. 3.

Two types of efferent neurons have been distinguished in the intermediate and deep layers of the superior colliculus on the basis of their axonal branching patterns: X and T cells. Neurons of the X type are large multipolar neurons. Their cell bodies are located primarily in SGI and occasionally in the stratum opticum. They provide an axon that descends ventrally through the stratum albican profunda and then leaves the superior colliculus to reach the underlying periaqueductal gray. The axon circumscribes the periaqueductal gray and then crosses the midline ventral to the medial longitudinal fasciculus to reach the contralateral predorsal bundle. The X neurons do *not* emit any commissural collaterals to the opposite superior colliculus. In contrast, the cell bodies of the T cells are small to medium in size and reside within the ventral portion of the stratum opticum and the more dorsal portion of stratum griseum intermediale. The axons of T cells have an initial course similar to that of the X cells. Within the stratum griseum profunda, the axons of these cells ramify to provide a large number of recurrent collaterals. The primary axon then descends further to the periaqueductal gray where it bifurcates. For all T cells, one branch is directed across the collicular commissure to ramify upon neurons in the

intermediate and deep layers of the opposite superior colliculus. The destination of the second collateral can be variable. In some T cells, the second collateral branch emits collaterals around neurons in the ipsilateral mesencephalic reticular formation, whereas the main axon proceeds to circumscribe the periaqueductal gray to eventually join the contralateral predorsal bundle. The axon collaterals of other T neurons contribute to the ipsilateral ascending or descending projections of the superior colliculus. The axons of the X cells are large and probably provide much of the tectal input to cervical levels of the spinal cord. The smaller axons of the T cells probably do not reach spinal levels but end at pontine or medullary levels.

The organization of the neurons in the intermediate and deep layers of the superior colliculus generally follows that of the cells in superficial layers. The neurons in the intermediate and deep layers of the superior colliculus discharge in association with rapid eye movements. This discharge is much greater when the saccade is made in light than in dark. Two primary types of neurons are recognized. Burst neurons begin to fire 30–50 msec before the onset of a rapid eye movement that will bring the fovea within a specific portion of the oculomotor range. The collection of the movements for which the neuron will fire is called the movement field of the cell, in analogy to the visual receptive fields of neurons in the more superficial layers. Build-up neurons begin to discharge at low frequency as long as 130 msec before saccade onset and have a burst of discharges that occurs 30–50 msec before saccade onset. These neurons tend to have larger movement fields than the burst neurons, and the outside edge of their movement fields is less well-defined. With the advent of unrestrained head and eye (i.e., gaze) movement recordings, it is now recognized that neurons in the caudal portion of the intermediate and deep layers of the superior colliculus are best activated for gaze and not the separate eye or head components of the movement. As such the responses of a single neuron in the caudal SC have been described as a "gaze," not a "movement," field, i.e., the group of combined head and eye movements that cause the neurons to discharge. The neurons in the intermediate and deep layers appear to be organized in spatial register with the superficial neurons located just above. Thus, the rostral pole of the superior colliculus contains neurons that fire before small primary to secondary saccades. Cells with larger movement fields are located more caudally. Cells with upward movement fields are located medially, whereas neurons with downward movement fields are located laterally.

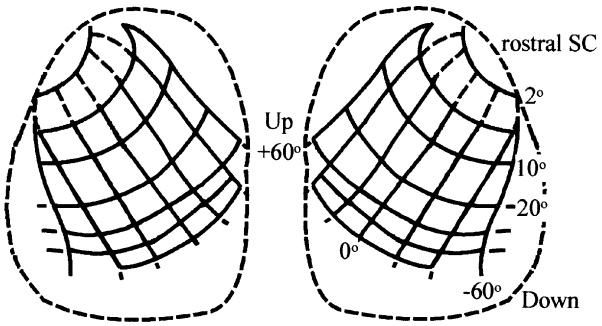

Figure 4 Physiological organization of the intermediate and deep layers of the superior colliculus based on electrical stimulation in head-fixed monkeys. Both colliculi are shown from above. The midline is between the two grids. Note that numbers along the sides of the diagrams are the amplitude of the saccade elicited in degrees. The numbers along the bottom indicate the elevation of the elicited eye movement. Positive numbers indicate upward movements found on the medial side of the colliculus, and negative numbers indicate downward movements found toward the lateral side of the colliculus. See Table I.

Electrical microstimulation in the SGI of monkeys whose head is restrained elicits saccades at short latency (<40 msec), whose maximal amplitude is primarily dependent upon the site, not the parameters of stimulation. These stimulation results have been used to generate a map of contralateral eye movement amplitudes that corresponds with the amplitude sensitivity of the cells recorded at each collicular site (Fig. 4). This will surely change in light of current experiments that are examining electrical microstimulation with the head free to move.

The possibility that the activity of the visual, superficial layers could be directly translated into the motor activity of the deeper collicular layers has driven research on the superior colliculus for longer than a century. Features of this concept have been demonstrated in many species of rodent (golden hamster and rat), but the interconnections of the superficial and deep layers have been less extensive in primates. Most likely, the reason for this species difference is dependent on the importance of the superior colliculus in visual processing. In afoveate animals (e.g., rodents), the superior colliculus is probably the primary visual and gaze processing region. Thus, direct projections from the superficial to the deep layers are advantageous. In foveate animals (i.e., monkeys and humans), the superficial layers of the superior colliculus play a much more secondary role in visual processing because of the size and complexity of the visual (occipital) cortex. The intermediate and deep layers, on the other

hand, retain considerable importance for the control of oculomotor and gaze-related behaviors, despite their duplication by other cortical bulbar pathways from the frontal eye fields and inferior parietal lobule of the parietal cortex. This is the reason that removal of the intermediate or deep layers of the superior colliculus (either by lesion or by reversible inactivation) in primates can produce an increased latency and some change in the trajectory of visually guided eye movements. Similarly, removal of the frontal eye fields alone produces minimal changes in eye movements. Simultaneous removal of both frontal eye fields and the superior colliculus produces a devastating reduction in the amplitude and speed of contralaterally directed saccadic eye movements. This deficit does not recover. In sum, the superficial layers of the superior colliculus in the primate provide visual information that is overshadowed by the amount of information provided by the occipital (visual) cortex. The intermediate and deep layers of the primate superior colliculus provide one of the parallel paths for the supranuclear control of gaze (head and eye movements.)

2. Oculomotor Complex

The oculomotor complex lies on the midline of the rostral midbrain beneath the aqueduct (Fig. 1) and contains the motoneurons whose fibers comprise the third cranial nerve innervating four of the six extraocular muscles. Medial rectus motoneurons are distributed throughout the rostral–caudal extent of the third nerve nucleus. There are three subgroups of medial rectus motoneurons. Large motoneurons of about 26 μm in diameter (cell group A) are located in the ventral portion of the rostral two-thirds of the oculomotor nucleus. Neurons of group B, again of large size averaging 30 μm in diameter, are situated in a dorsal lateral position and occupy the caudal two-thirds of the oculomotor complex. The motoneurons of groups A and B innervate the global "inner" muscle fibers situated close to the sclera of the eye. Smaller motoneurons 18 μm in diameter (cell group C) are a third population of motoneurons located in the dorsal portion of the rostral two-thirds of the oculomotor complex. Cell group C innervates the smaller "outer" fibers (i.e., the orbital muscle surface away from the globe of the eye) of the medial rectus muscle. The orbital portion of the medial rectus muscle inserts not on the globe, but on a specialized portion of the orbital tissue made up of collagen and connective tissue. This region serves as a pulley to permit shifts in the axis of rotation of the eye. Additional groups of large and medium-sized motoneurons in the oculomotor complex innervate the inferior rectus, superior rectus, and inferior oblique extraocular muscles. Interestingly, the inferior rectus motoneurons are intermingled with the medial rectus group C motoneurons in the dorsal portion of the rostral two-thirds of the oculomotor complex which participate in the generation of convergence and downward saccades. Evidence that small motoneurons of group C innervate primarily the orbital portion of the medial rectus muscle suggests that these fibers could participate in a caudal shift of the oculomotor pulley (located in the orbital tissues), thus shifting the muscle pulling directions during vergence or saccades from initial eye positions outside of primary (straight-ahead) position (i.e., secondary or tertiary positions).

A separate group of small interneurons resides within the oculomotor complex and has intracranial projections. The targets of these projections are varied but include the abducens motoneurons, reticularis tegmenti pontis, facial nucleus, cerebellum, spinal trigeminal nucleus, dorsal column nuclei, principal and dorsal accessory olivary nuclei, rostral medulla, parabrachial region, and cervical spinal cord. A role in divergence has been hypothesized for neurons projecting to the abducens nuclei, but the roles for the other projections have not been formulated.

The major inputs to the oculomotor complex include projections from the abducens nucleus and the nucleus prepositus hypoglossi (the location of the horizontal neural integrator). The terminals of the abducens internuclear neurons reach the midbrain by crossing through the contralateral abducens nucleus to the contralateral medial longitudinal fasciculus, which ascends to midbrain levels. They synapse directly on the motoneurons in the oculomotor complex, with the vast majority terminating on medial rectus motoneurons. Projections from the rostral interstitial nucleus of the medial longitudinal fasciculus (see later discussion) and the interstitial nucleus of Cajal have been demonstrated to reach the motoneurons of the primary vertical movers of the eye, including the inferior rectus, superior rectus, and inferior oblique extraocular muscles. The circuitry for the light reflex includes the crossed projections from the pretectal olivary nucleus via the posterior commissure to reach the Edinger–Westphal nucleus.

3. Medial Longitudinal Fasciculus (MLF)

The medial longitudinal fasciculus is a prominent axonal bundle running in the ventral portion of the

central gray that surrounds the aqueduct in the midbrain (Fig. 1). The medial longitudinal fasciculus connects the interneurons of the abducens nucleus with the motoneurons of the contralateral oculomotor nucleus and yokes the two eyes together. This provides a final common pathway for the generation of horizontal visually guided saccadic eye movements. The medial longitudinal fasciculus also carries fibers from the vestibular nuclei directed toward the oculomotor and trochlear nuclei as well as the interstitial nucleus of Cajal. These fibers are activated during head movements in which the vestibulo-ocular reflex is active.

4. Trochlear Nucleus

The large motoneurons of the trochlear nucleus are located within the central gray adjacent to the aqueduct of Sylvius and dorsal to the medial longitudinal fasciculus at the level of the inferior colliculus (Fig. 1). The axons of the motoneurons course caudally along the aqueduct and then ascend to the dorsal lateral aspect of the central gray. The nerves decussate completely within the anterior medullary velum (the roof of the aqueduct) to exit from the *dorsal* aspect of the brain stem just caudal to the inferior colliculus. The fourth cranial nerve then wraps around the pons lying between the superior cerebellar and posterior cerebral arteries. The nerve then ascends in the prepontine cistern along the free edge of the tentorium cerebelli before piercing the dural attachment of the tentorium to reach the cavernous sinus. The trochlear nerve enters the orbit through the superior orbital fissure to innervate a single muscle, the superior oblique. This muscle is a primary intorter of the eye in primary and abducted positions and a primary depressor of the eye in adducted (toward the nose) positions. Within the brain stem the trochlear nuclei receive direct projections from the rostral interstitial nucleus of the medial longitudinal fasciculus, which is the premotor nucleus for the coordination of vertical eye movements.

5. Mesencephalic Reticular Formation (MRF)

Anatomically, this region (Fig. 1, also referred to as nucleus cuneiformis) is linked to other oculomotor structures. It sends and receives projections from the superior colliculus. The mesencephalic reticular formation is heavily connected to the paramedian pontine reticular formation because it is reciprocally connected to the excitatory burst region and sends a heavy projection to the omnipause region (i.e., raphe interpositus) of the paramedian pontine reticular formation. The cells of the raphe interpositus pause for each saccade. The mesencephalic reticular formation provides contralateral descending projections to the nucleus reticularis tegmenti pontis (one of the major sources of oculomotor input to the cerebellum) and ipsilateral projections to the cervical spinal cord. It also provides ipsilateral ascending projections to the intramedullary lamina of the thalamus.

A number of different lines of evidence support a role for the mesencephalic reticular formation in the control of eye movements. Electrical stimulation in the mesencephalic reticular formation produces contraversive saccades at short latency and low threshold. The amplitude of these movements varies with the dorsoventral position within the mesencephalic reticular formation and not the strength of the stimulation: dorsal sites produce small contraversive horizontal saccades, whereas ventral sites produce larger, contraversive goal-directed movements. Cells in the mesencephalic reticular formation are long-lead burst neurons whose low-level discharge can begin up to 150 msec before eye movement and culminates in a high-frequency (>800 spikes/sec) burst that peaks just before the onset of spontaneous and visually guided saccades. Monkeys may develop a trimodal neglect of the contralateral sensorium (somatosensory, auditory, and visual) following electrolytic lesions of the mesencephalic reticular formation.

a. cMRF The central mesencephalic reticular formation (cMRF), located more caudally within the nucleus cuneiformis just lateral to the oculomotor nuclei (Fig. 1B), contains neurons that discharge before and during contraversive, horizontal saccades. The discharge characteristics of these cells and their anatomic connections suggest that the cMRF may participate in the local feedback pathway by providing current eye position and/or velocity to the superior colliculus or to the cerebellum via connections to the nucleus reticularis tegmenti pontis. The discharge is closely correlated with current eye displacement and/or velocity. In addition, about half of these neurons discharge in association with the appearance of visual stimuli and during the delay portion of a remembered saccade task.

b. riMLF Both clinical and experimental evidence has distinguished another subdivision of the midbrain reticular formation located in the prerubral fields near midline (Fig. 1C). The rostral interstitial

nucleus of the medial longitudinal fasciculus (riMLF) serves as the immediate premotor area for the coordination of conjugate vertical and torsional movements of the eyes. This region receives projections from other eye-movement-related areas, including the paramedian pontine reticular formation, the omnipause region (the raphe interpositus), the superior colliculus, and probably also the nuclei of the posterior commissure as well as the opposite riMLF.

The primary efferent connections of the riMLF are to the third (oculomotor) and fourth (trochlear) cranial nerve nuclei, the paramedian pontine reticular formation, the interstitial nucleus of Cajal, the vestibular nuclei, and the prepositus hypoglossi. The connections of the riMLF to the oculomotor and trochlear nuclei are ipsilateral for the downward movers (to the inferior rectus innervated by the third cranial nerve nucleus and to the superior oblique innervated by the trochlear nucleus) and bilateral to the upward movers (to the superior rectus and inferior oblique of the oculomotor nucleus). Connections from the riMLF to that of the opposite side travel across the posterior commissure to assist in the coordination of the upward movers of the eyes or travel across a commissure ventral to the aqueduct to coordinate downward movements.

6. Interstitial Nucleus of Cajal (INC)

The interstitial nucleus of Cajal is adjacent to the riMLF within the central gray (Fig. 1C). It is separated from the riMLF via the fasciculus retroflexus. As already indicated, fibers from the riMLF pass through the interstitial nucleus and provide an axon collateral. Interpretation of data from recordings, stimulation, and lesions within the interstitial nucleus and riMLF is difficult because these structures are tightly interconnected anatomically and physiologically. However, there are significant differences in the connectivity of these two structures. In contrast to the riMLF, the interstitial nucleus does not receive projections from the paramedian pontine reticular formation. In addition, the interstitial nucleus receives very strong vestibular input from the medial and superior vestibular nuclei as well as from the Y-cell group of the vestibular nuclei (i.e., it receives input from the vertical semicircular canals) and is closely connected to the opposite interstitial nucleus. Whereas earlier work suggested an input from the superior colliculus to the interstitial nucleus, more recent detailed analysis has not been able to substantiate this projection. Sparse input from the nuclei of the posterior commissure has been suggested.

The output of the interstitial nucleus is to the third, fourth, and seventh cranial nerve nuclei, as well as to the vestibular nuclei, the nucleus prepositus hypoglossi, the nucleus paramedianus, and the nucleus of Roller. The projections from the interstitial nucleus to the oculomotor and trochlear nuclei are specific for the vertical muscles and spare the medial rectus subdivisions of the oculomotor complex. In addition, the projection to the oculomotor complex is contralateral and provides a pathway for the riMLF to influence the contralateral vertical eye muscles. There are also very strong projections to the spinal cord via heavily myelinated fibers that extend to the lumbar region. The cells of the interstitial nucleus fire in the planes of head movement that activate either the anterior or the posterior semicircular canals. However, interstitial nucleus neurons that project to spinal levels are *not* responsive to vestibular stimulation.

The interstitial nucleus serves as the integrator for vertical and torsional eye movements. Unilateral electrical stimulation produces rotatory eye and head movements rather than purely vertical movements. Upward saccades were spared following bilateral interstitial nucleus lesions in cats. Impairments in downward saccades were thought to be the result of interruption of efferent fibers from the rostral riMLF. After unilateral kainic acid lesion of the interstitial nucleus in the cat, vertical saccades in all directions were preserved. Unilateral muscimol injections in the interstitial nucleus suggested that there was a significant impairment in vertical gaze holding (combined eye and head movement), producing vertical movements with torsional components (out of Listing's plane). Bilateral inactivation of the interstitial nucleus led to impairment of all vertical and torsional gaze holding. In addition, a contraversive head tilt has been documented following unilateral interstitial nucleus muscimol injections. The deficits in neck posture and vertical eye movements seen in patients with progressive supranuclear palsy have been attributed to the involvement of both the interstitial nucleus and riMLF.

7. Nuclei of the Posterior Commissure (NPC)

Five different cell groups of nuclei of the posterior commissure can be identified in the dorsal portion of the meso-diencephalic reticular formation: (1) the principal part, (2) the magnocellular part, bordering the central gray medially and within the central gray

itself, (3) rostral, (4) subcommissural, and (5) infracommissural portion below the posterior commissure. The principal and magnocellular parts are the ones typically observed. The afferents to the nucleus of the posterior commissure include a strong projection from the frontal eye fields. This cortical input is much more prominent than similar afferents destined for the paramedian pontine reticular formation or the riMLF. The superior colliculus and the dentate nucleus also provide other prominent inputs to the nucleus of the posterior commissure. The connection with the superior colliculus is reciprocal, with the nucleus of the posterior commissure providing the largest contribution of brain stem afferents to the superior colliculus.

Projections from the nucleus of the posterior commissure include one via the posterior commissure to the contralateral nucleus and a bilateral projection to the interstitial nucleus. There is some controversy about whether afferents of the nucleus of the posterior commissure reach the oculomotor nucleus. Most likely this projection is to the supraoculomotor central gray, which is concerned with lid movements. The nucleus of the posterior commissure also has a strong projection to the mesencephalic reticular formation and paramedian pontine reticular formation that may represent an alternative extracollicular pathway for cortical input for the control of horizontal saccadic eye movements (see later discussion). Smaller projections are present from the nucleus of the posterior commissure to the spinal cord and to the nucleus Darkschewitsch. Electrolytic lesions of the nucleus of the posterior commissure in monkeys and damage to this area in patients have demonstrated an upgaze paralysis and eyelid retraction (Collier's sign).

8. Nucleus Darkschewitsch (ND)

This small nucleus is located just rostral and dorsal to the interstitial nucleus of Cajal near the most rostral pole of the oculomotor complex (Fig. 1C). Its relationship to oculomotor control is unclear. It has strong projections to the dorsal cap of Kooy of the inferior olive (which projects to the flocculus of the cerebellum) and receives strong projections from the dentate nucleus of the cerebellum and from the cortex (pre- and postcentral gyrus). The afferents to the nucleus Darkschewitsch from the vestibular nuclei (via the medial longitudinal fasciculus) are small compared to the vestibular input to the interstitial nucleus of Cajal. The nucleus Darkschewitsch is closely associated with both motor (dentate nuclei and precentral gyrus) and oculomotor structures (providing floccular input), and it may participate in some aspects of hand–eye coordination (the dentate mediates control of distal upper limb segmental motoneurons).

9. Pretectal Complex and the Accessory Optic System

The optic tract fibers that do not synapse in the lateral geniculate nucleus are directed along the brachium of the superior colliculus toward the pretectum and the superior colliculus (Fig. 1C). The nuclei of the pretectal complex are situated within and below these fibers as they enter the dorsal portion of the brain stem at mesodiencephalic levels. The pretectal complex includes the nucleus of the optic tract, the olivary pretectal nucleus, the medial pretectal nucleus, and the posterior pretectal nucleus. These receive contralateral retinal efferents (Fig. 5). There is also a prominent contribution from the ipsilateral eye. There is a smaller contralateral projection from the optic tract to the medial pretectal nucleus. Other than the retina, the largest source of afferents to the pretectal nuclei is from the striate and adjacent visual association cortex, and there is also a projection from frontal eye fields and the cingulate cortex. Projections from middle temporal and middle superior temporal areas to the nucleus of the optic tract have also been demonstrated, which suggests that the nucleus may participate in smooth pursuit as well as velocity storage. Within the brain stem, the pretectal complex receives inputs from the ventral division of the lateral geniculate body, the superior colliculus, the accessory optic nuclei (medial, lateral, and dorsal terminal nuclei), and the cerebellum (dentate and interposed nuclei).

The pretectal complex provides both ascending and descending projections. The ascending efferents are primarily to the thalamic nuclei, including the intralaminar, dorsal and ventral lateral geniculate body, pulvinar, and zona incerta (subthalamus). The descending projections are clearly oculomotor and reach the interstitial nucleus of Cajal, the nucleus of the posterior commissure, the superior colliculus, the mesencephalic reticular formation, and the precerebellar nuclei in the pons and medulla (nucleus reticularis tegmenti pontis and inferior olive, respectively). The olivary pretectal nuclei have strong projections to the contralateral Edinger–Westphal nuclei via a crossing in the posterior commissure (see the section on Edinger–Westphal nuclei for functional considerations).

The accessory optic system comprises three nuclei: medial, lateral, and dorsal terminal nuclei. These

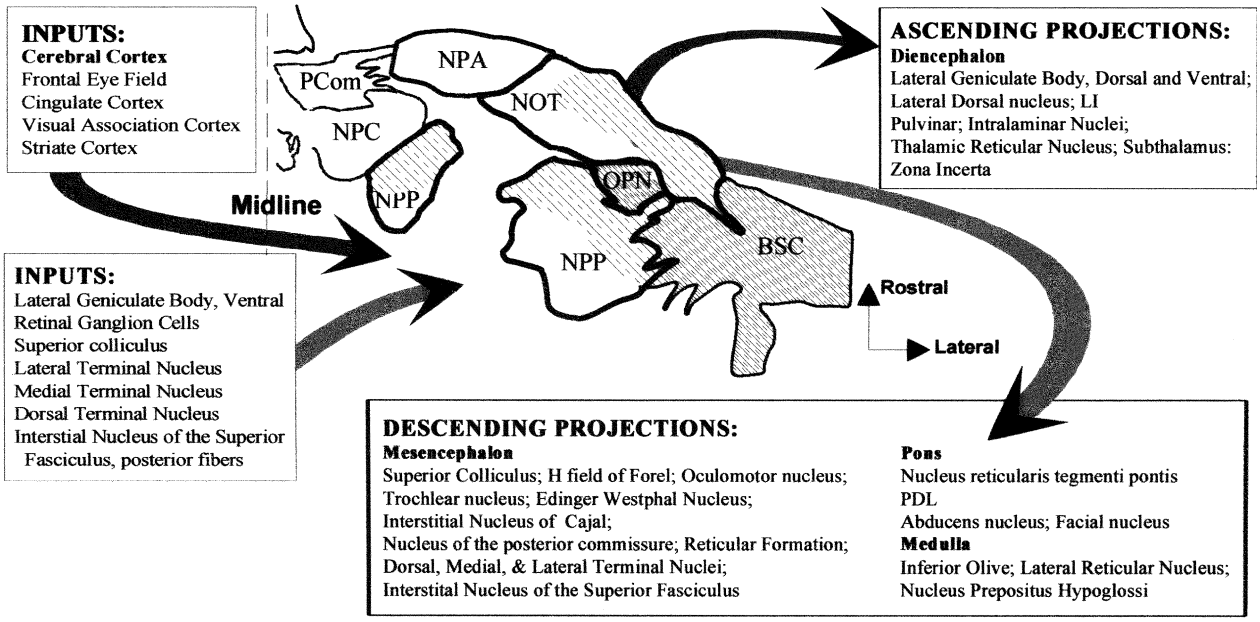

Figure 5 Inputs and outputs of the pretectal complex. The degree of shading in each portion of the horizontal section through the midbrain of the monkey illustrates the distribution of transported label over the contralateral pretectal complex following an intraocular injection of tritiated amino acids. The intensity of the hatching indicates the density of the label that was transported to the pretectum from the contralateral eye. Rostral is at the top and lateral is to the right. See Table I for abbreviations. (After Hutchins and Weber, 1985.)

nuclei are located in the rostral midbrain. The dorsal terminal nucleus is located just ventral to the nucleus of the optic tract at its most lateral extension. The lateral terminal nucleus is located ventral to the dorsal terminal nucleus, just dorsal to the substantia nigra, and lateral to the red nuclei. The medial terminal nucleus is located just lateral to the central gray and ventral to the red nucleus. These structures receive separate direct retinal input via a pathway known as the transpeduncular tract, which courses on the surface of the brain stem just anterior to the superior colliculus, travels over the brachium of the superior colliculus and then posterior to the medial geniculate body, and finally runs over the surface of the cerebral peduncle to enter the brain stem at the medial edge of the peduncle where it breaks into a number of fascicles to reach each of the terminal nuclei.

Functionally the nucleus of the optic tract and the dorsal terminal nucleus are essential in the production of the slow phases of optokinetic nystagmus (OKN) to the ipsilateral side. Electrical stimulation within the nucleus of the optic tract produces nystagmus. Lesions (both electrolytic and excitotoxic) in the nucleus of the optic tract and dorsal terminal nucleus reduce the slow rise of horizontal OKN and reduce or abolish optokinetic after-nystagmus. This suggests that the indirect path for velocity storage that produces compensatory eye-in-head and head-on-body movements via the vestibular system is impaired following lesions of the nucleus of the optic tract. This suggested that one role of the nucleus of the optic tract is to stabilize gaze in space during both passive motion and active locomotion in light. These effects are probably mediated via the strong input of the nucleus of the optic tract to the dorsal cap of Kooy (i.e., via the inferior olivary climbing fiber inputs to the flocculus) because the contribution to the medial vestibular nuclei is sparse. Evidence of cells with foveal receptive fields that are sensitive to retinal slip velocity suggested a role for the nucleus of the optic tract in smooth pursuit. This idea has been strengthened by evidence of a strong efferent projection from area MT to the nucleus of the optic tract. In the cat and rabbit, the majority of neurons in the medial and lateral terminal nuclei are sensitive to motion of the visual world along the vertical (i.e., vertical OKN). These nuclei are yet to be studied in the primate.

B. Control of Horizontal Gaze in the Midbrain

The primary focus of the current discussion is to point out particular characteristics and possible functions of midbrain structures that may participate in the

generation of horizontal saccades. The superior colliculus has received considerable attention in the control of rapid eye movements in both horizontal and vertical directions. A map of the contralateral field of movement has been demonstrated in the intermediate and deep layers of the primate superior colliculus using supramaximal electrical stimulation (Fig. 4). Movement fields (that is, the group of saccades that causes a cell to be activated during movements of particular size and direction) are characteristic of the neurons in the intermediate and deep layers of the superior colliculus. Cells in a particular portion of the colliculus have movement fields that correspond to the amplitude and direction of saccades electrically elicited from that site. Thus, activation of a particular group of neurons in the superior colliculus leads to the generation of an eye movement of particular size and direction. This has been called a *place code*. This pattern of neuronal activation is quite different from that actually required to rapidly move the eyes. The motoneurons of the abducens and oculomotor nuclei increase their discharge in relationship to the size of the upcoming movement, i.e., a *temporal code*. One of the primary problems that must be solved by supranuclear neurons in the midbrain oculomotor system is to change the place code activation of the SC into the temporal pattern of activity needed to rapidly shift the eyes. A second issue facing neurons arranged in a place code is how is this separated into horizontal and vertical signals required to move the eyes. The answers to both of these questions are not complete yet, but the following should provide some insight into how the brain stem performs these transformations.

The first step in solving these transformations is to reevaluate the connections of the superior colliculus with downstream structures involved in the generation of horizontal eye movement in the pontine reticular formation (Fig. 6). The superior colliculus provides both crossed mono- and polysynaptic inputs to the burst neurons in the paramedian pontine reticular formation (PPRF), the center for controlling horizontal gaze. A subgroup of burst neurons (the excitatory burst neurons) in the paramedian pontine reticular formation projects directly to the abducens nucleus, and its removal leads to a complete loss of rapid eye movement to the ipsilateral side. This signal is relayed by internuclear neurons, also located in the abducens nucleus, to the medial rectus subdivision of the oculomotor complex in the midbrain. The axons of these internuclear neurons travel in the medial longitudinal fasciculus to reach the midbrain (Fig. 6). At the same time, the excitatory burst neurons provide the same burst signal to the neurons of the nucleus prepositus hypoglossi. This structure is responsible for changing this pulse of activity (most closely associated with eye velocity) into a prolonged step of activity that is most closely related to eye position. This step response is then relayed back to the abducens nucleus and is responsible for holding the eyes steady at the new position. The abducens motoneurons provide an axon that reaches the lateral rectus muscle, which moves the eye toward the temporal side. Similarly, the oculomotor motoneurons provide an axon that travels in the oculomotor nerve to reach the medial rectus muscle, which moves the eye toward the nose. The combination of the PPRF, abducens nucleus, oculomotor nucleus, nucleus prepositus hypoglossi, medial rectus muscle, lateral rectus muscle, and

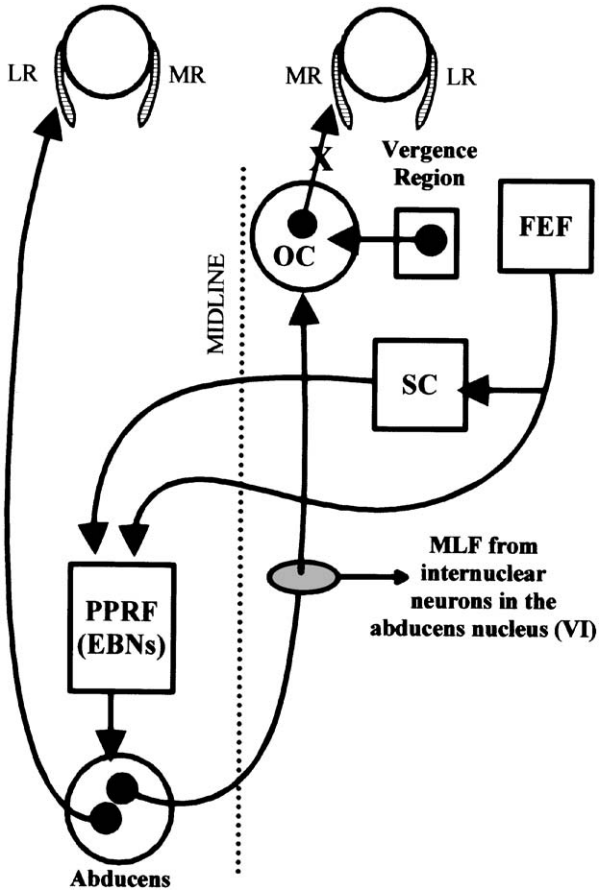

Figure 6 Schematic diagram of the final common pathway for horizontal saccades. Supranuclear inputs to the paramedian zone of the pontine reticular formation arise from the superior colliculus and frontal eye fields in parallel. Note that X marks the location of a third nerve lesion and the filled circle is a MLF lesion. A lesion in the MLF would preserve vergence, whereas a third nerve palsy would impair vergence. See Table I for other abbreviations.

medial longitudinal fasciculus is called the final common pathway responsible for the generation of horizontal saccadic eye movements.

Despite the clear connections of the final common pathway, how the superior colliculus directs eye movement control remains unclear. Work in the monkey suggests that the superior colliculus neurons provide monosynaptic connections to the long-lead burst neurons and not the excitatory burst neurons of the PPRF. In fact, most papers suggest that the input to the excitatory burst neurons of the PPRF is polysynaptic and not monosynaptic. The activity of long-lead burst neurons (LLBNs) is not uniform. Instead, a subgroup of LLBNs discharges only for particular directions (e.g., horizontal) of ipsilateral eye movements (directional LLBNs), whereas other LLBNs discharge for eye movements of very specific amplitude regardless of direction (i.e., vector long-lead burst neurons). As a result, one could generate a horizontal eye movement by projections of superior colliculus neurons to a select subgroup of vector LLBNs, which in turn activate the directional LLBNs and subsequently activate the excitatory burst neurons that project to the abducens nucleus. This scheme would explain the transformation from spatial coordinates in the superior colliculus to temporal coordinates in the excitatory burst neurons, as well as the selection of just the horizontal component of movement from a group of neurons that encodes both horizontal and vertical saccade directions.

Surprisingly, removal of the superior colliculus produces only minor eye movement deficits. An increased latency for saccades and the elimination of express saccades (i.e., saccades with latencies < 160 msec) are seen, but there are no changes in saccade accuracy. Following injections of the GABA agonist muscimol, which produces temporary inactivation of the intermediate and deep layers of the SC, saccade trajectory becomes curved and most saccades are hypometric (i.e., they fall short of the target). However, bilateral removal of both the superior colliculus and the neocortical frontal eye fields produces persistent deficits in the generation of rapid eye movements in all directions. This suggests that there are two pathways for saccade signals originating in the cerebral cortex to reach the paramedian pontine reticular formation: (1) a superior-colliculus-dependent route and (2) an extracollicular route. These experimental findings have been confirmed by clinical experience. No clinical oculomotor syndrome has been associated with damage to the superior colliculus alone. In fact, one patient examined following removal of an angioma in the superior colliculus showed increased latency for contralateral saccades, and these movements were hypometric.

On the other hand, damage (i.e., electrolytic lesion, stroke, or tumor) to the mesencephalic reticular formation is associated with distinct problems in contraversive horizontal saccades and ipsilateral smooth pursuit. One possibility is that mesencephalic reticular formation lesions interrupt the direct projections from the frontal eye fields to the paramedian pontine reticular formation. However, as pointed out earlier, these fibers are sparse. Midbrain lesions could also interrupt fibers from the nuclei of the posterior commissure to the paramedian pontine reticular formation or other parts of the reticular formation. More likely, corticobulbar projections from the frontal eye fields and parietal cortex reach the mesencephalic reticular formation and nuclei of the posterior commissure, and these structures relay them to the PPRF.

C. Control of Vertical Gaze in the Midbrain

A rostral portion of the midbrain reticular formation adjacent to the periaqueductal gray (riMLF) contains neurons whose primary on-directions are related to vertical gaze (combined head and eye movements), as do regions near the interstitial nucleus of Cajal (Fig. 1C). These burst neurons (both excitatory and inhibitory) fire during every vertical or torsional saccadic eye movement as well as during the quick phases of vertical, vestibularly induced nystagmus. Efferent projections from the riMLF synapse in, but also pass through and lateral to, the interstitial nucleus of Cajal (Fig. 7). As a result, electrolytic lesions or ischemic insult to the interstitial nucleus destroys the output of the riMLF as well as that of the neurons in the nucleus. This probably accounts for the long-held view that the interstitial nucleus of Cajal rather than the riMLF was the premotor center for coordinating vertical gaze. Instead, the cells in the interstitial nucleus produce a prolonged step of activity in response to every vertical rapid eye movement. This suggests that the interstitial nucleus is a critical structure for vertical gaze holding. In this way, it serves the same function for the vertical oculomotor system that the nucleus prepositus hypoglossus does for the horizontal eye movement system.

The projections from the riMLF and interstitial nucleus to the oculomotor nuclei account for the ability of these structures to generate vertical eye movements (Fig. 7). During downward movements, the riMLFs on both sides of the midbrain must be

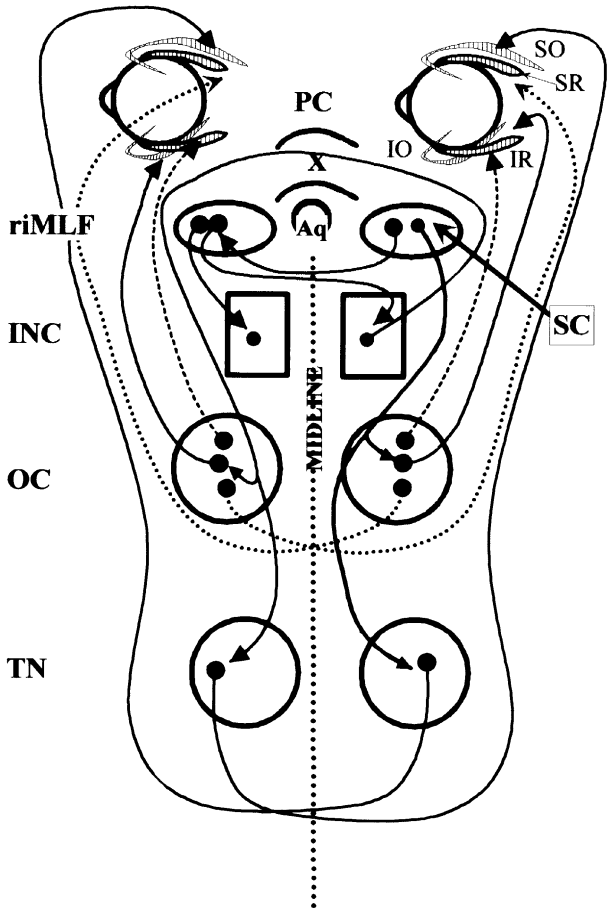

Figure 7 Schematic diagram of the final common pathway for vertical saccades. X marks the location of a cut in the posterior commissure (PC) that would produce the dorsal midbrain syndrome (see Table II). See Table I.

active. Projections from one riMLF reach the riMLF on the opposite side. There are direct projections from the riMLF to the inferior rectus and superior oblique motoneurons on the ipsilateral side. This produces a downward movement of *both* eyes (i.e., inferior rectus on the same side and the axons of the trochlear motoneurons cross the brain stem to reach the contralateral superior oblique muscle, which causes the opposite eye to be depressed and intorted). To coordinate upward movements, the riMLF provides efferent projections that synapse on the motoneurons in the superior rectus and inferior oblique subdivisions of the oculomotor complex on both sides. Similar to the efferent projections of the riMLF, the output of the interstitial nucleus is directed to the motoneurons of the oculomotor and trochlear nuclei as well as to the contralateral interstitial nucleus.

Inactivation experiments of the riMLF unilaterally demonstrated a 50% reduction in conjugate vertical eye velocity and a complete loss of one torsional direction. Clockwise (CW) rotation disappeared when the right riMLF was inactivated, whereas after inactivation of the left riMLF counterclockwise (CCW) torsion disappeared. Interestingly, changes in horizontal movements also occurred, suggesting that the short-lead burst neurons of the riMLF are divided into four groups: CW–up–left and CW–down–right in the right riMLF and CCW–up–right and CCW–down–left in the left riMLF. Bilateral inactivation led to complete abolition of both torsional and vertical saccadic eye movements. Unilateral inactivation or destruction (with kainic acid) led to similar modifications of torsional eye movements and a shift in Listing's plane. Clinical material supports the idea that the riMLF is the region equivalent to the paramedian pontine reticular formation (where horizontal movements are coordinated) for the coordination of eye movements in the vertical plane (see later discussion). On the other hand, unilateral inactivation of the interstitial nucleus of Cajal led to the loss of vertical gaze holding, skew deviation with hypertropia of the ipsilateral eye, extorsion of the contralateral eye, intorsion of the ipsilateral eye, and a contralateral head tilt (ocular tilt reaction). This confirmed the important role that the interstitial nucleus plays in maintaining vertical gaze positions. Similar to the discussion found on horizontal gaze, the separation of signals for the generation of vertical movements must occur as projections reach the riMLF. However, the same analysis of long-lead burst neurons found in the PPRF has not occurred for the vertical long-lead bursters. Finally, whereas projections from the superior colliculus, nucleus of the posterior commissure, long-lead burst neurons of the midbrain, and pontine reticular formations to the riMLF have been described, *no* direct projections from the frontal eye fields to the riMLF have been identified. This has suggested that cortical supranuclear control of vertical eye movements may be mediated through the nuclei of the posterior commissure, which receive a strong frontal eye field projection.

D. Clinical Correlation: Localization of Up and Down Gaze in the Midbrain

Experimental material and clinical cases agree that damage to the posterior commissure produces a paralysis of up gaze and a variety of associated

Table II
Features of the Dorsal Midbrain Syndrome

1. Limitation of upward eye movements:
Saccades, smooth pursuit, vestibulo-ocular reflex, Bell's phenomenon
2. Lid retraction (Collier's sign): occasionally ptosis
3. Disturbances in downward eye movements:
Downward gaze preference (setting-sun sign)
Downward saccades and smooth pursuit may be impaired, but vestibular responses are preserved
Down-beating nystagmus
4. Disturbances of vergence eye movements:
Convergence retraction nystagmus (Koerber–Salus–Eischnig syndrome)
Paralysis of convergence
Spasm of convergence
Paralysis of divergence
"A" or "V" pattern exotropia
Pseudo-abducens palsy
5. Fixation instability (square-wave jerks)
6. Skew deviation
7. Pupillary abnormalities (light–near dissociation)

findings (Table II). This condition is known by a plethora of names: Parinaud's syndrome, Koerber–Salus–Eischnig syndrome, pretectal syndrome, dorsal midbrain syndrome, and Sylvian aqueduct syndrome. Eyelid abnormalities also occur, such as Collier's tucked lid sign (i.e., lid retraction). Vergence may also be affected. Many of the features of the dorsal midbrain syndrome result from damage of the fibers crossing the posterior commissure, including those from the riMLF and interstitial nucleus destined for their namesakes on the contralateral side. Invariably, damage to other nearby structures may also occur during these lesions, the most important of which are the nuclei of the posterior commissure, the interstitial nucleus of Cajal, the fasciculus retroflexus, and the riMLF. Destruction of the riMLF bilaterally results in complete paralysis of all vertical eye movements (both up and down). Furthermore, as indicated earlier, damage to the interstitial nucleus of Cajal almost always includes damage to the fibers of passage from the riMLF. A single occlusion to the thalamoperforating artery has sometimes led to bilateral infarction of the rostral midbrain–posterior diencephalon near the midline and paralysis of vertical eye movements.

E. Autonomic Control of the Eyes in the Midbrain

1. Edinger–Westphal Nuclei (EW)

The Edinger–Westphal nuclei are located just dorsal to the third cranial nerve motoneurons and represent the visceral (parasympathetic portion) component of the oculomotor complex. The Edinger–Westphal nuclei provide preganglionic input to the ciliary ganglion mediating the pupillary light reflex and accommodation responses of the lens (i.e., the ciliary body). The nucleus of Perlia (located between the somatic nuclei of the primate) may also provide direct input into the iris and ciliary body, which bypasses the ciliary ganglion altogether. The primary input to the Edinger–Westphal nuclei is from the pretectal olivary nuclei, which receive direct crossed retinal input. Early physiologic and anatomic evidence supported direct ipsilateral and contralateral projections from the pretectal olivary nuclei to the Edinger–Westphal nucleus. Recent anatomic studies (injections of the retrograde tracer WGA–HRP into the Edinger–Westphal nuclei) have confirmed that there are no reciprocal connections between the olivary pretectal nuclei on opposite sides of the brain stem. Instead, each pretectal nucleus sends both contralateral and ipsilateral projections to each Edinger–Westphal nucleus. In addition, the Edinger–Westphal nuclei receive projections from the supraoculomotor region of the midbrain as well as from the fastigial nuclei of the cerebellum. Most neurons in the Edinger–Westphal nuclei also respond during changes in accommodation (see later discussion) used to view a near target.

2. Pupillary Light Reflex

The preceding connections permit a modern understanding of the pupillary light reflex. Light shone in one eye (e.g., the right eye) is conducted via the right optic nerve to both sides of the pretectum after crossing in the optic chiasm. The pretectal olivary nuclei on each side will then receive a neural signal related to the brightness of the light shone in one eye. This signal is relayed by each pretectal nucleus to both Edinger–Westphal nuclei. As a result there is a crossing at the chiasm and at least once in the brain stem, across the posterior commissure. A relative afferent pupillary defect (RAPD) reflects a disparity in the amount of pupillary light constriction in both eyes in response to light shone in one eye compared to light shone in the other eye. This occurs in patients who have an optic nerve lesion, and thus it localizes the defect in the

conduction of light impulses to the 2 cm of optic nerve anterior to the optic chiasm. It does not occur from a cataract or retinal disease (e.g., diabetic retinopathy).

3. Control of Vergence and Accommodation

The supraoculomotor region of the midbrain is directly involved in the control of the movement of the two eyes in opposite directions, i.e., vergence. This region is located just dorsal and lateral to the oculomotor nuclei. These neurons provide a direct, ipsilateral projection to the medial rectus subdivision of the oculomotor complex. In addition, there may also be a projection to the Edinger–Westphal nuclei on the same side, and this could account for the accommodative responses found in Edinger–Westphal neurons. The supraoculomotor region receives direct projections from the interposed nuclei of the cerebellum as well as from portions of the frontal and parietal lobes of the cerebral cortex. The cerebral regions that are known to project to this region include the prearcuate frontal cortex (area 8), area LIP, and areas MT and MST of the temporal–parietal lobes. The neurons in this supraoculomotor region are termed near-response cells because they increase their firing rate for near viewing, but not during vertical or horizontal conjugate eye movements. In addition, most of these neurons were tested in tasks that could distinguish vergence from accommodation. These neurons fired in association with changes in both vergence and accommodation. A small subset of the supraoculomotor neurons was sensitive solely to accommodation or vergence.

III. PAIN MODULATION AND OTHER MIDBRAIN SYSTEMS

A. Periaqueductal Gray (PAG)

The periaqueductal or "central" gray is a group of neurons that surrounds the aqueduct and is divided into four major zones: dorsomedial, dorsolateral, ventrolateral, and medial (Fig. 8). The medial portion immediately surrounds the aqueduct. Modulation of at least five primary behaviors has been attributed to portions of the periaqueductal gray: (1) modulation of pain pathways; (2) reproductive behavior (i.e., lordosis); (3) fear and anxiety; (4) vocalizations; and (5) autonomic regulation (i.e., control of blood pressure). The functions of the periaqueductal gray in reproductive behavior and vocalization have been demonstrated primarily in rats and cats and have not been investigated in humans. Moreover, studies have demonstrated coordinated responses between blood pressure, anxiety, and analgesia, which are mediated via competing columns of periaqueductal gray cells. As a consequence, the following discussion will be directed toward understanding three of the five primary physiologic functions: pain control, autonomic regulation (e.g., blood pressure, pulse, respiration, etc.), and the generation of fear and anxiety.

The role of the periaqueductal gray in gating pain information arising from the spinal cord has been known for at least 30 years. Electrical stimulation in the midbrain periaqueductal gray produced a level of anesthesia that was compatible with performing an exploratory laparotomy in a rat. Similar "endogenous" analgesia has been demonstrated during such activities as environmental stress, long-distance running, or sexual activity. Analgesia may also be modulated by mood and circadian rhythms. How are these functions organized?

Most of the antinociceptive effects of midbrain periaqueductal gray stimulation can be mediated via connections to the nucleus raphe magnus located in the ventral rostral medulla. In turn, the nucleus raphe magnus provides afferents to the dorsal horn of the spinal cord via the dorsolateral funiculus. Two primary pathways target the nucleus raphe magnus. An opioid-dependent pathway, located in the ventrolateral portion of the midbrain periaqueductal gray has been confirmed using a variety of experimental techniques. Injection of morphine into the ventrolateral portion of the periaqueductal gray induces analgesia. Periaqueductal gray neurons are inhibited by enkephalin, an endogenous opioid pentapeptide. The effects of stimulation in the ventrolateral portion of the periaqueductal gray (either by morphine or by electrical stimulation) can be reversed by the injection of Naloxone, an opioid antagonist. A second, nonopioid pain-modulating pathway arises from the dorsolateral portion of the periaqueductal gray. A similar level of analgesia can be generated by the injection of neurotensin or substance P, two peptide transmitters, into this region of the periaqueductal gray. The effects of these peptides and dorsolateral periaqueductal gray stimulation are not reversed by the injection of Naloxone, supporting the idea that the dorsolateral pathways are nonopioid-mediated. Some of these effects may also be modulated via *ascending* projections from the midbrain periaqueductal gray to the thalamus to cause a release of β-endorphin. The

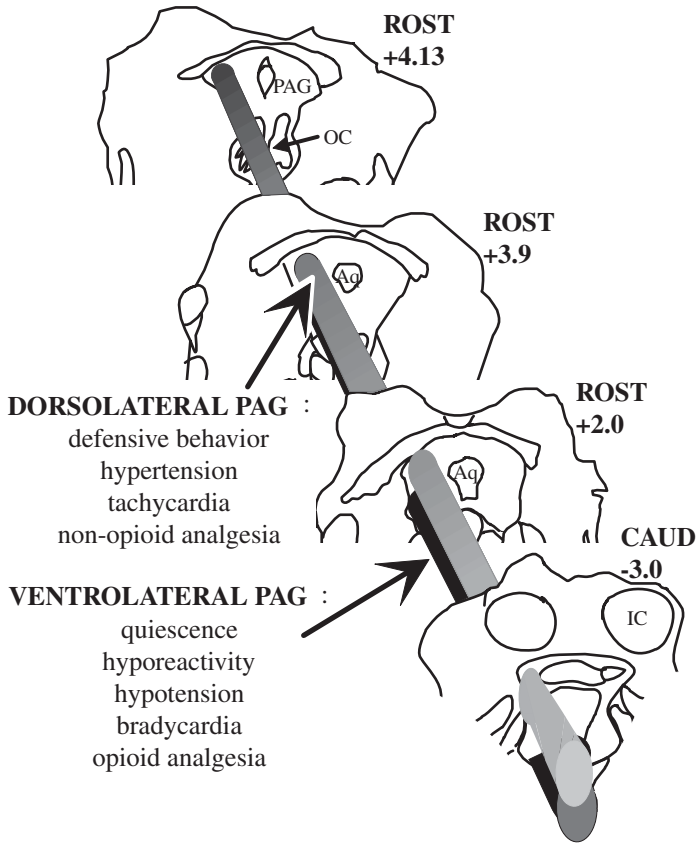

Figure 8 Schematic diagram of the dorsolateral and ventrolateral longitudinal cell columns of the periaqueductal gray controlling the fight (dorsolateral) or flight (ventrolateral) responses. See Table I.

thalamus may then reciprocally activate the midbrain periaqueductal gray. The periaqueductal gray also receives afferents from the prefrontal and insular cortices as well as the lateral and medial preoptic areas of the hypothalamus. The latter connections are much more important in the generation of lordosis behaviors than pain modulation. In sum, the primarily centrally acting, antinociceptive drugs provide much of their relief by activating opioid cells in the ventrolateral portion of the periaqueductal gray. Whereas there are a number of segmental and supraspinal descending antinociceptive systems, the periaqueductal gray provides the major descending control for both opioid and nonopioid-mediated analgesia.

Forebrain connections from the amygdala to the periaqueductal gray participate in the aversive responses of animals and in the fear and anxiety generated in humans from activation of dorsal regions of the periaqueductal gray. In addition, activation of the dorsolateral periaqueductal gray produces threat, associated with vocalization (''fight''), whereas activation of the caudal ventrolateral periaqueductal gray produces immobility or freezing effects (''flight''). These effects of stimulation (dorsolateral versus ventrolateral) are also associated with changes in blood pressure and level of intrinsic nociception. The primary networks for maintaining the blood pressure and controlling respiration and heart rate are located in the medulla. The periaqueductal gray is part of an indirect path that regulates blood pressure in response to emotional state. The periaqueductal gray is interconnected with the lateral hypothalamic nucleus, periventricular nuclei, medial preoptic nucleus, amygdala, prefrontal cortex, and insular cortex. It also has projections to all of the medullary nuclei that participate in the regulation of blood pressure. Stimulation in the dorsolateral periaqueductal gray increased blood pressure, whereas activation of the ventrolateral periaqueductal gray produced hypotension.

This has led to the concept that a constellation of physiologic responses occurs following activation of these two different regions of the periaqueductal gray (Fig. 8). The fight response following dorsolateral activation is characterized by marked hypertension,

increased blood flow to the face, decreased blood flow to the limbs and viscera, tachycardia, and nonopioid analgesia. Activation of the ventrolateral periaqueductal gray is characterized by quiescence, hyporeactivity, hypotension, bradycardia, and opioid analgesia. The blood flow increases to the limbs but decreases to the viscera and face.

The ventrolateral and dorsolateral regions are probably mutually inhibitory, mediated by the action of intrinsic GABAergic interneurons. Injection of bicuculline (a blocker of GABA-A receptors) during stimulation of the dorsal periaqueductal gray blocked the anxiolytic (antianxiety) effect of injected diazepam. Two additional neurotransmitters participate in the pharmacology of anxiety and fear: 5-hydroxytryptophan (serotonin) and CCK (cholecystokinin). In humans $5HT_{1A}$ (serotonin receptor subtype) agonists have been shown to be anxiolytic and this effect is probably mediated by inhibition of dorsal raphe neurons. Injections of CCK in human volunteers generated panic attacks. CCK also decreased the threshold to painful stimuli, whereas activation of the ventrolateral periaqueductal gray with enkephalin produced inhibition of nucleus raphe magnus projecting neurons.

Careful anatomic studies have further demonstrated that these two regions of the periaqueductal gray are organized in longitudinal rostral–caudal columns of cells with different afferent and efferent connections. The periaqueductal gray lateral, ventrolateral, and dorso*medial* to the aqueduct project to the ventromedial and ventrolateral medulla. The dorsolateral periaqueductal gray, on the other hand, projects to the cuneiform nucleus and the periabducens regions of the rostral dorsomedial pons, but not the medulla. The dorsolateral periaqueductal gray column does not stain for cytochrome oxidase, but it has intense staining for acetylcholine-esterase or NADPH–diaphorase. In addition, the labeling experiments have demonstrated that the lateral and ventrolateral portions of the periaqueductal gray have differential projections to the medulla. The ventrolateral portion of the periaqueductal gray projects to the periambigual region of the lateral medulla, which supplies vagal innervation to the heart. Ascending projections from the spinal cord and other brain stem regions have been shown to have topographic projections to the periaqueductal gray. In particular, precisely somatotopically organized afferents arising from lumbar and cervical enlargements target the dorsolateral column of the periaqueductal gray. In contrast, the ventrolateral column is targeted by lumbar and cervical afferents but without any specific somatotopic arrangement. This correlates well with the observed differential behaviors of activating the dorsolateral (fight) versus ventrolateral (flight) portions of the periaqueductal gray.

Cortical inputs to the periaqueductal gray have differential projections to the dorsolateral and ventrolateral cell columns. In the rat, descending corticofugal projections target restricted parts of the periaqueductal gray and terminate as one or two longitudinal columns along the rostrocaudal axis of the periaqueductal gray. Massive subcortical projections to the periaqueductal gray arise from the medial preoptic region and central nucleus of the amygdala and probably mediate many of the observed behavioral responses to periaqueductal gray stimulation. The medial preoptic region has been strongly implicated in neuroendocrine (gonadal steroid) regulation, sexual behavior, thermal regulation, and sleep. The projections of the medial preoptic region are primarily to the dorsomedial and dorsolateral columns of the periaqueductal gray at rostral levels. Further caudally the projection becomes distinctly bicolumnar with dense labeling in the dorsomedial and lateral cell columns. The central nucleus of the amygdala has been strongly implicated in the mediation of defensive behaviors and antinociception. Its projections at rostral levels to the periaqueductal gray are primarily confined to the medial periaqueductal gray. At the level of the oculomotor nuclei, the projection density increases markedly and forms dense dorsomedial and ventrolateral input columns separated by the dorsolateral periaqueductal gray, which receives much less input from the central nucleus of the amygdala. Caudally the central nucleus of the amygdala projects primarily to the lateral and ventrolateral but to neither the dorsomedial nor the dorsolateral periaqueductal gray column. In conclusion, there is compelling evidence for three manifestations of the columnar organization of the periaqueductal gray: (1) discrete physiologic–behavioral functions (fight or flight responses); (2) differential projections from the dorsolateral and ventrolateral portions of the periaqueductal gray to the medulla; and (3) respect of specific, longitudinal columnar boundaries for the various inputs and outputs of the periaqueductal gray.

B. Red Nucleus

The red nucleus occupies a large portion of the ventral midbrain tegmentum rostrally and contains very large

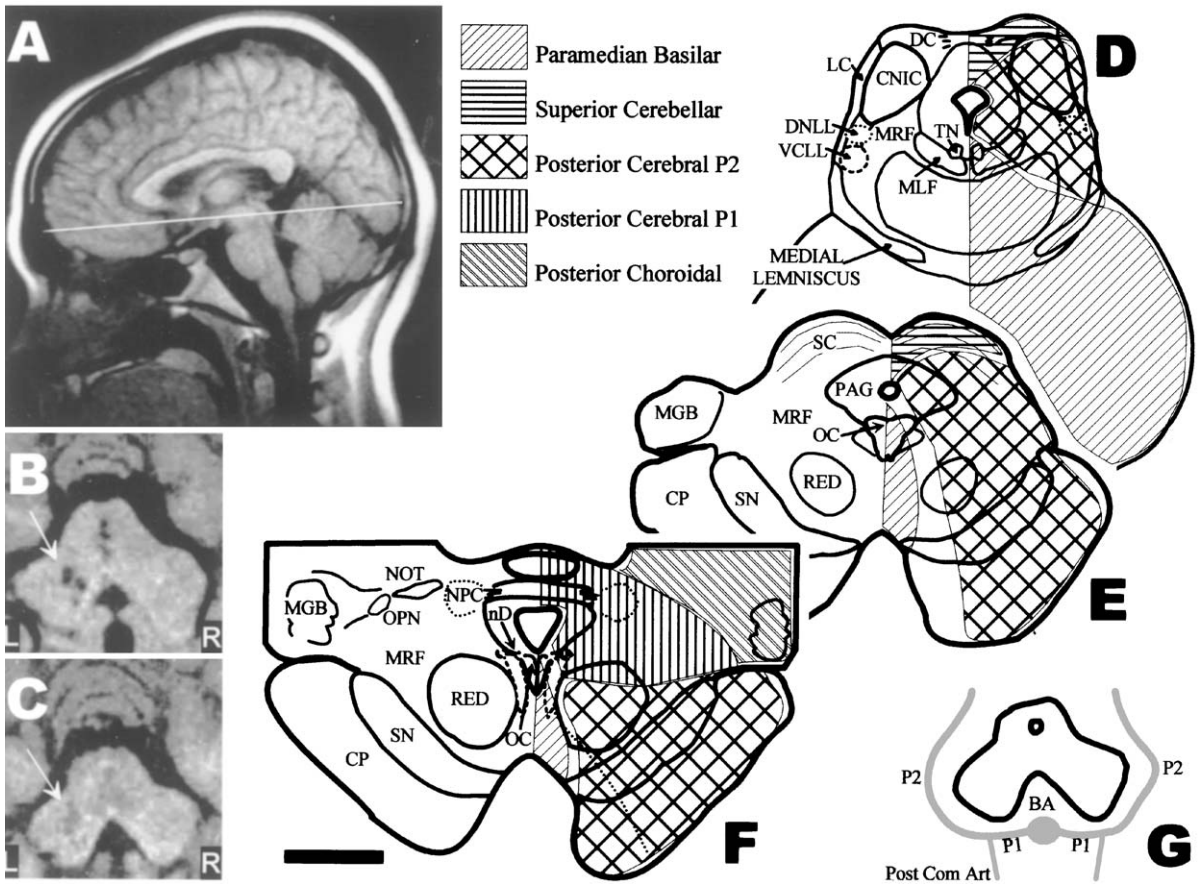

Figure 9 Blood supply of the midbrain. (A) Sagittal section of the human brain showing the horizontal plane of the brain stem sections of (B) and (C). (B) and (C) show serial sections of a patient who suffered a midbrain stroke (arrows) resulting from hemorrhage of a perforating branch of the P2 segment of the posterior cerebral artery on the left (L). Initially the patient experienced bilateral loss of eye movement, bilateral inability to open the eyes (ptosis), and mild weakness of the right upper extremity. The blood has cleared by the time of the MRI study and there is no evidence of infarction of the occipital lobes or other regions supplied by this artery. (D, E, and F) Caudal to rostral outline drawings showing the differential blood supply of the midbrain. (G) Schematic drawing of blood supply to the midbrain. Paramedian branches arise directly from the basilar artery, whereas the remaining blood supply arises from proximal (P1) and distal (P2) branches of the posterior cerebral artery. See Table I.

cells. It is primarily involved in limb control especially during reaching movements. The dentate and interposed nuclei of the cerebellum provide a large number of afferents to the red nucleus via the superior cerebellar peduncle (brachium conjuctivum). The other major input to the red nucleus comes from the motor cortex. Outputs of the red nucleus include two major descending tracts, one to the spinal cord (crossed) and one to the inferior olive (uncrossed).

Lesions within the red nucleus lead to fascicular third nerve palsies, which can involve separate divisions of the oculomotor nerve, as well as contralateral ataxia (Benedikt's syndrome). The ataxia is thought to develop from interruption of both the rubro-olivary and the dentatothalamic fibers, which travel in the adjacent brachium conjunctivum. More ventral strokes that spare the red nucleus may produce a fascicular third nerve palsy and a contralateral hemiparesis (Weber's syndrome).

IV. VASCULAR SUPPLY OF THE MIDBRAIN

The blood supply to the midbrain is via branches of the basilar artery, which bifurcates at the level of the third cranial nerves into a left and right posterior cerebral artery (PCA). The initial portion of the PCA, the P1 segment, is proximal to the posterior communicating

artery, whereas the P2 segment is distal (Fig. 9G). In as many as 10% of patients, a fetal circulation persists and the basilar communicating segment (i.e., the mesencephalic artery) is hypoplastic. In this situation the PCA is derived primarily from the internal carotid artery via a large posterior communicating artery.

In the caudal midbrain (Fig. 9), the blood supply to the ventral portion is from the basilar artery, whereas the dorsolateral midbrain is perfused via the superior cerebellar artery. At more rostral levels, the dorsal midbrain is supplied by the basilar artery and direct branches from the proximal PCAs. The vessels arising from the initial portion of the PCAs can be variable but include paramedian mesencephalic arteries and peduncular penetrating branches, which arise from the PCAs after the posterior communicating arteries join to form the P2 segment of the PCAs (see Figs. 9B and 9C).

Midbrain infarction may accompany thalamic infarction. Branches to the mesencephalon may arise either directly from the basilar artery or as a common trunk with the thalamic paramedian vessels. It is the occlusion of these paramedian thalamic–subthalamic perforating vessels that can often infarct both rostral interstitial nuclei of the medial longitudinal fasciculus and produce a complete paralysis of both upward and downward vertical and torsional eye movements. The thalamogeniculate arteries originate further posterior along the PCAs just at or after the connection with the posterior communicating artery, and they supply the posterior lateral thalamus, including the lateral geniculate, the pulvinar, portions of the hippocampal gyrus, the dentate fascia, and the dorsolateral nuclei of the thalamus. Infarctions of the midbrain are distinguished from the meso-diencephalic junction by third nerve involvement.

Migraine

MARGARITA SANCHEZ DEL RIO and STEPHEN SILBERSTEIN
Thomas Jefferson University Hospital

GLOSSARY

familial hemiplegic migraine Hereditary subtype of migraine with aura that presents with motor paresis as part of the aura.

incidence The onset of new cases of a disease in a defined population over a given period of time.

prevalence The proportion of a given population that has a disorder over a defined period of time.

triptans Family of drugs that are widely used as migraine abortives based on their agonism on serotonin receptors of the subtype 1B, 1D, and 1F.

Migraine is a recurrent episodic headache disorder characterized by repeated attacks of pulsating or throbbing, often unilateral, headache pain of moderate to severe intensity that last 4–72 hr. Headache is typically accompanied by nausea, phonophobia, and photophobia. Migraine can be subdivided into migraine with or without aura, depending on whether focal neurological symptoms precede or accompany the headache.

I. EPIDEMIOLOGY AND COMORBIDITY

A. Migraine Prevalence

Migraine is a highly prevalent condition affecting approximately 10% of the population. Migraine prevalence is age, gender, and race dependent. Women are more affected (lifetime prevalence, 12–17%) than men (4–6%). In the American Migraine Study, the 1-year prevalence of migraine increased with age among women and men, reaching the maximum at ages 35–45 and declining thereafter. Migraine prevalence decreases in older women but never decreases to prepubertal or even male prevalence. Migraine prevalence is influenced by race and geographical region. It is highest in North America and Western Europe and more prevalent among Caucasians than African or Asian Americans. The influence of environmental and genetic factors varies. Migraine without aura is influenced by a combination of genetic and environmental factors, whereas migraine with aura has a stronger genetic influence. Behavioral, emotional, and climatologic changes may trigger migraine, modify the vulnerability to migraine, or impact on its prevalence.

Recent evidence suggests that migraine incidence is increasing. Stang and colleagues, in a population-based survey of migraine in Olmsted County, found that from 1979 to 1981 there was a striking increase in the age-adjusted incidence in those under 45 years of age. Migraine incidence increased 34% for women and 100% for men. In this study, the overall age-adjusted incidence was 137 per 100,000 person years for men and 294 per 100,000 person years for women. This was confirmed in a study conducted among schoolchildren in Finland: The prevalence of migraine increased over

an 18-year period from 1.9 to 5.7%. Neither study provided evidence for the cause of this increase.

Migraine incidence and prevalence also vary by age and sex. Migraine without aura reaches its peak at ages 14–17 in females (0.2%) and 10 or 11 in males (0.1%). Migraine with aura has maximum incidence at the age of 12 or 13 in females (0.14%) and at the age of 5 in males (0.6%). This suggests that migraine with aura in men appears very early in life. In contrast, women more often develop migraine (with or without aura) as teenagers, during or following puberty.

B. Comorbidity of Migraine

The term comorbidity refers to the greater than coincidental association of two conditions in the same individual. Migraine is comorbid with many disorders (Table I). This can alert clinicians to identify them. Comorbid illness impacts pharmacologic treatment of migraine headache. One drug may be useful for more than one disease (i.e., valproate and topiramate may be therapeutic for both migraine and epilepsy). On the other hand, some treatments may be contraindicated in certain comorbid illnesses. Beta-blockers should be avoided in patients with migraine and depression. Careful attention to a drug's effect on comorbid conditions optimizes health care use and may improve patient's quality of life.

Individuals who seek medical care are more likely to have two independent diseases than are individuals who do not seek medical care, a phenomenon referred to as Berkson's bias. This can result in associations that are not apparent in population-based studies.

1. Stroke

In a general population study conducted by the National Health and Nutrition Examination Survey I, both migraine and severe nonspecific headaches were

Osteoarthritis	Sternfeld *et al.* (1995), Peroutka *et al.* (1997)[a]

[a]Population-based study.

associated with a significantly increased risk for schemic stroke, particularly in young women (rate of stroke was 3.7% in migraineurs versus 2.6% in nonmigraineurs). This association decreases in older patients. The association between migraine and stroke is greater for migraine with aura [odds ratio (OR) 6.2; 95% confidence interval (CI), 2.1–18.0] than migraine without aura (OR-3.0; 95% CI, 1.5–5.8), and it is greater for women than men. In women younger than age 45, migraine with and without aura is associated with a fourfold increase in the risk of stroke. The risk of stroke increases substantially in female migraineurs who are using oral contraceptives (OR-13.9; CI, 5.5–35.1) or who smoke $\geqslant$20 cigarettes a day (OR-10.2; CI, 3.5–29.9).

There appears to be a stronger association between migraine and posterior circulation stroke, a vascular territory that is otherwise infrequently affected (4%) in the general population younger than age 45. Migraine may cause stroke. Bousslavsky *et al.* reported that among patients with stroke, if the stroke occurred during a migraine attack only 9% had arterial lesion, but if the stroke was remote from a migraine attack 91% had an arterial lesion. Mitochondrial DNA mutations have been implicated as one cause of migraine-related strokes in young adults. Majamaa and colleagues found the mitochondrial encephalomyopathy, lactic acidosis, and stroke-like syndrome (MELAS) mutation in 6% of patients with juvenile occipital migraine stroke. Eighty-three percent of the migraine stroke patients carried the U mtDNA haplotype in a higher proportion than the nonmigraineur or the migraine with or without aura population, indicating that this haplotype is a risk factor for migraine stroke. Associations between migraine stroke and coagulopathies have been inconsistent. These findings suggest mechanisms other than arterial disease are responsible for migraine-related infarction.

2. Epilepsy

The 1-year prevalence of epilepsy in the population is approximately 0.5%, the prevalence of migraine in persons with epilepsy ranges from 8 to 15%, and the prevalence of epilepsy in migraine patients is approximately 5.9%. Ottman and Lipton explored the comorbidity of migraine and epilepsy based on the assumption that migraine and epilepsy share a common genetic basis. These investigators found that the incidence of migraine is 2.4 times higher in persons with epilepsy than in persons without epilepsy. The risk of migraine was not associated with the age of onset of epilepsy but was elevated in every subgroup of epilepsy defined by seizure type (higher risk for partial versus generalized onset seizures), etiology of epilepsy (higher risk for epilepsy caused by head trauma than idiopathic epilepsy), or family history of epilepsy. The risk of migraine was elevated both before and after seizure onset, indicating that migraine is not solely the cause or consequence of epilepsy. Genetic and environmental risk factors probably play an important role in the development of migraine and epilepsy, both of which share an alteration in neuronal excitability.

3. Mood, Anxiety, and Somatoform Disorders

The cooccurrence of migraine and psychiatric disorders has been studied extensively in several population-based and longitudinal surveys. Migraine is associated with both affective and anxiety disorders. Breslau and colleagues reported on the association of International Headache Society (IHS)-defined migraine with higher lifetime rates of affective disorder, anxiety disorder, illicit drug use disorder, and nicotine dependence. Migraine with aura was associated with an increased lifetime prevalence of both suicidal ideation and suicide attempts, controlling for sex, major depression, and other concurring psychiatric disorders. The relative risk for the first onset of major depression in migraineurs after the onset of migraine versus no prior migraine was 4.1 (95% CI, 2.2–7.4), whereas the relative risk for the first onset of migraine in persons with prior major depression versus no history of major depression was 3.3 (95% CI, 1.6–6.6). These data indicate that the lifetime association between migraine and major depression could result from a bidirectional influence, from migraine to subsequent onset of major depression, and from major depression to first migraine attack. Furthermore, persons with migraine have increased prevalence of bipolar disorder, panic disorder, and one or more anxiety disorders.

The mechanisms of these associations between migraine and affective/anxiety disorders are poorly understood. The simple causal model—major depression in migraineurs represents a psychological reaction to repeated disabling migraine attacks—cannot account for their comorbidity. A shared common underlying etiopathologic mechanism could be a better explanation. Several antidepressant or anxiolytic agents provide effective treatment for migraine, but the mechanism of action of these drugs seems to be independent of their antidepressant action.

4. Other Conditions

Migraine has been associated with many other conditions, including systemic lupus erythematosus, primary antiphospholipid antibody syndrome, Raynaud's phenomenon, osteoarthritis, and gastrointestinal disorders. It has been suggested but not proven that antiphospholipid antibodies may play a critical a role in the comorbidity of migraine and lupus erythematosus; however, recent studies do not support this idea. The prevalence of migraine attacks in patients suffering from lupus does not differ from that the general population. In addition, gastric ulcer disease and colitis have been associated with migraine and chronic recurrent headaches, but again a precise link is lacking. In one study, peptic ulcer occurred more often among patients with recurrent headaches (13%) than in the age- and sex-matched general population (7.5%), whereas in another study gastric ulcers were associated with migraine only among smokers. Migraine is comorbid with allergies and asthma. The risk of bronchial asthma in children whose mothers had a history of migraine was almost twice that children whose mothers were headache free (RR = 1.8; 95% CI, 1.2–2.8).

C. Quality of Life

Migraine has profound effects on daily functioning, both in the work environment and at home, as ascertained by health-related quality-of-life and functional status questionnaires. Functional status questionnaires measure how headache affects physical and emotional functioning, whereas quality-of-life questionnaires evaluate the subjective effects of the condition.

The American Migraine Study estimated that 23 million U.S. residents have severe migraine headaches. The American Migraine Study II raised this estimate to 28 million. Twenty-five percent of migraineurs have more than four severe attacks a month. Patients with migraine with or without aura are more disabled than patients who suffer from tension-type headache. In approximately 70% of adult migraine subjects, interpersonal relationships are impaired. Regular activities are limited during 78% of migraine attacks and 50% of migraineurs cancel normal activities. About 50% of subjects believed that their headaches had an effect on their families. Headache subjects tends to modify their behavior to avoid precipitating attacks. More than 75% avoided certain headache-triggering factors, such as smoke, noise, emotional stress, and certain physical activities, even if job responsibilities were affected.

Despite the high disability headaches impose on individuals, only 66% of migraineurs ever seek medical attention. Most migraineurs rely on over-the-counter medication and are at risk for analgesic abuse and rebound headache. Education of the headache population is needed to encourage them to seek appropriate medical treatment of their attacks.

D. Economic Cost

The estimates of lost work time due to migraine range from 1.570 to 4.271 days per year. The costs from lost productivity are determined not only by missed work days but also by reduced work efficiency. Approximately 80% of employed migraineurs report that their job performance has been negatively impacted by migraine. Estimates of the level of efficiency during the attack vary from 56 to 73% of full capacity. Although the estimation of efficiency is subjective, there is striking consistency in the assessment of this parameter in different studies. Extrapolating the experience of these subjects, the projected amount of lost work resulting from migraine would cost employers nationally between $5.6 and $17.2 billion annually.

Although the cost to society from lost work productivity is substantial, this may be an underestimate of migraine-related economic loss, because these measures do not take into account such things as reduced productivity resulting from sufferers who attempt to work during migraine or the cost of household productivity losses due to migraine. Appropriate and timely migraine treatment is the most cost-effective strategy. Today, there are more pharmacological, educational, and behavioral approaches to headache treatment than ever before. The ultimate success of new headache therapies may not only depend on efficacy but also may be determined by the outcome of cost-effectiveness analyses on these agents.

II. PATHOPHYSIOLOGY

With the development of minimally invasive imaging techniques, we are starting to better understand the processes that develop in the human brain during migraine attacks. The two leading theories of migraine are the vasogenic theory and the neurogenic theory.

The vasogenic theory posits that migraine aura develops as a consequence of focal ischemia secondary to vasospasm. This hypothesis predicts that decrements in blood flow precede the onset of the aura due to constriction of the blood vessels supplying the affected occipital lobe. Reactive vasodilation would explain the genesis of pain through the stimulation of the perivascular sensitive fibers. This mechanism would explain the throbbing quality of pain, its varied location, and the relief of pain with the use of vasoconstrictive agents such as ergotamine. In the 1980 s, ^{133}Xe blood flow techniques were used to investigate the hemodynamic changes during aura-like symptoms. In general, these investigations reported 17–35% reductions in cerebral blood flow in posterior regions of the brain, values arguably below ischemic thresholds. In certain cases, an anterior spread of the hypoperfusion across neurovascular boundaries was observed. It has been speculated that reported values may be underestimated due to the artifact of Compton's scatter and that the decreases in cerebral blood flow would actually be within ischemic range. Recent positron emission tomographic scan studies on the migraine aura that do not suffer from Compton's scatter clearly show spreading hypoperfusion.

In contrast, the neurogenic theory posits that neuronal dysfunction and a phenomenon similar to cortical spreading depression underlie occipital lobe dysfunction. This theory predicts that alterations in blood flow develop as a consequence of neuronal events. Thus, augmented blood flow followed by reduced perfusion during cortical spreading depression reflects a wave of neuronal and glial depolarization followed by long-lasting suppression of neural activity. Recent high-resolution, high-field functional magnetic resonance imaging studies using blood oxygenation level-dependent (Bold) and perfusion-weighted imaging during migraine with aura attacks have revealed signal changes suggestive of cortical spreading depression within the human brain. Time locked to the onset of scintillation was an initial vasodilation within extrastriate cortex that progressed contiguously over occipital cortex at 3.5 ± 1.1 mm per minute, congruent with retinotopy and visual percept. The initial vasodilation was then followed by hypoperfusion. The facts that the BOLD signal changes during aura abort at major sulci, that the light-evoked visual responses were suppressed during migraine with aura attacks and took 15 min to return to 80% of baseline, and that those areas first affected were the first to recover provide strong evidence that an electrophysiological event such as cortical spreading depression generates the migraine aura in human visual cortex.

Meningovascular or brain mechanisms have been proposed to explain pain generation. In the mid-1940s, Ray and Wolff demonstrated that the human brain is an insensate organ. Sensory nerve fibers originating from the ophthalmic division of the trigeminal nerve innervate the meningeal blood vessels and the dura mater. Together, they constitute the trigeminovascular system. These sensory fibers transmit nociceptive information centrally into the trigeminal nucleus caudalis, and peripherally may promote a sterile inflammatory response within dura mater by releasing vasodilating and permeability-promoting peptides from perivascular nerve endings (substance P, calcitonin gene-related peptide, and neurokinin A). Immunoreactive calcitonin gene-related peptide levels are elevated in external jugular venous blood during migraine attacks, and return to normal after administration of sumatriptan and amelioration of the headache. This is consistent with neuropeptide release from activated sensory nerves during the migraine attack and blockade of peptide release by sumatriptan, mediated via 5-HT1B/1D prejunctional receptors on sensory terminals. A preliminary single photon emission computerized tomography study using Tc-99 human serum albumin provided the first direct evidence of the presence of plasma protein extravasation localized to extraparenchymal regions ipsilateral to the side of pain during a spontaneous migraine attack. Neurogenic inflammation can explain the sensitization of sensory nerve fibers to previously innocuous stimuli (e.g., vessel pulsations or venous pressure changes), which manifests itself as increased intracranial mechanosensitivity and hyperalgesia worsening by coughing or sudden head movement.

Trigeminovascular activation does not account for the initiation of a migraine attack. Brain stem or neocortical structures may play an important role in the genesis or the modulation of migraines or both. It is unclear what triggers the cortical events in migraine aura, but there seem to be genetic differences that render migraineurs more hyperexcitable. These may be related to genetic factors (point mutations in genes encoding calcium channels), mitochondrial energy impairment, magnesium deficiency, or environmental factors such as stress and ovarian steroid.

Upper brain stem nuclei may participate in migraine pathogenesis. Stimulation of periaqueductal gray, locus coeruleus, and dorsal raphe nuclei either generates pain resembling migraine or suppresses pain in animals and humans. Noradrenergic and

serotoninergic nuclei participate in stress responses, anxiety, and depression. Migraineurs may exhibit central hypersensitivity to dopaminergic stimulation, which has been linked to behaviors observed during migraine such as yawning, irritability, hyperactivity, gastroparesis, nausea, and vomiting. Molecular genetic studies have provided further evidence for the involvement of the dopaminergic system. Migraine is associated with the dopaminergic hypersensitivity phenotype overexpression of the DRD2 receptor. The possibility of a "migraine generator" in the rostral brain stem was raised by a positron emission tomography blood flow study performed during spontaneous unilateral headache in nine patients without aura. Increased rCBF was found in medial brain stem predominantly contralateral to the headache, which persisted after relief of migraine pain with sumatriptan. Whether these brain stem nuclei serve as migraine generators, participate in modifying the threshold for neuronal activation, or are part of the neuronal system that terminates an attack remains to be clarified.

III. IHS CLASSIFICATION AND DIAGNOSIS OF HEADACHE

The IHS classification committee created operational diagnostic criteria and a system of classification for headache disorders in 1988 (Tables II–IV). The classification is under revision and will include diagnostic criteria for entities such as chronic daily headache. The purpose of the criteria was to standardize nomenclature and avoid ambiguous diagnosis. Headaches are broadly classified into primary and secondary disorders. In secondary headache disorders, there is an identifiable underlying cause, whereas in primary headache disorders no such underlying abnormality has been identified. Tension-type, migraine, and cluster headaches are the most common primary headache disorders.

Table II
IHS Migraine Classification

1. Migraine
1.1. Migraine without aura
1.2. Migraine with aura
1.2.1. Migraine with typical aura
1.2.2. Migraine with prolonged aura
1.2.3. Familial hemiplegic migraine
1.2.4. Basilar migraine
1.2.5. Migraine aura without headache
1.2.6. Migraine with acute onset aura
1.3. Ophthalmoplegic migraine
1.4. Retinal migraine
1.5. Childhood periodic syndromes that may be precursors to or associated with migraine
1.5.1. Benign paroxysmal vertigo of childhood
1.5.2. Alternating hemiplegia of childhood
1.6. Complications of migraine
1.6.1. Status migrainosus
1.6.1. Migrainous infarction
1.7. Migrainous disorder not fulfilling above criteria

Table III
Migraine without Aura Diagnostic Criteria

A. At least five attacks fulfilling B–D
B. Headache attacks lasting 4–72 hours
C. Headache has at least two of the following characteristics
1. Unilateral location
2. Pulsating quality
3. Moderate or severe intensity
4. Aggravation by walking stairs or similar routine physical activity
D. During headache at least one of the following
1. Nausea and/or vomiting
2. Photophobia and phonophobia
E. At least one of the following
1. History, physical, and neurological examinations do not suggest one of the disorders listed in IHS groups 5–11
2. History and/or physical and/or neurological examinations do not suggest such disorder, but it is ruled out by appropriate investigations
3. Such a disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder

The migraine attack can be divided into four phases: prodrome, aura, headache phase, and resolution (Fig. 1). However, not all phases can be recognized in all individuals.

A. Migraine without Aura

The headache is characterized by episodes of head pain lasting 4–72 hr and having at least two of the following characteristics: pulsatile quality, moderate to severe intensity, unilateral location, and worsening with physical activity. To fulfill the IHS criteria for migraine, headache must also have occurred on at least five occasions and have been accompanied

Table IV
Migraine with Aura Diagnostic Criteria

A. At least two attacks fulfilling B
B. At least three of the following characteristics
1. One or more fully reversible aura symptoms indicating focal cerebral cortical and/or brain stem dysfunction
2. At least one aura symptom develops gradually over more than 4 min or, two or more symptoms occur in succession
3. No single aura symptoms lasts more than 60 min. If more than one aura symptom is present, accepted duration is proportionally increased
4. Headache follows aura with a free interval of less than 60 min
C. History, physical examination, and, where appropriate, diagnostic tests exclude a secondary cause

by nausea or by photophobia and phonophobia (Table II).

B. Migraine with Aura

The migraine aura is a recurrent neurologic symptom that develops gradually (in more than 4 min) and persists for less than 1 hr. Headache, nausea, and/or photophobia usually follow within 60 min after resolution of the aura but may not necessarily develop (acephalgic migraine). Visual aura is most frequently reported (99%), followed by sensory (31%), aphasic (18%), and motor aura (6%). The stereotypical visual aura is a serrated arc of scintillating, shining, crenelated shapes that begins near the point of fixation and slowly expands, leaving a partial homonymous visual field disturbance. Symptoms referable to more than one brain region (e.g., visual and somatosensory symptoms) usually develop in sequence, and when they do occur they can prolong the total duration of the aura to more than 1 hr. Aura symptoms that persist for more than 1 hr but less than 1 week are called prolonged aura (if neuroimaging studies are normal). Symptoms that persist for longer than 7 days or are associated with ischemic infarction on neuroimaging are classified as migrainous infarction.

Table V
Diagnostic Criteria for Chronic Migraine

A. Daily or almost daily (>15 days/month) headache for >1 month
B. Average headache duration of >4 hr/day if untreated
C. At least one of the following
History of episodic migraine meeting any IHS criteria
History of increasing headache frequency with decreasing severity of migrainous features over at least 3 months
Headache at some time meets IHS criteria for migraine 1.1–1.6 other than duration
D. Does not meet criteria for new daily persistent headache or hemicrania continua
E. At least one of the following
There is no suggestion of a secondary disorder as the cause
Such a disorder is suggested, but it is ruled out by appropriate investigations
Such a disorder is present, but first migraine attacks do not occur in close temporal relation to the disorder

C. Basilar Migraine (Bickerstaff's Migraine)

Basilar migraine is characterized by aura symptoms characteristic of a brain stem disturbance (e.g., diplopia, tinnitus, ataxia, dysarthria, bilateral paresthesias or weakness, cranial nerve signs, and occasionally decreased consciousness) or from both occipital lobes. The aura often lasts less than 1 hr and is followed by headache. This syndrome affects children, adolescents, and young women, although it can occur in all age groups and in both sexes.

D. Familial Hemiplegic Migraine

Familial hemiplegic migraine is a rare autosomal-dominant migraine syndrome in which patients experience recurrent visual and somatosensory auras and prolonged hemiparesis in the context of migraine attacks. It may be associated with dysphasia, drowsiness, confusion, coma, and, in some, cerebellar symptoms, tremor and epilepsy. To establish a diagnosis, the patient must have at least one first-degree relative with identical attacks. This

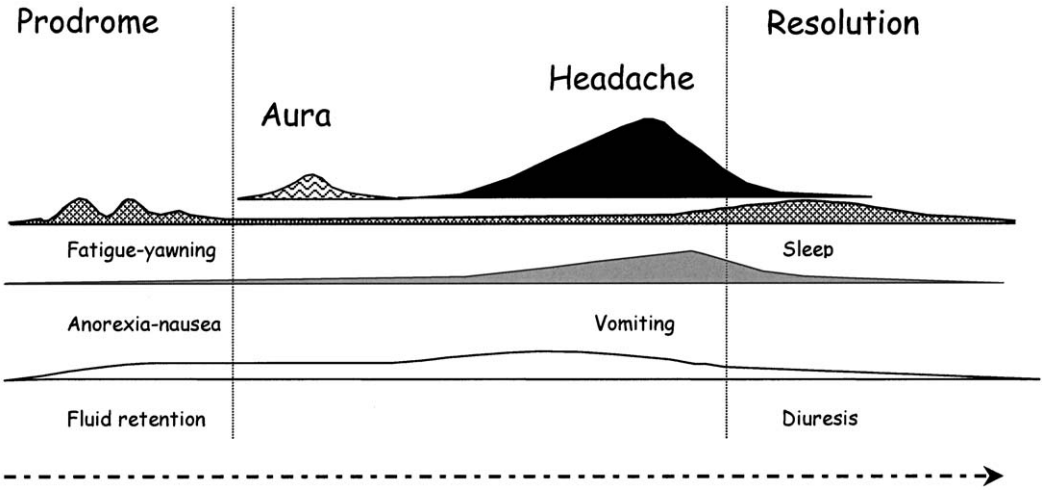

Figure 1 Phases during a migraine attack. The IHS Classification Committee states that premonitory symptoms may precede a migraine attack by hours to up to 24–48 hr. Typical symptoms consist of physical or mental hyper- or hypoactivity, depression, craving for special foods, repetitive yawning, increased bladder and bowel activity, and increased thirst. There is a growing body of biological, pharmacological, and genetic data that support a role for dopamine in the pathophysiology of the symptoms observed during the prodrome.

rare subtype has been linked to point mutations in chromosomes 19 and 1.

E. Chronic Migraine

Under the term chronic migraine, or transformed migraine, we propose to include all cases of chronic daily headache with features of a both migraine and tension-type headache that do not meet criteria for new daily persistent headache or hemicrania continua. Table V proposes criteria for chronic migraine. The typical patient is a woman with a past history of episodic migraine who develops a daily or almost daily headache that is mild to moderate in severity, with superimposed typical migraine attacks. The associated symptoms, such as phonophobia, photophobia, nausea, and vomiting, often become less severe and frequent.

Many patients with chronic migraine overuse analgesics, triptans, and ergots, leading to increased frequency of headaches, some of them in the context of "withdrawal" from acute medication—the so-called "rebound headache." Rebound headache leads to the consumption of more analgesics, creating a vicious cycle. Patients benefit from a detoxification treatment, thereby breaking the cycle, as either inpatients or outpatients. Chronic migraine may also develop from episodic mild pain without acute treatment overuse.

IV. GENETICS

Migraine genetics has experienced remarkable advances in the past 5 years. Molecular biology techniques have led to new insights into the pathogenesis of migraine.

A. Migraine with and without Aura

Migraine has a strong genetic component. In a Danish population-based survey of migraine using IHS criteria, the sex- and age-standardized risk of suffering from migraine with aura and migraine without aura among first-degree relatives was 1.9 (95% CI, 1.6–2.2) and 1.4 (95% CI, 1.0–1.8), respectively. This suggests that migraine without aura is caused by a combination of genetic and environmental factors, whereas migraine with aura is more heavily influenced by genetic factors.

Proposed modes of inheritance for migraine include autosomal-recessive inheritance for migraine with aura and sex-linked transmission, multifactorial, or autosomal-recessive inheritance for migraine without aura. Russell's epidemiology study, which included a segregation analysis of migraine with and without aura, found that both entities have multifactorial inheritance. This analysis cannot detect genetic heterogeneity and therefore cannot exclude a

mitochondrial or Mendelian pattern of inheritance. Migraine is very common. No single gene could be the cause of migraine either with or without aura; if it were, it would be more common than any other known disease-causing gene.

Migraine with aura and migraine without aura are associated with the familial hemiplegic migraine locus on chromosome 19p based on sibling pair and parametric linkage analysis of 28 unrelated migrainous families. Genetic linkage is also supported by a twin study using a polygenic, multifactorial model. In men, concordance rates were 22% in monozygotes and 4% in dizygotes. In women, concordance rates were 32% in monozygotes and 19% in dizygotes. This study estimated that 40–50% of a patient's liability to migraine is based on genetic factors; this estimate is much higher than those of previous twin studies.

B. Familial Hemiplegic Migraine

Familial hemiplegic migraine is an autosomal-dominant subtype of migraine with aura with strong penetrance. Approximately 55% of affected families can be linked to chromosome 19, 15% on chromosome 1, and 30% are still to be determined. Joutel *et al.* found that familial hemiplegic migraine was linked to chromosome 19 in two large French pedigrees. The critical area was mapped to a 30-cm region of the short arm of chromosome 19p13.1. Familial hemiplegic migraine is due to missense mutation in a pore-forming human α_{1A} subunit of neuronal P/Q-type Ca^{2+} channels (CACNA1A). More than 15 missense mutations in the CACNA1A have been reported. P/Q calcium channels are coupled to neurotransmitter release and expressed on soma and dendrites throughout the mammalian brain. How these mutations affect the functioning of the calcium channel is not well understood. Recent reports show calcium currents attributed to α_{1A} channel mutations partially diminished, and, in some studies, increased in other mutations. Tottering mice have a similar genetic defect in the α_{1A} calcium channel. These mice have resistance to the induction of cortical spreading depression. Familial hemiplegic migraine has been linked to two other gene loci on chromosome 1q21–23 and chromosome 1q31, respectively. Patients with the chromosome 19 mutation may also have cerebellar signs and essential tremor, and those with chromosome 1 mutations have associated epilepsy and febrile convulsions.

C. Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-like Syndrome

Migraine-like headaches are part of the clinical spectrum of MELAS, a well-characterized genetic disorder. MELAS is an inherited mitochondrial disease, resulting from different point mutations in the mitochondrial DNA. Most common is an A-to-G point mutation in the mitochondrial gene encoding for tRNA[Leu(UUR)] at nucleotide position 3243. Other point mutations occur at codons 3271 and 3252. Several studies analyzing the mitochondrial DNA in peripheral blood from migraine with and without aura patients have consistently failed to show an association between the commonly studied point mutations or deletions in mitochondrial DNA and migraine. In a Japanese study, 26% of migraine patients showed an A-to-G mutation in the coding region for the ND4 subunit of the respiratory complex I. Thus, migraine as a monosymptomatic expression of a defined mitochondrial cytopathy seems rare.

D. Cerebral Autosomal-Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is due to mutations in the *Notch 3* gene located on chromosome 19. The *Notch 3* gene encodes a transmembrane complex protein that functions as a cell surface receptor; one part of the protein complex resembles epidermal growth factor. The gene defects lead to either a gain or a loss of a cysteine residue in the extracellular N-terminal part of the molecule, probably causing a conformational and functional alteration. Accumulation of basophilic, PAS-positive, and osmiophilic material (electron microscopy) between degenerating smooth muscle cells in dermal arteries is a pathognomonic finding. The disorder can be diagnosed on skin biopsy.

Approximately one-third of CADASIL patients have migraine early in life with prolonged visual, sensory, motor, or aphasic aura. Recurrent strokes occur between 30 and 50 years of age secondary to a generalized arteriopathy. The arteriopathy develops slowly, resulting in destruction of smooth muscle cells and thickening and fibrosis of the walls of small and medium-sized penetrating arteries with consequent narrowing of the lumen. Multiple lacunar infarcts,

mainly in the frontal white matter and basal ganglia, lead to progressive permanent brain damage. Currently, no specific therapy is available.

Whether the appearance of aura symptoms early in the course of CADASIL is related to changes in the *Notch 3* gene or merely reflects the proximity of the *Notch 3* gene to the familial hemiplegic migraine gene defect remains to be clarified.

V. TREATMENT

Diagnosis of migraine will commence treatment. Patients want to know what is wrong with them and the cause of their headache. Treatment varies from patient to patient, based on their "expectations," headache frequency, severity, disability, comorbid disorders, and family and work environment. Recently, a multispecialty consensus has been reached to develop a unified, evidence-based approach to treating migraine by the U.S. Headache Consortium (www.AAN.com).

The folowing are general principles of treatment:

1. Use not only pharmacotherapy but also physical and psychological therapy.
2. Treat early in an attack.
3. Provide sufficient but not excessive symptomatic treatment, with backup alternatives for moderate and severe attacks, and rescue treatment when initial and backup therapy fails in order to stop suffering and avoid emergency department visits.
4. Encourage the avoidance of emergency department treatment except when all means of "at-home" therapy have proven ineffective. Do not deny patients the use of the emergency department treatment for acute, resistant headache. In case of recurring or inappropriate emergency service utilization, consider hospitalization since rebound or confounding factors are often present.
5. Provide firm limits on frequency and usage per week. Generally, the use of acute treatment should not exceed 2 days a week. Educate the patient on rebound headaches. Rebound headache results from frequent use of acute medications and is a pattern of increasing headache frequency often resulting in daily headache.
6. Treat at least two different attacks to assess effectiveness of a given acute medication. Determine that there is no interfering medication, increase the dose, and change formulation/route of administration before switching or adding another class of drug.
7. Acute treatment drug should be changed when the onset of action is too slow, response is incomplete, headache recurs, responsiveness is inconsistent, or these are important side effects or patient dissatisfaction.
8. Use oral, rectal, or nasal spray preparations initially.
9. Use nasal, rectal, or parenteral forms of medication when attacks are accompanied by significant nausea or vomiting or when there is evidence of delayed gastrointestinal (GI) absorption (gastroparesis).
10. Use adjunctive oral metoclopramide to reverse gastroparesis and improve absorption from the GI tract during severe attacks when oral symptomatic drugs are administered.
11. Administer nasal, rectal, or parenteral forms of symptomatic medication (DHE, sumatriptan, and indocin suppositories) for attacks that are not responsive to oral medication.
12. Consider hospitalization prior to the development of complications and/or addiction/dependency syndromes for patients with severe attacks who overuse treatment or whose treatments are clearly ineffective.
13. Encourage patients to participate in their own management.
14. Provide patients with a headache calendar to establish headache frequency, duration, intensity, associated symptoms, and benefits, and side effects of treatment.
15. Develop a program of symptomatic and preventive medication, often in combination, to establish the most beneficial treatment.

A. Nonpharmacological Treatment

Nonpharmacological treatments include behavioral methods and psychological treatment. Behavioral methods include biofeedback, relaxation techniques, and reinforcement of maintaining a regular schedule, exercise, healthy diet, and regular sleep. There are several modalities of biofeedback; one can monitor body temperature on electromyography. The final goal is the same: the extinction of pain behavior. Relaxation techniques include progressive muscle relaxation and imaginary- and suggestion-based relaxation. These treatments have been proven to be useful for children, pregnant women, and patients for whom stress is a major trigger.

Many patients (34–40%) consult alternative practitioners. Neck manipulation, acupuncture, hypnosis, and herbal therapy are sometimes used. There are no well-designed clinical trials to validate their efficacy.

B. Pharmacological Treatment

Depending on the severity and frequency of headache, patients may be amenable to receive acute or preventive treatment or both.

1. Acute Drug Treatment

Acute treatment is given only at the time of the migraine attack in an effort to shorten the attack duration and decrease the severity of the attack and its associated symptoms. In migraine with aura triptan, treatment during the aura phase has not proven to stop the aura progression or the subsequent headache. Therefore, in migraineurs with aura, treatment with triptans should be administered during the pain phase. Try to avoid pharmacological treatment of very mild headaches; behavioral or relaxation techniques are preferred. Stratify patients' treatment; the goal is to use information available at the initial consultation to predict treatment needs. Treatment plans are formulated based on diagnosis, severity of illness, symptom profile, treatment history, and patient's preference such as willingness to take medication and preferred route of administration. According to this, the initial acute treatment for mild to moderate pain with slow escalation consists of non-specific therapy such as NSAIDS and simple and combination analgesics. For moderate to severe pain, less severe pain and fast escalation, or poor response to NSAIDS or analgesics, go directly to specific therapy—triptans or DHE.

2. Preventive Treatment

Preventive treatment is administered on a daily basis to decrease the frequency and lessen the severity of the attacks. Indications for preventive treatment include the presence of disorders such as hemiplegic migraine, recurrent migraine attacks that significantly interfere with daily function despite acute treatment attacks that occur more than twice a week, or acute treatment that is not satisfactory is excessive, or contraindicated. Maximum benefit may take 3 months. If effective, reevaluate after 6 months and consider if medication needs to be continued. Concomitant acute treatment should be considered for acute attacks that escape preventive measures.

VI. DIFFERENTIAL DIAGNOSIS

The primary headache disorders, such as migraine, tension-type headache, and cluster headache, are those in which headache represents the primary symptom of a physiological disorder. These disorders do not have identifiable gross microscopy pathology. The secondary headache conditions are those in which the headache represents a symptom of a pathological organic process. Some conditions, such as severe hypertension, withdrawal syndromes, or cerebral venous thrombosis, may mimic benign disorders such as migraine. The importance of accurate and timely diagnosis cannot be overestimated because a delay in appropriate treatment may in certain settings result in death or permanent neurological injury. Depending on the temporal profile of presentation of headaches they can be divided into sudden, abrupt, onset headaches, which should be assumed to be the result of an acute neurological event; subacute onset headaches, in which the symptoms appear over minutes, hours, or days; and insidious onset headaches that include those illnesses that have a slow onset and a progressive course.

Note that all cases of "new onset" headache must be evaluated carefully. New onset headaches refers to headaches that have never been present before or in which the pattern or accompanying symptoms are new.

VII. CONCLUSION

Migraine is probably the most important primary headache syndrome due to its high prevalence and the disability that it causes. Recent research with both genetic and imaging techniques has led to a better understanding of the pathophysiology of migraine. However, diagnosis remains a clinical procedure and is the first step for treatment. Stratifying the treatment to meet the patient's needs' decreases disability and is a cost-effective method of managing migraine, delivering improved clinical outcomes at a small additional cost.

Mild Head Injury

JEFFREY T. BARTH, JASON R. FREEMAN, and DONNA K. BROSHEK
University of Virginia School of Medicine

GLOSSARY

acceleration–deceleration injury Brain injury typically noted at the cellular level (diffuse axonal injury), caused by high-speed deceleration (e.g., automobile accidents).

cerebral autoregulation System that serves to maintain sufficient cerebral flow to balance blood supply and cellular glucose metabolism demands (facilitate homeostasis).

cerebral concussion Mild traumatic brain injury with brief or no loss of consciousness and no permanent neuropathological deficits or changes.

complicated mild head injury Trauma to the head that results in sequelae that meet the criteria for mild head injury but that reveals neuroimaging evidence of a related cerebral lesion; may also refer to mild head injury with persistent postconcussion disorder.

diffuse axonal injury Widespread histological brain trauma characterized by stretching and breaking of neuronal fibers, usually secondary to acceleration–deceleration and rotational forces of the brain inside the skull.

fluid percussion Rodent animal research model in which a saline solution is introduced under pressure to the extracerebral/subcranial space to simulate nonimpact/deceleration brain injury.

Glasgow Coma Scale A brief head injury observational scale that assesses the general level of consciousness and correlates moderately with severity of injury. This measure involves the evaluation of a patient's best oculomotor, verbal, and motor responses, yielding a severity score from 3 to 15 (3–8, severe; 9–12, moderate; and 13–15, mild).

glucose metabolism The use of glucose (sugars) to create energy for neural activation; directly related to cerebral autoregulation.

postconcussion disorder or postconcussion syndrome A constellation of symptoms including one or more of the following: headache, dizziness, nausea, vomiting, memory, learning and problem-solving impairment, attentional difficulties, problems in abstract reasoning, confusion, fatigue, frustration, depression, sleep disturbance, apathy, diplopia, tinnitus, and slowed thinking, which may persist in some mild head injuries for 6 months postinjury or longer. Postconcussion disorder is the term used in the *Diagnostic and Statistical Manual of Mental Disorders* and postconcussion syndrome is the terminology listed in the *International Classification of Diseases–9-CM*.

posttraumatic amnesia Loss of memory and confusion for events following a head injury.

second impact syndrome An often catastrophic neurological trauma resulting from two mild head injuries in close temporal proximity to each other involving a disconnection of the cerebral blood flow autoregulation system, vascular engorgement, and intracranial pressure, resulting in significant morbidity and/or mortality.

shear strain Stretching and breaking of the axonal fibers due to rotational and deceleration forces in mild head injury. Shearing trauma is usually associated with diffuse axonal injury, but it may also be focal in nature.

Mild head injury is defined as blunt trauma or acceleration–deceleration injury to the head resulting in a Glasgow Coma Scale >12, less than 20 min of unconsciousness or some brief alteration in consciousness, less than 48 hr of hospitalization (no serious extracranial injuries), and no neuroimaging evidence of brain lesion(s). Mild head injury can result in neurocognitive deficits and functional impairments, which may be temporary or persisting. There are considerable ambiguities and uncertainties associated with the study of mild head injury, and this article presents scientific facts and discusses some of the many controversies that

contribute to what has been referred to as "the silent epidemic" and those who suffer from it as the "miserable minority."

I. INTRODUCTION

Mild head injury/concussion has become the single most important disorder in neuropsychological assessment practice in the United States in the past two decades, and it will likely remain a primary focus of clinical and research endeavors for years. Its dominance in neuroscientific study is predicated on several factors: prevalence and costs, morbidity, forensic relevance, societal sensitivity, and its controversial underpinnings.

It is difficult to estimate the prevalence of head injury in the United States each year since statistical analyses must rely on information generated through emergency room records, regional and state traumatic brain injury registries, and Centers for Disease Control data collection. Most of these systems are limited to monitoring moderate to severe disorders that require active medical assessment, intervention, hospitalization, and significant rehabilitation, which are often irrelevant in mild head injury cases. Fifty-five to 75% of all emergency room-reported head traumas are considered mild in nature, and the U.S. Census Bureau estimates the incidence of mild head injury to be approximately 1.3 million per year. This figure must be considered conservative since many mild head injuries occur with little or no loss of consciousness, require no medical treatment, have rapid and complete recovery, and therefore do not come to the attention of the medical/health care community. Traumatic brain injury has long been viewed as a major public health concern. Nevertheless, as a National Institutes of Health consensus development panel suggested, the likely society burden is even greater than previously conceptualized since mild head injury is frequently underdiagnosed. Costs associated with this disorder, when considering assessment, treatment, and lost work, are estimated to be in the billions of dollars each year.

Most studies indicate that the vast majority of individuals experiencing mild head injuries suffer little if any lasting neuropsychological deficits (morbidity), but there is a substantial group of patients who demonstrate deficits in neurocognitive functioning at 1 month postinjury and a small minority with longer lasting sequelae. These latter individuals may be diagnosed with a complicated mild head injury or postconcussion disorder/syndrome. These postconcussion disorder symptoms, even though usually temporary, can be devastating to the socioeconomic, emotional, interpersonal, and occupational functioning of these individuals, who have been termed the "miserable minority."

Although the percentage of patients with mild head injury who experience more severe and longer lasting neurocognitive, medical, and emotional deficits appears to be small, the absolute number of patients in this postconcussion disorder group is likely quite large given the high overall incidence of mild head injury. Since these individuals are the exception to the rules of fast recovery and no permanent impairments, the veracity of their complaints and symptoms are often questioned, which argues for forensic considerations and solutions to personal injury compensation issues. In this context, comprehensive neurocognitive assessments and evaluation of effort and symptom validity are of critical importance. The financial implications for patients, expert medical/neuropsychological witnesses, and attorneys are substantial.

In recent years, society has become more aware and sensitive to the negative consequences of mild head injury through media exposure of celebrities, specifically athletes (particularly in professional football and hockey), who have experienced multiple concussions and whose careers have been threatened. Multiple concussive and subconcussive blows have also been linked to early development of degenerative neurologic conditions such as dementia puglisitca (boxer's encephalopathy), which has also afflicted high-profile athletes and brought sports such as boxing under greater scrutiny by safety commissions.

Finally, mild head injury has been the focus of considerable neuropsychological interest and research based on the many controversies that surround it and obfuscate our complete understanding. Controversial issues include the following:

1. Can we achieve a universally accepted definition?
2. Does mild head injury result in an identifiable neurologic injury/process?
3. What is the natural recovery curve for mild head injury and what roles do individual vulnerability and risk factors play in outcome?
4. What are the best methods for assessing mild head injury and effort/symptom validity in the forensic setting?
5. How can we best assess return to play criteria to avoid catastrophic outcome (second impact syndrome) in sports concussion?

II. DEFINITIONS

The term mild head injury has been linked to other descriptors, disorders, and controversial concepts, such as minor head injury, mild traumatic brain injury, complicated mild head injury, cerebral concussion, postconcussion disorder, posttraumatic stress disorder, somatization disorder, compensation neurosis, the silent epidemic, and the miserable minority. In the early 1980s, investigators at the University of Virginia used the following criteria to define their mild head injury research population: head injury with Glasgow Coma Scale greater than 12, loss of consciousness of less than 20 min, and hospitalization less than 48 hr. This research definition was later expanded to include the absence of neuroimaging evidence of cerebral lesion(s). Variations of this definition with minor modifications have been the mainstay for mild head injury and concussion research ever since.

In 1993, controversy arose when a special-interest group of the American Congress of Rehabilitation Medicine (ACRM) published a definition for mild traumatic brain injury. Although it was similar to the previous research definition of mild head injury, it included factors such as alterations in consciousness or mental state at the time of the accident and posttraumatic amnesia less than 24 hr. Of note, neither the ACRM nor the research definition require loss of consciousness or neuroimaging evidence of impairment. Table I presents the clinical criteria for mild traumatic brain injury. The ACRM definition goes on to state that medical, cognitive, and emotional symptoms of this mild brain injury may persist (the development of postconcussion disorder) and may produce functional disability. The symptoms of postconcussive disorder are presented in Table II.

Table I
Mild Traumatic Brain Injury: Clinical Criteria

Encompasses all aspects of mild head injury research definition and
Infers physiologic impairment and possible histologic damage at least at the time of injury
Requires some altered mental or neurologic state
Slightly more liberal research criteria (LOC < 30 min; PTA < 24 hr)
Symptoms of brain injury may or may not persist (these include physical, cognitive, behavioral, emotional, and psychosocial deficits)
Symptoms can result in temporary or permanent disability
Implies persistent postconcussion disorder
Implies possible complicated mild head injury

Table II
Postconcussion Disorder/Syndrome Symptoms

Headache	Depression/anxiety
Dizziness	Problems in abstract reasoning
Memory impairment	Impaired learning process
Impairment of attention	Confusion of mental state
Slowed mental processing/ reaction time	Disturbance in sleep
Mental and physical fatiguability	Nausea
Lowered frustration tolerance/ irritability	Vomiting
Decreased tolerance for stress and medications	Tinnitus
Apathy/poor motivation	Blurred vision

The most striking aspect of this expanded definition is not its inclusion of potential outcome statements, which is an important consideration and should be part of any clinical definition, but the fact that the general criteria for mild head injury are applied to a new term—mild traumatic brain injury. There is an obvious distinction between "head injury" and "brain injury." The research definition for mild head injury implies some temporary alteration in consciousness at the time of the accident, which also suggests the possibility of some brain impairment but not necessarily persistent functional or neurologic deficits. The ACRM definition, though it is somewhat more specific and directly addresses possible outcomes, is entirely consistent with the research definition of mild head injury. In contrast, it espouses the use of the words brain injury as more accurate terminology since an altered state of consciousness, even if momentary, is required. The use of the term mild traumatic brain injury with this definition has had a secondary, and perhaps profound, effect on society and the medical/neurological sciences, the forensic system, and the patient. Just as Jellnick did in the 1960s when he proposed the disease concept of alcoholism, the ACRM has sensitized the health care community and society to the potential "medical" seriousness of mild head injury and its possible, real underlying neuropathology. Its focus on brain injury has thus established and promoted the disease concept of mild head injury. In addition, the term brain injury to the layperson, or perhaps a jury in a personal injury case, can have an emotionally laden meaning. This meaning may include the perception that there is either a permanent lesion or functional disability, when this may or may not be the case with an appropriately

defined mild traumatic brain injury. Although no studies have directly focused on this issue, it stands to reason that patients and families may well have different reactions to being told that they have suffered a mild head injury versus a mild traumatic brain injury. This again speaks to the issue of emotionally laden terms, societal labels, and a sense of permanence and perhaps hopelessness. There is no consensus regarding the appropriate use of these terms; therefore, mild head injury and mild traumatic brain injury are often used interchangeably. Most researchers and clinicians agree, however, that these two definitions address the most important mild head injury classification criteria, even though they do not offer suggested guidelines for assessing the vague lower limits of mild head injury.

Ronald Ruff and Paul Jurica suggested a unified definition of mild traumatic brain injury that incorporates the classic research and ACRM criteria *Diagnostic and Statistical Manual of Mental Disorders (4th ed.)* as well as the suggested criteria for mild traumatic brain injury. Under their definition of postconcussion disorder, three categories of mild traumatic brain injury were created to address issues of loss of consciousness, posttraumatic amnesia, and neurological symptoms. A type I traumatic brain injury refers to individuals experiencing an altered or transient loss of consciousness, 1–60 sec of posttraumatic amnesia, and one or more neurological symptoms. A type II injury requires a definite loss of consciousness of less than 5 min or unknown duration, 1 min to 12 hr of posttraumatic amnesia, and one or more neurological symptoms. A type III injury includes loss of consciousness of 5–30 min, posttraumatic amnesia that persists more than 12 hr, and one or more neurological symptoms. This definition is broad and allows subclassification that highlights the fact that mild traumatic brain injury is multifactorial and reflects a spectrum from very mild and perhaps simple to more severe and complex.

III. HISTORY AND NEUROPSYCHOLOGICAL FINDINGS

As early as 1962, neuroscientists voiced concerns regarding the possibility of permanent effects from mild concussions, and later during that decade at least one investigator found microscopic lesions on autopsies of patients with histories of mild head injuries. These positions were reinforced in the 1970s and early 1980s by research in New Zealand and at the University of Virginia. These investigations documented neurocognitive deficits in attention, memory, new problem solving, mental flexibility, and cognitive processing speed and delayed return to work in previously employed mild head-injured patients 3 months posttrauma. These findings were in stark contrast to the prevailing medical view at the time, which suggested that mild head injury involved no neurological or cognitive morbidity and that anyone who did not make a rapid, complete recovery and return to work was likely suffering from a psychiatric/personality disturbance such as depression or hysteria.

In light of clinical research findings of neurocognitive morbidity in this population, animal studies were initiated to study neuropathological changes in primates subjected to linear acceleration–deceleration mild head injuries, similar in nature to some of the forces in motor vehicle accidents. Results revealed shear-strain trauma characterized by stretching and breaking of axonal fibers due to deceleration forces on the brain, which was particularly evident in the brain stem and the focus of the mechanical stress in these studies. These histological lesions were not apparent on gross nonmicroscopic inspection.

Although these groundbreaking human neurocognitive and animal studies alerted the medical community to the possibility of identifiable microscopic lesions and significant neurocognitive morbidity in some of the mild head injury population, the experimental designs utilized did not account for confounding factors. They also did not address issues related to differences in primate and human anatomy and physiology. In the mid-1980s and early 1990s, studies in Texas, New York, California, and Washington attempted to control some of these confounding factors, such as previous head injury, substance abuse, and litigation, by selecting participants with no history of these aforementioned risk factors. This sample of patients with uncomplicated mild head injury demonstrated neurocognitive deficits 1 month postinjury in comparison to controls, with good recovery for almost all this population after 3 months.

During this same time period, a unique approach to the study of the effects of mild head injury, preinjury neurocognitive baseline status, and extent and speed of recovery was pioneered at the University of Virginia with the development of the Sports as a Laboratory Assessment Model (SLAM). This methodology involved the study of mild head injury through a highly controlled sports "laboratory" that examined acceleration–deceleration injuries. In this investigation, more than 2300 football players at 10 universities were assessed before the football season using brief

neurocognitive tests, with the same test battery administered again postseason. Players who sustained a mild concussion, as well as a matched control student athlete, were assessed again at 24 hr, 5 days, and 10 days postinjury, in addition to postseason assessments. Statistically significant differences in neurocognitive performance were noted between the scores of concussed players and the scores of controls at 24 hr and 5 days postinjury. By 10 days postinjury, however, concussed players had made sufficient recovery to take advantage of the practice effect and closely approximated the performance of their matched control. This important research demonstrated that the recovery curve was swift in young, healthy, motivated athletes, who demonstrated very few confounding psychosocial or medical factors.

The 1990s saw many scientific studies that borrowed from all these research models. Although some results showed persistent neurocognitive and neuroimaging deficits in patients with postconcussion disorder or complicated mild head injury, other findings suggested little difference between control subjects and patients with mild head injuries at 3 months postinjury. The question remains: Does anyone really suffer in mild head injury? Although the answer may seem obvious, most investigators agree that (i) the vast majority of mild head injury patients make rapid and full recoveries; (ii) some mild head injuries can result in significant neurocognitive deficits that may persist; and (iii) outcomes are likely related to pathophysiological issues, individual risk factors or vulnerability, and recovery curves.

IV. SPORTS CONCUSSION

Perhaps the best empirical evaluation of the functional impact of mild head injury, typically referred to in the sports arena as concussion, comes from the application of the aforementioned SLAM methodology. Because the neurocognitive sequelae of concussion are often subtle and therefore difficult to detect, it is advantageous to have baseline assessments of premorbid functioning against which to compare concussed individuals. Sports involving high risk for acceleration–deceleration injury, such as football and soccer, serve as a natural laboratory in which one can obtain baseline measures of neurocognitive abilities of each athlete for later use that may be compared to his or her postconcussion functioning.

Review of the professional and amateur sports literature indicates that the incidence of mild head injury can be as high as 91% but generally ranges between 2 and 20%. Incidence varies from sport to sport, with the following rates: equestrian, 3–91%; boxing, 1–70%; rugby, 2–25%; soccer, 4–22%; and American football, 2–20%. Frequency of sports-related mild head injury extends to children and adolescents, with potential for greater morbidity in this younger population.

American football has received considerable attention due to the number of high-profile athletes sustaining concussions. Although the concussed football players in the University of Virginia study demonstrated little decline from their preseason baseline data, they failed to take advantage of the practice effects 24 hr postinjury. Many injured players achieved the same learning curve as uninjured controls by the fifth day and there were no statistical differences in performance 10 days after injury. Of note, head-injured players reported neurological symptoms, including headaches, dizziness, and memory problems, that also generally resolved by the 10th day. Other research has found that head-injured athletes performed below their baseline level on most neuropsychological tests, with the greatest decline in verbal fluency and information processing speed.

Soccer has gained increased notoriety as a source of concussion with increased popularity in the United States. Although publicity has focused on the negative effects of heading the ball, concussion most frequently results from impact collisions, such as head-to-head or head-to-goalpost contact. Some research has indicated that soccer players reported a higher frequency of head injury than boxers, with the vast majority endorsing persisting subjective deficits in memory and concentration. Other studies of active and retired soccer players revealed mild electroencephalogram abnormalities, age-inappropriate cerebral atrophy on computed tomography (CT) scans, and more than twice the rate of demonstrated neurocognitive deficits compared to age-matched controls. Given that professional soccer players average 5250 headings during their careers, recent studies have focused on the impact of heading a 12- to 14-ounce ball traveling as fast as 120 km/hr. A prominent study of Dutch professional soccer players found neuropsychological deficits in memory, planning, and visuoperceptual tasks relative to a control group of elite athletes from noncontact sports, with more severe deficits associated with increased frequency of both concussions and headings. Decreased neuropsychological functioning, such as impaired attention, concentration, mental flexibility, and general intellectual ability, was also documented

in high school, college, and professional soccer players, and it correlated with both frequency of ball heading and years of play.

SLAM not only provides a vehicle for research but also potentially yields the best protection of athletes. Optimally, a brief, 20- to 30-min preseason neuropsychological assessment provides a measure of each player's baseline abilities, including processing speed, attention/concentration, and memory. Since athletes would then serve as their own controls, neuropsychological assessment can provide a sensitive tool in identifying concussion-related impairments, even in the absence of radiographic or neurologic findings.

The danger in overlooking or minimizing a concussion is that an initial injury creates a vulnerability that can have devastating consequences if even a very mild

Table III
Virginia Concussion Guidelines[a]

Grade 1—very mild	Grade 2—mild	Grade 3—moderate	Grade 4—severe
Severity of concussion (one or more of the following symptoms in bold are essential to determine category)[b]			
"Bell ringing"—stunned, temporarily dazed/clouded	Clouded consciousness for short time	LOC less than 1 min, clouded consciousness for longer time	LOC more than 1 min. clouded consciousness for longer time
No LOC	**No LOC**	**LOC <1 min**	**LOC >1 min**
Confusion <1 min	**Confusion 1–5 min**	**Confusion 5–15 min**	**Confusion >15 min**
No neuro symptoms	**Neuro symptoms <5 min**	**Neuro symptoms 5–15 min**	**Neuro symptoms >15 min**
Acute headache	Acute headache	Persisting headache	Persisting headache

		Day of injury management	
Return to play if no symptoms after 15 min with exertion; continue close monitoring	Return to play if no symptoms after 30 min with exertion; continue close monitoring	No return to play; monitor by team physician/ATC; refer to ER/neurosurgeon for consultation if symptoms persist past game/practice	No return to play; refer to ER/neurosurgeon
		Follow-up criteria for return to play/practice	
Monitor for recurrence of symptoms with exertion. Hold from play until symptom free with exertion. Athlete takes CRI[c]—look for green light for possible return to play. Notify team physician/ATC/neuro surgeon/ neuropsychologist if symptoms develop or persist.	Monitor for recurrence of symptoms with exertion. Hold from play until symptom free with exertion. Athlete takes CRI—look for green light for possible return to play. Notify team physician/ATC/neurosurgeon/ neuropsychologist if symptoms develop or persist.	Minimum 1 week out. No contact for minimum 1 week. Must be symptom free with exertion for 1 week before considering return to play. Athlete takes CRI—look for green light for possible return to play. Consult with team physician/ATC/ neuro-surgeon/ neuropsychologist.	Minimum 3 weeks out. No contact or exertion for minimum of 1 week. Must then be symptom free for 2 weeks with exertion (no contact) and be re-evaluated at least once a week by team physician/neurosurgeon. Athlete takes CRI each week—look for green light for return to play. Consult with team physician/ ATC/neurosurgeon/ neuropsychologist.

[a]Repeated concussions with persisting postconcussion symptoms merit evaluation by neurosurgeon/neuropsychologist and consultation with ATC, physician, family, and athlete to consider ending a season. Confusion does not equate with post injury amnesia, which is defined as an inability to lay down new memories after a traumatic event. Therefore, amnesia does not mean the inability to recall the event, which is quite common. This table is intended to serve as a conservative guideline for the protection of athletes. It should enhance, but not replace, the clinical judgment of trained personnel on the field. Modifications to these guidelines may be made with appropriate consultation among the aforementioned professionals and consensus to adjust guidelines for individual circumstances.

[b]The items in bold are the essential features that are used to grade a concussion. The nonbold items are nonessential symptoms and typically accompanying features. Therefore, headache is not used to make the diagnosis in and of itself. The key symptoms are LOC, confusion, and neurological symptoms.

[c]CRI, Concussion Resolution Index (Head Minder, Inc.)—a web-based neurocognitive screening of sustained attention, processing speed, spatial memory, reaction time, and two-step problem solving.

second injury occurs in close temporal proximity. This traumatic sequence of events is called second impact syndrome (SIS). When an athlete returns to play prior to full recovery after a first mild concussion and sustains a second very mild impact to the head, a devastating process, though rare, may develop even though the athlete initially remains alert, successfully finishes the play, and walks off the field. The athlete may soon collapse, become semicomatose, and develop loss of eye movement, rapidly dilating pupils, and respiratory failure. This appears to result from disrupted autoregulation of cerebral blood flow (CBF), leading to vascular engorgement and increased intracranial pressure, followed by compression of the brain stem and possible death. Prevention of SIS is crucial, despite its relatively low prevalence rate, since it has an approximately 50% mortality rate and a morbidity rate near 100%. According to neurosurgeon Robert Cantu and the American Academy of Neurology, athletes must not be allowed to return to play or practice in contact or collision sports while still experiencing any symptoms of concussion and ideally not until at least 1 week after resolution of symptoms.

In order to allow sufficient recovery time following concussion, return–to–play criteria have been developed and implemented to specify the amount of time that a concussed athlete should be withheld from play. The most widely used criteria are those developed by Robert Cantu and the American Academy of Neurology, but a total of 18 such guidelines exist. Although these guidelines are generally formulated through professional consensus, there is little empirical basis for the decisions regarding length of time that head-injured athletes are withheld from play. In an attempt to develop criteria that combine elements of many conservative guidelines, the University of Virginia has created suggested return-to-play criteria and on-field management recommendations for use by certified athletic trainers and other sports medicine professionals on the sideline. These concussion management guidelines are presented in Table III.

The study of risk factors associated with mild traumatic brain injury via the sports arena has also focused on the investigation of the influence of genetics on boxers. Because boxers suffer repeated head injuries of varying severity, which is the primary objective of the sport, cumulative and delayed effects have been documented, including dementia pugilistica and Parkinson's-like syndromes. Additionally, recent investigations have suggested that the different expressions of the apolipoprotein (APOE) allele differentially affect the risk for morbidity in boxers who have sustained repeated concussions. Although the APOE 2 allele may serve as a protective factor, reducing the incidence of poor neurocognitive outcomes following repeated head injury, having the APOE 4 allele appears to increase the risk for developing neuropsychological deficits and degenerative neurologic conditions.

V. PATHOPHYSIOLOGY

Much of our understanding of the pathophysiology of mild traumatic brain injury (TBI) stems from animal research, which has demonstrated that physiological and metabolic disruption occurs with cerebral concussion and the previously mentioned shear strain. Although knowledge of the neurobiology of concussion is in its infancy, animal models have proven useful in delineating trauma-induced ionic flux, metabolic changes, and disruptions to CBF. Head trauma sufficient to cause concussion triggers changes in intracellular concentration of several ions, including increased potassium and calcium and decreased magnesium, also known as ionic flux. Ionic flux is thought to activate glycolysis (glucose metabolism), which reflects increased energy demands for cell membrane pumps to restore cellular ionic homeostasis. This increased glycolysis has been observed in studies of fluid percussed animals within minutes of injury, with disruption of several metabolic pathways lasting up to 10 days in mature rodent brains. Regions of the brain most prominently affected include the region of the cerebral cortex that is ipsilateral to the injury site and the hippocampus. The pathophysiology and metabolic changes associated with mild TBI are outlined in Table IV.

Ionic flux and metabolic disruption can be conceptualized as an increased "demand" for energy to restore the homeostatic functions of neuronal cells, which places these cells in a vulnerable state. Demand, however, is only part of the issue. Across animal studies of experimental TBI, CBF is reduced by as much as 50% of normal. Therefore, supply of glucose and other cellular energy nutrients required for the restoration of homeostasis can be drastically compromised even in mild head injury. This imbalance of supply and demand is referred to as "uncoupling" and reflects a disruption of the autoregulation of CBF. During changes in cerebral perfusion pressure, cerebral autoregulation serves to maintain constant CBF. Autoregulation in the normal (uninjured) brain is

Table IV
Pathophysiology of Mild Traumatic Brain Injury

Concussion-induced ionic flux		
Potassium (K^+)	**Calcium (Ca^{2+})**	**Magnesium (Mg)**
Massive increase in extracellular K^+ concentration	Massive increase in intracellular Ca^{2+} concentration	Marked decrease in intracellular Mg
Caused by sudden intense neuronal discharges	Ca^{2+} plays role in secondary cell death, which alters metabolism	Mg is important to glycolysis and oxidative phosphorylation
Extracellular K^+ surpasses physiological ceiling causing rapid release of neurotransmitters and additional K^+ fluxes		Reduced Mg may have implications for cerebral metabolic recovery
Acute metabolic changes following concussion		
Glucose metabolism (GM)	Oxidative metabolism	Lactate accumulation
Increased GM	Oxygen utilization is increased in first few minutes following trauma injury	Increased glycolysis after TBI produces decline in high-energy phosphates, which may stimulate anaerobic glycolysis
Hypothesis is that acute increase in glucose utilization following experimental TBI is due to the massive release of extracellular K^+	Likely due to disruption of mitochondrial functions	Results in accumulation of lactate and development of intracellular acidosis
Chronic metabolic changes following concussion		
Long-term effects on glucose metabolism	Long-term effects on oxidative metabolism	
Beginning 6 hr after diffuse brain injury, many brain regions enter state of hypometabolism lasting up to 10 days	Preliminary studies suggest that following concussion, TBI, or cortical ablation, oxidative metabolism is reduced for at least several days, especially within cerebral cortex and hippocampus	
Neurobehavioral deficits accompany this period of metabolic depression (diaschisis)		
Secondary cell death usually does not occur, but it may produce a level of ionic flux and metabolic derangement		
Although sublethal, this may disrupt cellular processes for several days, rendering them vulnerable to secondary insult		

responsible for maintaining the balance of cellular metabolic demands and supply of these needs via blood flow regulation. Although the mechanisms by which disrupted autoregulation occurs are not fully understood, proposed factors include vasospasm, decreased or depleted nitric oxide or nitric oxide synthetase activity, and/or the massive release of vasoconstrictive agents such as neuropeptide Y and endothelins.

Animal research has consistently demonstrated changes in CBF, metabolic function, and ionic flux immediately following experimental TBI. Although this bench research provides a process for understanding the basic pathophysiology in concussion, this process may not generalize to humans and is insufficient in terms of documenting cognitive changes associated with these injuries. Therefore, the need to move from animal models to a more specific analysis of

effects of TBI in humans is clear. Animal models do provide evidence of "windows" of change and opportunity. These changes, however, are doubleedged, indicating both a vulnerability to secondary insult and a critical period during which potential physiology-specific interventions could be effectively utilized. This will be discussed in the following review of the physiology of concussion in humans.

Impaired cerebral autoregulation following mild TBI has been observed in humans. In addition, humans also demonstrate increased glucose metabolism after TBI coupled with reduced CBF, which may represent the insufficient supply of needed energy to restore ionic homeostasis in humans. Researchers at UCLA have speculated that the duration of reduced CBF after head injury is likely to be the primary predictive factor in outcome. Additionally, the endothelial accumulation of calcium appears to have the detrimental effect of inducing vasoconstriction and limiting CBF and necessary nutrients for restoring homeostasis. Observed alterations in CBF in patients with mild TBI are an exciting new frontier for the study of mild brain injury. Frequently, these patients do not experience loss of consciousness, significant retrograde or posttraumatic amnesia, or evidence of pathology on standard neuroimaging (e.g., magnetic resonance imaging or CT), and these factors have generally been poor predictors of functional outcome. A review of the neurovascular and neurochemical effects of mild head injury in humans is warranted because such an endeavor may yield more sensitive, accurate predictors of outcome.

By examining "minor cerebral contusion" using a noninvasive technique known as Xenon inhalation, investigators have found that mild head-injured patients demonstrate significantly reduced CBF relative to controls within 10 days after insult. A significant number of these patients can demonstrate persistent CBF declines for 2 weeks, with recovery to control CBF levels appearing to take place within 4 weeks. Interestingly, those patients who show lateralized hypointensities on CT demonstrate CBF deficiencies in the ipsilateral cerebral hemisphere. Although this research is still in its infancy, patients' return to normal CBF is correlated with improvements on gross measures of cognitive functioning.

Fluorodeoxyglucose positron emission tomography has been used as a noninvasive measure of neurometabolic function in severely head-injured patients, and investigators have found regional and global hyperglycolysis. Although the pathogenesis of increased glucose metabolism is unclear, it is postulated that contributing factors include high concentrations of extracellular potassium (ionic disequilibrium), fluctuating levels of extracellular excitatory amino acids, and localized seizure activity. Of note is the fact that observed metabolic changes persist up to 2 weeks following trauma; however, using the aforementioned Xenon inhalation technique, CBF levels were not so low as to be ischemic. This human research documents metabolic destabilization (specifically heightened glucose metabolism) observed in animal models of mechanical injury. Investigators hypothesize that since animal models utilize a mechanical injury that induces a concussed state involving brief (seconds) loss of consciousness and slow recovery, this is equivalent to mild/moderate head injury in humans. Therefore, if the animal model were extended to human pathophysiology, then cerebral concussion would result in at least a brief period of hyperglycolysis concurrent with diminished supply of glucose through reduced CBF.

Recent technological advances have permitted more accurate but still noninvasive measurement of CBF in mild head injury. Using transcranial Doppler ultrasonography, investigators have compared CBF and mean arterial blood pressure in mild head-injured patients (Glasgow Coma Scale scores between 13 and 15) within 48 hr of injury with matched controls. Although head-injured patients and healthy controls demonstrate equivalent mean arterial blood pressure at rest, head-injured patients show reduced autoregulation in response to induced rapid and brief changes in arterial blood pressure. Because this reduces cerebral perfusion pressure as well as decreases CBF, it can potentially lead to ischemia. Additionally, sudden increases in mean arterial blood pressure may also contribute to secondary hemorrhage and/or edema in the head-injured patient.

In summary, disrupted autoregulation of the vascular supply creates vulnerability from two related states: reduced supply of nutrients (energy) and increased demand for those nutrients. This leaves the head-injured victim at great risk for life-threatening consequences should a second such injury ensue. Accurate assessment of the length of metabolic disruption in humans is critical because animal models likely underestimate the period of cerebral vulnerability. Unstable autoregulation in even mild TBI also has implications for decisions regarding surgery for peripheral injuries. Because blood pressure changes are common during surgical procedures, the risk for ischemia increases dramatically in patients with disrupted autoregulation and reduced cerebral perfusion pressure.

Although some consider the young brain more resilient than the mature brain, this is the subject of continued debate with regard to TBI, particularly given the occurrence of SIS. There is increasing support for a "critical period" related to cerebral maturation that affects recovery and vulnerability. Animal models yield a controlled physiological environment for studying the neurochemical and neurophysiological effects of shear strain or axonal injuries across the life span. Investigation at UCLA of fluid percussion brain injury in 17-day-old, 28-day-old, and adult rodents demonstrated increased intracranial pressure after injury in all animals, but the mortality rate for the younger rodents was greater than that for the mature ones. In the severe injury category, all immature rodents died compared to 55% of the adults. Younger animals even showed an increased duration of postinjury apnea relative to older animals at the mild injury level despite the lack of histopathological differences. These investigators postulated that physiological differences, including brain water content and skull dimensions, might account for the increased morbidity in younger rodents. Additionally, a decrease in cerebral perfusion pressure, which is essential for meeting the energy demands of the postinjury brain and restoring metabolic homeostasis, may result in vasodilation and hence increased intracranial pressure. In any case, it appears that the animal literature, at this early stage of investigation, supports the view that the immature brain is more vulnerable to injury and requires a longer time frame for physiological recovery than the mature brain.

An additional issue in the area of physiological risk and protective factors is the effect of hormones. Animal research investigating gender as a factor in TBI outcome found that estrogen has differential effects in rats undergoing experimental brain injury. It provided protective effects for males and exacerbated the injury of females. Female rats have also been noted to have higher mortality rates following fluid percussion injury. Under conditions of hyponatremia, depressed oxygen use and CBF were observed in female rodents. These animal studies suggest a pathophysiological basis for the reported poorer outcome for females following TBI.

VI. RECOVERY CURVES AND TREATMENT

The natural recovery curve for moderate to severe head injury is 18–24 months, with further restitution of function occurring at a slow rate for years after. Most investigators agree that the majority of mild head injury patients recover in less than 3 months, and only a small percentage of these patients suffer from persistent postconcussion disorder symptoms. Therefore, what are the risk factors for slow recovery and poor long-term outcome?

The first and most obvious risk factor for poor recovery is greater severity of injury and related neurological/physiological dysfunction. A complicated mild head injury defined by positive neuroimaging findings or a high probability of axonal shear strain injury (based on documented loss of consciousness, posttraumatic amnesia, and/or retrograde amnesia) places a patient in a high-risk category for slow and poor recovery. Other factors, such as pain (e.g., headache and back and neck trauma), depression, stress, sleep disturbance, poor premorbid health, and cognitive abilities, previous head injuries, psychiatric disorders, substance abuse, advanced age, poor social support systems, inadequate information about mild head injury recovery, and pending litigation, can all contribute to a patient's individual vulnerability to and risk for poor outcome. Given the complexity of these factors, and the previously mentioned neurocognitive deficits that may accompany these injuries, a comprehensive and interdisciplinary approach to assessment is clearly warranted in some cases. Neuropsychologists, neurologists, neurosurgeons, neuropsychiatrists, physiatrists, neuroradiologists, speech and language therapists, pain and sleep management specialists, and others may be called on to evaluate the mild head injury patient with incomplete recovery.

The most effective treatment approach to most mild head injuries focuses on enhancing the natural recovery curve. Unlike more severe brain injury, significant medical intervention, cognitive rehabilitation, and physical therapy are rarely indicated. Interventions that focus on the previously mentioned individual risk factors will allow the individual to take advantage of natural recovery. Specific suggestions include increasing rest and reducing stress levels, reducing or eliminating alcohol consumption, treating depression with supportive psychotherapy and medications where warranted, assessing and treating pain and sleep disturbance, and educating the patient, family, and significant others regarding the typical mild head injury symptoms and natural recovery course. Early in the intervention process, it is important for everyone involved to have appropriate reassurances and positive expectations but an appreciation for the possible development of symptoms and an understanding that although recovery is usually swift and complete, in

fact, full recovery can take weeks or months in some cases. Realistic but positive expectations can be critical for good outcome, particularly if they reduce stress and allow sufficient time for healing. Recently, researchers have begun to examine the use of pharmacological agents (e.g., psychostimulants) in the management of mild head injury. Further investigations are necessary to conclusively determine the impact of these agents on the recovery curve.

VII. CONTROVERSIES AND FUTURE DIRECTIONS

For two decades, mild head injury has been the focus of intense neuropsychological study, and significant progress has been made in our understanding of this not so silent epidemic. On the other hand, continuing controversies fire our interest in this growing area of intense medical and forensic concern. Although we have validated animal models that help to elucidate the mechanism and pathophysiology of some mild head injuries, we are still uncertain as to the prevalence and extent of real neurological (histological) impairment, the persistence of functional deficits, and possible disability. Typical recovery curves for the majority of these mild head injury patients are generally well-known; however, the risk factors (individual vulnerability) that contribute to poor recovery have not been subjected to sufficient scrutiny to enable researchers to be certain about their relative or absolute effects on outcome. In the forensic arena, we continue to face questions about the presence of underlying neuropathology, the best way to measure premorbid functioning to accurately assess the extent of neurocognitive compromise, and the relationship of compromised function to the trauma. Furthermore, we must continue to examine the veracity of subjective complaints by considering base rates for symptoms in the normal population and resolving questions regarding test-taking effort, symptom validity and exaggeration, and malingering-like behavior.

New neuroimaging techniques are evolving that enhance our capacity to identify lesions, and interfacing these techniques with physiological assessment (e.g., glucose supply and demand) and neuropsychological evaluation will certainly contribute to a better understanding of the mild head injury phenomenon. Use of formulas to estimate premorbid intellectual functioning and interviews with significant others and employers/teachers can help to establish pretrauma cognitive and functional abilities. Tests of symptom validity and effort have been developed; although controversial, they can provide important data in a comprehensive neuropsychological assessment model. Finally, in the sports arena, although return-to-play guidelines have been developed to protect athletes against possible SIS, these criteria remain controversial since they lack a sufficient empirical basis. Even with limited controlled studies, however, experts in the field have established conservative guidelines, based on medical/neuropsychological experience, for measuring severity of concussion and reduced-risk return to play.

The complexity of mild head injury issues and our lack of clear scientific data and knowledge have created discomfort in the scientific/clinical community. When faced with this complexity, there is a tendency to become reductionistic in order to limit uncertainty and increase comfort. This reductionism may lead to simple, and perhaps inaccurate, understandings and extreme positions (i.e., all mild head-injured patients are either malingerers or neurologically devastated). These simple extremes can breed scientism (extreme scientific skepticism) or charlatanism with regard to views on the previously mentioned issues in mild head injury.

One of the solutions to these problems is to develop a level of comfort with the ambiguity and lack of knowledge that we have concerning mild head injury. Recognition of the complexity of these issues will allow us to embrace this as a challenge to our clinical and scientific skills. Finally, it will be important for us to confront these controversies in our scientific inquiries and to share our concerns about issues with our patients, colleagues, and the forensic system.

University of Pennsylvania

GLOSSARY

traumatic brain injury Any disturbance of the cellular integrity and/or homeostasis of the brain tissue or brain cells due to mechanical forces leading to reversible or irreversible cellular dysfunction or cell death in the brain.

An estimated 2 million cases of traumatic brain injury (TBI) occur in the United States every year, with around 500,000 sufficiently serious to require hospitalization. Additionally, a large number of cases of mild TBI remain unreported or undiagnosed each year. Therefore, TBI, with its estimated incidence of 100 per 100,000 persons, occurs more often than many of the better known diseases affecting the central nervous system tissue (e.g., Parkinson's disease, Alzheimer's disease, multiple sclerosis). Epidemiologically, TBI is most often associated with motor vehicle, bicycle, or pedestrian–vehicle accidents followed by falls and violence- and sports-related incidents, occuring primarily in people 15–24 years of age. Estimates for the lifetime cost of care for a severely injured person range from $600,000 to $1,875,000 and add up to a yearly cost of $9–10 billion for rehabilitation for new cases in the Unites States alone. Although the development of neurochemical, histopathological, and molecular techniques to study human TBI has enabled researchers to begin to elucidate the pathologic sequelae following TBI, no neuroprotective therapy is currently available and TBI remains one of the leading causes of disability and death of young adults in industrialized countries.

I. INTRODUCTION

Human head injury involves different forms of focal and diffuse injury to the brain, and the great majority of patients display more than one abnormality upon neuropathological investigation. Focal injury is characterized pathologically by the presence of contusions and lacerations, often accompanied by hematoma. In contrast, the term diffuse injury is most often used for the finding of diffuse axonal injury (DAI) observed in the direct vicinity and also remote from the injury site. Classification becomes even more complex because TBI is often classified according to different grades of injury severity, and the pathologic sequelae after TBI can be separated into primary and secondary (delayed) injury. The term primary injury encompasses the immediate damage to the central nervous system (CNS) that occurs at the moment of impact. This damage to the brain cells and tissues is nonreversible and, therefore, not curable. In contrast, secondary or delayed injury is initiated at the moment of the traumatic insult and progresses for days or months. This secondary injury to the CNS is a complex and poorly understood network of interacting cellular, structural, functional, and molecular changes, including breakdown of the blood–brain barrier, formation

of edema, impairment of energy metabolism, changes in cerebral perfusion and intracranial pressure, ionic dyshomeostasis, activation and/or release of autodestructive neurochemicals and enzymes, inflammation, and pathologic–protective genomic changes. Alone or in combination these events may lead to delayed cell death, but because many are potentially reversible a chance exists for therapeutic intervention to attenuate cellular damage directed at improving functional recovery during rehabilitation and in the chronic phase of the injury.

Experimental models of TBI have been designed to mimic closely the clinical sequelae of human TBI and play a crucial role in the process of evaluating and understanding the physiological, behavioral, and histopathologic changes associated with TBI. Because human TBI is very much a heterogeneous disease, no single animal model of TBI can mimic the whole spectrum of clinical TBI. Rather, the concurrent use of a number of distinct yet complementary models is necessary to reliably reproduce the whole range of injury severity and characteristic features observed upon clinical and post mortem examination of TBI patients. Experimental models have contributed to our insight into the posttraumatic sequelae and have prompted the development of several novel diagnostic and treatment strategies that are now either part of standard clinical practice or under intense preclinical and clinical investigation.

This article attempts to provide a broad overview of the most widely used and popular experimental models of mechanically induced TBI in whole animals. Because rodents are the species of choice in the vast majority of studies due to their obvious advantages (small size, modest cost, extensive normative data available), this article will mainly focus on results obtained in studies with rodents, except where such data are not available. Moreover, this description will not extensively review the existing literature concerning nonmechanical models to produce brain damage (thermal, chemical, or electrical), *in vitro* models, or inanimate finite element computational model characterizations.

II. IMPORTANT VARIABLES IN MODELING TRAUMATIC BRAIN INJURY

Despite differing objectives, any model designed to reliably produce experimental TBI should fulfill a number of criteria. The injury severity and the exact injury location must be defined, and the injury response must be quantifiable and reproducible not only in the same laboratory but also between different investigators. Additionally, the damage caused from the traumatic event should be part of a continuum, increasing with increasing mechanical forces applied to the head or brain. The most widely used models in the majority of studies employ standardized surgical protocols and techniques, including sham (uninjured) animals with identical surgical treatment to control for systemic variables. This experimental design controls for the possible influence of the operative procedure, anesthesia, changes in body or brain temperature, brain damage due to head restraint or the placement of intracranial probes, etc. on the posttraumatic sequelae. Additionally, the majority of the trauma devices employ computer-based measurements of the applied load, such as pressure gradients, the velocity of the impactor, or the speed of acceleration–deceleration forces to measure variations in the mechanical parameters that define inflicted injury severity. This information is used to make adjustments to the device and allows for the maintenance of a narrow range of inflicted injury severity within a particular study.

A. Injury Severity

The most commonly used clinical classification for human head injury is based on the Glasgow Coma Scale, which allows clinicians to divide admitted patients into three major categories of mild (score higher than 13), moderate (score between 9 and 12), and severe TBI (score below 9). Studies conducted to define and characterize outcomes in each of these three categories that can be used to predict spontaneous outcome and response to therapeutic intervention have proven its reliability and usefulness. To closely mimic the range of TBI severity in the clinical situation, experimental studies have modified the existing injury models to be capable of producing brain trauma over a spectrum of severity. This goal is accomplished by adjusting the main mechanical parameters of the injury device (e.g., height or mass of the free-falling weight, depth of the traumatic impact or impact velocity, height of the pressure impulse by adjusting the pendulum of the fluid-percussion device, or changes in the plane or velocity of the rotational forces). Although a scoring method for injury severity comparable to the Glasgow Coma Scale has been developed for the cat, it has yet to be defined for the

rodent. However, a number of experimental studies performed have exposed a close relationship between injury severity and the animals' posttraumatic responses and rates of recovery. As a result, a classification for the severity of experimental TBI has been developed and established that is similar to the clinical categories of mild, moderate, and severe.

B. Types of Injury

Human head injury is not a single pathophysiological entity, and the majority of patients suffering from TBI display more than one lesion upon careful diagnostic evaluation. Because the clinical situation is seldom as controlled as the experimental setting, different injury models are employed to elucidate the main characteristics of TBI, which include focal and diffuse damage. Focal abnormalities involve contusions and lacerations not always accompanied by skull fracture or hematoma formation. This type of damage occurs in the direct vicinity of the site of mechanical impact to the head and typically involves the underlying cortical and, in the case of injuries of higher severity, subcortical structures. Several experimental models have been established that mimic these aspects of focal TBI over a wide range of injury severity (weight-drop closed head injury, fluid-percussion brain injury, and rigid indentation injury). However, all models are associated with concussive events, and, if the injury severity exceeds a certain threshold, substantial displacement of the brain occurs, which adds a new, more remote component of axonal injury to the predominantly focal damage (Fig. 1). Diffuse injuries may include concussions and diffuse axonal pathology. This type of injury is sometimes more difficult to detect in the clinical setting but appears to occur more commonly than previously believed and is presumably present in the whole range from mild to severe head injury. Diffuse brain injuries are thought to occur primarily from the tissue distortion, or shear, caused by inertial forces that are present at the moment of injury. Experimental models that predominantly mimic this type of damage (e.g., models of inertial acceleration and, to a lesser extent, impact acceleration) lead to substantial diffuse injury in the absence of profound focal damage. These changes are usually observed peripheral to the vicinity of the impact and also remote to the injury site (Fig. 1).

C. Determining Injury-Induced Changes and Outcome

A number of scales have been created to evaluate spontaneous and therapeutically modified

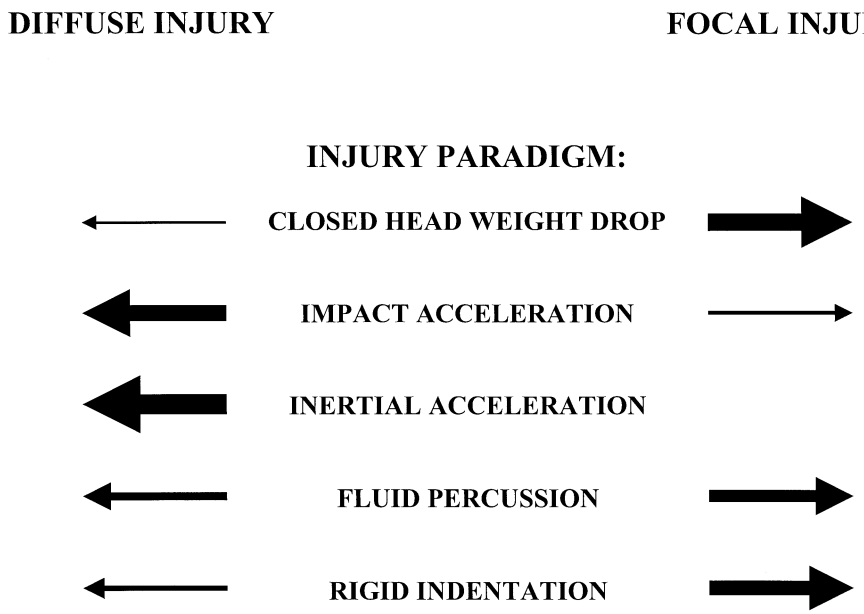

Figure 1 Injury characteristics of different experimental models to produce TBI. Each model produces a distinct pattern of focal and/or diffuse brain injury.

posttraumatic recovery, characterize permanent deficits, or estimate life quality in the chronic phase after clinical TBI. Although a satisfactory system to determine outcome of head-injured patients has yet to be described, the Glasgow Outcome Scale, which divides patients into five subgroups according to their level of recovery or persisting impairment, seems to be the most popular and widely accepted scoring method at present. Thorough evaluation of patients has made it unequivocally clear that behavioral impairments, particularly with respect to neurologic motor function and cognitive deficits, comprise the most persistent deficits after TBI, lasting for months and even years. Additionally, a number of radiological and histological studies have revealed that morphological damage to the brain tissue represents another very consistent feature of human TBI that remains unresolved and persists over time. In contrast, a broad variety of different posttraumatic events occur in the immediate and acute phase after TBI (e.g., changes in electrophysiology, blood–brain barrier dysfunction, edema formation, changes in cerebral perfusion and intracranial pressure, activation of ion channels and ion shift, genomic changes, production of free radicals, inflammation, etc.). Some of these changes are transient, but the duration of others has yet to be determined. To follow and describe injury-induced changes in the experimental setting, research tools have been developed to determine both the reversible and the persistent posttraumatic sequelae after experimental TBI in the laboratory (Table I). Although the great majority of experimental studies have been conducted with posttraumatic survival times of hours or days, a smaller number of studies have successfully identified persistent neurobehavioral impairments and histological changes in the chronic phase after experimental TBI up to 1 year postinjury. Because these persisting alterations (morphologic and behavioral changes)

Table I
Popular Methods to Detect Changes after Experimental TBI

Outcome measurement	Methods
Electrophysiological changes	EEG, somatosensory or brain stem evoked potentials
Breakdown of the blood–brain barrier	Magnetic resonance imaging, immunostaining for plasma constituents (e.g. IgG, albumin), detection of administered tracers (e.g., Evans blue, horseradish peroxidase)
Edema formation	Gravimetric detection of hemispheric swelling and increased water content, determination of specific gravity
Changes in cerebral perfusion	Laser Doppler flow measurements, arterial spin-labeled magnetic resonance imaging, microsphere or hydrogen clearance technique, autoradiography
Increase in intracranial pressure	Intracranial inserted probes
Metabolic alterations	Microdialysis and chromatography of metabolites, staining for respiratory function, determination of local cerebral glucose utilization, nuclear magnetic resonance spectroscopy, assessment of mitochondrial function
Genomic changes	*In situ* hybridization, immunohistochemistry, Western blot analysis, semiquantitative reverse transcriptase PCR
Neurotransmitter release	Microdialysis
Ionic changes	Nuclear magnetic resonance spectroscopy, ion- autoradiography, ion- selective electrode technology, microdialysis
Activation of autodestructive enzymes	Immunohistochemistry for activated enzymes or proteolysis products, electron microscopy for proteolysis products, Western blot analysis
Production of free radicals	Measurement of cyclic voltammetry, salicylate trapping method, chemiluminescence
Inflammation	Microdialysis, immunohistochemistry, *in situ* hybridization, ELISA
Cell damage and cell death	Immunohistochemistry, electron microscopy, measurement of lesion or cavity volume, measurement of cortical thickness, estimates of contusion volume or axonal damage with MRI, regional cell counts
Impairment in neurological motor function	Neurological severity score, Rotarod, rotating pole, beam walk and beam balance, composite neuroscore, spontaneous motor activity, wire grip test
Deficits in cognitive function	Morris water maze, Barnes table, water finding task, win-shift paradigm

seem to be investigated more comprehensively than any of the listed early and transient changes, it appears reasonable to use these persisting characteristics for a brief description of the most popular models to produce experimental TBI.

III. OVERVIEW OF CURRENT MODELS TO PRODUCE TRAUMATIC BRAIN INJURY

A. Models without Trephination of the Skull

1. Weight-Drop Closed Head Injury

In this model, injury is produced using the gravitational forces of a free-falling, guided weight after exposing the skull of the anesthetized animal and attaching it to the impactor or bottom end of the trauma device. The majority of investigations have been performed with the head of the animal placed unrestrained on an adjustable platform; however, in several studies the head has been restrained before the impact is delivered. Due to the height and mass of the weight, injury severity can be varied from mild to severe TBI. Because the head is freely moveable in the majority of studies and no trephination is performed, the exact injury site can be selected on the basis of the special objectives of the particular study. This aspect, together with the relatively short duration involved in the preparation of the animal for the induction of TBI (no trephination of the skull or fixing of protective plates to the skull), makes this model easy and fast to use. However, because the vertex of the skull in rodents is extremely thin, a variable and somewhat uncontrolled number of skull fractures causes variability in the results when animals are subjected to higher magnitudes of injury severity.

With low injury severity, this model is able to produce concussive-like TBI without overt contusion or focal lesion. However, in a rigorous histological evaluation of the brains of mildly injured animals, cortical cell loss directly beneath the impact site and bilateral damage to selectively vulnerable regions remote from the direct injury site have been described. If animals are submitted to an injury of higher magnitude, this model is designed to produce mostly focal damage, thus replicating contusions found in the clinical situation. This characteristic feature is confirmed by the presence of acute hemorrhagic lesions in the acute and hemosiderin-laden macrophages when traumatized brains are evaluated in the more chronic posttraumatic period. Additionally, a necrotic cavity surrounded by a rim of rarefied tissue evolving over time from the hemorrhagic contusion has been reported. Robust impairments in neurological motor function and cognitive deficits, closely correlated with injury severity, have been shown to occur after experimental TBI employing this method. However, no long-term study has evaluated behavioral dysfunction in the more chronic period after TBI using this injury paradigm.

2. Impact Acceleration Model

To overcome the risk of experimentally induced skull fracture, which is a rare finding in human TBI, a model of impact acceleration was developed that uses a stainless steel protection helmet to avoid fracture when animals are subjected to TBI of higher magnitude. This protective shield is glued to the vertex of the skull after opening the scalp and distributes the load widely over the skull, thereby minimizing the likelihood of fracture. When combined with a large blunt weight that causes acceleration of the head and minor contact phenomena, this impact predominantly leads to shear forces. To perform the trauma, the head of the anesthetized animal is placed unrestrained and in prone position on the platform, adjusted to the end of the device, and the impact is delivered via a free-falling weight. The platform has to be covered by a foam of known spring constant to allow defined movement of the head after the impact, which has been shown to profoundly determine the injury-induced changes. Because the mass and height of the weight can be varied, the posttraumatic response has been characterized over a broad range of severity.

This model was characterized to produce mainly diffuse brain injury. Massive diffuse axonal swelling with its severity related to the level of trauma was observed after injury (e.g., in cerebral peduncles, rubrospinal or corticospinal tracts, medulla oblongata, corpus callosum, and internal capsule). Moreover, structural changes in dendrites and mild subarachnoid hemorrhage without focal contusions or lesions have been reported with mild impact, whereas increasing the impact energy leads to more extensive subarachnoid and petechial hemorrhage in the acute posttraumatic period. However, neuronal damage in the supraventricular cortex directly beneath the impact site that is correlated with injury severity and cell death in the hippocampus have been described.

Evaluation of the animal's posttraumatic behavioral function showed cognitive deficits and impairments

in neurologic motor function. Although in one study the more severely injured animals did not show full recovery from behavioral impairments during the investigation period, no long-term studies have been performed to test for persisting impairments in neurologic motor and cognitive function in the more chronic period of months after TBI.

3. Inertial Acceleration Brain Injury

Rotational acceleration of the head due to unrestricted movement causes rotation and deformation of the brain if the loading conditions exceed a certain threshold. Moreover, the rotational acceleration forces necessary to induce damage increase exponentially with decreasing brain size, and no injury device exists that can meet the parameters to reliably produce experimental TBI in rodents. Because a high percentage of patients suffer from TBI not associated with direct contact forces to the head but with rotational forces leading to diffuse brain injury, a model of inertial acceleration injury has been modified from earlier studies conducted in primates to allow for further studies of this type of damage. This model uses the minipig as the species of choice because of its gyrencephalic brain structure and relatively large brain mass compared to its body weight. To produce injury, the anesthetized miniature swine is positioned prone on the injury device, the head is tightly fixed, and inertial loading is produced through a biphasic centroidal rotation for 110° within 20 msec. Additionally, a model using sheep has been developed that is considered to produce mainly diffuse TBI due to mechanical loading to the head. At present, these are the only existing models that are available to produce widely distributed traumatic axonal pathology in the deep white matter at the root of the gyri and the junction of white and gray matter. Additionally, neuronal loss in the cortex and cerebellum next to bilateral damage to hippocampal structures that are known to be selectively vulnerable to TBI is reported. Unfortunately, the lack of availability of tests to assess neurobehavioral impairment in these animals and high costs and technical demands limit the utility of these models at present. To date, only two research centers have performed a small number of histological and radiological investigations elucidating the characteristic posttraumatic sequelae after inertial loading to the brain in the experimental setting.

B. Models with Trephination of the Skull

1. Fluid-Percussion Brain Injury

The fluid-percussion model of brain injury in the rodent is the most commonly used and well-characterized experimental model of TBI. After the skull is exposed and trephination is performed, injury is produced by the impact of a rapid fluid bolus, which strikes the intact dural surface and then moves in the epidural space concentrically from the injection area leading to diffuse loading to the brain. This model subsequently has been used and modified over the past decades to produce injury in a wide range of different animal species. The fluid-percussion technique to produce TBI in the rat was first evaluated with the trephination site placed centrally in the midline. It was subsequently shifted to a lateral location and later modified for use in the mouse. Due to the height of the pendulum, which determines the force of the fluid pressure pulse that is transmitted through a saline-filled reservoir, the injury severity can be varied reproducibly, and studies using this injury model have been conducted over a range of mild to severe experimental TBI.

The fluid-percussion model reproduces contusions as the hallmark of focal (gray matter) damage with accompanying petechial or intraparenchymal and subarachnoid hemorrhages. In fact, central fluid percussion leads to a contusion in the direct vicinity of the site of the maximal fluid impulse, whereas the more pronounced contused area in the lateral fluid-percussion injury tends to be more lateral than the actual trephination and injury site. The extent of this damaged area is associated with injury severity, and a necrotic cavity evolves from the contusion over weeks, which progressively expands due to ongoing cell death up to 1 year postinjury. Injury-induced damage has also been described remote from the injury site. To date, cell damage or cell death has been demonstrated in the thalamus and hippocampus and parallels the cortical cell death up to 1 year postinjury. Although the lateral fluid-percussion model was initially considered to represent a model of unilateral damage, a number of studies have conclusively shown that contralateral damage occurs. Additionally, lateral fluid-percussion injury has been associated with diffuse white matter damage remote from the injury site, reminiscent of human traumatic white matter injury.

Transient impairments in a broad variety of tests for different aspects of neurologic motor function and cognitive deficits have been described. Moreover,

long-term investigations have reported persistent cognitive and motor impairments up to 1 year after severe lateral fluid-percussion brain injury.

2. Rigid Indentation Injury

This method to produce experimental TBI employs a rigid impactor to generate the mechanical energy to the intact dura after trephination of the exposed skull, with the head of the animal usually restrained. The most popular method to produce this type of injury employs pressurized air as the source of the mechanical energy for loading to the brain and is referred to as controlled cortical impact injury (CCI). This method was first described in the ferret and subsequently adapted for use in the rat and mouse. The advantage of closely controlling deformation parameters with pneumatically driven devices (time, velocity, and depth of impact) and the absence of risk for rebound injury make the CCI model superior to devices that are driven by the gravity of a free-falling, guided weight. However, to date, only one study has evaluated for differences in the pathologic sequelae between these two methods to produce experimental TBI.

Besides minor concussive events with low injury severity, this model is able to mimic a whole spectrum of contusions, including intraparenchymal petechial hemorrhages accompanied by epidural and subdural hematomas. Following CCI brain injury, widespread cortical damage and ablation of the gray and, to a lesser extent, the underlying white matter are frequently observed. These changes are dependent on injury severity and, in particular, the depth of indentation and impact velocity. It has been shown that the resulting cell death and hemispheric loss increase up to 1 year postinjury. At moderate and high injury severity with central trephination, axonal injury in the adjacent white matter, corpus callosum, and internal capsule has been described. However, with sensitive immunohistochemical techniques, axonal changes have been observed after mild rigid indentation over the parietal cortex. Consistent neuronal cell loss in selectively vulnerable brain structures, including the hippocampus and dentate gyrus or thalamus ipsilateral to the traumatic impact, has been reported in a number of investigations, and contralateral damage starts to occur following rigid indentation brain injury of higher magnitude. Behavioral evaluations have revealed impairment in various aspects of gross motor function and fine motor coordination following TBI employing this technique. Additionally, deficits in cognitive function (working memory, information acquisition, spatial or place learning) have been reported. The deficits in neurologic motor function seem more transient in nature but have not been comprehensively investigated in the chronic period after TBI, whereas cognitive deficits appear to persist up to 1 year postinjury.

C. Models Complicated by Secondary Events after the Traumatic Brain Injury

1. Hemorrhage–Hypotension–Hypoxia–Ischemia

A high number of patients that suffer from head injury often present with accompanying severe injury to other parts of the body, with profound hemorrhage at the site of injury. Additionally, hypotensive episodes have been found to occur in head-injured patients despite intensive care. Due to the duration and/or extent of these secondary episodes (SEs) accompanied by profoundly impaired autoregulation after TBI, these events may or may not be associated with hypoxia or ischemia to the brain, however. To test for the contribution of these SEs to the posttraumatic cascade after TBI, a number of experiments have included volume- or pressure-controlled hemorrhage, hypoxia, or pharmaceutically induced hypotensive episodes in their study design. Additionally, models of cerebral ischemia or hypoxia have been added to produce secondary ischemic or hypoxic insults to the injured brain directed to evaluate for aggravation of trauma-induced changes after TBI. To date, the models of impact acceleration, fluid-percussion brain injury, or rigid indentation combined with episodes of either hemorrhage, hypotension, ischemia, or hypoxia (or a combination of more than one of these pathologic conditions) have been used to experimentally mimic these frequent complications of clinical TBI.

Due to the broad spectrum of different investigation protocols and numerous possible combinations of the previously mentioned pathologic conditions, comprehensive conclusions are difficult to draw at present. Evidence suggests that animals showed some ability to cope with these posttraumatic SEs without further damage to CNS structures or behavioral impairment if the SE does not occur for a prolonged period. In contrast, a substantial increase in injury-induced pathologic changes has been reported if the duration of the SE or its severity exceeded a certain level or if the animal was subjected to a combination of more than one SE after the traumatic CNS insult.

To date, an increase in cell death in selectively vulnerable brain regions has been reported when trauma and SE were combined. Additionally, tests for neurologic motor function or cognitive ability revealed increased impairment if SE was added to the experimental protocol after TBI. The time frame of exposure to SEs appears to influence the magnitude of additional damage to the CNS. Longer periods of ischemia result in more pronounced damage to the cortex and subcortical hippocampal structures. Moreover, another variable that has to be considered is the time point after the traumatic impact to the brain when the SE occurs. Whereas the subcortical regions seem to be affected in the early period after TBI (immediately until 1 hr), the extent of cortical contusion increased markedly when the ischemia occurred several hours after TBI, although these reports have been contested.

Taken together, the data support a detrimental role of these secondary pathologic events in the sequelae after TBI if they exceed a certain threshold that is dependent on a number of factors. Among others, the magnitude of the single SE, the number, the temporal course and the duration appear to play a crucial role in increasing TBI-induced damage and impairment.

2. Multiple Head Injuries

Repetitive head injuries occur in a wide variety of individuals engaged in contact–collision sports. Due to reports of unfavorable outcomes and epidemiological data suggesting an increased risk for the early onset of neurodegenerative diseases for certain populations of susceptible patients suffering from repetitive head injury, experimental laboratories have begun to develop models that reproduce the effects of repetitive TBI (second impact syndrome). Different techniques described earlier in this article have been used to mimic repetitive head injury, including fluid-percussion injury and closed head injury. The majority of patients suffer from repetitive head injury of mild severity, and, accordingly, the experimental mechanical injury parameters have been designed to produce repetitive mild experimental TBI. However, the interval between the different episodes of TBI and the number of traumatic insults are important variables that have not been thoroughly assessed due to the small number of published studies. Drawing conclusions from these limited results is difficult at present, but it appears that repeated, mild head injury leads to histological damage and behavioral impairments not observed after a single mild TBI. Due to the wide popularity of contact–collision sports, these results warrant further investigation.

IV. MAJOR LIMITATIONS OF THE EXISTING EXPERIMENTAL MODELS OF TRAUMATIC BRAIN INJURY

A. Species Differences

Profound differences in brain geometry, craniospinal angle, gyral complexity, and white to gray matter ratio are well-characterized differences between the human CNS and the brains of laboratory animals. In addition to these anatomical differences, more subtle alterations in the physiologic responses to the traumatic insult, neurotransmitter receptor distribution, or genomic differences must be considered before data obtained in experimental research are translated into clinical concepts. The situation becomes even more complex because profound differences in the behavioral and histopathological responses to TBI within different rodent strains have been described and are additionally influenced by the age of the animal and its laboratory environment.

B. Modeling Injury Severity

In contrast to the clinical situation, no commonly used scoring system for injury severity based on neurological examination has been adopted for the rodent. Therefore, the classification of mild, moderate, and severe experimental TBI continues to be based on measurements of the somewhat arbitrary mechanical injury parameters. Moreover, most injury devices are custom-made and show subtle differences. As a result, scoring systems based on mechanical parameters may be specific only for a particular laboratory. Additionally, different TBI impact sites produce a distinct pattern of injury-induced changes, making experimental findings from different centers difficult to compare at best. Besides these more technical difficulties, the whole heterogeneous spectrum of human TBI is broader than can possibly be modeled in the experimental setting, and both the posttraumatic sequelae after mild TBI without overt morphological damage and the severest cases of TBI with high mortality have not been comprehensively studied.

C. Survival Times and Outcome Measurements

The great majority of studies of experimental TBI have been conducted with short survival times in the range of hours or days. Although the results obtained in these studies may help us to gain insight into the acute posttraumatic sequelae, these histological or behavioral endpoints do not represent a valid assessment of long-term outcomes. Therefore, more studies evaluating injury response and behavioral deficits in the chronic phase (weeks or months after TBI) are warranted. Additionally, the limitations linked with neurobehavioral outcome measurements (high biological variability resulting in a high number of animals required, time- and cost-intensive) have restricted the number of studies evaluating behavioral outcomes after experimental TBI. Because the main effort in patient care is directed toward the attenuation of behavioral dysfunction and chronic disability, more research designed to evaluate neurobehavioral deficits and the therapeutic efficacy of new drugs to attenuate cognitive and neurologic motor functions after TBI is sorely needed.

Although robust impairments in neurologic motor function and cognition have been reported following TBI from moderate or severe magnitude, a great majority of patients suffer from mild clinical TBI. Although the majority of these mildly head-injured patients are not clinically observed or reported, a small percentage register complaints about postconcussive symptoms weeks and months after the traumatic insult. A thorough examination employing sensitive tests directed to detect impairments in higher cognitive or emotional function have indeed shown persistent deficits after mild clinical TBI. However, no such tests are available in the laboratory setting at present. Because the high incidence of mild TBI and the related long-term impairments warrant further investigation, more sensitive tests to elucidate the posttraumatic sequelae after experimental mild TBI must be developed.

V. CONCLUSION

The number of experimental and clinical studies attempting to gain insight into the posttraumatic sequelae following TBI has expanded enormously over the past decade and has generated an abundant amount of preclinical and clinical data suggestive of a number of divergent cascades involved in the delayed damage after TBI. However, no single animal model is entirely successful in reproducing the complete spectrum of pathological changes observed after clinical TBI. Together with the existing *in vivo* models of experimental TBI, *in vitro* models and finite element characterizations have contributed to the current theories of posttraumatic sequelae. Further effort will be necessary to elucidate the acute and chronic changes occurring after TBI in a number of different preclinical models to gain greater insight into the cellular cascades. These studies must be directed at clarifying and validating the present concepts, establishing new therapeutic strategies, and extending the pharmacological armamentarium toward more effective treatment for head-injured patients. New technical breakthroughs, including new methodologies in radiological examination and the use of genomic chip arrays or transgenic animals, seem to be powerful tools in this effort. However, the living animal remains necessary to prove new concepts and make clinical trials successful and safe.

Mood Disorders

ERAN CHEMERINSKI and ROBERT G. ROBINSON
University of Iowa College of Medicine

GLOSSARY

limbic system A group of subcortical structures (such as the hypothalamus, the hippocampus, and the amygdala) of the brain that are concerned especially with emotion and motivation.

melancholia A mental condition characterized by extreme depression, bodily complaints, and often hallucinations and delusions.

neurotransmitter A substance (as norepinephrine or acetylcholine) that transmits nerve impulses across a synapse.

proband An individual being studied in a genetic investigation.

The relationship between brain and mood disorders has been investigated based on numerous brain-related functions. This article attempts to summarize the historical development of these areas of research as well as the focus of current investigation.

I. HISTORICAL BACKGROUND

Hippocrates (460–377 BC) is credited with what is probably the earliest statement known to man relating the brain with mood disorders. He stated,

> *and men ought to know that from nothing else but hence [from the brain] comes joys, delights, laughter and sports, sorrows, grieves, despondency and lamentations … and by the same organ we become mad and delirious, and fears and terrors assail us.*

In the 18th and 19th centuries, techniques for neuropathological studies of the brain were developed, and therefore a more precise taxonomic division of mental disorders emerged. In Paris, Philippe Pinel (1745–1826), who became famous for abolishing the restraints of patients at Bicêtre and Salpétrière, divided mental disorders into melancholia and mania with and without delirium. In *Des Maladies Mentales*, Esquirol (1772–1840) created the new term "lypemania" in which the patient had fixed delusions and sadness that overwhelmed and debilitated him or her. Opposite to this was mania, defined by him as a state of generalized delusions and excited emotions.

Contemporary terms for mood disorders, however, are mostly influenced by the work of Emil Kraepelin (1856–1926). In his textbook issued between 1883 and 1914 he applied the method of systematic collection and description of facts for the clinical delineation of mental disease entities. Under the term "depressive states," he included melancholia simplex, melancholia gravis, fantastic melancholia, delirious melancholia, and stupor. Perhaps the greatest contribution of Kraepelin to modern psychiatric classification, however, was the distinction of affective disorders (for him, all forms of recurrent affective psychoses) from the more severe dementia praecox. Whereas dementia praecox exhibited a chronic deteriorating course resulting in poor long-term prognosis, manic–depressive illness had a recurrent course with full remission between psychotic episodes.

II. CLASSIFICATION OF MOOD DISORDERS

A. Background

Although modern psychiatrists seek to classify psychiatric disorders based on biochemical, genetic, and immunologic findings as well as the interaction with the environment, almost all existing psychiatric classifications use the descriptive method in which diseases are named and grouped based on similar patterns of clinical presentations across different individuals. Leonhard (1959) suggested that unipolar (UP) and bipolar (BP) disorders were different entities. After Angst (1966) and Perris (1968) reported systematic family history data supporting Leonhard's theory, these disorders were independently included in modern psychiatric classifications. In 1948, a committee was instituted by the American Psychiatric Association to create a single national system of classification that would solve the chaotic situation existing as new psychiatric diagnoses were being independently devised by different researchers since the 19th century. In 1952, the first system of classification was published, the *Diagnostic and Statistical Manual of Mental Disorders*, known as *DSM-I*. The current fourth edition (*DSM-IV*), published in 1994, uses specific diagnostic criteria (i.e., a list of individual features required for a diagnosis to be made) and a multiaxial approach to classify psychiatric disorders. Axis I refers to clinical disorders. Therefore, the presence of UP or BP disorder would be recorded in this axis. Supplemental information for the clinician is provided by axis II, which consists of personality disorders, as well as axes III and IV, which record associated physical conditions and psychosocial stressors, respectively. Using axis V, which consists of the Global Assessment of Functioning Scale, the clinician can also assess the patients' highest level of social, occupational, and psychological functioning at the time of evaluation.

B. Clinical Subtypes of Mood Disorders

1. Depressive Disorders

The *DSM-IV* classification includes three types of depressive disorders.

a. Major Depressive Disorder This disorder is characterized by a clinical course of one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. In addition, the episodes are not due to direct physiological effects of a drug or a medical condition and are not present during the course of schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified. There are two types: major depressive disorder, single episode, and major depressive disorder, recurrent.

b. Dysthymic Disorder The essential feature of this disorder is a constant depressed mood for most of the day, and for more days than not, for at least 2 years.

c. Depressive Disorders Not Otherwise Specified This category includes depressive disorders that do not meet the criteria for major depressive disorder, dysthymic disorder, adjustment disorder with depressed mood, or adjustment disorder with mixed anxiety and depressed mood such as minor depression (based on suggested research criteria).

2. Bipolar Disorders

There are four types of bipolar mood disorders.

a. Bipolar I Disorder This disorder is characterized by the occurrence of one or more manic or mixed episodes. Although it is not a requirement, most individuals also have had one or more major depressive episodes. In addition, this disorder is divided into bipolar I disorder, single manic episode, with the presence of only one manic episode and no past major depressive episodes, and other types depending on the nature of the most recent episode—hypomanic, manic, mixed, depressed, or unspecified.

b. Bipolar II Disorder This disorder is characterized by the occurrence of one or more major depressive episodes accompanied by at least one hypomanic episode.

c. Cyclothymic Disorder This disorder is characterized by the occurrence of numerous periods of hypomanic and depressive symptoms not meeting criteria for major depressive episodes for a 2-year period without symptom-free periods of more than 2 months.

d. Bipolar Disorder Not Otherwise Specified This category includes disorders with bipolar features that do not meet criteria for any specific bipolar disorder.

3. Other Mood Disorders

a. Mood Disorder due to a General Medical Condition These disorders are caused by either a depressed mood or apathy or an elevated, expanded, or irritable mood that is the consequence of a direct physiological effect of a general medical condition. These disorders have generally been called secondary mood disorders.

b. Substance-Induced Mood Disorder Depressed or elevated mood develops either after the use of medication etiologically related to the disturbance or within 1 month of substance intoxication or withdrawal.

c. Mood Disorder Not Otherwise Specified This category includes disorders with mood symptoms that do not meet the criteria for any specific mood disorder.

III. EPIDEMIOLOGY OF MOOD DISORDERS

Epidemiology is the study of the distribution of a disease or condition in a population and of the factors that influence this distribution. Due to the high prevalence and morbidity of mood disorders for which effective treatment is available, there has been growing interest in recent years in assessing the epidemiological distribution of these disorders. Results from the National Comorbidity Survey (NCS) show that mood disorders, along with simple phobia and alcohol dependence, are the most frequent psychiatric disorders. Since World War II there have been major changes in the epidemiology of mood disorders, such as an increase in the overall cumulative lifetime rates of depression and the occurrence of these disorders at earlier ages in both men and women.

In the early 1980s, approximately 20,000 community and institutionalized (e.g., in mental hospitals, nursing homes, or prison) subjects were selected according to age group proportion by the 1980 U.S. census of adults ages 18 and older as part of the Epidemiological Catchment Area (ECA) study. The overall rate for mood disorders was 5.1%, with significantly higher rates in women (6.6%) compared to men (3.5%). The highest rates were found in the age group 25–44 years (6.4%), whereas the lowest rates were found in the are group $\geqslant$65 years old. Of the sociodemographic variables, marital status accounted for the only significant difference, with a 4.1% rate of mood disorders in married subjects compared to an 11.1% rate in separated and divorced subjects. A major depressive episode occurred in 2.2% of the population during the previous year, whereas a manic episode (necessary for the bipolar I disorder diagnostic criteria) occurred in the previous year in 0.4% of the population. Dysthymia was identified on a lifetime basis in 3.3%.

The NCS assessed a probability-based sample population of subjects between 15 and 54 years of age in the United States. In order to increase the reporting sensitivity of lifetime psychiatric disorders and substance use, the interviewers encouraged respondents to recall accurately past episodes of psychiatric illnesses using a structured interview that incorporated *DSM-III-R* criteria. This survey, conducted from 1990 to 1992, surprisingly showed much higher prevalence rates than the ECA. The NCS found that the lifetime prevalence of major depressive episode was 17.1% overall (12.7% in males and 21.3% in females). For major depressive disorder, the lifetime prevalence was 14.9% overall (11.0% among males and 18.6% among females), whereas the overall prevalence for dysthymia in this age group was 6.4% (4.8% in males and 8.0% in females). The NCS also found that in those respondents who had a substance use disorder on a lifetime basis, there was a prevalence of 51% of lifetime mental disorder. The variation in the assessment instruments used in the ECA and the more recent NCS could account for the substantial difference observed in the rates of prevalence between the two surveys.

A review by Rouchell, Pounds, and Tierney of recent epidemiological studies showed the prevalence of major depression in specific medical conditions: dementia, 11%; stroke, 27%; Parkinson's disease, 28.6%; epilepsy, 55%; diabetes mellitus, 24%; coronary artery disease, 16–19%; and cancer, was 20–38%.

IV. BRAIN-RELATED MECHANISM OF MOOD DISORDERS

A. Genetic Contributions

1. Background

In the 1850s, Morel initiated the application of genetics to mental diseases. His "psychopathic degeneration" theory expressed that mental disorders have a genetic origin and worsen over generations; therefore,

neurotic symptoms in a patient would ultimately give rise to severe mental illnesses in his or her progeny. In the 1920s, Rudin, Luxenburger, and Schultz from the Munich school of medicine intensively studied the mode of inheritance of schizophrenia and refined the methodology of twin studies. However, they soon found that Mendelian modes of inheritance, which made it easy to calculate the morbid risks for different degrees of relatives of probands, could not be applied to the study of the inheritance of major psychoses.

2. Family Studies

Most studies of bipolar disorder show that this illness tends to be familial, with significantly higher risk in relatives of bipolar probands compared to the general population. Kallmann reported that the lifetime risk for parents of bipolar probands was 23.4% and that for siblings was 22.7%, whereas for second-degree relatives the rates range from 1 to 4%. Winokur found that in sibs of bipolar patients, the lifetime risk for any mood disorder was 35%, whereas in their parents the risk was 34%.

3. Twin Studies

Although monozygotic (MZ) twins are genetically identical, dizygotic (DZ) twins share only half of the genome. The twin method compares concordance rates for a trait between MZ and DZ twins. A significantly higher rate in MZ compared to DZ twins who share a similar environment suggests that genetic influences are present. Most studies using this method have found two to five times higher concordance rates for BP disorder in MZ compared to DZ twins. A Danish twin study found that when the proband had BP disorder, the concordance in MZ twins was 69% compared to 19% in DZ twins (3.5 : 1 ratio), and when the proband had UP disorder the MZ concordance was 54%, whereas the DZ concordance was 24% (2 : 1 ratio).

4. Adoption Studies

This method separates the interacting roles of heredity and environment in the etiology of diseases by comparing the rates in the adoptive parents of a proband versus the rates in his or her biological parents. Mendlewicz reported higher rates of mood disorder in biological (28%) compared to adoptive parents (12%) among parents of adoptees with BP illness. The rate of the disorder in the proband's adoptive parents was similar to that of the adoptive parents of a normal offspring control group, whereas the rate of the disorder in biological parents of adoptees probands was similar to that of parents in a nonadopted bipolar group. Cadoret also found higher rates of UP depression in adopted offspring of biological parents with mood disorders compared to adoptees with biological parents without psychiatric conditions.

5. Linkage Studies

Two traits located proximately on the same chromosome by the phenomenon of linkage have a dependent assortment during the process of meiosis. Linkage studies compare the pattern of inheritance of blocks of genes among relatives with the inheritance pattern of a trait of interest. Although this method was useful in the study of rare Mendelian disorders with known mode of inheritance and clearly specified phenotypes such as Huntington's disease, it has been less successful when applied to disorders that do not exhibit simple Mendelian patterns of inheritance, such as the major psychiatric disorders. Recent studies have demonstrated a linkage of mood disorders to chromosome 18. In a linkage study of 22 bipolar families, Berretini *et al.* found evidence for a bipolar susceptibility gene in the pericentromeric region of chromosome 18. No single gene or region has been shown to be causative of the majority of familial mood disorders.

B. Neuroendocrine Contributions

The observation that mood disorders are sometimes associated with endocrine disorders, such as Cushing's syndrome and hyper- or hypothyroidism, has led to the hypothesis that abnormal secretion of neurotransmitters, themselves implicated in the mechanism of mood disorders, also disrupts the secretion of hypothalamic neuroendocrine cells leading to an association between mood disorders and hormonal dysfunction.

1. Hypothalamic–Pituitary–Adrenal Axis

Cortisol has been recognized as a stress–response hormone because plasma levels are altered by environmental stress. Disturbances in the hypothalamic–pituitary–adrenal (HPA) axis due to mood disorders in humans were reported as early as 1943 by Pincus and Hoagland, who observed an elevation of urinary

metabolites of adrenocortical secretion related to stress among test pilots. In response to anxiety or depression, an increase in norepinephrine (NE) activates the hypothalamus to release corticotropin-releasing factor, which stimulates the secretion of adrenocorticotropic hormone. This hormone stimulates the adrenal cortex, thereby increasing plasma concentrations of cortisol. By a negative feedback mechanism, cortisol lowers the levels of NE synthesis.

The best known challenge test related to mood disorders is the Dexamethasone Suppression Test. A level of $>5\,\mu g/dl$ of cortisol at 8, 16, or 24 hr after dexamethasone administration is abnormal and indicates a lack of suppression capability by the feedback inhibition system of the HPA axis. The highest rates of abnormalities (i.e., 60–90% abnormality) are found in more severe depressive patients, usually with melancholic or delusional symptoms.

2. Hypothalamic–Pituitary–Thyroid Axis

A number of researchers have reported subnormal pituitary thyroid-stimulating hormone (TSH) levels in response to the administration of the hypothalamic thyrotropin-releasing hormone among patients with depressive disorder. Moreover, a correlation has been found between relapse of depression and a persistently low TSH response after clinical recovery.

3. Growth Hormone

The levels of growth hormone (GH) secretion by the pituitary are increased by the hypothalamic growth hormone-releasing hormone as well as by noradrenergic and dopaminergic stimulation, whereas the release of GH is inhibited by somatostatin. Several studies have reported blunted responses of GH to clonidine in depressed men and postmenopausal women, suggesting dysfunctional α_2 adrenergic receptors in depression. Also, blunted responses of GH to imipramine that persist despite effective treatment of depression have been reported, suggesting that subnormal GH response could be a trait marker in depressed patients.

C. Neurochemical Contributions

1. Norepinephrine

The norepinephrine (NE) system is composed of nuclei located in the brain stem that project to cerebral cortex, limbic system, and cerebellum. This includes monosynaptic projections to the amygdala, hippocampus, cingulate gyrus, thalamus, hypothalamus, midbrain, and cerebral cortex. As early as 1929, Cannon described the role of NE in responses to threatening stimuli. NE has been linked to visual, auditory, and somesthetic stimuli as well as pleasurable experiences. The catecholamine hypothesis articulated by Schildkraut posits that mood disorders are the result of a deficit in noradrenergic activity leading to depressive states, whereas increased noradrenergic activity leads to mania. Although the exact relationship between mood disorders and NE activity is not fully understood, a vast amount of research has examined this hypothesis, which suggests that depression is in some way related to inefficient functioning of the NE system and that greater output is required to sustain adequate functioning. Since direct measures of NE or its urinary metabolite 3-methoxy-4-hydroxyphenolglycol are difficult to interpret, physiologic markers have been developed to identify disturbances in NE functioning during depression and the mechanisms of action of antidepressant therapies. One of these markers is the orthostatic challenge test, in which depressed patients show exaggerated increases of plasma NE when rising from a supine to a standing position without altered cardiovascular responses compared to normal subjects.

2. Serotonin

Reserpine, an antihypertensive drug used in the 1950s and 1960s, depletes noradrenaline as well as serotonin and dopamine and frequently led to depression in patients who took this medication. This finding led to the hypothesis that mood disorders were caused by depletions of serotonin and dopamine. Serotonin (5-HT) is produced by the dorsal and median raphe located in the brain stem. The dorsal raphe sends projections to the frontal lobe, amygdala, hypothalamus, and basal ganglia, whereas the median raphe projects to the cingulate gyrus, septum, and hippocampus. Most serotonin is secreted from the dorsal raphe, a well-organized nucleus that coordinates excitation responses in the frontal lobe and amygdala. In 1965, Coppen suggested that a deficiency of 5-HT in the central nervous systen (CNS) could lead to depressive illness. Although it is now possible to measure 5-HT's principal metabolite, 5-hydroxy indole acetic acid (5-HIAA), several studies have reported that a high percentage of depressed patients have normal levels of 5-HIAA in spinal fluid. In addition, 5-HT has been implicated in suicidal

behavior, and lower levels are associated with more violent methods of suicide.

D. Neuroanatomical Abnormalities

1. Background

During the past 15 years, neuroimaging has provided valuable information about the structural brain abnormalities that may play a role in the etiology or mechanism of primary and secondary mood disorders. The first study using computed tomography (CT) in patients with mood disorders was reported in 1980 and the first study using magnetic resonance imaging (MRI) in mood disorders was published in 1983.

One of the major problems in using neuroimaging techniques to study primary mood disorders is that the neuropathology that is etiologically related to this disorder remains unknown (hence the term primary mood disorder). In patients with secondary mood disorders, however, neuroimaging techniques are particularly suited to identify the location and size of structural lesions associated with mood disorders. This technique, based on clinical pathological correlation with spontaneous brain lesion, was first utilized by Broca in the 1860s to identify brain regions that play an important role in specific behaviors.

Broca (1878) also first described an area of cortex that he called the limbus cortex that surrounded the midbrain. This limbus cortex included phylogenetically older areas of cortex which formed a ring around the lower brain stem structures. This term gave rise to the limbic system, which has been the presumed anatomical basis of emotion in humans. Many of these phylogenetically older areas of cortex, such as the basal temporal and inferior frontal cortex, have also been implicated in the mechanism of mood disorders.

2. Generalized Brain Abnormalities

Studies of brain structure in patients with mood disorder have searched for both generalized brain changes and specific regional changes. These studies have usually examined ventricular to brain ratios as a measure of cortical and/or subcortical brain atrophy. Although a number of studies have reported increased ventricular to brain ratios in patients with mood disorders compared to controls, this remains an area of controversy. More than half of the studies using either CT scan measurements or MRI measurements have failed to find increased lateral or third ventricular to brain ratios which would indicate subcortical atrophy in patients with either UP or BP disorders.

One study of patients with secondary depression found that patients with poststroke major depression had significantly larger lateral and third ventricular to brain ratios compared to patients with stroke who were nondepressed. This study suggested that subcortical atrophy preceding brain injury might produce a vulnerability to depression in patients with secondary depression.

Measurements of cortical sulcal width as well as overall cerebral volume have not demonstrated significant differences between patients with UP or BP mood disorders and controls.

3. Regional Brain Abnormalities

a. Cortical Changes Studies of frontal lobe abnormalities among patients with mood disorders have reported findings such as smaller mean frontal area or higher T_1 values on MRI scan in the frontal lobe in patients with UP depressive disorder but not in patients with BP disorder. However, additional studies of prefrontal cortical gray matter volume with better definition of what constitutes medial, dorsal, lateral, and orbital frontal cortex are needed to determine whether structural frontal abnormalities are associated with primary mood disorder. Based on consistent findings using functional imaging techniques of abnormal function in prefrontal cortex, it seems likely that structural abnormalities of prefrontal cortex may be identified in the future.

Studies of temporal lobe structure have reported decreased temporal lobe area in patients with mood disorders. These findings, however, have been inconsistent; in fact, one study reported an increase in left temporal volume in BP patients compared to controls. Studies of temporal lobe asymmetries have reported smaller left compared to right temporal lobe volumes in BP patients compared to controls, but one study found the reversed pattern. Overall, there is lack of agreement as to whether structural temporal abnormalities occur in either BP patients or UP patients. Further studies need to be conducted using better definitions of temporal structures and including subregions within the temporal lobe.

b. Subcortical Changes Examinations of subcortical structures have found conflicting evidence about abnormalities of the thalamus. A recent study reported increased thalamic volume in patients with BP disorder

compared to controls and decreased thalamic volume in unipolars compared to controls. Since the thalamus constitutes part of the cortical–striatal–thalamic loops that have been proposed in numerous studies to constitute the anatomical substrate of mood disorders (Fig. 1), additional studies of thalamic structures including examination of specific nuclei need to be conducted.

Several studies have examined the amygdala and hippocampus. However, there is a lack of consistent evidence demonstrating structural abnormalities in the amygdala or hippocampus in patients with mood disorders. Although the amygdala–hippocampal complex volume was reported in one study to be not significantly different than that of controls, another study reported increased hippocampal volume in bipolars, with the left hippocampus being significantly larger than the right compared with controls.

The largest number of subcortical structural studies have examined abnormalities of the basal ganglia. Several studies have reported significantly smaller putamen and caudate volumes in patients with UP disorder compared to controls. A few studies of patients with BP disorder have reported larger caudate volumes bilaterally in males compared to females.

Studies of subcortical hyperintensities on MRI scan have generally reported that the presence of basal ganglia lesions is strongly associated with mood disorder. These focal hyperintensities (thought to be predominantly vascular lesions) have been the most consistent structural abnormality found in patients with primary mood disorders. However, this appears to be predominantly a phenomenon of the elderly since the majority of studies reporting hyperintensity have been conducted in this population. Only one or two studies of nonelderly depressives found these ischemic abnormalities.

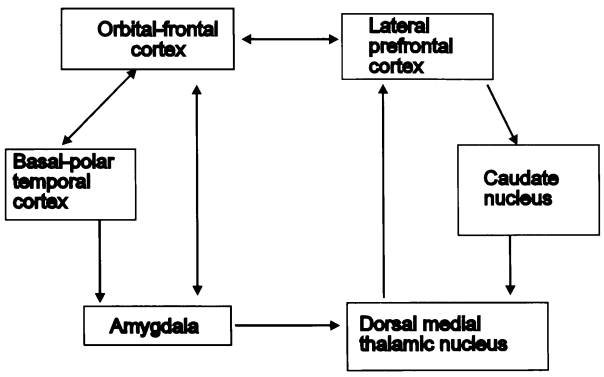

Figure 1 Schematic drawing of the relationship and direction of axonal projections for structures of the ventral–lateral limbic circuit. These interrelationships may explain why both acute lateral frontal (prefrontal) and basal ganglia (caudate) dysfunction could be associated with depression. These circuits may also explain why both metabolic and serotonin S_2 receptor changes in the temporal cortex (basal polar) may also be associated with depression.

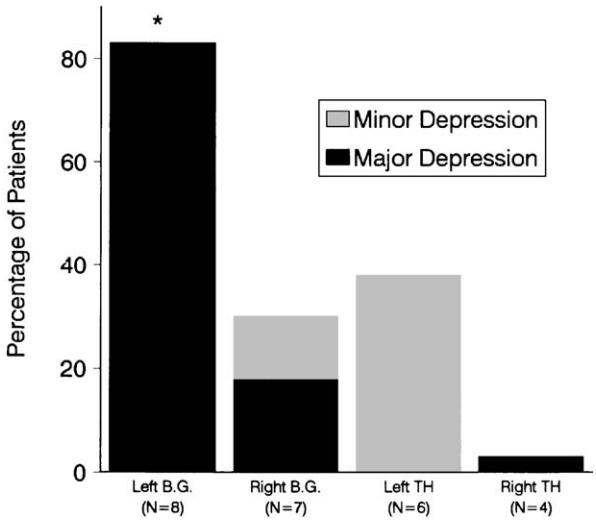

Figure 2 The percentage of patients with major or minor depression based on the localization of their subcortical lesions. Patients with left basal ganglia lesions had a significantly higher frequency of major depression than those with lesions at any other location. BG, basal ganglia; TH, thalamus (data from Starkstein *et al*., 1989, with the permission of Cambridge University Press).

Another new area of investigation in the structural brain imaging of patients with mood disorder has been the identification of silent brain infarctions. Two studies have reported an increased frequency of silent ischemic infarctions as imaged by MRI in patients with senile-onset major depression compared with presenile-onset depression. Silent cerebral infarction was found in 100% of patients with onset of depression after age 65 compared to 53.6% with onset of depression between ages 50 and 65 and 20% with onset of depression prior to age 50.

Among patients with secondary depressions, three studies have examined the role of basal ganglia lesions in depressive disorder. They have all reported a significant association between infarction in the basal ganglia and poststroke depressive disorder. In contrast, lesions of the thalamus have not been significantly associated with poststroke mood disorder (Fig. 2).

Laterality has also been examined with regard to the structural basis of mood disorders. Although

studies of primary mood disorders have not identified lateralized structural asymmetries associated with mood disorder, functional imaging studies in patients with primary mood disorders have frequently reported brain asymmetries. In addition, studies of secondary depressive disorder have frequently reported an association between laterality of brain injury and frequency of mood disorders. Five independent studies have reported that major depression was significantly more frequent among patients with acute or subacute left frontal or left basal ganglia lesions compared to those with lesions in other locations (Fig. 2). However, the association of left frontal and left basal ganglia lesions with major depressive disorder appears to be a phenomenon influenced by time since injury. Patients who are studied within the first few months following stroke show the most prominent association between the hemispheric side of the lesion and the frequency of major poststroke depression (Fig. 3). The studies that have failed to show a lateralized effect of brain lesions on depression have generally examined patients who are several months to several years poststroke.

Additional support for the suggestion that lateralized brain mechanisms may be involved in the production of mood disorders is provided by two controlled case studies and numerous anecdotal case reports of mania associated with injury to the right hemisphere. Thus, left frontal and left basal ganglia lesions have been associated with major depression, whereas right orbital frontal, basotemporal, basal ganglia, and thalamic lesions have been associated with mania.

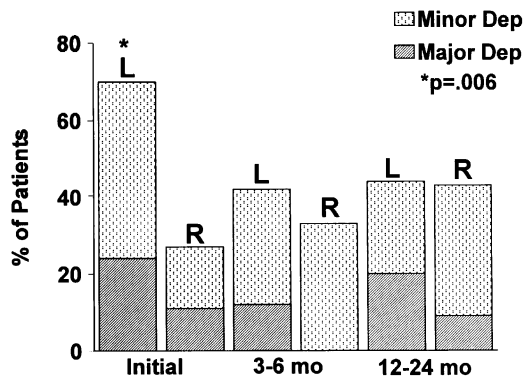

Figure 3 The frequency of major and minor depression defined by *DSM-IV* criteria associated with single lesions of the right (R) or left (L) hemisphere during the acute stroke period and at follow-up. The lateralized effect of left hemisphere lesions on both major and minor depression was found only during the acute stroke period. At short- and long-term follow-up, there were no hemispheric lesion effects on the frequency of depression. From Robinson (1998); reprinted with the permission of Cambridge University Press.

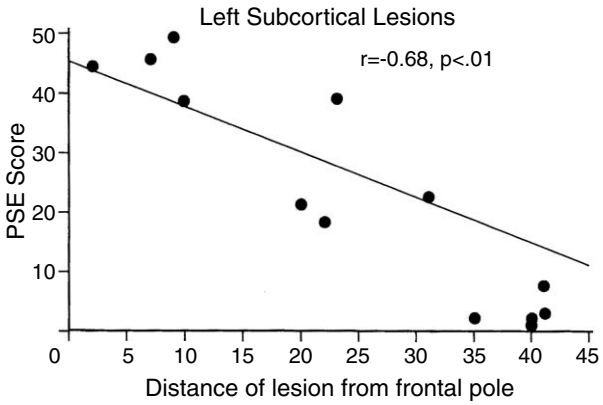

Figure 4 Scattergram showing the correlation between severity of depression based on total Present State Exam (PSE) scores and proximity of the anterior border of the lesion from the frontal pole. Patients all had subcortical lesions restricted to the basal ganglia, thalamus, or internal capsule (data from Starkstein, 1987, with the permission of Cambridge University Press).

Another phenomenon that has emerged from studies of patients with secondary mood disorders is the significant correlation between proximity of the anterior border of the lesion to the frontal pole and severity of associated depressive symptoms (Fig. 4). Eleven studies have found significant correlations between the proximity of a stroke lesion to the front of the brain and severity of depression as measured by a depression rating scale (Fig. 5). There is only one published study that has failed to identify this clinical pathological correlation, and it did so because patients with very large posterior lesions were included in the study. Some studies have found that this correlation holds for both left and right hemisphere lesions, whereas other studies have found that it is significant only among left hemisphere lesion patients or only among patients with lesions of the anterior portion of the left hemisphere. A recent study demonstrated that the clinical pathological correlation between proximity of the lesion to the frontal pole and severity of poststroke depression is also a time-related phenomenon. During the first few months following stroke, the correlation was significant only among patients with left hemisphere lesions. At 3–6 months poststroke, however, the correlation between severity of depression and proximity of the lesion to the frontal lobe was significant in both the right and left hemisphere.

Although the structural or physiological basis for this clinical–pathological correlation has not been identified, it nevertheless constitutes an intriguing phenomenon perhaps related to mechanisms of

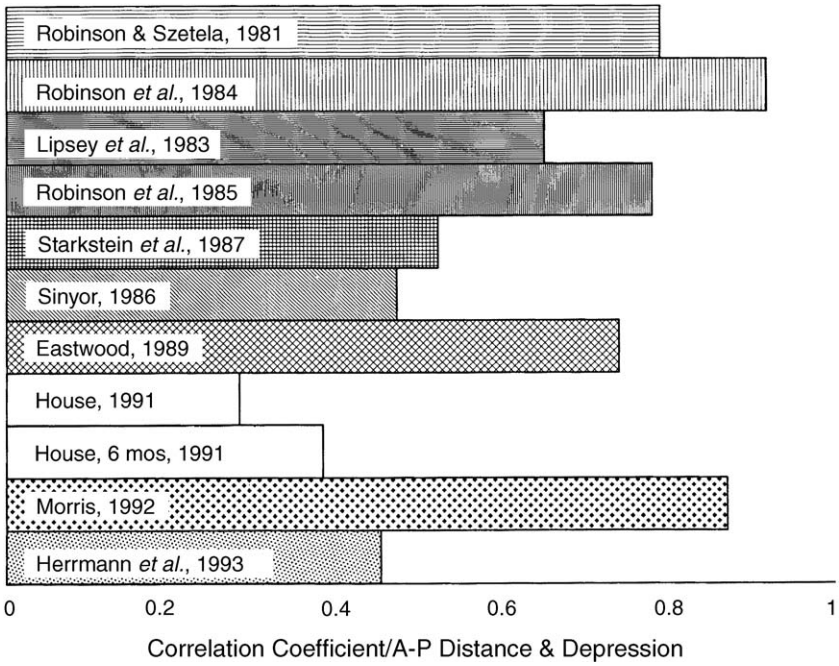

Figure 5 Magnitude of correlation coefficients between severity of depression and proximity of the anterior border of the brain lesion to the frontal pole (left hemisphere or combined left and right hemispheres) for all studies that have examined this correlation. All correlations were statistically significant and the magnitude ranged from relationships that would explain 8% to those that would explain 80% of the variance in depression severity. From Robinson (1998); reprinted with the permission of Cambridge University Press.

depressive disorder. It has been suggested that the pathophysiological basis for this linear correlation between severity of depression and proximity of the lesion to the frontal pole may be a consequence of frontal lesions producing more proximal injury to the norepinephrine- or serotonin-containing neurons and therefore greater depletions of these biogenic amine transmitters. Although other explanations might also be proposed to explain this phenomenon, the fact that multiple investigators have replicated this finding suggests that it may reflect some fundamental mechanism of mood regulation.

In summary, neuroimaging of structural changes in both primary and secondary depression has led to a number of intriguing clinical–pathological findings. Structural abnormalities of brain in primary depression and structural lesions in secondary depression have generally implicated dysfunction of the frontal cortex and basal ganglia in mood disorders. In addition, there may be a laterality effect on depression, with left hemisphere dysfunction associated with depression and right hemisphere dysfunction associated with mania. Alexander and De Long described five frontal–subcortical circuits that appear to play an important role in brain–behavior relationships: Each of these circuits involves the frontal lobe, striatum, globus pallidus, substantia nigra, and thalamus. Findings of abnormalities in primary and secondary mood disorders have suggested abnormalities in the function of one or more of these circuits (Fig. 1). These frontal brain areas associated with mood disorders also contain axonal projections from the biogenic amine-containing neurons located in the brain stem. Thus, frontal or basal ganglia lesions could disrupt function and release of noradrenergic, serotoninergic, or dopaminergic transmissions in the cortex. This combination of basal ganglia and cortical dysfunction associated with disruption of neurotransmitter mediation within the frontal and temporal cortex may provide a common mechanism for both primary and secondary depressive disorder.

E. Physiological Abnormalities

1. Background

The development of functional imaging techniques, including positron emission tomography (PET), single photon emission computed tomography, and xenon inhalation, has provided investigators with powerful tools to examine the physiological and biochemical

correlates of mood disorders. Most investigators, however, have used PET imaging with [^{15}O]-labeled water to measure regional cerebral blood flow or [^{18}F]fluorodeoxyglucose to measure regional brain metabolic abnormalities associated with mood disorders.

2. Positron Emission Tomography Studies

The most common findings of PET studies of patients with depression are caudate and prefrontal hypometabolism. One study examined brain metabolic activity in three types of depressive disorder: UP depression, BP depression, and obsessive/compulsive disorder with secondary major depression. This study demonstrated a decreased glucose metabolic activity in the anterior lateral prefrontal cortex in all three groups of patients compared to controls. There was also a significant correlation between left frontal cortical metabolic rate and Hamilton Depression Score. A study examining regional cerebral blood flow in patients with primary depression and controls found significantly reduced cerebral blood flow in the left anterior cingulate and left dorsal lateral prefrontal cortex. In addition to confirming the frontal and basal ganglia findings, another recent study reported hypometabolism in prefrontal cortex ventral to the genu of the corpus callosum in both familial BP and familial UP depression.

Studies of primary mood disorders have also identified regional brain abnormalities associated with disorders of both mental state (i.e., current clinical disorder) and trait (i.e., abnormalities that persist beyond the current clinical disorder). For example, a trait abnormality of increased blood flow in the left amygdala has been reported in patients with primary UP familial depression. On the other hand, treatment with antidepressants has been found to reverse a state of abnormality by returning blood flow in the left prefrontal cortex to control levels. A fluorodeoxyglucose study has also demonstrated a significant increase in the metabolic rate of the basal ganglia associated with treatment of depressive disorder. Another recent study of patients with UP depression demonstrated that rostral anterior cingulate hypometabolism uniquely differentiated depressed patients who did and did not respond to treatment.

Although receptor studies examining the pathophysiology of primary mood disorders have rarely been conducted, one study found an increase in mu opiate receptor binding in paralimbic areas in patients with UP depression.

Although secondary depressions have not been extensively studied using functional imaging techniques, PET studies have been conducted in patients with depression associated with stroke, Parkinson's disease, or Huntington's disease. A study of metabolic activity in patients with basal ganglia stroke demonstrated that patients with basal ganglia lesions not involving motor pathways (i.e., lesions of the head of the caudate, anterior internal capsule, or anterior or dorsal medial thalamus) had focal ipsilateral hypometabolism involving regions of frontal, temporal, or cingulate cortex. In contrast, patients with lesions of the motor pathways (putamen and posterior internal capsule) had widespread ipsilateral hypometabolism. When these patients with subcortical lesions were classified as having no mood disturbance, mania, or depression, patients with either depression or mania demonstrated hypometabolism in the temporal lobe. Patients with mania showed temporal hypometabolism in the right hemisphere, whereas those with depression showed bilateral temporal hypometabolism as well as cingulate hypometabolism.

Biochemical studies of patients with secondary depression have also been carried out using imaging of serotonin receptor binding. Serotonin S_2 receptor binding was examined in patients with unilateral stroke using ^{11}C-*N*-methylspiperone. This study found that patients with right hemisphere stroke had significantly greater ipsilateral to contralateral S_2 serotonin receptor binding in the temporal and parietal cortex than age-matched healthy controls or patients with left hemisphere stroke. However, there were no significant differences in the amount of S_2 receptor binding in the frontal cortex among patients with right or left hemisphere stroke or normal controls.

Another important finding from this study was that among patients with left hemisphere stroke, the amount of serotonin S_2 binding in the left temporal cortex was highly correlated with the Zung Depression Score (Fig. 6). This finding suggested that lower concentrations of S_2 receptor binding in the left temporal cortex were associated with higher depression scores. This only held true, however, for patients with left hemisphere stroke. There was no significant correlation between depression scores and S_2 receptor binding in the frontal, temporal, or parietal cortex following right hemisphere stroke.

This was the first study to demonstrate a lateralized biochemical response to brain injury in humans. It was also consistent with a previous finding in rats that ischemic lesions of the right but not left hemisphere produced significant depletions of norepinephrine in

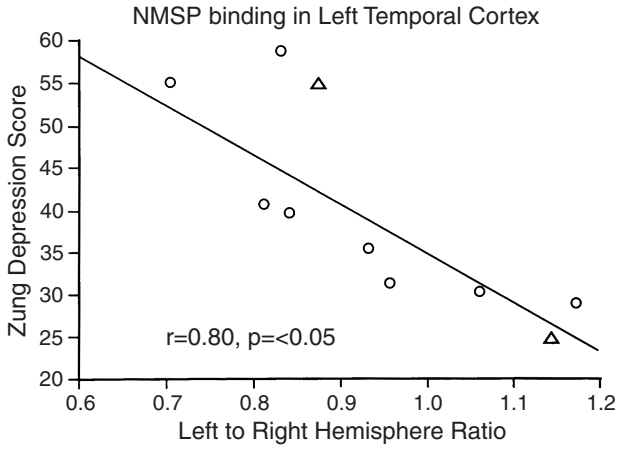

Figure 6 Relationship between Zung depression score and positron emission tomography measures of ^{11}C-*N*-methylspiperone binding to S_2 serotonin receptors in the temporal cortex following a left hemisphere stroke ($N = 8$). The binding is expressed on the horizontal axis as a ratio of binding in the left temporal cortex to binding in an identical region of the right temporal cortex. Lower numbers indicate less S_2 serotonin receptor binding. Lower numbers of S_2 receptors were associated with higher depression scores. The triangles indicate receptor changes in one patient who had spontaneous remission of a major depression. As the depression score fell from 55 to 25, the amount of serotonin S_2 receptor binding increased from 0.86 to 1.15. This patient, with a small left basal ganglia infarct, demonstrated that S_2 receptor binding may be a state marker for poststroke depression (data from Mayberg *et al.*, 1988, with permission of Cambridge University Press).

brain regions both ipsilateral and contralateral to the site of the lesion. Combining these findings from both human and animal studies, it has been hypothesized that left frontal cortical injury or left basal ganglia injury may produce mild to moderate depletions of both norepinephrine and serotonin (and perhaps dopamine). Depletions of serotonin resulting from left hemisphere injury may lead to serotonergic dysfunction in several uninjured brain regions including the temporal lobe. Temporal lobe dysfunction could then initiate changes in limbic circuitry (Fig. 1) through connections from the amygdala to the basal ganglia, thalamus, or orbital frontal cortex, and this could ultimately lead to the manifestations of depression. Right hemisphere lesions, in contrast, may initially produce even greater depletions of norepinephrine and serotonin compared with left hemisphere lesions. The combination of serotonin and norepinephrine depletion has been shown in rats to lead to greater upregulation of serotonin receptors than depletion of serotonin alone. Thus, large depletions of both norepinephrine and serotonin may lead to compensatory upregulation of S_2 receptors in the temporal and parietal cortex. This upregulation in uninjured cortex could lead to enhanced serotonergic function in the right temporal and parietal cortex and therefore block the development of depression.

In summary, functional imaging studies using patients with either primary or secondary mood disorders have, with a moderate degree of consistently, found abnormal activity in the frontal cortex (particularly in the left ventral inferior frontal cortical region) and basal ganglia. In addition, abnormalities have been reported in the cingulate, subgenual cortex, inferior temporal cortex, amygdala, and dorsal medial thalamus. These studies, as well as the structural imaging studies, are consistent with the previously stated hypothesis that frontal–striatal–substantia nigra–dorsal medial thalamus–prefrontal circuits form the anatomical substrate for mood disorders and that hypometabolic effects in the cortex produced by basal ganglia lesions disrupt the function of noradrenergic, serotonergic, and dopaminergic transmissions in the cortex, ultimately leading to either primary or secondary depression.

V. PSYCHOSOCIAL ASPECTS OF MOOD DISORDERS

Psychosocial factors have been correlated with the development and maintenance of mood disorders. Psychoanalytic theories of the etiology of depression concentrate on Freud's belief that the grievance of unresolved early losses undermines the patient's self-esteem. This theory explains that depression is an adult reaction that occurs when the patient is unable to tolerate the negative side of the ambivalence created from early lost objects.

Behavioral theories of depression are influenced by the concept of learned helplessness. Seligman showed that if an animal is repeatedly exposed to a painful stimulus from which it is impossible to escape, a passive acceptance of this stimulus occurs even when the condition is changed so that the animal can flee away from it. Therefore, patients who lack reinforcement of nondepressive behaviors, such as attention and affection, have problems responding positively to social challenges. Also, these patients learn that their depressive behaviors are rewarded with more attention from their significant others.

The cognitive model of depression maintains that biases in thinking play a central role in depression. Beck theorizes that early experiences lead to the development of schemata. These are stable negative

assumption or dysfunctional attitudes that develop during early life experiences and result in inflexible and negative views of the self, world, and future, increasing the patient's vulnerability to episodes of depression.

Although evidence suggests that depressed patients suffer an impairment of social adjustment, the impact of life events and social support on the course of depression is controversial. In their Cumberwell study, Brown and colleagues identified the following social factors that explained the more prevalent numbers of depression in working-class women compared to middle-class women: The working-class women (i) lacked an intimate relationship with a husband or cohabitant, (ii) had three or more children at home, and (iii) lost their mothers before age 11. Weissman and Paykel, using the Social Adjustment Scale, showed that depressed women had marital, parental, ocupational, social, and leisure adjustment deficits.

VI. THERAPY FOR MOOD DISORDERS

A. Antidepressant Drugs

1. Tricyclic Antidepressants

Introduced in 1959, the tricyclic antidepressants (TCAs) constituted the first line of treatment for depression until the appearance of the selective serotonin reuptake inhibitors in the 1980s. The first TCA to be introduced was imipramine, which was found to have antidepressant actions instead of sedative effects that were expected based on its structure analogous to phenothiazine. Currently, there are nine TCAs (imipramine, amitriptyline, desipramine, nortriptyline, clomipramine, trimipramine, doxepine, protriptyline, and amoxapine) and one tetracyclic (maprotiline) drug marketed in the United States. Central nervous system side effects are mostly due to their antimuscarinic action. Sedation, confusion, or seizures resulting from lowering of seizure threshold occur in about 15% of patients. Peripheral side effects include significant antimuscarinic effects on the cardiovascular system (arrhythmias and tachycardia) as well as blurred vision, dry mouth, constipation, and urinary retention.

2. Monoamine Oxidase Inhibitors

In 1952, Selikoff *et al.* reported that the antituberculosis agent iproniazid also possessed mood-elevating properties, and in 1965 Zeller explained its action as secondary to the inhibition of monoamine oxidase (MAO) enzymes. There are two isoenzymes: (i) MAO type A, which degrades mostly NE, epinephrine, and 5-HT, and (ii) MAO type B, which degrades mostly phenylethylamine, phentylamine, benzylamine, and phenylethanolamine. Tyramine and dopamine are nonselective substrates. The MAO inhibitors (MAOIs) can be classified according to the type of MAO inhibition they cause and whether the inhibition is reversible or irreversible. The available MAOIs in the United States are the hydrazine derivatives that are non-selective and have an irreversible action on the MAO enzyme. Moclobemide is a nonhydrazine MAO-A-selective and reversible compound, and deprenyl is useful in the treatment of Parkinson's disease because it increases the levels of dopamine in the CNS due to its MAO-B-selective effect in low doses. MAOIs have significant side effects and interactions. The increased availability of biogenic amines in the CNS causes an overstimulation with agitation and insomnia in some patients. Orthostatic hypotension is also a common side effect of this drug, which can precipitate falls in older people.

3. Serotonin Selective Reuptake Inhibitors

The serotonin selective reuptake inhibitors (SSRIs) are considered by most clinicians to be the first choice for the treatment of depression because of their relatively benign side effect profile. Their mechanism of action is similar to that of the TCAs but with a highly specific 5-HT reuptake inhibition action preventing the degradation of this neurotransmitter by MAO. There are currently five SSRI compounds marketed in the United States: fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram. Since these SSRIs differ in their potency, selectivity, and side effects profile, patients intolerant to one compound of this group can often be treated with another. SSRIs have a significant cytochrome P450 inhibition action that can result in a toxic level of coadministered drugs, such as alcohol, antihistamines, and anticholinergics.

B. Mood-Stabilizing Drugs

1. Lithium

After observing that lithium produced placidity in guinea pigs, in 1949 Cade suggested that this compound could possess antiexcitement properties in

humans. Although lithium was introduced as a treatment for acute mania, the antimanic effect is maximal after 7–10 days, thus, faster acting agents such as neuroleptics are often used in conjunction with lithium. Lithium has been shown to provide effective prophylaxis for BP disorder. Bipolar lithium-treated patients have a risk of relapse of 34–36% compared to more than 79% in comparable patients given placebo. Lithium has a narrow therapeutic index, however, and high levels can produce seizures, coma, and eventually death. Even when it is present in its therapeutic concentration range of 0.8–1.2 mEq/liter, patients treated with lithium can have gastrointestinal side effects, such as vomiting and/or diarrhea, endocrine side effects, such as inhibition of thyroid function, renal side effects, such as polyuria with polydipsia, and CNS side effects, such as drowsiness, memory deficits, and tremors.

2. Alternative Mood-Stabilizing Drugs

Anticonvulsants are a new choice for the stabilization of mood in BP disorder. Carbamazepine is an anticonvulsant with a tricyclic structure similar to that of imipramine that can be used in lithium-resistant or rapid-cycling BP patients.

The only placebo-controlled study with carbamazepine reported that 60% of a population of BP patients receiving this drug did not relapse compared to 22% of patients receiving placebo.

Another anticonvulsant that has been shown to be effective as a mood-stabilizing drug is valproate. The first double-blind study of valproate in acute mania found a significant effect of this drug in the treatment of acute mania as well as prophylactic effects in BP patients. Although the mechanism by which valproate produces this mood-stabilizing action is unknown, recent studies suggested that the increased CNS levels of γ-aminobutyric acid (GABA) appearing after the inhibition of its degradation by this drug might play an important role. Although it is usually well tolerated, it can produce irreversible hepatic failure that can be fatal.

C. Electroconvulsive Therapy and Rapid Transcranial Magnetic Stimulation

Since its introduction as a clinical tool by Cerletti and Bini in 1938, electroconvulsive therapy (ECT) has been the most effective treatment method for mood disorders. In a review of the literature comparing treatment for depression with real ECT or simulated ECT, placebo, TCAs, and MAOIs, Fink showed that real ECT was significantly more effective in each comparison. Studies have also shown that ECT is equally effective in depressed UP and BP patients. The mechanism of action of ECT is not completely elucidated, but animal studies have found enhancement of brain concentrations of several neurotransmitters, such as norepinephrine, serotonin, dopamine, and GABA. These studies suggest that ECT might produce similar changes in neurotransmitter receptors as those produced by antidepressant drugs. The side effects of ECT are generally less severe than those that accompany the use of antidepressants, although loss of memory is a common complaint.

Rapid transcranial magnetic stimulation (rTMS) is a new noninvasive technique that transfers energy from current in a magnetic coil to cortical neurons. The strength of the induced current is a function of the current in the stimulating coil, which develops about 1.5–2 T. The resulting electrical current is able to activate neurons up to 2 cm from the surface of the cortex. Since the energy used in rTMS is approximately 1 million times less than that used for a stimulus with ECT, this method has proven to be painless, thereby allowing its use without concomitant general anesthesia. Pascual-Leone *et al.* reported that left prefrontal stimulation has been shown to produce a significant clinical response in patients with UP medication-resistant psychotic major depression.

In summary, there are a wide variety of treatments for mood disorders that are mediated by brain mechanisms. The TCAs and MAOIs retain an important role for patients who do not respond to SSRIs. ECT remains the treatment of choice for patients who cannot take medications or who are treatment resistant. Finally, TMS is a new treatment approach with benign side effects and may play an important role in future treatment of mood disorders.

VII. SUMMARY

The relationship between brain and mood disorders has been investigated based on numerous brain-related functions, including genetics, neurotransmitters, hormonal activity, anatomical structure, physiological functions, psychosocial aspects, and treatment

response. Integrating these diverse areas of investigation into a coherent mechanism of mood disorders has not been accomplished, but significant progress is being made in all these areas of study. Since mood disorders are based on clinical and not laboratory criteria, the definition and classification of mood disorders play a central role in determining which brain changes are associated with mood disorder, and classification of mood disorders, continues to be an evolving area. The study of secondary depression, in which there is a well-defined neuropathology, has also contributed to our understanding of the brain-related mechanism of mood disorders. The exponential growth of genetic research has generated numerous investigations searching for the fundamental abnormality that leads to mood disorders. These studies continue to search for multigenic explanations for these disorders. Similarly, the development and growth of both structural and functional brain imaging techniques have led to a general consensus that the anatomical substrate of mood disorders involves dysfunction of the frontal cortical and basal ganglia–thalamic neuronal loops. In addition, neurotransmitter and neuroendocrine studies have established that changes in brain biochemistry are important elements that must be incorporated into any comprehensive explanation of the brain-related mechanism of mood disorders. Finally, one of the most successful areas of research in mood disorders is empirically based treatment. Although effective treatment suggests neurochemical mechanisms of mood disorder, the fact that controlled treatment trials have established a firm scientific basis for treatment selection has allowed clinicians to effectively manage these disorders while we await a fundamental understanding of the brain mechanisms involved.

GLOSSARY

adaptation The change in sensitivity of a neuron (or of the animal as a whole) in response to prolonged viewing of a stimulus.

bandwidth A measure of the neuron's selectivity for a property such as motion direction. A large bandwidth refers to a neuron that responds to a broad range of directions, whereas a narrow bandwidth refers to a neuron that responds to a more selective range of directions.

coherent motion A type of motion in which all the elements move in the same direction and at the same speed.

contrast A measure of the deviation of local light intensity from the average intensity.

direction selectivity A preferential response to light moving in a narrow range of directions.

gabor The profile described as the product of a sine wave grating and a Gaussian that is often used to describe the spatial sensitivity of neurons in striate cortex.

gaussian A smoothing function that has a bell-shaped profile described by a normal distribution.

grating A pattern of parallel light and dark bars.

heading direction The direction in which the observer is moving.

incoherent motion A type of motion in which the elements move in different directions or with different speeds. Each element's velocity is randomly changed over time.

mask A pattern that occurs closely in space or time to a test pattern and affects the response of the neuron (or of the observer) to the test.

motion transparency The perception of transparent sheets moving over one another produced when two sets of elements move in widely different directions or speeds.

optic flow The motion on the retina produced by observers moving relative to their environment.

preferred direction The direction of motion that evokes the strongest response in a motion-sensitive neuron.

psychometric function A function relating perceptual performance to a physical stimulus variable. The measure of perceptual performance is the proportion of perceptual decisions (e.g., rightward/leftward judgments or correct/incorrect responses).

sine wave (sinusoidal) grating A pattern of light and dark bars in which the contrast across the bars varies as a sine wave.

spatial receptive field The region of the visual field in which a visual stimulus evokes a response in a neuron.

space–time orientation A property of a receptive field that makes it sensitive to a particular direction and speed. The receptive field of the motion-selective unit has a spatial response profile that changes with time.

spatial frequency A measure that is inversely related to the width of the bars of a grating. The wider these are, the lower the spatial frequency. It is measured in cycles per degree of visual angle.

temporal frequency The analog of spatial frequency in time. It refers to the rate of alternation of a stimulus and is expressed in cycles per second or hertz.

threshold A criterion performance level between chance and perfect performance that is used to compare data across different conditions.

visual angle The angle that an object subtends at the eye.

Everyday visual experience is replete with moving objects. A successful interaction with the outside world depends on the accurate perception of motion. Motion information is critical in estimating one's heading direction, in estimating the time to collision with a moving object, in providing input to the vestibular and eye movement systems, and in breaking camouflage. Motion information also helps to order surfaces according to depth, and to reveal the three-dimensional (3D) structure of objects. Although the visual system of even the fly is capable of motion processing, primates have evolved sophisticated motion processing systems that are represented in multiple cortical areas.

I. INTRODUCTION

One of the first demonstrations of a motion-selective process was the waterfall illusion. After watching a cascading waterfall for a few seconds, Robert Addams shifted his gaze to the rocks on one side of the waterfall and was surprised to find that the stationary rocks appeared to move upwards, in the direction opposite to the water flow. This phenomenon, called the motion aftereffect, has been extensively studied. Prolonged viewing of motion in one direction (the adapting stimulus) desensitizes the observer to motion in that direction, such that a stationary stimulus appears to move in the opposite direction. Recent studies by Bob Sekuler and coworkers have shown that this desensitization occurs over a narrow range of directions centered on the direction of the adapting stimulus. These results suggest that the underlying motion sensors are direction selective and respond only to a narrow range of directions.

Another motion illusion is that stationary flashing lights on movie theater marquees appear to move. This phenomenon, called apparent motion, occurs when an object (such as a flashing light) appears briefly at one location, and after a short time delay a similar object appears at another location. In the case of theater marquees, the time and distance between adjacent flashing lights are large, so we can readily distinguish this motion from a real moving object. If the space and time intervals between successive presentations are small, apparent motion is indistinguishable from continuous motion. Although both television (NTSC 60 Hz or PAL 50 Hz) and movies (24 Hz) consist of animated sequences of static images, we generally perceive them as real motion. The perceptual equivalence of the real and sampled motions suggests that motion-selective neurons are insensitive to the additional information present in the continuous motion representation. In fact, the spatial and temporal sampling rates above which smooth and sampled motion are indistinguishable correspond to the human window of visibility—the limits of spatial and temporal frequency sensitivity of the human visual system (approximately 60 Hz and 50 cycles/degree).

Figure 1 provides a brief outline of the motion processing pathways in primates. It will serve as a road map as we discuss some of the important anatomical areas involved in motion processing. The pathway for visual motion processing in primates starts with the two main cell types in the retina: the magnocellular neurons that project mainly to areas involved with motion and depth processing and the parvocellular neurons that project mainly to areas involved with form and color processing. The magnocellular neurons project to two distinct layers in the lateral geniculate nucleus (LGN) in the thalamus on their way to cortex. From the LGN, these neurons project to layer 4ca in striate cortex, which is the first visual area in the brain (V1). About one-third of V1 neurons are selective for the direction of motion, but due to their small receptive fields they respond only to "local" motion. The V1 neurons in turn project to the middle temporal area (MT), which is an extrastriate area that is specialized for motion processing in primates. About 90% of the neurons in area MT are selective for the direction of motion; furthermore, these neurons are arranged in columns, according to the preferred directions of motion. There is a smooth gradation of preferred direction across neurons in neighboring columns. Neurons in area MT can detect combinations of local motions as well as the motion of a target relative to the background. The adjoining medial superior temporal area (MST) receives projections from area MT as well as from eye movement areas, such as the superior colliculus, the lateral intraparietal area, and the frontal eye fields. Area MST has neurons capable of analyzing

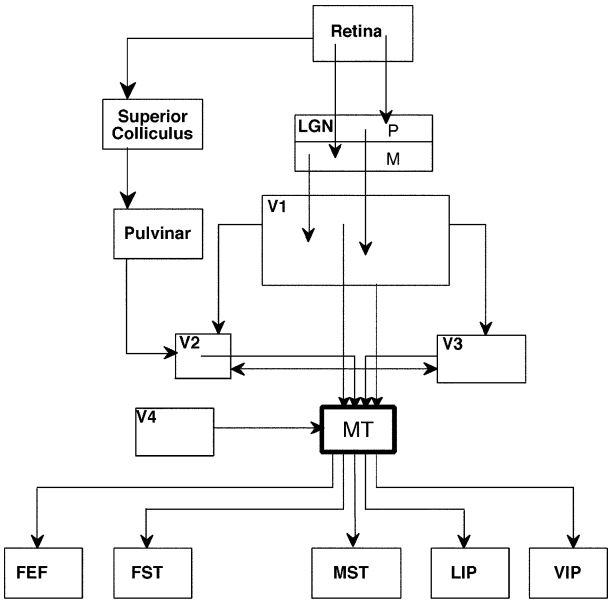

Figure 1 A broad outline of the brain pathways involved in processing visual motion information. Light is detected by the retina (top), which is connected to the lateral geniculate nucleus (LGN), which passes information to the visual cortex. Area V1 is the earliest cortical locus. From it, information is passed to the middle temporal area (MT) and the middle superior temporal area (MST), which are areas that specialize in the processing of motion information. The arrows show only the information going in the feedforward direction, but there are also feedback connections within cortical areas as well as from area V1 to the LGN. FST, fundus of the superior temporal area; VIP, ventral intraparietal area; LIP, lateral intraparietal area, FEF, frontal eye fields [modified with permission from Snowden, R. J. (1994). Motion processing in the primate cerebral cortex. In *Visual Detection of Motion* (A. T. Smith and R. J. Snowden, Eds.). Academic Press, London].

different patterns of optic flow and potentially estimating heading direction. This area also generates signals for smooth pursuit eye movements. During the course of this article, we will pose the problems that a generic motion analysis system must solve and present plausible candidate locations in the primate visual pathway. Although it is tempting to assume that a neuron with a particular property is responsible for the animal's sensitivity to that property, we believe that the animal's sensitivity is likely determined by a population of neurons sensitive to that property.

This article first discusses simple motion-related processing and then discusses more complicated motion phenomena. The organization of this article also reflects a progression from lower to higher visual areas. However, we must state that visual processing is not purely hierarchical; as evidence accumulates for certain interpretations of the visual scene, feedback from higher areas modulates the responses of lower areas, thus strengthening an emerging percept. The hardware for this interaction is certainly in place; there is abundant evidence for feedback connections from higher areas to lower areas. Also, perception might depend on more than the visual stimulus. The observer's past experience with visual stimuli can influence the perception and interpretation of a visual scene. For example, when a moving object disappears for a brief time behind an opaque occluder, there is no visual motion information during its traverse behind the occluder. However, we interpret the image correctly as an object moving smoothly behind an occluder rather than as an object that disappears for a brief time and coincidentally reappears with a similar trajectory at the other side of the occluder. This certainly has to do with our experience with the trajectories of moving objects and with occluders.

II. MEASUREMENT OF MOTION

A. Receptive Field Structure

Several biological systems need to measure motion, whether it is a frog trying to catch a fly, a prey trying to avoid a predator, or a human trying to catch a baseball. Motion is the change in position of an object over time. Therefore, one way to measure motion is to identify an object, or a complex feature of an object, measure its location at one instant in time and again at another instant in time, and use these measurements to compute both the speed and direction of motion. Human visual motion sensors do not employ this strategy of detecting high-level features and keeping track of their locations over time, but instead compute motion signals by responding directly to local changes in intensity over time. Evidence from physiology shows that although the earliest neurons sensitive to motion respond to a wide range of stimuli, they respond best to a narrow range of spatial sizes and temporal intervals. The responses of most of these neurons can be described by simple receptive fields, which are oriented in space–time and are selective for both direction and speed. Many experiments have characterized these neurons' receptive fields by determining their responses to bars of varying widths, orientations, and speeds.

As visual information is passed from the retina to higher level processing areas, the receptive fields of motion-sensitive neurons become increasingly complex. Here, we focus on how the brain achieves motion-

sensitivity in the striate cortex. The responses of motion-sensitive striate cortex cells are directionally *selective*, which means that their response to moving stimuli depends on the direction of motion. Motion-sensitive cells have large responses to motion in their preferred direction and much smaller responses to motion in the opposite direction. Direction selectivity requires receptive fields to be space–time oriented.

To appreciate how a space–time-oriented receptive field is built, we first consider the responses of nondirectionally selective neurons whose responses are independent of the direction of motion. These cells have simpler receptive fields that are space–time separable, which means that their space–time receptive field is the product of a spatial receptive field with a temporal weighting function. Readers are probably familiar with the concept of a spatial receptive field. The spatial profile of many V1 receptive fields is well characterized as a two-dimensional (2D) Gaussian, multiplied by a sinusoid as shown in Fig. 2A. This receptive field is localized in space and responds best to a particular orientation. The cell's preferred orientation and width are determined by the orientation and spatial frequency of the sinusoid. Neural responses to stimuli also depend on time. The neural response to a brief flash of light extends over a period of time (about 100 msec) and is described by a temporal weighting function (or temporal impulse response function). Space–time-separable receptive fields are the product of this spatial receptive field with a temporal weighting function. The temporal weighting function is generally modeled as a biphasic response with a positive response that is followed by a more extended negative response. Two examples of temporal response functions are shown in Fig. 2B. For space–time-separable receptive fields, the spatial receptive field polarity changes with time, but its profile does not change (i.e., it is not oriented along the time dimension). Figure 2C shows an x–t plot of a typical space–time-separable V1 receptive field that is selective for a static vertical bar. This space–time-separable receptive field is unselective for motion direction (i.e., it responds similarly to leftward and rightward motion). This can be seen by comparing such a receptive field profile to Fig. 3, which shows x–t plots of a bar that is moving rightward (Fig. 3B), moving leftward (Fig. 3C), or is static (Fig. 3D).

In contrast, a motion-sensitive cell responds strongly to motion in its preferred direction but weakly or not at all to motion in the opposite direction. Figure 4B shows four examples of motion-sensitive receptive fields that are oriented in space–time; their response at each spatial location depends on time. Such a neuron is selective for a particular velocity and direction. Achieving a spatial response that changes with time is difficult because stimulation of a particular receptive field region must produce a positive, negative, or zero response depending on the time. One way to construct a space–time-oriented receptive field is to combine space–time-separable receptive fields (Fig. 4A shows four space–time-separable receptive fields). Space–time-oriented receptive fields can be constructed by combining (either adding or subtracting) the outputs of two such cells, such that the response of the second is shifted in space and time relative to the first (Fig. 4B shows four different space–time-oriented receptive fields constructed by combining pairs of the receptive fields shown in Fig. 4A). Space–time-oriented receptive fields are selective for motion direction, but their responses are polarity specific; their response to a dark bar is inverted compared to their response to a bright bar. To detect the motion of an object reliably, the neuron's response should not depend on the polarity of the moving bar. One way of achieving this is to square the response. It appears that the visual system achieves a polarity-insensitive filter by taking the sum of the squared responses of the two filters shown at the top (or bottom) of Fig. 4B. This measure based on the squared responses of local direction- and speed-selective units is called motion energy. Ted Adelson and Jim Bergen proposed that this motion energy stage is followed by an opponent stage that takes the difference of local detectors tuned to opposite directions (e.g., the difference between rightward and leftward responses). Physiological measurements support the existence of space–time-oriented receptive fields that compute motion energy, but they do not support the existence of an opponent energy stage.

B. Direction Coding

Bob Sekuler and coworkers measured the human ability to discriminate the direction of motion of large patches of moving dots. They showed that observers could discriminate directions that were 1 or 2° apart. They estimate that the bandwidth of directionally selective mechanisms is about 60°, and that 12 such mechanisms evenly distributed about 360° can account for human direction discrimination. Humans likely achieve their sensitivity to small direction differences by comparing the patterns of activation across these broadly tuned mechanisms. This psychophysical bandwidth estimate is consistent with physiological

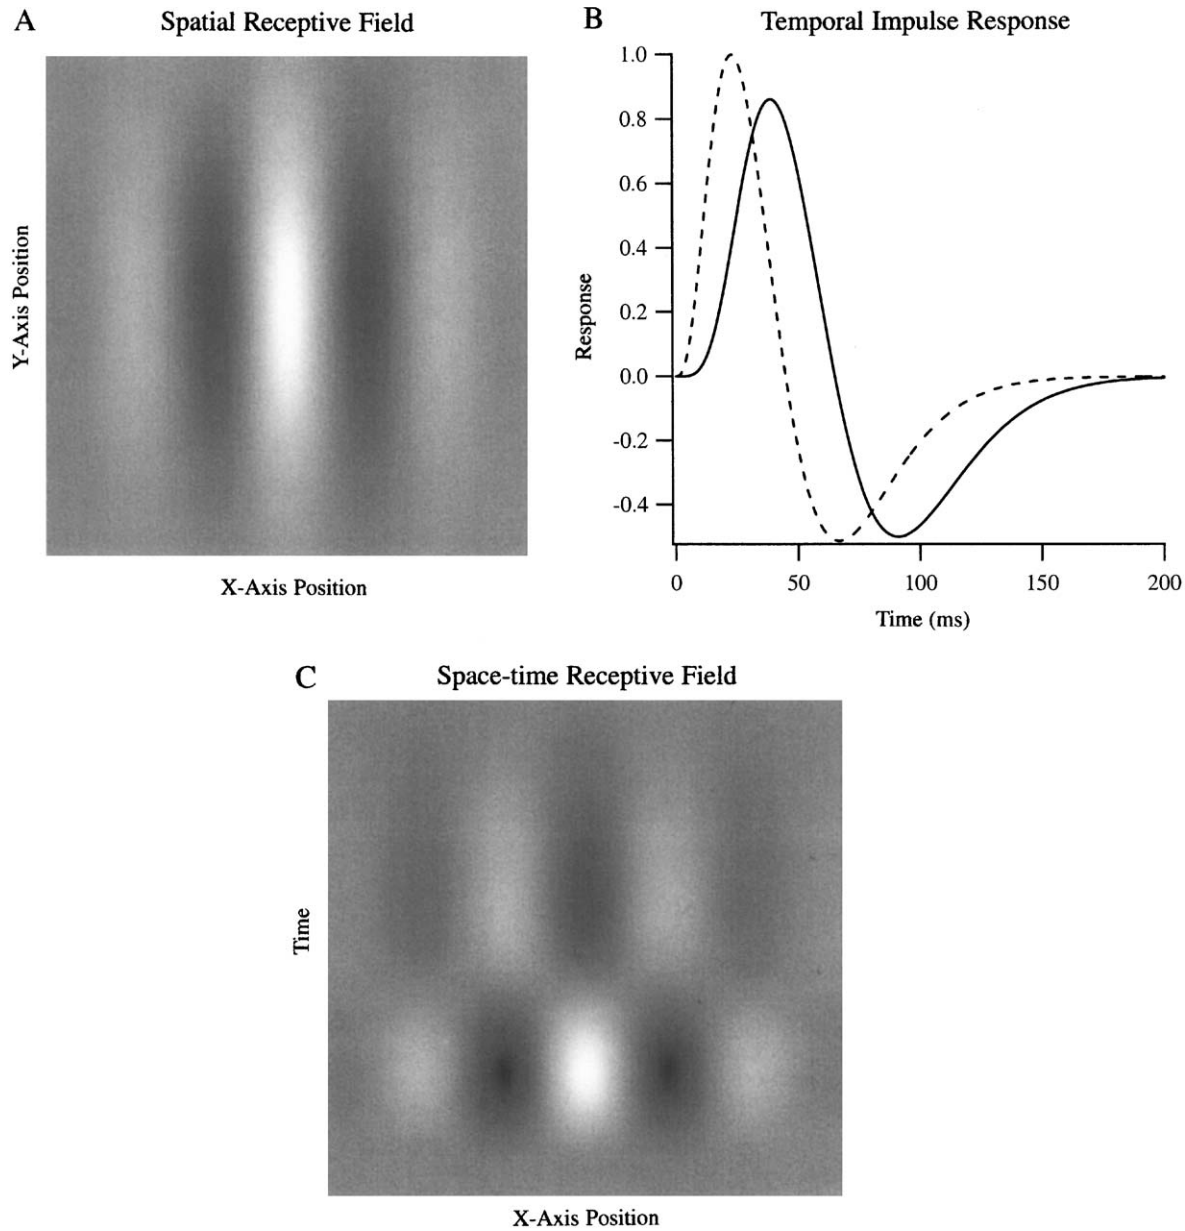

Figure 2 (A) A spatial receptive field. This is an x–y plot of a neuron's response to a spot of light at different positions. In general, the neuron's response to a spatially extended stimulus is computed by multiplying the stimulus contrast at each position by the receptive field value and summing over all receptive field locations. Bright regions indicate excitatory responses, whereas dark areas indicate inhibitory responses. The receptive field shown is a vertical spatial Gabor in cosine phase: $R(x,y) = \exp(-(x^2 + y^2)/\sigma^2) \cdot \cos(2 \cdot \pi \cdot f \cdot x)$, where σ is related to the spatial width of the Gaussian and f is the spatial frequency of the sine wave. This receptive field responds strongly to bright vertical bars with widths matched to the cell's excitatory center ($\sim 0.5/f$). (B) Two temporal weighting functions described by Adelson and Bergen. The response amplitude as a function of time to a brief pulse at time 0 is plotted. For temporally extended stimuli, the neuron's response at a given time is the sum over previous times of the weighting function multiplied by the stimulus contrast. The two temporal response functions shown have different delays: The dashed line function's response is maximal at 23 msec, whereas the solid line function's response is maximal at 39 msec. (C) An x–t plot of a space–time separable receptive field. This receptive field is unselective for direction of motion and responds best to a static bar. It was constructed by multiplying the spatial receptive field shown in A by the temporal impulse response function shown by the solid line in B and taking an x–t slice through the resulting x–y–t space.

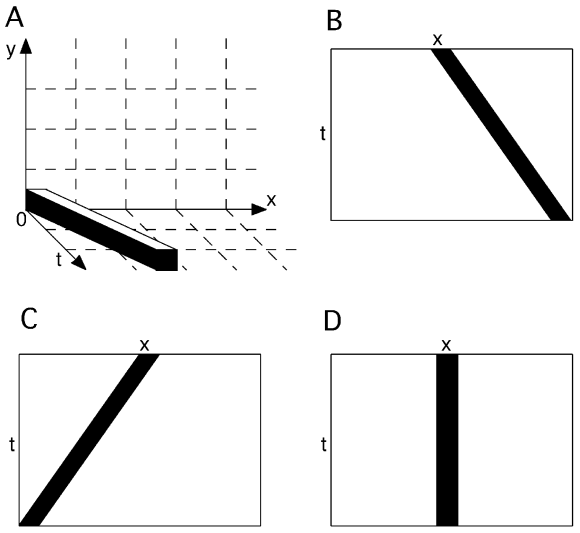

Figure 3 (A) A space–time plot of a dark rectangle translating rightward. It starts at x position = 0, and its x position (horizontal position) increases with time, whereas its y position (vertical position) remains constant. (B) An x–t plot of the rectangle's motion created by taking a slice through the space–time plot at a constant y value. Note that the x axis is horizontal and the t axis is vertical. The origin is at the midpoint of the x axis. Rightward motion starts at $x = 0$ and lies along a line that is tilted down and to right in this plot. (C) Leftward motion starts at $x = 0$ and lies along a line that is tilted down and to the left. (D) A static rectangle whose position remains fixed at $x = 0$. Because its position does not change with time, its graph is a vertical straight line.

estimates that show that primate MT neurons are arranged into direction columns according to their preferred directions of motion. There is a smooth gradation of preferred direction across neurons in neighboring columns. For similar moving dot stimuli, physiological estimates of the direction bandwidth of MT neurons range from 40 to 52°.

C. Speed Coding

Suzanne McKee and coworkers showed that humans are very sensitive to changes in speed and can discriminate a 5% speed difference despite small variations in the contrast, duration, and temporal frequency content of the stimulus. Currently, the way in which the brain processes and codes speed information is less well understood than the neural processing and coding of the direction of motion. Although the space–time-oriented receptive fields of motion energy detectors and complex cells in striate cortex of the cat do respond optimally to a unique velocity, the output of a motion energy unit also depends strongly on both the contrast and size of a moving stimulus. To extract velocity information, which is independent of stimulus contrast and size, Ted Adelson and Jim Bergen proposed a velocity computation stage that calculates the ratio of the outputs of pairs of motion-sensitive and static neurons. If the response of both the static and motion-sensitive cells depends equally on contrast and size, then this divisive normalization largely eliminates the effect of contrast and size on the output of the velocity computation stage. Nonetheless, large changes in contrast affect estimates of perceived speed, with higher contrasts associated with higher perceived speeds.

For a drifting sine wave grating, speed is the ratio of its temporal frequency to spatial frequency. Although earlier models proposed that the visual system codes speed by directly measuring temporal frequency, there is currently robust evidence that the visual system is sensitive to speed per se and not to the combinations of spatial and temporal frequency that characterize the motion. Several studies working with moving bars and dots have provided evidence for speed selectivity in areas V1 and MT. However, these studies do not distinguish between the possibility that the neurons are responding to changes in temporal frequency rather than speed. Bill Newsome and Tony Movshon have found evidence for MT neurons that are tuned to the speed of a moving grating rather than to its temporal or spatial frequency. Further experiments are needed to establish that MT is indeed the site that encodes speed.

III. INTEGRATING LOCAL MOTION SIGNALS

A. The Aperture Problem

As mentioned earlier, there is evidence for space–time-oriented units in visual area 1 (V1), the earliest cortical processing area for visual information. This area has units with small receptive fields that respond best to bars or edges that move in the cell's preferred direction within the receptive fields. Thus, these small units do not directly signal the motion of complex real-world objects but respond only to the motion of image fragments that fall within the aperture that is their receptive field. The problem that a local neuron faces is evident if one views the motion of an extended edge through an aperture. The direction of motion is ambiguous. This is the aperture problem, and it is

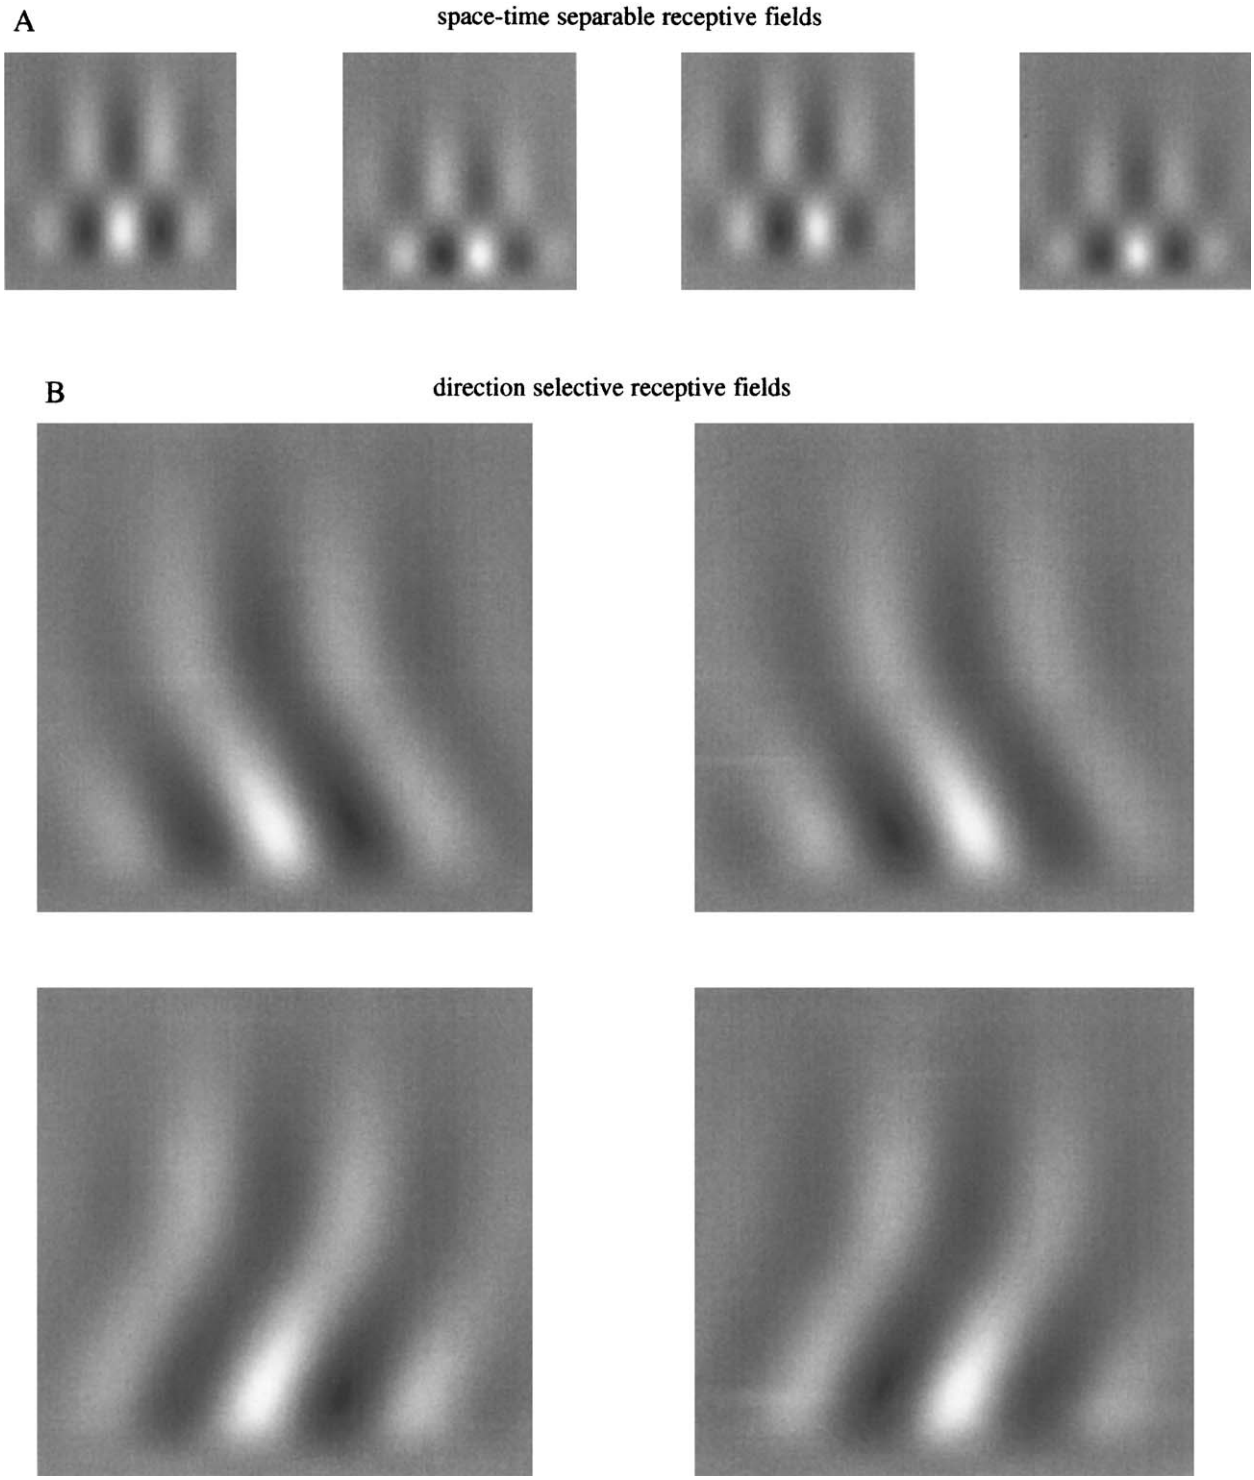

Figure 4 (A) Four space–time separable receptive fields are shown as x–t plots. These receptive fields were constructed by combining sine and cosine phase spatial receptive fields with the two temporal impulse response functions shown in Fig. 2B. All four receptive fields are not oriented in space–time and therefore are not direction selective. (B) Four direction selective receptive fields. The top two are selective for rightward motion (motion in the positive x direction), whereas the bottom two are selective for leftward motion (motion in the negative x direction). These receptive fields were constructed by taking the sum or difference of pairs of space–time separable receptive fields shown in A.

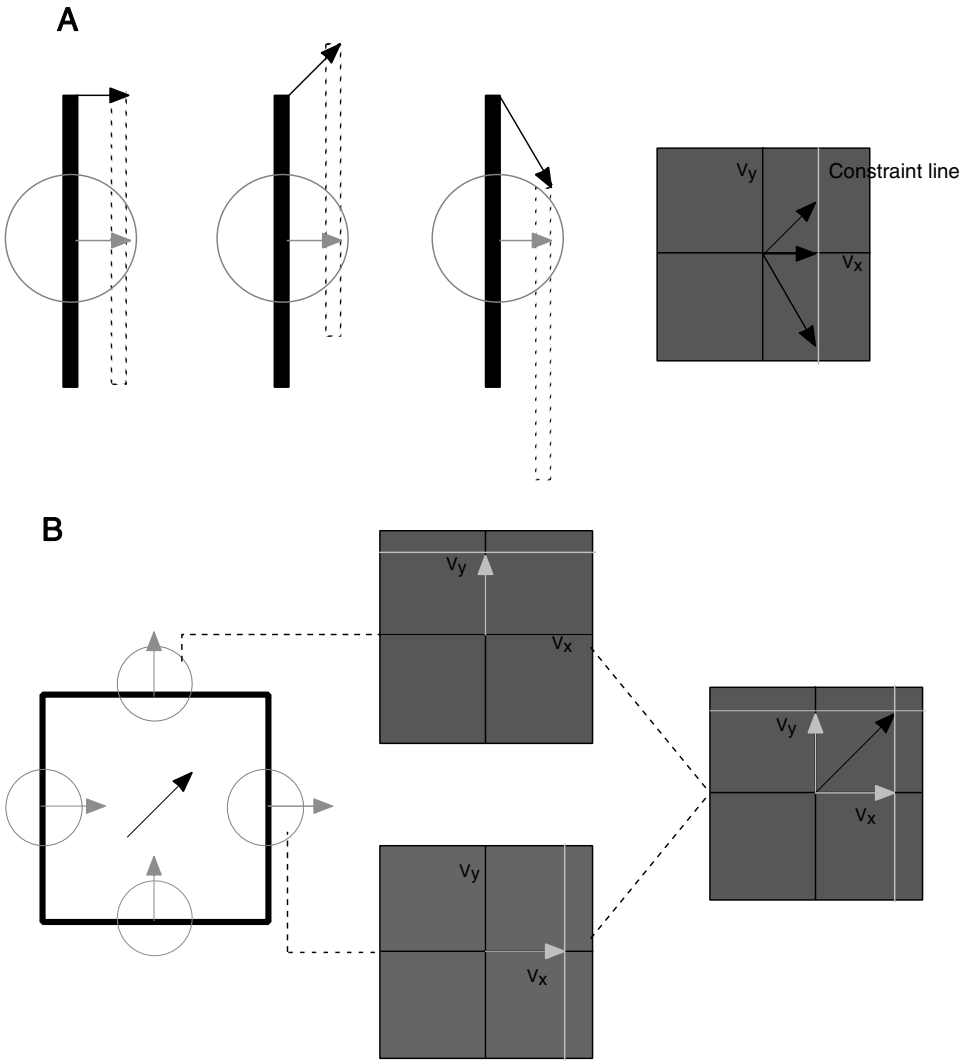

Figure 5 The aperture problem (A) Three instances of a vertical bar (thick black bar) translating in different directions, which all give rise to the same component of horizontal motion. The black arrows depict the true motion of the bar, whereas the gray arrows depict the horizontal component of the motion. The circles represent the spatial extent of a neuron's receptive field. The motion of the bar within this receptive field is identical for all three directions of bar motion. In the leftmost panel the true motion and the motion detector output are identical because the motion direction is orthogonal to the bar orientation. In the second panel the true motion is up and to the right and has a higher speed than in the first case, such that the horizontal component of motion in these two cases is the same. In the third panel, the bar is moving down and to the right but again has a horizontal component of motion equal to that of the first case. In general, an extended moving bar viewed through a small aperture provides only the component of motion perpendicular to the bar orientation. This is the aperture problem. Local measurements of motion within a restricted receptive field are thus consistent with many possible motion directions. As shown in the rightmost panel, all physical velocities with the same horizontal component lie along a constraint line that is parallel to the orientation of the bar. A motion detector tuned to rightward motion cannot distinguish between these three velocities or in fact any velocity that has an equivalent horizontal component. (B) Solving the aperture problem. The figure on the left shows a square translating diagonally upwards. As discussed for A, a detector responding to a single edge of the square can only code the component of motion perpendicular to the orientation of the edge. None of these individual detectors can signal the square's true motion, but its motion can be recovered by combining the constraints defined by the motion of at least two edges. The middle of the figure shows the constraint lines corresponding to the top and right edges of the square. The figure on the right shows that the square's true motion is determined by the intersection of these two constraint lines.

shown in Fig. 5. Figure 5A shows a moving vertical bar. The circle represents the receptive field of a motion unit that is selective for the motion of vertical stimuli. Since the preferred motion direction is perpendicular to the preferred orientation, a unit that is selective for vertical bars responds best to horizontal motion.

Figure 5A shows that this unit responds similarly to a small rightward motion as it does to a much larger diagonal (and rightward) motion. The true direction of object motion can lie anywhere along a constraint line parallel to the moving edge.

The directional ambiguity associated with local motion measurements can be resolved by combining motion estimates from more than one moving edge (Fig. 5B). Consider the case of a square that is moving diagonally upward. It has four edges at two different orientations. Local motion units that are selective for these orientations can only code the direction of motion orthogonal to these edges. Each of these measurements defines a constraint line. The intersection of these constraint lines gives the true direction of motion. The primate visual system also seems to implement such a solution. Units in V1 might detect motion of the top and bottom edges as upward and the motion of the left and right edges as rightward.

There is evidence that a proportion of units in the MT area of the brain, an area specialized for motion processing, combine these two component motions to give the true motion of the object. This corresponds to the direction specified by the intersection of constraint lines. Thus, these neurons are sensitive to the motion of 2D patterns. These pattern units respond best when the true direction of stimulus motion is in their preferred direction. Thus, they respond well to a single bar moving in their preferred direction and to a combination of bars whose intersection-of-constraints direction is their preferred direction. Furthermore, the receptive fields of cells in area MT are on average three times larger than those in corresponding retinal locations in V1, allowing them to integrate motion over a larger area. Their sensitivity to multiple directions of motion and their larger receptive fields make MT neurons well suited to solving the aperture problem. That humans are not normally subject to the aperture problem is proof that the primate visual system has implemented a solution.

B. Integration across Space

The early processing of motion is local; receptive fields of motion-sensitive neurons in area V1 are small (approximately 0.3° at an eccentricity of 1°). Receptive fields at comparable eccentricities in area MT are at least a factor of 3 larger. Although the pooling of motion signals across space reduces the accuracy of local motion estimates, it is useful for measuring large field motion in the presence of noise. Bill Newsome and colleagues demonstrated the ability of neurons in area MT to integrate local motion signals. Their stimulus was a large patch of dots, which were divided into two groups, signal and noise. Each noise dot was plotted at a new random position in each frame, but the signal dots all moved in a consistent direction. Awake behaving monkeys were trained to respond to the direction of motion of the signal dots and the response of individual neurons was recorded. The solid circles in Fig. 6A plot the proportion of correct trials as a function of the percentage of correlated dots. The solid curve through these points is the psychometric function. This function is usually summarized by the coherence threshold, which is the smallest fraction of signal dots that supports criterion performance in the animal. These researchers also showed that a neuron with a preferred direction that matched the signal had a response that increased with the proportion of coherent dots in the display. Furthermore, from the distribution of the neuron's responses to stimuli of various coherence levels, they were able to construct a neurometric function, the equivalent of a psychometric function for a neuron. The open circles and dashed line in Fig. 6A represent a neurometric function, which plots the probability that the neuron's response to stimulus motion in its preferred direction is larger than its response to stimulus motion in the opposite direction as a function of the stimulus coherence level. Thus, a neurometric coherence threshold can be measured in a manner analogous to the behavioral threshold. The resulting neurometric thresholds for the most sensitive MT cells are similar to the psychometric thresholds of awake behaving animals, and both are significantly lower than those predicted from measurements of local V1 units. This makes a good case for the role of MT in the integration of local motion signals.

Two further studies strengthen the role of MT neurons in the integration of this large field stimulus. Punctate lesions in area MT caused severe deficits in the ability of the animal to do the task when the stimulus was presented in the visual field location corresponding to the lesion site. The corresponding location in the (intact) contralateral hemifield served as a control; the monkey's response was unimpaired when the stimulus was presented at this location. Furthermore, electrical microstimulation of a neuron increased the probability that the monkey's perceptual response would be in the stimulated cell's preferred direction. Figure 6B plots psychometric functions with and without stimulation (dashed and solid lines, respectively). Note that the y axis is the proportion

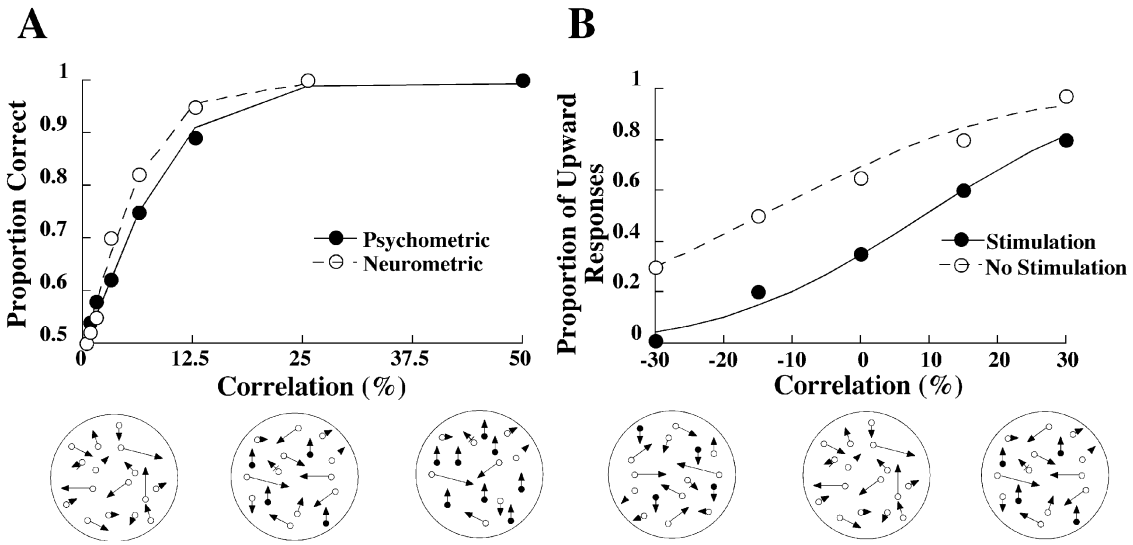

Figure 6 (A) Behavioral and neural responses to the same motion stimuli. The proportion of correct responses is plotted as a function of varying motion coherence as illustrated below the horizontal axis. The open and solid symbols represent psychophsyical and phsyiological data, respectively. (B) Psychometric functions measured with and without electrical stimulation of the neuron being recorded (solid and filled symbols, respectively). The preferred direction of the cell was upward, so the vertical axis plots the proportion of upward responses. In the absence of stimulation, an uncorrelated display (0% coherence) evoked 50% upward responses (chance performance). In the presence of stimulation, the function was shifted leftward so that an uncorrelated display evoked a significant proportion of upward responses.

of upward responses, and that a value of 0.5 represents equal upward and downward responses. In the absence of stimulation, the proportion of "upward" responses increased above 0.5 only when the stimulus had a significant number of upwardly moving signal dots. In the presence of electrical stimulation the proportion of upward responses increased above 0.5 even when the signal dots were actually moving downward (negative values of correlation). In fact, electrical stimulation shifted the psychometric function leftward so that a smaller coherence level in the presence of stimulation produces a response associated with a larger coherence level in the absence of stimulation. This effect of stimulation, along with the lesion studies and the close correspondence between behavior and neural response, provides strong evidence that MT neurons are involved in the processing of large field motion stimuli.

IV. MOTION TRAJECTORIES

Humans are very good at detecting motion along a smooth path. Vilayanur Ramachandran and Stuart Anstis showed that the direction of motion of an ambiguous motion stimulus (e.g., one that is equally likely to be perceived to move in two different directions) is resolved when it is embedded in a motion sequence that moves in a consistent direction. This phenomenon, called motion inertia, refers to the tendency to see motion along a consistent path, despite a brief motion ambiguity. Andrea van Doorn, Jan Koenderink, and coworkers showed that it is much easier to detect coherent motion embedded in incoherent motion when the stimulus is elongated in the direction of motion rather than perpendicular to it. Similarly, Scott Watamaniuk and coworkers showed that a single signal dot moving along a straight path is easily detected among noise dots moving in random directions, despite the fact that in single frames the signal dot and all the noise dots move an equal distance. A quantitative investigation of this effect showed that for extended trajectories (lasting 200 msec), human performance far exceeds the combined outputs of local motion units acting independently. This discrepancy occurs only for long trajectories. For brief trajectories (lasting 100 msec), human performance is predicted by local units with circular profiles. One explanation for this finding is that sensitivity to extended motion trajectories is due to specialized motion units that are elongated in the direction of motion. This explanation has been ruled out by experiments that show that motion signals

along any smooth motion path are easily detected, whether that path is linear, circular, or a triangular wave. It has been suggested that the detection of extended trajectories is mediated by a flexible network of local units that propagate activation among units tuned to similar directions of motion. A unit propagates activation to another unit if its preferred direction roughly points to that unit, thus facilitating the detection of motion signals along a smooth path. This interaction would have to be nonlinear to be consistent with the observed data. We have preliminary evidence that the signal that is propagated along the motion path is a measure of the probability of future motion in a particular direction, given the history of past motion.

V. SECOND-ORDER MOTION

So far, we have discussed motion for gray-scale backgrounds and objects, where the moving object is a region of luminance that changes its position over time. The moving object can also be defined as a region of color that changes positions over time. Luminance and color are regarded as first-order properties of the image. Motion that is produced directly as changes in position over time of these first-order image properties is also called Fourier motion. Our discussion of motion has so far assumed that the brightness and texture of the moving object's retinal image are constant over time. Humans accurately and reliably detect the motion of objects despite dramatic changes of luminance (motion through shadows in a forest) and rapid changes in the surroundings (animals running through waving grass). For conditions like theses, any luminance-based procedure, such as computer algorithms that detect motion by finding regions with matching luminance (or even contrast) over time, would be severely degraded. In these and other cases, there are other invariant properties that define the objects and their motion. Stimuli that have motion that is defined by higher order parameters such as changes in contrast are called second-order motion stimuli (also called non-Fourier motion). We define a second-order motion stimulus to be a stimulus that on average has equal first-order motion energy in opposite directions for all spatial and temporal frequencies. Equivalently, for second-order motion stimuli, the responses of motion energy units tuned to opposite directions are on average equal. Thus, purely first-order mechanisms would be unable to detect second-order motion. The ability of humans to perceive motion in second-order stimuli can provide important evidence about the type of motion mechanisms the brain uses.

Charles Chubb and George Sperling showed that humans perceive motion for many types of second-order motion stimuli. A single frame of a typical second-order motion stimulus is shown in Fig. 7A, and an x–t plot of its motion is shown in Fig. 7B. Humans reliably perceive this second-order motion stimulus to be moving. Chubb and Sperling showed that if the luminance values of certain second-order motion stimuli were subjected to a nonlinear transformation (such as rectification, taking the absolute value, or simple squaring), then the resulting stimulus could be detected by a standard first-order mechanism. The effect of applying a nonlinear transformation (absolute value) to the stimulus is shown in Fig. 7C. Some researchers have suggested that there are two separate motion pathways: one that processes first-order motion using motion energy detectors and a second that consists of a nonlinear stage followed by motion energy detectors. Others have proposed that a single pathway containing an early nonlinearity is sufficient to explain human perception of second-order motion. Although some experiments have found differences in the perception of first- and second-order motion stimuli, evidence is accumulating that motion perception of most second-order stimuli can be explained by a single pathway with an early nonlinearity. Many experiments have shown that there are similarities between the perception of first- and second-order motion. For instance, if a first- or second-order motion stimulus has a contrast high enough to be detected, its direction of motion can be discriminated. First- and second-order motion stimuli produce adaptation effects that are similar and are independent of which type of motion was used as the adapter and the test. They also produce similar evoked potentials. Recent work by Ethan Taub, Jonathan Victor, and Mary Conte showed that direction-discrimination and speed-discrimination thresholds of both first- and second-order motion stimuli were accurately predicted by a single pathway with an early nonlinearity. They showed that an early nonlinearity not only allows the second-order motion stimulus to be processed by first-order mechanisms but also necessarily produces other signals that behave like masks and can strongly influence motion perception. Although these effects depend strongly on the type of early nonlinearity, they likely explain why many experiments find differences between the perception of first- and second-order motion. The

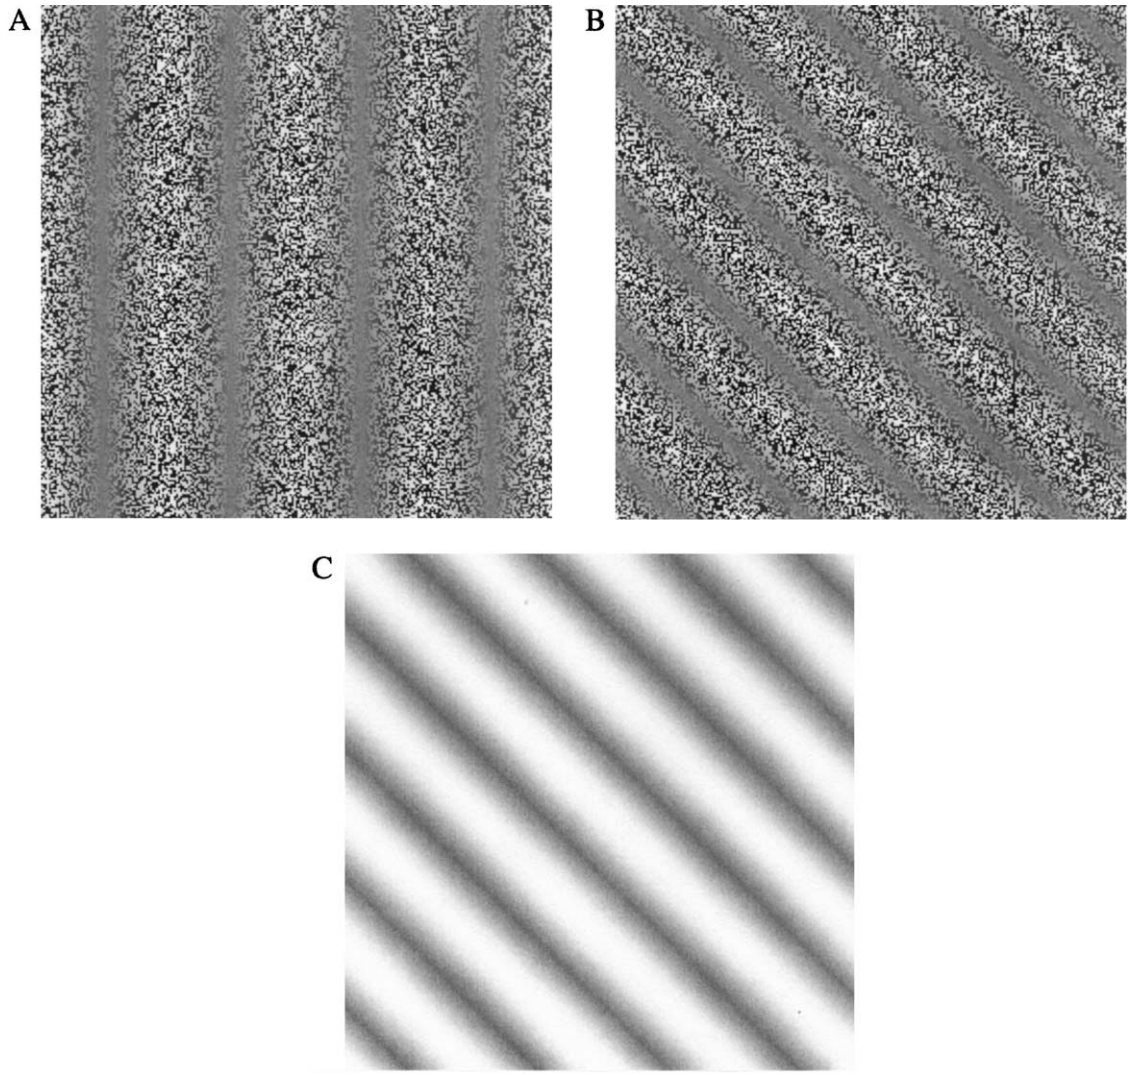

Figure 7 Non-Fourier motion. (A) An *x–y* plot of one frame of a second-order motion stimulus. This stimulus was generated by first creating a checkerboard of small squares and randomly choosing each square to be bright or dark and then multiplying each square's contrast by a sinusoid. This produces regions of very low contrast where the sinusoid is near zero (the approximately uniform gray regions) and regions of very high contrast where the sinusoid is near positive or negative one (the high-contrast speckled regions). (B) An *x–t* plot showing the second-order stimulus moving rightward. (C) The same moving second-order motion stimulus after it has been put through a nonlinearity. In this case the nonlinearity is the absolute value of the contrast. This operation ignores the sign of contrast so that bright and dark squares contrast become equally bright. This nonlinearity produces a moving rectified sinusoid.

investigation of second-order motion stimuli has thus revealed the importance of nonlinear stages in early visual processing.

VI. MOTION AND COLOR

So far, we have discussed the perception of motion defined by luminance. Motion can also be defined by another first-order property—color. Human color perception is described by three technical terms: hue, saturation, and luminance. In everyday usage the word color usually refers to the technical term hue (e.g., red, green, and blue), which is determined by the wavelength of light. Saturation measures how different the light is from white and quantifies the differences between white (zero saturation), pink (medium saturation), and pure red (high saturation). Luminance measures the total light intensity that our photorecep-

tors detect and is related to the brightness or darkness of a region. To investigate the dependence of human motion processing on color, physiologists and psychophysicists use two types of motion stimuli. In the first, luminant stimuli, the motion is created entirely by luminance differences (equal hues and saturations). In the second, isoluminant stimuli, the motion is created entirely by hue and saturation differences (equal luminances).

Many psychophysical experiments have shown that the perception of isoluminant motion is poorer than that of luminant motion. For some types of stimuli, luminant motion is readily perceived, but when the luminance differences are replaced by color differences (isoluminant motion) motion is no longer perceived. Other early experiments showed that isoluminant stimuli were perceived to move more slowly than luminant stimuli. Furthermore, basic anatomy and physiology have shown that the primate visual system has two major pathways as early as the retinal ganglion cells. The magnocellular pathway is primarily involved in motion processing and is not very sensitive to hue, whereas the parvocellular pathway is primarily involved in form and color perception and is not very sensitive to motion. Area MT receives direct input predominately from the magnocellular pathway and is most sensitive to luminant motion and less sensitive to isoluminant motion. These results led some researchers to conclude that luminant and isoluminant motion are processed by two separate pathways. Recent experiments by Brian Wandell and colleagues have directly tested this hypothesis. Extracellular recordings from area MT and functional magnetic resonate imaging results have shown that it does respond to isoluminant motion. The responses to isoluminant motion are similar to those to luminant motion but weaker. Psychophysical experiments have measured how perceived speed depends on contrast for different colors. The function relating perceived speed to contrast has the same shape for all colors but differs by an overall contrast sensitivity factor. For instance, to achieve the same perceived speed, blue stimuli require a contrast 10–20 times higher than that for yellow stimuli. This difference in the sensitivity of perceived speed to contrast is much larger than the differences in contrast detection thresholds for the blue and yellow stimuli. Thus, it is likely that area MT processes both isoluminant and luminant motion, but that MT is much less sensitive to isoluminant motion. The color-dependent differences in sensitivity can explain many of the perceptual differences between isoluminant and luminant motion, including the lower perceived speeds of isoluminant motion and the inability to perceive motion for low-contrast isoluminant stimuli.

VII. MOTION AS A CUE TO DEPTH

A. Kinetic Depth Effect

Relative motion can provide several different views of an object over time and information from these different views can reveal the 3D structure of the object. This is loosely analogous to the way stereo vision combines views from the two eyes to give depth information; since the eyes are horizontally displaced in the head, each eye provides a slightly different view of the world. These different views can be used to extract the relative depths in the image. We first consider the kinetic depth effect, where an object moves with respect to a stationary observer. Hans Wallach demonstrated this effect by projecting the image of an object rotating about a vertical (or horizontal) axis on to a screen. The object was a rigid 3D shape made up of a wire frame. The shadow of the moving object on the screen convincingly gave rise to the percept of a solid shape, showing that humans are able to integrate motion information to recover the 3D structure of objects.

B. Structure from Motion

Another compelling demonstration of how motion information gives strong 3D information is the rotating cylinder example. The observer sees a 2D projection of a pattern of dots that are painted on a rotating glass cylinder rotating about a vertical (or horizontal) axis (Fig. 8). When the cylinder is static the image on the screen looks like a random array of dots. When the cylinder rotates, the dots on the front and back surfaces move in opposite directions. Moreover, the dots in the center of the cylinder have a faster speed than the dots on the edge. Observers are able to integrate these different local motions into the percept of a transparent rotating cylinder.

How does the visual system extract depth from the 2D information generated by a moving 3D shape? Currently, there is not a clear physiological basis for this process. From geometrical constraints it has been shown that the 3D structure can be reconstructed from

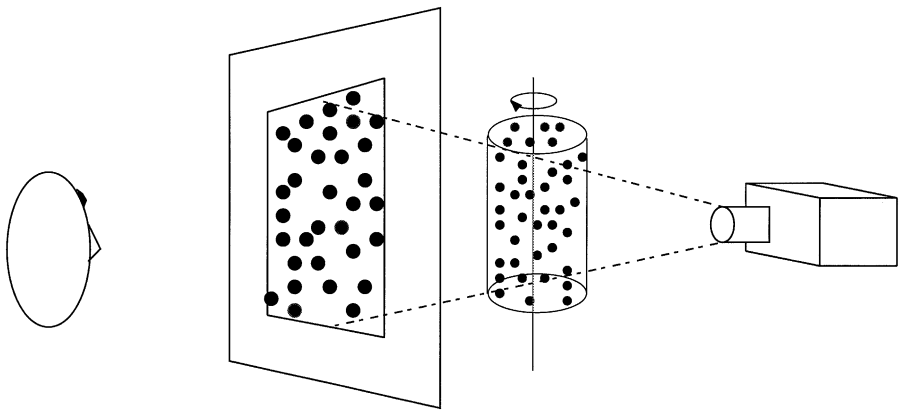

Figure 8 Structure from motion. The observer is viewing the projection of a glass cylinder rotating clockwise with dots painted on its surface. The projection falls on a 2D screen. At each instant in time the projection is a 2D pattern of dots, but as the cylinder rotates the dot pattern changes in a way that conveys the 2D shape of the cylinder. The 2D projection of the dots near the center of the cylinder appears to move at a high velocity (either leftward or rightward depending on whether the dots are on the front or back surface of the cylinder), whereas the 2D projection of the dots near the edges of the cylinder has a low velocity (because actual 3D motion of the dots is primarily toward or away from the projection screen).

just three different views of four points on a rigid object that are not in a single plane. Depth can also be mathematically reconstructed with fewer views of more points. Furthermore, the 2D pattern of moving dots on the screen is ambiguous; it is equally consistent with stationary dots affixed to a rotating cylinder and with a single plane of independent dots moving with different velocities. Humans appear to be biased to assume that the stimulus is an object that is moving rigidly. This is the rigidity constraint in the interpretation of optic flow. In fact, if we incorporate such a constraint it would have to be one of local rigidity since

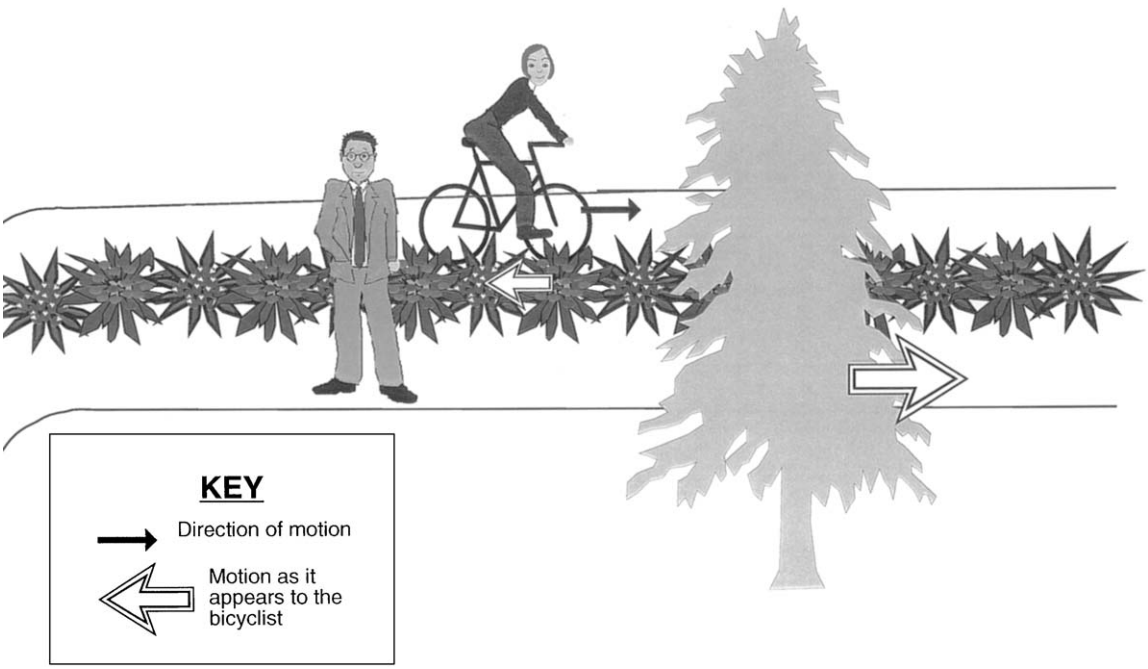

Figure 9 Motion parallax. The woman on the bicycle is looking at the man as she pedals. Objects farther than the man appear to move with her, whereas objects closer than the man appear to move in the opposite direction. Specifically, the tree appears to move in the same direction as she does, and the flower beds appear to move backward.

the movement of most animate objects is not consistent with rigid body motion. Typically, head and limbs move with respect to the torso. It is perhaps this locally rigid motion that makes the phenomenon of biological motion so compelling. Biological motion depicts only the motion of the major joints of a human or animal. Gunnar Johansenn showed that a movie of a person walking in complete darkness, except for small lights attached to major joints, was instantly recognized as a human walking.

C. Motion Parallax

Motion parallax is the relative motion of objects at different depths due to the motion of the observer. This is the kind of information that is available when we look out of the window of a moving vehicle or when we look around while on a moving bicycle. Objects farther than our point of fixation move with us; objects that are closer move in the opposite direction (Fig. 9). This is indeed a powerful monocular cue to depth. Brian Rogers and Maureen Graham demonstrated the effect of motion parallax in the laboratory. Observers viewed a flat screen with randomly positioned dots. They were asked to move their heads from side to side. This lateral motion was instantaneously measured and used to compute differential motion of the random dots for each head position. The dot motion was calculated so that it was consistent with motion parallax from a 3D surface corrugated sinusoidally in depth. This imposed motion was similar to motion that would have impinged on the retina if the observer were moving with respect to a real corrugated surface. Observers had the compelling percept of a surface modulated in depth, despite the fact that there were no stereo cues to the depth.

It is possible that neurons in MT can encode depth from motion parallax. It is known that populations of MT neurons have different preferred directions in the center and surround. A subset of these neurons have centers and surrounds with opposite preferred directions of motion. These cells could potentially encode a motion parallax signal generated by a moving observer fixating a point between two objects separated in depth. Furthermore, we also know that some cells in MT are disparity selective. A cell that combined relative motion specificity with disparity selectivity could potentially encode depth from both motion parallax and stereo information.

VIII. MOTION AS A CUE TO SEGMENTING THE VISUAL SCENE

Motion can help break camouflage; flounders on the seafloor are so well camouflaged that they are nearly impossible to detect until they move. However, when a flounder does move, we are immediately aware of its form. Such real-life examples seem to have inspired psychophysicists to use random dot patterns to study how an object defined by motion information alone segregates from the background. This is the figure-ground problem. In these experiments, the stimulus is a random dot pattern and a single patch of the stimulus moves between frames. Each frame by itself looks like an array of random dots. It is only when the frames are animated that the motion of the patch is visible. Neurons in area MT seem well suited to detecting this kind of motion. As discussed earlier, there is a class of neurons whose surrounds have direction and velocity preferences that are antagonistic to the center response. The cell has no response if the surround alone is stimulated. Some of these neurons have surrounds that are maximally suppressive when the neurons are stimulated by a large field stimulus moving in the preferred direction of the center. Other neurons have surrounds that produce suppression for field movement in any direction. These latter neurons respond optimally when stimulated with a patch that is matched in size to the center and moves in the preferred direction of the center. As the patch gets larger, the surround is also stimulated and the response of the neuron decreases. These neurons are well suited to segmenting an object that is defined by motion information alone, but they do not encode large-field motion generated by the animal's movements.

Recent studies have also shown that humans can use speed information to group areas of common motion. Mary Bravo and Scott Watamaniuk showed that dots moving at a single speed are seen as a coherent group even when their common speed is defined by different combinations of spatial and temporal displacements. Similarly, a motion stimulus composed of regions of different spatial and temporal frequencies appears to move as a single textured object if the spatial and temporal frequencies define a common speed across the object. Conversely, a pattern that differs from its surround only by a change in speed can be easily discriminated. To achieve segmentation by speed, the neurons in MT with antagonistic surrounds would have to have different preferred velocities in the center and surround.

Humans can also use speed and direction information to segment the visual scene. When overlapping sets of points move in different directions or at different speeds, the image segregates into two separate layers moving at different velocities. This phenomenon, called motion transparency, normally occurs when there are large differences in direction or speed between the overlapping motions. Ning Qian and coworkers showed that humans perceive transparency in a display with two overlapping sets of dots that move in opposite directions. Observes perceive flicker and not transparency when the dots are arranged as pairs of points that are very closely spaced and move in opposite directions. The opponent version of the motion energy model provides a potential explanation. The paired dots are at approximately the same location, so the opposing motion directions cancel each other. The unpaired dots are not closely spaced, so the two directions of motions do not cancel each other.

Andrea van Doorn and Jan Koenderink described the spatial and temporal conditions under which transparency is perceived. They used a display that was divided into horizontal strips of equal width. Alternate strips had dots that moved at two different velocities. If the strips were broad, the display appeared to be divided into separate horizontal strips moving at different velocities. If the strips were narrow, the division into horizontal strips was not perceived; instead, the percept was of "transparent sheets moving through each other." The width of the strip that supported the percept of transparency depended on the magnitude of the velocity: It ranged from 0.02 to 0.67° for velocities from .25 to 30°/sec. They also used a homogeneous display that alternated between two speeds at a variable rate. If this rate was slow, humans perceived a single sheet of dots, which changed its velocity over time. If this rate was faster than 10 Hz, then two transparent, simultaneously moving sheets of noise pattern with different velocities could be seen. Besides requiring that the alternations in space and time occurred over small distances and times, the displays appeared transparent only if speeds of the two motions differed by a factor of 4 or the directions were separated by at least 30°. At the level of MT, the spatial separation between signals that support the percept of transparency is typically small enough to fall within the receptive field of a single neuron. This suggests that the presence of two motions at adjacent locations is probably encoded within a single MT cell by subunits (V1 neurons) that have different preferred directions and speeds. In fact, Ning Qian and coworkers have shown that, on average, neurons in macaque MT respond more strongly to the unpaired dot stimuli that generate the transparent motion percept than to the paired dot stimuli that generate a flickering percept.

IX. MOTION INFORMATION GENERATED BY SELF-MOTION

Moving through complicated environments is an everyday necessity that depends critically on visual motion information. Humans, like other animals, are able to perceive and control their motion precisely through complex environments. We have two main types of sensory inputs that help us perceive self-motion: vestibular and visual. Vestibular input from the semicircular canals in the ears directly sense certain types of self-motion by detecting accelerations. Here, we focus on the ability of humans to perceive self-motion from purely visual cues, which are produced by the changing images (motion) our eyes receive as we move.

When a person moves, the environment generates a pattern of motion across the retina, which is called optic flow. As J. J. Gibson described, if the person is moving along a line without rotating (translating), the object toward which he or she is moving stays fixed on the retina but all other objects move in an outward radially expanding pattern that is centered about the direction of translation (Fig. 10A). For pure translation, this stationary point is called the focus of expansion (FOE), and the direction of self-motion is toward its location. When the person is translating slightly to the left of straight ahead, the resulting optic flow pattern is shown in Fig. 10B. Many studies have presented stationary observers with various types of translational optic flow patterns and found that humans can accurately (to within approximately 1°) determine the simulated direction of self-motion under a wide range of conditions. A different type of optic flow pattern results when the observer's position remains fixed but he or she rotates his or her eyes (or body). This rotation produces the optic flow pattern shown in Fig. 10C. If the self-motion is a combination of translation and rotation, resulting from the observer rotating his or her eyes to maintain fixation of an object while walking in a straight line in a different direction, the resulting optic flow pattern is the sum of the translational and rotational optic flow patterns

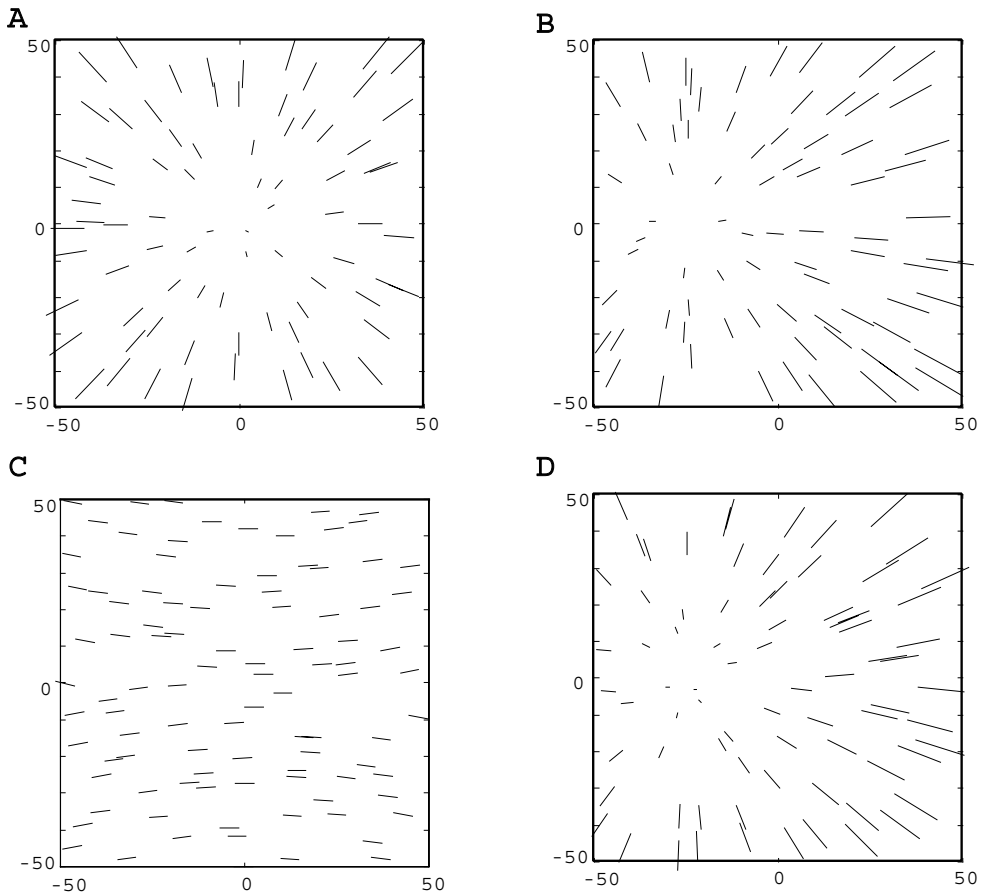

Figure 10 Optic flow (A) The flow field for an observer both looking and moving straight ahead toward a flat wall painted with dots. The lines plotted in the flow field represent the velocities of the moving dots on the retina. As the observer moves closer to the wall, the image expands and each dot moves directly away from the center of the screen. The point from which all the flow field vectors emanate is the focus of expansion (FOE). For an observer moving in a straight line in any direction, the flow field contains an FOE that is always located in the direction the observer is headed. Because the observer is moving toward the center of the wall, the FOE is in the center of the flow field. (B) The flow field produced when an observer is translating in a direction slightly to the left of straight ahead. The focus of expansion has now shifted to the left so that it remains aligned with the translation direction. (C) The flow field produced by an observer looking to the left by rotating her eyes (or head) about a vertical axis. Note that moving the eyes to the left causes all points to move predominantly to the right and that there is no FOE for rotational motion. (D) The flow field resulting from the combination of moving straight ahead, as in A, and rotating the eyes to the left, as shown in C. The resultant flow field is the sum of these two flow fields and looks very similar to the flow field in B. Although it contains a location that has no motion, this is not a true FOE and does not correspond to the direction of translation.

(Fig. 10D). The retinal motion in these optic flow patterns is more complex, and although they contain a location with no motion (a false FOE), this no longer corresponds to the direction of motion. Recent experiments have shown that humans are able to accurately perceive their self-motion in these conditions, suggesting that the brain performs a more complex computation than simply identifying the location of the FOE. Eye movements can also play a role in heading perception. Information about eye rotation has been found to improve the accuracy of heading estimation in some conditions.

The brain appears to process optic flow patterns in area MST and adjacent parietal areas such as area 7A. Complex motion-sensitive neurons are found in the dorsal portion of area MST (MSTd), which receives direct input from area MT and eye movement areas, such as the superior colliculus, the lateral intraparietal area, and the frontal eye fields. Many MSTd neurons have large receptive fields, some of which cover nearly the entire visual field. Instead of responding best to the simple motion of bars, these large-field neurons respond optimally to specific patterns of motion. Some of these cells respond best to the expansion

optic flow patterns produced by translations, other cells respond best to rotational optic flow patterns, and still others appear to respond best to specific combinations of expansion and rotation. Recently, Lee Stone and John Perrone developed a model that predicts both the response of MSTd neurons and the ability of humans to perceive their self-motion. In their model each neuron is tuned to a specific type of self-motion. The neurons have large receptive fields that receive input from MT neurons. Direct support for a role for MST in self-motion perception comes from microstimulation studies in area MST of awake behaving monkeys that were trained on a heading discrimination task. Ken Britten and coworkers showed that electrical microstimulation of MST frequently biased the monkeys' decisions about their heading, and these induced biases were often quite large. These results suggest that MST has a direct role in the perception of heading from optic flow.

X. TIME TO CONTACT

When a fly lands on a wall, a human catches a ball, or a pilot lands a plane, motion information about when the approaching object will arrive (time to contact) is necessary to interact successfully with the environment. Low-level measurements of the motion of an approaching object do not by themselves contain information about the absolute distance and velocity of the object. However, absolute knowledge of object distance and velocity is not required to determine the time to contact. David Lee showed that it is possible to calculate the time to contact with an approaching object by measuring the relative expansion rate (the ratio of the size of the object at a given instant to its rate of change of size). He referred to this ratio as τ. Humans appear to perform such a calculation and base their estimates of time to contact on the relative expansion rate, τ. Psychophysical studies show that human judgments of time to contact increase in proportion to parametric variation in τ, despite variations in initial expansion rate. Other studies suggest that certain motor actions are initiated when the time to contact reaches a critical value. For example, flies begin decelerating when the relative rate of expansion reaches a critical value; humans appear to use τ to initiate appropriate action during driving and catching or hitting a ball. However, research to date has not identified a neurophysiological correlate of τ in primates.

XI. MOTION AND PURSUIT EYE MOVEMENTS

The human visual field has a very high acuity central region, the fovea, and visual acuity declines rapidly for more peripheral regions. To position objects near the center of the fovea, humans and monkeys have developed sophisticated brain circuitry that produces two different types of eye movements: saccades and smooth pursuit. Saccadic eye movements are rapid, step-like changes in eye position, that are used to quickly look around a scene or to read. Saccades have latencies of about 200 msec, very short durations (<50 msec), and can have very high velocities (300°/sec). These extremely fast eye movements cause the world to move relative to the eye with high velocities during saccades, but we do not perceive the world to move. The high saccadic velocities and short durations generally produce world motion on the retina too fast for the visual system to detect.

Humans and monkeys use a different eye movement, smooth pursuit, to track the motion of objects (e.g., a ball rolling or a bird flying). Humans are able to pursue objects moving at speeds up to about 30°/sec with great accuracy. Pursuit eye movements are typically initiated very quickly, about 80–150 msec after the onset of motion, and accelerate rapidly to match the speed of the target in about 80 ms. During steady-state pursuit, the eye velocity approximately matches the target velocity, producing a retinal image in which the target is nearly stationary and the world is moving with a retinal velocity equal and opposite to the eye velocity. Humans nevertheless perceive the world as stationary and the target as moving, and we are able to maintain accurate smooth pursuit of the target even though its retinal velocity is close to zero. The brain computes motion signals in world coordinates by subtracting an eye velocity signal from the retinal motion signals. To obtain a very fast eye velocity signal, the brain appears to use an efference copy of the neural signal sent to the regions generating eye movements instead of direct measurement of eye velocity by proprioceptors. Evidence from several different types of monkey studies indicates that the computation of world velocity from retinal and eye velocities is performed in the lateral portion of area MST (and possibly also in the frontal eye fields). Intracellular recordings from MST neurons show that they receive retinal motion information from area MT and extraretinal eye movement signals. Lesions of MST produce deficits in both motion perception and the ability to generate smooth pursuit. Also, injecting small, carefully controlled electrical signals into localized

regions (microstimulation) of MST produces smooth pursuit and also influences the perception of motion.

Further evidence that the brain calculates an object motion signal that is shared by pursuit and perception is provided by recent experiments by Brent Beutter and Lee Stone that simultaneously measured the direction of pursuit and the perceived direction of motion. These studies examined both image segmentation and errors in perceived direction and showed that the perceptual data could be accurately predicted from measurements of pursuit. Furthermore, by using the pursuit data to predict the perceptual response to each trial, these studies showed that on a trial-by-trial basis perception and pursuit were correlated. Thus, it appears that object motion signals computed by MST are used by both perception and pursuit.

XII. CONCLUSION

Motion processing is critical to many aspects of everyday life. We discussed how the ability to extract motion signals from the environment affects diverse functions from breaking camouflage to navigating through the environment. These diverse functions are reflected in the multiple cortical areas that deal with different aspects of motion processing. Although humans can function without other aspects of visual function such as stereoscopic vision, the loss of motion processing is totally debilitating. This is not surprising considering that motion is a wealthy source of information about the environment, and that motion processing is probably the most important visual function of the brain.

GLOSSARY

agonist A muscle that generates movement toward a goal.

antagonist A muscle that generates force in a direction opposite to that of an agonist.

central pattern generator Neural network in the central nervous system that produces rhythmic motor commands.

forward dynamics Computation of movements that result when muscles generate a given pattern of force.

forward kinematics Computation of limb positions for a given pattern of joint rotations.

internal model A central nervous system representation of the kinematics and dynamics of a motor task.

inverse dynamics Computation of muscle activations and forces needed to reach a goal.

inverse kinematics Computation of joint rotations or limb movements needed to reach a goal.

synergists Muscles that work together to produce a given movement.

The human motor system controls goal-directed movement by selecting the targets of action, generating a motor plan, and coordinating the forces needed to achieve those objectives. Genes encode much of the information required for both the development and the operation of the motor system—especially for actions involving locomotion, orientation and reproduction—but every individual must acquire and store motor memories during his or her lifetime. Some of that information reaches conscious awareness, but much of it does not. This article focuses on the human motor system but draws heavily on knowledge about the motor system of other mammals, especially primates.

I. WHAT CONTROLS MOVEMENT

The motor system consists of two interacting parts: peripheral and central. The peripheral motor system includes muscles and both motor and sensory nerve fibers. The central motor system has components throughout the central nervous system (CNS), including the cerebral cortex, basal ganglia, cerebellum, brain stem, and spinal cord.

A. Peripheral Motor System

1. Muscles

Skeletal muscles consist of specialized cells, which fuse during development to form fibers (technically, a syncitium). There are two types of muscle fibers:

extrafusal and intrafusal. Extrafusal fibers, which attach to tendons and then to the skeleton, produce force and movement. Intrafusal fibers, which contain muscle spindles, attach to muscles and serve a sensory function.

Force and movement depend on muscle proteins, principally myosin and actin, both of which form strands within the muscle fibers. Molecules of myosin store kinetic energy as a result of metabolizing adenosine triphosphate (ATP), and muscle activation converts this chemical energy into mechanical force and work. Muscles generate force through a cascade of electrical and biochemical events, beginning with the release of acetylcholine by motor neuron synapses at the neuromuscular junction. This excitatory neurotransmitter binds temporarily with the muscle's cholineregic receptors, leading to depolarization of the postsynaptic membrane and mobilization of intracellular calcium ions. High intracellular calcium levels expose a site on the actin filaments to which myosin can attach. Once attached, the myosin molecules then reconfigure to force the actin and myosin filaments to slide relative to each other, which either shortens the muscle or generates force.

Whether these biomechanical events cause a force leading to movement or, alternatively, force without movement depends on the interaction of those muscles with their tendons, the skeleton, and the environment. As one consequence of the properties of actin and myosin, the length of a muscle affects the force (or tension) that it generates, a property known as the length–force (or length–tension) relation. As a muscle elongates, a given amount of activity generates a proportionately larger force. In addition, the properties of actin, myosin, and other structural elements also cause muscle fibers to behave approximately like a spring (technically termed viscoelasticity). Like metal springs, muscles have varying degrees of stiffness. For example, when pulled with a given amount of force, a spring made of thick, inflexible metal will increase its length much less than one made of thin, pliable metal. The former kind of spring is called stiff, and the latter is called compliant. Stiffness is defined as the ratio of force change to length change.

a. Rigor Mortis Muscle activation increases muscle stiffness, but so does death, which leads to rigor mortis. Death causes depolarization of the muscle fibers because the eventual depletion of ATP stops the sodium–potassium pump, upon which normal cell polarization depends, as well as the hydrolysis of ATP by myosin, upon which detachment from actin depends. In both rigor mortis and movement, attachment of myosin to actin causes stiffening of the muscle fibers.

2. Motor Neurons and Motor Units

In the ventral part of the spinal cord, motor neurons are organized into segregated motor pools, which innervate particular muscles. Alpha motor neurons send their axons from the spinal gray matter to terminate on extrafusal muscle fibers. Gamma motor neurons send their axons to intrafusal muscle fibers. Motor pools extend over two to four spinal segments, with medially situated motor pools innervating axial muscles (e.g., those of the neck and spine). Laterally situated motor pools project to limb muscles, with those contacting distal muscles located most laterally.

The term motor unit applies to a motor neuron and the muscle fibers it controls. Each motor neuron branches to innervate many muscle fibers, which receive input from only one motor neuron (except very early in development and in some disease states). The number of fibers in a motor unit varies according to function and within each muscle. Motor units that contribute to fine movements, such as those of the eye or the fingers, usually have a small number of muscle fibers. For example, motor units in the eye muscles consist of three to six muscle fibers. However, gastrocnemius, which forms the belly of the calf muscle, has thousands of muscle fibers per motor unit. Large motor neurons typically innervate more muscle fibers.

There are three basic types of motor units, each categorized by the speed with which it contracts upon electrical stimulation and its fatigability upon repeated stimulation. Fast, quickly fatiguing (FF) motor units have a short contraction time and produce a high twitch tension. However, with repeated stimulation the force they generate dissipates rapidly. Fast, fatigue-resistant (FR) motor units have an intermediate contraction time and can maintain force longer, whereas slow, nonfatiguing (S) motor units have a long contraction time and show little or no loss of force with repeated stimulation. FF motor units have large motor neurons, fast conducting, large-diameter axons, and muscle fibers of relatively large diameter. S motor units have the opposite characteristics. Muscles have various proportions of motor units: For example, S motor units make up nearly the entire diaphragm (one would not want to get tired of breathing), whereas gastrocnemius has a large proportion of FR and FF units (one certainly can get tired after a few strenuous jumps).

a. Poliomyelitis: A Disorder of Motor Neurons and Motor Units The poliovirus invades motor neurons, leaving adjacent nerve cells intact. Poliovirus receptors, located at the neuromuscular junction, allow the viruses to enter the motor neuron's axon, after which they migrate to its cell body. The infected cell either overcomes the virus or dies. If it dies, that motor unit is lost, and if the entire motor pool dies permanent paralysis results. However, some motor neurons usually survive. They develop new terminal axons that sprout to reinnervate "orphaned" muscle fibers. A single motor neuron may innervate up to 10 times the normal number of muscle fibers, restoring motor function. However, in a process called remodeling, which occurs in both healthy people and polio patients, motor units continually lose old sprouts and grow new ones. Decades after the onset of poliomyelitis, the enlarged motor units begin to break down, causing renewed weakness. According to one hypothesis, intense use of the relatively few remaining motor neurons causes this cell death.

3. Muscle Afferents

Certain sensory neurons innervate muscles and provide the CNS with information about muscle length and force. These and other sensory neurons have cell bodies in a dorsal root ganglion, with one axon projecting to sensory receptors in the periphery and another terminating in the CNS.

The diameter of muscle-afferent axons determines whether they belong to group I or group II. Group I, subdivided into groups Ia and Ib, has the larger fiber diameter and therefore faster transmission rates. Group Ia and II fibers innervate muscle spindles and are therefore called muscle spindle afferents. The term spindle refers to fine intrafusal muscle fibers that taper at the end and contain a fluid-filled capsule at the center. Muscle-afferent fibers wrap around muscular elements within the capsule. Group Ia fibers are termed primary muscle spindle afferents; group II fibers are called secondary muscle spindle afferents. Group Ib fibers innervate golgi tendon organs (GTOs), which are located in the transitional region between extrafusal muscle fibers and tendons. The role of muscle afferents in reflex responses is discussed in Section II.B.

B. Central Motor System

All levels of the CNS contribute to motor control, including the spinal cord, medulla, pons, midbrain, diencephalon, and telencephalon. The following sections survey the major components of the central motor system, beginning with the spinal cord and progressing up the neural axis to the telencephalon. Figure 1 shows some of the major components and projections of the central motor system. Notwithstanding the impression that this component-by-component description might convey, the various components of the motor system work as an integrated neural network, not as isolated motor "centers."

1. Spinal Cord

In addition to motor neurons, spinal components of the motor system include sensory pathways, the proprioceptive system, and central pattern generators (CPGs). Sensory afferents bring information to the CNS from the skin, joints, and muscles, and both cells and fiber tracts in the spinal cord relay that information to structures involved in motor control. For example, primary afferent neurons terminate on the dorsal column nuclei in the medulla, which relay that information to the thalamus through a fiber pathway called the medial lemniscus. In addition, an extensive and intricate system of intrinsic spinal cord neurons underlies a group of miscellaneous functions collectively termed proprioceptive. Proprioceptors are sensory transducers in muscles, tendons, and other internal tissues. However, the concept of the proprioceptive system extends beyond this definition to include a wide variety of interneurons that relay somatosensory signals locally and between segments in the spinal cord as well as carry descending motor commands, largely within the spinal cord. CPGs are neural networks that generate patterned, rhythmic movements, such as those involved in walking and running.

2. Brain Stem

The brain stem contains motor neurons that send their axons through certain cranial nerves, primarily to muscles of the tongue, face, and eyes. Like the spinal motor pools, many of these cranial motor nuclei receive direct input from sensory neurons and less direct influences from proprioceptive interneurons. Brain stem CPGs generate rhythmic movements, such as those underlying breathing and chewing.

Some parts of the brain stem interact with spinal CPGs and other components of the spinal motor system. One such region has been termed the midbrain locomotion region, which is thought to trigger the

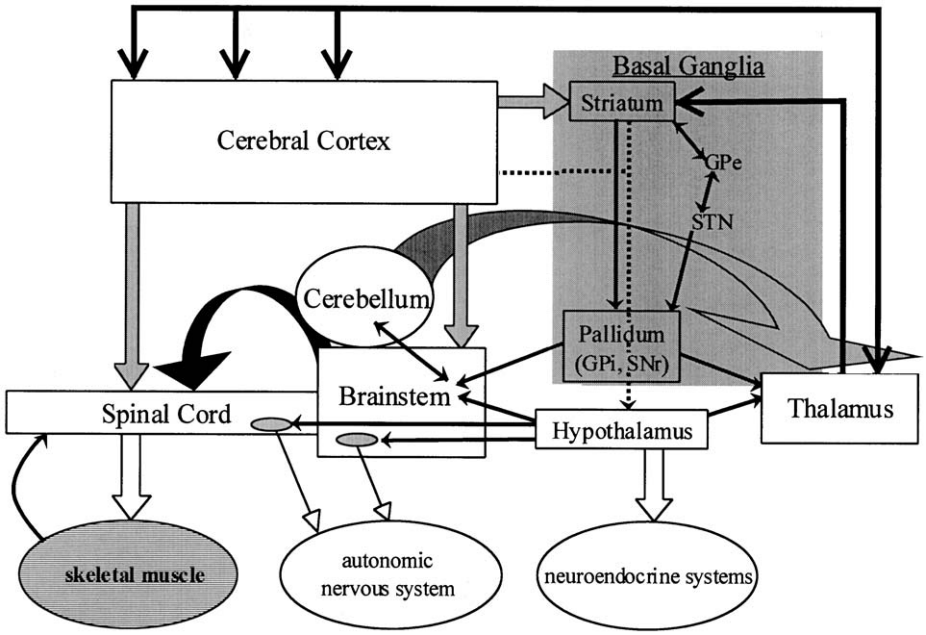

Figure 1 Major components of the motor system. Corticofugal projections are depicted as gray arrows. Projections to effectors are depicted as open arrows and arrowheads. The basal ganglia are contained within the gray box. Preganglionic autonomic motor nuclei are shown as stippled ovals. GPi, internal segment of globus pallidus; GPe, external segment of globus pallidus; STN, subthalamic nucleus; SNr, substantia nigra pars reticulata.

activity of spinal CPGs and thereby initiate locomotion. However, higher order networks, akin to CPGs but having more complex output patterns, have an important role in a number of instinctive behaviors, including aggressive posturing (a form of "body language") and inarticulate vocalization (such as crying, laughing, and screaming). Some of these networks are located in and near a midbrain structure called the periaqueductal gray.

a. Reticulospinal System Cells in the brain stem reticular formation that project to the spinal cord make up the reticulospinal system, which extends through medullary, pontine, and midbrain levels. The reticulospinal system performs a diverse set of functions, including the regulation of muscle tone, control of posture and locomotion, and integration of lower order motor signals with those emanating from the cerebellum and cerebral cortex. Different reticulospinal pathways exert influences on flexor versus extensor muscles and on proximal versus distal parts of the limb.

Part of the reticulospinal system serves as a fast transmission route to postural motor neurons and helps prevent movements from destabilizing balance. For example, when a person lifts a heavy object, the leg muscles need to stiffen before the elbow flexes. This postural adjustment prevents the object's weight from pulling the person off balance. The reticulospinal system activates leg muscles to stiffen them and help preserve balance. On the whole, while people are awake the reticulospinal system has a predominantly facilatory influence on motor pools. However, this effect changes dramatically during sleep. Then, reticulospinal neurons exert a strong inhibitory influence that, for example, prevents the performance of imagined actions during dreams.

Important influences over the reticulospinal system come from other systems, including vestibular afferents, which signal movements of the head and its orientation with respect to the earth's gravitational field, and the motor cortex, which provides information otherwise unavailable at brain stem levels. Through vestibulospinal projections, the vestibular system can contribute directly to various reflexes that adjust head position, posture, and limb movements. However, the vestibular afferents also provide inputs to the reticulospinal system. Consider the role of the reticulospinal system as a person runs through a field of obstacles. The signals conveyed by the reticulospinal

system to CPGs and spinal motor pools adjust posture and movement based primarily on vestibular and proprioceptive inputs. However, cortical and other higher order inputs supply the information needed for dynamic motor adjustments that allow people to step over and around visible obstacles.

b. Cerebellum and Red Nucleus The largest component of the brain stem motor system is the cerebellum. The medial cerebellum controls posture, whereas the lateral cerebellum participates more in voluntary movement. Accordingly, vestibular and propriospinal inputs predominate in the medial cerebellum, and inputs to the lateral cerebellum arise mainly from the cerebral cortex, relayed through mossy fibers originating in the basilar pontine nuclei. In addition, the cerebellum receives mossy fiber input from the red nucleus via the lateral reticular nucleus (which also has major spinal inputs) and from other sources. Mossy fibers terminate on the output nuclei of the cerebellum (the deep cerebellar nuclei) as well as on neurons in the cerebellar cortex. Another type of input, conveyed by climbing fibers originating in the inferior olivary complex, is thought to signal motor error or discoordination. These signals may play a central role in motor learning (see Section IV).

The output of the cerebellar cortex comes from GABAergic Purkinje cells, which inhibit neurons in the deep cerebellar nuclei and in one of the vestibular nuclei. The deep cerebellar nuclei send excitatory outputs to a variety of structures. Their largest projections terminate in the thalamus (Fig. 1), but other efferents reach the reticulospinal system, red nucleus, superior colliculus, and spinal cord. Cerebellar outputs to many of its targets are accompanied by return projections through a variety of direct and indirect pathways. One example is the cerebellar projection to the motor cortex (via the thalamus), which is returned by a cortical projection to the cerebellum (via the basilar pontine nuclei). Recurrent, excitatory circuits such as this are thought to form functional networks termed cortical–cerebellar modules.

The red nucleus plays an enigmatic role in motor control, especially in the human brain, but appears to be intimately related to cerebellar function. It receives a major projection from the deep cerebellar nuclei as well as from the motor cortex, and the largest part of the red nucleus (its parvocellular, or small-cell, component) projects predominantly to the inferior olivary complex, the source of cerebellar climbing fibers. The magnocellular (large-cell) red nucleus sends its axons directly to the spinal cord through the rubrospinal tract, which might be particularly important in stabilizing the limb by coactivating agonist and antagonist muscles. However, the magnocellular red nucleus is said to be relatively small in the human brain, which may reflect a dominant role of cortical motor control in our species.

c. Superior Colliculus The superior colliculus, although typically discussed in terms of eye-movement control, also has an important role in the control of head movements. Generally stated, its function involves the orientation of the retina and other receptors on the head, which the superior colliculus guides through its interaction with the reticulospinal system, premotor neurons in the brain stem reticular formation, and direct projections to the spinal cord (the tectospinal system).

3. Diencephalon

The hypothalamus and thalamus are the major parts of the motor system that lie within the diencephalon. The motor functions of the hypothalamus are discussed in Section II.A. The thalamus does not serve a primarily motor function when viewed as a whole. However, a major component of the thalamus receives projections from the cerebellum and basal ganglia, which play an important role in motor control. Two general regions of the thalamus receive these inputs—the ventroanterior and ventrolateral (VA/VL) nuclei. Anterior VA/VL receives basal ganglia projections; posterior VA/VL receives cerebellar input. Each part of VA/VL sends excitatory projections to the frontal cortex and receives excitatory projections from the same cortical areas. These reciprocal connections are thought to act as recurrent cortical–thalamic modules. Although the thalamic terminals from cerebellum and basal ganglia overlap very little, the thalamocortical components of these systems converge to influence most if not all motor areas jointly.

4. Telencephalon

Two large parts of the telencephalon have important roles in motor control: the cerebral cortex and the basal ganglia. Of course, the function of both structures extends beyond motor control, but this article addresses only that role.

a. Cerebral Cortex The number of functionally distinct motor cortical fields remains unknown. One

heuristically useful view of the frontal cortex divides it into three main parts: the primary motor cortex, a group of areas collectively known as nonprimary motor cortex, and the prefrontal cortex (Fig. 2). The first two components can be referred to collectively as the motor cortex, although this term is sometimes used as a synonym for primary motor cortex.

The primary motor cortex (abbreviated M1) corresponds approximately to Brodmann's area 4. It lies in the anterior bank of the central sulcus and contains a topographic representation of the musculature. Most textbooks depict this topography in the form of a homunculus (i.e., a projection of the body onto the cortical surface). Such pictures have validity only at the most superficial level. They correctly imply that the medial part of M1 contains the leg and foot representation, that a more lateral part includes the arm and hand representations, and that an even more lateral part has the face, tongue, and mouth representation. However, at any finer level of detail, the homunculus presents an inaccurate image of M1's organization. Instead, M1 consists of a mosaic of broadly overlapping muscle representations, with each part of the body represented repeatedly. The functions of M1 are discussed in Section III.

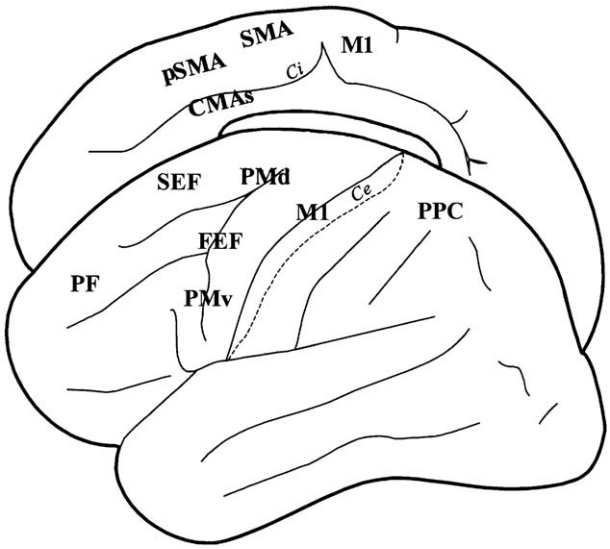

Figure 2 Motor areas of the human brain plotted onto a highly simplified sketch of the cerebral hemispheres. The lateral surface of the left hemisphere is shown below the medial surface of the right hemisphere. Rostral is to the left; dorsal is up. The dashed line indicates the fundus of the central sulcus, showing that the primary motor cortex is located mainly within the rostral (anterior) back of that sulcus. Ce, central sulcus; CMAs, cingulate motor areas; FEF, frontal eye field; M1, primary motor cortex; PF, prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; PPC, posterior parietal cortex; SEF, supplementary eye field; pSMA, presupplementary motor area; SMA, supplementary motor area.

By current estimates, there are about a dozen nonprimary motor areas. Many of these fields occupy parts of Brodmann's area 6. However, parts of areas 8 and 24, the latter also known as anterior cingulate cortex, also contain nonprimary motor areas. A medial group of areas includes the well-known supplementary motor area (SMA), an area immediately anterior to it (the pre-SMA), and two or more cingulate motor areas. A lateral group of areas, often termed simply the premotor cortex (PM), can be divided into separate dorsal and ventral components, and these two divisions can be subdivided further into rostral and caudal parts. At least two eye-movement fields, the frontal eye field, and the supplementary eye field, have been identified. Finer subdivisions and combinations of these regions have been proposed and may have some validity. The functions of these areas are discussed in Sections III and V.B.

The primary and nonprimary motor areas project to the other components of the motor system, at virtually all levels of the neural axis (Fig. 1). The cortical output system, often called the corticofugal system, arises exclusively from layer 5 and includes a direct projection to the spinal cord (the corticospinal system). Some motor areas, especially M1, have monosynaptic excitatory connections with alpha motor neurons. Accordingly, the oxymoron "upper motor neuron" has been applied to M1's corticospinal neurons. However, M1 exerts its influence over genuine motor neurons in large measure through relatively indirect pathways, and its synapses on spinal interneurons vastly outnumber those on motor neurons. Corticospinal axons accumulate in large bundles traversing the internal capsule, cerebral peduncle, pyramidal tract, and corticospinal tract on the way from the telencephalon to the spinal cord. Because corticospinal axons run through the pyramidal tract, the term pyramidal motor system is sometimes applied to it. However, many fiber systems coexist within the pyramidal tract, such as neurons projecting to the dorsal column nuclei and other targets in the brain stem. Thus, the corticospinal and pyramidal motor systems do not correspond exactly. Additional outputs from the motor cortex include massive projections to the basal ganglia, the red nucleus, the cerebellum (via the basilar pontine nuclei), and the reticulospinal system.

b. Basal Ganglia Long considered part of the so-called extrapyramidal motor system, much of the

motor output from the basal ganglia depends, ultimately, on the pyramidal tract. Accordingly, the concept of an extrapyramidal motor system has been largely abandoned. The striatum is the basal ganglia's input structure, encompassing the putamen, caudate nucleus, nucleus accumbens, and other regions within the ventral forebrain. Likewise, the pallidum is the basal ganglia's output structure, including not only the globus pallidus but also the substantia nigra pars reticulata (Fig. 1) and additional parts of the ventral forebrain. The pallidum sends GABAergic inhibitory projections to the brain stem and thalamus. These thalamic nuclei connect to nearly the entire frontal lobe as well as additional areas, such as the inferior temporal contex and the posterior papietal cortex.

The major excitatory inputs to the striatum come from the cerebral cortex (including the hippocampus) and the intralaminar complex of thalamic nuclei. A major input arises from the dopaminergic cells of the midbrain, located in the substantia nigra pars compacta and the adjacent ventral tegmental area. Degeneration of the striatum results in Huntington's disease, whereas degeneration of the dopaminergic neurons causes Parkinson's disease.

Much attention has recently focused on the modular organization of cortical and basal ganglia interconnections. This trend accords with the recognition of other important modules in the motor system, such as CPGs, reflex circuits, and cortical–cerebellar modules. The cortical–basal ganglionic modules, often called "loops," consist of cortical, striatal, pallidal, and thalamic elements that form, at least in principle, a recurrent excitatory pathway. This circuit includes the so-called "direct pathway," striatal output neurons (technically, medium spiny neurons) that project directly to the pallidal projection neurons (Fig. 1), including those in the internal segment of the globus pallidus (GPi). Another part of the basal ganglia, the "indirect pathway," begins with projections from the striatum to the external segment of the globus pallidus (GPe). These neurons influence the subthalamic nucleus and pallidum, in turn (Fig. 1).

This sketch of the basal ganglia has heuristic value in understanding Parkinson's disease and other consequences of basal ganglia dysfunction. However, the reader should recognize that it represents a coarse oversimplification. Many other features of its anatomy are important to basal ganglia physiology. The subthalamic nucleus, for example, excites not just GPi but also GPe; the GPe sends inhibitory inputs "back" to the striatum; and the motor cortex sends a direct, excitatory projection to the subthalamic nucleus. Furthermore, in addition to dopaminergic inputs, serotonergic inputs arise from the raphe nucleus, and there are a large variety of intrinsic neurons using other neurotransmitters, including acetylcholine.

c. Parkinson's Disease According to one current view, dopamine acts to support activation of the direct pathway's striatal neurons but to suppress those of the indirect pathway. Accordingly, the direct pathway's inhibitory influence over GPi might wane in the absence of dopamine. This decrease in inhibition from the striatal direct-output pathway would lead to GPi neurons having greater activity and therefore greater inhibitory output to the thalamus. The indirect pathway may also contribute to greater inhibition of the thalamus. This increased inhibitory influence on recurrent cortical–thalamic modules may cause the slowing of movement (technically, bradykinesia) that is a symptom of Parkinson's disease.

II. WHAT THE MOTOR SYSTEM CONTROLS

The motor system controls innate behavior, which is encoded genetically; a wide variety of reflex responses, defined as output generated relatively directly by sensory inputs; and voluntary movements.

A. Instinctive Action

The hypothalamus plays a central role in the control of instinctive behaviors, such as those involved in locomotion, orientation, and reproduction, and in neuroendocrine function. Pools of neuroendocrine neurons in the periventricular parts of the hypothalamus secrete hormones into the vascular system. Their terminals in the neurohypophysis (posterior pituitary) release oxytocin and antidiuretic hormone (vasopressin). Although it might seem counterintuitive to consider such secretions as motor in function, they serve as a mechanism through which the CNS controls other parts of the body, just as alpha motor neurons do.

Different cells in the periventricular hypothalamus serve a less direct endrocrine control role. These neuroendocrine cells secrete higher order control hormones, often termed releasing factors, into the portal blood supply of the pituitary. The adenohypophysis (anterior pituitary) responds to these hormones,

such as corticotropin-releasing factor, which increase or decrease the secretion of pituitary hormones such as adrenocorticotropin. These hormones play crucial roles in regulating growth and in homeostatic and reproductive functions.

The hypothalamus also affects the body through its control of the autonomic nervous system (ANS). The hypothalamus sends descending projections to the autonomic motor nuclei in the spinal cord and brain stem. There, neurons send outputs to the peripheral ganglia of the two components of the ANS, the sympathetic and parasympathetic systems. Sympathetic motor neurons are located at thoracic and lumbar levels of the spinal cord. Parasympathetic motor neurons are found in the sacral spinal cord as well as in the brain stem, from which they give rise to parts of cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus). Autonomic motor neurons, like alpha motor neurons, project to the periphery and release acetylcholine. In the sympathetic nervous system, most of these cholinergic influences terminate on ganglia relatively near the CNS. These sympathetic ganglia contain neurons that release noradrenaline, which induces a generalized arousal of the "fight, flight, and fright" variety. In the parasympathetic system, cholinergic motor neurons project to ganglia relatively far from the CNS, near their visceral targets. Thus, the ANS can address the targets of the parasympathetic system more specifically than it can for the sympathetic system. Most parasympathetic postganglionic synapses use acetylcholine as a transmitter, although many neuropeptides, such as vasoactive intestinal peptide, are released along with acetylcholine. The hypothalamus, through its control of the ANS, exerts an important influence over such motor functions as vasoconstriction, respiration, and heart rate.

However, the hypothalamus does not confine its motor functions to the ANS. Parts of the hypothalamus play an important role in ingestive behaviors (such as eating and drinking), defensive and agonistic behaviors (such as flight from danger and aggression), arousal and orientation, and social behaviors, including sexual and other behaviors involved in reproduction (e.g., rearing of progeny and other means by which genes are passed to future generations). Its motor roles thus include initiating complex action patterns, which include epigenetically expressed but genetically encoded motor programs often termed species-specific or species-typical behaviors. For example, aggressive displays such as snarling at or staring down an adversary might result from fear, intermale competition, or irritation, with each state and response mediated by different, partially overlapping networks in the hypothalamus. The hypothalamus effectuates many of these behaviors via projections to the thalamus and to various brain stem structures (e.g., the periaqueductal gray).

The several systems influenced by the hypothalamus—endocrine, autonomic, and instinctive—may seem dissimilar and unrelated. However, the hypothalamus (along with components of the amygdala) coordinates these aspects into a fully coordinated behavior. Imagine combat soldiers engaged in a stressful and dangerous situation. A variety of species-typical behaviors accompany such perilous situations, including heightened states of vigilance and arousal, which require high expenditures of energy. Parts of the medial hypothalamus detect inputs that signal such situations and, through their projections to the brain stem, release and intensify arousal and vigilance behaviors. Those hypothalamic regions also influence the periventricular hypothalamus to secrete corticotropin-releasing factor, which in turn induces the release and circulation of adrenocorticotropic hormone. This hormone stimulates the adrenal cortex to produce and release larger amounts of glucocorticoids. A parallel ANS control signal from the hypothalamus to the motor nucleus of the vagus promotes insulin secretion by the pancreas. Thus, the neuroendocrine system (through gluocorticoids) induces the liver to release more glucose at the same time as the ANS (through insulin) promotes the uptake of glucose into cells, especially muscle fibers. Together, the hypothalamus coordinates an adaptive response to a stressful state: the mobilization and utilization of stored nutrients to support high energy expenditure as well as the actions appropriate to that state.

B. Reflex Responses

The motor system controls a large number of reflexes, of which this article highlights only withdrawal and muscle-afferent reflexes.

1. Withdrawal Reflexes

Activation of cutaneous and deep receptors by a potentially damaging stimulus gives rise to an ipsilateral flexion reflex, accompanied by contralateral extension, called the crossed-extension reflex. A polysynaptic network in the spinal cord mediates this

response, which acts to retract the limb from the noxious stimulus (the flexion reflex) and enhance postural support, especially from the legs (the crossed-extension reflex).

2. Muscle-Afferent Reflexes

Two feedback systems, both involving muscle afferents, regulate force and muscle length through reflexes. Muscle spindle afferents transduce muscle length, whereas GTO afferents transduce muscle force.

a. Force Feedback GTOs lie in series with the extrafusal fibers and receive no motor innervation. They send force information to the spinal cord, where interneurons receive input from the brain that specifies the amount of force that a muscle should produce. If that muscle's force level exceeds this set point, the GTO inputs inhibit the alpha motor neurons innervating that muscle, which lowers the force produced unless some other mechanism cancels that signal.

b. Length Feedback In contrast to GTOs, muscle spindles lie in parallel with extrafusal fibers and have contractile elements that are activated by gamma motor neurons. Without efferent innervation, the muscle spindles would become slack when extrafusal fibers shorten. The spindle afferents would then become silent and the CNS would lose information about muscle length. Gamma motor neurons activate muscle spindles during contraction to maintain that information flow. During movement and steady posture, muscle spindle afferents sense muscle length with respect to a bias length set by their gamma motor neurons. When the gamma motor neurons have high levels of activity, the bias length is relatively short. If the muscle length exceeds this bias length, muscle spindle afferents increase their discharge rate and excite alpha motor neurons innervating the same muscle. Of course, this increase in activity tends to shorten the muscle, bringing it closer to the bias length. Generally, however, gamma motor neuron activity allows the CNS to control the sensitivity of muscle spindle afferents, which may play their most important role in regulating muscle stiffness.

Information regarding limb position does not depend entirely on muscle spindles. Other sources of input include cutaneous and joint capsule receptors, both of which contribute information about limb position and joint angle. In addition, group III and IV afferents also innervate the limbs but receive information primarily from deep receptors in the muscle and cutaneous receptors that appear to respond mainly to painful stimuli rather than force or limb position. Despite this diversity of receptors, the muscle spindles appear to be especially important for sensing muscle length, as demonstrated by the following experiment: Imagine a blindfolded person, seated with his or her elbows on a table and his or her forearm held in a vertical posture. If someone else moves one forearm, the blindfolded person can indicate the position of that arm by matching it with the other, free arm. People perform this task very accurately in normal circumstances. However, if vibration is applied to the belly of biceps, people consistently overestimate the angle of extension at the elbow. The explanation for this phenomenon involves muscle spindle afferents. Vibration provides a very powerful stimulus to muscle spindles, and the CNS wrongly interprets their increased discharge as reflecting a longer biceps muscle, which translates to increased extension at the elbow.

Muscle spindle afferents also mediate stretch reflexes, among which the monosynaptic stretch reflex is also known as the myotactic reflex or the knee-jerk response. For example, when one taps the skin surface over the knee's patellar tendon, this stretches the quadriceps muscle. Prior to the involvement of stretch reflexes, this increase in length makes the muscle generate more force through the length–tension relation. However, stretch also results in an elongation of the muscle spindles in the quadriceps, which in turn causes increased firing of the primary and secondary muscle spindle afferents. This sensory input excites alpha motor neurons and causes a knee-jerk within 15–20 msec. Particularly for the muscles of the arm, wrist, and fingers, a second pathway exists through which muscle stretch can activate motor neurons. This pathway, called the long-loop stretch reflex, also begins with muscle spindle afferents. Information from these afferents is transmitted to the thalamus and then to the somatosensory and motor cortex before returning to the spinal cord through the corticospinal projection. It takes 40–50 msec for the information to traverse this entire circuit. Although the long-loop reflex takes longer than the short-loop one, the brain can reprogram the long-loop response in a highly flexible manner. For example, if a stretch is expected, people can suppress the long-loop component of the reflex or choose to respond especially vigorously. The major role of stretch reflexes probably involves responses to an unexpected perturbation. If, during a movement, something suddenly displaces the arm, this input elicits a compensatory response from

both the short- and long-loop reflexes. These reflexes tend to change the activation levels of motor neurons in a manner that stabilizes and stiffens the limb as it moves along the desired trajectory. Reflexes may help the motor system overcome impediments that have never been experienced. If a person's goal includes producing the sound "pa," the lips must touch each other to achieve this goal. However, if an experimenter pulls on the lower lip, the motor system needs to produce more force than usual to make the lips contact each other (technically, occlusion). This response does not depend on experience with such perturbations; it occurs the first time the lip is pulled.

c. Disorders of Long-Loop Stretch Reflexes in Parkinson's Disease Normally, people can voluntarily suppress the long-loop component of the stretch reflex. In Parkinson's disease, however, patients appear to lose this ability. Regardless of the instructions given to them, stimulation of primary muscle spindle afferents produces a large response. In Huntington's disease, by contrast, there can be a complete loss of the long-loop stretch reflex. The relation between the basal ganglia and control of these reflexes remains unknown, but it probably involves its influence over the motor cortex. Recent research suggests that loss of the long-loop reflexes accounts for the jerky movements characteristic of Huntington's disease.

3. Role of Reflexes in Voluntary Movement

To what extent are reflexes used for generation of voluntary movements? Studies of patients with degeneration of large-fiber afferents (peripheral neuropathy) have led to the conclusion that reflexes play only an indirect role in volitional action. Such patients lose their stretch reflexes, limb position sense, and their ability to detect limb motion, but they can still make voluntary movements. In normal individuals, an electromyograph (EMG) pattern composed of three discrete bursts of activity characterizes the execution of a rapid, one-joint voluntary movement. First, the agonist muscle activates (AG1), followed by the antagonist muscle (ANT) and, finally, a second activation of the agonist muscle (AG2). AG1 accelerates the limb, ANT brakes the limb, and AG2 stabilizes the limb and dampens oscillations around the final position. When peripheral neuropathy patients make a rapid thumb flexion, the typical three-phase EMG pattern described previously (AG1, ANT, and AG2) appears in the normal manner. Therefore, the EMG pattern of voluntary movements appears to originate from descending motor commands to alpha motor neurons and does not depend on reflex loops. The motor command signal, however, may pass through some of the same neurons used in reflex loops, increasing the capacity of the system to integrate peripheral and central information.

C. Voluntary Movement

This article concentrates on the voluntary control of forelimb reaching movements. However, similar processes apply to other types of voluntary movements. These processes include generating torques on an articulated chain of limb segments, promoting stability through agonist–antagonist architecture, positioning end effectors, translating goals into plans for action, computing the joint rotations and patterns of force needed to implement those plans, and compensating for other forces.

1. Generating Torques on Articulated Limb Segments

A limb consists of a chain of articulated segments, with the muscles acting as the motors (technically, actuators) that control torques around those segments. Each segment of a limb can rotate with respect to the more proximal segment. The axis of rotation centers on the joint that connects the two segments, and muscles provide torques on that joint. For example, a person usually has to flex his or her elbow to lift a coffee cup and sip from it. Commands from the motor system reach the biceps muscle, activating it and producing force, which results in flexion torques on the elbow joint. As the elbow flexes, the resulting movement stretches the triceps, which in other circumstances would result in increased force output from the triceps because of the length–tension relation. This increased force would cause an extension torque on the elbow joint. For the hand to reach the mouth, flexion torques need to exceed extension torques. Thus, while sending the activating commands to the biceps to initiate the movement, the motor system usually sends an inhibitory command to the triceps' motor pool as well. This reduces some of the extension torque produced by the triceps, diminishing the resistance to the voluntary flexion that brings the cup to the mouth.

2. Producing Stability through Antagonistic Architecture

To hold a coffee cup steady requires a different approach: The motor system sends commands to activate both biceps and triceps. This coactivation results in both flexion and extension torques on the elbow joint. If the net torque, which is the sum of these two torques, equals zero, then the forearm will remain still. Why not simply shut down both muscles rather than waste the torques (and energy) to no effect? The answer has to do with limb stability. Consider what happens if an object suddenly hits a person's hand and causes the arm to flex at the elbow. During coactivation, the muscle that gets stretched because of the impact (triceps) will vigorously resist because intrinsic muscle stiffness increases with activation level. Without coactivation (i.e., with an inactive triceps), the impact would result in a much larger flexion of the elbow. Thus, coactivation promotes limb stability.

3. Positioning End Effectors

Although the final motor commands act on muscles to move limb segments, the goal of a movement often involves the positioning of an end-effector. For example, to sip from a coffee cup, most people attend to the cup and not to what the elbow is doing. Signatures provide another case in point. Everyone has a unique signature, and its distinctive character persists even if different joints and muscles perform the signing movement. This principle has been called motor equivalence. Its basis is that the pencil serves as an end effector regardless of which muscles move it. The preservation of unique elements in a signature indicates that the highest levels of the CNS represent voluntary movements not as a pattern of muscle activations but as a kinematic pattern, specifically the desired motion of an end effector.

Of course, signatures consist of complicated movement trajectories. In principle, an infinite number of possible hand trajectories can be made between two points—some straight, others curved to varying degrees. However, unless the goal includes a curved trajectory, people show a remarkable similarity in the movements that they produce in reaching from a given hand position to a target. The hand moves with a unimodal, smooth, and symmetric velocity over the time course of the action, and it takes a straight-line path. Even blind people show this feature in their arm movements. When an experimenter demonstrates the target to a blind person by moving his or her hand to the target position (later returning it to the original location), he or she makes straight and smooth reaching movements just like sighted people. This smoothness in hand trajectory contrasts sharply with the changes that occur in joint positions during the same movement. For example, consider a movement of the right arm that starts with the hand at the far left of the midline and reaches to a target at the far right. For most people, this movement would be a straight line in terms of hand position. However, examination of joint angles shows that the elbow initially flexes and then extends. Therefore, its velocity is not unimodal. Human arm movements generally appear simple when described in terms of hand positions and velocities but are complex when described in joint coordinates. This regularity remains when people perform movements with different end effectors. For example, movements remain smooth and simple when our hands hold a long stick. In this case, the end of the stick moves smoothly and in a straight line.

4. Translating Goals into Action

a. Inverse Kinematics The smooth and simple hand trajectory described previously represents a kinematic plan. Before that plan can be formulated, the motor system must estimate both current hand position and the direction and magnitude of the movement needed to reach the target. Estimation of current hand position is based on two sources: Vision and proprioception. Muscle afferents from the arm provide the information necessary for estimating the orientation of each limb segment relative to its proximal joint. If the motor system has this information, it can compute the hand position with respect to the body. The computation of limb position from a proximal, joint-coordinate-based system to a distal, hand-centered coordinate system is called forward kinematics. If someone moves a blindfolded person's hand, he or she still has a pretty good idea of that hand's location. This ability depends primarily on the computation of forward kinematics from the length sensors in the muscles. If the motor system knows the length of the limb's muscles, it knows the angles of its joints and, through forward kinematics, can compute the location of the hand. The inverse of this computation maps hand position to the joint angles that are appropriate for it. In order to move the hand to a desired position, the motor system needs information about what joint angles the muscles need to achieve in order to move the limb segments to that position. This computation is termed inverse kinematics. In other

words, if the motor system knows the desired hand position, it can compute the joint angles needed to put the hand in that position through the computation of inverse kinematics.

b. Inverse Dynamics In addition to computing the positions of the joints and the hand for a desired limb trajectory (kinematics), the motor system must estimate how much torque to produce on each joint (dynamics). Accordingly, the motor system must translate a desired motion of the end effector into a pattern of muscle activations. This does not imply that the brain calculates or represents the joint torques in absolute terms, joint by joint, but rather that the neural network must solve this problem to generate motor commands that will achieve the goal. Consider the torques needed to lift a full cup of coffee in contrast with those needed to lift an empty cup. Although the hand trajectories in the two cases may match perfectly, torques on the elbow will differ. Therefore, the motor system must take into account the weight of objects before it sends motor commands to the muscles. The computation that estimates the motion that will occur as a result of an applied force is called forward dynamics. The mass of objects held in the hand affects this computation: Activation of the biceps at a certain level will flex the elbow by a smaller amount for a full cup than for an empty cup. Forward dynamics consists of predicting the elbow angle after the biceps receives its activation command. The ability to predict the sensory consequences of motor commands relies on this computation. The inverse of this computation, called inverse dynamics, allows the motor system to transform the desired motion of the limb into the patterns of muscle activation that produce the torques required for the task.

However, in everyday life, even movements as simple as lifting a coffee cup can encounter impediments. When something disturbs arm movements (e.g., an unexpected change in the load on the hand), movements lose their smooth and regular character. However, provided that the perturbations have high predictability, with practice the movements again become straight in terms of hand trajectory. This convergence toward a straight, simple trajectory in hand coordinates (rather than joint coordinates) further supports the idea that the motor system plans movements in terms of the position of the hand and other end effectors rather than joint angles or patterns of muscle activity. In other words, the motor system plans in terms of goals rather than the components of movement. Motor learning and memory often underlies the ability to make smooth, straight movement despite external perturbations and the forces of each part of a limb acting on the others.

III. MECHANISMS OF MOTOR CONTROL

Neurophysiologists have only begun to understand the mechanisms of the motor system, and this section should be considered a highly provisional account of these mechanisms. Most of the relevant information comes from studies of neuronal activity in awake, behaving monkeys.

In generating the plan for a simple reaching movement, the initial problem involves kinematics, figuring out the current location of the end effector (often the hand), the location of the target, and perhaps the path between them. Both the premotor cortex (PM) and the posterior parietal cortex (PPC) appear to have key roles in solving this problem. The general locations of these cortical regions are depicted in Fig. 2.

A. Location of Targets and Initial Hand Position

PPC, in particular, plays an important role in determining the location of objects that could serve as the target of a reaching movement. Cells in one part of the PPC, the parietooccipital area (PO; approximately corresponding to areas V6 and V6A), respond to visual stimuli and, unlike most visual areas, their receptive fields have no bias toward the foveal representation. This characteristic suggests that the visual information PO processes relates to the control of movement rather than the analysis of an object's features. Some PPC neurons signal the presence of a target in retinal coordinates (i.e., the location of a target with respect to the fovea). These cells could be particularly important in controlling eye movements to that target, but they might also function to compute reaching, head, and eye movements within a single coordinate framework. One PPC region, the lateral intraparietal cortex, appears to be particularly important for eye movements, whereas a nearby region, the medial intraparietal cortex (MIP; also known as the partial reach region, PRR), plays a larger role in reaching movements. Other cells in PPC show an influence of "extraretinal" signals such as eye and head position. Some PO neurons, for example, appear to indicate target location with respect to the head (i.e., in head-centered coordinates). These signals mark the beginning stages of transforming visual information from a

receptor-based (retinal) coordinate frame into one more useful for reaching movements. For those movements, it is more useful to represent the target location relative to the end effector that will make the movement. Other parts of PPC play a larger role in determining the initial position of the end effector. One part of parietal area 5, for example, encodes hand position with respect to the shoulder. These and other parts of PPC operate in cooperation with the motor cortex, including both PM and M1.

Like the PPC, cells in the dorsal part of PM respond to a combination of signals relevant to voluntary reaching movement, including visuospatial and proprioceptive input, as well as inputs reflecting gaze direction, the location of objects in the environment, the orientation of spatial attention, and nonspatial visual information (such as color and form). Gaze effects show that the location of the target relative to eye position has some importance in motor control, perhaps for coordinated movements of eye and hand when people reach one place while looking at another. Attentional signals might be important when not all reaching targets can be foveated, as often is the case for a sequence of movements in a cluttered visual scene. In addition to these target-related signals, cells in dorsal PM (along with many in M1) are sensitive to the initial position of the hand, possibly through both proprioceptive and visual inputs. Similarly, cells in the ventral part of PM respond to both somatosensory and visual inputs as well as spatial acoustic signals. Whereas the PPC coordinate systems seem to reflect eye-, head-, and body-centered frames, ventral PM appears to be more specialized for the particular body-centered coordinate frame that is most useful for a given movement. In ventral PM, when a body part having a tactile receptive field moves, the visual receptive field moves in the same way: Visual receptive fields on the hand move with the hand, and those on the head move with the head. Therefore, it appears that these PM cells encode the potential targets of action relative to the body and update this map whenever the pertinent body part moves. Thus, PPC and the motor cortex derive much of the information needed for formulating a kinematic trajectory, including the starting position of the hand and the target of movement in each of several relevant coordinate frameworks.

B. Dynamics

At least two brain structures mediate the generation of force profiles that move the hand smoothly to a target: M1 and the cerebellum. The nonprimary motor cortex and basal ganglia appear to be less involved in this function.

It is likely that the network computing inverse dynamics includes the cerebellum. Damage to it results in movements that suggest an inability to compensate for the complex dynamics of multijoint reaching movements, including forces that arise due to interaction among limb segments (interaction torques). For example, the intact motor system approximates the inertia of the arm in programming activations of muscles, whereas cerebellar damage results in movements that suggest a deficit in this transformation. Normal individuals produce coordinated motion of the joints during reaching movements, whereas cerebellar patients produce movements that often consist of a sequence of single-joint motions. Neurons in the cerebellum have properties consistent with this view, including Purkinje cells that reflect movement velocity and the forces needed to achieve a certain trajectory.

M1 plays a role in limb dynamics as well, in part through its reciprocal interaction with the cerebellum. A century-long controversy has surrounded the question of whether M1 neurons encode primarily kinematics or dynamics. This problem, known informally as the muscle versus movement debate, consists of at least two parts. One part concerns how M1 addresses muscles. Some studies in the 1970s suggested that the M1 neurons address individual muscles, but refinements in research techniques have led to the understanding that individual neurons in M1 address multiple motor pools, usually of synergistic muscles. This view is consistent with the branching of corticospinal neurons to multiple motor pools and with the fact that they terminate principally on spinal interneurons rather than alpha motor neurons. These results support the ''movement'' side of the debate, but there is another issue. It involves the motor-control signal that M1 sends to the motor pools, and it yields a different answer—one more consistent with the ''muscle'' side of the debate.

A pure force signal in M1 neurons would support the view that they control muscles. Neurophysiologists have not completely settled this question, but three facts have been clearly established. First, when the hand generates a force that does not lead to movement (as happens when the hand pushes against an object so rigid that it does not move), cells in M1 have approximately the same patterns of activity as when the limb moves. Second, loads exerted on the hand can either assist a movement or oppose it. Neither kind of load changes the kinematics of movement appreciably,

but the forces involved in making the movement can differ greatly. Many cells in M1 differentiate between these two conditions, and they therefore appear to reflect limb dynamics. Third, the posture of the arm, which changes both joint angles and limb dynamics, affects the activity of M1 cells, even when the end effector path has nearly identical kinematics. The predominance of signals related to limb dynamics supports the muscle side of the debate and, therefore, a role for M1 in controlling limb dynamics. However, this view should not be taken to an extreme. There is evidence that limb kinetmatics is reflected by M1 cell activity, as well.

C. Kinematics

There is no evidence for a purely kinematic signal in M1. A purely kinematic signal would be invariant to loads on the limb or the initial posture of the arm. Such invariance has been observed in PPC (area 5), supporting the idea that it is mainly involved in movement planning in kinematic terms rather than movement execution in terms of limb dynamics. However, in M1 evidence points to a combination of kinematic and dynamic signals, as shown in the following experiment: Like people, monkeys can move their fingers upward by bending the wrist in different ways. If the palm is up, then the wrist can be flexed (i.e., moved in the palm's direction) to move the fingers upward. If the palm is down, then the wrist can be extended to achieve the same results. Some M1 neurons reflect only limb dynamics (i.e., flexion or extension), but others show an intermediate pattern of activity that takes into account both kinematics (end effector movement) and dynamics (muscle activity).

Large parts of nonprimary motor cortex, especially those on the lateral parts of the hemisphere, appear to function in the sensory guidance of movement at a kinematic level. For example, neurons in the dorsal and ventral PM have greater activity during visually guided movements than during memorized sequences, but they are not much affected by loads. The former observation points to a specialization for sensory guidance of movement, the latter to a specialization for kinematics. As noted previously, the activity of both PPC and PM neurons reflects the location of movement targets. However, this is not a purely sensory response in either PPC or PM. Instead, their activity reflects the motor significance of those signals at different levels. A term that has been used for motor significance in this sense is intention. For example, when monkeys indirectly move a spot on a video monitor by pushing or pulling on a joystick, researchers can distinguish neuronal signals related to the direction of spot movement from those reflecting the direction of limb movement. Many neurons in at least one part of PPC, MIP, signal the direction of hand motion, not spot motion. Also, they signal the location of movement-guiding spots only when the spot directs a reaching movement and not when it directs an eye movement. A population of cells in dorsal PM and the vast majority of cells in M1 do so as well. As another example, when a visual cue indicates the location of the next target of a reaching movement, but movement needs to be delayed until some future time, cells in both the PPC (area 5) and dorsal PM cortex signal the direction and amplitude of the planned movement. This "delay-period" activity begins about 100 msec after the cue appears and can continue for several seconds. PPC neurons do not distinguish between objects that will be the target of the next reaching movement and similar objects that indicate (e.g., by their color) that they will not be the subject of immediate action. Thus, PPC neurons signal potential movements or movement targets but not necessarily those that are currently planned. PPC neurons also reflect, in their activity, the expected benefit to be gained by moving toward a potential target. Neurons in dorsal PM, in contrast to PPC neurons, have delay-period activity only when the object will be the target of the upcoming movement. Thus, at the level of the nonprimary motor cortex, especially PM, neural activity appears to relate mainly to the implementation of near-term kinematic plans and other relatively high-level goals.

Cells in the basal ganglia also reflect the kinematics of reaching movements, such as direction and amplitude. However, the basal ganglia is unlikely to have a significant role in solving the inverse dynamics problem or computing the motor plan. Most basal ganglia activation or inactivation occurs too late to have a very large role in movement initiation or the planning that precedes it. Instead, the activity in basal ganglia develops at about the same time as muscle activity and continues during movement. Accordingly, it has been proposed that pallidal output plays a predominantly modulatory role. According to one hypothesis, motor-control signals depend, in part, on recurrent, mutually supporting activity in cortical–thalamic modules (or loops) that include motor cortex. Pallidal output may affect limb kinematics by facilitating or suppressing these recurrent circuits during an ongoing movement. It appears paradoxical that when the

motor parts of the basal ganglia's output projection are surgically destroyed, patients with Parkinson's disease can initiate movements more easily and move faster than before the surgery. Damage to motor-control structures usually causes rather than relieves motor dysfunction. However, the movement-modulation hypothesis resolves this paradox. Applying the brakes will slow a car, even though the brakes are not part of the movement-generation system. It is also thought that the basal ganglia function in context-dependent movement selection as well as in sequential and internally generated movements.

D. Goal Achievement

1. Limb Trajectory

M1 neurons reflect information about the direction, magnitude, and speed of the movement, in addition to postural signals. They have their greatest discharge rate for movements in one direction, with systematically less activity as the direction of movement diverges from that direction. They are therefore broadly tuned for movement direction, although this preferred direction can change with variations in starting hand position, the posture of the limb, and many other factors. On the assumption that these cells contribute to movements in their preferred direction, it is possible to compute a single vector, termed the population vector, representing the net contribution of a neuronal population. The M1 population vector anticipates the direction of limb movement for straight-line reaching movements (as well as for a variety of curved trajectories) by 30–120 msec.

Cells in the nonprimary motor cortex have properties similar to those of M1 cells but with some important differences. For example, cells in M1 are generally specific for the limb used, usually the limb contralateral to the hemisphere in which the cell is located. Cells in dorsal PM have activity broadly tuned for reaching direction like M1 neurons but have nearly the same directional preference for movements of the left hand or the right hand to the same visuospatial target. This finding shows that dorsal PM cells reflect the movement in terms of either visual targets or the trajectory of an end effector (in this case, a handle that the monkey moves). Evidence points to the former explanation. It appears that PM and M1 differ in the degree to which the visual inputs that guide a movement affect the activity of its neurons. Experiments have been done in which the monkey must follow a visual trajectory, but this visual input is projected directly to its eyes so that the relationship between vision and movement can be altered. Sometimes the visual target trajectory and the movement trajectory, perhaps an oval, are the same, but sometimes the hand trajectories must be circular to match an oval visual input or vice versa. PM populations reflect the visual target trajectory with more fidelity than the end effector trajectory, whereas M1 populations more closely reflect the movements of the end effector (the hand). This supports the idea that the motor system computes movement trajectories in terms of end effectors, with visual target trajectory predominant in PM and limb trajectory predominant in M1.

2. Compensation for External Perturbations

A part of the long-loop reflex, M1, receives somatosensory information that helps compensate for unexpected perturbations during movement. For example, when a hand movement is stopped in progress by an external force, M1 neurons that precede and accompany the movement with a burst of activity renew or increase that activity in response. This signal probably arises from the muscle spindles, which shorten in concert with the extrafusal fibers due to their input from gamma motor neurons. When the limb is stopped, both alpha and gamma motor neurons continue to discharge according to the motor plan. The extrafusual fibers build up force, but the muscle cannot shorten. The muscle spindle fibers continue to contract, which generates a signal comparable to that evoked by a muscle stretch. This signal is relayed to M1 and it causes the motor-control signal to be augmented. The resulting increase in activity serves to compensate, at least partially, for the perturbation, although it may not be adequate to overcome the impediment. This kind of mechanism could account for the achievement of goals upon the initial presentation of a particular perturbation.

IV. MOTOR MEMORY

A. Implicit and Explicit Memory Systems

The brain regions that store motor memories differ from those that store conscious memories. The former comprise an aspect of procedural memory or knowledge and the latter declarative memory or knowledge. Psychologists often refer to procedural knowledge as implicit memory and to declarative knowledge as

explicit memory. Some psychologists use the term "habit" interchangeably for procedural knowledge, but this usage should not be confused with its biological meaning, which involves instinctive behavior.

The idea that different brain structures underlie explicit versus implicit memory comes from observing the effects of brain damage. Damage to structures in and near the medial temporal lobe (MTL) results in loss of certain recently acquired information. Amnesic patients with MTL lesions can learn and retain skills such as mirror tracing, rotary pursuit, bimanual tracking, and compensation for complex forces applied to the limb during reaching movements. Despite this motor learning, the patients may not be able to recall the training episodes.

The distinction between an explicit memory system, which depends on the MTL, and an implicit motor memory system has several implications for motor control in the human brain. Voluntary actions have been defined as those that are learned, attended, and based on a comparison among alternatives. This awareness depends on the explicit memory system. Other actions, including but by no means limited to reflex movements, proceed without conscious awareness. Some subconscious movements bear obvious markings of this unawareness, such as the stretch reflex or the vestibuloocular reflex (VOR). The latter serves as a case in point. When people move their head left while looking at something, their eyes move equally fast and equally far in the opposite direction. They are probably aware of the object at the focus of attention. However, they cannot report anything about the motor memory that allows them to keep looking directly at that object, regardless of their head movements. Adjusting the VOR involves motor learning in the broadest sense but differs dramatically from that underlying voluntary movement. People cannot make VOR-like eye movements voluntarily. Movements such as the VOR and other reflexes can only be controlled implicitly.

Other movements that can be made without conscious awareness closely resemble voluntary actions. They can be guided either implicitly or explicitly. The best studied example of this phenomenon is termed blindsight. Normally, pointing to visible targets is accompanied by explicit knowledge of the action and the goal. However, some people with damage to the visual system can point to a visual stimulus while denying that they see it. Thus, some of the visuomotor networks remain functional even when the networks underlying visual perception fail. Phenomena such as blindsight have led to a distinction between CNS systems underlying vision for action (and therefore implicitly guided action) and those involved in vision for perception (which may or may not lead to explicitly guided action). The distinction between these two information processing systems does not depend on brain damage. Normal people can make finger movements that accurately match the size of objects they touch but nevertheless describe the size of those objects incorrectly due to visual illusions. People can also make accurate saccadic eye movements to fixate a visible target, although they report that the target moved in some different direction due to different kinds of illusions.

Which brain structures underlie motor memories, implicitly guided action, and procedural knowledge? To answer this question, it is useful to distinguish reflexes (such as for the VOR) from explicitly guided movements. Much of the information underlying the former is stored at the brain stem level, including the cerebellum. The cerebellum also has an important role in classical conditioning, through which sensory inputs are linked to stimuli that trigger reflex responses. Accordingly, it is clear that the cerebellum plays an important role in motor learning and memory at the reflex level. However, the situation is more complex for movements that are sometimes voluntary and under conscious control (explicitly guided action) but that also can become automatic and unattended as they become routine (implicitly guided action).

The oldest and most common idea holds that the MTL subserves explicit knowledge, whereas the basal ganglia underlies implicit knowledge. Patients with Parkinson's disease show particular deficits on tasks involving implicit estimation of event probabilities, for example, along with a wide variety of tasks involving motor skills. A newer idea holds that explicit knowledge is stored in prefrontal cortex and an associated part of the basal ganglia, along with the MTL, whereas some aspects of implicit knowledge are stored in motor cortex and their associated parts of the basal ganglia, along with the cerebellum. [The distinction between prefrontal and MTL function is that between long-term information storage of many months or years (prefrontal cortex) and intermediate-term storage of many weeks or months (MTL)]. Brain imaging studies, especially those that have explored the concept of attention to action, appear to be more consistent with the newer view. In motor learning, attention to one's actions and explicit knowledge of those actions (and outcomes) dominate the early part of training on a novel task. As a motor task becomes more automatic,

fewer attentive resources are engaged, and eventually it might be performed without awareness. Neuroimaging results have consistently shown increased blood flow, an indirect marker of synaptic activity, in the prefrontal cortex as subjects begin to perform motor tasks that involve learning a new skill. This increased activation generally declines to baseline as the task is extensively practiced and becomes automatic. Conversely, as a sequence or skill becomes more automatic, cerebellum (especially posterior parts), nonprimary motor cortex, and PPC show increases in activity. These findings support the hypothesis that prefrontal cortex–basal ganglionic modules subserve voluntary movement, whereas the motor cortex–basal ganglionic modules (along with the cerebellum and the PPC) underlie more automatic movements of the same kind.

Besides neuroimaging experiments, other evidence also implicates the cerebellum in motor learning. In a monkey trained to stabilize the wrist against an externally imposed load, for example, the cerebellum has been inactivated by cooling it. This manipulation eliminated the previously learned, predictive component of the muscle activity, which would oppose the imposed load. Furthermore, development of motor memory has been associated with an increase in the number of synapses onto the Purkinje cells in the cerebellum. Significant synaptic remodeling on Purkinje cells takes place within 1–4 hr after completion of initial training.

B. Internal Models

1. Acquisition

When a novice operator learns to control a novel mechanical system, the brain solves three types of computational problems: optimization of the task performance criteria to arrive at a kinematic plan (i.e., learning how the mechanical system should behave in order to accomplish the goals of the task), learning a model of the forward dynamics of the mechanical system (i.e., acquiring an ability to predict how the mechanical system will behave as a function of current input) and learning a model of the inverse dynamics of the controlled system (i.e., acquiring an ability to predict the inputs that should be provided to the mechanical system for a given desired change in state of that system). For example, consider the case of an operator acting on a joystick that controls the thrust produced by the motors of a remote underwater vehicle. The task involves moving the vehicle from point A to point B. The kinematic plan specifies a smooth vehicle trajectory. The forward model specifies how the vehicle will behave as the operator moves the joystick. The inverse model estimates how the operator should move the joystick so that the vehicle moves along the planned trajectory. An internal model (IM) is a blanket term used to describe the information contained in the solution to these three types of computational problems, and motor memory refers to the representation of IMs in the brain.

People use IMs in nearly every voluntary movement. For example, consider trying to lift an empty bottle of milk that has been painted white on the inside so that it appears full. The motor system will generate muscle activation patterns in the arm that provide the forces appropriate for lifting a full bottle, resulting in a flailing motion. This fact indicates that in programming the motor output to the muscles of the arm, the motor system uses certain visual characteristics of the object to predict and compensate for its mechanical dynamics. Learning IMs has been investigated in experiments in which a subject reaches to a target while holding the handle of a lightweight robotic arm. Disengagement of the robot's motors results in smooth and straight-line movements. Motor learning starts when the investigator programs a pattern of forces for the robotic arm to produce. These forces represent novel dynamics. When a person starts the training process, the computations that the brain performs in programming muscle activations do not take into account the novel forces, resulting in jerky hand movements. To compensate, initially people stiffen the entire limb through general coactivation of the muscles. This results in improved arm stability but serves only as a temporary and relatively ineffective strategy for responding to the perturbations. With training, stiffness returns to normal levels at the same time as the brain builds an IM of the novel dynamics. The motor output changes to specifically account for the additional forces. The development and use of a new IM can be demonstrated by turning off the robot's motors at the onset of movement. The resulting movement is a mirror image of that observed early in the training process. Therefore, the motor command that reaches the muscles includes a prediction by the IM of the forces required to overcome the imposed mechanical dynamics. The motor system retains this skill for months after the training session.

2. Consolidation

As one of its fundamental properties, the neural substrate of explicit memory gradually undergoes a

change, becoming more resistant to disruption. Newly acquired memories are more sensitive to new experiences and more susceptible to interference or brain injury. Posttraining treatments, including electric shocks, removal of key anatomical sites, or inhibition of protein synthesis, retard this progression and often result in loss of the recently acquired information. These interventions, however, have little effect on recall once a window of time has passed since acquisition. Consolidation refers to this time-dependent process. Does such a process occur in the storage of motor memories?

Until recently, little evidence supported the idea that time affected properties of motor memory. For example, it was found that whereas electroconvulsive shock interfered with conscious memories, it spared retention of a newly acquired skill (e.g., reading words in mirror image). Recent work, however, has found evidence for a temporal gradient in motor memory. The results suggest that within 4–6 hr after completion of training in a reaching task, functional properties of the motor memory gradually change. Subjects learned reaching movements in force pattern 1, leading to an internal model termed IM1, and then a second force pattern, termed force pattern 2, leading to an IM2. Their ability to learn IM2 depended on the time that had passed since completion of practice in force pattern 1. If only a short time had intervened (less than 4 hr), learning of IM2 was impaired compared to that of naive subjects. By the time 6 hr had elapsed, the interference caused by their training in force pattern 1 had subsided. This evidence points to the limited capacity of the system initially engaged in learning new skills. With time, the information maintained in this system fades, allowing the learning of additional skills. If this limited-capacity system serves a kind of intermediate-term memory stage for motor skills pending consolidation into a long-term memory store, then one would predict that its disruption might lead to an inability in long-term recall of motor memories. Indeed, learning IM2 within 4 hr after performing the movements in force pattern 1 results in an inability to recall IM1 in tests of long-term recall.

a. Apraxia as a Disorder of Motor Memory Apraxia occurs in numerous forms, of which at least two may represent disorders of motor memory. Ideomotor apraxia is characterized by kinematic errors made as patients copy movements or perform according to verbal instruction. Ideational apraxia is revealed by the incorrect miming of an action appropriate for a tool. In these patients, the ability to make the movements is relatively intact, but the motor system fails to produce the motor program that should be called up by the input, be it verbal or nonverbal instructions, as in ideomotor apraxia, or an object with a well-known use, as in ideational apraxia. The brain areas that fail in these situations have not been definitively established, but both PM and PPC appear to be involved. PM plays an important role in retrieval of a motor response as cued by visual or auditory stimuli, and PPC lesions cause some forms of apraxia. For example, a dentist with PPC damage suddenly complained that he "did not know" how to use a drill. This has been viewed as an example of a loss of a previously learned motor skill.

V. FLEXIBILITY IN MOTOR CONTROL

The ability to store motor memories enables the motor system to select a wide variety of movements in a highly flexible manner. People can select actions from a large repertoire of skills that have been previously learned, depending on context. In many contexts, achieving the goal of the motor system depends on movements made directly to targets, such as reaching to grasp an object. In others, more flexible relationships need to be established between objects and actions.

According to current thinking, different kinds of motor flexibility are afforded by different parts of the frontal cortex. Lateral nonprimary motor areas (such as dorsal PM) are thought to compute arbitrary mappings based on external (sensory) cues, whereas medial nonprimary motor areas (such as SMA) play an analogous role for internally generated actions, including memorized movement sequences. M1 is thought to enable a different sort of flexibility through the fractionation of motor synergies. Thus, it is commonly held that M1 functions mainly to permit motor "fractionation" (i.e., the independent control of muscle groups that usually work in concert). For example, the long muscles of the arm attach to several fingers to either flex or extend them. However, people can move their fingers one at a time.

A. Sensorimotor Mapping

Many reaching movements are made directly toward a target object. The term standard mapping applies to these kinds of movement. People often look at an object, orient attention toward it, and reach directly to

touch or grasp it. However, human behavior would be scarcely recognizable were it limited to standard mapping. People can also look in one direction while attending to a different place and reaching to a third, and everyone can use both spatial and nonspatial information to guide action.

1. Transformational Sensorimotor Mapping

In explaining the difference between standard and nonstandard mapping, prism adaptation serves as a case in point. When a diffracting prism distorts visual input, objects that lie directly in front of a person might appear to be 10° off to the right. When the person tries to reach to the object, he or she will reach ~10° too far to the right. However, the motor system can recognize this error and correct it through the process of motor adaptation, similar to that described previously for studying internal models (see Section IV.B). This behavior serves as a paradigmatic example of standard mapping: The motor system achieves the goal of directing the hand to the object, even though the prism distorts the object's location. In contrast, people can decide voluntarily to make a movement ~10° to the right of an object's location. This behavior serves as an example of nonstandard mapping. The motor system can produce an output that uses the spatial information in an object and transforms it according to some algorithm (such as 10° to the right) to produce a more flexible motor output than a system limited to standard mapping. This form of nonstandard mapping can be termed transformational mapping because the motor output depends on some transformed function of the spatial input.

2. Arbitrary Sensorimotor Mapping

Both of these spatially guided movements contrast with another form of nonstandard mapping termed arbitrary mapping. When nonspatial visual inputs, such as color, are used to determine the goals of action, an arbitrary mapping must be learned. Imagine a building with rooms of two colors: yellow rooms that require doorknobs to be twisted clockwise and blue rooms that require the opposite. Reaching toward the doorknob relies on standard mapping. Opening the doors requires arbitrary mapping, at least to do so reliably on the first attempt. Although this example is artificial, most signal- or symbol-guided behavior, including almost all language-guided behavior, depends on arbitrary mapping. Examples include stopping at a red light or at the sound of the word "stop."

B. Internal versus Sensorimotor Mapping

The idea that lateral nonprimary motor areas (such as PM) underlie external control of action, whereas medial areas (such as SMA) subserve internal control, has a link to related ideas concerning the motor functions of the basal ganglia and the cerebellum. It has been proposed that the cerebellum functions preferentially in externally guided action, whereas the basal ganglia controls mainly internally guided action. However, the functions of these structures are more complex than can be captured by such a simple dichotomy. The cerebellum participates in movements based on internal as well as external cues, and the basal ganglia plays a role in movements modulated by sensory as well as nonsensory information. Furthermore, contrary to earlier views, influences from both cerebellum and basal ganglia converge on both medial and lateral nonprimary motor areas.

How can these differing views be reconciled? Some progress can be made by recognizing functional subdivisions with both the basal ganglia and the cerebellum and by eschewing all-or-none dichotomies. Cells in caudal parts of one deep cerebellar nucleus, the dentate nucleus, have a preference for movements based on visual inputs (externally guided action) compared to kinematically similar movements generated from memory, whereas rostral parts have fewer cells with such preferences (i.e., they are relatively nonselective). Likewise, cells in the dorsal parts of the GPi have a strong preference for memorized sequences (internally guided action), whereas the ventral parts of GPi lack such selectivity. M1 and SMA receive their largest inputs (via the thalamus) from the less selective parts of the basal ganglia and cerebellum. Accordingly, M1 and SMA play a fairly general role in motor control and lack strong specializations for either internal or external control.

In contrast, PM receives its predominant inputs from the part of the dentate nucleus more selective for externally guided movements. Accordingly, PM has a large role in externally (often visually) guided action. For example, lesions to or inactivation of dorsal PM prevent monkeys from using color (or other nonspatial visual information) to choose an action.

The internally selective (dorsal) part of GPi preferentially influences the pre-SMA, which likewise appears to be specialized for internally guided action. Cells in pre-SMA have their greatest activity for internally guided movements, including movement sequences, and show other sequence- or order-specific patterns of activity. Temporary inactivation of the

pre-SMA disrupts the ability to produce a memorized (internally guided) sequence but not a visually triggered one. Brain imaging and brain lesion research also suggests the involvement of medial nonprimary motor areas in the learning of both limb- and eye-movement sequences and the "spontaneous" generation of action. In particular, pre-SMA, has been proposed to function in changing or updating motor plans based primarily on signals internal to the CNS.

Therefore, both medial and lateral parts of the motor cortex contain generalized as well as specialized components. Generalized parts include SMA (medially), and M1 (laterally). Specialized elements include the laterally situated PM, which maps sensory information onto motor outputs in a highly flexible manner, and the medially situated pre-SMA, which along with SMA maps a vast array of memorized and other nonsensory information onto motor output. A medial specialization for internal information accords with the role recently proposed for the rostral cingulate motor area in linking incentive magnitude to the selection of action, as occurs when one must choose an action based on some estimation of preferred outcome.

VI. EVOLUTION OF THE MOTOR SYSTEM

The motor system was born, not made, and many of the characteristics of the human motor system reflect its history. The CNS's chief function involves the acquisition of a behavioral repertoire, which can be stored both genetically and epigenetically, and the selection from that repertoire of the actions most likely to enhance an individual's fitness, in the inclusive sense of that term.

It seems likely that the ability to move in a goal-directed manner developed in an invertebrate ancestor of vertebrates. Many experts believe that the coordinated guidance of action represents the principal function of the CNS and comprises, in all likelihood, the crucial adaptive breakthrough made by the vertebrates and their ancestors. (Other animals made the same leap, but this article focuses on the human lineage.) The emphasis on motor control in evolution may seem paradoxical because, to us, complex and sophisticated cognition seems to be the principal characteristic of advanced animals, not motor control. However, in evolutionary history, long before our ancestors possessed the capacity for language, abstract reasoning, or highly general problem solving, they moved in relation to objects and places in their environment. It seems likely that the invertebrate ancestors of vertebrates (technically, cephalochordates) evolved from filter-feeding ancestors. They could swim in a coordinated manner, and they directed those actions with a brain and sense organs concentrated on the head, including paired eyes. The ability to do these things allowed our very distant ancestors to adopt a hunting life, one probably dominated by olfaction and vision. According to the fossil record, this revolutionary advance occurred about 500–550 million years ago. The human motor system, along with that of other vertebrates, has developed its capabilities by building on the original system. The motor system that people use to run, walk, talk, and manipulate objects evolved from the same one that originally evolved to control swimming and that was adapted to control flying, burrowing, and galloping in other species.

Thus, the motor system has a high degree of functional plasticity, at least as measured over geologic time. This plasticity of function contrasts with the conservatism of this basic morphological organization throughout vertebrate evolution. In the past, authorities have speculated that the brain evolved from caudal to rostral. That is, early comparative anatomists thought that the basal ganglia, for example, being located mainly in the telencephalon, evolved relatively recently in evolution. Anatomical names such as neostriatum testify to this notion. However, recent evidence from comparative morphology shows that the basal ganglia evolved very early in vertebrate evolution, probably at about the same time as the appearance of the first true vertebrates. Most of the remainder of the motor system also reflects our inheritance from our distant vertebrate ancestors. In addition to the basal ganglia, the superior colliculus, the red nucleus, the reticulospinal system, CPGs, and the alpha motor neurons retain their basic organizational patterns and functions from the earliest history of the vertebrate brain. The evolution of the cerebellum remains less certain, but it clearly emerged relatively early in the history of vertebrates as well.

What has changed in the past 500 million years or so? Of course, many of the basic components of the motor system have been elaborated and modified in many ways. In addition, an entirely new component has been added. In contrast to the ancient components of the motor system enumerated previously, the motor areas of neocortex have evolved much more recently. In a form that people can recognize as distinctively neocortical, a clear-cut motor cortex appears only in mammals. Thus, a separate motor cortex appears to have evolved only approximately 180 million years ago, a short time by evolutionary standards, especially

compared to the ancient lineage of the motor system's other main components. The relatively recent development of the motor cortex suggests that an important aspect of motor cortex function involves the modulation and control over subcortical motor systems, including the introduction of novel levels of flexibility in the motor system, such as transformational and arbitrary mapping, and the fractionation of relatively hardwired motor synergies.

GLOSSARY

basal ganglia A system of subcortical nuclei that receive cortical input and project to thalamic nuclear groups that project in turn to cortex. The basal ganglia thus contribute to a feedback loop for the control of movement as well as cognitive and often nonmotor functions. The globus pallidus and substantia nigra are the basal ganglia components that control motor cortical areas.

cerebellar nuclei Deep nuclei of the cerebellum that, together with the basal ganglia, control motor cortical areas via their projections to the motor thalamus.

cingulate motor cortex Motor cortical areas located in the cingulate sulcus and cingulate gyrus on the medial wall of the frontal lobe of primates.

motor cortex Cortex involved in control of movement. Often, it refers to only the primary motor field, M1, but premotor and other motor areas of frontal cortex may be included as well.

motor thalamus The part of the ventral thalamus that projects to motor cortex.

premotor cortex Nonprimary motor cortex on the dorsolateral brain surface, anterior to M1. Investigators currently describe this cortical region as having dorsal and ventral subdivisions.

supplementary motor area A motor area first described in the cortex of the medial wall of the frontal lobe of humans. It is sometimes called the second motor area, M2.

Motor cortex is the part of the neocortex of mammals that is devoted to evoking and controlling movements rather than receiving sensations and creating ideas or perceptions. Motor cortex is located in the posterior part of the frontal lobe or frontal cortex, just anterior to somatosensory cortex. Motor cortex includes a primary area, M1, where electrical stimulation of neurons evokes muscle contractions at low levels of current. M1 is characterized by large pyramidal or Betz cells and the lack of an obvious layer 4 of granular cells. Thus, M1 is referred to as agranular cortex and as area 4 of Brodmann's classical terminology. The pyramidal cells in M1 project via the pyramidal tract to motor neuron pools in the contralateral brain stem and spinal cord. A number of premotor areas are also involved in motor control. Muscle contractions can be evoked by electrically stimulating these premotor areas. Many of these areas connect to M1 and project to the spinal cord, thus directly influencing motor control.

I. HISTORY

The concept of a motor cortex, a specialized part of the neocortex of the forebrain devoted to causing movements, dates back over 130 years to the theories of the British neurologist, John Hughlings Jackson. This prominent clinician reasoned from the sequences of movements that spread from an initial site in patients with focal ("Jacksonian") epilepsy that body movements must be represented in part of neocortex in a systematic way. Jackson's theory of an organized motor cortex received substantial support in 1870 when two German investigators, Eduard Hitzig and G. Theodore Fritsch, electrically stimulated the surface of

the exposed neocortex in dogs and found that they could evoke muscle contractions on the contralateral side of the body. Soon, the British neurologist David Ferrier (1874) electrically stimulated the neocortex in monkeys and described a number of regions of cortex in which body and eye movements could be evoked. In further studies, Ferrier surgically removed the cortex where electrical stimulation evoked hand movements in monkeys, causing hand paralysis. By 1906, Charles Sherrington, a British neurophysiologist, had used electrical stimulation to map much of primary motor cortex in chimpanzees. Sherrington later received the Nobel prize. Although movements could be evoked from many regions of the brain, Sherrington stressed that movements could be evoked at the lowest stimulation thresholds from the cortex just anterior to the central sulcus in primates. This cortex was the "Betz cell" region containing large pyramidal cells first described in 1874 by the Russian anatomist Vladimir Betz, who considered the region motor in function. Later, the German neuroanatomist Korbinian Brodmann (1909) described a motor area (area 4) with giant pyramidal cells in humans and a number of other mammals. The first systematic description of the representation of movements in motor cortex of humans was by the German neurologist Otfried Foester in 1925. In the 1930s, the Canadian neurosurgeon Wilder Penfield stimulated motor cortex during surgery in patients with epilepsy and described the orderly way in which movements of body parts are represented in M1. Penfield illustrated the organization of M1 as a distorted little man, or homunculus, on the surface of cortex with the lips and the hand occupying much of M1. However, many of our current views on the organization of motor cortex were shaped by the detailed investigations of monkeys by Clinton Woolsey in the 1950s and 1960s. These studies established the basic organization of the primary motor area, M1, just anterior to somatosensory cortex. Within M1, a sequence of movements could be evoked from tail to foot, trunk, hand, face, and tongue when stimulating electrodes were moved from medial to lateral across precentral cortex.

Efforts were also made to distinguish premotor cortex from M1 and subdivide the premotor region into fields. The Betz cells of M1 were considered to be the major contributors to the pyramidal motor tract projecting to the spinal cord. Foester distinguished M1 as the cortex of the "pyramidal" system and more anterior regions of motor cortex as belonging to an "extrapyramidal" system. However, we now know that a number of areas contribute to the pyramidal corticospinal tract, and that only a minority of the axons are from the large Betz cells. The same areas also contribute to the extrapyramidal system, which indirectly projects to the spinal cord.

In approximately 1950, Penfield described a second orderly representation of movements in frontal cortex along the medial wall of the cerebral hemisphere in humans and monkeys. He referred to this motor region as the supplementary motor area (SMA). Woolsey soon described the SMA in more detail in monkeys, referring to this area as the second motor area, M2. Modern studies have greatly extended these early efforts, first by subdividing the dorsolateral premotor region into separate dorsal and ventral premotor areas and then by discovering evidence for more motor areas in cortex along the medial wall of the frontal lobe (Fig. 1).

Currently, 10–12 motor areas are thought to exist in primates. Fewer motor areas have been described in other mammals. Taxonomic groups of mammals apparently differ in the number of areas devoted to motor control. Marsupials may not have separate motor areas of the neocortex. Instead, somatosensory areas, which also contribute to motor functions in all mammals, seem to mediate the motor functions. Most mammals, however, have a M1 and at least one or more additional premotor areas. The SMA or M2 is likely to be a motor area common to most or all placental mammals.

II. PRIMARY MOTOR CORTEX

M1 occupies a broad band of cortex just anterior to somatosensory cortex (Fig. 1). In primates with a central sulcus, M1 is located just anterior to somatosensory areas 3a and 3b, on the anterior bank of the central sulcus, and extends onto the surface of most of the precentral gyrus. M1 closely corresponds to the region described by Brodmann as area 4 or the area of giant pyramidal cells (Betz cells). The term area 4 is commonly used as an alternate designation for M1. However, not all portions of M1 contain Betz cells. The lateral part of M1 is characterized by smaller size pyramidal cells. Thus, some definitions of the cortex comprising M1 may have included some of area 6. M1 is one of the thickest portions of cerebral cortex. M1 can be identified by its characteristic representation of body movements, unique histological appearance (most notably, a lack of an obvious layer 4 of granule cells and large layer 5 pyramidal cells), and consistent

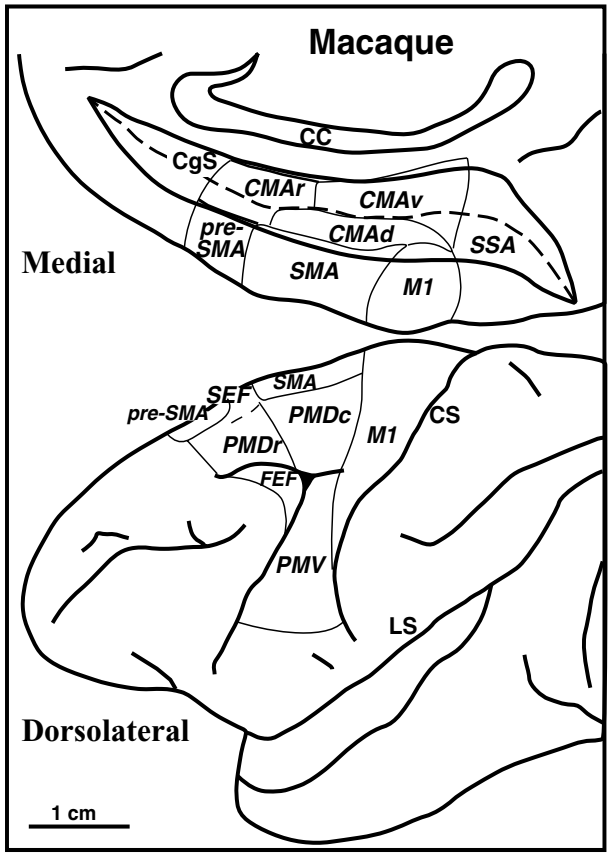

Figure 1 Motor areas of primates shown on a macaque monkey brain. (Bottom) A dorsolateral view of the frontal two-thirds of the brain. (Top) A view of cortex of the medial surface of the left cerebral hemisphere of the brain below shown rotated out so that ventral is at the top, allowing the motor areas to remain continuous. Primary motor cortex (M1) is on the precentral gyrus and it extends into the depths of the central sulcus (CS). Premotor cortex includes dorsal (PMD) and ventral (PMV) fields that appear to have rostral (PMDr) and caudal (PMDc) subdivisions (not shown for PMV). The supplementary motor area (SMA) was the first well-defined premotor area. Recently, a presupplementary motor area (pre-SMA) has been defined just rostral to SMA. On the medial surface of the cerebral hemisphere, two rostral (CMAr) and caudal (CMAc) cingulate motor areas have been defined. Some investigators divide CMAc into ventral (CMAv) and dorsal (CMAd) areas. pattern of connections with somatosensory areas, premotor cortex, and the spinal cord.

The basic topographic organization of M1 has long been known from early studies in which many locations were electrically stimulated with electrodes placed on the surface of the cortex. Recently, the detailed pattern of how M1 represents movements has been determined with microelectrodes advanced into the cortex to allow the electrode tip to be placed close to the layer 5 pyramidal cells that project to the spinal cord. Thus, lower levels of current can be used to stimulate these output cells and cause movements, a technique known as microstimulation.

A long-standing debate has been whether M1 represents muscles or movements. Recordings from muscles, made while the cortex is microstimulated, indicate that single sites in M1 activate a number of pools of motor neurons in the spinal cord and brain stem so that each site of cortical stimulation activates several muscles that seem to be related in some form of movement. Although one muscle may be activated more strongly than others, the cortex seems to be subdivided into clusters or columns of neurons related to different types of movements or the generation of specifically directed forces. Cortical neurons typically activate several muscles that work together to cause a movement, while they inhibit outputs to muscles that produce the opposite movement. However, the specific muscles involved in making the movement are closely reflected in the activities of at least some neurons in M1.

Overall, movements of different body parts are represented in a systematic pattern across the mediolateral length of the M1 belt of cortex (Fig. 2). The most medial sites cause tail, toe, foot, and leg movements, whereas more lateral sites cause trunk movements, and a large lateral region is devoted to digit, wrist, and arm movements. The most lateral sites contribute to face and tongue movements. Because the projections of M1 via the pyramidal tract cross in the lower brain stem to terminate on motor neurons on the opposite side of the brain stem or spinal cord, these movements are all of muscles of the opposite side of the body. Parts of M1 that represent the trunk and proximal limbs of the two hemispheres are linked by connections through the corpus callosum. However, callosal connections are distinctly sparse or absent in M1 areas that represent the hands and feet. Thus, movements of hands or feet are controlled independently by a single M1. Although M1 is devoted to movements of the opposite side of the body, some coordination of movements of the two sides may occur via connections of one M1 with the other, especially for trunk and other proximal movements.

There have been various attempts to characterize the detailed local organization of M1. There does not seem to be a simple topographic pattern. Instead, the same or similar movements can be evoked from several nearby sites in the same region of M1, whereas

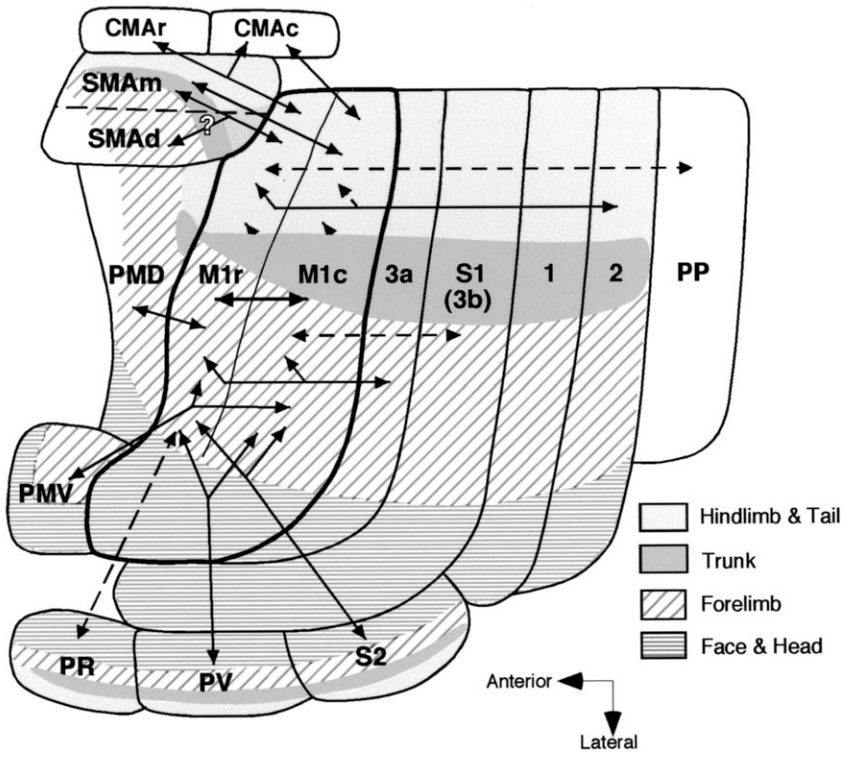

Figure 2 Some of the ipsilateral cortical connections of primary motor cortex, M1, in New World owl monkey. Most of these connections have also been reported for other species of monkeys. The organization of the sensory and motor representations in each area is indicated by shading. Major interconnections are indicated by thick arrows. Less dense connections are indicated by dashed arrows. Motor areas include M1 with rostral (M1r) and caudal (M1c) subdivisions, ventral (PMV) and dorsal (PMD) premotor cortex, supplementary motor area (SMA), presupplementary motor area (pre-SMA), and rostral (CMAr) and caudal (CMAc) divisions of cingulate motor cortex. Somatosensory areas include areas 3a, 3b, 1, and 2 of anterior parietal cortex; the second somatosensory area (S2); and the parietal ventral (PV) and the parietal rostral (PR) areas of lateral parietal cortex and posterior parietal cortex (PP).

adjoining sites evoke different but related movements. Thus, M1 appears to consist of a mosaic of small efferent zones or modules, with each module evoking a specific movement. Modules related to a given body region are grouped; within a region a specific type of module often occurs more than once. For example, modules moving different digits tend to be grouped; while bordering each other in different ways. These, in turn, border on modules for wrist, elbow, and even shoulder movements. Since neighboring modules might easily facilitate each other through local interconnections, this arrangement might allow different combinations of useful movements to be programmed in M1.

Stimulation of sites in M1 evokes small or restricted movements only when low levels of current are used. At higher levels of current, additional body parts become involved in more complex movement. For example, wrist movements may be added to digit movements. Thus, cortical sites may be involved in the control of a number of related muscles, provided that the recruitment of additional movements is not due to current spread. In addition, the local circuits in motor cortex are modifiable so that the consequences of electrical stimulation depend somewhat on ongoing sensory events or on recent activity patterns in M1. Conditioning by periods of electrical stimulation of M1, for example, can alter the precise nature of the response evoked by a subsequent stimulation. These effects are likely mediated by local connections within and between cortical modules in M1, allowing some flexibility in performance.

The details of the representations of movements in M1 can be modified by experience and training. The organization of M1 in humans can be evaluated in a noninvasive manner by stimulating motor cortex through the scalp by placing a magnetic coil over various parts of motor cortex and inducing current

flow in cortex (transcranial magnetic stimulation). Finger movements can be evoked over a larger region of cortex in highly skilled musicians who use their fingers to play instruments, suggesting that years of practice have changed the organization of their motor cortex so that more neurons in M1 are used to control finger movements. Changes in M1 with practice may also play a role in the recovery of motor control after partial lesions of motor cortex accompanying stroke. Monkeys with damage to parts of M1 that represent finger movements may reorganize so that remaining parts of M1 reinstate control over finger movements. Possibly as a result of cortical reorganization, the monkeys improve in their ability to skillfully use their fingers. Thus, the reinstatement of cortical representations may be responsible for the recovery of motor skills. Other motor areas may also be modified by experience as new motor skills are acquired.

M1 is considered to be a major area for initiating and controlling voluntary movements. Damage to M1 in humans may severely impair the ability to initiate movements, although much recovery occurs over time. Typically, lesions result in decreased use of the impaired contralateral limb or limbs and deficits in manual skill and speed of movement. Partial recovery of lost abilities may depend on the reorganization of remaining parts of M1 to devote more neurons to the needed functions as well as increased involvement of other intact parts of the motor system.

The discharge patterns of neurons in M1 reflect the important role that M1 plays in evoking movements. Neurons subserving a body part activate prior to the movement of that part, as one would expect if they function to initiate and control movements. For a particular movement, many neurons may be active, some much more than others. For a similar but slightly different movement, other neurons will be most active, but many of the same neurons will respond to a lesser degree. Neurons tend to be activated preferentially with some movements. A population of activated neurons has a different activity profile for each type of movement. The type and strength of a given movement depend on what neurons are active and on their levels of activity. In addition, some neurons become active in advance of intended movements. A sensory signal indicating that a movement should start soon initiates activity changes in such neurons.

The functions of M1 depend on its connections with other parts of the brain (Fig. 2). Motor behavior may be modified by sensory information, especially from receptors in the skin and muscles. Some of this information reaches M1 from areas of somatosensory cortex, especially areas 3a and 2 of anterior parietal cortex. These areas are activated by inputs from muscle spindle receptors. Feedback from muscle receptors during movements is very important in motor control. Other inputs come from higher order areas of somatosensory cortex such as the second somatosensory area, S2. In addition, many of the premotor areas are densely interconnected with M1. These premotor areas may influence motor behavior partly or largely through altering activity patterns in M1. Another source of sensory information is less direct. The cerebellum receives sensory inputs from muscle receptors and other receptors, integrates and adjusts this information, and sends projections to the specific region of thalamus, which in turn projects to M1 and several premotor areas. M1 sends feedback connections to the thalamus, somatosensory, and premotor cortical areas. The feedback connections from M1 to somatosensory areas of cortex alter the responses of neurons to sensory stimuli so that inputs related to self-initiated movements may be ignored. This feedback may produce corollary discharge in neurons leading to a sensation of movement. M1 also receives the broad cortical input indirectly by way of the internal segment of the globus pallidus, the portion of basal ganglia of the extrapyramidal system that projects to the motor thalamus. Thus, the processing loops in the motor network are complex. A major output of the M1 is via the pyramidal tract to motor neurons distributed in the brain stem and spinal cord. Most of the axons in the descending pyramidal tract cross from their side of origin to the other side in the lower brain stem as the pyramidal decussates. A small portion of these axons continue to descend in the ipsilateral spinal cord, where they may later cross to the opposite side or remain on the same side to influence ipsilateral motor neurons and ipsilateral body movements.

Recent anatomical and physiological data suggest that M1 has two functionally distinct subregions (Fig. 2). Cytoarchitectonic evidence for rostral (M1r) and caudal (M1c) subdivisions was found in both monkey and human brains. On the basis of differences in the cortical and subcortical connectivity of these two regions, as well as differences in the response properties of neurons, it has been proposed that these two divisions are specialized for the control of different stages of movement. M1r, which is less excitable than M1c and receives stronger projections from premotor cortex, may preferentially be involved in early stages of movements, including the postural adjustments required to maintain balance during reaching for an

object. These movements could be programmed by nonprimary motor areas and carried out with the aid of kinesthetic information reaching M1r from somatosensory areas. M1c, which is more excitable and receives diverse somatosensory inputs, may be more involved in the control of later stages of movement, such as grasping and holding objects, in which cutaneous feedback is especially important.

III. DORSOLATERAL PREMOTOR CORTEX

Premotor cortex is the cortex just anterior to M1 where electrical stimulation evokes movements, but at higher levels of current than in M1. Premotor cortex also projects much less densely to the spinal cord than M1. Premotor cortex is generally thinner than M1, but like M1 it has an indistinct or poorly developed layer 4 and thus is agranular or dysgranular in appearance. Unlike M1 (area 4), premotor cortex lacks a dense population of large pyramidal cells (Betz cells). Brodmann characterized most of this region as area 6. The frontal association cortex just rostral to area 6, generally termed prefrontal cortex, is recognized by the appearance of a distinct layer 4.

Premotor cortex is uniform in neither structure nor function, and it clearly contains several cortical fields. Most investigations distinguish at least two nonprimary motor fields: a dorsal premotor area (PMD) and a ventral premotor area (PMV) (Figs. 1–3). PMD is agranular in histological appearance, whereas PMV is dysgranular, having a thin granular layer 4. Both PMD and PMV lack a significant number of giant pyramidal cells, which are numerous in M1. The density of myelinated fibers, the density of reactivity of some metabolic enzymes, and the intensity of some types of immunoreactivity are distributed differently in PMD and PMV. Descending projections from both areas are also differently organized. These areas require different levels of electrical stimulation to evoke movements and have different patterns of movement representation.

PMD is located just anterior to M1 and lateral to the SMA. PMD extends laterally to the level of the frontal eye field. PMD is significantly less responsive to intracortical microstimualtion and has markedly higher thresholds for eliciting muscle contractions than M1. Electrical stimulation evokes hindlimb movements in medial PMD and forelimb movements in lateral PMD. Although movements of both the proximal and the distal limbs can be evoked from PMD, proximal limb movements (involving shoulder or shoulder and elbow) are most common. Neurons subserving face and eye movements may be located most laterally, just posterior to the frontal eye field.

PMD may be engaged in movements that require orienting the eyes, head, and trunk toward the target when limb movements are directed toward nearby objects and when posture is adjusted. Neurons in PMD project in such a way that those projecting to spinal cord motor pools for the leg are medial to neurons projecting to spinal cord motor pools for the arm. Anteriorly, PMD borders on prefrontal cortex, where neurons do not project to the spinal cord.

Neurons in PMD typically respond to cues that indicate that a motor response will soon be necessary. The neurons also fire during the waiting period and during the movement. As in M1, many neurons in PMD are activated during particular movements and during limb movements in a particular direction. Thus, PMD appears to have roles in the preparation and guidance of movements. Important sensory inputs to PMD originate in somatosensory and visuomotor

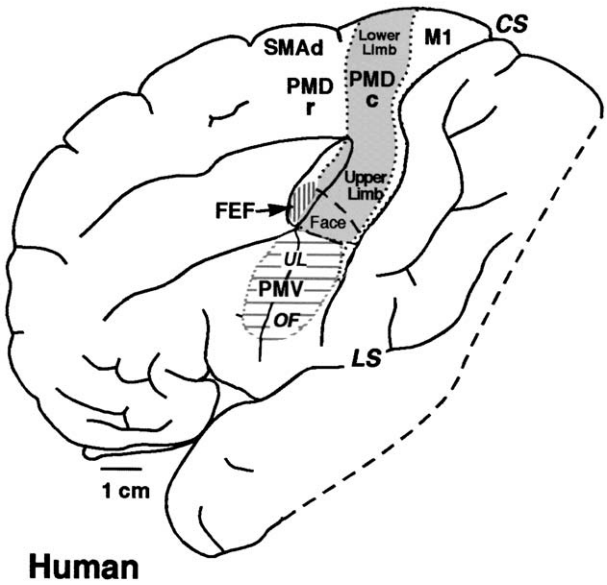

Figure 3 Proposed locations of primary motor cortex (M1) and premotor fields in the frontal lobe of humans. Rostral (r) and caudal (c) subdivisions of dorsal premotor cortex (PMD) are indicated, as are the ventral premotor area (PMV), the frontal eye field (FEF), and the dorsal division of supplementary motor area (SMAd). In PMV, the upper limb is represented medial to the face and mouth (UL and OF). Most of M1 is buried in the rostral bank of the central fissure (CS). Previous interpretations have extended M1 further onto the surface of the precentral gyrus to cortex we consider to be PMD.

areas of posterior parietal cortex. PMD is reciprocally connected with PMV, M1, the SMA, and cingulate cortex.

The rostral half of PMD is sometimes distinguished as a separate rostral field, PMDr, because current levels for evoked movements are higher and eye and face movements are sometimes evoked. Moreover, a scattering of Betz cells can be found in caudal PMD, whereas in the rostral PMD such large cells are essentially absent. Both caudal and rostral PMD regions are interconnected and the two areas may function in concert.

The PMV is located immediately anterior to the representation of face and tongue movements in M1. PMV can be distinguished from M1 and PMD by the presence of a thin but distinct internal granular layer 4. A layer 5 containing medium-sized pyramidal cells is prominent. Electrical stimulation of PMV results in forelimb, face, tongue, and eye movements. Hand movements are generally produced from cortex just dorsal to cortex subserving face movements. There is no clear evidence for a region devoted to hindlimb movements. Since the currents needed to evoke the movements can be as low as those for M1, PMV has been included within M1 by some authors.

PMV has been divided into separate rostral and caudal areas based on histological differences and different response properties of neurons or into medial and ventral parts based on differences in cytoarchitecture and connectivity. In humans, part of PMV of the left cerebral hemisphere (Fig. 3) may be specialized and is known as Broca's area, which is involved in the motor control of speech.

PMV appears to have a major role in visually guiding arm movements. Neurons in caudal PMV tend to respond to touch on the hand, arm, face, and mouth and to visual objects close to or approaching the hands, arm, face, and mouth. Neurons that respond to touch on the hand or arm have visual receptive fields that move with the hand or arm. Neurons in caudal PMV respond to appropriate sensory stimuli and during reaching and grasping movements. The more rostral part of PMV may be more involved in initiating grasping movements of objects such as bits of food and in bringing them to the mouth. Neurons in rostral PMV tend to respond while an object that is to be grasped, such as a desired food object, is observed and during reaching and grasping. Other neurons in rostral PMV, termed mirror neurons, respond during an action such as grasping a bit of food but also when another individual is observed performing the same action. These mirror neurons may have a role in learning from others by imitation or in mental rehearsal. Some investigators propose that learning by imitation plays an important role in language acquisition in humans. Thus, mirror neurons in ventral motor cortex, especially in the left hemisphere, may have language functions in humans. In monkeys, lesions of PMV disturb visually guided reaching movements. PMV's role in guiding reaching movements may depend on its inputs from visuomotor areas in posterior parietal cortex and somatosensory parts of the lateral sulcus. PMV also has connections with M1, PMD, SMA, and cingulate cortex as well as direct projections to the cervical spinal cord, in which motor neurons subserve arm and hand movements.

The dorsolateral premotor region also contains an area with visuomotor functions, the frontal eye field (FEF), which is located just rostral to the junction of PMD and PMV (Figs. 1 and 3). Electrical stimulation within the FEF evokes either saccadic or smooth-pursuit eye movements. The subregion for smooth-pursuit movements is caudal to the subregion for saccadic movements. The FEF receives inputs from a number of visuomotor areas in the temporal and parietal lobes, from adjoining regions of prefrontal cortex, and from frontal visuomotor regions such as the supplementary eye field. Important outputs are to the superior colliculus and to brain stem visuomotor nuclei.

IV. SUPPLEMENTARY MOTOR CORTEX

The SMA was first described in the cortex of the medial wall of the frontal lobe of humans more than 50 years ago. In monkeys, SMA extends onto the dorsal surface of the medial frontal lobe just rostral to M1 and medial to PMD (Fig. 1). The area is also known as the medial premotor cortex (MPC). Although SMA is usually considered to be a single area, it has been divided into medial (SMAm) and dorsal (SMAd) subdivisions in monkeys (Fig. 2). SMAm appears to be more densely connected to M1, whereas SMAd is somewhat more myelinated. More consistently, the SMA region has been divided into a SMA-proper (SMAd plus SMAm), located immediately rostral to the mesial sector of M1 representing foot, and a pre-SMA, extending toward prefrontal cortex just anterior to a SMA-proper. Both regions border the agranular cingulate cortex in the cingulate sulcus.

SMA was initially recognized when electrical stimulation of the region evoked movements in humans.

SMA has subsequently been described in monkeys and carnivores. The region known as M2 in rats is likely to be SMA. Thus, SMA may be an area that exists in many mammals. Stimulation of posterior SMA evokes movements of the contralateral leg, the middle portion is related to movements of the arm and hand, and the most anterior portion is devoted to the face. Current thresholds for evoking movements are generally higher in SMA than in M1. The internal organization of SMA is like a smaller version of M1. Like M1, similar movements may be elicited from more than one site in SMA. Matching bilateral movements are occasionally evoked from sites in SMA.

SMA is within the medial part of Brodmann's area 6. The cortex is agranular, without an obvious layer 4 of granule cells. The layer 5 pyramidal neurons are generally smaller than in adjoining M1. SMA has dense interconnections with M1 and dense projections to the motor neuron pools in the spinal cord. Inputs include those from visual, somatosensory, and auditory association and multimodal areas of the temporal and parietal lobes. SMA receives major inputs from regions of the thalamus with inputs from the internal segment of the globus pallidus, and a minor input from that part of the thalamus receiving inputs from the cerebellum.

Neurons in SMA respond to visual, auditory, and tactile stimuli when these stimuli are used as signals to start a movement or series of movements. When the signal indicates that a movement must be delayed for a short period of time, SMA neurons respond strongly during the delay period. This is partial evidence that SMA has a role in initiating and planning movements.

SMA was originally thought to have a significant role in coordinating movements of the two hands, partly because electrical stimulation of SMA neurons was once thought to commonly evoke ipsilateral movements. This has proven to be rare, however. During movements of one side of the body, only contralateral SMA shows significant activity. Although connections are strong between the SMA of each cerebral hemisphere, lesions of SMA do not produce deficits that suggest a major role in bimanual coordination. Instead, SMA appears to be important in the initiation of contralateral movements, motor programming, motor planning, and motor learning. After lesions, voluntary movements can be elicited by sensory cues and skilled movements can be executed. However, lesions impair the ability to self-initiate learned movements and sequences of movements when no sensory cue indicates the time for movement onset.

Pre-SMA is a small region of cortex just rostral to SMA. Movements are usually not evoked by electrical stimulation of pre-SMA unless much higher current levels are used and a series of current pulses of longer duration are employed. Pre-SMA lacks direct connections with M1, and it does not project or projects very weakly to motor neurons in the spinal cord. Pre-SMA has strong connections with prefrontal cortex, SMA, and cingulate motor areas. Neurons in pre-SMA are preferentially active prior to movement, and they respond less frequently to somatosensory stimuli but more frequently to visual stimuli. Pre-SMA is thought to be involved in the more cognitive aspects of motor behavior, possibly in updating motor plans and in the learning of new motor sequences.

In addition to somatomotor areas, a separate oculomotor area, the supplementary eye field (SEF), is found in the dorsomedial frontal cortex. SEF lies rostrolateral to the SMA and pre-SMA, and it is distinguishable from these two areas by its close relation to eye movements and its anatomical connections with cortical and subcortical oculomotor centers.

V. CINGULATE MOTOR CORTEX

Cingulate cortex along the medial wall of the cerebral hemisphere has traditionally been associated with the limbic system. The functionally significant subdivisions of cingulate cortex are not well established. Architectonically, the region is formed by two clearly distinct regions, areas 23 and 24 of Brodmann, with the more posterior granular area 23 having an obvious layer 4 and the more anterior agranular area 24 lacking a clear layer 4. Both areas are located ventral to the agranular cortex of pre-SMA, SMA, and M1. These two large cingulate regions have been further subdivided into smaller architectonic fields, such as area 24c and area 24d. Cingulate cortex is generally thought to be involved in emotional behavior. Recently, however, parts of cingulate cortex have been associated with the motor system.

There is good evidence for at least two motor fields in cingulate cortex (Fig. 2). Just ventral to pre-SMA along the medial surface of cortex, a rostral cingulate motor area, CMAr, occupies both the dorsal and the ventral banks of the cingulate cortex of monkeys. CMAr corresponds closely to part of area 24c of architectonic studies. Electrical stimulation of neurons in CMAr causes movements of contralateral body parts. Neurons related to hindlimb movements

are located caudally and neurons related to forelimb movements are located rostrally. The forelimb and hindlimb portions of CMAr project to the forelimb and hindlimb portions of M1 and the spinal cord. Neurons in CMAr are active before movements as well as during movements. Thus, these neurons are active during the intention to move, and they are not simply responding to the sensory consequence of movement.

A caudal cingulate motor area, CMAc occupies the dorsal and ventral banks of the cingulate sulcus just behind CMAr and ventral to SMA and M1. The cortex has a thin layer 4 and is within area 23c. Some investigators divide this region into dorsal and ventral fields (Fig. 1). CMAc projects to both M1 and the spinal cord. Electrical stimulation of CMAc evokes movements. The forelimb representation in CMAc appears to be rostroventral to the hindlimb representation. Other connections of the cingulate motor areas include dorsal and ventral premotor areas and regions of prefrontal cortex. The distribution of thalamocortical projections to CMAr and CMAc indicates that nuclei of the motor thalamus (ventral anterior nucleus and the caudal part of the mediodorsal nucleus) have projections that are greatest to area 24. Area 23 receives its principal thalamic inputs from the anterior nuclei, which are thought to participate in memory and emotion.

The functional roles of CMAr and CMAc are not well understood. The more caudal area, CMAc, with a thin layer 4 would appear to be more sensorimotor rather than purely motor in function. One proposal is that CMAr is involved in more executive functions and CMAc in more evaluative functions, such as monitoring the outcome of actions.

In addition to CMAr and CMAc, a more caudal portion of cingulate cortex projects to the spinal cord and possibly to M1. This cortex has a well-developed layer 4, and it is well within Brodmann's area 23. This portion of cingulate cortex, just ventral to somatosensory cortex, may include the region sometimes described as the supplementary sensory area (SSA; Fig. 1). The well-developed layer 4 suggests that this subdivision of cingulate cortex has important sensory functions, but the motor connections indicate a role in motor behavior as well.

In addition to CMAr and CMAc, electrical stimulation of more rostral parts of area 24 in monkeys evokes vocalizations. This region has been called a vocalization area. Vocalizations in monkeys are associated with emotional states, much like crying and laughing in humans.

VI. INFLUENCE OF THE CEREBELLUM AND THE BASAL GANGLIA ON THE MOTOR CORTICAL AREAS

Two main subcortical motor centers, the cerebellum and the basal ganglia, modulate the activity of cortical motor areas by providing feedback circuits. Their output nuclei [the cerebellar nuclei for the cerebellum and the internal segment of the globus pallidus (GPi) and the substantia nigra for the basal ganglia] receive indirect inputs from a variety of cortical somatosensory, motor, and associative areas and send their outputs, via the thalamus, back to the motor and premotor areas along with prefrontal, parietal, and other cortical areas. These motor areas receive cerebellar and pallidal inputs primarily through relays in the ventral lateral (VL) and ventral anterior (VA) regions of the thalamus. GPi sends a large number of GABA-containing fibers to the anterior region of the motor thalamus (VA nucleus) and the anterior part of the ventral lateral nucleus (VLa). Recent evidence shows that particular subsets of GPi neurons project to zones of VL that in turn project to individual cortical motor areas such as M1 or SMA, each of which contributes to the corticospinal tract. Thus, the multiple projections from GPi back to the cortex influence different cortical zones with different motor function. The deep cerebellar nuclei send excitatory input mostly to the posterior region of the motor thalamus (VL nuclei). The thalamus is not a simple relay of information from the cerebellum and globus pallidus to the cortex but, rather, a center for the integration these subcortical motor inputs with feedback from motor cortex.

The degree of overlap between the terminal fields of cerebellar and pallidal afferents in the thalamus is not well established. Although there is a broad consensus that the thalamic projections from the cerebellum and globus pallidus are mostly segregated, there is evidence for partial overlap in the motor thalamus. Cerebellar projections are concentrated posteriorly, whereas pallidal projections are concentrated anteriorly within VL nuclei. Pallidal and cerebellar afferents are highly segregated in the central core of these thalamic nuclei, but both inputs can be found within transitional zones between nuclei. In such regions the two inputs usually interdigitate, although occasionally they may overlap.

The motor cortical areas are reciprocally connected with the specific thalamic nuclear groups from which they receive their primary input, and these thalamocortical projections are critical for the functional output of the motor cortices. M1 has dense

topographically organized connections with the VL complex. The caudal part of M1 is most strongly connected with the posterior VL nucleus, a recipient of cerebellar projections, whereas the rostral part of M1 is most strongly connected with the anterior VL nucleus, a recipient of pallidal projections. Thus, both cerebellar and pallidal inputs to the thalamus are relayed to M1. Similarly, the SMA and pre-SMA areas receive both transthalamic inputs, although these inputs are largely derived from GPi. Finally, the dorsal and ventral premotor areas receive projections from anterior and posterior VL regions activated by both the pallidum and the cerebellum.

The functional contributions of the cerebellum and the basal ganglia to motor action are not clear, but both are necessary for smooth movements and posture. Degenerative diseases of the basal ganglia produce involuntary movements, paucity of movement, and abnormalities in posture. Damage to the cerebellum produces characteristic loss of coordination and accuracy of limb movements. Damage to either region may result in tremor.

VII. MOTOR FUNCTIONS OF SOMATOSENSORY CORTEX

The somatosensory areas of the parietal lobe make a substantial contribution to the pyramidal tract, and it is not surprising that movements can be evoked by electrically stimulating sites in these areas. Somatosensory cortex of humans and other primates includes four architectonic fields in anterior parietal cortex: areas 3a, 3b, 1, and 2, after Brodmann (Fig. 2). All these fields were once considered to be parts of a single primary somatosensory area, S1, but we now know that each architectonic field corresponds to a separate representation of body receptors and only area 3b corresponds to S1 of other mammals, such as rats and cats. Electrical stimulation of these fields and other higher-order fields such as the second somatosensory area, S2, of the lateral sulcus evoke movements related to the body part providing sensory inputs to the representation, but the levels of current needed to evoke movements are substantially higher than those for M1. The exception is area 3a, in which the thresholds for evoked movements are only slightly higher than those needed for M1. Area 3a may be especially involved in motor functions since it is activated by muscle spindle receptors, and these receptors provide feedback about ongoing movements. In addition, area 3a projects strongly to M1. Area 3a contains many pyramidal cells projecting to the spinal cord. Some investigators have described area 3a as having histological features of both sensory and motor cortices. S2 also projects densely to the spinal cord and to M1. Although some of the motor functions of somatosensory cortex might be mediated through these connections with M1 in intact primates, movements can still be evoked by electrically stimulating somatosensory cortex after complete lesions of M1. Also, as already noted, opossums and other marsupials do not appear to have any separate motor areas, but they have somatosensory areas that are sensorimotor in function.

VIII. CONCLUSIONS

Descriptions of motor cortex often include only the primary motor area, M1. However, humans and other primates also have a number of other cortical areas that are involved in the generation of motor behavior. Recently, evidence has been presented that at least 11 motor areas can be distinguished (9 somatomotor and 2 oculomotor). Each area is architectonically different and has a unique combination of connectivity to subcortical nuclei and cortical areas. The functional relationship of these areas involves both hierarchical and parallel components. Whereas the primary motor cortex is involved mainly in the execution of voluntary movements, nonprimary motor areas, including SMA, PMD, PMV, and cingulate areas, are engaged in higher order motor processing, such as preparation, and programming of sequences of movements and coordination of bilateral and other complex movements. These areas make up a second level of motor fields that interact with M1 and act in parallel with M1 by projecting to the motor neuron pools in the spinal cord and brain stem. By projecting to the spinal cord, each of these areas has the potential to influence the generation and control of movement independently, even when M1 is lesioned. A pre-SMA and possibly other fields represent a third level of areas with motor function. These fields interact with areas of the second level but not directly with M1 and not in parallel with M1. Areas of somatosensory cortex, especially areas 3a and S2, have motor as well as sensory functions. These cortical areas interact as part of a complex motor control network that also involves the motor thalamus, the substantia nigra, the cerebellum, and the basal ganglia. The motor thalamus receives cerebellar,

pallidal, and nigral inputs. Most motor behaviors probably involve the majority of cortical areas, and they likely have overlapping functions. However, there is evidence for specialization of fields so that different impairments emerge from lesions of different areas. There is much yet to learn about motor cortex, especially how the populations of neurons in each area contribute to specific types of motor behavior.

Motor Neuron Disease

PHILIP C. WONG, DONALD L. PRICE, and JEFFERY ROTHSTEIN
Johns Hopkins University School of Medicine

The motor neuron diseases, an etiologically heterogeneous group of disorders, are manifested by weakness (muscle atrophy) and/or spastic paralysis, reflecting the selective involvement of lower motor neurons and/or upper motor neurons, respectively. Amyotrophic lateral sclerosis, the most common adult-onset motor neuron disease, involves both lower and upper motor neurons. Spinobulbar muscular atrophy (or Kennedy's disease) and spinal muscular atrophy selectively affect lower motor neurons, whereas hereditary spastic paraplegia predominently involves upper motor neurons. During the past several years, significant progress has been made in identifying some of the genes/chromosomal loci associated with these illnesses. We briefly describe the clinical features/neuropathology of several of these diseases and then discuss recent progress in understanding the genetics and molecular/cell biology of these diseases and the status of investigations of *in vivo* and *in vitro* models relevant to some of these illnesses.

I. AMYOTROPHIC LATERAL SCLEROSIS AND FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS

A. Clinical Features/Neuropathology

With a worldwide prevalence of $\sim$5 per 100,000, amyotropic lateral sclerosis (ALS) usually occurs in mid to late life and is manifest as progressive muscle weakness accompanied by hyperreflexia and spasticity associated with fibrillations, fasciculations, and giant polyphasic potentials. Muscle biopsies demonstrate denervation and muscle atrophy, and patients usually die of intercurrent illnesses. Muscle atrophy and weakness reflect selective degeneration of large motor neurons of the brain stem and spinal cord; spasticity, hyperreflexia, and extensor plantar signs are attributable to lesions of upper motor neurons.

Lower motor neurons show several abnormalities: the presence of phosphorylated neurofilament and ubiquitin immunoreactivities in inclusions within cell bodies, Lewy body-like intracytoplasmic inclusions, NF swellings of proximal axons, fragmentation of the Golgi, and attenuation of dendrites. In some cases of superoxide dismutase-1 (SOD1)-linked familial ALS (FALS), intracytoplasmic inclusions contain SOD1, ubiquitin, and neurofilament immunoreactivities, and neurofilaments accumulate in cell bodies and neuronal processes, particularly proximal axons. The roles of these inclusions are unclear. The presence of ubiquitin immunoreactivity suggests that these inclusions contain proteins destined for degradation, presumably in part via the proteosome. Whether components within these aggregates sequester essential molecules needed for the biology of motor neurons or whether the

malfolded protein can perform aberrant catalytic reactions is unknown.

Motor nerves show axonal atrophy and Wallerian degeneration. Eventually, the numbers of motor neurons in brain stem nuclei and spinal cord are reduced and there is a loss of large pyramidal neurons in motor cortex. These lesions are accompanied by degeneration of axons in peripheral motor nerves and corticospinal tracts, respectively, and denervation of target fields of these axons. Although the mechanisms of neuronal death in ALS are poorly characterized, recent studies have documented that motor neuron degeneration structurally resembles the process of apoptosis. In ALS motor cortex and spinal cord anterior horn, there is evidence of DNA fragmentation, caspase-3 activation, and redistribution of cell death proteins such as Bcl-2, Bax, and Bak.

A variety of mechanisms, including excitotoxicity, copper toxicity, oxidation/nitration-mediated damage, protein misfolding, aggregation of critical components, apoptosis, calcium-mediated processes, and alterations in the biology of neurofilaments are among the processes that have been suggested to play roles in ALS and FALS.

B. Genetics of ALS

Several gene/loci associated with ALS have been identified (Table I).

1. SOD1 Gene

Approximately 5–10% of ALS cases are familial, and in almost all cases inheritance exhibits an autosomal-dominant pattern. Approximately 15–20% of patients with autosomal-dominant FALS have missense point mutations in the gene that encodes cytosolic Cu/Zn SOD1 (Table I), the enzyme that catalyzes the conversion of $\cdot O_2$ to O_2 and H_2O_2. To date, >70 different mutations have been identified in the SOD1 gene. There is clear evidence of allelic heterogeneity, with phenotypes associated with different mutations sometimes showing differences; for example, cases of A4V SOD1 FALS have limited involvement of the corticospinal tract, whereas other SOD1 mutations are associated with a more classic ALS syndrome.

2. Other Genes/Loci Relevant to ALS

A variety of chromosomal loci have been linked to autosomal-dominant, autosomal-recessive, and X-linked-dominant forms of ALS. Notably, investigators have described a large family with autosomal-dominant juvenile ALS (JALS) linked to a locus at the 9q34 region. Manifested by the presence of slowly progressive distal atrophy, weakness, and corticospinal signs, these cases show a marked loss of spinal motor neurons and less pronounced degeneration of the corticospinal tracts. The peripheral nerves and dorsal and ventral roots show prominent axonal and

Table I
Genes and Chromosomal Loci Associated with Different Classes of Motor Neuron Disease

Motor neuron disease	Genes/chromosomal loci	Comments
Amyotrophic lateral sclerosis	NF-H	Mutations in KSP repeats; risk factor
	EAAT2	RNA editing errors; decrease in protein level
Familial amyotrophic lateral sclerosis	SOD1; Ch 21	Autosomal dominant; largely missense mutations
Juvenile amyotrophic lateral sclerosis	Ch 2q33	Autosomal recessive
	Ch 9q34	Autosomal dominant
Spinal muscular atrophy	SMN; Ch 5	Autosomal recessive; homozygous deletions
Spinobulbar muscular atrophy	Androgen receptor; Ch X	Expanded CAG repeats
Hereditary spastic paraplegia	Proteolipid protein; Ch Xq21	X-linked
	Neural cell adhesion molecule L1; Ch Xq28	X-linked
	Paraplegin; Ch 16q	Autosomal recessive; homozygous deletions
	Spastin; Ch 2p	Autosomal dominant
	Ch 2q, 8p, 12q, 14q, 15q, and 19q	Autosomal dominant
	Ch 8q	Autosomal recessive

swellings and axonal degeneration, with marked loss of both large and small myelinated fibers. These findings extend the spectrum of FALS and JALS to include a slowly progressive, autosomal-dominant, nonfatal but debilitating disease.

To date, deletion/insertion mutations in the KSP repeat motif of the neurofilament (NF)-H tail domain have been identified in 10 of 1047 patients with sporadic ALS and in 1 of 295 FALS patients. Although they are considered a risk factor, there is no direct evidence that mutations of NF genes are a primary cause of ALS. In a subset of patients with sporadic ALS, levels of EAAT2 protein were reduced compared to those of controls and individuals who died of other neurodegenerative diseases. In 17 of 28 cases of ALS, aberrant EAAT2 mRNA was found; significantly, lower levels of the EAAT2 protein were observed in these same tissue samples. Functional studies indicated that the mutant RNA species led to a dominant downregulation of EAAT2 protein synthesis. However, recent studies indicate that these aberrant RNA species were also observed in control cases. Further work is under way to clarify the importance of aberrant EAAT2 mRNA in the pathogenesis of sporadic ALS. Finally, a locus for disease has also been identified on the X chromosome in at least one ALS family.

C. Copper-Mediated Mutant SOD1 Neurotoxicity

As discussed previously, mutations in SOD1 cause up to 20% of cases of familial ALS, a fatal adult-onset motor neuron disease characterized by the selective loss of spinal and cortical motor neurons. A variety of *in vivo* and *in vitro* studies have demonstrated that the mutant enzyme causes selective neuronal degeneration through a gain of toxic property rather than a loss of SOD1 activity, consistent with FALS displaying an autosomal-dominant pattern of inheritance. Although some FALS-linked SOD1 mutants show reduced enzymatic activities, others retain nearly wild-type levels and mutant SOD1 subunits do not appear to alter the metabolism/activity of wild-type SOD1 in a dominant-negative fashion. Transgenic mice expressing different FALS-linked SOD1 mutants exhibit progressive motor neuron disease resembling that occurring in cases of ALS, and mice deficient in SOD1 do not develop a motor neuron disease-like phenotype. Taken together, these results are consistent with the view that mutant SOD1 causes disease through a gain of neurotoxic property.

Although the role of SOD1 in scavenging superoxide free radicals is well established, other functions, such as peroxidase activity or buffering against Cu toxicity, have been documented. However, the molecular mechanisms whereby mutant SOD1 causes selective motor neuron death remain uncertain. One hypothesis is that the Cu bound to mutant SOD1 plays a key role in generating the toxic property in SOD1-linked FALS; that is, mutations induce conformational changes in SOD1 to facilitate the interactions of the catalytic Cu with small molecules, such as peroxynitrite or hydrogen peroxide, to generate toxic free radicals that damage a variety of cell constituents important for the maintenance and survival of motor neurons.

Consistent with the peroxynitrite hypothesis are results showing increased levels of free nitrotyrosine in G37R mutant SOD1 transgenic mice and in both sporadic and familial ALS. However, there is no documentation of increased levels of nitrated proteins in mutant SOD1 mice compared to control mice. In addition, disease progression in G93A mutant mice lacking either neuronal or endothelial nitric oxide synthase genes showed no significant difference when compared to that of G93A mice; these results do not support a critical role for neuronal-derived nitric oxide in the pathogenesis of FALS. In support of the peroxidase-mediated mechanism, markers of oxidative damage are increased in the cortices of sporadic cases of ALS, and it has also been demonstrated that the glutamate transporter, GLT1, is inactivated by oxidative reactions initiated by hydrogen peroxide and catalyzed by FALS-linked mutant SOD1. Studies in mutant SOD1 mice, however, failed to show increased levels of hydroxyl radical when compared to control mice. Furthermore, recent studies have provided evidence against the generation of free hydroxyl radicals from the interaction of SOD1 and hydrogen peroxide. Indeed, the onset and progression of disease in G85R mutant mice are independent of the level of wild-type SOD1 activities; this is inconsistent with the peroxynitrite and the peroxidase hypotheses.

Recent studies have shown that the loss of zinc from either mutant or wild-type SOD1 is sufficient to induce apoptosis in cultured motor neurons by trophic factor withdrawal. Because the toxic effect observed required Cu to be bound to SOD1 and endogenous nitric oxide to be produced, these studies suggested that zinc-deficient SOD1 might play a role in disease of both sporadic and familial ALS through a nitric oxide-mediated mechanism. However, no *in vivo* demonstration for these aberrant Cu chemistries, proposed to be

central to the pathogenesis of FALS, has been established. Although the Cu-mediated toxicity models remain controversial, the discovery of CCS provides the opportunity to directly test whether Cu within mutant SOD1 mediates motor neuron degeneration in SOD1-linked FALS.

1. Copper Trafficking and CCS

The delivery of Cu to specific proteins is mediated through distinct intracellular pathways of copper trafficking. A family of soluble proteins termed Cu chaperones is required to deliver Cu to specific intracellular metelloproteins. Recently, the yeast Cu chaperone, termed Lys7 or its mammalian homolog CCS (copper chaperone for superoxide dismutase), was shown to be necessary to deliver copper to SOD1 in yeast. CCS is able to rescue the Lys7 null mutant and is shown to interact physically with SOD1. Biochemical and structural analysis of yeast CCS indicates that the insertion of Cu into SOD1 requires interactions among three distinct domains of the copper chaperone: an Atx1p-like amino-terminal domain responsible for Cu uptake, an SOD1-like central domain that functions in SOD1 recognition, and a carboxyl-terminal domain unique to copper chaperones that mediates Cu incorporation into SOD1. Moreover, yeast CCS is sufficient to incorporate Cu into SOD1 through a direct transfer of Cu from the metallochaperone to its target enzyme under restricted concentrations of intracellular free Cu, indicating that a pool of intracellular free Cu is not used to activate SOD1.

2. Testing the Copper Hypothesis: CCS Knockout Mice

Recent studies have shown that a common property of both wild-type and FALS-linked mutant SOD1 is that Cu incorporation is CCS dependent. Thus, with regard to mutant SOD1, aberrant Cu chemistry may mediate degeneration of motor neurons in FALS. Consistent with this view are findings that CCS physically interacts with SOD1 and that both proteins are colocalized in many cell types, including motor neurons. To determine whether CCS is necessary for incorporation of Cu into SOD1 and to test the role of Cu in the pathogenesis of FALS using a genetic approach to alter the amount of Cu bound to mutant SOD1, mice were generated with targeted disruption of *CCS* loci ($CCS^{-/-}$ mice). Although $CCS^{-/-}$ mice are viable and possess normal levels of SOD1 protein, they reveal marked reductions in SOD1 activity when compared to control littermates. Metabolic labeling with radioactive ^{64}Cu demonstrated that the reduction of SOD1 activity in $CCS^{-/-}$ mice was the direct result of impaired Cu incorporation into SOD1 and that this effect was specific because no abnormalities were observed in Cu uptake, distribution, or incorporation into other cuproenzymes. Consistent with this loss of SOD1 activity, $CCS^{-/-}$ mice showed increased sensitivity to paraquat and reduced female fertility, phenotypes that are characteristic of SOD1-deficient mice. These results demonstrate the essential role of mammalian and have important implications for the development of novel therapeutic strategies in FALS.

As discussed previously, the view that Cu bound to mutant SOD1 mediates toxicity in SOD1-linked FALS remains controversial. However, the demonstration that CCS null mice are viable and possess marked reductions in SOD1 activity offers an opportunity to directly test whether Cu bound to mutant SOD1 plays a key role in the pathogenesis of mutant SOD1-induced FALS. Cross-breeding strategies using these CCS null mice and several lines of FALS mice (G37R, G93A, and G85R) are currently under way and outcomes of these studies should be instructive in deciphering the role of Cu in SOD1-linked FALS. During the past several years, these mutant SOD1 transgenic mice have been valuable in testing other hypotheses regarding the molecular mechanisms of selective motor neuron degeneration induced by mutant SOD1, and the results of these investigations are reviewed next.

D. Mutant SOD1 Transgenic Mice

1. G93A SOD1 Mice

The G1H line of mice, which express G93A human SOD1 at approximately five times the endogenous level, develop hindlimb weakness at 3 months of age. By 5 months of age, these mice are moribund. The number of choline acetyltransferase-positive motor neurons is reduced, and the Golgi is fragmented. Vacuoles, seen in cell bodies and dendrites, are thought to represent degenerating mictochondria. Some axons are swollen, showing accumulations of neurofilaments, and other axons are reduced in caliber; fast and slow transport appear to be impaired. In late stage, there is a loss of motor neurons. In another line of mice expressing low levels of SOD1, ubiquitin immunoreactivty and Lewy body-like inclusions are present in cell bodies of motor neurons; these mice also show

axonal swellings, loss of motor neurons, and local astrogliosis.

G93A SOD1 transgenic mice have been used to test a variety of therapeutic approaches. Vitamin E and selenium modestly delay the onset and progression of disease without affecting survival; in contrast, riluzole and gabapentin do not influence onset/progression but do slightly increase survival. Although initial studies showed that oral administration of *d*-penicillamine delays the onset of disease, recent results revealed no significant effects. Overexpression of Bcl-2 extends the survival of these transgenic mice, but the presence of the gene does not change the progression of the disease. Recently, the level of Bax, a molecule that promotes apoptosis, was shown to be increased in G93A mice. However, this increase in Bax was augmented by an increase in Bcl-2/Bax heterodimers in G93A mice overexpressing Bcl-2. Interestingly, there is evidence that an apoptotic mechanism may be involved in motor neuron loss in ALS. In a small group of G93A SOD1 mice overexpressing a dominant-negative inhibitor of interleukin-1B converting enzyme, a cell death gene, there is a modest slowing of progression of disease. Recently, it was documented that oral administration of creatine significantly delays the onset of disease and extends the life span of the G93A mice. To date, it appears that agents that act in an antioxidant/antiapoptotic manner delay disease onset, whereas antiexcitotoxic agents do not affect onset of disease but do significantly prolong survival.

2. G37R SOD1 Mice

These mice accumulate the G37R SOD1 to 3 to 12 times those levels of endogenous SOD1 in the spinal cord; the mutant SOD1 retains full specific activity. Levels of the mutant transgene product determine the age of onset. At 5–7 weeks of age ($\sim$2 or 3 months before the appearance of clinical signs), SOD1 accumulates in irregular swollen intraparenchymal portions of motor axon, the axonal cytoskeleton is abnormal, and vacuoles are present in the axon. Radiolabeling studies demonstrate that both endogenous SOD1 and G37R SOD1 are transported anterogradely in axons. Deficits in slow or fast axonal transport prior to disease onset have been documented in G37R and G85R mice and in G93A mice, respectively. Thus, toxic mutant SOD1 is transported anterograde, accumulates early in the disease, and associated with early structural pathology in axons. Small vacuoles are also present in dendrites, and some vacuoles appear to originate in the space between the outer and inner mitochondrial membranes, with prominent distention of the outer mitochondrial membrane, displacement of the inner membrane, and disruption of the cristae. Both axonal and dendritic abnormalities occur months before the onset of clinical signs. By 20 weeks of age, motor axons show vacuoles, cytoskeletal alterations, and Wallerian degeneration. The cell bodies of some neurons show ubiquitin-immunoreactive inclusions and phosphorylated NF-H immunoreactivity. Recently, motor axon inclusions immunoreactive with peripherin, an intermediate filament protein that when overexpressed in transgenic mice causes motor neuron death, have been documented in presymptomatic G37R mice. The number of motor neurons was reduced. Astrogliosis is present in proximity to abnormal neurons. These findings suggest that the accumulation of mutant SOD1 is associated with subtle and early damage to organelles within axons/dendrites of motor neurons. If these early axonal and dendritic lesions occur in ALS, they are virtually impossible to detect because they occur early and are subtle; in humans, they are masked by end-stage processes, immediate antemortem events, and postmortem delays.

NFs have been implicated in the pathogenesis of ALS. To test the role of NFs in motor neuron disease caused by SOD1 mutations, transgenic mice expressing G37R SOD1 were cross-bred to transgenic mice that accumulate NF-H–β-galactosidase fusion protein (NF-H–lacZ), which crosslinks neurofilaments in neuronal perikarya and limits their export to axons, and to transgenic mice expressing human NF-H subunits. In G37R SOD1 mice expressing NF-H–lacZ, NFs are withheld from the axonal compartment, but there is no influence on the progression of disease. These results indicate that neither initiation nor progression of disease require an axonal NF cytoskeleton and that alterations in NF biology observed in some forms of motor neuron disease may be secondary responses. In contrast, the expression of wildtype human NF-H transgenes in SOD1 mutant mice significantly increases the mean life span of the G37R SOD1 mice. In contrast to the striking axonal degeneration observed in 1-year-old transgenic mice expressing G37R SOD1, NF-H transgenic mice show remarkable sparing of motor neurons. The reasons for this protection of G37R SOD1 mice by increased levels of human NF-H, particularly in cell bodies but not in axons (in which neurofilament content is reduced), are not known; it could be related to the ability of NF-H to bind calcium and therefore influence calcium-mediated damage. Consistent with

a role for calcium in disease is the observation that overexpression of the calcium binding protein calbindin D (28K) confers protection against mutant SOD1-mediated death of PC12 cells.

3. G85R SOD1 Mice

In multiple lines with different number of copies (2–15 copies), the accumulation of mutant G85R protein ranged from ~20% in endogenous mouse SOD1 (in the lowest expressing line) to endogenous levels (in the highest expressing line). The age of onset of weakness varied from 8–10 months for the highest expressing line to 12–14 months for the lowest expressing line. Two weeks after initial weakness in one hindlimb, these mice were completely paralyzed. In the preclinical period, there was a defect in axonal transport, and astrocytes contained SOD1 and ubiquitin-immunoreactive Lewy body-like inclusions; at later stages, motor neurons also exhibited SOD1 and ubiquitin-positive inclusions. At 6.5 months (coincident with the earliest pathology), there was no significant loss of axons in the motor roots, but 1 or 2 weeks after the onset of clinical signs many axons had degenerated. Similar pathology has been reported in two individuals with FALS who had a two-base pair deletion in codon 126 of SOD1, leading to a frameshift and truncation of the final 27 amino acids of SOD1. To test the role of neurofilaments in disease, NF-L null mice were mated to G85R SOD1 transgenic mice. G85R mutant mice without neurofilaments show delayed onset of disease and extension of survival. Thus, although assembled neurofilaments are not required for mutant SOD1-induced disease, the absence of neurofilaments does appear to slow the G85R SOD1-mediated disease. To further examine disease mechanisms, G85R SOD1 transgenic mice were mated to wildtype SOD1 mice or to SOD1 null mice; elevation or elimination of wildtype SOD1 did not influence the SOD1 mutant-associated disease. These studies indicate that SOD mimetic may not be useful and is inconsistent with the view that mutant SOD1-mediated toxicity derives from superoxide-associated oxidative stress.

4. G86R SOD1 Mice

Mice expressing this mutant transgene, the murine equivalent of the G85R SOD1 mutation, developed progressive paralysis at 3 months of age; some neurons exhibited cytological evidence of degeneration. At end-stage disease, there was accumulation of phosphorylated NF inclusions in surviving motor neurons, a reduction in the number of motor neurons and interneurons, and reactive gliosis. Vacuolar pathology was not observed. Calbindin-containing nerve cells appeared to be relatively spared.

As discussed previously, the observations of astroglial inclusions in ALS and in mutant SOD1 transgenic mice indicate the possibility that astrocytes might participate in the pathogenesis of ALS. To assess the involvement of astrocytes, transgenic mice expressing the G86R SOD1 restricted to astrocytes (GFAP-m SOD1 mice) were generated. Although astrocytes from GFAP-m SOD1 mice showed hypertrophy with increased GFAP immunoreactivity, these animals developed normally with no motor neuron degeneration. These observations indicate that expression of mutant SOD1 in astrocytes is not sufficient to cause motor neuron disease. However, because these mice do not express high levels of G85R SOD1, additional lines of mice expressing higher levels of the mutant protein in astrocytes may prove useful.

E. Excitotoxicity in ALS

Excitotoxicity has been suggested as one mechanism by which motor neurons are damaged in ALS. About 60–70% of sporadic ALS patients have a 30–95% reduction in the astroglial glutamate transporter EAAT2 (excitatory amino acid transporter 2), also termed GLT-1 in motor cortex and spinal cord. Loss of the major transporter could lead to an increase in extracellular concentrations of glutamate, as seen in some patients with ALS, and excitotoxic degeneration of motor neurons. Significantly, in a subset of patients with sporadic ALS (65%), multiple abnormalities of *EAAT2* mRNA, including intron retention and exon skipping, have initially been identified in tissues from the affected areas. The aberrant mRNAs were highly abundant, found only in neuropathologically affected areas of ALS patients and not in other brain regions, and detectable in the CSF of living ALS patients early in the disease. *In vitro* expression studies suggest that proteins translated from these aberrant mRNA can undergo rapid degradation and/or produce dominant-negative effects on normal EAAT2, resulting in loss of protein and activity. These findings suggest that a reduction of EAAT2 in ALS could be due to the presence of aberrant EAAT2 mRNA, presumably resulting from RNA processing errors. This aberrant RNA processing reduces the levels of this type of glutamate transport, and accumulation of glutamate could predispose to excitotoxic damage of motor

neurons. Consistent with this idea is the finding that experimental reductions in EAAT2 by antisense olgonucleotide injection *in vivo* produce progressive limb weakness and motor neuron degeneration. However, recent observations have shown that these aberrant EAATS mRNAs were also found in control cases. The significance of these aberrant mRNAs in ALS pathogenesis remains a focus of future research.

II. SPINAL AND BULBAR MUSCULAR ATROPHY

Spinal and bulbar muscular atrophy (SBMA or Kennedy's disease), an X-linked disorder, usually manifests with slowly progressive proximal weakness in the third through fifth decades. The disease, mapped to Xq11–q12, is caused by expanded CAG repeats encoding a polyglutamine tract in the androgen receptor protein. Disease-linked alleles (37–66 CAGs) change length when transmitted from parents to children, with an increased tendency to change when inherited through the father. Individuals with longer CAG repeats have early onset disease. Neuropathologically, there is degeneration of lower motor neurons in spinal cord and brain stem, accompanied by local gliosis and atrophy of skeletal muscles. Both the wild-type and the mutant androgen receptor are widely distributed, predominantly in the cytoplasm of neurons. Nuclear ubiquitin-immunoreactive inclusions containing the mutant androgen receptor are observed in spinal motor neurons of SBMA but not in other, unaffected neural tissues. Similar nuclear inclusions are seen in some nonneural tissues. The mechanism whereby the expanded trinucleotide repeats cause disease, including Huntington's disease, is the subject of exciting recent research. Although there is an indication that the expanded repeat causes some loss of transcriptional activity by the androgen receptor, the major influence of the expansion is likely related to a gain of toxic function.

Recent advances in neuronal cell culture and transgenic models have documented pathological findings that resemble those observed in individuals with Kennedy's disease. Cell culture studies have indicated that the aggregation and proteolytic processing of the androgen receptor are dependent on the length of the polyglutamine repeat. Moreover, the abnormal metabolism of the expanded repeat androgen receptor is associated with cellular toxicity. These results suggest a molecular basis for the neurotoxic gain of function associated with neuronal degeneration in SBMA. Initial transgenic mice expressing the human androgen receptor cDNAs with 45 or 66 CAG repeats driven by a variety of promoters failed to reveal any pathological phenotype. Recently, mice expressing a truncated androgen receptor with 112 CAG repeats driven by the prion protein promoter showed a remarkable neurological abnormality associated with tremor, gait problem, circling behavior, and seizures. As observed in SBMA cases, nuclear inclusions are found in motor neurons of these transgenic mice. Several lines of yeast artificial chromosome (YAC) transgenic mice carrying 45 CAG repeat expansions in the androgen receptor showed an $\sim 10\%$ rate of repeat length instability. In addition, the 45 CAG repeat tracts caused greater instability with maternal transmission and with older transmitting female. These studies indicate that human locus-specific sequences are necessary to generate trinucleotide repeat instability in mice. Further efforts to identify the *cis*-acting elements that permit CAG tract instability and the *trans*-acting factors that regulate repeat instability will be useful to clarify the molecular basis of trinucleotide repeat instability in SBMA.

III. HEREDITARY SPASTIC PARAPLEGIA

Hereditary spastic paraplegia (HSP), a genetically heterogeneous illness, is characterized by weakness, progressive and bilateral spasticity of the lower limbs, increased deep tendon reflexes, and extensor plantar responses—signs reflecting involvement of corticalspinal pathways. Axonal degeneration of the corticospinal tracts and posterior columns is a common characteristic of all types of HSP. Although this disease can be inherited as an autosomal-dominant disease (AD-HSP), an X-linked illness (X-HSP), or an autosomal-recessive disease (AR-HSP) (Table I), AD-HSP represents the majority of cases ($\sim 80\%$).

X-HSP has been linked to two regions of the X chromosome. At Xq28, mutations in the gene for neural cell adhesion molecule L1, an axonal glycoprotein involved in neuronal migration and differentiation, cause one form of HSP linked to mental retardation, whereas mutations in the proteolipid protein gene at Xq21 cause another form of HSP.

A subset of autosomal-recessive cases of HSP have been shown to be homozygous for a 9.5-kb deletion involving paraplegin, a member of the AAA protein family that is homologous to several yeast mitochondria ATPases. These ATPases exhibit both proteolytic and chaperone-like activities at the inner mitochondrial membrane. Paraplegin is localized to the inner

mitochondrial membrane, and muscle biopsies from affected individuals show impairments in oxidative phosphorylation in these tissues. The AAA family of proteins possesses diverse cellular functions, including microtubule rearrangement, protein degradation, organelle biogenesis, and vesicular transport. The membrane-bound AAA proteases have been shown to possess metal-dependent peptidase activity and serve to degrade nonassembled membrane proteins. Studies of yeast have demonstrated that Yme1, a yeast homolog of paraplegin, mediates binding of substrates through the amino-terminal region of the AAA domain to degrade unfolded membrane proteins. In addition, the purified AAA domain of Yme1 was shown to bind unfolded polypeptides and prevent their aggregation. These studies indicate that the chaperone-like activity of AAA proteins resides within the AAA domain.

Six AD-HSP loci have been mapped (Table I) and the locus at chromosome 2p accounts for ~50% of all AD-HSP pedigrees. Recently, mutations of another AAA protein, termed spastin, have been linked to a subset of AD-HSP at the chromosome 2p locus. Sequence analysis revealed various modifications of the spastin gene, including missense, nonsense, and splice site point mutations, as well as deletions and insertions. Spastin, ubiquitously expressed in both fetal and adult tissues, is thought to be an ATPase involved in the function or assembly of nuclear protein complexes. Generation of mouse models for HSP should further clarify the molecular mechanisms whereby these genetic abnormalities lead to the various types of HSP.

IV. SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA), the most frequent fatal autosomal-recessive disorders in infants and one of the most important neuromuscular disorders of children, is characterized by muscle weakness and atrophy. The disease is classified as type I, II, or III on the basis of age of onset and functional ability. The incidence of type I SMA (Werdnig–Hoffmann disease) is estimated to be ~1 in 10,000 live births, with a carrier rate frequency between 1 in 50 and 1 in 80. Affected infants become weak prior to 6 months of age, ~30% of individuals show reduced fetal movements *in utero*, and these infants develop respiratory and bulbar difficulties and die before 2 years of age. Type II SMA is usually recognized before the first birthday; these children are never able to walk independently. Type III SMA begins in early childhood; affected individuals have milder degrees of disability. Affected siblings have a very similar severity of phenotype, suggesting a significant effect of allelism on phenotype or the presence of a tightly linked disease-modifying gene.

Although much remains to be learned about the neuropathology of SMA, the most characteristic feature of affected individuals is the paucity of large α motor neurons in the spinal cord and brain stem, with associated degeneration of motor roots and denervation of skeletal muscle. Some of the surviving neurons appear normal, and no characteristic neuronal inclusions have been demonstrated with the disorder. A minority of surviving motor neurons demonstrate chromatolysis, accumulations of phosphorylated NF in neuronal cell bodies. Relatively spared are cranial nerve nuclei III, IV, and VI as well as motor neurons of the phrenic nerve (which innervates the diaphragm) and Onuf's nucleus (which innervates the male genitalia and anal sphincters). Upper motor neurons do not appear to be affected.

Molecular genetic studies have mapped SMA types I–III to a single, highly complex genetic locus on chromosome 5q11.2–q13.3. The genomic organization of this region is polymorphic and complex, with numerous repeated DNA elements that occur in different orientations on chromosomes from different individuals. Two SMA candidate genes were described within this region, survival motor neuron (*SMN*) and neuronal apoptosis inhibitory protein (*NAIP*). Recent evidence is consistent with the idea that *SMN1* is the SMA–determining gene; *NAIP* may play a role in modifying the severity of the disease.

The *SMN1* gene, encoding a 294–amino acid polypeptide (32 kDa), lies in the telomeric portion of chromosome 5q11.2–q13.3, and a homologous copy of *SMN1*, termed *SMN2*, is located in a more centromeric position. Although the two ~20-kb genes encode identical proteins, they can be differentiated by single-strand conformational polymorphism analysis or reverse transcriptase-polymerase chain reaction because of differences in the transcripts at two nucleotides in exons 7 and 8. Transcripts encoded by the two genes are subjected to alternative modes of posttranscriptional processing; whereas *SMN1* produces full-length RNA, *SMN2* produces mainly transcripts lacking exon 7. Recently, it was demonstrated that exon 7 skipping is caused by a single nucleotide difference between the *SMN1* and *SMN2* genes. Thus, it has been observed that the ratio of transcripts lacking exon 7 to full-length *SMN2* transcripts correlates with the severity of SMA. The mouse

contains only one copy of *SMN*, which is also closely linked to NAIP on mouse chromosome 13. *SMN* is highly conserved between mice and humans, with 82% identity. *In situ* hybridization of adult mouse brain and spinal cord demonstrates expression of *SMN* in large motor neurons as well as most other cells. Similarly, almost all neurons in the brain express *SMN*, with highest levels seen in the hippocampus and cerebellum.

Mutations are found in nearly 100% of affected individuals, and levels of *SMN1* are different in the different types of SMA; SMA type I has the least amount of SMN in spinal motor neurons. Partial or complete deletions are detected in *SMN1* in more than 95% of well-characterized cases, with other disabling mutations found in many of the remaining cases. Homozygous deletion of *SMN1* has not been found in controls. *SMN2* has not been found to be deleted in any affected individual, although it is deleted in 4% of normal controls. This suggests that homozygous deletion of the centromeric and telomeric copies of SMN may be nonviable and likely results in an embryonic lethal event, and that levels of full-length SMN proteins govern whether the individual has SMA type I, II, or III. Thus, *SMN2* is predicted to be able to partially substitute for *SMN1*.

SMN, a member of a multiprotein complex, is involved in small nuclear ribonucleoprotein (snRNP) biogenesis and pre-mRNA splicing. In HeLa cells, SMN is present in the nucleus associated with small intranuclear structures termed ''gem bodies'' (Gemini of coiled bodies), which are closely associated with but distinct from coiled bodies. Because of the similarity between gems and coiled bodies, it is suggested that gems and SMN might play roles in the processing of small nuclear RNAs. In the cytoplasm, SMN complex is associated with snRNP Sm core proteins and is involved in spliceosomal snRNP assembly. A variety of methods have shown that SMN forms a stable heteromeric complex with a novel 32-kDa protein termed Gemin2; Gemin2 was formerly called SIP1 (SMN-interacting protein-1). Gemin2 and SMN are found in a large stable complex ($\sim$300 kDa) together with spliceosomal snRNP proteins (B, D1-3, and E) in both the nuclear and cytoplasmic fractions. SMN was shown to physically associate with Sm proteins and functional studies have revealed that Gemin2 plays an important role in the assembly of snRNPs. Studies using a dominant-negative form of SMN (SMNΔN27) showed that SMN also participates in the cytoplasmic assembly of snRNPs; overexpression of SMNΔN27 caused abnormal snRNP assembly with an enlarged gem/coiled body complex in the nucleus. Additional functional analysis revealed that SMN is required for recycling of snRNPs in pre-mRNA splicing.

Recently, other components of the SMN complex, termed Gemin3 (a DEAD box protein with putative RNA helicase activity) and Gemin4, have been identified. Gemin3 colocalizes and interacts directly with SMN in gems, and this interaction has shown to be decreased in some SMA cases in which there is deficiency in snRNP regeneration activity. Gemin4 is associated with the SMN protein complex through direct interaction with Gemin3 and it is thought that Gemin4 function as a cofactor for Gemin3. It has also been shown that Gemin4 physically interacts with several Sm core proteins and is colocalized with SMN in the cytoplasm and in gems. It is proposed that the complex composed of SMN, Gemin2, Gemin3, and Gemin4 represents an active functional unit that serves to bind substrates such as Sm proteins.

SMN has previously been documented to interact with fibrillarin, a common component of small nucleolar RNPs (snoRNPs), and hnRNP U, a member of the hnRNP protein family, which bind nuclear RNA. In yeast, fibrillarin is required for pre-rRNA processing and is essential for viability, whereas hnRNP U is believed to play a role in the transport and processing of mRNA. Recently, it was demonstrated that Gemin4 is also localized to the nucleoli. Thus, it is possible that the SMN complex may participate in snoRNP assembly and ribosomal RNA metabolism.

Taken together, these studies showed that the SMA disease gene *SMN* is linked to several fundamental biochemical pathways. It has also been demonstrated that SMN mutants found in SMA patients are defective in binding to Sm proteins because mutant SMN is incapable of forming large oligomers, which is essential for high-affinity binding to spliceosomal snRNP Sm proteins. These findings further support the view that abnormalities of spliceosomal snRNP biogenesis and metabolism are directly involved in the pathogenesis of SMA.

In an effort to further examine the *in vivo* function of SMN in SMA, mice deficient in SMN were generated. $Smn^{-/-}$ embryos died with massive cell death during the periimplantation stage corresponding to the initiation of embryonic RNA transcription, precluding analysis of any postnatal phenotype. These results are consistent with the view that SMN functions in essential cellular pathways, including the biogenesis of spliceosomal snRNPs and pre-mRNA splicing. To test whether *SMN2* can complement the embryonic lethality of $Smn^{-/-}$ embryos and to generate a mouse model for SMA, several groups generated transgenic

mice expressing human *SMN2* and cross-bred them with $Smn^{+/-}$ mice to generate *SMN2* transgenic mice lacking mouse endogenous SMN. These $Smn^{-/-}/SMN2$ mice showed neuropathological abnormalities in the spinal cord and skeletal muscles, similar to cases of SMA. The severity of the pathology in these mice correlated with the level of SMN polypeptide that retained the amino acids encoded by exon 7. These results demonstrated that *SMN2* could partially compensate for the endogenous mouse SMN and the variable phenotypes observed in the $Smn^{-/-}/SMN2$ mice recapitulate those seen in SMA types I–III. These $Smn^{-/-}/SMN2$ mice revealed clinical symptoms that can be grouped into three categories. Type 1 mice, the most severe pathological form, did not develop furry hair and died by Postnatal Day 10. Type 2 mice showed poor activity and died between 2 and 4 weeks of age. Type 3 mice survived and bred normally and had short and enlarged tails. Furthermore, the level of full-length SMN protein in these $Smn^{-/-}/SMN2$ mice correlated with the severity of the disease. These studies strongly support the view that the level of intact SMN is a determining factor for SMA severity.

Analysis of $Smn^{+/-}$ heterozygous knockout mice revealed an $\sim$50% reduction of SMN protein in the spinal cord of these mice that resulted in a progressive loss of motor neurons between birth and 6 months of age, and the phenotype of these mice resembles SMA type III. Taken together, these studies support the view that SMA is caused by insufficient level of SMN and the severity of the disease is dependent on the level of SMN generated from the *SMN2* gene. These mouse models of SMA will be useful in obtaining a better understanding of disease mechanisms and for testing therapeutic strategies.

To clarify the role NAIP played in SMA, mice with targeted deletion of *NAIP1* were recently generated. Although mice lacking *NAIP1* showed no overt phenotype, the survival of pyramidal neurons in the hippocampus after kainic acid-induced injury is greatly suppressed in these mice compared to controls. Although *NAIP1* is not required for normal development of the nervous system, it is necessary for neuronal survival under stressful situations. These studies further strengthen the view that although *NAIP* may modify the severity of the disease, *SMN1* is the SMA-determining gene.

V. MOUSE MODELS OF TAUOPATHIES

During the past several years, mutations in the tau gene linked to a heterogeneous group of neurodegenerative disorders characterized by filamentous tau inclusions have been identified. These disorders, collectively termed tauopathies, include sporadic and familial frontotemporal dementia with parkinsonism linked to chromosome 17, progressive supranuclear palsy, and Pick's disease. In humans, six tau isoforms (three isoforms with three microtubule-binding repeats and three isoform with four microtubule-binding repeats) are generated by alternative splicing of the tau gene in adult brain. In rodents, there are three four-repeat isoforms. To model neurodegenerative tauopathy, investigators have developed transgenic mice expressing high levels of wild-type tau isoforms. Overexpression of either the shortest or the longest tau human isoform in the brain and spinal cord of transgenic mice using either the Thy1 or the prion protein promoter, respectively, resulted in an age-dependent phenotype characterized by insoluble, hyperphosphorylated tau and intraneuronal inclusions composed of tau-immunoreactive filaments. These tau inclusions are found in large numbers in spinal motor neurons. These mice showed axon degeneration and decreased axonal transport. Not surprisingly, they revealed motor impairments. Although these studies showed that the overexpression of a single tau isoform can develop filamentous tau inclusions and neurodegeneration, other features of tauopathies such as filamentous tau tangles were not observed. Future efforts to generate additional tau transgenic models should provide further insight into the molecular mechanisms and pathobiology of tauopathies.

VI. CONCLUSIONS

During the past several years, substantial progress has been made in understanding the molecular events that underlie motor neuron disease. Significantly, several genes and a variety of loci have been linked to motor neuron disease. Free radical-mediated chemistries, copper toxicity, neurofilament biology, axonal transport, RNA metabolism, excitotoxicity, protein folding/aggregation, etc. appear to influence the function/viability of neurons. The mechanisms that account for "selective" neuronal degeneration are uncertain. However, the identification of specific genes/proteins that are mutated/deleted in the inherited forms of the disease has allowed investigators to create *in vivo* and *in vitro* model systems. For example, transgenic mice that recapitulate some of the features of human diseases have provided important information about the biology of these diseases. The availability of new

models will allow investigators to examine the molecular mechanisms by which mutant proteins cause selective dysfunction/death of motor neurons. Moreover, pathogenic hypotheses can be tested by experimental manipulations and by breeding mice carrying mutant genes to mice that express other transgenes or to gene-targeted mice. The results of these approaches should provide a better understanding of the pathogenic mechanisms of disease. In turn, this new knowledge should lead to the design of novel therapeutic strategies that can be tested in these animal models.

GLOSSARY

adaptation Skill learning tasks that require a remapping of motor commands to sensory feedback.

apraxia A neurological syndrome involving deficits in the production of voluntary movements without paralysis or sensory loss.

closed-loop movements Movements for which sensory feedback is used to modify the ongoing motor commands.

efference copy An internal copy of a signal to the muscles that is compared to afferent signals from the periphery.

open-loop movements Movements for which the motor commands are sent to the muscles without opportunity for modification due to sensory feedback.

sensorimotor integration Skill learning tasks that require the formation of novel associations between sensory events and motor commands.

Motor skills are learned behaviors that require patterns of activity across sets of muscles. Such a broad, encompassing description reflects the diversity of phenomena that are considered forms of motor skill learning. It is therefore not surprising that many neural systems are involved in the development of motor skills. This article focuses on the primary neural systems associated with motor learning and discusses functional hypotheses associated with these structures.

I. BACKGROUND

Our daily lives are replete with behaviors that our species had never attempted a few hundred years ago. Human activities and abilities vary dramatically across culture, occupation, and recreational taste. This diversity is the product of our brains' ability to develop new skills. Indeed, motor skill learning is a primary function of the central nervous system. Organisms see, smell, hear, and think in order to appropriately guide overt behavior.

Neuropsychology has often focused on perception, particularly vision, as a paradigmatic cognitive operation, perhaps because clinical populations have presented striking and specific deficits. In contrast, motor deficits, although diagnosed as distinct syndromes, have proven less amenable to attempts to decompose the neural systems underlying the control of action into functionally distinct neural systems. Although syndromes such as Parkinson's disease are associated with a unique set of symptoms, the difficulty in mapping the symptoms onto properties of the external world has made it difficult to develop functional models of the various neural structures involved in motor control.

Two aspects of motor control have been particularly problematic for researchers attempting to identify the neural substrates of motor learning. First, motor

behavior is thought to be governed by two distinct learning systems: declarative (or explicit) memory and procedural (or implicit) memory, a collection of memory systems including motor learning. For example, when learning to play tennis, one may initially attempt to consciously control the position of certain body parts. In this case, behavior is being shaped by the individual's declarative memories. However, as the individual becomes more practiced, the movements become fluent and less attention is required to control and coordinate the various parts of the body. In this latter case, implicit learning is taking place. Because brain lesions can lead to dramatic deficits in declarative memories while leaving many aspects of motor learning intact, two forms of learning are assumed to exist, supported by a different neural systems. However, determining the relative contributions of these two systems to a given behavior is a formidable task for researchers. In particular, given that experimental subjects may apply declarative knowledge and conscious strategies to guide their performance, it can be difficult to obtain pure measures of procedural motor learning.

Second, neural structures that are presumed to be critical for motor learning may also be involved in the production of movement. When evaluating the performance of individuals with damage in these brain regions, it can be difficult to distinguish between deficits in learning and deficits in execution. That is, the neural structures necessary to encode a motor skill may be intact, but the person may be unable to express that knowledge because the structures controlling output are not operating adequately. Similarly, impairments in performance may make movements so variable that learning is reduced even though there is no damage to the systems that normally encode new behaviors.

Despite these obstacles, dramatic progress has been made in our understanding of motor learning and its neural substrates. Much of our understanding of how the brain learns to refine motor signals in response to sensory feedback has come from studies examining neural activity in awake, behaving animals. These neurophysiological studies record changes in the firing rates of sets of neurons that accompany motor learning while interfering minimally with the brain's normal operation. Similarly, the advent of functional whole brain imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has allowed researchers to observe changes in brain metabolism and blood flow as human subjects become more practiced with motor tasks.

These procedures have revealed learning-related changes in almost every region of the brain associated with motor control. In the cerebral cortex, these regions include the primary motor cortex (M1), the premotor cortex, the supplementary motor cortex (SMA), and both superior and inferior parietal cortex. Subcortical structures, including the basal ganglia and cerebellum, also play a critical role in motor learning in addition to their roles in motor execution.

Differentiating the roles of these various structures presents many intricate problems. Although lesions to many of these brain structures can lead to characteristic deficits in performance, understanding these impairments in terms of motor learning has been fraught with controversy. The controversy stems in part from the fact that the domain of these systems in many cases has yet to be determined. The systems may necessarily interact during the performance of most behaviors, blending their computational operations. When one system fails, the others may act in a degraded or altered fashion. Thus, determining what each of the many areas involved in motor control contributes to our diverse and multifaceted abilities has proven to be a thorny task.

II. LEVELS OF REPRESENTATION

Learning to modify actions based on sensory inputs and previous experiences is a complex computational problem. In fact, the pervasiveness of skill acquisition makes it difficult to define. For example, learning a novel, multicomponent series of movements, such as when we throw a baseball, is certainly considered motor skill learning. However, do we include other skills, such as learning to use a mouse or blink in anticipation of a puff of air? In all these cases, new relationships between particular actions and environmental events must be encoded. However, in some cases, the new behavior requires the precise timing and modulation of different muscles. In other cases, the movements are already well entrained and acquiring the new skill requires learning the appropriate goal that is associated with a particular set of environmental conditions. For example, in eye-blink conditioning, the movement is well established and learning primarily consists of determining the stimulus conditions in which this response should be emitted.

Another behavior, handwriting, serves as a useful example when considering the different processes involved in motor learning. Learning to write requires the complex coordination of multiple effectors to

produce elaborate spatiotemporal patterns of output. Handwriting is usually produced by a set of effectors including the muscles of the fingers and wrist of the dominant hand. However, it can also be produced —and with considerable skill—with other, nonoverlapping sets of effectors. For example, writing can be performed relatively effortlessly with the muscles of the right arm and shoulder, such as when writing large words on a chalkboard.

These transfer effects have led to the hypothesis that skilled movements are constrained by abstract motor programs. An abstract motor program does not specify the commands sent to the muscles or even which muscles must be activated; this information must be provided by downstream systems that implement a motor program. Exactly what a motor program represents remains controversial. However, the absence of effector-specific commands makes the abstract motor program so powerful. Once established, it can be useful in a variety of contexts, depending on the goals and circumstances confronting the organism. Given the complexity of our environments, it is advantageous since learning acquired with one set of effectors can transfer to other sets, thus allowing behavior to be both skilled and flexible.

However, transfer of knowledge to different effectors does not always appear to be complete. When right-handed individuals are asked to write with their left hands, their movements are comparatively slow and awkward, and the resulting trajectories can be considerably distorted. Such difficulty indicates that many components of the learned behavior do not transfer well to this new set of effectors. Even so, many features of an individual's unique style are present in their production with the nondominant hand. That is, the shape of the letters appears to match, although with less precision, the same template used to generate those produced by the dominant hand.

The partial transfer of handwriting to novel effectors suggests that multiple representations can subserve a single learned behavior. Representations about the desired trajectory of the movement appear to be encoded in spatial coordinates that can be accessed by various effectors. However, such representations are not sufficient to rapidly produce fluent performance. In addition to requiring a representation of the desired goal of the movement, individuals must also learn how to accomplish the goal with a specific set of muscles.

This example illustrates the distinction between the two classes of knowledge required to perform motor acts, often referred to as "knowing what to do" and "knowing how to do." Although it is tempting to associate the former with declarative knowledge and the latter with procedural knowledge, several lines of evidence suggest that "knowing what to do" can be encoded without awareness. That is, in many cases, decisions about what to do appear to be facilitated by implicit knowledge.

Understanding how these multiple levels of representation are supported by the neural structures associated with motor learning is critical for a comprehensive theory of motor skill learning. In this article, we review some experimental tasks that have been used to identify the neural loci of motor learning and develop functional hypotheses regarding the computations performed by these structures.

III. THE CEREBELLUM

The brain structure most frequently associated with motor learning is the cerebellum. Tucked beneath the visual cortex in the posterior cranial fossa, the cerebellum is the largest subcortical structure, constituting approximately 15% of the brain's mass and containing more than half of the entire neurons in the brain. The structure is divided into three lobes, which are composed of 10 lobules. Given its tremendous size, it is likely that the cerebellum contributes to many behaviors, and much recent speculation has focused on nonmotor functions of the cerebellum. Nonetheless, as emphasized in the classic observations of the British neurologist Gordon Holmes, the hallmark of cerebellar dysfunction in humans is the breakdown of skilled movement.

Some remarkable features of the cerebellum serve as a useful background for considering how this structure might perform essential computations for motor learning. Perhaps the most striking feature of the cerebellum is its uniformity. Inputs to the cerebellar cortex come from two distinct pathways, the mossy fibers and the climbing fibers. Mossy fibers originate in various brain stem nuclei and synapse onto the cerebellar granule cells. The axons of the granule cells, or parallel fibers, extend for as long as a few centimeters, synapsing with various cell types within the cerebellar cortex. Principal among these are the Purkinje cells, the sole output of the cerebellar cortex, providing an inhibitory signal on the deep cerebellar and vestibular nuclei. The parallel fibers can also influence the Purkinje cells indirectly via inhibitory interneurons called basket cells and Golgi cells. A given Purkinje cell may receive input from 200,000 parallel fibers, although each parallel fiber will only

synapse once on a particular Purkinje cell. Climbing fibers originate in the inferior olive. In stark contrast to the extreme divergence of information deriving from the mossy fibers, each Purkinje cell receives input from a single climbing fiber.

A. Eye-Blink Conditioning

Eye-blink conditioning is perhaps the best studied model system for examining the neural basis of sensorimotor learning in mammals. In this form of Pavlovian conditioning, a neutral stimulus such as a tone is repeatedly paired with an aversive stimulus such as an airpuff to the eye. The airpuff is an unconditioned stimulus (US): It automatically elicits an unconditioned response (UR), either a blink in humans or the extension of a protective membrane in rabbits. Initially, the tone, or conditioned stimulus (CS), causes no response. However, after training, the animal produces a conditioned response (CR) following the tone. The CR is timed to occur just prior to the onset of the US, and in this way it is adaptive as it attenuates the aversive consequences of the US. The order and timing of the CS–US events are critical. The tone must precede the airpuff (i.e., be predictive of the US). Also, the two events must be separated by a fixed interval or small set of fixed intervals. Training is poor or absent if the interval between the CS and US is random.

Despite the fact that eye-blink conditioning requires only extremely simple movements, the task contains some basic ingredients of motor learning: First, the appropriate response, the blink, must have no previous associations with the critical stimulus (e.g., the tone). Second, the characteristics of the response are critical for evaluating performance. If the blink is not timed correctly, then it will be of no benefit. For example, the blink is not adaptive if it occurs immediately upon presentation of the tone or if the air puff will not occur for another 500 msec. Thus, the behavior must be refined with practice so that the motor commands are precisely coordinated with environmental events. Finally, it appears that learning for this task is largely implicit. Individuals with anterograde amnesia are able to learn during eye-blink conditioning, at least under certain conditions.

Richard Thompson and colleagues have established the involvement of the cerebellum in eye-blink conditioning. Lesions of the cerebellum can abolish the CR in animals that have undergone conditioning and prevent the acquisition of the CR in a naive animal. Importantly, the UR remains largely intact, indicating that the deficit is not one of motor production but specifically related to learning. Although most work has been done on the rabbit, the relationship between cerebellar pathology and eye-blink conditioning has been observed in a range of species including humans.

Lesion and physiological methods have been used to identify the component pathways supporting eye-blink conditioning within the cerebellum. When the tone is replaced by stimulation to the mossy fibers, eye-blink conditioning proceeds normally, indicating that parallel fibers represent the CS. Similarly, when the US is replaced by stimulation to the climbing fibers, conditioning is also normal. Thus, the two input pathways to the cerebellum convey representations of the CS and US. The locus at which an association is formed between the CS and US (i.e., the site of learning) has been a subject of considerable debate. One possibility is the primary site of convergence of these inputs—the Purkinje cells of the cerebellar cortex. Another possibility is the deep cerebellar nuclei given that both the mossy and climbing fibers send collaterals to the nuclei. Indeed, lesions of the nuclei completely abolish the CR, whereas lesions of the cerebellar cortex disrupt the timing of the CR. It thus appears that the association of the CS and US can occur at multiple levels. For the CR to be acquired, the cerebellar nuclei must be intact; for the response to be appropriately timed and thus adaptive, the cerebellar cortex is required.

B. The Vestibular–Ocular Reflex

The vestibular–ocular reflex (VOR) is a second form of motor learning whose neural substrate has been largely identified within the cerebellum. The VOR causes movements of the eyes that are intended to compensate for movements of the head and body so that visual images remain stable on the retina. When we move our heads, our eyes rotate effortlessly so that the world does not appear to move in the opposite direction. If magnifying spectacles are worn, head movements lead to larger displacements of the visual scene, and the VOR adapts so that the eye movements have the appropriate magnitude.

Evidence from single-unit recordings and ablation studies shows that this adaptation requires the floccular complex of the cerebellum. Animal studies of the VOR are typically performed in the dark, with the animal placed on a turntable so that visual signals and body movements do not provide a potential source of

the neural and behavioral responses. Rotations of the head cause changes in the rate of simple spike discharges for the Purkinje cells within the floccular complex. When vision is provided and experimental manipulations cause the VOR to incorrectly compensate for the movement, the magnitude of these changes is modulated in a manner that is consistent with the appropriate alteration of the VOR gain.

In some respects it is surprising that similar circuits should be involved in adaptation-like tasks, such as adjusting the VOR, and eye-blink conditioning. Eye-blink conditioning involves discrete movements whose magnitude and trajectory require little on-line adjustment. In contrast, the VOR is a continuous behavior that involves the coordination of multiple muscles whose degree of activation must be precisely modulated. However, there is considerable overlap in the computational requirements for the two tasks. For either behavior to be successful, the organism must learn to precisely time specific muscle commands with sensory events to minimize an unwanted stimulus. For eye-blink conditioning, the stimulus is the puff of air on the animal's eye; for the VOR, the stimulus is movement of the image on the retina.

In the VOR, the initial motor reflex and vestibular inputs are represented along the parallel fibers and the Purkinje cells learn to produce the pattern of activation to tune the motor command so that the eye movement correctly compensates for the change in the head's position. Climbing fibers provide signals about the slippage of the image on the retina. Thus, there is another parallel between VOR adaptation (and normal function) and eye-blink conditioning. The simple spikes provided by the mossy fibers provide a representation of the current environmental context—a representation that likely includes an efference copy of the animal's own movements but also sensory information relevant for these actions. The climbing fibers provide an error signal, a representation of the unexpected and aversive air puff or of a mismatch between expected and actual eye position.

C. Adaptation

The VOR belongs to a broader class of motor learning termed adaptation. During adaptation the sensory consequences of movements are altered so that subjects must learn new relationships between their motor commands and the environment. In the case of the VOR, compensatory eye movements must be remapped to vestibular signals so that the same degree of head movement results in a new amount of eye movement.

The eye movements learned during VOR adaptation differ critically from many other forms of learned movements, such as reaching movements. Unlike the dynamics of the eye, the dynamics of a multijoint system, such as the arm and hand, has many degrees of freedom and is highly nonlinear. For most multijoint systems, including that composed of the wrist, arm, and shoulder, determining what muscles to activate given the desired trajectory is an ill-posed problem. Ill-posed problems are those that are insufficiently constrained so that there are multiple possible solutions. For example, there are many different sets of muscle commands that will cause the hand to move to a particular location. This situation complicates motor programming considerably because the control system must determine which solution to pursue as it attempts to optimize behavior. Therefore, attributing errors to the appropriate muscle commands becomes a complex procedure.

A common form of adaptation is prism adaptation. In this experimental paradigm, the subjects wear goggles fitted with prisms that laterally displace the visual image on the retina. Thus, if the goggles displace the image to the right, information from the left side of the visual field will fall on the fovea as the subject looks straight ahead. This apparatus alters the relationship between movements of the body and visual information. For example, in order to reach for an object that appears on the fovea when the eyes and head are pointing directly ahead, one must move the arm to a position that is displaced to the left or right of the body. This new relationship between vision and action contradicts a lifetime of experience, but particular movements can be successfully relearned in a matter of minutes.

When first worn, the prism goggles cause pointing movements to be systematically displaced from their targets, with the magnitude of the distortion approximately equal to the extent that the goggles displace the visual signal. However, performance improves quickly with practice. Within approximately 20 trials, the systematic error is eliminated and performance matches that observed before the goggles were introduced. This improvement can stem from distinct forms of behavioral adjustment that are unrelated to motor learning per se. Conscious strategies can compensate for the shifted visual image if one intentionally directs movements a few degrees to the left or right of the target to adjust for the displacement. To obtain measurements of adaptation that are uncontaminated

from compensatory strategies, data are collected after adaptation has occurred and the goggles are removed. Under these conditions, subjects initially exhibit negative aftereffects of similar magnitude but in the opposite direction of the displacements observed when they first wore the goggles. Presumably, after removing the goggles subjects abandon any conscious compensatory strategies. Thus, the negative aftereffect indicates that the adaptation reflects a learned automatic process remapping visual information and motor commands.

To better understand the computational processes that are altered during adaptation, it is useful to distinguish between open-loop and closed-loop movements. Open-loop movements are programmed without reference to any sensory feedback. Thus, error signals from the visual and proprioceptive systems are unable to alter the motor programs. In contrast, closed-loop movements allow for sensory feedback to indicate adjustments in the ongoing motor command. When movements are made relatively slowly, in a closed-loop manner, the effects of the prism goggles may not be obvious. However, when movements are made ballistically, in an open-loop manner, they will terminate in a location that is displaced from the desired endpoint.

Importantly, adaptation based on interactions between visual and proprioceptive feedback does not transfer to unpracticed movements or effectors. That is, if an individual learns to make accurate rapid pointing movements exclusively with the right arm, performance with the left arm will show little benefit. This finding indicates that learning does not entail a generic remapping of visual coordinates to an internal model of space. Instead, the remapping involves specific motor commands to coordinates in egocentric space. However, although learning appears to be specific to particular sets of movements, it does generalize to other portions of the visual field. In summary, learning appears to be better characterized as motoric rather than perceptual.

Individuals with cerebellar damage demonstrate deficits in their ability to adapt to the prism goggles. Although the patients do exhibit some improvement in performance when wearing the goggles, there are no aftereffects once the goggles are removed, suggesting that the improvement was based on conscious strategy rather than true adaptation. This finding is consistent with the proposal that the cerebellum plays a critical role in coordinating motor commands with sensory information, and that such learning occurs at a procedural level.

Adaptation can also occur without manipulating visual inputs. Peter Gilbert and Thomas Thach trained monkeys to move a manipulandum with the muscles of the wrist to a specific target location. The manipulandum was fitted with a torque motor that could apply forces to the handle for random intervals so that the monkey had to change the amount of force exerted on the handle to return it to the target location. Once the monkeys learned to maintain the handle's location with two levels of force (one requiring activation of extensor muscles and the other requiring activation of flexor muscles), a new level of force was introduced, replacing one of the learned levels. The task is considered to measure adaptation because after training with the novel level, effects are observed on the unchanged force level.

As the monkeys performed this task, single-unit recordings were made from Purkinje cells in the cerebellar cortex. The frequency of complex spikes, driven by climbing fiber activity, increased when the novel force was introduced and returned to baseline rates as the animals adapted. The frequency of simple spikes, driven by activity along the parallel fibers, decreased as the complex spike frequency increased and remained depressed as the complex spike frequency returned to baseline. These findings indicate that the climbing fiber activity is affected by learning and that the climbing fibers may serve to modulate the strength of the Purkinje cell–parallel fiber synapses.

D. General Cerebellar Function

The uniformity of the cerebellum's architecture and its well-established role in motor control, including the control of posture and multijoint movements, have motivated theorists to seek a general, unified account of cerebellar function and how it might contribute to motor control and learning. Indeed, given recent anatomical neuroimaging and neuropsychological findings associating the cerebellum and nonmotor functions, these theories have been extended to consider how the cerebellum might provide a computation that is common to a variety of motor and cognitive tasks.

Valentino Braitenberg proposed that the long parallel fibers, through the sequential synapses that they form across a series of Purkinje cells, might constitute a set of delay lines. These delay lines would allow for muscular patterns to be coordinated across synergistic muscle groups recruited in the course of complex actions. Although it appears unlikely that

delay lines based on the length and transmission velocity of the parallel fibers can produce a sufficient range of delays, the general idea that the cerebellum is essential for regulating the timing of movements is viable. As noted previously, the cerebellum, especially the cerebellar cortex, is essential for learning when the task requires the precise representation of the temporal relationship between successive events. Indeed, the cerebellum may perform similar timing computations for nonmotor tasks that require this type of representation, providing a general characterization of this system as an internal timing system. Recent computational models indicate that the representation of temporal information may emerge from the complex physiological interactions between the various cells of the cerebellar cortex that shape the output of the Purkinje cells.

Turning to a more mechanistic account of the cerebellum and motor learning, computational models have emphasized that the interactions of the parallel and climbing fibers within the cerebellar cortex can function as a supervised pattern-recognition device. The climbing fibers provide a training signal that modifies the synaptic strength of the connections between the parallel fibers and Purkinje cells. In this manner, the Purkinje cells can shape the topography of movements based on the previous reinforcement history associated with the input patterns provided by the parallel fibers.

Such a mechanism provides an excellent means for learning arbitrary input–output associations but is less obviously useful for computing the temporal relationships necessary for the fine-tuning of motor commands. Researchers, including James Houk and Mitsuo Kawato, have developed this basic model to allow for the dynamic control of the motor system. These models share the properties that critical information about the present and desired state of the effectors, or body parts, is represented along the parallel fibers and that training signals are propagated through the climbing fibers. The initial motor commands originate upstream from the cerebellum. The inhibitory output of the Purkinje cells transforms or sculpts this signal into the appropriate pattern activity to control the actual effector.

Within this framework, it has been proposed that the cerebellum serves as an inverse model of the controlled effector, a forward model, or a combination of the two. A forward model directly simulates the controlled effector, taking as input the motor commands issued to the effector and producing as output the predicted sensory feedback. One might question the use of a forward model in learning since it merely approximates the actual behavior of the controlled effector. However, sensory feedback is quite slow in relation to the speed at which movements are performed and thus, at least during ballistic movements, may be of little help during execution. A model of the effector that can anticipate the behavior of the body in response to motor commands provides one way in which feedback can be rapidly used to contribute to on-line control. The forward model can be used to anticipate the sensory consequences of motor commands, and the difference between the expected and actual sensory feedback can be used as a sort of error signal.

An inverse model, as its name suggests, performs the inverse of the computation performed by the forward model. It takes as input the present and the desired state of the controlled effector and produces as output the motor command required to achieve the desired state. Such a computational device is of obvious use: With an accurate inverse model, a system need only compute the desired trajectory for the effector and allow the model to determine the necessary motor command.

Learning to encode a forward model is straightforward: The system takes as input the present state of the effector and the motor command and learns to produce as output the sensory feedback. Learning to encode an inverse model is much more difficult because the appropriate motor command is not available to the system (if it were, then there would be little need to learn an inverse model). For an inverse model to be correctly trained, observable sensory errors must be converted into motor errors. Therefore, inverse models are comparatively computationally expensive.

Mitsuo Kawato and colleagues proposed that the cerebellum houses the neural circuitry supporting both forward and inverse models. Evidence for the presence of each type of model has come from analyses of the patterns of neural activity within the cerebellum. Such evidence is indirect, however, and researchers continue to strive to characterize the computation performed by the structure.

IV. INTERNAL MODELS AND SENSORIMOTOR INTEGRATION

Adaptation can be thought of as belonging to an even broader class of motor learning phenomena termed sensorimotor integration. Although adaptation is restricted to a remapping of motor signals to sensory

feedback, learning to track an object or move a mouse requires mapping particular sensory signals to sets of motor commands in a goal-dependent manner. These latter tasks differ from adaptation paradigms because these relationships involve unfamiliar sets of stimuli and responses.

Prominent among sensorimotor tasks has been mirror drawing. In this task, subjects are asked to trace geometric shapes with a pencil. However, they are not permitted to view their hands or the shapes directly but instead must view them indirectly via a mirror. With this apparatus, the visual feedback is opposite what one expects from his or her movements. For example, as the hand moves to the left, the feedback displays a movement toward the right. Initially, mirror tracing is quite difficult. However, after several trials of practice, subjects are able to learn to trace the shapes rapidly and smoothly, eventually approaching levels of performance that match those achieved when the hand and shape can be view directly.

The mirror-tracing task has played an important role in studies of the motor learning capabilities of patients with severe amnesia. Despite their severe memory deficits, these patients will show improvements across separate sessions of mirror drawing that are equivalent to the improvements observed in age-matched control subjects. Such behavioral evidence of learning is especially striking given that the same patients may be unable to recall having ever performed the task. The dissociation provides a powerful demonstration that motor learning is subserved by an independent set of neural structures from those associated with explicit memory.

This is not to deny that people with intact explicit memory cannot use this system to improve their performance on the mirror-drawing task. For example, an individual can learn to make movements in the reverse direction without ever performing the task. This explicit strategy can also lead to a dramatic facilitation of performance, but it is not generally referred to by the term "motor learning." In neurologically healthy individuals, it is likely that learning is occurring in parallel within both declarative and procedural memory systems.

Daniel Wolpert and colleagues used sensorimotor integration tasks that alter the visual feedback of arm movements. In these experiments, individuals make reaching movements to targets that are projected onto a mirror-lined horizontal surface. The participant's arm is below this surface, hidden from view. The phenomenal experience is that of reaching to positions along the same surface as that on which the hand is located. Feedback of arm position can be provided by the projection of a cursor onto the mirrored surface and can be either veridical or artificially distorted by the experimenter. A basic finding in the motor control literature is that the hand trajectory generally follows a straight path during arm movements, a result that mandates a more complicated trajectory of each limb segment in joint space. However, when the feedback is altered so that such movements appear curved, participants will automatically adjust the trajectory so that the perceived path is straight. To do so, they must produce curved hand trajectories, thus implying an adjustment in the transformations associated with the internal model. This finding emphasizes the importance of visual information in providing feedback for motor learning. Studies using this technique have explored whether such modifications are applied in a general manner or whether they are restricted to particular regions of space. The results of such studies show that the tuning of the internal model is specific to particular regions of space. That is, the distortion diminishes as the distance from the practice location increases.

A second common experimental procedure used to measure sensorimotor integration is rotary pursuit tracking. Like mirror tracing, individuals with dense amnesia are able to improve by practicing rotary pursuit despite being unable to remember having performed in the earlier sessions. This task requires subjects to maintain contact with the moving object with a stylus as it follows a predictable circular path. In some versions of the task, participants simply follow the target with their eyes. Accurate performance of this task requires subjects not only to make smooth, well-timed movements but also to anticipate the trajectory of the target. Unlike many of the tasks considered so far, the desired movements form a fixed sequence that can be learned to improve performance.

This task is frequently used to assess the motoric consequences of brain damage. Although levels of ability can vary significantly across different clinical populations, one can determine whether individuals are able to improve with repeated exposure to the predictably moving target. We are unaware of any studies testing participants with cerebellar damage on this task, perhaps because these individuals do not easily make the smooth tracking movements that are required during performance. In general, this problem can be addressed by slowing the movements of the target and evaluating individuals' ability to improve over time. Using such techniques, several researchers

have reported that damage to the basal ganglia impairs learning during rotary pursuit. We examine the role of the basal ganglia during the performance of predictable movement sequence in our discussion of the serial reaction time task.

The distortion and rotor-pursuit tasks demonstrate that individuals can modify internal models based solely on visual information. Other researchers have created experimental settings that emphasize proprioceptive feedback. Reza Shadmehr investigated the ability of subjects to learn to counteract predictable forces exerted on a manipulandum. In this task, subjects must grip a handle that is attached to a robot arm and attempt to move the handle to a specified position in space. As the handle is moved from its starting position, torque motors in the robot arm exert a force that is dependent on the velocity of the movement. When first performed, the added force dramatically distorts the movement trajectory so that the handle moves in a curved path toward the target location. During practice, the movements adapt to the force field and eventually form a straight path.

There are two possible ways that the brain might learn to produce straight movements in the force field produced by the robot arm: The muscles of the arm might increase their stiffness or the trajectory of the arm might be altered to compensate for the field. Because movements show an aftereffect when the force field is removed, the latter explanation appears to be correct. Thus, experimental participants must learn an internal model of the force field that is used to reprogram motor commands and adapt to the task demands.

The formation of the internal model appears to go through a consolidation process that occurs hours after exposure to the force field, even if the time is not spent performing the task. To demonstrate this, Shadmehr and colleagues used an interference paradigm in which, after a delay period, participants were trained on a second, orthogonal force field. When the interval between the two sessions was separated by more than 5 hr, internal models for both force fields appeared to be learned. However, if the interval was less than 5 hr, learning of the new field was slower and interference was observed when the participants were retested in the original force field.

A series of PET studies were conducted to identify the neural regions associated with the formation of the modified internal models as well as those involved in the consolidation process that allows for the long-term retention of these new models. During training, few systematic increases were observed as the participants became more adept at making movements in the force field. Neural activity decreased in right frontal cortex and the left motor cortex, likely reflecting the reduced error as the trajectories became more linear. Interestingly, when the participants returned to the same force field after a 5.5-hr delay, increases were observed in the left posterior parietal and premotor cortices and the right anterior cerebellum. Control participants, who performed the task in a novel force field after the delay, did not show these increases. These findings suggest that the identified regions play a critical role in the representation of the internal model, but only after consolidation has occurred.

The activity in the cerebellum is of particular interest because it indicates that the structure, along with the others, plays a role in the retention of the internal model. This hypothesis has received further support from the computational and imaging studies of a group led by Mitsuo Kawato. In their model, the cerebellum stores a large repertoire of internal models. These models not only define how we produce gestures such as reaching movements in an efficient manner but also underlie the transformations required when we interact with tools. They assume that the error signals provided by the climbing fibers are distributed widely during the course of a movement. As the error is reduced, the overall activity of the cerebellum will decrease. However, in the restricted region involved in representing a task-specific internal model, activity should increase. This general pattern—an overall decrease in cerebellar activity during learning with foci of increased activation—has been confirmed in an fMRI study. The fact that the changes are bidirectional also sheds light on the discrepancies found in the imaging literature concerning the role of the cerebellum in motor learning, with some studies emphasizing an increase in activity and others a decrease.

Imaging studies have also provided insight into the neural bases of the interference effects. Shadmehr measured brain activity during performance under a novel force field for two groups of participants, with the training occurring 10 min after the training with the original force field for one group and 5.5 hr after training with the original force field for the other group. The 10-min group showed marked increases in activity in the brain stem and ventrolateral prefrontal cortex compared to the 5.5-hr group. These regions did not overlap with those associated with learning the first field. Therefore, the researchers proposed that the prefrontal regions were suppressing the expression of the learned internal model for performance in the novel field. Such suppression was not required for the

5.5-hr group, presumably because the inverse model associated with the original force field had been consolidated.

In summary these sensorimotor tasks indicate that neural structures throughout the brain are recruited to encode novel motor behaviors. In addition to the cerebellum, the basal ganglia and cortical structures appear to play a role in the acquisition of new behaviors. Next, we examine some other motor skill learning tasks that have been shown to recruit multiple brain structures.

A. The Cerebellum and Sequence Learning

Skilled behavior rarely involves tasks that require a single discrete movement or the involvement of a single joint. Many of our skills are more complex, involving the successful integration of a series of movements into a coordinated action. One popular task for studying sequence learning is the serial reaction time (SRT) task. In this task, participants perform a sequential choice reaction time task. The stimuli can occur in a repeating sequence or in a random order. In the typical experiment, random probe blocks are interspersed with learning blocks, and after an extended training period on sequence blocks, the difference between the reaction times on the two types of blocks provides a measure of learning. Reaction times are faster on sequence blocks even when participants report being unaware of the presence of the sequence and perform poorly on tests designed to assess their explicit knowledge of the sequence.

Before discussing to the numerous neuropsychological and neuroimaging studies of the SRT task, it is useful to consider some behavioral findings that highlight important computational issues. First, though it is frequently used as a measure of motor skill learning, there is debate as to what information is actually encoded by participants. This controversy stems in part from the finding that sequence knowledge acquired during the SRT task transfers to different effector systems. That is, participants initially trained on the task with finger movements will exhibit substantial transfer when tested with another effector system, such as arm movements or vocal responses. This aspect of the learning can be contrasted with many forms of adaptation in which the learning is effector specific.

However, these findings do not imply that sequence learning is largely perceptual. There is also strong evidence that sequence knowledge transfers to novel sets of stimuli or—when more than one stimulus is used to indicate a response—new orders of stimuli, as long as the sequence of responses remains constant. Thus, it is widely assumed that learning in SRT task involves encoding some abstract representation of the response sequence, although what information is included in this representation remains to be determined.

It should also be noted that the timescale of the movement sequence acquired during the SRT task is considerably different from that of the movements optimized in adaptation and sensorimotor integration tasks. In these latter cases, the learned behavior consists of a continuous movement and typically lasts less than 1 sec, whereas the SRT studies involve linking together series of discrete movements that can be separated by 1 sec or longer. This relates to a second property of the SRT task that distinguishes it from the others. Responses made in the SRT task are typically composed of simple and distinct actions; the precise timing of movements and the coarticulation of multiple effectors are not required. That is, the keypresses used in the SRT task tend to be single finger flexions that do not require the coordination of other muscle groups. It is true that these simple movements must be linked to others in the sequence, but the timing of these actions need not be precisely controlled for successful performance of the task.

Finally, it is generally believed that, as with the mirror-tracing task, learning on the SRT task may occur implicitly (i.e., outside awareness). Of course, under certain conditions sequence knowledge may become explicit. Although the critical boundary conditions for these two forms of learning remain controversial, there is evidence that they reflect the operation of separate neural systems. Although both forms of sequence encoding are highly interesting, we focus on implicit learning because its properties more closely match what is generally meant by the term "motor skill learning."

With these considerations in mind, we discuss the question of what neural systems support learning during the SRT task and what computations these systems perform. In contrast to behaviors such as the adaptation of the VOR, much of our understanding of the brain structures supporting learning during the SRT task comes from whole brain imaging techniques such as PET and fMRI. These procedures have an advantage over neurophysiological techniques in that they allow researchers to observed changes in activity across the entire brain.

Changes in activation within the cerebellum have been reported during SRT learning, but the picture

painted by these findings remains somewhat unclear. There have been considerable differences in the locations of the identified foci within the cerebellum, which may stem from differences in the experimental procedures employed by the researchers. Interestingly, there is the question of what sorts of changes one might predict within the cerebellum as learning progresses. If one supposes that the cerebellum plays a greater role in producing the appropriate motor commands as participants learn the sequence, then an increase in activity should be observed in this structure; if one supposes that the cerebellum is fine-tuning motor representations that are housed elsewhere in the brain, then decreases should be associated with learning. Of course, both types of changes could occur, similar to what has been reported in studies of tool use. In fact, both increases and decreases in cerebellar activity have been observed as learning in the SRT task progresses. However, the dominant finding is that sequence learning is associated with decreases in cerebellar activation.

A more consistent picture emerges in neuropsychological studies in which patients with cerebellar lesions are tested on the SRT task. Across a number of studies, these patients consistently fail to exhibit evidence of learning, except when the sequence is composed of just a few elements. Interestingly, even when the patients were explicitly informed of the sequence in advance of the testing in one study, they still failed to exhibit faster reaction times on the sequence blocks compared to the random blocks. The fact that the patients' reaction times fail to decrease over either condition raises the possibility that a performance deficit may make it difficult to observe learning, were it to occur. However, that learning is observed with short sequences undercuts this explanation to some degree.

Whatever reasons emerge to explain the complex patterns of activity, it appears likely that the cerebellum may play multiple roles during the acquisition and production of complex behaviors. Based on the distribution of projections from the cerebellum to cortex and spinal tract, lateral portions of the cerebellum are generally assumed to be involved in motor planning, whereas medial portions are assumed to be involved with motor execution. Motor learning likely involves both these sets of processes.

B. The Basal Ganglia

Perhaps the most frequently identified structure in neuroimaging studies of the SRT task is the subcortical collection of nuclei called basal ganglia. Increases in the basal ganglia's activity have been observed during both implicit and explicit sequence learning, although researchers have tended to emphasize automatic processing when characterizing its computational role. They have done so in part because several lines of evidence indicate that the basal ganglia are a key component of a habit learning system, especially in relationship to the production of sequential movements.

Neurological disorders have also emphasized the role of the basal ganglia in motor control, particularly in the production of sequential movements. Two prominent degenerative disorders, Parkinson's disease and Huntington's disease, involve a loss of tissue in the basal ganglia. For the former, the disorder primarily involves a loss of dopaminergic neurons arising in the substantia nigra. For the latter, the genetic abnormalities result in extensive atrophy of the striatum, at least in the initial stages of the disease. Patients with either Parkinson's or Huntington's disease exhibit a learning deficit on the SRT task. In both disorders, the coordination problems are most pronounced during the production of sequential actions.

Kent Berridge and colleagues have taken a neuroethological approach to the study of sequential behavior, exploring the neural basis of grooming in the rat. This behavior is highly stereotyped, consisting of three distinct arm strokes arranged in an essentially fixed order. Although lesions of the cerebral cortex and cerebellum produce only transient disruptions in this behavior, extensive striatal lesions can produce a chronic impairment in grooming. Interestingly, the deficit is not manifest as a loss of particular component elements, nor are the elements produced in a shuffled order. Rather, following the lesions, the animals frequently fail to complete the production of the complete sequence.

Because the grooming sequence performed by the rat is thought to be innate, the basal ganglia's function in this example is likely unrelated to learning per se. Thus, although many researchers have emphasized that the basal ganglia are necessary for learning new associations between stimuli and responses (S–R associations), it appears that the structure is critical for performing behaviors that are well established in the organism's repertoire. Given that the component elements are still performed after the basal ganglia damage, one possible contribution of the basal ganglia may be scheduling to elements in the appropriate order. That the structure is critical for both the acquisition of new sequences and the performance of

old ones provides an intriguing clue to its computational role.

Finally, neurophysiological studies have revealed that neurons within the monkey striatum are sensitive not only to which response in a sequence is being performed but also to the context of that response. In other words, these neurons show increases in activity that are dependent on the particular response occurring in a particular sequence. For example, a monkey can be trained to perform two movement sequences, one consisting of response sequence ABC and the other consisting of response sequence CBA. A context-sensitive neuron may show increases in activity before response B in the sequence ABC but not in the sequence CBA. This pattern is consistent with the hypothesis that the basal ganglia have chunked a series of discrete responses into a sequence, a process that is essential for the automatization of skills. However, similar context dependency is also observed in the supplementary motor area (SMA), a cortical area that is reciprocally connected with the basal ganglia. These results suggest a variety of computational interpretations. One hypothesis is that as skill develops, the basal ganglia form a representation of the sequence, enabling a shift in the locus of control from the cortex to the subcortex. In contrast, it may be that the representation of the sequence remains cortical and that the basal ganglia provide a mechanism to rapidly progress through the series of gestures as the sequence unfolds. The latter hypothesis would be consistent with the grooming studies showing that the striatal lesions result in a failure to complete the sequence.

C. Comparing the Basal Ganglia and the Cerebellum

In evaluating the role of the basal ganglia and cerebellum in skill learning, it is useful to compare these two prominent subcortical structures in terms of both anatomy and physiology. Although the neural circuits of each are unique, there are correspondences between the features of the cerebellum and basal ganglia that warrant a brief description. First, both form loop-like circuits in which inputs from the cortex are processed and then relayed back to the cortex via the thalamus. Second, both have inhibitory projections to their output targets: The internal capsule of the globus pallidus inhibits the thalamic nuclei and the Purkinje cells of the cerebellar cortex inhibit the cerebellar nuclei. Finally, both the cerebellum and the basal ganglia appear to use a divergent–convergent architecture in which input signals are distributed across a vast range of neural networks before recombining into a more compact, topographic organization. In the basal ganglia, this occurs as small cortical regions project to many loci within the striatum, which in turn project reconverging output to focal regions with the globus pallidus. In the cerebellum, inputs from mossy fibers are distributed to and reintegrated by thousands of Purkinje cells. One possible function of this design is to allow for inputs to form associations with information from many sources.

Given these shared principles, it is important to consider some differences between the two structures. First, unlike the cerebellum, the basal ganglia do not have any direct efferent or afferent connections to the spinal cord and comparatively few connections to the brain stem. In this manner, the basal ganglia are positioned to modulate the cortical selection and instantiation of actions, whereas the cerebellum is likely involved in both the planning and execution of movements.

Second, the two subcortical systems seem to use feedback in a differential manner. As described previously, the climbing fiber inputs to the cerebellum are generally considered to be the source of an error signal that is minimized as learning progresses. In contrast to the prevalence of error signals in theories of cerebellar learning, models of basal ganglia have emphasized reward systems based on the dopaminergic pathways. Thus, whereas the cerebellum is assumed to learn based on negative feedback from error signals, the basal ganglia appear to learn using positive feedback from reward signals.

In trying to understand how the computational roles of the two structures may be distinguished, theorists have emphasized the role of cerebellum in movements that require precise coordination and timing: Eyeblink conditioning, VOR, and multijoint movements all necessitate that motor commands that are exactly timed in relation to environmental events or changes in the positions of other body parts. In contrast, the basal ganglia are generally associated with learning tasks in which a particular action or series of actions must be performed in a novel context. For example, in the SRT task, the simple finger press responses are easily made and benefits are likely accrued when the correct one can be anticipated.

Along these lines, Daniel Willingham has argued that the basal ganglia perform motor learning computations that are distinct from those tapped by sensorimotor integration tasks. Willingham evaluated

performance of individuals with Huntington's disease across a variety of motor learning tasks and found that the learning impairments appear limited to a subset of the tasks, including rotary pursuit, the SRT task, and a tracking task in which the target followed a fixed pattern. The patients showed normal learning on mirror tracing and on a tracking task in which the target moved randomly. Noting that the Huntington's patients' deficits appeared to be restricted cases in which the movements were predictable, Willingham proposed that the basal ganglia are critical for learning sequences of open-loop responses.

In this sense, the basal ganglia can be thought of as operating on higher level representations that involve selecting a particular goal. In contrast, the cerebellum has been shown to be required when fine-tuning is required in the motor programs responsible for accomplishing a set goal. These generalizations suggest that the basal ganglia are critical for SRT learning, whereas the cerebellum is involved in learning tasks that require precise movements and the on-line coordination of effectors with sensory input. That is, the basal ganglia support "knowing what to do" and the cerebellum underlies "knowing how to do" motor tasks. Computational models have generally been consistent with this view. The successive inhibitory processing stages of the basal ganglia, from striatum to globus pallidus and then from pallidus to thalamus, have been shown to offer the unique feature of operating as a winner-take-all process, a mechanism for selecting the appropriate output given a particular context. In contrast, the inhibitory output from the cerebellar cortex is well suited for appropriately tuning the output from the cerebellar nuclei.

Features of this proposed distinction are likely to prove useful, but in some cases it is almost certainly an oversimplification. For instance, this framework cannot easily account for the fact that patients with cerebellar lesions are most impaired on SRT learning. We would expect that the patients could learn the pattern, but that they would have difficulty in producing the coordinated sequence of actions. Perhaps the cerebellum does not distinguish between error signals associated with poor movements and those associated with meeting the task requirements (e.g., pressing the correct button).

Contrary to earlier views of brain function, the functional domains of both the cerebellum and basal ganglia are no longer restricted to motor control and motor learning. Both structures project to various association areas of the cerebral cortex, suggesting a role in higher level cognition. Moreover, imaging studies consistently reveal metabolic changes in these areas that cannot be accounted for in terms of the motor requirements of the tasks, and neuropsychological studies have found that lesions in both the basal ganglia and cerebellum can disrupt performance on a wide range of cognitive tasks. The manner in which these subcortical structures contribute to motor skill acquisition may prove useful in understanding how they influence learning more generally.

V. THE CEREBRAL CORTEX

Thus far, we have focused on the subcortical structures, the cerebellum and the basal ganglia, and their roles in motor learning. Although it is clear that the cerebral cortex is intimately involved in many aspects of motor and nonmotor learning, there is a comparative dearth of rigorous computation models regarding the role of cortical structures in skill acquisition.

There is abundant evidence that the cortical structures play a critical role in encoding new motor behaviors. For example, imaging studies of motor learning tasks, including the SRT task, have identified many activation foci in the frontal and parietal lobes. These regions include the primary motor cortex, the premotor cortex, the supplementary motor cortex (SMA), and anterior parietal cortex, all of which possess neurons whose activity is closely related to motor activity.

A. Motor Cortex

The primary motor cortex, Brodmann's area 4, is an obvious starting point. It sends direct projections to the spinal cord and is unique among cortical areas in that it possesses reciprocal connections with all of the premotor regions that project to the spinal cord. Stimulation of this cortical area produces overt movement and the neural activity is more closely related to movement parameters than other cortical motor structures. For these reasons, the motor cortex has traditionally been considered an area associated with motor output rather than performing the higher level operations associated with motor learning.

However, there is strong evidence that the physiology of motor cortex changes as new motor skills are developed. Across a variety of sequence learning tasks, motor cortex activity has been shown to increase during the course of training. Interestingly, these

changes appear to be strongest when the sequence knowledge is implicit; under conditions that favor the development of explicit knowledge, PET studies have failed to show learning-related changes in motor cortex.

One potential consequence of skill learning is that the motor fields of task-related neural ensembles are enhanced over the course of practice. Indeed, anatomical studies in the rat have shown a functional reorganization of the topographic map within motor cortex as a function of practice. The cortical region associated with the involved effectors becomes larger, paralleling learning-related changes that have been observed in various sensory cortices. The motor "receptive" field can also be measured in humans with transcranial magnetic stimulation (TMS). With this method, a large magnetic field is generated in a coil applied to the scalp and the underlying neural tissue is excited. When applied over motor cortex, discrete finger movements can be elicited. During SRT training, the region over which finger movements could be generated increased. Interestingly, as soon as the participants became aware of the sequence, the motor fields returned to their original size.

The previous results suggest an involvement of motor cortex during implicit sequence acquisition. However, these studies have all involved training that was restricted to a single session. Avi Karni and colleagues conducted a sequence learning study that spanned a much longer period. Participants were required to practice a series of finger movements over a period of several months. fMRI was used to measure activity within the motor cortex at various points during the training regimen, with the comparison made between epochs in which the participants produced the learned sequence and epochs in which the participants produced an alternative sequence. During the scanning sessions, the movements were paced so that the number of actual responses was equated for the two conditions. Nonetheless, after 3 weeks of practice (but not before), the trained sequence produced greater signals in primary motor cortex than an untrained control sequence. This increase was apparent despite the fact that the participants had full awareness of both the trained and control sequences.

There are at least two ways to reconcile the discrepancy between the results of this study and the SRT results. First, after many weeks of training, performance on the highly trained sequence may no longer depend on explicit representational systems. Indeed, at this point in training, the participants would show minimal cost on the sequencing task if required to concurrently perform a second, attention, demanding task. By this hypothesis, increases in motor cortex activity are again restricted to implicit sequence performance. Second, the increased signal may be a consequence of the pacing manipulation during the scanning sessions. By slowing down the production rate during the scanning session, motor cortex neurons may have remained active in anticipation of the next response. This latter hypothesis underscores a potential limitation with imaging studies of sequence learning. Neural activity may increase in an area not because there is a representational change within the area but because the input signal from an upstream neural region has become stronger.

Neurophysiological studies have also provided evidence for learning-related changes in motor cortex. Several groups of researchers have reported that the response properties of motor cortex neurons change as the animal learns to perform new tasks. These neurons may become more responsive to a given stimulus as the animal learns to associate it with a particular response, or they may alter their responsiveness to reflect the operation of a particular set of S–R mapping rules, regardless of the actual stimuli. Thus, it is unlikely that this region's computation is restricted to simple output properties.

B. The Premotor Cortex and SMA

Lying immediately rostral to the primary motor cortex is Brodmann's area 6. This secondary motor area is composed of two primary regions, the premotor cortex and SMA. Premotor cortex includes the lateral aspect of area 6, whereas SMA spans the medial aspect. Recent work has emphasized that there are likely many subareas within these areas; for example, four distinct motor areas can be identified within SMA. Premotor cortex and SMA are well positioned to modulate motor output given their projections to motor cortex as well as their reciprocal connections with prefrontal, parietal, and SMA regions.

Functional hypotheses concerning the role of premotor cortex and SMA have primarily been derived from physiological studies with primates. The relevant experiments have generally investigated neural activity during two types of tasks: learning to form novel associations between stimuli and responses and learning to perform novel sequences of actions. For the tasks involving the formation of S–R associations, the single-unit recordings have predominantly examined

the premotor cortex. However, for the tasks involving response sequences, the recordings have focused on the SMA.

Steven Wise and colleagues performed several experiments demonstrating that neurons in premotor cortex change their responses as monkeys learn to produce particular responses to specific stimuli. That is, these neurons become more responsive to particular stimuli as they become associated with particular responses, suggesting that they may contribute to the encoding of the S–R mapping. Other studies have recorded from neurons in motor, premotor, and parietal cortex, examining if the activity is associated with the response, the stimulus, or both. Neurons showing each of these types of response properties have been observed in all three regions. Nonetheless, there are differences in the proportions of types across the three regions, with the emphasis changing from stimulus linked to response linked between parietal and motor cortex. Thus, the functional differences within the cortex may be more quantitative than qualitative.

The emergence of a new motor skill results from the combination of basic motor elements into meaningful, sequential gestures. To type, we learn to chain together a set of simple finger and wrist movements. Moreover, to type a frequent word such as ''the,'' we encode a specific pattern of such movements. The gesture used to produce the ''e'' in this context is distinct from that associated with typing the word ''hose.'' Neurophysiologists have examined the context dependency of motor neurons to identify those that are involved in sequence learning and sequence performance. Jun Tanji and collaborators provided extensive evidence that SMA neurons exhibit such context dependency. For example, animals might be trained to press three horizontally aligned response keys in one of two sequences, left–right–middle or middle–right–left. Some SMA neurons will fire prior to the response on the right key in the first pattern but not the second; the opposite pattern will be observed in other neurons. Thus, the neural activity is associated with a specific movement (press right key) only when that movement occurs within a particular context or as part of the actions associated with a specific goal.

The association of SMA with sequential movements is one way in which this area appears to differ from motor cortex. Motor neurons show much less context dependency. Their response is much more closely tied to the individual movements that form the sequence rather than features of the overall sequence. A motor cortex neuron that responds when the right key is pressed will generally fire similarly within any sequence that contains this response.

An intriguing demonstration of the contribution of SMA to the organization of sequential behavior in humans comes from TMS study performed by Christian Gerloff and colleagues. With this technique, a coil capable of producing a strong magnetic field is placed on the skull. When engaged, the field induces widespread firing of the neurons in the cortical region lying under the coil, causing a disruption of the endogenous activity of this area. In a sense, TMS causes transient ''virtual'' lesions. In the study, TMS was targeted to disrupt activity in either motor cortex or SMA while people performed a series of finger movements. Motor cortex stimulation led to errors in the production of the ongoing movement: The selected finger might freeze or another finger might be activated and press an incorrect key. In contrast, SMA stimulation led to errors in subsequent movements. The participants reported losing track of their place in the sequence, of momentarily forgetting the series of associations. This dissociation is in accord with the hypothesis that the representation of SMA is not linked to individual movements but, rather, the sequence of movements that constitute the skill.

Neurons within premotor cortex also exhibit context dependency, responding during a particular movement, but only when that movement is performed within a specific context. However, there is one important difference between the sequential properties of neurons in premotor cortex and those in SMA/pre-SMA. The majority of premotor neurons fire when the movements are cued by external signals such as the illumination of a response key. In contrast, neurons in SMA fire most vigorously when the movements are internally generated. Thus, within either area, one will fire neurons that respond prior to the right keypress during the sequence left–right–middle. However, the typical premotor neuron will fire when the movements are signaled by an external cue, whereas an SMA neuron will fire when the sequence is being produced from memory.

The distinction between external and internal modulation of activity may offer clues to the functional specialization within secondary motor areas in terms of their contribution to motor learning. As noted previously, premotor cortex is critical for learning arbitrary associations between stimuli and responses. Externally cued movements by definition involve transforming stimulus information into the appropriate action goals (S–R translation), making such behaviors the purview of the premotor cortex. In

contrast, producing a complex sequential action likely requires that the successive movements be organized in relation to internal states, thus requiring the operation of the SMA.

From this perspective, it would be reasonable to expect both premotor cortex and SMA to be involved in the performance of skilled behaviors. Throwing a dart requires the sequential and exquisitely timed engagement of a specific set of muscles as well as the use of visual feedback to fine-tune the movements from one toss to the next. Indeed, many neuroimaging studies have observed activity in both regions over the course of learning. Although the pattern of activation in premotor cortex and SMA is frequently similar, dissociations have also been reported. Harri Jenkins and coworkers used PET to observe the neural correlates of sequential movements at different stages of learning. Unlike the serial reaction time task, these studies used a trial-and-error method for sequence learning. In each trial, the participant presses one of four keys. Following the response, a tone is generated indicating whether or not the selected response was correct. Learning progresses rapidly so that after about 10 min of practice, the sequence can be repeatedly produced without any errors. Paralleling these performance changes, the focus of cortical activity shifts from premotor cortex to SMA. If a new sequence is then introduced, premotor cortex is again engaged. As with the primate studies, these results emphasize that premotor cortex is most prominent when behavior is dependent on external sources of information; when performance can be guided by internal cues, SMA appears to become more important.

C. The Parietal Cortex

The final region to be considered in this article is the parietal cortex. Both neuropsychological and neurophysiological evidence suggests that the function of this region may be closely related to that of the premotor cortex. Extensive reciprocal connections exist between parietal and premotor cortex, and the two structures may work together to transform information about the environment into representations used for motor programming.

The classic neuropsychological syndrome involving the loss of skilled movement is apraxia, first characterized by Hugo Liepmann. The term likely includes a variety of syndromes, although a taxonomy of apraxic subtypes remains controversial. By definition, apraxia involves deficits in the production of movements, when the deficits cannot be attributed to problems in motor execution (e.g., paralysis or weakness), perception (e.g., agnosia), or comprehension (e.g., aphasia). Many investigators have limited the definition of apraxia to deficits in learned motor acts rather than novel behaviors. Apraxia can be summarized as a failure to translate goals into movements.

Apraxia can be observed following lesions of either cerebral hemisphere. In general, the deficits are most severe following left hemisphere lesions, with these patients exhibiting the disorder when using either the contra- or ipsilesional hand. Patients with apraxia resulting from right hemisphere lesions usually exhibit deficits only when using the contralesional side of the body. Within either hemisphere, apraxia has been associated with lesions of either the frontal or parietal lobes. Considerable neuropsychological research has attempted to dissociate apraxia stemming from parietal lesions from apraxia stemming from frontal lesions.

Kenneth Heilman and colleagues tested apraxic individuals with either premotor or parietal damage. They determined that although both groups demonstrated deficits in the production of learned motor behaviors, the group with parietal damage was also significantly impaired at discriminating well-performed and poorly performed actions in a task involving the perception of skilled actions. For example, the patients might not be able to judge which of three video clips depicted a person pantomiming how to use a key to open a lock. Thus, the more anterior lesions appear to disconnect the motor programs from the structures that are necessary for performance, whereas the more posterior lesions appear to disrupt the representations of the motor programs.

Neurophysiological studies have also compared how movements are represented in the frontal and parietal lobes. Much of this research has focused on "mirror neurons"—cells that become active both when a monkey performs a particular act and when the animal observes that same act being performed by another monkey (or person). The fact that the cells are responsive during both observation and performance suggests that they are coding abstract properties of the actions rather than particular motor parameters. Although the initial work on mirror neurons focused on premotor cortex, Vittorio Gallese recently reported that neurons in this inferior parietal lobe also respond during both performance and observation of goal-directed actions. It appears that the inferior parietal neurons may represent the motor acts at an even more abstract level than the premotor neurons in that the

former may be insensitive to the actual effectors used to achieve the goal. Thus, the parietal lobe may serve as a critical interface between perception and action. As the animal views the environment and identifies possible actions (e.g., obtain a banana), an abstract representation of the goal may be translated into an abstract action designed to achieve the goal, with the projections to premotor and motor areas serving to specify a particular reaching gesture.

To date, there has been little neurophysiological work addressing how the responses of neurons within the inferior anterior parietal cortex change during the course of skill acquisition. However, activation in this region is frequently observed during the encoding of new motor skills. For example, increases in area 40 are often reported during SRT learning, particularly in the left hemisphere. Several lines of evidence are consistent with the proposal that the activity in this region is associated with an abstract level of program. First, Scott Grafton and colleagues trained participants in a version of the SRT task in which the sequential key presses were made on a large keyboard that required whole arm movements. After training, the participants were transferred to a smaller apparatus on which the responses were made with finger movements. The behavioral data demonstrated that the sequence knowledge transferred from the arm movements to the finger movements. The PET data showed that whereas activity in the motor cortex was contingent on the effectors used to produce the sequence, activation of the inferior parietal lobe in the left hemisphere was contingent on the presence of the sequence regardless of how the movements were made.

VI. SUMMARY

In this article, we have focused on the neural regions involved in the performance of learned motor skills. The article is admittedly selective. For example, the cortical section did not discuss the contribution of prefrontal cortex despite extensive imaging evidence showing consistent activation in this region during motor learning and motor performance. However, the role of prefrontal cortex is likely not specific to motor learning. The prefrontal cortex is often characterized as performing operations relating to executive control rather than encoding motor skill for long-term storage. Thus, this structure may be most critical during the initial performance of novel tasks, playing a smaller role as learning progresses.

This article included a description of several cortical regions. Nonetheless, the emphasis was on the basal ganglia and cerebellum. The cerebellum and basal ganglia do not project directly to one another, and the cortex, particularly sites within the frontal lobe, is most likely the locus of interaction between the two structures. We characterized the cerebellum and basal ganglia as performing very different functions, with the cerebellum tuning motor commands in relation to sensory feedback and the basal ganglia scheduling action goals for motor processes to achieve.

Our focus on the subcortex reflects a bias in the literature: It is striking how many computational theories have been developed concerning the function of the cerebellum and basal ganglia, and that there is a dearth of such theories for cortical function, at least in terms of motor learning. Does this dominance of subcortical structures reflect limitations in our current understanding or does it indicate that the cerebellum and basal ganglia play a predominant role in motor learning? Although these possibilities are not exclusive, one factor to bear in mind is that the comparatively homogeneous architecture of the subcortical structures may make them excellent systems to model. That is, the connections within these neural structures follow a mostly linear arrangement, with neural signals moving along well-defined pathways. In contrast, the organization of the cortex appears much more complex, and the flow of information is much less easily determined. In short, the state of computational models may stem from general differences in the neural architecture of cortical and subcortical regions.

Movement Regulation

JOHN F. SOECHTING and MARTHA FLANDERS
University of Minnesota

GLOSSARY

feedback A signal derived from afferents used to control the movement and correct for errors in an ongoing movement.

feedforward A signal derived from efferent commands used to predict the movement that will ensue.

kinematics Dealing with movement; includes parameters such as position, velocity, and acceleration.

kinetics Dealing with the forces that generate a movement.

physical plant The mechanical properties of muscles and of the skeletal system.

Movement regulation is thought to involve a combination of feedback and feedforward mechanisms. The nature of the feedforward and the feedback control depends crucially on the characteristics of the motor plan and the properties of the physical plant that is being regulated. This article reviews current concepts of motor planning, the properties of the musculoskeletal system, and control systems models for movement regulation. The focus is on the regulation of limb movements, although many of the concepts apply equally to the control of eye movements.

I. OVERVIEW

At the beginning of the 20th century, Charles Sherrington put into place a conceptual framework concerning movement regulation and initiation that held sway for a considerable amount of time. The central component of this framework was the reflex—sensory input leading to the initiation of the movement and also providing for its ongoing control by means of feedback. The most studied of these reflexes was perhaps the stretch reflex, but a large variety of other postural reflexes involving somatic, vestibular, and even visual sensory afferents were also elaborated over the course of time. In this viewpoint, reflexes were not obligatory; instead, they could be gated and regulated by higher centers in the nervous system, thus providing for the idea of a hierarchical organization. Another important component of this framework was the concept of synergy—a group of muscles acting together in a common purpose in a particular movement and being controlled together as a unit.

In this conceptualization, limb motion from one posture to another involved two opposing groups of muscles, agonists and antagonists, each activated as a unit. Another important discovery, developed by Elwood Hennemann in the middle of the 20th century, provided an explanation for the orderly recruitment of individual motor units within the agonist and antagonist muscles. Specifically, according to Hennemann's size principle, motor units are recruited in a stereotypic fashion, according to their size. The pattern of muscle activation producing a limb movement was thought to be quite simple. There is an initial burst of agonist activity, arising from descending commands and providing for the movement's initiation. This is

followed by a burst of antagonist activity and a second (smaller) burst of agonist activity, providing for the movement's arrest and stabilization and arising at least in part from the stretch reflex.

The primacy of reflexes in controlling movement was not acknowledged universally, however. For example, although some investigators initially thought that locomotion was the result of a chain of reflexes, it was ultimately demonstrated that the locomotor pattern of alternating, rhythmic activation of flexors and extensors of each of the limbs was the result of a central pattern generator. These investigations also showed that this central pattern generator for locomotion was located in the spinal cord and that rhythmic motion could be elicited from deafferented preparations (i.e., in the absence of sensory feedback).

Thus, there were two competing viewpoints. According to one, movements were regulated essentially and importantly by feedback mechanisms dependent on sensory information generated by the movement. A diametrically opposite position held that movements were accomplished open loop in a feedforward fashion, and that the delays in feedback loops were too long for afferent information generated during the movement to modify the ongoing trajectory.

The conceptual framework from which we view movement regulation has changed dramatically in the past 20 years, but feedback and feedforward regulation remain central to the issue. One major change is the recognition that movements cannot be controlled by feedback alone and that they also cannot be performed accurately using simply feedforward. Thus, movement regulation involves a hybrid of feedforward and feedback controllers.

Furthermore, our concept of what needs to be regulated by the central nervous system has become more sophisticated. Thus, it is now clear that the physical properties of the plant—the muscles and the skeletal system—introduce appreciable complexities. Similarly, movement regulation usually involves the synthesis of sensory information derived from different modalities, such as vision, somatosensation, and the vestibular system. Sensory information from these different modalities is combined into a common frame of reference, introducing additional computational burdens. Finally, there is a growing appreciation that the control system regulating movements is not "hard-wired" but, rather, that it is subject to modification by experience and learning. We discuss each of these points in the following sections.

II. THE PHYSICAL PLANT

A. Kinetics and Kinematics

Kinetics refers to the forces (or torques) that generate a movement, whereas kinematics refers to a description of the motion—position, velocity, and acceleration. Kinematics and kinetics are related by Newton's second laws of motion. When the motion is restricted to a single joint, this relationship is simple:

$$F = ma \text{ or } T = I\alpha$$

where F is the force, m is the mass, and a is the object's acceleration. Similarly, for rotational motions, T is the torque, I is the moment of inertia, and α is the angular acceleration. Now consider the problem of predicting the movement that a particular force will generate. The solution to this problem is simple because position (or angular displacement) can be found by integrating force (or torque) twice. It is also easy to compute the force needed to produce a given movement by differentiating the desired linear displacement $p(t)$ [or the desired angular displacement $\theta(t)$] twice.

Since it is known that neural circuits can perform the mathematical equivalents of integration and differentiation, controlling simple movements does not appear to be particularly challenging. Furthermore, it was thought that more complicated movements could be generated by simply combining several simple movements. Thus, the distinction between kinematics (movements) and kinetics (forces) becomes academic; accelerations and forces are proportional to each other.

This is not the case when a movement involves rotation at more than one joint—for example, an arm movement that involves the shoulder, the elbow, and the wrist. Consider a simple example in which the arm is in the horizontal plane and is supported against gravity. Also imagine that a single shoulder muscle is activated, generating a torque about the shoulder joint. This torque will produce an angular acceleration at the shoulder. However, if the elbow and wrist joints are free to rotate, the acceleration at the shoulder will also impart a rotation at the elbow and wrist joints. Similarly, contraction of a pure elbow or a pure wrist muscle will affect the shoulder joint, changing the motion of the humerus, the limb segment proximal to the elbow. Torque is proportional to the angular acceleration at each of the joints in a skeletal linkage; conversely, the angular acceleration at one joint is proportional to the torques generated by muscles acting at each of the joints.

The equations relating kinetics and kinematics for multijoint motion also include terms known as Coriolis and centripetal accelerations. These terms are related to the angular velocities of the joint motions. Furthermore, the inertia of a linkage such as the arm depends on the angles of the joints in the linkage. Thus, torque is generally related to angular acceleration, angular velocity, and angular position. This relation is illustrated in Fig. 1. The relation between angular acceleration and torque is shown to depend on several parameters: the inertia of the limb, its angular velocity, and its posture. Posture enters into the equation in two ways: It affects limb inertia and it also determines the gravitational loads that need to be opposed.

The crucial point that emerges from this picture is the following: Inertia, posture, and velocity all vary during a movement. Therefore, if the motion that ensues from a torque profile is to be predicted, it is necessary either to measure each of these parameters accurately or to be able to predict them accurately. (Note that in principle, a single-joint movement could be performed accurately knowing only the amplitude of the required movement because the inertia of one limb segment does not change with time.) Sensing the position and velocity of a movement involves time delays. Consequently, parameters entered into the equation of motion will be in error because they are based on the state of the system in the past. Similarly, estimating position and velocity from the torque commands will also introduce errors arising, for example, from uncertainties in estimating the starting posture of the limb.

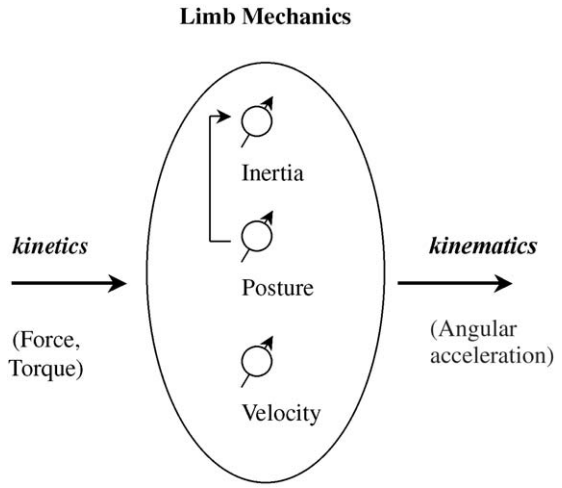

Figure 1 Relationship between kinetics (forces or torques) and kinematics (acceleration) as determined by limb mechanics. For a multijointed limb, the equations relating kinematics to kinetics include terms that depend on positional and velocity parameters, which change over time. The inertia of the limb also depends on posture and consequently also changes as the movement progresses.

Gravity is ubiquitous and gravitational torques also depend on the posture of the limb but not on the speed with which the limb moves. Thus, the control of a limb movement would need to account for the effects of gravity as well. In the mid-1980s, John Hollerbach made an important observation that provides for a potential simplification of the control of movement in a gravitational environment. He showed that despite all the apparent complexity of the relationship between torque and angular acceleration, the equations relating these parameters scale with the speed of the movement. In other words, movements of different speeds can be generated by taking one template of torques and scaling it in amplitude and in time. Since the gravitational torques do not depend on the speed, movement control can be simplified by separating the controller into two components: a postural component that does not depend on speed and a movement component that is speed dependent. Subsequent investigations have provided experimental support for this supposition.

The laws of motion relating kinematics and kinetics have other implications. First, the direction of force and the direction of movement generally do not coincide. Consider the following example. Ask a subject to exert an isometric force with the hand in some particular direction against a resistance, and then release the resistance. The hand will begin to move in a direction that need not coincide with the direction in which the force was exerted. Second, because of the interactions between the motions of the various limb segments, the sign of the torque at a particular joint need not be the same as the sign of the angular acceleration at that joint. For example, elbow extension may require elbow flexor torque. Consequently, eccentric contractions (i.e., activation of muscles that lengthen during a movement) are not uncommon. Movements depart in the correct direction, with the activation of the appropriate muscles predicted on the basis of mechanics. Accordingly, the central nervous system (CNS) must take these factors into account in specifying which muscles should be activated.

B. Muscles

The mechanical properties of muscles also need to be taken into account by the CNS. Since the work of A. V.

Hill in the 1930s, it has been appreciated that muscle force depends on muscle length (the length–tension relation) and on the rate at which muscle length changes (the force–velocity curve). Tendon compliance also affects the dynamical relation between muscle activation and force generation, and it is an important factor in mechanical models of muscle, such as those developed by Felix Zajac. It is also well recognized that the moment arm of a muscle can change with changes in the limb configuration. Since muscle torque is equal to muscle force times moment arm, changes in a muscle's moment arm will also affect the amount of torque generated by a specific level of muscle activation.

Most muscles generate torque about more than one axis. For example, biceps brachii acts as shoulder flexor and as an elbow flexor and supinator. Similarly, anterior deltoid acts as a shoulder flexor and adductor. One can always define a torque axis, a vector defining the mechanical action of that muscle. The question arises, do these actions depend on the posture of the limb? In other words, does the torque axis remain fixed as limb posture changes? If the answer is the affirmative, one can imagine two possibilities: (i) The torque axis remains fixed relative to the orientation of the distal segment, and (ii) it remains fixed relative to the proximal segment. For example, considering deltoid, one could imagine that the mechanical action was fixed relative to the trunk (proximal segment) or that it was fixed relative to the humerus (the distal segment). In fact, the answer is neither, and torque axes depend on limb posture in a manner that is intermediate to the two possibilities just outlined. The axis moves along with the distal limb segment, but not by as much as the limb segment moves. The postural dependence of the mechanical actions of muscle reinforces the conclusion drawn in the previous section: The CNS needs to take into account posture and rate of change of posture in planning and regulating movement.

Although the postural dependence of the mechanical actions of muscles is not negligible, it need not be overly complicated. For example, for shoulder muscles, simple linear models relating the directions of the torque axes to the orientation of the humerus could adequately account for the experimental data. Muscles are customarily modeled by assuming that their forces are exerted in a straight line from an effective origin to an effective insertion. (The effective origins and insertions need not coincide with the anatomical origins and insertions.) These "rubber band models" are indeed adequate to account for the actions of shoulder muscles, even those that have widely distributed origins such as the heads of deltoid. Thus, it appears that fairly simple models can be used to account for the mechanical actions of muscles and for their postural dependence.

As noted previously, the initial conception of movement regulation was that for any particular movement, there were two distinct groups of muscles —agonists and antagonists. Muscles within these groups would act as synergists (i.e., they would be activated synchronously). Initially, it was also thought that this grouping would hold for all movements [e.g., a classification of muscles as flexors and extensors (or gravity vs antigravity)], and that synergies would be hardwired. This viewpoint was subsequently modified to account for the fact that a pair of muscles could be synergists for one movement and antagonists for another. Furthermore, the need for synchronization was also abandoned and it was posited that a group of muscles belonging to a synergy could be activated in a fixed, sequential order. In this concept of "flexible synergies," the relative timing of the activation of different muscles would be fixed, at least for a broad class of movements.

A detailed investigation of the patterns of muscle activation for arm movements in different directions has shown that this is not the case. Although the basic "three-burst" pattern of electromyographic activity does hold for multijoint movements as well as for single-joint movements, the timing of the bursts in individual muscles is asynchronous. Furthermore, the relative timing of muscle bursts, among the various shoulder and elbow muscles, varies with the direction of movement. For any given muscle, there is an orderly progression of the timing of muscle activation with movement direction, but this pattern is different from muscle to muscle. Accordingly, it is not possible to define even pairs of muscles that are synergists, in the strict sense of this word. However, these studies did provide support for the idea introduced by Hollerbach in the sense that it was possible to identify for each muscle a "tonic" pattern of activity related to static postures and counteracting gravity and a "dynamic" component that scaled with the speed of the movement.

Thus, in general, it does not appear that control is simplified to two groups of muscles, acting as agonists or as antagonists for a given movement. Is it possible to conceive of movement regulation on a muscle-by-muscle level? It has long been known that some muscles are compartmentalized, with muscle fibers having mechanical actions that differ from compartment to compartment. Nevertheless, it was supposed

that, at least within each compartment, motor units were recruited in an orderly fashion, according to the size principle, and that except for this proviso motor units would be recruited similarly and simultaneously. Recent studies do not support such a simplifying assumption. Instead, they indicate that the control and activation of motor units is effected in a distributed fashion.

This assertion is based on results of studies of the recruitment of single motor units of elbow and shoulder muscles, primarily biceps and deltoid, under isometric conditions (Fig. 2). Under isometric conditions (as well as during reaching movements), muscles generally exhibit "cosine tuning." When force is exerted in a particular direction, muscle activation is greatest. When the same amount of force is exerted in a different direction, the amount of muscle activity decreases in a manner that is approximated by a cosine function. Thus, muscles can have a "best direction." (Sometimes, the tuning curve shows two peaks and thus there are two best directions.) As shown in Fig. 2A, this tuning property is also obeyed by single motor units. However, the best directions of individual motor units in one muscle do not coincide but are dispersed over a wide range of directions (Fig. 2B). Furthermore, there is no evidence for a clustering of these best directions; thus, the results cannot be explained by assuming muscle compartmentalization.

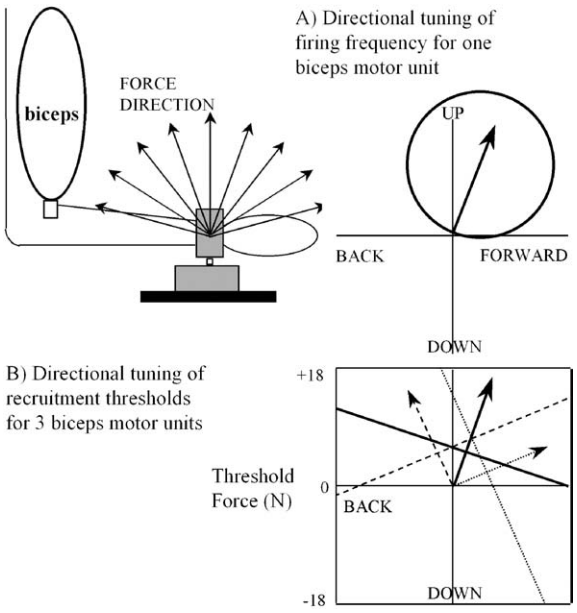

Figure 2 Directional tuning of motor units. (Top left) A typical experiment used to define directional tuning of motor units. The arm is maintained isometrically and force is exerted in a variety of directions. For each direction of force, firing frequency and the threshold of recruitment of single motor units are determined. (A) The typical tuning curve, with the distance from the origin to the edge of the closed curve representing firing frequency when the same amplitude of force is exerted in different directions. The arrow denotes the best direction for this motor unit. (B) The thresholds for recruitment of three motor units. Note that the threshold for each unit is defined by a straight line (equivalent to cosine directional tuning in A), but that the slope of the line is different for each unit. The arrows show the best direction for each unit. Note that the recruitment order of these three units depends on the direction in which force is exerted.

The threshold for recruitment of a motor unit is lowest when force is being exerted in that motor unit's best direction. If the best directions of motor units vary over a fairly wide range, as was found for the muscles studied so far, then there is no fixed recruitment order of motor units within a given muscle because there will be a different recruitment order for every force direction (see the threshold levels for the three motor units in Fig. 2B).

In summary, the experiments discussed in this section lead to two main conclusions. First, in order to predict the forces and torques developed by activation of any muscle, the motion and posture at each of the joints must be sensed (or predicted accurately) throughout the movement. Second, neural control of the musculature is not exerted over groups of muscles (synergies) or even at the level of individual muscles. Rather, this control is distributed, with individual motor units within a muscle having individual tuning characteristics.

III. MOVEMENT PLANNING

A. Robotic Models

Computationally, the control of a robotic arm by means of a computer and the control of a biological arm by the brain share many similarities. Accordingly, investigators studying the neural control of limb movements have often attempted to use the algorithms that have been used successfully by roboticists as a template for understanding biological motion. In fact, robotic models of movement planning have had considerable influence on models for neural control of movement.

Computer algorithms for movement planning evolve in a serial fashion, with one stage devoted to movement kinematics and a second stage devoted to movement kinetics. Consider the kinematic aspects of movement planning first. In this module, the first step

is to define the location of the target of the motion. This specification is said to be in extrinsic (or task) coordinates; for example, the x, y, and z coordinates with reference to some origin. Generally, the extrinsic coordinates do not define a unique configuration of robot or human arms because these arms have more than three degrees of freedom. For example, the human arm has 4 degrees of freedom, counting only the shoulder and elbow, and 7 degrees of freedom if the wrist is included. Therefore, there is not a unique solution; more than one posture is compatible with the target location. A unique solution is imposed by introducing some constraints. For example, it could be desired that the limb posture be as far away as possible from the limits of motion at each of the joints, or it could be desired to limit the amount of motion at each joint.

Two other things also need to be specified in such robotically inspired models before the movement can be constructed: the spatial and the temporal evolution of the movement. Thus, it has been suggested that movements are planned to follow straight lines with a velocity profile that is bell shaped. According to this suggestion, movement planning would involve the following sequence of steps, organized and executed serially: localization of a point in extrinsic space, specification of a rectilinear hand trajectory, and the computation of the joint angles (in intrinsic space) that correspond to each point in extrinsic space. As stated previously, there is not a unique set of joint angles for any given hand position, and a unique solution is obtained by invoking kinematic constraints.

The last step in these models of movement planning involves kinetics. Specifically, necessary joint torques are derived from the desired kinematics (joint angles). This step is commonly referred to as inverse dynamics (Fig. 3) because the forces are derived from motion rather than the opposite, as would be implied by cause and effect. For a biological system, there would be one last step—namely, the partitioning of the torque across the redundant actuators (the motor units), taking into account the musculoskeletal properties described in the previous section.

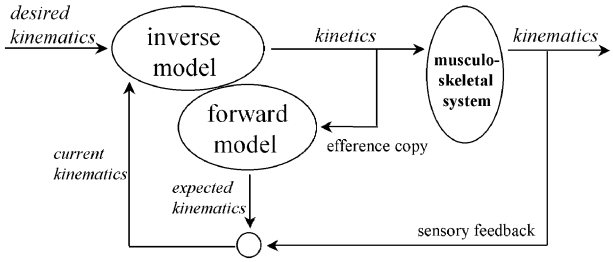

Figure 3 Hybrid model of feedforward and feedback control. The *desired kinematics* of a planned movement are transformed into motor commands (*kinetics*) through the inverse model. The motor commands are transformed by the musculoskeletal system into the actual movement *kinematics*. These are sensed by afferents to provide sensory feedback. An efference copy of the motor commands is transformed into the *expected kinematics* via a forward model. The difference between the expected kinematics and the actual kinematics (provided by sensory feedback) provides an error signal used to update the motor commands.

B. Trajectory Planning of Human Limb Motion

The robotic model has been influential in guiding experimentation and it has also received considerable support. For example, it is generally found that for arm movements from one point in space to another, the wrist follows a path that is close to straight and the wrist's speed is well approximated by a bell-shaped profile.

Furthermore, the results of psychophysical studies in humans and electrophysiological studies in nonhuman primates have been interpreted from this perspective. For example, there has been considerable work dealing with errors in pointing to targets in three-dimensional space. In these experimental paradigms, a target is presented visually or proprioceptively (by moving the arm into a given posture), and the subject is instructed to move the arm to the target in the absence of visual guidance. Both constant and variable errors in this type of task are usually very reproducible, and these errors have been interpreted as arising from errors in kinematic coordinate transformations. Specifically, it has been proposed that errors arise because of approximations in transforming target location in extrinsic, eye-centered coordinates into intrinsic, shoulder- or hand-centered coordinates.

Also, single unit recordings from parietal and frontal cortical areas have been related to kinematic parameters defined in different frames of reference. In general, cortical neurons whose activity is related to limb movement are tuned to the direction of movement (a kinematic parameter). Moreover, in some areas, direction is defined in eye-centered coordinates (i.e., a direction relative to the foveal direction of gaze). In other instances, direction appears to be specified in arm-centered coordinates (i.e., a direction relative to the orientation of the arm).

Thus, considerable evidence supports the first stage of the robotically inspired models—a transformation of a specification of target location in extrinsic space (or, more precisely, in retinotopic coordinates) into a specification of target location in joint coordinates. The question then arises: Is there also a kinematic plan of the trajectory? Evidence has been offered in support of such a supposition. Essentially, the velocity profiles of movements are highly repeatable and predictable. Specifically, if movements are relatively straight, bell-shaped (unimodal) velocity profiles are observed. If a curved trajectory is produced intentionally during drawing movements or when a curved path is necessary to avoid an obstacle, there is a precise relation between speed and the trajectory's curvature: The smaller the radius of curvature, the slower the speed. Taken at face value, these observations imply a precise plan of the moment-to-moment evolution of a movement's kinematics.

However, such a kinematic plan of movement does not require that kinematics be determined first without regard to the kinetic requirements. In fact, extensive modeling studies undertaken by Mitsuo Kawato and colleagues led to the opposite conclusion. They began with the observation that wrist trajectories for pointing movements are usually gently curved, and they were able to predict this curvature by assuming that the hand followed a path according to a "minimum torque change" criterion. Thus, kinetic constraints determined the kinematic plan of movement. Our own studies on limb posture at the end of pointing movements also support this interpretation. When subjects made arm movements from different starting locations, the arm's posture at the target depended on the starting location. This variation in the final posture could be predicted by invoking a kinetic criterion, one related to minimizing energy expenditure during the movement.

Thus, it seems clear that movement trajectory is regulated, even when it does not need to be (such as during pointing movements in the absence of obstacles). However, it is not clear that the observed regularities occur because a particular trajectory is planned explicitly, since they could also occur implicitly from regulation of the movement's kinetics.

IV. FEEDBACK REGULATION

As mentioned previously, feedback regulation of movement was a central component of the framework developed by Sherrington and followers. As is well-known, the stretch reflex involves monosynaptic excitation from primary muscle spindle afferents (as well as disynaptic inhibition arising from Golgi tendon organ afferents) onto the homonymous muscle. It has long been recognized that this arrangement provides for a regulation of muscle length through spindle feedback and for a regulation of force by means of tendon organ afferent feedback. Furthermore, since stiffness is the ratio of length to tension, the combination of length and force feedback could provide a means for stiffness regulation. Thus, as has long been recognized, this reflex potentially provides for feedback regulation of posture. In the 1950s, it was postulated that it could also provide a mechanism for a feedback control of movement. The fusimotor innervation of muscle spindles (from γ motoneurons) can change the spindles' rest length. Accordingly, it was hypothesized that the gamma innervation provided a reference length (the desired kinematics) and that spindle afferents provided an error signal proportional to a deviation from the desired kinematics.

Thus, in this classical view, the stretch reflex has the possibility of affording movement control on a muscle-by-muscle basis. Whether or not it does so effectively depends on the reflex gain. This value has been notoriously difficult to estimate because of the inherent nonlinearities in muscle mechanics. However, the best available estimates assign a relatively modest value to the reflex gain. Furthermore, there is good experimental evidence that feedback regulation is not on a muscle-by-muscle basis. As mentioned previously, the control of motion in a limb with two or more joints often involves eccentric contractions of muscles that are agonists for the movement. Similarly, when perturbations evoke rotations at more than one joint, reflex excitation of muscles that shorten consequent to the perturbation has been observed, contrary to the classical view. Spindle afferents are known to project not only to motoneurons of homonymous and synergistic muscles but also, either directly or indirectly, to motoneurons of muscles spanning distant joints. Thus, the reflex actions observed when a perturbation affects more than one joint could be purely spinal. However, there is also experimental support for "long-loop reflexes" involving supraspinal structures, including the cerebral cortex and the cerebellum.

In the classical view, feedback regulation via the stretch reflex would compensate primarily for external perturbations, but it is equally conceivable that feedback could compensate for inaccuracies in the motor

commands sent to the muscles. In fact, this supposition has experimental support. The effective moment of inertia of the arm varies with the direction of arm movement, and Claude Ghez and colleagues suggested that the initial descending motor commands do not take into account this inertial anisotropy. For movements of equal amplitude, the initial acceleration of the arm is largest for movements in directions for which the effective inertia is smallest. Nevertheless, the final amplitude of the movement is equally accurate for all directions. These investigators suggested that this was achieved by means of feedback compensation, a conclusion based on the additional observation that movement amplitude in deafferented patients varies in proportion to the variation in the initial acceleration of the arm. In other words, these patients do not exhibit any compensation for inertial anisotropies.

A final point should be made concerning feedback regulation of movements. The previous discussion considered the effects of kinesthetic feedback on the control of the evolving movement (i.e., an on-line regulation of the movement). There is also evidence that afferent inflow of information during one movement alters the execution of a subsequent movement. A simple, everyday example illustrates this point. Consider lifting a suitcase of unknown weight. If the suitcase is much heavier than it appears, the movement is likely to be hypometric, or it may even be aborted. However, the next attempt at lifting the suitcase will most likely be successful, implying that the motor commands have been modified based on previous experience. Visual feedback can also provide both on-line and trial-to-trial regulation.

V. CONTROL SIGNALS FOR MOVEMENT REGULATION

A. Feedback and Feedforward

There is consensus that neither purely feedforward, open-loop control nor purely feedback control is adequate for the regulation of movement in a biological system. Feedforward control alone cannot work because it requires that all the parameters of the system (its inertia, the starting posture, muscle mechanics, etc.) be known with a precision that appears to be beyond the realm of biological sensors. Similarly, pure feedback control is inadequate because the feedback gain is low. If the feedback gain were higher, the inherent time delays would lead to instability.

Thus, movement regulation appears to involve a hybrid of feedforward and feedback. In this conceptualization (Fig. 3), the feedforward pathway involves a model of the inverse dynamics of the limb that is a prediction of the forces that would be required to generate a desired movement. Thus, the inverse model transforms desired kinematics into motor commands (kinetics) acting on the musculoskeletal system to generate movement (kinematics). If the inverse model is accurate, the actual kinematics will match the desired kinematics. As stated previously, the inverse model will never be completely accurate, and accuracy is achieved by means of feedback.

In Fig. 3, the sensory feedback signals the actual kinematics resulting from the motor commands. These are compared to the expected kinematics, obtained using an efference copy of the motor commands. This comparison requires a transformation from the kinetic signal carried by the efference copy to kinematics. Because the transformation is in the forward, causal direction from kinetics to kinematics, it is called a forward model. The feedback regulation would then provide for a comparison of the expected motion, derived from the forward model, with the actual motion that is sensed by various afferents. This error signal could be used as an input to the inverse model to update the motor commands.

In this scheme, a mismatch between the predicted motion and the actual motion would have two effects, occurring on two different timescales. First, the motor commands would be modified, through the inverse dynamic model, to correct the ongoing motion. Second, if errors persist over many trials, the inverse dynamic and the forward dynamic models would be modified so as to bring their predictions into better accord with the actual performance.

Note that this hybrid scheme bears some resemblance to the robotically inspired scheme for movement planning outlined previously. Recall that this scheme involved kinematic stages in which ultimately the desired trajectory was specified in terms of the motion of each of the joints. A second stage converted this desired trajectory into the torques at each of the joints (and forces at each of the muscles) required to produce the requested motion. In terms of the hybrid model just described, this stage corresponds to the feedforward, inverse dynamics model part of the process. What has now been added is a feedback controller, correcting for errors inherent in the feedforward stage.

B. Anatomical Correlates and Distributed Processing

The hybrid scheme described in the previous section appears to be an attractive hypothesis, but is there any evidence that it represents the manner in which the brain regulates movements? It is a truism that the brain contains an inverse dynamic model. Consider a pointing movement to a target. Clearly, the input to this movement is information on the retina (in kinematic variables) and the output is activation of motoneuron pools generating forces (kinetics). Somewhere in between is a transformation from kinematics to kinetics.

Can one be more precise than that? Can the inverse dynamics model be localized to one particular brain structure? There is no good answer to this question, partly because there is no clear agreement concerning the parameters that are encoded by neural activity in major structures of the motor system. Consider, for example, the primary motor cortex. Almost since the time that the role of the motor cortex in generating movement was first appreciated, a debate has raged: Does motor cortex control movements or muscles? In other words, does motor cortical neuronal activity encode kinematic parameters (movements) or does it encode kinetic parameters (muscle forces)? Depending on the answer, the inverse dynamic model would be located either before or after the motor cortex, or it could in fact be within the motor cortex.

Unfortunately, there is no clear answer to this question. For limb movements in three-dimensional space, motor cortical neurons are tuned to the direction of the motion, as are neurons in parietal cortical areas and the cerebellum. At first glance, this might be taken to suppose that these structures encode kinematic parameters. However, kinetic parameters, such as torque or muscle activation patterns, also show directional tuning, and therefore this observation *per se* does not resolve the question. One way to resolve the question is to record neuronal activity for the same movement in the presence of different loads (i.e., the same kinematics but different kinetics). Such experiments have found a continuum of responses (even in one brain area): Some neurons are related only to kinematics, whereas others depend strongly on kinetic parameters as well.

An alternative approach to resolve the question takes advantage of the finding that the mechanical actions of individual muscles change in a predictable manner with changes in limb posture. For example, the directional tuning of wrist muscles for flexion/extension and abduction/adduction depends on the extent of forearm pronation/supination. When the directional tuning of motor cortical neurons in the wrist area was examined, it was found that some changed in parallel with the directional tuning of the muscles (suggesting a coding of kinetics), others changed in parallel with the changes in posture (suggesting a kinematic code), and yet others showed changes that were intermediate between these two.

Thus, it appears that the robotic models, with transformations from kinematics to kinetics and vise versa, do not show any simple isomorphisms to neural activity in different brain areas because a variety of parameters are found to be encoded in any one area. Nevertheless, it is possible that the conceptual scheme is reasonable but that the processing stages are distributed throughout and over many brain areas. However, it is equally possible that the models that have been proposed are inappropriate. Certainly, in the few instances in which behaviors are clearly understood in terms of neural processing, it has been possible to define distinct stages of transformations from sensory to motor domains and to associate neural structures with each of these stages. Some of the examples that can be cited are the processing of binaural sounds for sound localization, the jamming avoidance response in electric fish, and saccadic control of eye movements. Each of these examples involves processing in subcortical structures; processing of information in cortex may be inherently more distributed.

C. Learning and Modularity

No matter what the answer to the question posed in the preceding section turns out to be, it seems certain that the neural regulation of movement involves inverse dynamic and forward dynamic models, be they distributed or implemented in well-defined anatomical loci. Furthermore, it seems certain that these models are shaped by experience and by learning. This question has received considerable attention in recent years, and it has been shown that humans and nonhuman primates have a remarkable capacity to adapt to altered environments. For example, subjects can readily adapt to manipulations of visual input imposed by displacing prisms and they can also adapt to experimentally induced changes in kinematic or kinetic transformations. Specifically, subjects have been shown to gradually adapt when they are asked

to make directional movements against a variety of force fields.

Adaptation is usually restricted to the particular movement on which subjects were trained or to movements that are very similar. This observation has led to the conclusion that movement regulation is achieved in a modular fashion. Taken to the extreme, this viewpoint holds that there is one internal model (with inverse and forward components) for each movement. Such an arrangement would make learning feasible because only the parameters of one module would need to be modified. There are several reasons to be skeptical of this hypothesis. Although it would simplify learning, the complexities are shifted to the process of selecting the appropriate module, interactions among them, and the amount of memory required to store them all. Furthermore, there does not seem to be any compelling evidence for such an arrangement.

Nevertheless, learning does appear to be modular. For example, subjects trained to make a movement in one direction in a novel force field will adapt so that movements in that direction and in neighboring directions are correct but movements in directions far from the one in which they train will be unaffected. Similarly, the vestibuloocular reflex can be adapted in a wide variety of ways, even to generate vertical eye movements in response to head rotations in the horizontal plane. However, this adaptation is frequency specific, being greatest at the frequency at which the subject oscillated.

The apparent modularity of learning is not inconsistent with a system in which information processing is widely distributed. The apparent contradiction can be resolved by considering the tuning characteristics of individual neurons. For example, as mentioned previously, motor cortical neurons are tuned to the direction of a movement. If one supposes that adaptation is restricted to circuits only involving neurons whose best direction is similar to the direction at which subjects are being adapted, then one can readily imagine a scenario of modular adaptation.

In conclusion, although the general form of the scheme by which the nervous system regulates and controls movement is known (Fig. 3), many of the details of the implementation of this scheme are not.

Multiple Sclerosis

LORRI J. LOBECK
Medical College of Wisconsin

GLOSSARY

Lhermitte's phenomenon Tingling or electrical-type sensation experienced as a result of neck flexion, felt due to mechanosensitivity of demyelinated axons.

major histocompatibility complex An area on chromosome 6 that encodes immune response genes; possible area of genetic susceptibility in multiple sclerosis.

myelopathy Disease of the spinal cord, typically with weakness and/or sensory disturbance below the level of demyelination.

plaque Lesions of multiple sclerosis characterized pathologically by light gray to pink discoloration in white matter regions of the central nervous system.

relapse Neurologic signs or symptoms occurring in individuals with multiple sclerosis, persist for days to weeks, followed by partial or complete recovery.

Multiple sclerosis (MS) is an inflammatory, demyelinating disease of the central nervous system that results in destruction of both myelin and axons. The cause of the disease is unknown; however, it is believed to be an immune-mediated process. The disease is characterized by relapses and remissions of neurologic signs and symptoms early in the course, followed in some cases by progressive decline of neurologic function. Although most individuals are between 15 and 60 years of age at the time of diagnosis, the disease affects all age groups and causes varying levels of disability. Women are twice as likely to develop the disease as men.

I. DESCRIPTION OF MULTIPLE SCLEROSIS

An important feature of multiple sclerosis is the marked variability in neurologic symptoms and clinical course. Four different types of disease course have been described. Most patients present with relapsing–remitting disease. An individual develops neurologic symptoms and signs over hours to days and typically recovers in 6–8 weeks. This is followed by various lengths of disease-free periods. Some individuals have few relapses and no residual symptoms, whereas others have frequent relapses and accumulating disability. Approximately one-half of the patients with relapsing–remitting disease go on to develop secondary progressive disease. In this case, features of relapsing–remitting disease are followed by a gradual decline in function with or without superimposed relapses. Primary progressive disease, which affects 10–15% of individuals with MS, is characterized by a gradual decline in neurologic condition from onset, without relapses. This form of disease progression is typically seen in older individuals, more often males, as a progressive myelopathy. A fourth type, progressive–

relapsing MS, is similar to primary progressive MS but with superimposed relapses. The term benign MS is used carefully. Current estimates of disease that truly remains benign are low—5–10% of all patients.

Based on epidemiologic and genetic data, MS is believed to be caused by some environmental agent that triggers the disease in susceptible individuals. The trigger is unknown but likely infectious. Advances in biotechnology and better trial design have led to new therapies that are at least partially effective in treating the disease.

II. EPIDEMIOLOGY

There are an estimated 400,000 individuals in the United States who have MS and 1 million worldwide. The prevalence of the disease in individuals of Northern European descent is 1 in 1000, whereas in Asians the prevalance is 2 per 100,000. The highest prevalence rate is 250 cases per 100,000 individuals in the Orkney Islands, north of Scotland. Hispanic, Asian, and African Americans are less likely than Caucasians to have the disease. MS is usually sporadic, and often there is no documented family history. However, some families have shown an increased frequency of the disease and thus attention has focused on the genetic versus environmental features of the disease. The prevalence of MS varies along a north–south gradient worldwide, increasing as one moves away from the equator, even in countries with relatively homogenous racial populations. This gradient of disease prevalence suggests an environmental cause. There are exceptions to this pattern, such as Sicily and Malta, two areas in close proximity, which have a 10-fold difference in prevalence rate. Additionally, there are ethnic groups that appear resistant to the disease in high-risk areas, such as the Hutterites of western Canada and Native Americans in North America, reinforcing the genetic features of the disease. Furthermore, the north–south gradient may be explained by the migration pattern of ethnic groups, as they tended to migrate to similar climates. Studies of individuals moving from high-risk to low-risk areas after puberty show that these individuals carry the risk of the first location for developing MS, suggesting that an environmental factor may trigger the disease early in life. Clusters of cases of MS have been described, but many have not withstood further scrutiny to provide evidence that epidemics of MS occur. In summary, the data indicate that the geographical distribution of MS cannot be due to a single environmental factor, nor can genetic factors alone explain the distribution.

III. ETIOLOGY

A. Genetic

Epidemiologic studies provided early, albeit indirect, evidence of a genetic susceptibility toward developing MS. Studies of monozygotic twins illustrated a 25–30% lifetime risk of developing the disease if one sibling is effected. Dizygotic twins have a risk similar to that of their nontwin siblings (2–5%), which is higher than that for the normal population. Additional studies have shown that the risk is higher in full siblings rather than half-siblings. Siblings of individuals with MS raised in separate homes retain a higher risk of developing the disease. First-degree, adoptive, nonbiologic relatives do not have an increased risk compared to the general population; thus, genetic rather than environmental factors are more likely to explain familial clustering of disease. In the early 1970s, an association between the risk of developing MS and the major histocompatibility complex (MHC) on chromosome 6, which encodes immune response genes, was recognized. The MHC class I and class II molecules are glycoproteins located on a cell surface that present antigen to antigen-specific T cells. An individual's ability to react to an antigen is determined by the MHC region. $CD8^+$ T cells interact with MHC class I molecules on the surface of all nucleated cells in humans; those molecules are known as human leukocyte antigens (HLA)-A, -B, or -C. Class II molecules are present on only some cells, including monocytes, macrophages, endothelial cells, and microglial cells. These antigens are described as HLA-DP, -DQ, and-DR. Although there may be a weak association with HLA-A3, multiple studies have shown an increased occurrence of HLA-DR2 haplotypes associated with MS. Most individuals with MS do not have this HLA-DR haplotype; thus, it is not essential or sufficient to cause the disease. It is also possible that an unidentified gene close to the HLA gene is the susceptibility locus. Recent genetic studies indicate that multiple unlinked genes may influence the risk for developing MS. Each gene may add to the risk. Different genes may influence susceptibility in some individuals and not others. A screen of the entire genome for regions related to risk of MS with anonymous genetic markers identified a susceptibility loci in the MHC region.

One model for MS in animals is experimental allergic encephalomyelitis (EAE). In this animal model, the susceptibility to developing demyelination is based on genetic risk. Specific chromosomes and segments have been identified in the animal model that

increase the risk. The model suggests that initial events that occur in the disease may be mediated by different genetic factors than those that cause later progression of the disease.

B. Infections

The search for an infectious cause of MS has been pursued for many years. Bacteria, spirochetes, and atypical bacteria have be considered, although not confirmed. Viruses have been the focus of the search based on epidemiologic, genetic, pathologic, and serologic studies. The nonrandom North–South gradient of disease occurrence, described previously, is atypical for other autoimmune diseases and suggests the role of an environmental trigger. The low rate of concordance for monozygotic twins is evidence against MS being a purely genetic diseases. Because twins share many childhood diseases one would expect the concordance rate to be much higher if MS was a result of a nonspecific response to multiple agents. More likely, a specific, poorly transmissible agent leads to activation of the disease. Pathologic studies show that the changes seen in the central nervous system are similar in MS and viral illnesses. Both can produce inflammatory demyelinating lesions in the brain. Persistent viral infections can cause chronic demyelination.

Immunologic studies have noted the cerebrospinal fluid is similar in viral infections and MS. In viral infections, however, the oligoclonal bands can be identified as due to specific viral antigens. In MS, the oligoclonal bands are not known to react with a specific antigen. Antibodies are elevated in the cerebrospinal fluid and serum in patients with MS to such viruses as measles, Epstein–Barr virus, rubella, mumps, and herpes simplex, but this is more likely due to a nonspecific increase due to genetic or immunologic factors rather than a specific response to a virus.

There are animal models of viral demyelinating diseases, that resemble MS, including canine distemper virus, Theiler's murine encephalomyelitis, murine coronavirus, and visna. Furthermore, viruses are known to result in demyelinating diseases in humans. For example, postinfectious encephalomyelitis or acute disseminated encephalomyelitis (ADEM) have occurred following infection with measles, varicella, or Epstein–Barr virus. Persistent infections with papovavirus cause progressive multifocal leukoencephalopathy (PML) in immunocompromised individuals.

Proposals to explain how viruses may cause MS include an immune system response to a chronic or transient virus, reactivation of a persistent infection, or viral infection of immunocompetent cells including lymphocytes. "Molecular mimicry" may explain the immune system response to virus, or other infectious agents. This model suggests that a viral peptide is similar to a component of myelin. The immune system recognizes the foreign viral peptide but cross-reacts with a myelin, resulting in activation of the immune system. Further damage results with exposure of additional myelin antigens. Exposure of antigens may result in epitope shifting, in which the initial inciting antigen no longer remains the sole perpetrator in the immune process. Some viruses (e.g., Epstein–Barr virus, cytomegalovirus, and measles) are known to have peptides that are similar to antigens identified on myelin components. Furthermore, the antigen may not be a component of myelin but an enzyme or regulatory protein, which may affect the immune function in other ways (e.g., permeability of the blood–brain barrier or myelin metabolism). Superantigens, bacterial or viral envelope components that activate large populations of T cells or multiple clones of T cells, may be another mechanism by which a clone of auto reactive T cells may be activated. Others argue that a latent viral infection results in disease. Periodic relapses would be explained by reactivation of the virus. Progression may be due to failure of the host to inactivate the viruses. Several viruses are known to exist in the human central nervous system and to reactivate. For example, herpes zoster causes chicken pox in childhood and then reactives in the adult as shingles, a disease with rash in a dermatomal pattern. In other cases, a virus remains as a persistent infection. The measles virus causes subacute sclerosing panencephalitis. HIV infections result in various neurologic complications, including dementia. HTLV1 causes a progressive myelopathy. Whether the virus causes direct injury to neural tissue or causes bystander inflammation and demyelination is unknown. Finally, it is possible that viral infection of lymphocytes or other immune cells leads to changes in function of these cells and ultimately altered immunity.

Many viruses have been suggested as inciting agents for MS. Recently, there has been interest in human herpesvirus 6 (HHV-6). Most, if not all, types of herpes are latent in the nervous system. They are transported within axons and are known to cause demyelination. HHV-6 causes roseola or sixth disease in children, and

like other herpesviruses it may reactivate in the adult nervous system. The presence of this virus has been confirmed in the brains of individuals with MS and others. Determination of the role of this virus in MS requires additional testing.

IV. IMMUNOLOGY

Most authorities believe the inflammatory, demyelinating disease process is immunemediated, even though the cause remains unknown. The target of inflammation may be a component of myelin. The process most likely begins with the T cell. Antimyelin T cells are recognized in the normal adult peripheral blood, but in MS these cells migrate to the central nervous system. Humeral immune responses are also likely, based on the intrathecal presence of immunoglobulins. The antigen recognized by these antibodies has not been determined. Myelin basic protein (MBP) and proteolipid protein make up 30–50% of myelin protein. Myelin oligodendroglia protein (MOG) makes up 50% of central nervous system myelin. This protein is not present in the peripheral nervous system and may be the antigen in this exclusively central nervous system disease. MOG is located on the oligodendroglia surface of the outer lamella of the myelin sheath and is thus accessible to attack. Other possible targets include myelin-associated glycoprotein, $\alpha\beta$ crystalline, 2–3-cyclic nucleotide, 3′-phosphodiesterase, and viral antigens.

The marmoset model of relapsing experimental allergic encephalomyelitis, which is histologically similar to MS, has demonstrated that T cells recognize MBP and MOG. These T cells induce inflammation, but demyelination does not occur unless the MOG antibody is present. Although MOG may be the initial antigen and inciting factor, exposure as a result of inflammation induces new antigens and epitope shifting. The antigen for this disease is difficult to identify possibly because there are multiple antigens.

Figure 1 illustrates the proposed mechanisms for the immune-mediated injury in MS. Genetic or environmental factors (viruses, bacteria, or superantigens) cause activation of circulating T cells. Adhesion molecules on the circulating T cell surface, very late

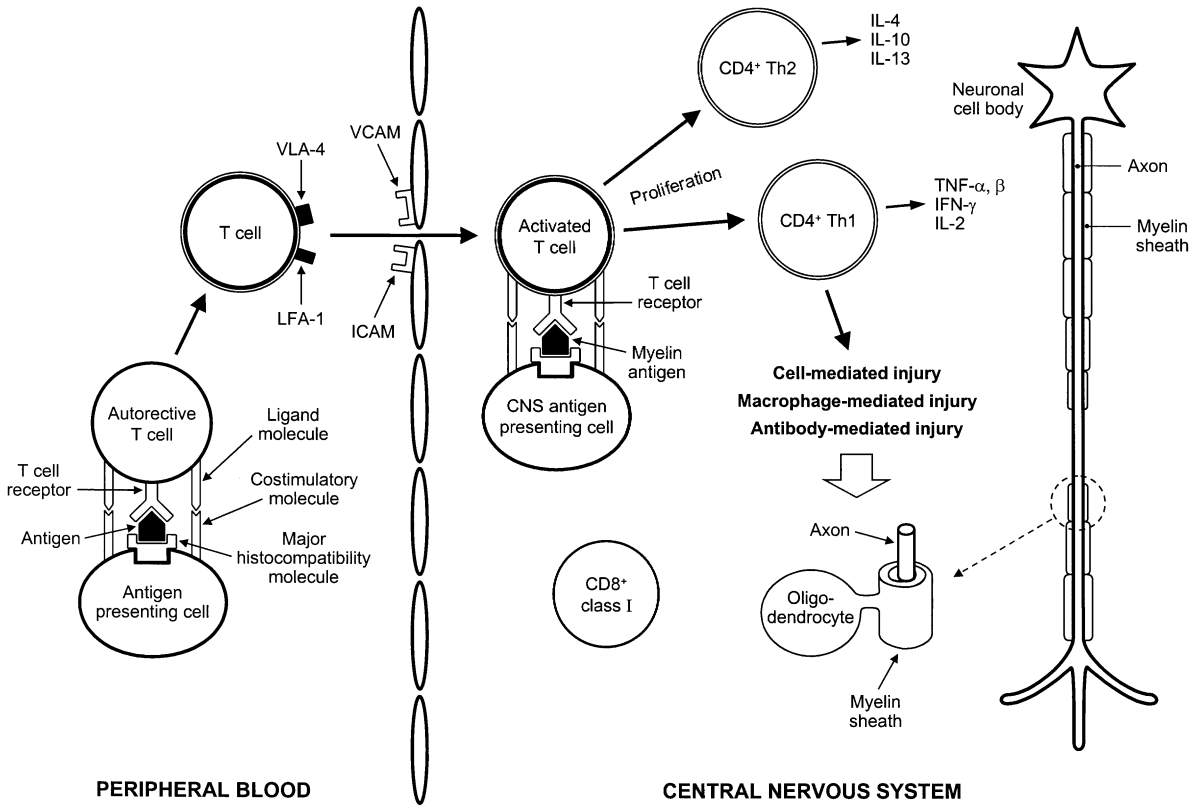

Figure 1 Proposed mechanisms for immune-mediated injury in MS.

antigen (VLA-4) and lymphocyte function associated antigen (LFA-1), bind complementary receptors on the endothelium, intracellular cell adhesion molecule-1, and vascular cell adhesion molecule-1. Once in the central nervous system, the activated T cell secretes cytokines, including tumor necrosis factor-β (TNF-β) and interferon-γ (IFN-γ), which in turn activate antigen presenting cells (APCs) including astrocytes, macrophages, and microglia. Class II MCH molecules on APCs and T cells interact in the presence of central nervous system antigen. Costimulating molecules on the APC and T lymphocytes are necessary for activation of T cells. $CD4^+$ cells differentiate into proinflammatory cells ($CD4^+$Th1) or antiinflammatory ($CD4^+$Th2) cells. Proinflammatory cells (Th1) secrete cytokines such as TNF-α or -β or IFN-γ. The result is activation of various process, that cause injury to myelin or oligodendrocytes. Antibody-mediated injury may be cell dependent or occur via complement activation. Cell-mediated injury induces damage by further release of proinflammatory cytokines. Binding between FAS–ligand and FAS or binding of $\alpha\beta$ crystallin will result in apoptosis or programmed cell death. Macrophages induce myelin injury by phagocytosis and secretion of toxic substances, such as proteases, nitric oxide, oxygen radicals, and proinflammatory cytokines. Apoptosis may occur via the FAS–ligand interaction.

In some cases, cytotoxic $CD8^+$ autoreactive T cells may be the primary cause of injury by binding class I MHC antigens on oligodendrocytes. They may also bind via FAS and induce apoptosis. In addition, these cells may release perforins, which create membrane pores and kill cells. Finally, other factors may lead to injury of the oligodendroglia, resulting in "dying back oligodendrogliopathy." The result is varying degrees of demyelination and axonal destruction.

Even as some areas are damaged, others are in various stages of repair. An antiinflammatory process activated via the CD4 Th2 cells, which secrete cytokines such as IL-4, -10, and -13, decreases inflammation and downregulates the immune response. This process occurs simultaneous to the inflammatory response.

Thinly myelinated axons in pathologic specimens indicate that remyelination occurs in patients with MS. Repair likely begins with resolution of inflammation and edema. New sodium channels may develop in a demyelinated axon to allow for propagation of active potential. It is not known if these sodium channels develop from the neuron or surrounding glial cells. Oligodendroglia progenitors capable of proliferation have been identified but the specific role of these cells is not clear. It is known that remyelination can occur if inflammation is controlled.

The final result of this inflammatory process, irreversible axonal injury, is known to occur early in the disease. These findings suggest that early intervention of the disease course, which prevents or decreases inflammation, may prevent axonal injury and allow for remyelination. Multiple potential sites for therapeutic interventions can be considered including blockage of adhesion or co stimulating molecules, cytokine therapy, or modulation of the T cells via vaccination.

V. PATHOLOGY

Pathology sections of the brain in individuals with MS reveal well-demarcated lesions or plaques that appear pink or gray. Microscopically, the lesions are characterized by inflammation, demyelination, or gliosis. Inflammatory lesions have both perivascular and leptomeningeal infiltration of lymphocytes, monocytes, and macrophages. Histopathologic studies show that macrophages and $CD4^+$ T cells are the most prominent cell types within lesions. There are fewer B cells and plasma cells. Lesions can be further characterized as active (acute), chronic active, or chronic inactive. In the acute lesion, perivascular and parenchymal infiltration with mononuclear cells, such as T cells and macrophages, exists. Cells are mostly large, round, and lipid-laden macrophages. There are variable numbers of CD4 and CD8 cells present. MHC class II positive cells are abundant. Similar findings are seen in ADEM and animal models that have T cell-mediated immune responses. In these cases, the demyelination that occurs with MS-type plaques is not present. This implies that there must be another factor present for demyelination to occur. Chronic active plaques have MHC class II cells and lipid-laden macrophages at the border of the lesion but not centrally. Chronic inactive lesions have few MHC class II-positive cells and are hypocellular. Recently evidence indicates that the pathologic process may vary between individuals. Lucchinetti and Lassmann described different types of pathological appearances based on immunohistochemical studies. The first type shows areas of demyelination with no oligodendroglia loss. There is local deposition of demyelinating antibodies and complement activation. The preserved oligodendroglia cells favor remyelination and recovery. A second type has demyelination; however, there is destruction and loss of oligodendroglia cells with the

presence of T cells and macrophages in these areas. Local precipitation of antibody and complement is not evident. A third type involves primary demyelination and a gradient loss of oligodendroglia cells toward the center of an inactive plaque. In inactive plaques there is profound oligodendroglia loss. A fourth type describes primary oligodendroglia destruction in white matter near the plaque and resultant secondary demyelination. A fifth type describes demyelination with profound loss of axons, oligodendrocytes, and astrocytes. This is not likely to be due to different stages of the disease since individuals tend to have similar patterns of pathologic changes throughout the brain. Rather, the types of injuries may be the result of different immunologic mechanisms that occur between patients and not within a patient.

The irreversible disability of MS has been attributed to axonal injury, which is evident in autopsy specimens. Charcot recognized degeneration of axons in MS as early as 1877. Recently, axonal transection has been demonstrated even in the early stages of the disease. These findings suggest that accumulating axonal injury from early on may result in progressive disability. Attempts to prevent axonal damage may prevent long-term disability.

VI. NEUROPHYSIOLOGY

Myelin acts as an electrical insulator in the brain and spinal cord. This lipid sheath is produced by oligodendrocytes in the brain and spinal cord. One oligodendrocyte insulates 1–100 axons. The myelin, produced in layers or lamellae, is interrupted by nodes of Ranvier. At the node of Ranvier there is a high density of sodium channels, which are responsible for sodium ion shifts for depolarization. These areas allow for production and propagation of action potentials. Conduction is a saltatory (not a continuous) process. The internodal areas (areas between the nodes of Ranvier under the myelin sheath) have a low proportion of sodium channels and a high proportion of potassium channels, especially in the perinodal region. These potassium channels oppose depolarization. Depolarization produces an electrical charge, which is conducted through the myelinated segment to the next node for depolarization. Myelin increases the speed of conduction and efficiency. With demyelination, slowing of action potentials and conduction block occur. Conduction block prevents propagation of any axon action potential. Sodium channels develop along the demyelinated internodal area as a way to allow for propagation of an action potential, although this is slower. This reorganization of the demyelinated axon results in a higher than normal density of sodium in demyelinated regions. Other factors may interfere with conduction, such as circulating immune factors or edema. In addition to reorganization of sodium channels, resolution of edema or clearance of these factors may restore conduction. Synaptic changes and conduction through normal unmyelinated axons may also restore function.

It is known that small changes in temperature and electrolytes can produce conduction block in demyelinated axons. Patients' symptoms may recur when they have an elevated body temperature as a result of illness or increased environmental temperature. Uthoff's phenomenon is one of the best known of these phenomena. With elevation of body temperature, such as during exercise, individuals develop decreased visual acuity in an eye previously affected by optic neuritis. Symptoms resolve when body temperature returns to normal. Trains of impulses can also block propagation of action potentials by prolongation of the refractory period—the time during which a neuron cannot depolarize. Clinically, this occurs as patients complain of fatigability of muscle strength with repetitive use of any extremity, such as occurs during walking. It is possible that modification of the sodium and potassium channels in demyelinated neurons may result in improvement in clinical symptoms.4-Aminopyridine, a potassium channel blocker, is a drug that improves symptoms for patients with MS, especially those who are heat sensitive. Currently, it is not a Federal Drug Administration (FDA)-approved drug, but further research into modification of sodium and potassium channels may lead to therapies, that provide improved conduction in demyelinated axons.

Paroxysmal symptoms of MS are a unique feature of the disease that have their basis in the physiology of demyelinated axons. These symptoms include episodes of recurrent hemibody sensory symptoms, paroxysmal dysarthria, and paroxysmal pain such as trigeminal neuralgia. These phenomena may be a result of ephaptic transmission, which occurs when adjacent demyelinated axons communicate in a lateral fashion and result in recurrent abnormal stimuli. Lhermitte's phenomena is a transient electric shock-like sensation in the spine and/or extremities believed to be due to increased mechanosensitivity of demyelinated axons in the spinal cord and it results when neck flexion causes mechanical changes in the spinal cord.

VII. CLINICAL FEATURES

The clinical features of MS are based on the location of lesions rather than the severity of these lesions. Lesions must occur in eloquent areas to produce symptoms. Many lesions occur in areas that are not clinically recognized as symptomatic, including periventricular white matter lesions identified near the lateral ventricles. A relapse of MS is defined as an exacerbation or clinical worsening of neurologic signs and symptoms that persists for weeks to months. This is followed by a period of remission. Symptoms must be present for at least 24 hr to be considered a relapse, but generally they are present longer. Most common are sensory symptoms. They are often the earliest symptoms and occasional are peculiar in distribution. In addition, sensory symptoms may not have objective findings; thus, they are ascribed to other causes such as stress. Patients often complain of "numbness," but they are often experiencing positive sensory phenomena such as tingling or dysesthesias. The ability to detect vibration in the extremities is often decreased and identified by neurologic examinations early in the disease. Often, the sensory symptoms of MS are due to lesions of the posterior columns rather than the spinothalamic tracts; however, decreased pinprick and temperature sensation can occur. Lhermitte's phenomenon is a sensory symptom in which patients experience sudden, brief electrical sensations along the spine or in the extremities. Less commonly, a radicular pattern of pain may occur and is likely due to demyelination of the sensory root entry zone. Lancinating neuralgias or dysesthesias are not uncommon. A "useless hand" develops when there is sensory disruption in the sensory spinal tracts that affects vibration, two-point discrimination, and proprioception. Often, this occurs as a result of a high cervical spinal cord lesion of the posterior columns or in the medial lemniscus system of the brain stem. Although strength is preserved, the hand is difficult to manipulate for tasks because of the sensory disruption. This may occur in other spinal disorders, but when it occurs in young individuals it is most likely due to MS.

Disorders of the visual system are common at the onset of MS. Optic neuritis results in acute or subacute monocular loss of vision. Patients complain of blurred vision or dimming of vision, often associated with photophobia and pain that increases with eye movement. Examination often discloses decreased visual acuity and central scotoma of visual loss. The optic nerve head may appear swollen, with hemorrhages or exudate (papillitis), or may be normal appearing (retrobulbar neuritis) by funduscopic examination. Color vision is often affected and can easily be tested by asking a patient view a red object with each eye separately and compare the difference of appearance. An afferent pupillary defect, elicited by shining a bright light on each pupil, may demonstrate delay of pupillary response or dilatation when the light is brought to the affected eye. Often, visual acuity returns to normal within several weeks. Later, optic atrophy may be detected as a pale optic nerve head evident by funduscopic examination. Other types of visual field defects have been described, including bilateral homonymous hemianopia and quadrantanopias, indicative of lesions more posterior in the visual system. Although optic neuritis is commonly associated with MS, other conditions including systemic lupus erythematosus or sarcoidosis must be considered.

Extraocular movement disorders are also relatively common. Examination will often show horizontal nystagmus, which is asymptomatic. Rotary, upbeating and downbeating nystagmus has also been described. A bilateral internuclear ophthalmoplegia (INO) is a result of a lesion in the brain stem in the medial longitudinal fasciculus. Patients develop failure of the ipsilateral eye to adduct, whereas the contralateral eye develops abducting nystagmus. Patients may be asymptomatic with central gaze, but with horizontal gaze they develop diplopia or oscillopsia, a sense of movement of images. The INO may be bilateral or unilateral. Incomplete INO is frequent, detected only by slowed adduction or mild abducting nystagmus. A skew deviation occurs when one eye is slightly elevated compared to the other. Sixth nerve palsies resulting in horizontal diplopia occur, although third and fourth cranial neuropathies are rare.

Vertigo may occur with demyelinating lesions in the brain stem. It is often difficult to determine if vertigo is due to a peripheral or central disorder. Other features of brain stem injury may be helpful in defining the cause of vertigo but are not necessary to conclude that vertigo is a result of MS. Although infrequent, hearing loss is known to occur. Dysfunction of the facial nerve develops from a lesion of the seventh nerve in the brain stem or with a subcortical lesion, causing a central or upper motor neuron type of weakness confined to the lower aspect of the face. Myokymia, which is an involuntary wave-like fasciculating movement in the face, also results from demyelination.

Speech abnormalities include scanning dysarthria, in which each word or syllable is given equal emphasis. Other types of dysarthria, including pseudobulbar or nasal speech, are less common. Symptoms due to

cortical dysfunctions, such as aphasias or agnosias, are not typical of MS. Seizures are rare and tend to occur later in the disease. Cerebellar findings are not common early in the disease, but with progression ataxia, dysmetria, intention tremor, and dysdiadochokinesias may all occur.

Cognitive dysfunction is estimated to occur in: 15–50% of all patients with evidence of neuropsychological dysfunction. This aspect of the disease can be very mild to extremely severe with profound dementia. The most common features of cognitive dysfunction include difficulties with recent memory, sustained attention, verbal fluency, conceptual reasoning, and visual–spatial perception as determined by neuropsychological testing. These difficulties are not easily defined by simple procedures in the clinic, such as the Mini-Mental status examination. The severity of physical disease does not correlate well with cognitive dysfunction. Cognitive difficulties are significantly disabling and secondary to fatigue, which is the most likely cause of patients discontinuing to work. Depression is very common and may interfere with cognitive function. Euphoria, when present, is associated with significant cognitive difficulties or subcortical forebrain lesions.

Bladder dysfunction, although unusual at onset, is common with progressive disease. Symptoms include frequency, urgency, and incontinence. These symptoms are a result of a failure to store or a failure to empty the bladder. With failure to store, the bladder wall is sensitive and expels small amounts of urine unexpectedly due to bladder wall contractions. With failure to store, the detrusor muscle is weak and urine difficult to expel. Incontinence occurs with overflow of a full bladder. Often, patients have a combination of these problems, referred to as detrusor dyssynergia. Bladder wall contraction occurs simultaneously to closure of the external urethral sphincter and prevents emptying of the bladder. With long-term retention, vesicular ureteral reflux may occur along with hydronephrosis and renal failure. Bowel dysfunction includes constipation, bowel urgency, or incontinence. In an attempt to control bladder symptoms, many patients decrease fluid intake, which worsens constipation. Sexual dysfunction is common and is likely a result of both physiologic and psychosocial factors. Male sexual dysfunction, which has been studied more extensively, includes erectile dysfunction, decreased sensation, and decreased libido resulting in an inability to have erections or ejaculate. Female patients experience decreased sensation, decreased or absent orgasm, decreased arousal, and vaginal dryness.

One of the early manifestations of MS may be transverse myelitis. Patients develop acute or subacute motor and sensory symptoms in the lower extremities extending into the thorax with a definable sensory level. Transverse myelitis may represent the first episode of MS or remain as a monosymptomatic illness, similar to optic neuritis. Para-, hemi-, or quadriplegia may develop during exacerbations. With progressive disease, patients develop a myelopathy with progressive weakness in lower extremities, later involving upper extremities. Associated with the weakness is an increase in muscle stretch reflexes and spasticity. Patients experience stiffness or cramping and intermittent spasms. Discomfort or pain may result.

Finally, paroxysmal symptoms—the stereotypical, repetitive symptoms and signs that occur in clusters, are a unique feature of MS. Patients may develop "tonic seizures" in which dystonic posturing of the hand or arm lasts from seconds to minutes. The individual is unable to control the involuntary flexion or stiffness. Other paroxysmal symptoms include transient dysarthria and sensory phenomena. One of the most common paroxysmal symptoms is trigeminal neuralgia, in which patients experience severe lancinating pain in the face on a repetitive basis. Trigeminal neuralgia may occur in individuals without MS, but it tends to occur at a younger age and is more frequently bilateral in individuals with MS.

VIII. DIAGNOSIS

The diagnosis of MS is based on the clinical features of the illness. There is no one definitive test for MS. Signs and symptoms define lesions that develop over time (at least 1 month apart) and space (different areas of the central nervous system). Most symptoms tend to develop over several days and then persist for several weeks to months, with improvement and in many cases return to normal. The neurologic examination generally provides objective evidence of the patient's symptoms, however, sensory symptoms may be entirely subjective. Paraclinical data, which include magnetic resonance imaging (MRI), cerebrospinal fluid (CSF), and evoked potentials (EPs), are used to confirm or dispute the clinical diagnosis. The most recent criteria were developed by an International panel of experts in the field MS (Table I), These criteria incorporate MRI as a tool of assessing subclinical disease activity and providing for a diagnosis before a second clinical event. The criteria includes visual

Table I
MS Diagnostic Criteria[a]

Clinical attacks	Objective lesions	Additional requirements to make diagnosis
2 or more	2 or more	None
2 or more	1	Dissemination in space by MRI or positive CSF and 2 or more MRI lesions consistent with MS or further clinical attack involving different site
1	2 or more	Dissemination in time by MRI or second clinical attack
1	1	Dissemination in space by MRI or positive CSF and 2 or more MRI lesions consistent with MS
(clinically isolated syndrome)		AND
		Dissemination in time by MRI or second clinical attack
		Positive CSF
		AND
0	1	Dissemination in space by MRI evidence of 9 or more T2 brain lesions
(progression from onset)		or 2 or more cord lesions or 4–8 brain and 1 cord lesion
		or abnormal VEP with 4–8 MRI lesions
		or abnormal VEP with less than 4 brain lesions plus 1 cord lesion
		AND
		Dissemination in time by MRI or combined progression for 1 year

[a]Modified from McDonald, *et al.* (2001). Recommended Diagnosic Criteria for MS. *Ann. Neurol.* **50,** 121–127.

evoked potentials as the only form of evoked potentials to support the diagnosis of MS. Although unusual, the paraclinical data can be normal in some patients with the clinical diagnosis of MS.

IX. CEREBROSPINAL AND BODY FLUIDS

CSF has been evaluated from diagnostic and research standpoints. Typical CSF findings in patients with MS include less than 20 white blood cells per cubic milliliter. These cells are mostly lymphocytes and occasionally macrophages. Total protein and glucose levels are usually normal; however, protein levels may be slightly elevated but rarely above 100 mg/dl. The abnormalities in CSF are primarily those of immunoglobulin production. Oligoclonal bands (O bands) represent multiple monoclonal globulins that are mostly of the immunoglobulin-G (IgG) type. O bands are determined by agarose electrophoresis or isoelectric focusing and indicate two or more IgG bands in the gamma region. Agarose electrophoresis is less sensitive but currently more commonly performed. Once O bands are present, they persist indefinitely. There is a low false-positive rate of approximately 4 or 5%. The presence of O bands may be a predictor of the chances of developing clinically definite MS in those individuals with monosymptomatic disease. Patients with O bands in the CSF are more likely to have a confirmed diagnosis of clinically definite MS. Other measures of CSF IgG production include the IgG synthesis rate and the IgG index, which are based on comparison of albumin and immunoglobulin production in the CSF to serum. These measures are considered less specific and sensitive than oligoclonal bands, but they are useful in indicating immune abnormalities and confirming the clinical diagnosis.

Because CSF is more difficult to obtain, other markers for disease activity have been pursued. Urine is an easily accessible fluid, although volume, collection timing, and infections may influence results. Myelin basic protein-like (MBP-L) is smaller than MBP found in the CSF. It has a cryptic epitope that is not exposed in central nervous system myelin—possibly a small peptide. MBP-L fluctuates independent of acute relapses; however, a sustained increase is present in patients with secondary progressive MS. Levels were also elevated in those individuals with relapsing–remitting MS who went on to develop secondary progressive MS. There are currently no markers in the blood that are used for diagnosis of MS. Markers that have been considered include circulating adhesion molecules, antibodies, cell subpopulation, cytokines, and cytokine receptors.

X. EVOKED POTENTIALS

Evoked potentials were more frequently used in the diagnosis of MS prior to the advent of MRI. The data are generated by presenting repeated stimuli and recording a wave form or EP from scalp surface electrodes. An alternating checkerboard pattern is used as a visual stimuli for visual EP, repeated auditory clicks are used for brain stem auditory EP, and repeated electrical sensory stimulation is used for tibial and somatosensory EP. As a result of repeated stimulation, the EP has a defined latency and amplitude. Based on standards established in each laboratory, a prolongation of the latency of these responses suggests that demyelination has occurred. A loss of amplitude of those responses is abnormal but not necessarily due to demyelination. These studies are nonspecific and are most helpful in confirming a suspicious clinical finding. For example, a distant history of unusual symptoms suggestive of optic neuritis may be confirmed by a prolonged visual evoked response recorded from stimulation of one eye. Confirmed clinical findings do not need to be further assessed with EPs since additional information is not gathered. Currently, EPs are not used to define prognosis or as surrogate markers of disease activity in clinical trials.

XI. MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging was first used in 1981 to study patients with MS. The technique was rapidly accepted in the clinical realm. Images are generated as a result of energy release from protons (positively charged hydrogen nuclei) that have been aligned in the axis of a strong magnet. Water, lipids, and other molecules contain hydrogen atoms, which spin and precess around the main axis. This axis is referred to a magnetization vector. Radio frequency pulses cause the protons to rotate and spin away from the main axis. Once the radio frequency pulse is removed, a signal is induced as the protons return to their original rotation. The signal decays over time and is referred to a longitudinal decay (T1) and transverse relaxation (T2) time. T1 and T2 times are the result of the environment in which these proteins exist (e.g., CSF protons require a longer time to return to equilibrium). The radio frequency pulses can be given at different times and for different lengths of time to generate different types of images that are "weighted" toward T1 or T2. This weighting is based on repetition time (TR) or time between pulses and echo time (TE), the time to generate the echo. T1 images have both short TE and TR, whereas T2 images have both long TE and TR. CSF is white in T2-weighted images, as are demyelinating lesions of MS (Fig. 2). On T1-weighted images some chronic lesions appear as dark areas or "black holes," which indicate tissue destruction and probable axonal loss. Newer techniques, such as fluid-attenuated inversion recovery imaging, cancel the signal from CSF, and as a result demyelinating periventricular lesions are more easily detected (Fig. 3). Gadolinium, a rare element with paramagnetic substance, is given intravenously to provide contrast enhancement of areas of breakdown of the blood–brain barrier. Because gadolinium shortens the T1 and T2 relaxation time, images appear bright where the blood–brain barrier is disrupted. This enhancement, which is the earliest standard MRI evidence of a newly developing MS lesion, indicates acute inflammation and often persists 2–6 weeks in areas of demyelination.

In general, the lesions of MS are ovoid or round and located adjacent to the body or temporal horn of the ventricles, in the corpus callosum or infratentorial or cortical–subcortical areas. Size ranges from a few millimeters to larger confluent areas. Lesions change in size over time and may disappear, however, often an abnormality will persist on T2-weighted images. The white matter may appear diffusely abnormal (i.e., "dirty white matter"). Cortical lesions are present pathologically but more difficult to detect with MRI. New lesions or enlargement of old lesions occur while other lesions are shrinking. Spinal cord lesions are detected most often in the cervical region. The spinal cord may appear swollen during the acute phase and may be enhanced with use of gadolinium. Optic nerve abnormalities are visualized with special techniques to suppress signal from orbital fat.

Because of the frequency of nonspecific white matter changes in MRI, various criteria have been suggested to define when brain MRI abnormalities are consistent with the clinical diagnosis of MS. One frequently used set of criteria defines significant findings as three or more lesions, that are equal to or greater than 3 mm, with at least one located in periventricular or infratentorial areas. At least 90% of patients with clinically definite MS have MRI abnormalities. Other explanations for white matter abnormalities exist and include patchy white matter abnormalities related to hypertension or diabetes mellitus. Lacunar lesions due to strokes appear isointense to CSF because of complete tissue destruction, which is not typical of MS lesions. Other individuals with risk for cerebrovascular disease

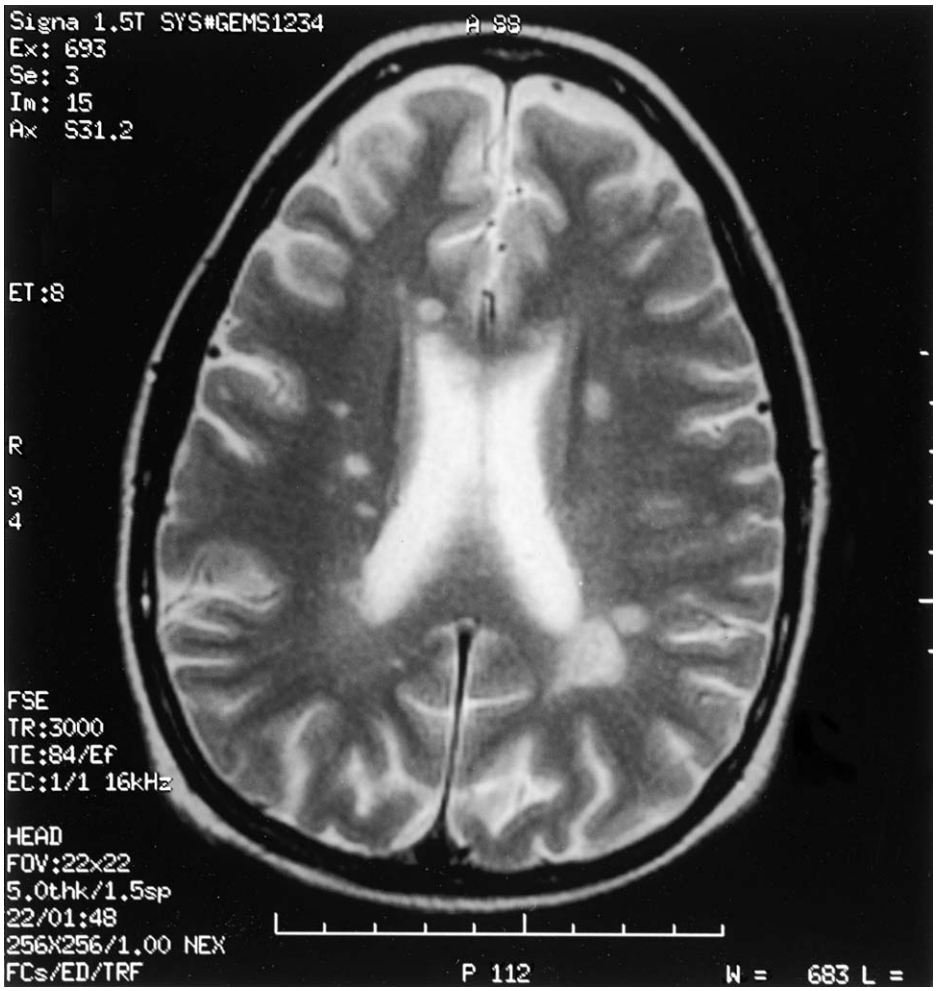

Figure 2 T2 weighted MRI demonstrating white matter lesions consistent with a diagnosis of MS.

may have incidental lesions scattered in the deep white matter. Lesions seen with systemic lupus erythematosus are also located in the deep white matter but are not typically periventricular. Neurosarcoidosis may cause white matter abnormalities but frequently has associated meningeal enhancement due to leptomeningitis. ADEM may appear identical to MS. Lesions tend to resolve and do not recur. Gliomas may appear as solitary lesions, as may ''pseudotumor'' lesions of MS. Follow-up MRI may be definitive, although biopsy may be necessary to distinguish the two. Finally, inherited disorders of myelin, the leukodystrophies, demonstrate symmetric confluent rather than patchy, discrete lesions. A clinical history and examination are most helpful in providing alternate explanations for these abnormalities.

MRI has provided much information about the underlying pathophysiology of MS. Serial imaging has demonstrated that white matter lesions are present even when individuals are not clinically aware of disease activity. This is not a consistent process and varies from month to month, however, the frequency of subclinical lesions may be 5–10 times greater than clinical disease. Clinically evident lesions tend to be present in the brain stem and spinal cord. Subclinical lesions in the cerebrum tend to increase with clinical events. The extent of lesions present on T2 scan does not correlate well with the clinical examination, other than a possible correlation with cognitive dysfunction. However, an increase in the extent of lesions over time correlates with increasing physical disability. The number and area of contrast-enhancing lesions does not correlate with disability. In primary progressive MS, there are often very few lesions present on T2-weighted images, compared to relapsing–remitting or secondary progressive MS in which multiple new and

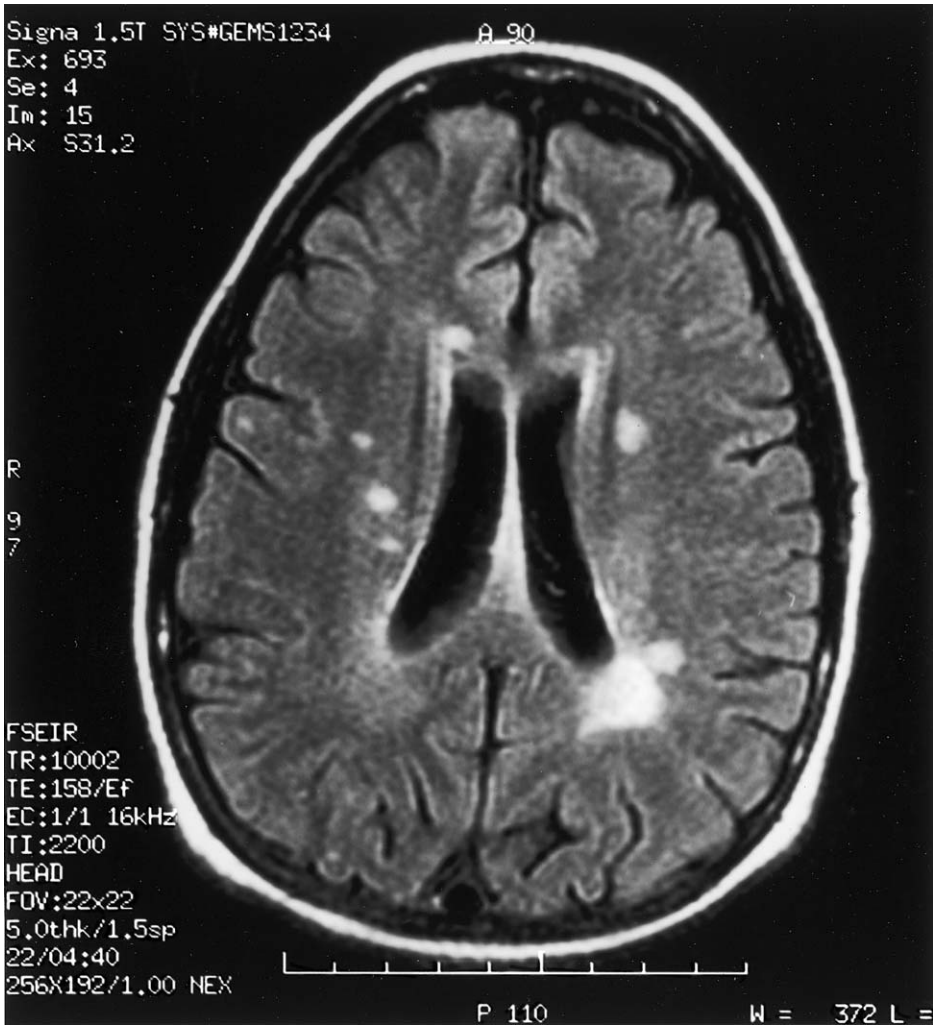

Figure 3 Fluid attenuated inversion recovery sequence demonstrating white matter lesions as seen in MS.

enhancing lesions tend to develop over time. This may indicate a pathophysiologic difference in disease type. MRI also has a predictive value for the diagnosis of MS in individuals who have had monosymptomatic disease, such as transverse myelitis or optic neuritis. The risk for an eventual diagnosis of clinically definite MS is higher in those individuals with abnormal brain MRI. MRI has been used as a tool in the clinical trial realm, allowing for a shorter clinical trial because it is a surrogate marker for disease activity. This becomes increasingly important as the partially effective therapies available will need to be incorporated into clinical trials of new agents, thus requiring more patients in order to prove efficacy. Problematic in the use of MRI has been clinical trials showing an effect on the clinical or MRI aspect but not vice versa. This apparent mismatch of data will need to be clarified.

Newer techniques add to our understanding of why T2-weighted images may not correlate well with clinical disability. Magnetization transfer imaging (MTI) relies on a different relaxation time of protons bound to macromolecules versus that of those protons that are freely moving in water. The normal appearing white matter of T2 weighted scans is abnormal when assessed with MTI, implying a more diffuse process than demonstrated by conventional T2 images. Magnetic resonance spectroscopy (MRS) uses MRI to generate a spectra of hydrogen or high energy phosphorus-containing metabolites. The spectra is used to define pathology of lesions, including tumors and demyelination. The spectra reveal major resonances from choline, creatine and phosphocreatine, and *N*-acetylaspartate (NAA). Choline is present in membranes and also present with increased myelin

breakdown products. Creatine and phosphocreatine tend to be stable in MS other than acute lesion. NAA is present only in neurons and neuronal processes and can be used as a specific axonal marker in white matter. Decreased NAA is indicative of axonal pathology. MRS has shown a decreased NAA concentration throughout the brain of individuals with MS, implying diffuse injury beyond the site of lesions detected by routine imaging techniques.

Brain atrophy documented by MRI shows volume loss around the third and lateral ventricles and decreased corpus callosum area and brain width. Atrophy has been documented early in the course of the disease, before significant clinical disability, and is likely another indicator of underlying axonal damage.

Thus, standard and newer MRI techniques have shown that MS can be a subclinical process resulting in increasing MRI burden of disease. Findings also support the hypothesis that axonal injury occurs early in the course of the disease and may be more diffuse than previously thought.

XII. DIFFERENTIAL DIAGNOSIS/DISEASE VARIANTS

Prototypic MS is one of a spectrum of inflammatory demyelinating diseases. This includes acute MS (Marburg variant), Balo's concentric sclerosis, neuromyelitis optica (Devic's disease), and ADEM. Acute MS presents as a fulminant disease that causes severe disability shortly after onset and often death within 1 year. Lesions are more destructive than those of typical MS with axonal destruction and neurosis. Age of lesions is mixed, suggesting that disease is present prior to the clinical diagnosis. Balo's concentric sclerosis is another acute illness that has bands of demyelination alternating with preserved myelin areas. The cerebellum, brain stem, optic chiasm, and spinal cord are often spared. Devic's disease or neuromyelitis optica is defined by optic neuritis and myelopathy occurring together or within a short period of time. Pathologically, necrosis has been evident in both optic nerves and spinal cord, probably as a result of ischemia from swollen tissues.

ADEM is a polysymptomatic disease that occurs after upper respiratory infection or other viral infection or following immunization. The disease occurs more commonly in children than in adults and includes demyelination in multiple areas, including brain stem, spinal cord, optic nerves, cerebrum, and cerebellum. Patients may have associated febrile illness and can become comatose in rare cases. The percentage of patients that ultimately have a diagnosis of MS is low (i.e., 5%), but initial presentations, especially if not fulminant, can be confused with the first event of MS. Pathologically, there is infiltration of mononuclear cells with limited periventricular demyelination.

Other illnesses that present as a relapsing–remitting type of illness include Behcet's disease, characterized by oral or genital ulcerations, iridocyclitis, meningoencephalitis, and thrombophlebitis. Lyme disease typically has radicular or peripheral nerve involvement but can be mistaken for MS because of its relapsing–remitting course and occasionally by its appearance on MRI. Sjogren's syndrome, in which individuals have vasculitis of the skin and peripheral nervous system associated with dry eyes and dry mouth, has also been confused with MS, in part because of MRI abnormalities that may mimic MS. Neurosarcoidosis may be a relapsing–remitting type of illness, but it generally has multiple cranial mononeuropathies. MRI shows leptomeningeal enhancement associated with intracranial disease. Cerebrovascular disease may be confused with MS, especially when interpreting MRI scans. Primary central nervous system vasculitis or systemic lupus erythematosus (SLE) may mimic the disease because of relapsing–remitting-type illnesses and white matter lesions present on MRI. The lesions seen with SLE tend to be subcortical and not periventricular. Vitamin B_{12} deficiency remains in the differential of MS; however, it tends to be a progressive-type disease with symmetric findings consistent with myelopathy and peripheral neuropathy. Myasthenia gravis may fluctuate in severity and could be confused with MS, especially when presenting with diplopia. Other bulbar features are uncommon in early MS, and lack of upper motor neuron findings can be helpful in distinguishing this illness. The hereditary dysmyelinating disorders are usually not confused with MS, although with adult onset of progressive myelopathy one must consider illnesses such as adrenolmyeloneuropathy.

XIII. PROGNOSTIC FEATURES

Much has been written about the natural history of MS. Because effective therapies will alter the natural history of the disease, this information is invaluable. Many patients expect to have a progressive disease when they are told a diagnosis of MS. In reality, 50% of patients will be walking without assistance 15 years after the diagnosis. As mentioned previously, the majority of patients present with relapsing–remitting disease. Approximately one-half of relapsing–remitting

patients experience progression. Many features have been assessed as prognostic markers for future outcome, including the extent of disability at 5 years, age, sex, the extent of initial symptoms, complete or partial remission, type of symptoms at onset (e.g., optic neuritis, sensory symptoms, and cerebellar findings), and attack frequency in the first 2 and 5 years. Favorable prognostic factors are outlined in Table II. Because of the unpredictable nature of the disease, no firm predictions for an individual's course can be determined early in the disease. Of all predictors, the extent of disability at 5 years is most reliable, but patients who have a very mild early course may later develop significant disability. Death as a result of a relapse is extremely rare, although it may occur as a complication of the disease, such as pneumonia or suicide.

XIV. TREATMENT

Advances in biotechnology have had a significant impact on the treatment of MS. For many years, treatment relied on the use of broad-spectrum immunosuppressive agents that had numerous toxicities. Early trials reported success with agents that did not withstand larger or more detailed investigations. Historically, the disease has been difficult to study because of the wide variability in presentation and clinical course. Large numbers of patients are necessary to show a consistent reproducible response from a drug. The gold standard for measuring disease activity has been the Kurtzke Expanded Disability Scale (EDSS). This 10- point scale, with half-step gradients, measures physical disability. Unfortunately, it is not a linear scale and is heavily weighted toward gait, especially in the middle range of the scale. Newer measures of disability include the Functional Composite, which evaluates gait (25-ft timed walk), upper extremity function (9-hole peg test), and cognitive function (Paced Auditory Serial Addition Test). MRI is used as a surrogate marker for disease activity.

Table II
Prognostic Features of Multiple Sclerosis

Favorable	Less favorable
Onset of disease before age 40	Onset after age 40
Monosymptomatic onset	Polysymptomatic onset
Complete recovery of symptoms	Lack of recovery from the first attack
Female sex	Male sex
Optic neuritis or sensory symptoms at onset	Early cerebellar or motor symptoms
Little disability at 5 years	

Genetic engineering has led to the manufacture of compounds such as interferon-β (IFN-β), which is where produced by *Escherichia coli* or mammalian ovarian cells after gene insertion. Copaxone (glatiramer acetate) is a synthetic compound made of four amino acids. These agents allow for selective immunomodulation and thus lower toxicity. There is conclusive evidence from large-scale trials that these agents are partially effective in the treatment of MS. IFN-β-1b (Betaseron) was the first of these agents to be assessed. The drug was shown to effectively decrease the risk of exacerbation of MS and had the effect of slowing accumulation of new lesions on MRI. Although the drug did not show an effect on slowing progression of disease, as measured by the EDSS, the effect on MRI led many to believe that the long-term outcome of a patient treated with this will be better than the expected natural history. IFN-β-1a (Avonex) was the second agent to be approved by the FDA. This drug has a similar effect on decreasing the rate of relapse. The primary end point of the clinical trial was efficacy in slowing disability as measured by the EDSS, and this drug has the unique feature of FDA approval for that indication. Copaxone was initially investigated as a potential agent to induce EAE. Conversely to what was expected in the animal model, there appeared to be a protective effect, which led to additional clinical trials. Copaxone decreases the risk of a relapse and has favorable effects on MRI. Currently, it is difficult to argue that one of these agents is superior to the others for treatment of relapsing–remitting MS. Fortunately, it allows for patients to have an option. Worldwide use and access are limited by the high cost ($12,000 per year) and administration (intramuscular or subcutaneous injections). The National Multiple Sclerosis Society has issued a recommendation advocating the use of these drugs early in the course of the disease based on increasing evidence that early treatment is likely beneficial in decreasing the inflammatory phase of the disease and preventing axonal injury. Recently, trials of secondary progressive MS have found mixed results with use of beta-interferons. Mitoxantrone (Novantrone) has received FDA approval in the United States for treatment of secondary progressive MS. This immunosuppressive agent was shown to be effective in European studies in slowing progression of

individuals with secondary progressive disease or relapsing–remitting disease unresponsive to other therapies.

Future clinical trials will likely lack a placebo group because it is unethical to leave a patient untreated when partially effective therapies are available. As a result, larger and lengthier clinical trials will be necessary to show an effect of newer agents. Surrogate markers for disease activity, including MRI, will be used to assess the utility of drugs prior to large phase 3 trials needed to show clinical efficacy. As our understanding of the pathological processes of the disease increases, it is possible that different therapies will be indicated for different types of MS. For example, in individuals with a notable inflammatory component as determined by MRI or an other tool, use of immunomodulator therapies that have a specific effect on inflammatory aspect of the disease may be most beneficial. In other cases in which little inflammatory disease appears evident, growth factors or other means to stimulate regenesis of cell life may be more appropriate. In cases in which drugs are not shown to be efficacious for MS, the understanding of the pathophysiology of MS increases and thus the trials cannot be considered failures. Finally, until the cause of the disease is found, a cure is not likely. Fortunately, advances in understanding the disease process have been exponential in recent years, allowing hope for control, if not cure, for this disease in the near future.

Multisensory Integration

BARRY E. STEIN, PAUL J. LAURIENTI, MARK T. WALLACE, and TERRENCE R. STANFORD
Wake Forest University School of Medicine

GLOSSARY

cross-modal From two or more different sensory modalities. Used here to refer to (i) combinations of stimuli from different sensory modalities (e.g., a combination of light and sound) that normally evoke different subjective experiences, (ii) the spatial register among the different receptive fields of a multisensory neuron, and (iii) the spatial register among different sensory maps.

modality specific From a single sensory modality (i.e., unimodal). Used here in two forms: (i) to categorize a neuron based on the stimuli to which it can respond (e.g., a neuron responsive only to light would be a modality-specific neuron) and (ii) to categorize a particular neuronal response regardless of the type of neuron from which it is evoked (e.g., a response to light, even in a multisensory neuron, is a modality-specific response).

multisensory Refers to neurons that are capable of responding to stimuli from more than a single sensory modality and to the neural processes associated with these responses (e.g., multisensory integration).

multisensory integration A statistically significant difference between the number of impulses evoked from a neuron by a combination of cross-modal stimuli compared to the responses to the most effective of these stimuli individually.

qualia (singular quale) Bits of experience; used here to refer to the particular subjective impressions that are associated with a given sensory modality (e.g., hue, pitch, tickle, and itch).

receptive field The area in space (or on the body) in which a stimulus can evoke a response from a particular neuron.

topographic Used here to define a systematic arrangement of the components of a sensory or motor representation in the brain (e.g., the arrangement of the visual receptive fields into a map of visual space).

Multisensory integration refers to the brain's ability to synthesize the information that it derives from two or more senses. There are a number of other terms in use, such as cross-modal integration and intersensory integration, but all refer to the same phenomenon. The longstanding interest in the underlying neural mechanisms by which multisensory integration is accomplished is due, in large part, to its remarkably robust perceptual and behavioral products, products which cannot be understood by dealing with the senses as independent of one another. The present discussion will use the individual multisensory neuron in the midbrain as a model, and will focus on how its responses are altered in predictable ways by converging inputs from the visual, auditory and somatosensory modalities.

I. CROSS-MODAL PERCEPTION

One of the driving forces in evolution has been the creation of multiple means by which animals can sample their environments. This has involved the development of numerous sensory systems that are responsive to very different forms of physical energy, because a primary imperative of survival is knowledge

of environmental circumstances, information that is as important for the location and capture of prey as it is for the avoidance of danger. Extant animals maintain a rich variety of such systems, thereby increasing the probability of their survival and the circumstances in which they can flourish. Being able to detect many of the same events with different sensors allows some to substitute for others when the circumstances require it. For example, touch and hearing can substitute for vision in the darkness. The combination of inputs from sensors that can function simultaneously also provides an animal with multiple "views" of a single event. As a result, the inherent ambiguities that may be present when evaluating an event along one sensory dimension (e.g., how it looks) can be obviated by the additional information provided along another sensory dimension (e.g., how it sounds).

Our sensory systems function so well in these regards that we have come to have great faith in the accuracy with which they reflect the properties of the physical world. Consequently, we are sometimes amused and sometimes distressed to learn that our sensory judgments are not absolute and can vary considerably in different situations. However, it appears that our reactions to this knowledge differ in different contexts, and for most people it is far less surprising when errors are made in estimating the intensity of a sound because of the presence of background noise than when a sound is mislocated because of the confounding influence of a visual stimulus. Perhaps this is because we are more familiar with the relativity of perceptual judgments within a given sensory modality than across different sensory modalities. We readily accept the fact that visual judgments are influenced by context in the visual arts—painting, photography, and film—and we are not at all disturbed by the use of perspective and shading to alter our judgments of dimensionality, relative distance, or even the stature of a vertically challenged actor. However, finding that a sensory judgment can be substantially altered by seemingly irrelevant cues from another sensory modality is somehow more surprising and less intuitive. Nevertheless, cross-modal influences on perception are both common and potent. The presence of a neutral auditory cue can make a dim light appear substantially brighter, the vibration of the muscles on one side of the neck can make a stationary light in a darkened room appear to be displaced or even appear to be moving toward the contralateral side, rotation of the body can make a horizontal line appear oblique, and changing gravitational forces can seriously disrupt our localization of visual cues.

Of course, cross-modal influences are not restricted to altering visual judgments; judgments in all sensory modalities are subject to such influences. A common example of the sensitivity of the vestibular system to the effect of visual cues is evident in modern wide-screen cinematography, in which films are made from the perspective of a pilot flying much too low and much too fast over steep mountain peaks and into deep canyons or from the front seat of a roller coaster. Inevitably, the viewer experiences the same vestibular and gastrointestinal sensations that make clear air turbulence and high seas so amusing.

The general impression that different senses function in entirely separate realms and are thus unlikely to interact with each other may also be partly a consequence of the unique subjective impressions associated with each of them. These impressions, called "qualia," are modality specific. For example, the perception of hue or color is specific to the visual system. Although we may speak of the smell or taste of green, this is really a consequence of associations that are developed through experience because there is simply no nonvisual equivalent to the experience of "green." This becomes quite obvious when trying to describe color to a congenitally blind person. The same sort of problem would be encountered in trying to describe music to someone who is congenitally deaf because pitch is unique to the auditory system. Similarly, the sensations of tickle and itch are peculiar to somatosensation, and there is no nontaste equivalent to "salty," nor a nonolfactory equivalent to "burnt almond." The unique nature of these qualia has been the subject of discussion for much of the history of neuroscience and led Johannes Muller to propose a theory of "specific nerve energies" in 1826. According to Muller, each subjective impression is attributable to the activation of modality-specific nerve fibers and their target neurons in the brain, a concept that has been supported by studies in which electrical stimulation of modality-specific cortical regions in patients (which is helpful in avoiding sensory areas during brain surgery) produced the appropriate modality-specific sensations.

These observations might lead one to expect that the brain must avoid cross talk between the modalities in order to maintain their unique qualia. However, this is not the case. Not only do the senses regularly affect each other, as indicated by the cross-modal influences on perception noted previously, but when cross-modal

stimuli are slightly discordant, this cross talk can often result in any of a host of unexpected and intriguing illusions. One of the best known of these is the ventriloquism effect, and few people have not delighted in the illusion that a wooden doll is actually speaking. The name of the effect is derived from the world of entertainment, but the phenomenon properly refers to a broad class of events in which a visual cue produces the apparent translocation of an auditory cue. Although this illusion need not involve speech, the impact of television and movies has rendered speech translocation its most common form. Each voice in a movie or television program seems to come from the appropriate character regardless of his/her location on the screen. However, in reality all sounds are derived from the same location: speakers at the sides of the television cabinet or the movie screen. This underscores the fact that despite the apparent skills of some entertainers, the ventriloquist's trick is less a reflection of his ability to ''throw his voice'' than the susceptibility of the brain to use the visual system to localize external events. Thus, the lip movements and gestures associated with speech produce the compelling illusion that the corresponding sound must be coming from the source of those movements, even if it is a dummy.

Among speech professionals, the so-called McGurk effect reigns supreme. In this illusion, the meaning rather than the location of the auditory signal is altered by lip movements. Its popularity is due to its ability to dramatically demonstrate how important the integration of visual and auditory cues is to speech perception and the significance of this cross-modal integration when, for example, trying to understand a spoken message in a noisy room. The integration of visual and auditory signals has also recently been shown to play a significant role in nonhuman primate communication. Originally, the McGurk effect was shown by having the lips of the demonstrator form a syllable, for example, ''ga,'' but the sound associated with the lip movements (prerecorded and played through a speaker in synchrony with them) was ''ba.'' The listener perceived ''da,'' a percept that represents neither of the original cues but rather the product of their synthesis. The McGurk effect has also been shown to be readily induced by using strings of spoken or visible (lip movements) sounds, each of which has no meaning by itself but when combined they result in an intelligible sentence (Fig. 1). It has even been shown to work with words that already have meaning, but their combination results in the perception of an entirely different word (e.g., hearing ''bows'' and seeing ''goes'' results in the percept ''doze'').

There are many cross-modal illusions, some of which seem like curiosities and others that must be fully appreciated because they can confound judgments in life-threatening circumstances. A recently described auditory–tactile illusion that is particularly compelling, but that is unlikely to produce significant problems in daily life, is the so-called ''parchment-skin'' illusion. In this case, a subject is fitted with

Figure 1 An example of the McGurk effect. Here, the pairing of a nonsense phrase delivered from the speaker (''my bab pop me poo brive'') combined with the visual cues of a person whose lips are forming a different nonsense phrase (''my gag kok me koo grive'') results in the meaningful percept: ''My dad taught me to drive'' (adapted and reprinted with permission from Stork and Massaro, *American Scientist* **86,** 236–244, copyright 1998).

headphones and a microphone, which is routed through the headset, is placed near one of his hands. Then, the subject rubs his fingers together and the sound of the rubbing is amplified and played through the headphones. The result is that the subject perceives his skin to feel rough and dry, and the degree of roughness perception changes with variations of the composition of the sound frequency. On the other hand, visual–vestibular illusions are of particular importance to aircraft pilots, who must correctly judge the speed with which the nose of the aircraft is rising despite the potent, and often confusing, influences of vestibular cues produced by the strong gravitational forces of the high-speed takeoff. Errors in judgment in this circumstance can have severe consequences for both pilot and plane.

The few cross-modal illusions described here should be sufficient to emphasize the point that changing the normal relationships among cross-modal stimuli can have substantial disruptive effects on perception. Sensory systems have evolved to function in concert, and the neural integration of their inputs, as well as the perceptual products that result from this integration, reflect the normal mode of brain function. Some of the direct behavioral consequences of the integration of cross-modal signals involve both an increase in the probability of detecting an external event and a substantially more rapid response to it. Often, these changes in detection and reaction speed exceed statistical models based on reactions to each of the individual modality-specific stimuli alone.

One of the key features that can be used to predict whether cross-modal stimuli will produce enhanced neural, perceptual, and/or behavioral responses is whether or not these stimuli are derived from the same event because such cues are generally coincident in both space and time. The relative timing of the different stimuli is critical because if cross-modal stimuli are sufficiently disparate in time, the brain does not integrate them, but treats them as separate events. However, from the perspective of neural function, the temporal window during which this information can be integrated is very long, lasting hundreds of milliseconds. This makes it possible for the nervous system to integrate, for example, visual, auditory, and somatosensory cues that are derived from the same event despite the fact that these inputs arrive at a multisensory neuron at very different times. The difference in arrival time is due to the nature of the stimuli and the nature of the nervous system. Somatosensory cues do not travel in space; they are delivered to the skin of the observer and have a reasonably short conduction time to the brain. Sound is also rapidly transmitted from the ear to the brain, but it travels very slowly in space and takes an appreciable time to reach the ear. Although for all practical biological purposes light transmission is instantaneous, it requires a good deal of processing time in the retina before it can be sent to the brain.

The spatial relationships among cross-modal stimuli are also critical, not only for determining whether a multisensory interaction will take place in the brain but also for determining the kind of interaction that will occur. Spatially coincident stimuli generally result in enhanced brain signals and enhanced perception and behavior; spatially disparate stimuli either produce no interaction and are treated as separate events or they inhibit one another and degrade brain signals as well as their perceptual and behavioral products. It is when these spatial and temporal relationships are neither so close that they produce "normal" products nor so discrepant that they are treated as separate events that aberrant neural, perceptual, and behavioral consequences result. The illusions discussed previously are good examples of some of these "anomalous" products.

The integration of cross-modal inputs (multisensory integration) is also responsible for providing unity to our perceptions. This observation was obvious to Aristotle and was discussed in *De Anima*. Aristotle was one of the first to grapple with the concept of multisensory integration by noting that although each of our five senses provides us with different information, the resultant perception is of a single world. He concluded that there must be a mechanism by which the disparate information that is obtained from different sense organs is brought together into a unified whole, a view that anticipated modern discussions of what has become known as the "binding" problem. If we state this problem from a modern neurological perspective, it might be posed as follows: How can we perceive objects as unitary entities when their individual features are processed separately in different populations of neurons in different regions of the nervous system? This issue is as germane to within-modal issues as to cross-modal issues, because individual components of a modality-specific stimulus (e.g., its motion, direction of movement, and color) are dealt with by different populations of neurons in different regions of the brain, just as different modalities engage different populations of neurons in different regions of the brain (e.g., their different modality-specific pathways). Although there is no widely accepted theory explaining how the brain solves this "problem," there

are a number of reasonable possibilities that are currently being considered.

II. MULTISENSORY INTEGRATION: EVOLUTIONARY CONSIDERATIONS

We are far from ignorant about some of the neural mechanisms that underlie the integration of information from different sensory modalities. The study of single neurons that receive inputs from more than a single sensory modality has produced a growing body of information about the sites in the nervous system in which cross-modal convergence takes place as well as some of the mechanisms by which information from different sensory modalities is brought together and integrated. The manner in which these multisensory neurons deal with their converging inputs and the consequences of their action are among the subjects of this article. However, before dealing with this issue, it is important to note that although we often tend to frame questions about the phenomenon of multisensory integration in terms of human experience (especially when considering its perceptual consequences), its appearance did not await the evolution of *Homo sapiens*. Rather, it is an ancient scheme of information processing that is likely to have been present in the presumptive primordial unicellular organism. The caveat "presumptive" is used here because no one can say with certainty what that unicellular organism was like. Nevertheless, it is reasonable to suppose that it, like its modern counterparts, had different sensory receptors tuned to the transduction of chemical, mechanical, and/or photic energy, and that each of these sensory transducers used the same signaling mechanism (an electrical current produced by the movement of ions across the cell's membrane). Consequently, the primordial unicellular organism, like its extant cousins, was a multisensory organism. Because the various currents produced by activating its different sensory receptors can readily affect one another, unicellular organisms are obligatory multisensory integrators. Simple multicellular organisms are also unable to sequester specific sensory signals because of the nature of their intercellular connections, and the segregation of at least some modality-specific information probably did not occur until the appearance of advanced invertebrates. Thus, multisensory integration, rather than sensory segregation, is likely to have been the initial form of sensory information processing.

The capacity for multisensory integration was retained in some form throughout the evolution of multicellular organisms, and there is no known beast, vertebrate or invertebrate, in which there exists a complete segregation of sensory signals on a sense-by-sense basis. Presumably, the ability to derive information from the combined action of different senses that would be unavailable from their individual action had considerable survival value and thereby engendered the maintenance and elaboration of systems capable of multisensory synthesis. However, during the evolution of complex species, an interesting duality was formed;

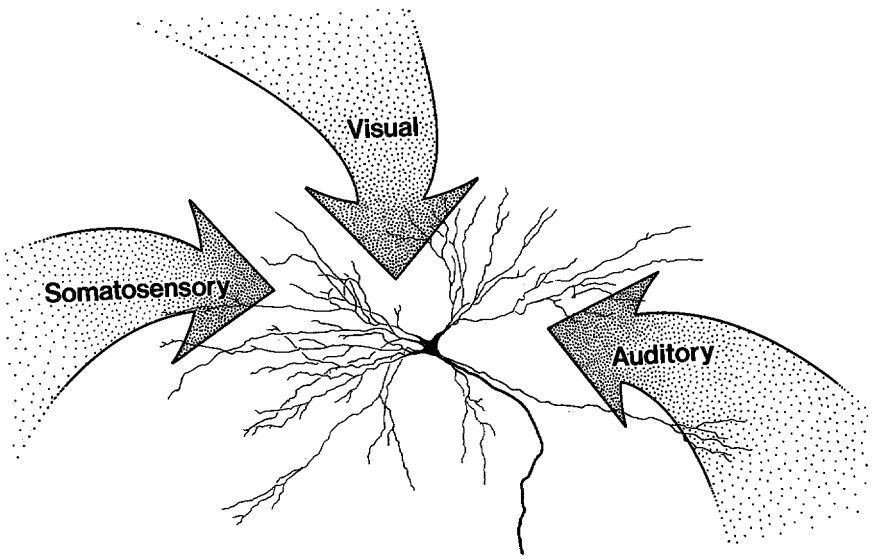

Figure 2 Inputs from multiple sensory modalities converge on an individual neuron in the superior colliculus (reprinted from Stein and Meredith, "The merging of the senses," 1993, with permission from The MIT Press).

some regions of the nervous system became specialized for processing information based on its modality and others for processing information regardless of the modality from which it was obtained. Presumably, it is the action of the former systems that accounts for the sensory qualia referred to previously. The preeminent example of such a system is the primary projection pathway (but see Section VII for evidence that cross-modal influences are evident even in the primary projection systems). In the vertebrate visual system, for example, this involves the projections from the retina to the primary thalamic relay station (the lateral geniculate nucleus) and from there to primary visual cortex. Multisensory areas exist outside the primary projection pathways and have been found at every level of the neuraxis.

In light of the importance of multisensory information processing for normal perception and behavior, it is surprising to note that we are only beginning to understand the neural bases by which the brain accomplishes this feat. When compared to our understanding of how modality-specific sensory cues are processed, our knowledge of multisensory integration seems rudimentary. However, we do know that whenever different modality-specific inputs converge at the level of the single neuron (Fig. 2) there is the opportunity to synthesize them.

III. THE SUPERIOR COLLICULUS: A MODEL FOR UNDERSTANDING THE NEURAL BASES OF MULTISENSORY INTEGRATION

Perhaps the brain's best studied multisensory neurons are those in the superior colliculus (SC). This structure, which is located on the surface of the midbrain (Fig. 3) plays its primary role in attentive and orientation behaviors. It uses visual, auditory, and somatosensory information individually or in concert to direct the peripheral sensory organs toward an object or event of interest. Its best known role is in the initiation and control of eye and head movements (collectively referred to as gaze) in order to fixate a target; however, in species with highly mobile ears, it has also been shown to be involved in generating coordinated and directed ear movements. Recent evidence has also implicated the SC in the control of some limb movements. The importance of the SC in the current context is that it has been used as a general model for understanding the neural principles of multisensory integration and relating them to overt behavior.

The SC receives its inputs from many sources, both sensory and motor. Most of the sensory structures that project to the SC contain neurons responsive only to a single sensory modality—visual, auditory, or somatosensory. Thus, rather than reflecting multisensory information that is preprocessed elsewhere, the SC is a primary site of cross-modal convergence. This is underscored by the finding that although association cortex, one of the major sources of input to the SC, contains both modality-specific and multisensory neurons, only its modality-specific neurons project to the SC. Despite the counterintuitive nature of this finding (it would seem fitting to have multisensory neurons communicate directly with other multisensory neurons), the independence of this cortical circuit has been an experimental asset. It has allowed investigators to test whether the principles of multisensory integration found in the SC also apply to this independent multisensory circuit and, by extension, to other multisensory regions of the brain.

A. Single-Neuron Studies

1. Topographic Register of Sensory and Motor Representations

Regardless of their origin, the visual, auditory, and somatosensory inputs that reach the SC are arranged systematically to form topographic, or map-like, representations. These sensory maps, like those found in other areas of the brain, are based on the organization of receptive fields (Fig. 3). A neuron's receptive field defines that region of space from which it can be activated by a sensory stimulus, and the arrangement of neurons in the SC is such that adjacent neurons have their receptive fields in adjacent regions of space. When one speaks of a topographic or map-like representation, a frame of reference is always implied, if not stated explicitly. For example, in primary visual structures, the position of a neuron's receptive field is indexed relative to the fovea, which defines the center point of the axes of "visual space." Similarly, the receptive field of a neuron in a primary auditory structure would be referred to the center of the head, and in the case of a somatosensory neuron the referent would be the body surface (e.g., face, hand, and leg). One could write volumes about how a topographic representation is an efficient way to encode information about the nature of objects as defined by the spatial relationships of their components (e.g., size, shape,

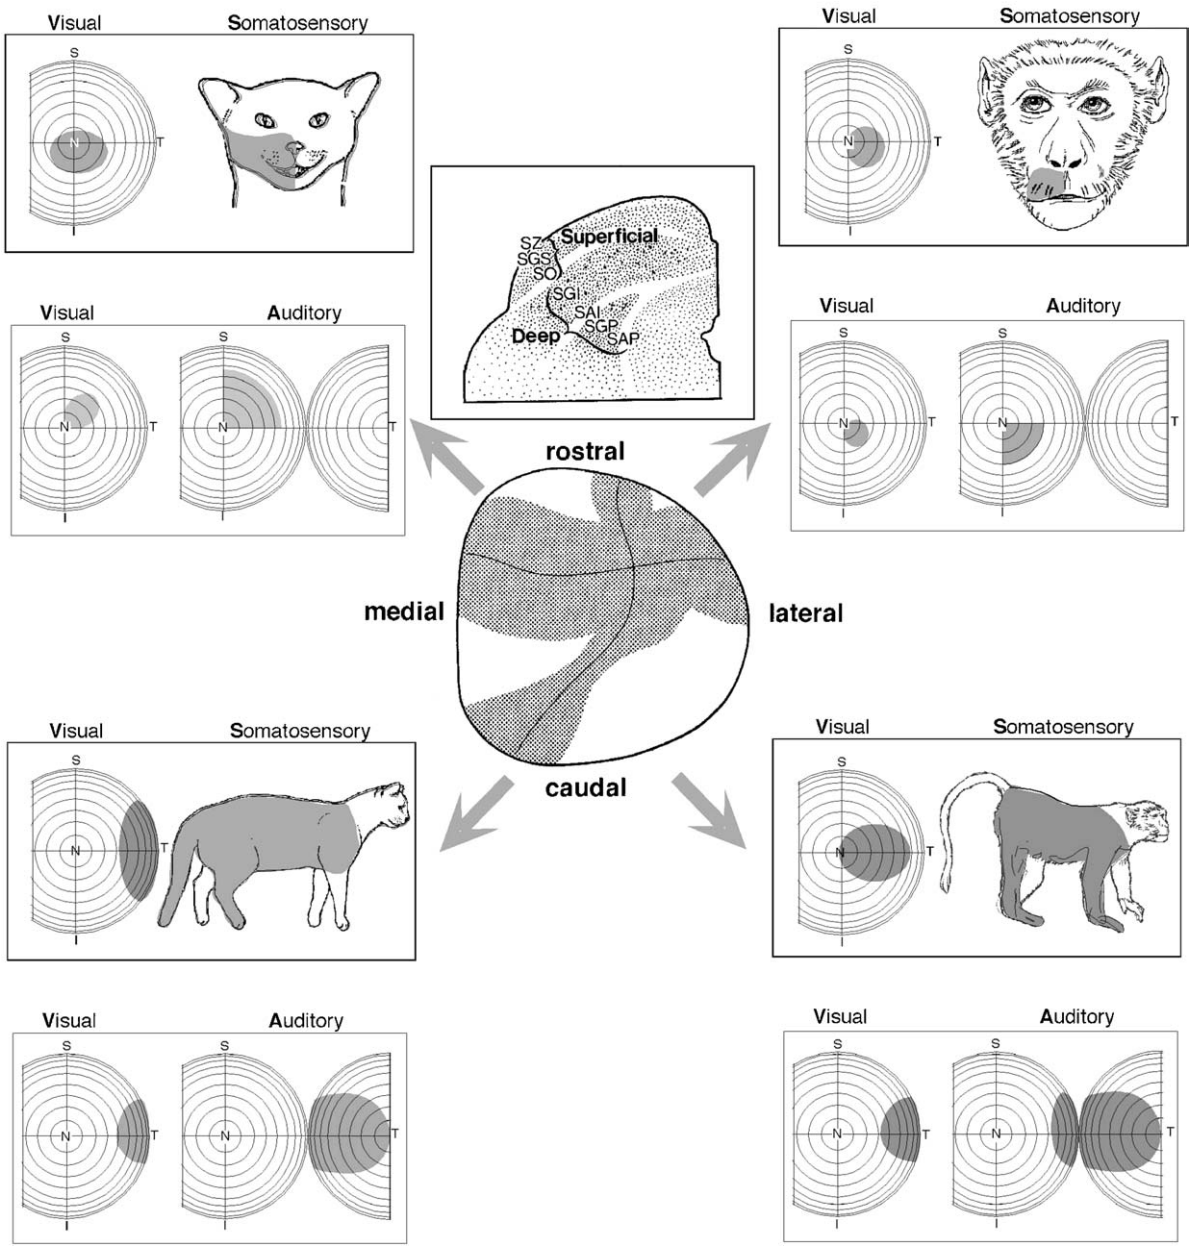

Figure 3 Visual, auditory, and somatosensory receptive fields are organized in map-like fashion in the superior colliculus (SC) and all share the same axes. The overlapping nature of these representations is particularly evident in individual multisensory neurons. Shown here at the center is a schematic of the left SC as viewed from the top of the brain. Rostral aspects of the SC contain receptive fields that are found in frontal space, caudal locations contain receptive fields in temporal or caudal space, etc. (see text for further detail). The curved line running from the rostral to the caudal SC is the horizontal meridian, which divides the representation of superior from the representation of inferior sensory space. Similarly, the curved line running from medial to lateral represents the vertical meridian, which divides ipsilateral and contralateral sensory space. Representative receptive fields (shading) for multisensory neurons from cat (left) and monkey (right) SC are drawn from rostral (top) and caudal (bottom) sites in the SC. Each concentric circle in the schematics of visual and auditory space represents 10°. In the representation of auditory space, the caudal half of contralateral space is shown by the split hemisphere that has been folded forward. Note the register among the receptive fields for visual–somatosensory and visual–auditory neurons. Visual receptive fields in nasal (frontal) space on the right are linked to somatosensory and auditory receptive fields in frontal space on the right. Similarly, temporal (or caudal) receptive fields in one modality are linked to similar locations in other modalities. Multisensory neurons are found in the deep layers of the SC. These layers are illustrated on a schematic of a coronal (vertical) section through the structure. S, superior; I, inferior; T, temporal; N, nasal; SZ, stratum zonale; SGS, stratum griseum superficiale; SO, stratum opticum; SGI, stratum griseum intermediale; SAI, stratum album intermediale; SGP, stratum griseum profundum; SAP, stratum album profundum.

and texture). However, the ''sensory'' topographies found in the SC do not serve this purpose and are thus quite distinct from those found in primary sensory structures. The principal function of the SC is to generate motor commands for the purpose of orienting to a sensory stimulus. Thus, whether one is dealing with a visual, auditory, or somatosensory stimulus, the problem is the same: to determine where the stimulus is with respect to the part of the body that must be oriented to it. For example, knowing where a visual stimulus is with respect to the fovea is not sufficient for programming a movement to reach out and grasp the object; for this, one needs to know where the stimulus is with respect to the hand. Similarly, knowing the location of an auditory stimulus with respect to the head is not sufficient to program an eye movement (i.e., gaze shift) to look at the stimulus; one needs to know where the stimulus is with respect to the current position of gaze. In other words, the topographic referent must be based on the structure or body part that is to be oriented toward the stimulus.

The SC is known to be involved in the generation of many types of orienting movements. The best established of these motor representations is the one that controls gaze. Therefore, the following description of the motor topography is based on what is known about gaze control, although in theory similar schemes could be constructed with ear or limb movement maps. Within the SC there is a gaze topography so that the site of activity codes for the distance and direction of a gaze shift. The components of this ''motor'' map are neurons that each have a ''movement field,'' the motor analog of a sensory receptive field. Neurons with movement fields discharge in association with gaze shifts within a particular range of amplitude and direction and are arranged systematically according to this movement range; neurons that represent small contralateral movements are located in rostral SC; neurons representing progressively larger contralateral movements are located in progressively more caudal aspects of the structure. From medial to lateral in the SC the gradient is from neurons representing movements with upward directions to those representing movements with downward directions. The relationship between the SC sensory and motor representations is summarized as follows: The locus of sensory-evoked activity represents the location of a sensory stimulus with respect to the current gaze position; the location of motor-related activity represents the amplitude and direction of the movement required to shift gaze from the current position toward the location of the stimulus.

Tying the sensory topographies to the position of gaze ensures that the activity evoked by a sensory stimulus activates a region of the SC in which motor-related activity would be appropriate for shifting gaze to the stimulus. It also means that visual, auditory, and somatosensory stimuli share the same reference frame and will activate the same region of the SC if they originate from the same location in space. As such, the maps of visual, auditory, and somatosensory modalities will always be in register, regardless of the relative position of the eyes, head, and body to each other. The general alignment of these representations has been demonstrated in studies carried out in anesthetized animals with eyes, ears, head, and body facing forward so that the axes of visual, auditory, and tactile space are in approximate alignment with the direction of gaze. For each sensory modality, receptive fields shift systematically across space as one samples neurons in any given direction across the SC. For example, visual or auditory neurons in the rostral aspect of the SC have their receptive fields in central contralateral space (consistent with sites in the motor map that produce small contralateral gaze shifts), whereas those located progressively further rearward (caudal) in the structure have their receptive fields shifted progressively more eccentric into the peripheral aspects of contralateral space (in register with sites that produce larger contralateral gaze shifts). In short, when the animal is facing forward, neurons in the front of the structure represent the space in front of the animal and those in the rear of the structure represent space in the periphery. The somatosensory representation corresponds to this organization in that neurons with receptive fields on the face are located rostral in the SC and those with receptive fields progressively further back on the body (toward the rump) are located progressively more caudal. Neurons found medial in the structure have receptive fields in upper space (or on the upper body) and laterally located neurons have receptive fields progressively lower in space (or lower on the body).

Because many SC neurons are responsive to stimuli from more than one sensory modality, they contribute to the formation of multiple sensory representations in the SC. There are several varieties of SC multisensory neurons, and the order of incidence of bimodal neurons is as follows: visual–auditory, visual–somatosensory, and auditory–somatosensory. Although trimodal (visual–auditory–somatosensory) neurons are sometimes encountered, their incidence is

comparatively low. However, regardless of its specific modality convergence pattern, each multisensory neuron has multiple receptive fields (Fig. 3), one for each of the sensory modalities to which it responds. As would be expected based on the topographic register described previously, the different receptive fields of each multisensory neuron correspond with each other (Fig. 3). One of the consequences of this receptive field correspondence is that any of the different sensory cues that are derived from the same event can activate the same neurons and thereby access the same circuitry to evoke a given orientation response. As discussed later, this cross-modal register of receptive fields is crucial for proper integration of the information derived from different sensory modalities.

2. Response Enhancement and Response Depression in Multisensory Neurons

Multisensory neurons do more than simply respond to a variety of different sensory stimuli: They transform the signals arriving from multiple sensory channels into an integrated multisensory product. In operational terms, multisensory integration is defined as a statistically significant difference between the number of impulses evoked by a cross-modal combination of stimuli (e.g., a visual and an auditory stimulus) and that evoked by the most effective of these stimuli alone. The integration results in either a response enhancement that can exceed the arithmetic sum of the individual modality-specific responses (Fig. 4), or a response depression that can eliminate responses altogether. The specific multisensory response that is achieved depends on the spatial relationships among the cross-modal stimuli. When two cross-modal stimuli are derived from the same event, they originate from the same location in space. Because the different receptive fields of the same multisensory neuron overlap one another in space, such an event can stimulate both excitatory receptive fields. These two inputs interact synergistically, and the degree to which the response is enhanced (above that evoked by the best modality-specific stimulus) depends on the relative effectiveness of these stimuli; combinations of weakly effective modality-specific stimuli usually result in the largest multisensory enhancements. Thus, multisensory enhancements are particularly beneficial when modality-specific stimuli are weak. If, on the other hand, the same cross-modal stimuli are spatially disparate, as would happen if they were derived from separate events, and one of them falls outside its receptive field, either no interaction results (the extrareceptive field stimulus produces no input to the neuron) or response depression is produced. The latter effect is generated when the extrareceptive field stimulus falls into an inhibitory region that borders the excitatory receptive field of some SC neurons, thereby generating an inhibitory input powerful enough to degrade or suppress the excitation produced by a stimulus within its receptive field.

B. Behavioral Studies

Behavioral experiments have been conducted to determine whether the cross-modal stimulus configurations that enhance multisensory responses at the single-neuron level also enhance multisensory responses at the behavioral level and whether the cross-modal stimulus configurations that reduce multisensory responses at the single-neuron level also degrade multisensory responses at the behavioral level. In these experiments groups of cats were trained in a simple perimetry device (Fig. 4), conceptually similar to the device used by ophthalmologists to map a patient's visual field. Each animal learned to fixate on a point directly ahead. If a light came on anywhere in that perimetry, the animal's task was to break fixation, look at the light, and immediately approach it. The reward for correct behavior was a food treat. Some of these animals were taught to respond in the same way to a brief sound (group 1). Others were trained to ignore the sound (group 2) by never being rewarded for responding to it, and still others had no auditory training (group 3). To examine the possibility that response enhancement would be induced with spatially coincident cross-modal stimulus pairs, it was necessary to keep performance to the individual stimuli below 100%. Thus, when testing, the intensities of the stimuli were lowered so that they were very difficult to detect, and correct performance for either one alone was 50% or less. When the light and the sound were presented simultaneously and in spatial register, correct responding was enhanced dramatically, far more than predicted based on performance in response to either cue individually. On the other hand, even when the intensity of the visual stimulus was increased so that it could be detected on every trial, when the auditory cue was spatially disparate to the visual cue there was a dramatic drop in performance. This was true not only for animals that learned to ignore the sound during training but also for animals that were never exposed to it during training (only groups 2 and 3 were tested for response depression). These results indicate that

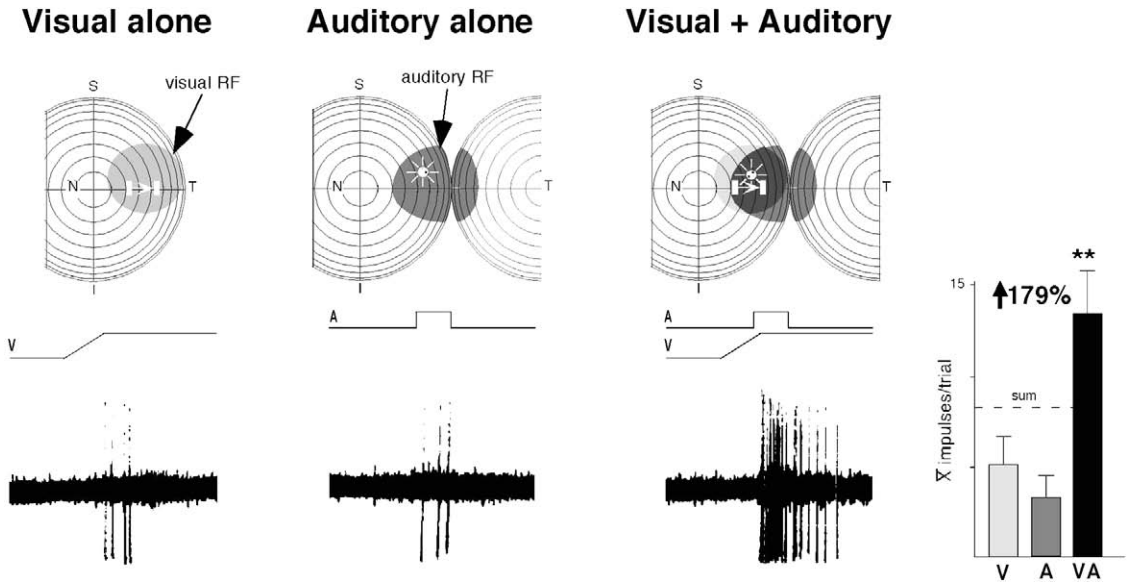

Figure 4 Multisensory response enhancement. Observations are taken from studies of a visual–auditory neuron. Receptive fields (shading) and the locations of the visual and auditory stimuli (icons) within these receptive fields are shown in the schematics at the top (see Fig. 3 for conventions). The visual stimulus (V) was a moving bar of light, and the auditory stimulus (A) was a noise burst. Below the receptive fields are shown the neuronal responses to the visual stimulus alone (left), the auditory stimulus alone (center), and the visual–auditory combination (right). The ramps above the oscillograms (V) represent the movement of the visual stimulus across its receptive field, and the square wave (A) represents the onset, plateau, and offset of the auditory stimulus. The oscillographic traces at the bottom show the neuronal impulses that were evoked by these stimuli on a single trial. The summary bar graph on the right shows the averaged response for each of the conditions as well as the predicted sum based on the addition of the two modality-specific responses. Note that the magnitude of the multisensory response enhancement was greater than predicted by the sum of the modality-specific responses. ** Statistical significance ($p < 0.01$) (reprinted from Wallace *et al.*, *J. Neurophysiol.* **80,** 1006–1010, copyright 1998, with permission from The American Physiological Society).

the same principles that govern multisensory responses at the level of the single SC neuron are operative at the level of overt orientation behavior.

IV. THE ROLE OF ASSOCIATION CORTEX IN MEDIATING MULTISENSORY INTEGRATION IN THE SUPERIOR COLLICULUS

A. Single-Neuron Studies

It might reasonably be assumed that whenever different sensory inputs converge on a single neuron, that neuron is immediately rendered capable of integrating those inputs. In this way, any of the various cross-modal convergence patterns that are possible among the more than 40 subcortical and multiple cortical inputs to the SC would be effective in creating the substrate for multisensory integration. However, this assumption proved to be incorrect. In cat, one of the primary models used for understanding the neural bases of multisensory integration, it has been estimated that 20% of the multisensory neurons in the SC are incapable of synthesizing their cross-modal inputs (i.e., "nonintegrative"). These neurons respond quite well to different modality-specific inputs and come in all varieties (visual–auditory, visual–somatosensory, auditory–somatosensory, and trimodal), but their responses to cross-modal combinations of cues are no greater or less than their responses to the most effective of these stimuli alone. A key component of the SC circuitry underlying multisensory integration appears to be the inputs from association cortex.

Inputs from two regions of association cortex have been found to be critical in this regard: the anterior ectosylvian sulcus (AES) and the rostral portion of the lateral suprasylvian sulcus (rLS). This conclusion is based on studies in which the modality-specific and multisensory responses of cat SC neurons were studied before, during, and after reversibly blocking (via cryogenic deactivation) the neuronal activity in these areas. The profound effect of blocking these cortical inputs is illustrated in Fig. 4. In this example, blocking AES activity eliminated the multisensory response enhancement in the SC. However, as was typically

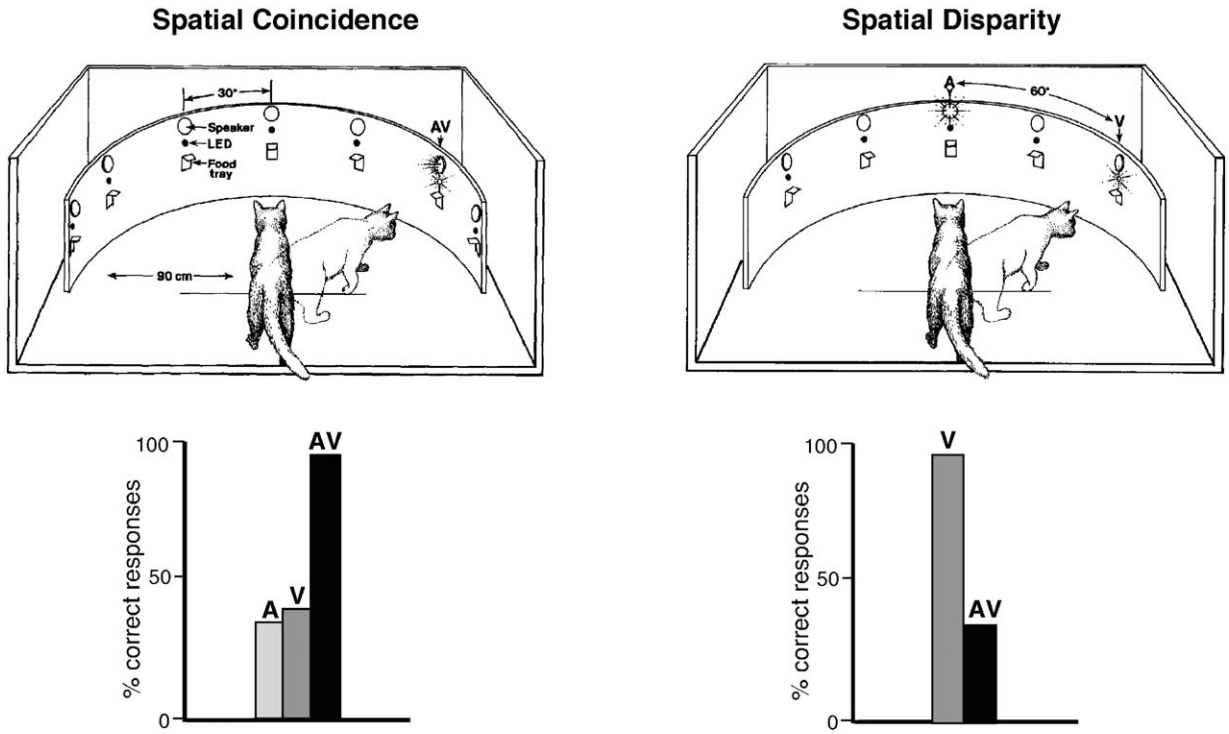

Figure 5 Orientation behaviors are altered by multisensory stimuli such that cross-modal stimulus combinations at the same location enhance performance while those at different locations impair performance. Cats were trained in a perimetry device (top) to attend straight ahead and then to orient to and approach a flashed light-emitting diode (LED) or a brief noise burst (see text for details). When the stimuli were of low intensity, they were difficult to notice and the animal responded correctly to them in less than 50% of the trials (left). However, when they were presented simultaneously and at the same location (AV) performance was enhanced more than predicted by their sum. Another animal was trained to respond only to the visual stimulus (it was never presented with the auditory stimulus during training). Its responses to the LED were markedly impaired when the neutral auditory stimulus was presented 60° medial to the LED, and this was most evident when correct responses were high (right). In this training paradigm performance could also be enhanced when the LED was made dimmer and the two stimuli were presented at the same location (not shown here) (reprinted from Stein *et al.*, *J. Cogn. Neurosci.* **1,** 12–24, copyright 1989, with permission from The MIT Press).

found, the influences from the AES (or rLS) were quite selective; they were critical only for multisensory integration. The neuron's responses to modality-specific stimuli were not significantly altered.

Some SC neurons depend only on influences from AES to exhibit multisensory integration, and others depend only on influences from rLS. However, many receive combined influences from these two cortical areas, and both cortices influence the multisensory integration of such SC neurons. In most of these cases, it is necessary to maintain the influences from both cortices; if either one is removed, the SC neuron loses its capacity for multisensory integration. It is not clear why these different patterns of dependence on AES and rLS among multisensory SC neurons have emerged, but it does raise the possibility that one cortex could compensate for early damage to the other.

B. Behavioral Studies

Whatever the reason that two cortical areas have assumed shared control over multisensory integration in SC neurons, it is interesting to note that these "association" cortices achieve at least some of their associative functions via a very distant subcortical structure. This allows them to influence, quite directly, SC-mediated behaviors. One might expect, then, that the same perturbations that compromise multisensory integration in single SC neurons would also compromise SC-mediated multisensory behaviors.

This possibility was tested experimentally using a paradigm similar to that described earlier. Although cats were trained to respond as described previously, their performance was assessed when association cortex was intact or temporarily deactivated. Cortical

deactivation was accomplished either by locally anesthetizing an area via lidocaine injections through chronically implanted cannulas or by cryogenic blockade of the activity in that area via implanted cooling probes. Deactivating association cortex had no effect on orientation to an individual modality-specific cue, but the spatially coincident combination of visual and auditory stimuli no longer could enhance performance and spatially disparate cues could no longer degrade performance. These effects were not seen when other visual or auditory cortical regions were deactivated. That these effects were dependent on disrupting SC multisensory integration by depriving its neurons of critical cortical inputs, and were not due to the loss of association cortex *per se*, was evident from the results of experiments in which the functional integrity of the SC was destroyed with a neurotoxin. In these cases, the enhanced multisensory behaviors were lost in the absence of the SC despite the functional integrity of association cortex. However, modality-specific behaviors were unaffected. The results of behavioral and electrophysiological experiments underscore the dependence of SC multisensory integration on influences from association cortex.

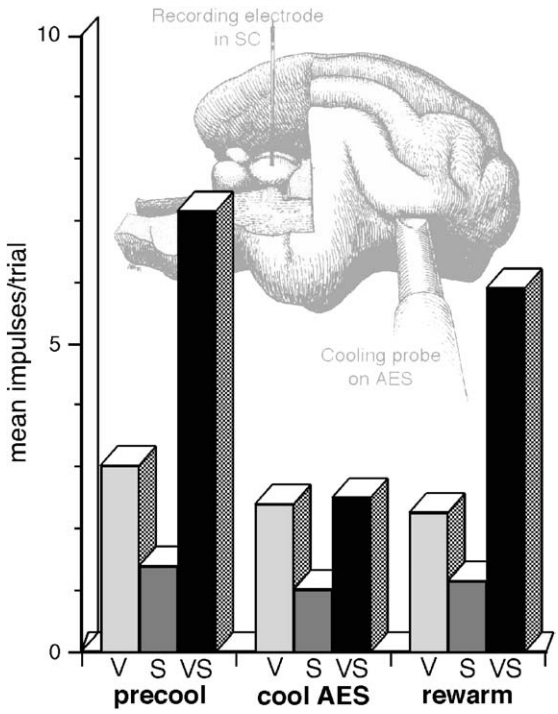

Figure 6 Deactivation of association cortex disrupts multisensory integration in the SC. The shadowed image shows the electrophysiological paradigm. While recording from a multisensory neuron in the SC, the anterior ectosylvian sulcus (AES) was reversibly deactivated by cooling. Representative data are shown for a single SC visual–somatosensory neuron. Prior to AES deactivation (precool), this SC neuron showed a modest response to the visual and somatosensory stimuli when presented individually and a large response enhancement when they were paired. When the AES was deactivated, the neuron's modality-specific visual and somatosensory responses remained intact, but its multisensory response enhancement was abolished. Multisensory response enhancement was reinstated after rewarming the AES.

V. DEVELOPMENT OF MULTISENSORY INTEGRATION IN THE SUPERIOR COLLICULUS

Scientists have argued for some time about whether the newborn brain is already capable of engaging in multisensory integration or if it requires postnatal sensory experience to do so. In the perceptual literature this issue has sometimes revolved around a syndrome called synesthesia. The literal meaning of synesthesia is "joining of the senses" and, in synesthetes, strong modality-specific stimuli initiate not only the "proper" sensations but also sensations that are appropriate for other modalities. For example, a sound is not only heard but also may trigger a specific taste or visual image. These cross-modal effects have recently been related to specific changes in brain activity.

Some investigators hold that synesthesia is the normal condition in neonates—that sensory impressions form a "primitive unity" at birth and that only with age and experience are they differentiated from one another. Others believe quite the opposite—that the senses are differentiated at birth and one must learn to associate among them. Studies of SC neurons in animals seem more consistent with the latter view. In newborn cat there are no multisensory neurons in the SC. Initially, the only sensory-responsive neurons are those that respond to somatosensory cues, presumably to help the neonate in finding the nipple. Auditory responsiveness develops in SC neurons at approximately Postnatal Day 5, and visual responses in the multisensory regions of the structure do not appear until about 3 weeks. Multisensory neurons appear in the second week of life (the first are auditory–somatosensory) and gradually increase in number. Although these neonatal multisensory neurons can respond to cues from different sensory modalities, they cannot integrate them to produce the response enhancement or response depression that is characteristic of the mature SC. In this regard, neonatal multisensory neurons appear very much like the nonintegrative multisensory neurons in adult animals described earlier. It is only after many weeks

that adult-like multisensory integration can take place. The initiation of this event in any individual neuron is linked to the maturation of functional inputs to it from association cortex. Thus, early neonatal multisensory neurons, mature nonintegrative neurons, and mature integrative neurons that have been deprived of their inputs from association cortex all respond in the same way to cross-modal cues.

At birth, the rhesus monkey is far more mature than is the cat. It already has a complement of multisensory SC neurons, although one that is not equal to that found in the adult monkey. Nevertheless, like multisensory neurons in the neonatal cat, these neurons are incapable of synthesizing cross-modal cues to produce response enhancement. Presumably, these neurons also await the development of cortical influences, but this remains to be determined. Nevertheless, it is safe to say that, based on experiments in cats and monkeys, the newborn SC is incapable of multisensory integration. Whether this is also true of neurons in other polysensory areas of the brain is not known. Most important for perceptual theorists would be testing whether multisensory integration is possible in polysensory cortex, and one excellent structure in which to examine this question is association cortex, specifically AES. As noted earlier, AES contains multisensory neurons that form a circuit independent of the SC, and baseline studies of the multisensory properties of adult AES neurons have already been performed.

VI. COMMONALITIES AMONG STRUCTURES: SUPERIOR COLLICULUS VERSUS MULTISENSORY CORTEX

Using the information obtained from the SC as a guide, experiments were conducted with multisensory neurons in AES to determine if they are governed by the same principles of multisensory integration. This cortex consists of three largely modality-specific subregions (visual, auditory, and somatosensory), with multisensory neurons clustered most heavily at the borders between these subregions. AES multisensory neurons proved to have overlapping receptive fields, much like their counterparts in the SC. This was particularly surprising given that no overall topographic organization appears to be present in the visual and auditory subregions of AES. Only the somatosensory representation is topographic. This suggested that cross-modal receptive field register would also be a key feature of multisensory integration in these neurons.

Indeed, just as in SC neurons, the spatial correspondence of cross-modal cues was a critical determinant of the nature of an integrated multisensory response: spatially coincident stimuli produced multisensory response enhancement in AES neurons, whereas combinations of spatially disparate cross-modal cues either failed to produce an interaction or resulted in response depression (albeit overall the response depression appeared to be less severe than in SC neurons). Furthermore, the greatest proportionate response enhancements were produced by combining weakly effective modality-specific cues, just as in the SC, and the temporal window within which multisensory integration was possible was similar to that found in the SC. Unfortunately, it is not known if it is possible to selectively depress multisensory integration in AES neurons by deactivating a specific input without eliminating their modality-specific responses.

Similar principles of multisensory integration have also been found in polysensory cortical regions in rodents, and the overlapping nature of cross-modal receptive fields has proved to be present in nearly every polysensory area of primate cortex, suggesting that here, too, the spatial principles of multisensory integration will be operative. Such a constancy in the principles of multisensory integration would be a parsimonious way of uniformly increasing (or decreasing) the salience of the same stimulus complex throughout the brain and would also be an effective way of appropriately matching the intensity of immediate behaviors with the higher order perceptual, cognitive, and emotive processes that provide conscious dimension to sensory experience.

VII. STUDIES OF MULTISENSORY INTEGRATION IN HUMAN CORTEX

In the past few years there have been a number of studies exploring the neural bases of multisensory integration in human cortex. Initially, such studies utilized event-related potential (ERP) recording techniques in which the averaged responses of thousands of neurons are recorded from surface electrodes on the scalp. The temporal resolution of ERP recordings is excellent (events can be measured in milliseconds) and can easily be combined with conventional behavioral or perceptual measures in order to examine the covariance between changes in behavior/perception and neural activity. One of the surprising results of these studies is the finding that activity in primary sensory cortex (e.g., auditory) can be modulated by

"nonappropriate" sensory stimuli (e.g., visual), an observation that questions the accepted dogma that each primary sensory cortex is responsive only to a single sensory modality. It also confirms some early observations (that were largely ignored) from single-neuron studies in animals suggesting that some of the neurons in primary sensory cortex are not modality specific and can, in fact, be activated by stimuli from other sensory modalities.

ERP studies have also identified presumptive polysensory cortices in humans. The changes in human brain activity that are induced by multisensory stimuli have also been associated with an increased response accuracy and reaction speed to these stimuli. Unfortunately, the spatial resolution of the ERP technique is not sufficient to allow researchers to identify the specific sulci and gyri that are involved in these processes.

It is in specifying the locus of evoked activity in the human brain that functional imaging techniques have had their greatest impact, because they have centimeter or subcentimeter resolution. Two imaging techniques, both of which utilize changes in cerebral blood flow to assess neural activity, have become quite popular in studies of multisensory integration: positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). These techniques have confirmed the ERP observation that the activity in primary visual and auditory cortices can be modulated by other sensory stimuli, and they have also identified specific regions of cortex that are devoted to processing multisensory stimuli, including right insulaclaustrum, left basal posterior temporal lobe, and the medial inferior parietal lobe. Recently, fMRI techniques have strongly suggested that multisensory integration in human cortex is subject to some of the same rules of multisensory integration that have been demonstrated at the single-neuron level in the midbrain and cortex of animals. Thus, superadditive response enhancement (Fig. 7) was obtained in the left superior temporal sulcus when the visual signal (lip movements) matched the auditory signal (heard speech), whereas responses became subadditive when the lips and the heard signal were mismatched.

Surprisingly, these imaging studies have demonstrated that primary sensory cortex is subject to a remarkable degree of developmental plasticity. Blind or deaf individuals have their denervated cortices "taken over" by other sensory modalities. Thus, for example, disrupting the activity of visual cortex in a blind subject via transcranial magnetic stimulation interferes with the subject's ability to read Braille. Apparently, the absence of visual input allowed visual cortex to capture some of the normal functions of somatosensory cortex, thereby expanding the brain tissue devoted to processing information from the body. Similar changes in the brain are likely to accompany damage to each of the senses. Nevertheless, whether blind or deaf people are actually better at using the information they process in their remaining senses than are normal individuals remains a controversial issue.

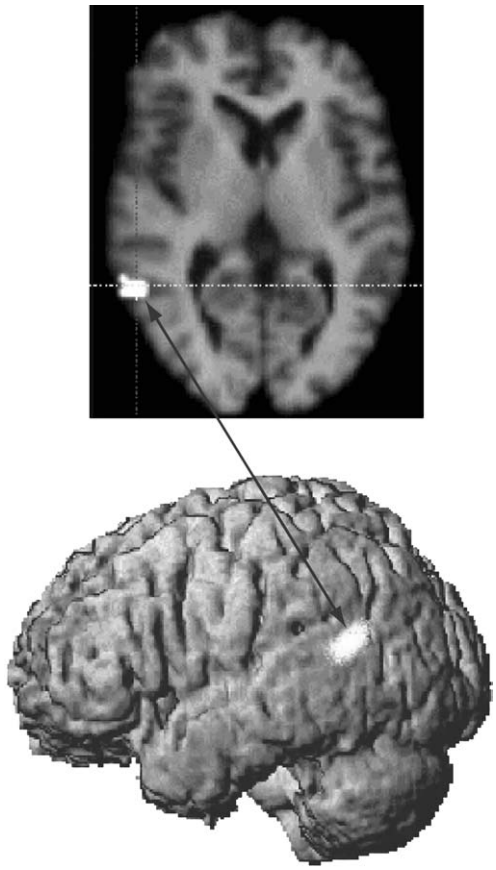

Figure 7 (Top) A magnetic resonance image (MRI) of multisensory enhancement in the human brain. An illustration of a horizontal section through the brain is shown. The white area (double–headed arrow) is a region of activation as measured by functional MRI (i.e., increased blood flow). The region is located in the ventral bank of the left superior temporal sulcus and is known to be involved in speech perception. Its response to a cross-modal (visual–auditory) stimulus combination exceeded that predicted by the sum of the individual modality–specific responses. The area is also illustrated on an image of the whole brain. (reprinted from *Curr. Biol.* **10,** Calvert *et al.*, 649–657, copyright 2000, with permission from Elsevier Science).

VIII. CONCLUSIONS

The observations detailed previously suggest that at least some of the fundamental principles of multisensory integration are generalized across species and brain structures. Undoubtedly, specialized multisensory properties will be found that are best adapted to the specialized needs of different species and different brain regions, and this is one of the challenges of future research. Nevertheless, it is likely that such specialized properties will prove to be overlaid on a fundamental core of principles that have common evolutionary origin and widespread utility. Despite a remarkable degree of diversity among species and their ecological circumstances, the presence of striking commonalities in individual sensory systems argues for similar commonalities in the principles that interlink them. From the perspective of the individual, a constancy in the fundamental principles of multisensory integration at different levels of the neuraxis ensures that the salience of a given event is approximately equivalent in the many different areas of the brain that contribute to the same behavior.

Music and the Brain

DAVID W. PERRY
University of California, San Francisco

GLOSSARY

absolute pitch A rare ability possessed by some individuals who can name the pitch of a musical tone, or sing a named pitch on demand, without referring to any other sounds.

amusias Acquired disorders of music perception, performance, reading, or writing that are due to brain damage and are not attributable simply to the disruption of basic perceptual, motoric, or cognitive functions.

consonance A subjective quality of the pleasantness of combinations of tones.

contour The pattern of changes in frequency direction within a tone sequence, regardless of the magnitude of those changes.

harmony The subjective effect produced by the simultaneous sounding of musical tones or tone sequences.

melody A sequence of tonal pitches, usually varying in duration, organized to express a musical idea.

meter A repeated pattern of stress against which other temporal variations are ordered.

pitch A subjective quality of the relative highness or lowness of sounds.

rhythm The musical organization of the temporal durations of sounds.

scale The basic set of pitches used in a particular musical composition (identical in every octave), arranged in ascending or descending order.

song A short musical composition integrating words and music.

timbre A subjective quality imparted to harmonic complex sounds by the relative distribution and time course of energy at the different harmonic partials but distinct from their pitch.

tonal melody The pattern of intertone intervals formed by a tone sequence, including their specific size and order, that may be transposed in frequency.

tonal working memory The ability to hold sequences of tones in mind, often in order for more complex processing to be carried out.

tone A sound of distinct pitch and duration, such as a musical note.

The study of how the human brain produces musical behaviors, both receptive and expressive, is at least as complex as the similar study of language. As in the study of language, the neural substrates of these highly evolved and complex human activities, such as listening to (or performing in) an orchestra with chorus, are best approached by breaking them down into component processes, each of which depends on distributed networks of neural processors.

I. INTRODUCTION

The following fundamental questions occupy most of the energies of those engaged in attempting to unravel the brain's role in musical perception and production:

1. How does the brain *receive* musical sound?
2. How does the brain *process* and organize musical sounds and extract the "information" they convey?
3. How does the brain *store* and *retrieve* musical sounds and information and the motor programs required to reproduce them?
4. How does the brain control the *production* of musical sounds (whether audibly by singing, instru-

ment playing, or whistling or inaudibly, for the "mind's ear" alone, through mental imagery)?

5. How does the brain control the *writing* and *reading* of graphic notations used to record and transmit musical ideas or "road maps" for musical production?

6. How does the brain mediate *emotional* responses to music and emotional expression through music?

7. How does the brain mediate the integrated perception and production of *music and language* as in song?

8. How is the brain *changed* by musical experiences, not just in the sense of "engrams" or "circuits" underlying memory for specific musical ideas or actions, but in more generalized ways?

Most of what is known about how the human brain perceives and produces music comes from the study of two very different sources of information: (i) neurophysiological activity measured noninvasively during the exercise of musical perceptual, motoric, and/or cognitive functions and (ii) measurement of the behavioral effects of focal brain lesions on these same musical functions. The study of how the brain produces musical behaviors is in fact a microcosm of the field of cognitive neuroscience in general, with different aspects of music touching on most of the fundamental questions of that domain. This article can be viewed as a framework for studying the neural organization of the range of normal musical functions as well as for studying the range of musical disorders that may follow the disruption of normal neural functioning.

II. MUSICAL PERCEPTION

Musical perception may be considered in terms of the reception of those perceptual–acoustic characteristics that define the basic elements of musical sounds, such as frequency, pitch, consonance, timbre, duration, intensity, and spatial location. This level of inquiry has received by far the most attention by researchers and is amenable to investigation in both human and animal brains.

A. Perceptual Acoustic

Pitch can be considered the most essentially musical of these acoustic characteristics, being a central organizing principle for virtually any imaginable musical culture.

1. Pitch

Pitch is a subjective quality, the exact physical correlates of which have been controversial since the time of Heinrich von Helmholtz in the late 19th century. Pitch is traditionally understood to be derived by the auditory nervous system through analysis of the spectral frequencies in sounds. In fact, the physical attribute of frequency (for pure tones) can be mapped point for point from the inner ear, in the topography of the basilar membrane (apex, high frequency; base, low frequency), through portions of the brain stem nuclei, culminating in the ventral division of the medial geniculate nucleus and projecting to tonotopically organized cortical fields, the most well studied of which is the primary auditory cortex.

Pitch can be dissociated from frequency by studying responses to stimuli with virtual pitch, or pitch experienced at a "missing" fundamental frequency that is derivable from the pattern of upper harmonics, as the root of a corresponding harmonic series. Several pivotal experiments have taken advantage of such stimuli. In 1976, Henry Heffner and I. C. Whitfield demonstrated that cats could be trained to discriminate periodicity pitch as well as frequency. In 1980, Whitfield showed that following bilateral lesions of primary auditory cortex, the cats lost the ability to discriminate virtual pitch but could still discriminate absolute frequency. This suggests that auditory cortex may be essential for the discrimination of pitch but not frequency.

In 1988, Robert Zatorre tested patients whose temporal lobe surgeries for the control of seizures either included or excluded Heschl's gyrus, the anatomical landmark for human primary auditory cortex, based on surgeons' reports. Patients with right temporal lobe removals including Heschl's were the only group impaired in discriminating virtual pitch.

Christo Pantev and colleagues used a noninvasive imaging technique, magnetoencephalography (MEG), to examine the magnetic fields evoked by tones with virtual pitch and pure tones and found that the source of the primary component of the evoked magnetic field (the M100) was identical for a tone composed of the fourth through the seventh harmonics and for a pure tone at the frequency of the missing fundamental. However, corroborating evidence is scant, and controversy exists regarding the interpretation of MEG demonstrations of the topographic mapping of pitch, and even of frequency.

Recalling some of the patients mentioned previously, Ingrid Johnsrude, Virginia Penhune, and Robert

Zatorre determined from high-resolution magnetic resonance imaging (MRI) that only excisions extending into right Heschl's gyrus disrupted thresholds for the judgment of the direction of a change in frequency. No excisions impaired the ability to discriminate the presence or absence of a frequency change.

Taken together, these results suggest that certain higher level aspects of pitch perception, such as the perception of virtual pitch and the *direction* of frequency change, may depend on the integrity of primary auditory cortex and, in man, particularly on that in the right hemisphere.

As mentioned earlier, the exact nature of the physical parameters corresponding to the subjective experience of pitch has been controversial for more than 100 years because the neural excitation patterns produced by the cochlea contain not only spectral peaks, from which the pitch of harmonic sounds may be derived, but also repetition rates that correspond to the pitch of the sound. For virtual pitches formed by upper harmonics (i.e., above the eighth in the series), spectral peaks are no longer resolvable and yet pitch is still experienced. Sounds ("iterated rippled noises") can be synthesized that are spectrally identical to one another by passing a random noise through a cascade of delay-and-add networks and yet produce different subjective pitches, with a pitch corresponding to the reciprocal of the time delay.

Using positron emission tomography (PET), Timothy Griffiths and colleagues presented rapid sequences of tones differing in pitch that varied progressively in the number of iterations from 0 to 16 (and hence in the strength of the pitch percept). They sought brain areas whose activation covaried with the number of iterations. The only such areas found were near the primary auditory cortex bilaterally, probably just lateral and/or inferior to it, and were approximately symmetrical. These results indicate that the temporal integration allowing this time-based code to be transformed into a spatial one occurs at or before the primary auditory region. Animal studies by Gerald Langner and Christoph Schreiner indicate that this integration occurs in the cat by the level of the inferior colliculus and results in a mapping of pitch that is orthogonal to that for frequency. Results suggestive of a similar arrangement within human auditory cortex have been obtained by Langner, Mikko Sams, and colleagues using MEG but remain to be fully confirmed. Furthermore, cortical neurons do not exhibit sufficient temporal sensitivity to encode pitch in the temporal patterns of their firing rates. Nevertheless, Griffith's PET study suggests the possibility that at the cortical level the temporal analysis of pitch within the auditory nervous system may be more bilaterally distributed than the spectrally based analysis. However, this study differs in other ways from most studies demonstrating right auditory cortical superiority, e.g., in the rapidity of the tone sequences (96 events within 1 sec).

Although interpretation of far-field neurophysiological measures such as MEG is controversial, near-field measurements have provided more direct evidence for a tonotopic gradient within human auditory cortex. Catherine Liegeouis-Chauvel and colleagues, using intracranially measured auditory evoked potentials (from depth electrodes placed for seizure localization), demonstrated a medial (high frequency) to lateral (low frequency) gradient within Heschl's gyrus, more sharply tuned in frequency within the right hemisphere. In addition, they measured evoked potentials (EPs) to voiced (/ba/) and unvoiced (/pa/) speech syllables and found that only EPs from sites in left Heschl's gyrus were differentially sensitive and showed evidence of encoding the timing of voice onset.

Zatorre proposed that greater spectral resolution within the right primary auditory cortex is fundamental to the development of complementary hemispheric specialization. Specifically, the inherent trade-off between spectral and temporal resolution resulted in the development of complementary specializations for their processing and was probably driven first by the demands on temporal processing imposed by perceiving speech. To test this hypothesis, he and Pascal Belin examined the correlation of cerebral blood flow (CBF), as measured with PET, with two parametrically varying characteristics of pure tone sequences: increasing frequency discrimination (with rate held constant) and increasing temporal rate (with frequency difference a constant). An area in the anterior temporal lobe showed increasing CBF with rate in the left hemisphere and with frequency discrimination in the right.

Regardless of whether right or left auditory cortex specialization came first in human evolution (and thus possibly music and language in human history), there is ample evidence supporting a preferential role for the right auditory cortex in the processing of spectral pitch.

2. Consonance

Consonance is a subjective quality of the pleasantness of combinations of tones. Its physical counterpart is found in the phenomenon of roughness, or changes in the amplitude of components of a complex signal that

can result in the sensation of beats. When the discharges of single fibers in the auditory nerve, which projects from the cochleae to the first brain stem relay (the cochlear nucleus), are measured, these beating patterns can be discerned. Mark Tramo, Peter Cariani, and Bertrand Delgutte measured such responses in the cat to pairs of pure tones, the ratios of whose frequency components constituted a subset of the musical intervals central to many musical systems: the major fifth (1:2), major fourth (2:3), minor second (16:l5), and tritone (32:45). They also examined the responses to pairs of complex tones (composed of six harmonics) whose fundamental frequencies formed the same musically relevant ratios. For pure tone pairs, only the most discordant minor second produced beating patterns. For complex tone pairs, beating patterns resulted from the most closely spaced component frequencies, and there was a high positive correlation between the total number of auditory nerve fibers showing beating patterns and the perceived dissonance of the musical interval, maximal for the minor second and intermediate for the tritone.

Tramo recorded the responses of single cells in auditory cortex to these same stimuli and found evidence for a dual time code. Local periodicities in the submillisecond range appear to encode the harmonic relationship among partials, whereas local periodicities in the range of tens of milliseconds encode the total roughness among partials.

These results suggest that the perceptual attribute of dissonance results from the integration of temporal information across populations of auditory nerve fibers. It is not clear how or where this integration takes place. Furthermore, as Tramo pointed out, measures of roughness alone do not distinguish between the perfect fourth and fifth, suggesting that the perception of harmony may derive more from higher leve1 analysis of pitch relationships than from physiological roughness.

3. Timbre

Timbre refers to another subjective quality imparted to harmonic complex sounds by the relative distribution of energy at the different harmonic partials. In a dynamic sense, the time course of this spectral distribution contributes to our ability to distinguish different musical instruments (e.g., the differences in attack between a trumpet and an oboe). In 1962, Brenda Milner demonstrated deficits on the timbre discrimination subtest of the Seashore Tests of Musical Talent after right but not left temporal lobectomy. Severine Samson and Robert Zatorre confirmed and extended this observation by finding deficits in both spectral and temporal aspects of timbre recognition.

Recognition of musical instruments is also often severely disturbed in cases of generalized auditory agnosia, or a loss of the ability to recognize auditory "objects" following bilateral auditory cortical damage and, in some cases, unilateral right hemisphere damage. However, even in cases in which such loss of recognition is restricted to musical sounds, such as those studied extensively by Isabelle Peretz and colleagues, musical instrument recognition may be selectively spared (e.g., patients CN and GL both display profound deficits in the recognition of previously familiar tunes, but musical instrument recognition was disturbed for CN but not for GL). At least for recognition, bilateral cortical contributions are suggested, but with a right temporal lobe predominance. More investigation is needed before further conclusions can be drawn regarding the critical stages in the auditory pathway for processing musical timbre.

4. Intensity

The detection of changes in sound intensity is of great musical relevance, forming the basis of musical "dynamics" or expressive changes in sound intensity, both abrupt and gradual. Cortical contributions to the perception of intensity are suggested by studies of the response properties of neurons in animals. In particular, some cells in the primary auditory region of cats and monkeys show sharp tuning of response to particular intensities, especially, as demonstrated by Gregg Recanzone and colleagues in awake behaving macaque monkeys, within the tonotopically organized field just anterior to the primary area (field R).

Pascal Belin and associates measured CBF changes using PET while human subjects detected progressively finer intensity differences between tones. Similar increases were observed within the right posterior temporal gyrus regardless of the subjects' intensity discrimination performance. These results are partially corroborated by Brenda Milner's finding in 1962 that right but not left anterior temporal lobectomy resulted in a decrement on the intensity subtest of the Seashore Tests of Musical Talent. Increases were also observed that varied with individual performance level in the right inferior frontal gyrus and, linearly, in right parietal cortex. This frontal–parietal network is very similar to that observed by Robert Zatorre and Todd Mondor during auditory attention to either frequency or spatial location, and it may be involved in the

allocation of attention to various acoustic attributes and even to particular sensory modalities. It thus appears that simply discriminating between the intensity of two tones involves not only the encoding of basic acoustic parameters within auditory cortex, but more widespread cortical networks.

It remains to be investigated whether higher level judgments of intensity change, such as the direction of change (i.e., louder vs softer), show dependence on cortical levels of auditory processing, as do analogous judgments of frequency direction. The processing of more complex intensity changes (e.g., decrescendo and crescendo) extended in time also awaits investigation.

5. Duration

Studies of the behavioral performance of patients with temporal lobe lesions have shown deficits in thresholds for temporal discrimination following damage to the left hemisphere. A recent study of patients with medial temporal lobe epilepsy by Severine Samson and associates examined thresholds for the detection of deviations within otherwise isochronous tone sequences. For detection of interonset intervals (IOI) of 80 msec, left temporal lobe patients showed increased thresholds when compared to right temporal patients and normal controls. At IOIs of 300 msec and higher, thresholds for anisochrony detection were normal. Detection of temporal perturbations within familiar melodies (i.e., lengthening one interval by 25%) was measured following right vs left temporal lobectomy. Only left temporal lobectomy resulted in a decrement in the detection of temporal deviations within a melodic context.

Since mesial temporal lobe atrophy is accompanied by decreased metabolism in the lateral temporal lobe, these results support the hypothesis that the left temporal lobe is critical for the fine-grained perception of temporal variations.

6. Sound Localization

Whereas *frequency* is a physical attribute that is known to be "mapped" directly in the spatial organization of cortical neurons throughout the main ascending auditory pathway, the *spatial locations* of sounds are computed primarily from differences between the inputs to the two ears (but also from monaural spectral cues resulting from the shape of the pinnae). Recent evidence from animal neurophysiology favors an interpretation of the cortical encoding of acoustic space within the population structure of neuronal responses.

Although not the most musically relevant of the basic perceptual–acoustic attributes of musical sounds, auditory spatial localization can aid in the segregation of particular instruments or musical groupings from competing sounds. Auditory scene analysis, or the extraction of individual auditory "objects" from a complex mixture of sounds, is a higher level function dependent on the integration of spectral, temporal, and/or spatial attributes of auditory stimuli and is discussed in the following section. Human and animal studies indicate the involvement of both primary and secondary auditory cortices and portions of the posterior parietal lobe in simple localization of sounds in space.

B. Perceptual–Organizational

Musical perception can also be studied at the level of the perceptual organization of auditory events along these basic perceptual–acoustic axes, both when the events occur simultaneously or overlap in time, and when they are extended across time sequentially. Although the previous section touched on this level, the following discussion focuses on the perceptual organization of multiple auditory events.

1. Pitches

As discussed in the previous section, there is considerable evidence supporting a critical role for the right auditory cortex in the processing of pitch, as distinguished from frequency, particularly when judgments must be made. In this section, we consider what is known about the perceptual processing of multiple pitched auditory events, occurring either simultaneously (as in musical chords of two or more notes) or sequentially (as in tone sequences or melodies).

a. Harmonic (Simultaneous) Few studies have systematically examined the localization of component processes involved in the perception of harmony or the subjective effect of particular combinations of musical pitches or pitch sequences. Mark Tramo, Jamshed Bharucha, and Frank Musiek asked a patient with bilateral temporal lobe strokes to make judgments of mistuning within a three-note chord that was preceded by a different three-note chord. Normal subjects showed facilitation of mistuning judgments when the preceding chord was harmonically related. Even though the patient was impaired in tuning judgments, with a bias toward dissonance, his judgments were still normally "primed" by the harmonic

relatedness of the preceding chord. This result suggests that simple judgments of consonance, which may be dependent on primary auditory cortex, can be dissociated from higher level effects of harmonic relatedness and expected sequence, which may be mediated by secondary auditory cortical areas.

b. Tonal (Sequential) The processing of sequences of auditory events possessing pitch is obviously central to music perception. In its simplest form, each of these events consists of a harmonic complex tone with a relatively constant pitch. The neural basis for processing sequences of such tones has been explored using several different methods. Sequences of tones differing in pitch can be encoded relatively crudely in terms of the pattern of changes in frequency direction, regardless of the magnitude of change. This type of pattern is called contour. Alternatively, the specific pitches (or the *size* of the intervals they form) can be encoded, and the resulting melodic contour or tonal melody may be transposed in frequency.

Only a few neurophysiological studies have examined single cell recordings in response to the individual tones contained in such stimuli. Norman Weinberger and T. McKenna studied the responses of neurons to five-tone sequences in the cat's auditory cortex. Strong responses were obtained only to the first tone of each sequence under anesthesia, so measurements were carried out while awake, resulting in strong responses to each tone. Discharges to the same tone varied depending on the contour of the particular sequence in which they were embedded, within both primary and secondary auditory cortical areas.

In a related study using three-tone sequences, I. Espinosa and George Gerstein recorded from primary auditory cortex in the cat, testing all permutations of the three tones. In a groundbreaking experiment, they recorded up to 24 neurons simultaneously, permitting analyses of the functional connectivity between pairs of neurons. These patterns of connectivity, elicited in response to the same tone as it occurred in different sequences, were varied, suggesting that contour and/or tonal melody are encoded in the responses of *populations* of neurons.

Techniques for recording from many neurons or neuronal clusters simultaneously have undergone rapid advances recently, thus permitting further investigation of these phenomena. Only then will we be able to proceed beyond these initial suggestive inquiries toward a more complete understanding of how sequences of pitches are encoded within the tonotopic auditory nervous system. Also, only then will we be able to judge the prescience of William James, who speculated in 1890 that memories might be retained as "'paths' … in the finest recesses of the brain's tissue," recalled by "the functional excitement of the tracts and paths in question."

Using PET, Zatorre and colleagues measured increases in CBF in response to standard Western diatonic melodies, in contrast to amplitude envelope-matched noise bursts. In a recent (2000) reanalysis of the original 1994 report, the localization of the focus within the right superior temporal gyrus was further refined to its ventrolateral aspect, anterior to Heschl's gyrus, and the smaller increase in the left superior temporal gyrus reached significance (Fig. 1). Although

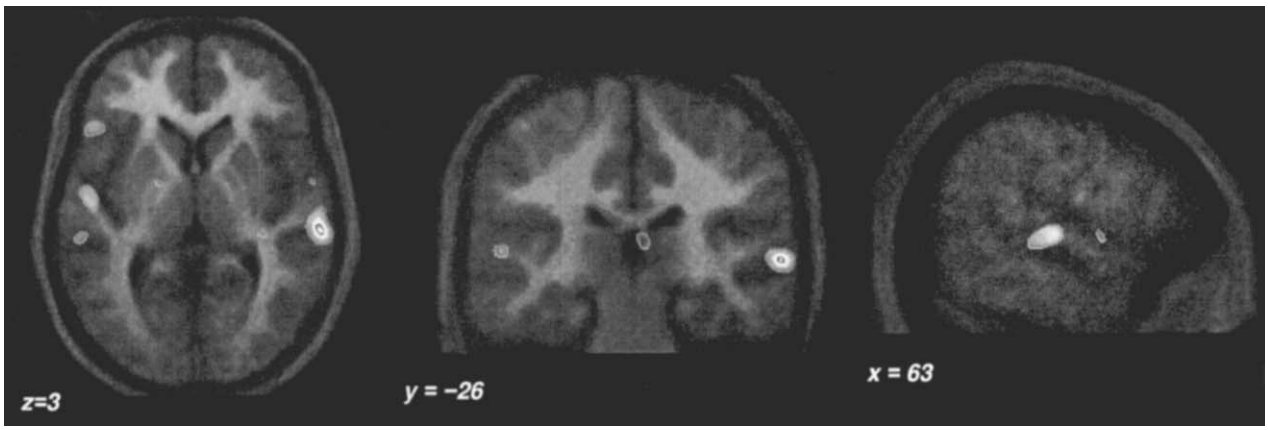

Figure 1 Melody perception vs matched noise bursts. Horizontal, coronal, and saggital views through the peak of CBF increases in the superior temporal gyrus, as measured with PET, superimposed on the group-averaged MRI volume. The peak is located on the lateral surface of the right superior temporal gyrus, posterior to Heschl's gyrus (original data from Zatorre *et al.*, 1994; reanalysis and figure reproduced with permission from Zatorre and Binder, 2000).

the contrast between melodies and noise sequences is complex, these results suggest the involvement of secondary auditory cortical areas in the processing of melodies, with a right hemisphere predominance that is nevertheless relative.

A recent study by Anniruddh Patel and Evan Balaban measured the magnetoencephalogram while subjects listened to tone sequences varying parametrically in structure from random to music-like. Patterns of temporal synchronization between brain regions were greatest for the most structured, melody-like sequences and suggested a high degree of inter-hemispheric connectivity.

Although a number of studies of the effects of brain damage on the processing of tonal melody indicate a relative right hemisphere predominance, many also indicate a critical involvement of processing in the left hemisphere as well, particularly for more complex sequences and tasks. Ensuring that the melodies do not have associated lyrics, that they are novel, and that the task does not involve naming is not sufficient to eliminate potentially critical left hemisphere contributions to tone sequence perception.

For example, Peretz found that groups of patients with right or left hemisphere lesions were both impaired on a task of making same–different judgments to pairs of novel melodies, relative to normal control subjects. The right hemisphere group was more impaired for trials in which the contour was violated. However, both groups were equivalently impaired when contour was preserved, and comparison was thus based solely on pitch interval information. Peretz hypothesized that the right hemisphere is predominant for the encoding of contour and the left hemisphere for the encoding of specific pitch intervals. She further proposed that the encoding of specific pitch intervals is dependent on the formation of a representation of contour, resulting in the observed pattern of deficits. However, studies by Zatorre and colleagues found normal effects of these cues on melody recognition regardless of which hemisphere was lesioned and overall found greater and more consistent effects of right hemisphere excisions, particularly those that encroach on the primary auditory region.

Differences in tasks and in the types and extents of lesions are no doubt critical, but clearly cortical areas in the left hemisphere also contribute to melody perception.

2. Duration

The musical organization of durations is called *rhythm*, and it often reflects an underlying *meter* or repeated pattern of stress against which other temporal variations are ordered. These aspects of music perception have received less study than tonal pitch organization, and there are fewer hypotheses regarding their neural substrates.

a. Metric Peretz compared rhythm and meter discrimination by groups of right and left hemisphere-damaged patients. Although rhythm discrimination was impaired for both groups, neither group was impaired in meter discrimination. This evidence that meter discrimination is more resistant to cortical damage may implicate subcortical and/or spared cortical processing.

b. Rhythmic A recent study using PET carried out by Virginia Penhune, Robert Zatorre, and colleagues found right-sided activity in the superior temporal gyrus when the perception and manual reproduction of isochronous sequences were contrasted to perception alone. These results suggest the involvement of secondary auditory cortical areas in the right hemisphere for the simplest form of rhythmic perception and/or reproduction. When reproduction of more complex rhythmic sequences was contrasted to reproduction of a similar repeated, well-learned sequence, increases were seen in the cerebellar vermis and hemispheres for both auditory and visual stimulus presentation. This cerebellar activation may result from its contribution to the flexible production of precisely timed sequential movements and/or to the perception of complex, changing rhythms, but in either case it is not unique to auditory rhythms. The perception of visual rhythm may itself be considered an important musical function, at least for members of conductor-led ensembles.

3. Intensity

Although the intensity patterns underlying musical phrase structure have been studied extensively by cognitive scientists such as Henry Shaffer, Eric Clarke, and Caroline Palmer, the neural basis of their perceptual processing remains to be explored.

4. Integration of Tonal, Rhythmic, and Intensity Organizations

In actual musical performance, and thus in its product, musical sound, the tonal structure, rhythmic structure, and intensity pattern are usually highly interrelated. Their integrated product, the musical phrase at one

level of local detail, is perhaps one of the most essential and defining elements of music. However, a neural understanding of the mechanisms supporting this integration must follow further study of the component processes outlined previously.

Finally, more complex levels of perceptual organization can be considered, such as the perception of an auditory "scene" and the integration of auditory and visual perception across time.

5. Auditory Scene Analysis

Spatial location is only one potential attribute of musical sounds that may be used dynamically, along with temporal and spatial cues, in order to extract auditory objects or events from complex sound mixtures. The physical separation of players in an orchestra can facilitate their extraction from the sound of the orchestra as a whole, finding an extreme in the off-stage ensembles sometimes employed in complex orchestrations. However, temporal and spectral cues also play prominent roles in the segregation of auditory objects. Sufficient differences on at least two of these three axes are needed in order to segregate an auditory object from its surround. In an experiment examining the combination of spectral and spatial differences, David Perry and Pierre Divenyi found lower thresholds for spatial separation within the left auditory hemifield in normal controls and disturbances following cortical damage in the contralateral temporoparietal junction. The normal asymmetry is suggestive of a right hemisphere preference for some aspect of auditory scene analysis based on temporal/spectral integration and could be explained simply by the demand for spectral processing.

A recent study of professional conductors found evidence from EPs of enhanced auditory localization when compared to that of nonmusicians or pianists. Although the ability to accurately localize the sources of sounds is critical for a symphony conductor, auditory spatial perception can also enhance the perception of music for casual listeners, whether real, as in live performance, or virtual, as in studio-produced recordings for two or more speakers. Specifically musical investigations must in large part follow further basic neuroscientific investigations of auditory scene analysis.

6. Auditory–Visual Integration

The integration of auditory and visual information is an active focus of basic neuroscience research that has relevance for understanding music perception. Although music can be enjoyed as a purely auditory phenomenon, without correlated visual input, live or videotaped performances of music present the listener with the correlated movements of players, singers, and conductors. Choreography set to music, live or videotaped dance, movie musicals, music videos, cartoons, and other music-video compositions present the listener/viewer with artificially assembled auditory–visual coincidences. Concomitant visual inputs can influence music perception, just as they can influence speech perception. Advances in basic research on low-level auditory–visual integration (e.g., a tone paired with a spatial grating) and on visual influences on speech perception will facilitate investigations of the neural mechanisms supporting auditory–visual integration in specifically musical contexts.

7. Absolute ("Perfect") Pitch

Some individuals, who are said to possess absolute or perfect pitch (AP), can name the pitch of a musical tone or sing a named pitch on demand without referring to any other sounds. Gottfried Schlaug measured the planum temporale or secondary auditory cortex on the superior temporal plane posterior to Heschl's gyrus and found that AP possessors exhibited an exaggerated leftward asymmetry.

Robert Zatorre, David Perry, and Christine Beckett used PET to measure CBF increases while musicians with and without AP performed a series of simple tasks involving pairs of complex tones. The musicians either simply listened to the tone pairs or decided whether they formed major or minor intervals. For listening in contrast to noise bursts, both groups showed bilateral activation of auditory cortex, but only the AP group showed an additional focus in the left posterior dorsolateral frontal cortex. However, when making interval judgments both groups showed activation in this region (Fig. 2). Studies in nonhuman primates by Michael Petrides have implicated this region as critical for conditional associative learning. AP can be conceptualized as a form of conditional associative learning, in which a stimulus attribute (tonal pitch) is arbitrarily associated with a verbal label (note name). Therefore, the activation of left posterior dorsolateral frontal cortex when simply listening to the associated stimulus (and while note names are obligatorily retrieved) may be explained by the retrieval of these associations. Its activation when musicians labeled intervals as "major" or "minor" may similarly be explained by the association between an arbitrary label

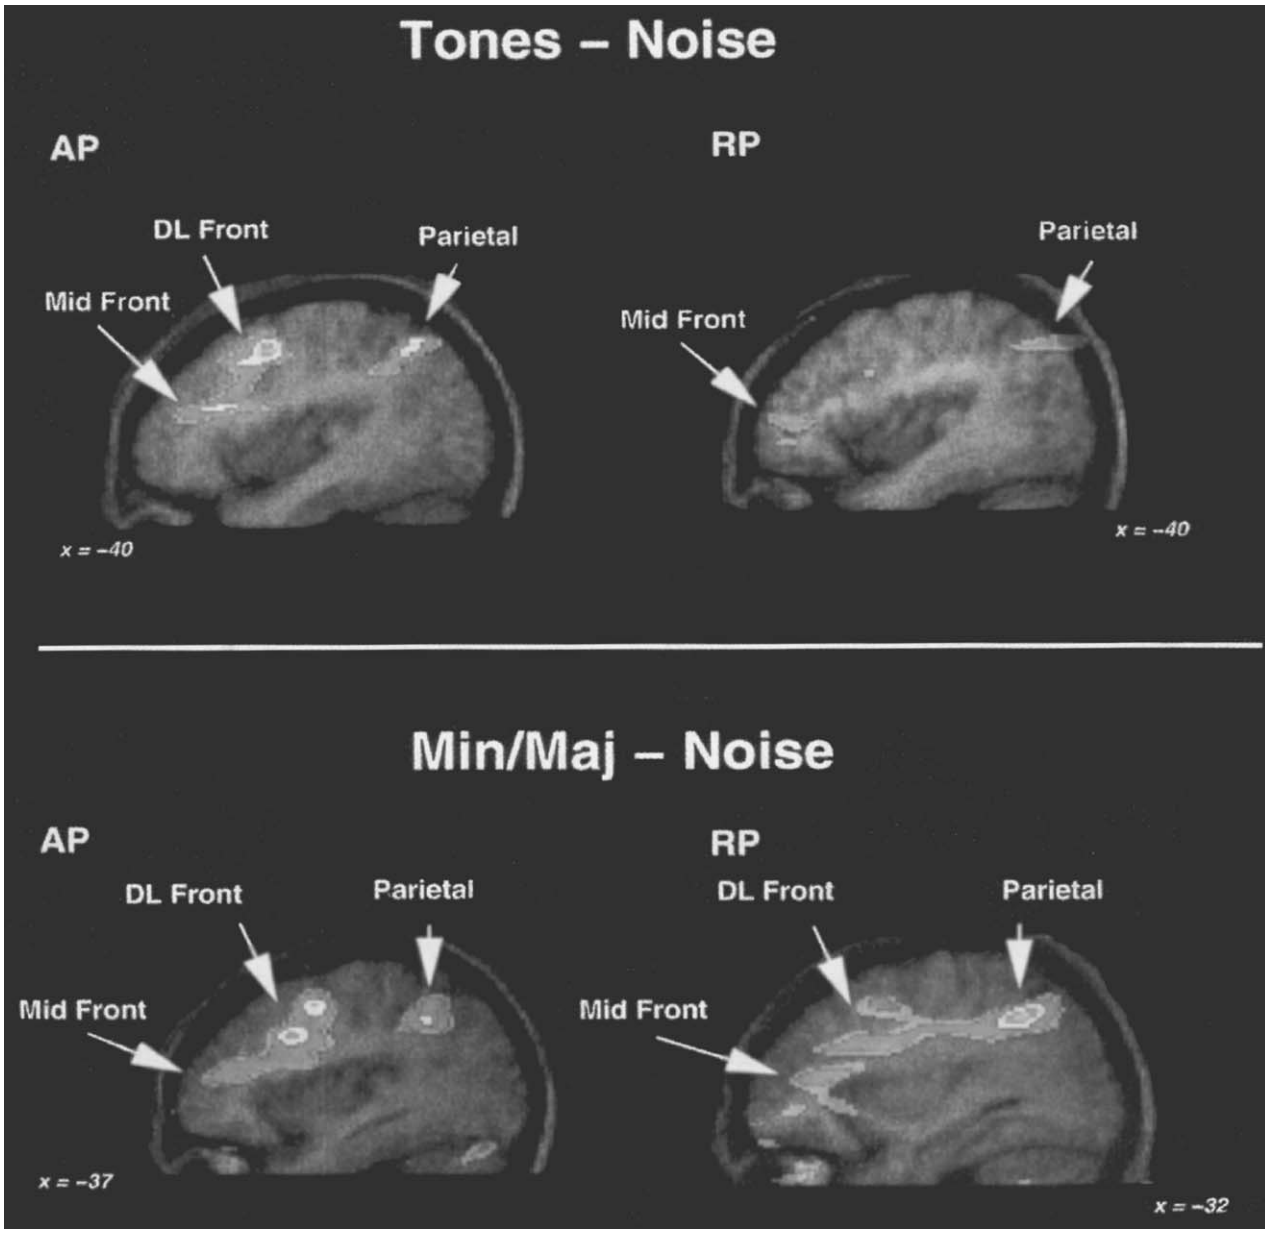

Figure 2 Musicians with absolute vs relative pitch ability. Tones-Noise: CBF increases while listening to pairs of sequential tones that formed either major or minor intervals vs amplitude envelope-matched noise bursts. An increase within the left posterior dorsolateral (DL) frontal cortex was observed for musicians with absolute pitch (AP) but not for those with only relative pitch perception (RP). Min/Maj-Noise: CBF increases while listening to the same tone pairs, but with the instruction to press a button if they formed a minor interval. Increases were seen within posterior DL frontal cortex in both groups, consistent with the hypothesis that these activations are related to retrieving conditional associations between particular auditory stimuli [pitches (AP) or the ratio of two pitches (AP or RP)] and verbal labels (note or interval names) (reproduced with permission from Zatorre *et al.*, 1998).

and a *relative* pitch stimulus attribute (the ratio of the fundamental frequencies of the tones making up a pair), an association learned by both groups as part of their conservatory training.

III. MUSICAL MEMORY

As in other cognitive domains, memory functions of several distinct types support musical processing and

behavior. Since music is inherently extended across time, music perception demands an ability to retain sounds temporarily in memory, either passively, as in short term or "echoic" auditory memory, or actively as the contents of auditory working memory. Other cognitive operations can then be applied to these contents. If sufficiently encoded, they may become part of long-term episodic memory, consciously recallable along with the original context ("They're playing our song"). Procedural memories for musical information, and for the motor movements to produce them, may also be formed even without conscious awareness ("What's that tune I'm whistling?").

A. Sensory Short-Term Retention

Zatorre and Samson presented a task to temporal lobectomy patients in which they compared the pitch of two tones across a silent interval. Neither right- nor left-sided excisions resulted in impairment on this task. Although more posterior excisions or longer retention intervals might result in deficits in short-term retention of pitch, these results indicate that unilateral lesions involving the primary auditory region did not impair brief sensory retention.

B. Auditory Working Memory/Imagery

In a second condition of the same experiment, Zatorre and Samson presented patients with the same task, but with the retention interval filled by interfering tones. The right temporal lobe patients were impaired in this version of the task, regardless of whether Heschl's gyrus was involved. A group of patients with right frontal lobectomies were similarly impaired. Although the laterality of the frontal effect could not be assessed, the right temporal lobe effect was clear-cut and indicated a critical role in auditory working memory for secondary auditory cortex in the right hemisphere.

David Perry carried out a study of ear-of-presentation asymmetry (a small behavioral effect presumed to result from predominance of the contralateral ascending auditory pathway) for the subsequent recall of melodies by experienced pianists who replayed them on a computer-interfaced keyboard. The interval between the end of the melody and the beginning of attempts at keyboard reproduction was recorded. During this interval, most subjects reported mentally resinging and rehearsing their memory of the melody before beginning to play. A right ear asymmetry was observed in sequence recall accuracy. Furthermore, an asymmetry was observed in this delay interval that was positively correlated with that in accuracy, such that the delay between stimulus and response (lasting several seconds on average) was longer after presentation to the preferred ear.

This asymmetry in an interval associated with internal rehearsal of just heard information by "inner singing" suggested the possibility of an asymmetry in the neural substrate for *auditory–tonal working memory*, conceived of by analogy to Alan Baddeley's "phonological loop." Just as inner speech can serve to refresh the contents of a specialized auditory–verbal store (as when remembering a just heard phone number), so too inner singing (based on vocal fundamental frequency control rather than articulatory control processes) can refresh the contents of a specialized tonal store through the functioning of the "tonal loop" (Fig. 3). It is possible that for instrumentalists "inner playing" might also be utilized as an internal rehearsal strategy, although whether mental

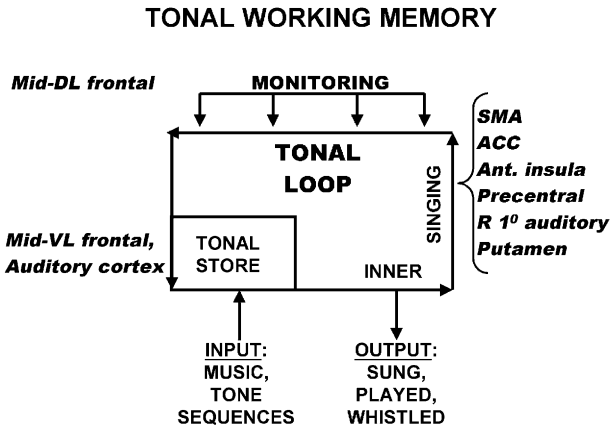

Figure 3 Tonal working memory. Tonal loop model of auditory–tonal working memory based on the phonological loop model of Alan Baddeley for auditory–verbal working memory. Music or nonmusical tonal information is first held in a time-limited tonal store, whose proposed neural substrate includes auditory cortex and mid-ventrolateral (VL) frontal cortex. The contents of this store can be refreshed and held on-line through inner rehearsal (e.g., "inner singing") based on vocal fundamental frequency control processes (rather than on articulatory control processes as proposed for inner speech by Baddeley). Inner or imagined singing is proposed to depend on most of the areas active during actual singing. The supplementary motor area (SMA) is particularly strongly associated with imagined singing. Finally, the contents of working memory may be consciously monitored, e.g., to update an ongoing record of events or actions, an executive working memory function for which the mid-dorsolateral frontal cortex is critical (adapted with permission from Marin and Perry, 1999).

motoric rehearsal and its associated auditory image can be fully dissociated from inner singing remains an empirical question.

Based on their studies of anatomical projections in the macaque brain between the frontal lobe and posterior sensory association cortex, Deepak Pandya and associates hypothesized that retention of *auditory* information might involve specific temporal–frontal projections, just as Patricia Goldman and colleagues had proposed for *visuospatial* retention and parietal–frontal projections.

Based on a long series of behavioral lesion analyses in nonhuman primates and further analyses of posterior association cortex–frontal projections, one of Pandya's associates, Michael Petrides, has articulated a hierarchical theory of frontal contributions to mnemonic processing. Petrides proposes that each major sensory modality represented in the posterior association cortices (auditory, visual–spatia1, visual–object, and somatosensory) projects, with some degree of topographical specificity, to each of several frontal lobe cortical regions critical for distinct executive functions. As mentioned in the discussion of absolute pitch, the posterior dorsolateral frontal cortex is proposed to play a role in conditional associative learning, one higher order frontal lobe memory function.

First in the hierarchy of proposed frontal lobe contributions, ventrolateral frontal cortex is hypothesized to be critical for the repetition, selection, comparison, and judgment of stimuli held in working memory. Auditory cortex may be sufficient for the passive retention of tonal information, but ventrolateral frontal cortex may be required for any form of more active maintenance. Furthermore, as suggested by the patient study of Zatorre and Samson and the asymmetry in the aforementioned rehearsal intervals, there may be a complementary right hemispheric asymmetry in frontal as well as temporal cortical contributions to pitch processing.

In a PET experiment inspired in part by the lesion analysis of pitch retention described previously, Zatorre presented eight-note melodies and instructed subjects to simply listen or to compare the pitch of either the first and the second notes or the first and final notes. The melody perception condition was discussed previously. When the two-note condition was contrasted to melody perception, frontal activation was observed in right frontopolar cortex. For comparison of the first–last pitch vs perception, additional increases were observed bilaterally in both ventrolateral and mid-dorsolateral frontal cortex, and there was also an increase in the right middle temporal gyrus.

Thus, only in the first–last condition was activation seen in the frontal regions predicted by Petrides' model of frontal lobe contributions to working memory. The two-note comparison, despite the fact that it requires judgment of pitch direction, was designed to make minimal demands on active maintenance of pitch information, which may not have been sufficient, particularly in contrast to melody perception, to result in measurable ventrolateral frontal activation. However, the first–last condition requires maintenance of the first pitch across interfering tones and then comparison to the last pitch. Since all the tones in the melody are related, it may not be possible to hold one tone in mind and simply ignore the rest. If subjects hold the entire sequence briefly in mind and compare the first and last tones mentally, then they are monitoring the contents of their working memory store. In a sense, this task thus resembles the *n*-back tasks, in which subjects are asked to compare the current item to one *n* items back, which have been demonstrated to activate mid-dorsolateral frontal cortex just as the self-ordered tasks do. Therefore, activation of both stages of Petrides' model by the first–last eight-note melody task is consistent with the task demands.

In a PET study designed to isolate the "monitoring" component of auditory–tonal working memory, Perry, Petrides, and Zatorre presented subjects with two tasks requiring them to monitor the contents of working memory. In a self-ordered condition, subjects were asked to sing six-tone sequences composed of two pitches by choosing each at random until a sequence with an equal number of both pitches was completed. In an externally ordered condition, they listened to five-tone sequences and sang the final pitch such that the sequences again had an equivalent number of high and low pitches. Both conditions were contrasted to a sensorimotor control involving singing a single pitch at the same rate. Increases were observed in both mid-dorsolateral and ventrolateral frontal cortex (Fig. 4), consistent with Petrides' two-level hypothesis of frontal lobe contributions to working memory that emphasizes the role of projections between mid-dorsolateral and mid-dorsolateral frontal cortex in monitoring. The activations within mid-dorsolateral frontal cortex were both greater in the right hemisphere, whereas no consistent asymmetry was observed within ventrolateral frontal cortex.

The portion of ventrolateral frontal cortex activated was actually deep within the upper bank of the horizontal ramus of the Sylvian fissure, part of cortical area 45 according to recent cytoarchitectonic analyses of this region of human frontal cortex by Petrides and

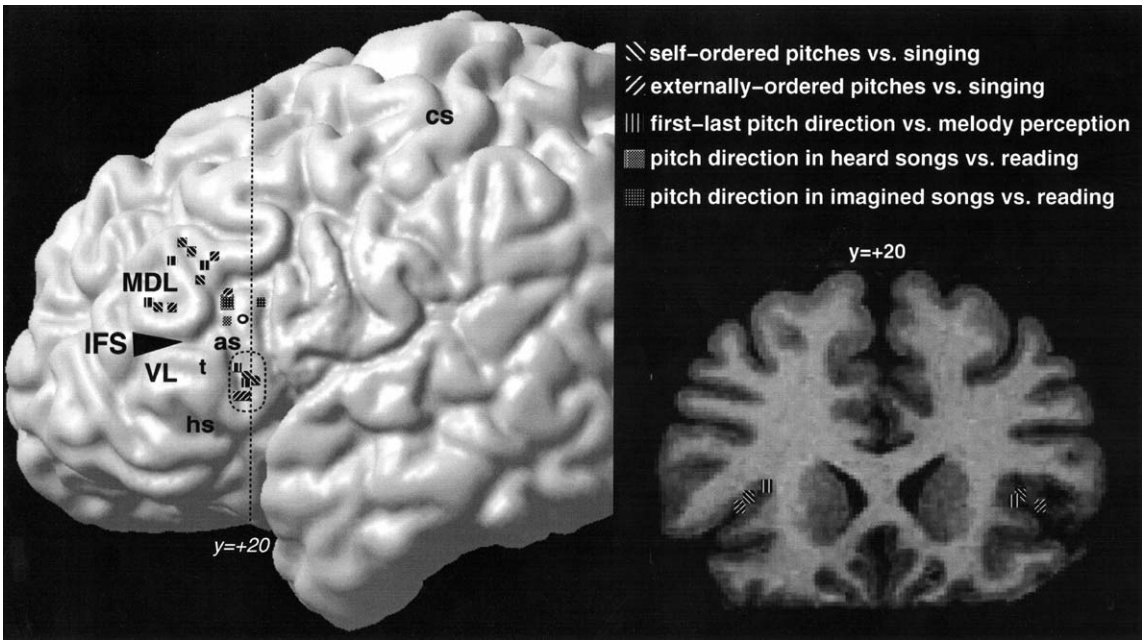

Figure 4 Mid-dorsolateral and mid-ventrolateral frontal activation during musical tonal working memory tasks. The coordinates of peaks of activation from three PET studies of rCBF changes during tasks involving working memory for musical tones. All data are group averaged and transformed into a common proportional stereotaxic space (i.e., Taillarach and Tournoux). (Left) The coordinates are plotted onto one hemisphere of a surface reconstruction of a similarly transformed normal brain chosen at random from the Montreal Neurological Institute database. All foci are displayed on the surface of the left hemisphere by projecting a line perpendicular to the ac–pc line until it meets the cortical surface. The black arrowhead marks the inferior frontal sulcus (IFS) that separates mid-dorsolateral frontal cortex (MDL), or cytoarchitectonic areas 46 and 9/46 in the nomenclature of Petrides and Pandya, from ventrolateral frontal cortex (VL), or areas 45 (pars triangularis; t), 47/12, and 44 (pars opercularis; o). The ascending sulcus (as) that forms the border between the pars triangularis and opercularis and the horizontal sulcus (hs), which branches from the end of the Sylvian fissure, are also indicated, as is the central sulcus (cs). Note that the self-ordered and externally ordered "monitoring" tasks and the first–last note judgment of pitch direction within melodies all resulted in highly overlapping sets of foci within MDL frontal cortex. All require maintaining and examining a mental record of recent events (i.e., tones). In contrast, the tasks involving pitch direction judgments within familiar songs, either heard or imagined, resulted in more ventral foci that fell in or just below the IFS within the pars opercularis or area 44. Finally, the monitoring tasks also resulted in a highly circumscribed and overlapping area of activation within the depth of the upper bank and fundus of the horizontal sulcus, part of area 45. The dotted circle around these foci serves to emphasize the fact that these foci are located deep to the cortical surface. The dotted line indicates the plane of the adjacent MRI slice. (Right) Coronal slice through the portion of sulcal area 45 with the coordinates of regional peaks of CBF increase marked by crosses. All foci fell within ± 2 mm along the y axis from the slice depicted [Perry *et al*., 1993; Zatorre *et al.*, 1994, 1996].

Pandya. Their localization accords precisely with the frontal opercular peaks observed by Zatorre in the first–last condition vs melody perception (Fig. 4) and in the first–last vs two-note in a later reanalysis.

Further evidence comes from another study by Perry, Zatorre, and Petrides designed to measure CBF during the simple operation of the tonal loop with no monitoring requirements. Subjects listened to two-note sequences drawn from a major scale, followed by a silent interval twice as long as the stimulus. In one condition they listened with no task imposed. In contrast to a silent baseline, this condition resulted in activation of right ventrolateral cortex as well as bilateral auditory cortex, more extensively in the right posterior temporal plane. The portion of ventrolateral cortex activated was also within the upper bank of the horizontal sulcus but near the lateral surface. Petrides and colleagues noted a similar distinction within the same region associated with auditory–verbal memory tasks (i.e., more lateral foci for simple verbal repetition vs rest, and more medial foci for free recall vs repetition). This simple and basic musical task thus activated the basic substrate proposed for the first stage of frontal executive processes in auditory–tonal working memory with a clear-cut right hemisphere asymmetry in both temporal and ventrolateral activations.

In order to measure activation during inner singing, or the covert rehearsal component of the tonal loop,

subjects were asked to immediately repeat the two tones once either was "in their head." The imaged condition, when contrasted to listening, resulted in activation of motor cortical areas, including the supplementary motor area and the right putamen —areas proposed to form part of the network supporting vocal fundamental frequency control and thus the rehearsal component of the tonal loop.

Robert Zatorre, Andrea Halpern, and David Perry examined CBF increases during a more complex task involving imagery for familiar songs with lyrics. Subjects were given two words and asked to judge whether the pitch associated with the second was higher or lower than the first. They either replayed the songs in their "mind's ear" until able to make the comparison or listened to a recorded rendition. In order to perform the imaged task, subjects had to play out the song in their minds in real time, as Andrea Halpern demonstrated by varying the distance between the two words in the song and examining reaction times. Both tasks activated very similar regions bilaterally in the temporal and frontal lobes, in the supplementary motor area (pre-SMA), and in the left supramarginal gyrus (Figs. 5.I–5.III). Their bilateral nature is in keeping with the integration of lyrics and tune in song representations, and the specific regions activated are consistent with the task's demands (i.e., the superior temporal gyri and lateral frontal cortex due to the involvement of both auditory–tonal and auditory–verbal working memory).

The foci of frontal activations fell in lateral frontal cortex just below or within the inferior frontal sulcus (Fig. 4) and thus in ventrolateral rather than mid-dorsolateral frontal cortex as did those during the similar first–last pitch comparison within novel melodies. Because the songs were very familiar, no record of events, mental or actual, needed to be kept. Ventrolateral frontal cortex activation is clearly predicted by Petrides' model due to the requirement to make a judgment on stimuli held in working memory (i.e., of pitch direction).

Activation of the superior temporal gyrus was of course much greater in the song perception condition but was nevertheless observed, exclusively within auditory association cortex, during song imagery without any auditory stimulation.

The common activation of SMA by both the perceptual and imaged task variants may be due to the fact that subjects were still at least partially "singing along" mentally with the presented song in order to disentangle the normally integrated representation of lyrics and melody in familiar songs.

Activation unique to imagery was seen in frontopolar cortex bilaterally, in subcallosal cingulate cortex, and in the right thalamus, possibly due to the retrieval demands of the imagery task (Fig. 5.IV).

In a recent study, Halpern and Zatorre measured CBF changes during tasks based on imagining well-known lyricless tunes, cued by the first few notes. When cued tune imagery was contrasted to hearing a random permutation of the five-note cue, activations were seen in the right superior and inferior temporal gyri, left sulcal 45, bilateral mid-dorsolateral frontal cortex, bilateral precentral gyri, anterior cingulate and the SMA. Of these areas, only the SMA and precentral gyri were activated during imaging of the random control sequence vs hearing it, without cued melody retrieval.

The activation of mid-dorsolateral and -ventrolateral frontal cortex by cued recall is consistent with the results of studies in other informational domains. The lack of ventrolateral frontal cortex activation during recall of the random sequence may be due to the fact that the contrasted condition (listening to the same sequences) also activated ventrolateral cortex, just as listening to two-note musical sequences did in contrast to silence.

All three studies of musical imagery demonstrated activation of the SMA, a motor area also active during singing out loud. This accords well with the proposed inner singing component of the tonal loop. It remains to be demonstrated whether auditory imagery for less clearly vocalizable sounds will also activate SMA. However, for imagery of melody, song, or musical intervals, inner singing and hence activation of SMA and other motor areas associated with vocal motor control may be obligatory. Thus, a remaining question concerns the dissociability of auditory imagery from inner vocalization.

C. Long-Term or Episodic Memory

After being thoroughly encoded, and perhaps after many repetitions, musical information may be stored in long-term memory so that it can be consciously retrieved even after it has been erased from the contents of working memory. For example, a melody may be consciously retrieved ("What is the theme to 'The Lone Ranger' or the 'William Tell Overture'?"), as may memorable instances or episodes of hearing it.

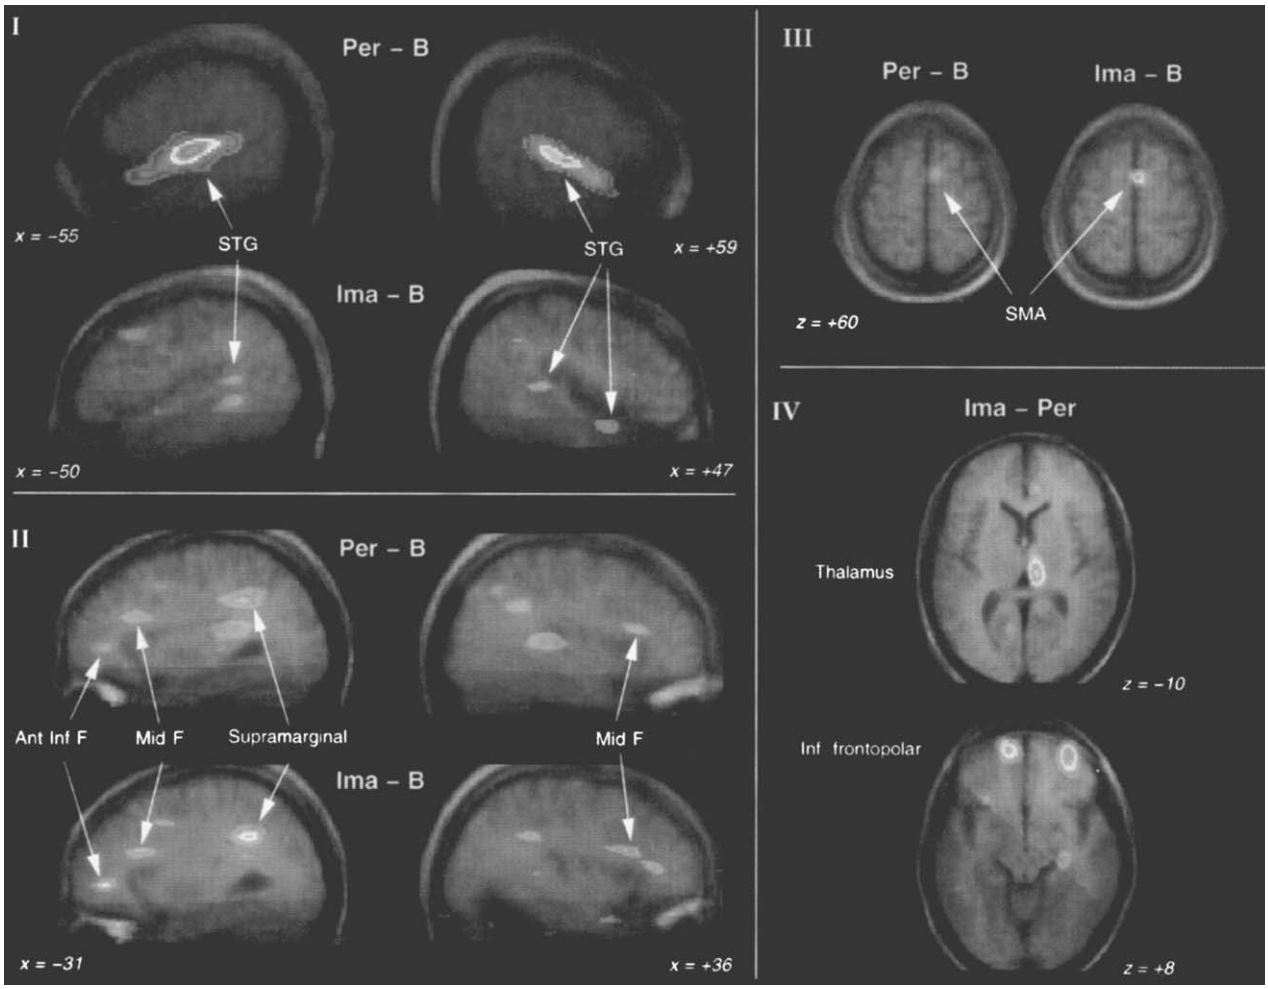

Figure 5 Pitch direction judgments within perceived or imaged songs. CBF increases during pitch comparisons between two notes within familiar songs, cued by the presentation of two words from their lyrics. Both conditions were contrasted to a visual baseline consisting of reading similar words. In the imagery (Ima) condition, subjects had to replay the song mentally, whereas in the perception (Per) condition they heard a recorded rendition. (I) Left and right saggital views through peaks in the superior temporal gyri. Although much less robust, activation similar to actual perception was observed during song imagery in secondary auditory cortices, with no auditory stimulation. (II) Left and right saggital sections through frontal lobe foci. The overall patterns of activation are strikingly similar for perception and imagery and include activation in mid-dorsolateral frontal cortex, consistent with the monitoring demands of this task. (III) CBF increases within the supplementary motor area (SMA), believed to be associated with inner singing, are more robust during imagery. (IV) Increases during imagery in contrast to perception. Foci are in the right thalamus and bilateral frontopolar cortex (reproduced with permission from Zatorre *et al.*, 1996).

The formation of long-term memories has been extensively studied, and general mechanisms, such as the critical importance of entorhinal cortex in the formation of new long-term memories, must be common to music. However, little work of specific musical relevance has been carried out. Important observations from the cognitive study of memory for melody, such as the greater importance of exact interval information in long-term memory for melody as opposed to the predominance of contour in short-term recall, will no doubt inform the design of such experiments.

D. Procedural Memory

Procedural or implicit memories can also be formed without conscious awareness. Their effects can be detected in facilitated responses to primed stimuli. The chord priming paradigm developed by Jamshed

Bharhucha has been used to test an auditory agnosic, and the results suggest that this sort of priming depends on secondary rather than primary auditory cortex. Procedural learning can also be demonstrated in melodic paradigms, in which previous exposure to a tone sequence can prime choices for its completion later without conscious awareness of having heard it before. The neural bases underlying the formation and retrieval of such procedural memories have not been explored in specifically musical contexts. Procedural learning is ubiquitous in music perception and in music production. A full understanding of how the human brain processes and produces music will depend in part on further studies in this area.

E. Lexical–Semantic or Cultural Memory

Musical stimuli are often associated with linguistic labels. In the PET study of musicians with absolute pitch, the association of verbal labels (note names) with musical pitches was hypothesized to depend in part on left dorsolateral frontal cortex, as was the association of the names of musical intervals (e.g., major/minor third) with pairs of tones whose frequencies formed the same ratio. Many other types of verbal labels are associated with musical sounds: the names of melodies, songs, or pieces; composers; styles; and specific musical elements or functions (e.g., eighth note and decrescendo). Amusias following focal damage or dementia may sometimes be confined to the loss of the ability to retrieve such verbal associations, particularly following left hemisphere damage.

IV. MUSICAL EXPRESSION

In order to perceive music, someone must first produce it. Although computer-generated music can be highly abstract, most music is played on an instrument, sung, or possibly whistled. These are fundamentally motoric functions. What makes them uniquely musical, besides the high level of skill embodied in virtuoso performance, is the fact that the end result is musical sound, and an exquisite degree of sensorimotor integration (and attention to auditory feedback) is required.

Two levels of motor nervous system functioning relevant to musical expression are discussed next: motor productive, or the basic aspects of motor control necessary to produce musical sounds, and motor programmative, or the cortical control required to produce these sounds and the movements that engender them in sequences of varying length and complexity, from single notes to complex pieces 1 hr or more in length.

A. Motor Productive

Probably the most fundamental musical motor activity is singing. Perry, Zatorre, Petrides, and associates measured increased CBF during simple singing using PET. Repetitive singing of a single pitch was contrasted with listening to complex tones at the same pitch and rate. The set of regions activated overlapped those previously observed during speech (SMA, anterior cingulate, insula/frontal operculum, and precentral gyrus) (Fig. 6). The main differences were in the direction of hemisphere asymmetry within a subset of these regions. First, the CBF increase was much greater in the right primary auditory region, a result that Perry and Zatorre later replicated for singing a single pitch continuously on each breath in contrast to listening to playback of that singing. They hypothesized that this asymmetry may be related to deriving the fundamental frequency of one's own voice for feedback guidance of vocal motor production (given a right auditory cortex preference for spectral analysis).

This hypothesis received support from a subsequent analysis. The fundamental frequency of subjects' vocalizations was measured. When the total amount of pitch excursion within each continuously sung note was quantified and covaried against CBF in the whole brain, a region of positive covariation was observed in the right primary auditory region.

Second, though less striking, an asymmetry favoring the right hemisphere was also observed within the right ventral precentral gyrus or the orofacial region. The close correspondence between the regions activated by singing and speaking suggests that both may have evolved from a complex system for the voluntary control of vocalization. Their divergences suggest the later evolution of complementary hemispheric specializations for both the perception and production of singing and speech.

An incredible variety of musical instruments have been developed by human cultures, our knowledge of which begins with 5000-year-old Neanderthal flutes made from bone. The proliferation of wind, string, percussive, and other instruments for the production of musical sound is ongoing, and the basic aspects of motor control required vary from purely labial and respiratory (e.g., bugle) to labial, respiratory, and manual (e.g., trumpet) or purely manual (e.g., violin and piano). Although peripheral aspects of this motor

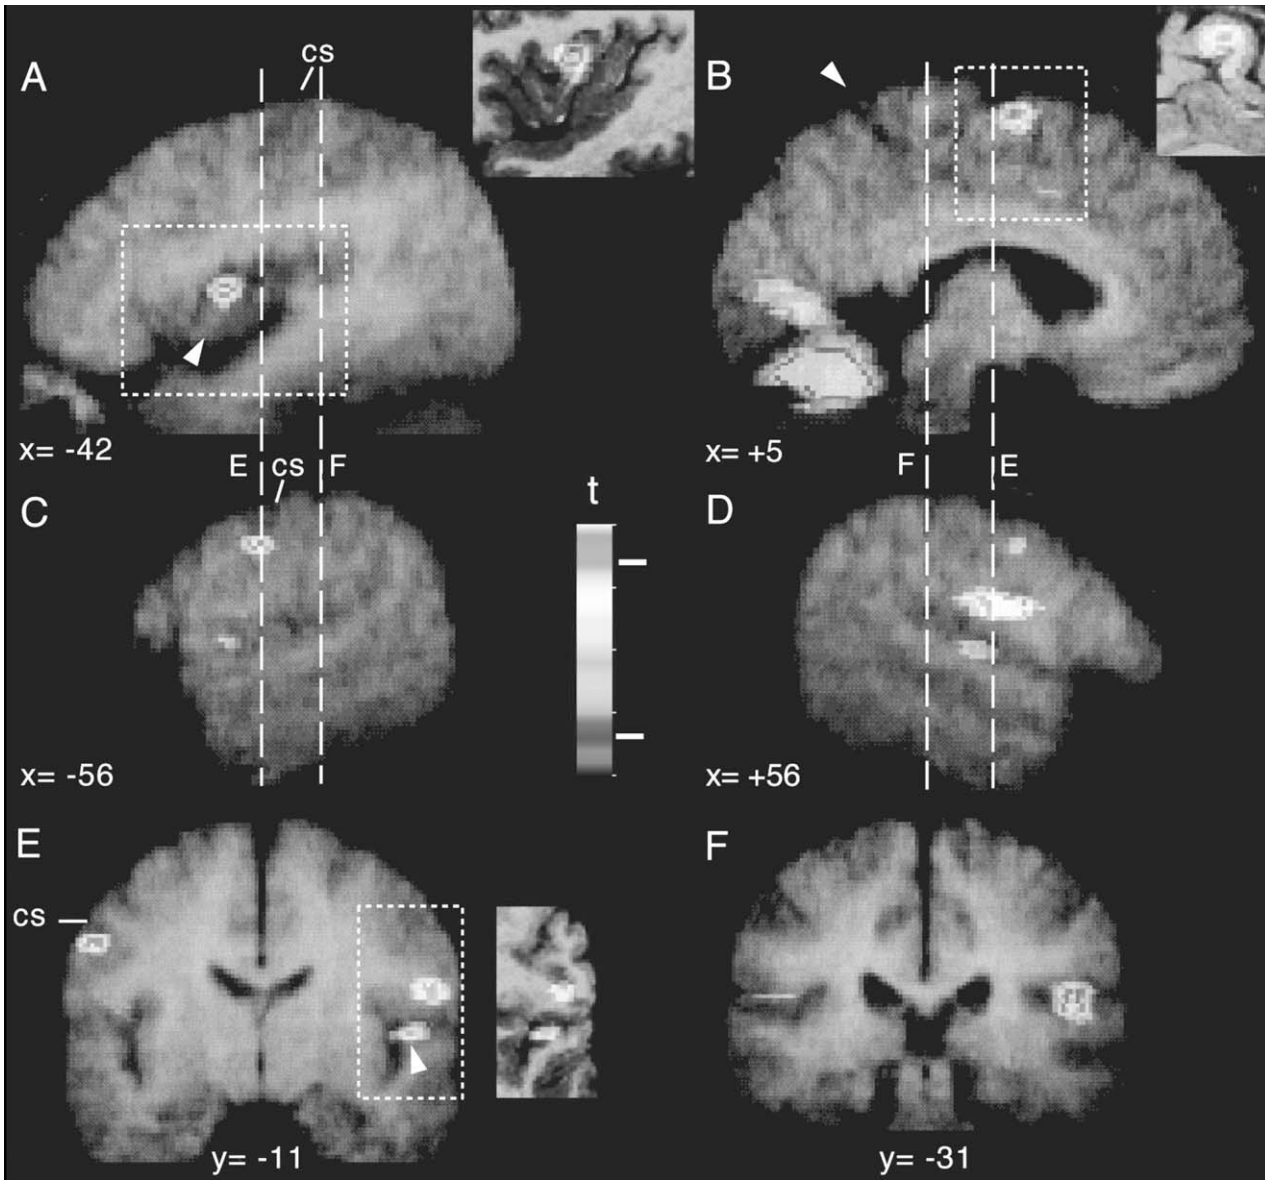

Figure 6 Localization of cerebral activity during singing. Peaks of CBF during repetitive singing of a single pitch on the vowel /a/ at a rate of about 1250 msec as measured with PET. Saggital (A–D) and coronal (E and F) slices from the mean CBF change t-statistic volume superimposed on the averaged MRI in Taillarach coordinates from a group of 13 nonmusician subjects. In critical regions, the same rCBF data are shown superimposed on an individual MRI in order to view their relationship to sulci not clearly visible in the group average. The dotted rectangles in slices A, B, and E correspond to the regions depicted in the individual MRI offset to the right. Peaks were observed as follows: (A) in the first long gyrus (precentral) of the insula, also critical for motor speech; (B) (from top to bottom) the supplementary motor area, anterior cingulate sulcus (note the marginal ramus of the cingulate sulcus; arrowhead), visual cortex activation that is part of a right lingual peak, and cerebellar activation coextensive with more lateral peaks; (C) relatively dorsal left central sulcus (note the position of the central sulcus at the dorsal edge of the slice and in the more medial slice A) (also visible is the lateral extension of the insular peak seen in A); (D) dorsal and ventral right central sulcus—the activated voxels just below the Sylvian fissure extend from the more medial peak in Heschl's gyrus; (E) right Heschl's gyrus (position indicated by the arrowhead and more clearly visible on the individual MRI), dorsal left central sulcus (seen also in C), and ventral right central sulcus (also seen in D); (F) right superior temporal plane (STP) and the overlying right parietal operculum and the left parietal operculum (reproduced with permission from Perry *et al.*, 1999).

control have been studied for many years (e.g., the work of Otto Ortmann on piano performance), study of the cortical control required in specifically musical contexts is sparse. A few studies have utilized computer-interfaced piano keyboards to study piano performance by musicians, the cortical control of sequential finger movements in nonmusicians, or the production of rhythms using a single computer key as if it were a piano key. The simplest sequences studied were repetitive, isochronous presses of a single key. In contrast to the vocal studies mentioned previously, in several of these studies no sound was produced. Although the behaviors are thus not fully musical, they allow separation of motor control from the auditory–motor integrative aspects.

Penhune and Zatorre measured CBF increases during the reproduction of an isochronous sequence (cued either visually or auditorily) on a single computer key using the right hand, in contrast to perception of the cue alone. Common areas of activation were seen in the contralateral somatomotor cortex, basal ganglia, and ipsilateral cerebellum. Activation in the SMA was also seen, but only for the auditorily cued condition. In a similar auditorily cued task, Stephen Rao and colleagues used functional MRI to examine CBF as subjects continued tapping a key at a fixed rate with the right hand. Increases were seen in the same areas: contralateral somatomotor cortex, basal ganglia, ipsilateral cerebellum, and SMA.

These studies illustrate the cortical areas involved in the control of manual motor output in a quasi-musical context, consistent with what would be expected for timed manual movements in general. These areas are similar to those seen during isochronous, isofrequency vocal motor output, except that processing of auditory feedback is excluded and somatosensory feedback is emphasized.

B. Motor Learning

Even the simple acts of motor production described previously (e.g., singing an isochronous series of a single pitch or tapping an isochronous sequence on a single key) require the execution of a learned motor program or an integrated sequence of movements. More complex sequences that follow a precise temporal plan and involve multiple vocal or instrumental pitches and variable timing and intensity are integral to musical expression. Such sequential movements performed as a unit require advance programming prior to their execution.

In the experiment discussed previously (see Section III.B), Perry, Zatorre, and Petrides asked their subjects to listen to a two-note sequence drawn from a major scale and either imagine it in their heads, or hum it out loud. When they hummed out loud, in contrast to just listening to the sequences, activation was seen not only in motor cortex, SMA, and the right putamen as seen during imaging but also in the left putamen, cerebellum, right primary auditory region, and more extensively in motor cortex bilaterally. Thus, this simple act of musical motor programming activated the same areas thought to be involved in the execution of movement sequences generally (i.e., primary and premotor cortex, SMA, basal ganglia, and the cerebellum).

The SMA activation fell anterior to that seen during simple, repetitive singing of a single pitch. Rather than falling in "SMA proper," as defined by Nathalie Picard and Peter Strick in their cross-species neuroanatomical analysis, it fell in pre-SMA, a cortical area thought to be important for producing organized sequences of movements. Thus, more complex sequential singing resulted in additional activation of premotor cortex, pre-SMA, and the basal ganglia (putamen).

Justine Sergent and associates carried out a study of right-handed piano performance using PET. When playing a scale was contrasted to listening to scales, CBF increases were seen in contralateral primary motor cortex, SMA proper, and the ipsilateral cerebellum.When sight-reading an unfamiliar Bach melody was contrasted to reading a score of it while listening to a recorded performance, additional activation was seen in contralateral premotor cortex and in pre-SMA. Although the increase in motor programming complexity between playing scales and sight-reading a melody would seem to be much greater than that between singing a single pitch and singing two-note sequences, the results are highly similar. Both comparisons emphasize the activation of premotor cortex and pre-SMA during the expression of more complex and variable motor programs.

Although these two studies measured actual musical expression, few others have done so. However, others have studied quasi-musical tasks helpful for isolating components of musical expression.

In the study of rhythm production described in Section IV.A, Penhune and Zatorre asked subjects to reproduce sequences with elements of variable durations, either short (250 msec) or long (750 msec), again cued either visually or auditorily. In one condition, subjects reproduced a previously learned sequence

repetitively. When contrasted to the isochronous condition, additional activation during sequence reproduction was seen in the cerebellum and in the contralateral primary motor cortex only for the visually cued condition. In another condition, they reproduced novel sequences. In contrast to the repeated sequence condition, additional activation was seen across tasks in the cerebellar vermis and bilaterally in the cerebellar hemispheres. Additional activation was seen in pre-SMA and the basal ganglia for the auditory condition only.

At least for the auditorily cued condition, these results for rhythm production parallel those described previously for singing and piano performance: activation of SMA proper for simple, predictable movements and of pre-SMA for more complex and less predictable movement sequences. The activation of the basal ganglia by the task placing more demands on motor programming and execution is also consistent for both the vocal pitch and manual rhythm reproduction tasks.

Christian Gerloff and associates used repetitive trains of transcranial magnetic stimulation (TMS) that temporarily disrupt neural activity to examine its effects on the performance of finger sebquences on a (silent) piano keyboard. The sequences differed in complexity, and TMS was applied over the contralateral primary motor cortex or over the SMA. Subjects thoroughly learned the 16-item sequences first. The simplest sequence consisted of 16 repeated index finger presses of a single key; a scale-like sequence consisted of alternating 4-item ascending and descending subsequences; and the most complex was a variable 16-item sequence. Stimulation over the primary motor cortex induced errors in both the complex and scale-like sequences and, with sufficient intensity, in the simple repetitive sequence. Stimulation over the SMA disrupted only the complex sequence.

These TMS results are consistent with activation studies that demonstrated increased activation of primary motor cortex and pre-SMA with increased demands for motor sequence planning. Although the role of primary motor cortex was once thought to be restricted to the execution of simple voluntary movements by individual muscles, increasing evidence indicates its involvement in the learning and execution of more complex movement sequences.

Norihiro Sadato and colleagues measured CBF increases during the execution of sequential finger movements (touching fingers to thumb) of varying complexity using PET. Each sequence (4–16 items) was thoroughly learned before the PET scan, and the rate was determined by following a metronome. Activation in one set of motor-related areas did not vary with the complexity of the sequences: bilateral primary sensorimotor cortex, contralateral ventral premotor cortex, SMA proper, contralateral putamen, and ipsilateral cerebellum. Four areas showed a linear increase in CBF with increasing sequence length: right dorsal premotor cortex, right superior parietal cortex, left thalamus, and the cerebellar vermis. The association of sequence complexity with premotor cortex activation agrees with results of subtractive studies mentioned previously. However, the basal ganglia were activated equivalently by all tasks and activation of pre-SMA was not demonstrated.

Subtle differences in task and experimental design are well-known to affect the outcome of imaging studies, and major differences exist between all these tasks. For example, Sadato's study required synchronization with an auditory metronome, perhaps resulting in activation of the basal ganglia across tasks. Future studies systematically varying such task parameters will further our understanding of the roles of each of these areas in movement sequencing.

Precise programs for movement sequences must first be learned. Then they can be retrieved and executed as one unit. Some studies have attempted to minimize learning by having subjects thoroughly learn the sequences beforehand (e.g., Gerloff, Sadato). Obviously, study of the brain mechanisms supporting learning as well as retrieval and execution of complex motor sequences that produce musical sound is central to a biological understanding of musical behaviors.

One study used TMS in a very different manner to investigate cortical changes associated with learning a motor sequence on a piano keyboard with auditory feedback. Alvaro Pascual-Leone and colleagues repeatedly mapped the contralateral motor cortex over a 5-day period during which subjects practiced a simple five-finger exercise on a computer-interfaced piano keyboard. They learned to play a 10-item scale-like sequence consisting of 5 ascending and 5 descending elements, with the goal of playing it evenly at a specified rate. None had any musical instrument-playing experience. Thresholds for the production of motor evoked potentials (MEPs) in response to single TMS bursts were measured from the contralateral hand (flexor and extensor muscles). Contour maps of the probability of inducing MEPs demonstrated increases in the cortical motor areas targeting the practiced hand and decreases in threshold. No such changes were seen for the untrained hand, and only modest gains were seen for subjects who simply played the piano at will for the same length of time (Fig. 7).

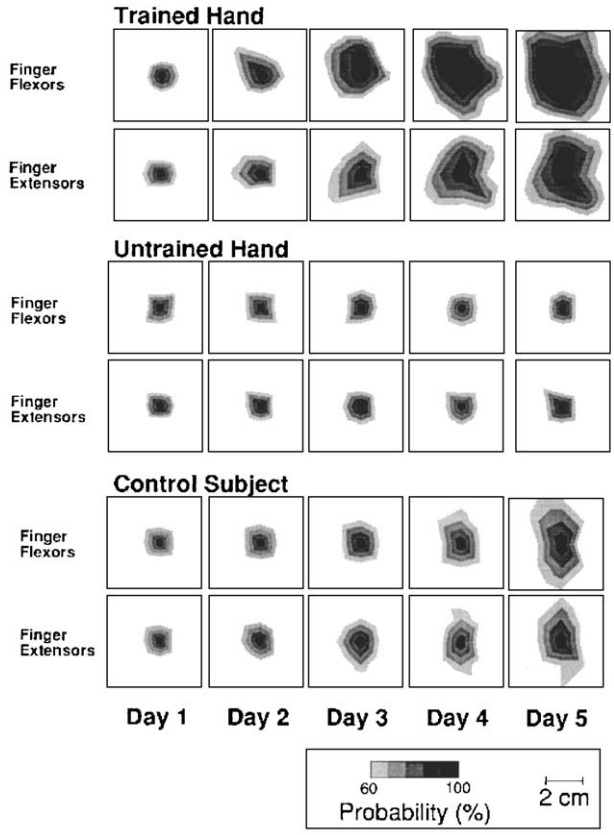

Figure 7 Piano exercise learning, trained vs untrained hand. Representative examples of cortical motor output maps for the long finger flexor and extensor muscles on Days 1–5 from a subject who practiced 2 hr/day (trained right and untrained left hand) and from one control subject who played random sequences for the same amount of time (trained right hand) (reproduced with permission from Pascual-Leone *et al.*, 1995).

Other functional imaging studies of motor sequence learning are less directly related to musical expression. Nevertheless, they are relevant for understanding the motor sequence learning component, isolated from sound production. Though complex, the results suggest an expansion of the representation of the involved fingers within primary motor cortex. A. Karni and colleagues asked subjects to learn a particular sequence of finger-to-thumb opposition movements (e.g., 4–1–3–2–4) for 10–12 min a day over the course of 5 weeks. Once a week, cortical activity was measured during performance of the practiced sequence and during performance of an unpracticed sequence (e.g., 4–2–3–1–4) with fMRI.

After 3 weeks of practice, the extent of primary motor cortex activated by the learned sequence was greater than that activated by the unpracticed one. When retested several months later, the skill and the increased extent of motor cortex activation persisted. Because the same fingers were used in both sequences, this increase is not in the cortical representation of particular fingers but in the representation of a particular sequential combination of finger movements.

William James' speculations regarding the brain mechanism underlying memory as "paths" within the brain's tissue can be applied not only to melodic memory but also to memory for the movement sequences used to produce them (i.e., as paths within somatotopically ordered cortical areas).

Other studies have shown activation of cerebellum, basal ganglia, thalamus, and dorsolateral frontal cortex during skill learning, decreasing with increasing acquisition. Plateaus in the increased activation within motor cortex during skill learning have been demonstrated, as have decreases after complete acquisition. The precise contributions of cortical and subcortical areas, including the basal ganglia, to the execution, learning, and retrieval of movement sequences remain controversial and a subject of active research.

Movement sequence learning in the service of musical expression adds further complexity by introducing the production of musical sound as the ultimate goal. It also introduces the possibility of sampling across wide variations in the degree of skill acquisition.

Extending his previous research, Pascual-Leone used single pulses of TMS and measurement of the consequent MEPs to map changes in cortical output maps during implicit and explicit sequence learning. Subjects rested four digits over four computer keys and pressed the keys sequentially in response to a visual cue. Unbeknownst to them, these cues corresponded to particular sequences of varying length. Even before becoming aware of this sequence, reaction times progressively declined (implicit learning) and rebounded when the order was changed. During this phase, the cortical motor output map to the involved contralateral muscles increased. Uninvolved muscles (i.e., the thumb) showed no change. After subjects became aware of the sequence, learning could proceed by both implicit and explicit means, and the maps tended to plateau. Finally, once the sequence was fully, explicitly learned and response times plateaued, there was a rapid reduction in the cortical output map toward baseline.

Using a different technique, trains of TMS were used to disrupt learning in the serial reaction time task during 60-sec blocks over dorsolateral frontal cortex

or SMA. The effects of stimulation were inferred from task performance and were also tested during a final random block. Stimulation over the contralateral dorsolateral frontal cortex resulted in a complete disruption of implicit learning, indicating that it is not only activated during such learning but also critical to its success.

Motor sequence learning in musical context is always explicit, at least for the intended auditory result. Nevertheless, simultaneous implicit learning must play a crucial role, particularly for the actual sequence of fingers. Thus, these results are directly relevant to hypotheses for the motor learning underlying musical expression.

C. Motoric Working Memory/Imagery

As many musicians have discovered, musical instrument playing can be rehearsed mentally. For example, in the piano keyboard melody recall task described previously, the pianists reported mentally rehearsing their keyboard recall attempts, not only through inner singing but also through mental simulation of keyboard fingering, prior to actually playing. To investigate the effects of mental practice, Pascual-Leone, in the piano keyboard sequence learning experiment described previously, also studied changes in motor cortical output maps and in performance following 5 days of *mental* practice. Subsequent performance improved steadily across the 5 days, although not as much as after an equivalent amount of physical practice (Fig. 8A). However, the increase in the extent of the cortical motor output maps was the same (Fig. 8B).

Brain imaging studies have demonstrated the activation of many of the same areas during the mental simulation of motor acts as during their overt physical performance (e.g., SMA, premotor cortex, basal ganglia, and sensorimotor cortex). In fact, all these areas were activated when subjects mentally sang musical intervals in the experiment described in Section III.B. However, for *musical* motor tasks, imagined sound output is also involved and in fact constitutes the explicit focus of attention. Activation was also seen in the ventrolateral frontal cortex and the posterior superior temporal sulcus.

In fact, this study, one of the simplest examples of musical expression or imagery, indicates the complexity involved in their study. Both fundamentally involve integrated motoric and auditory representations and the integrated functioning of motoric and auditory

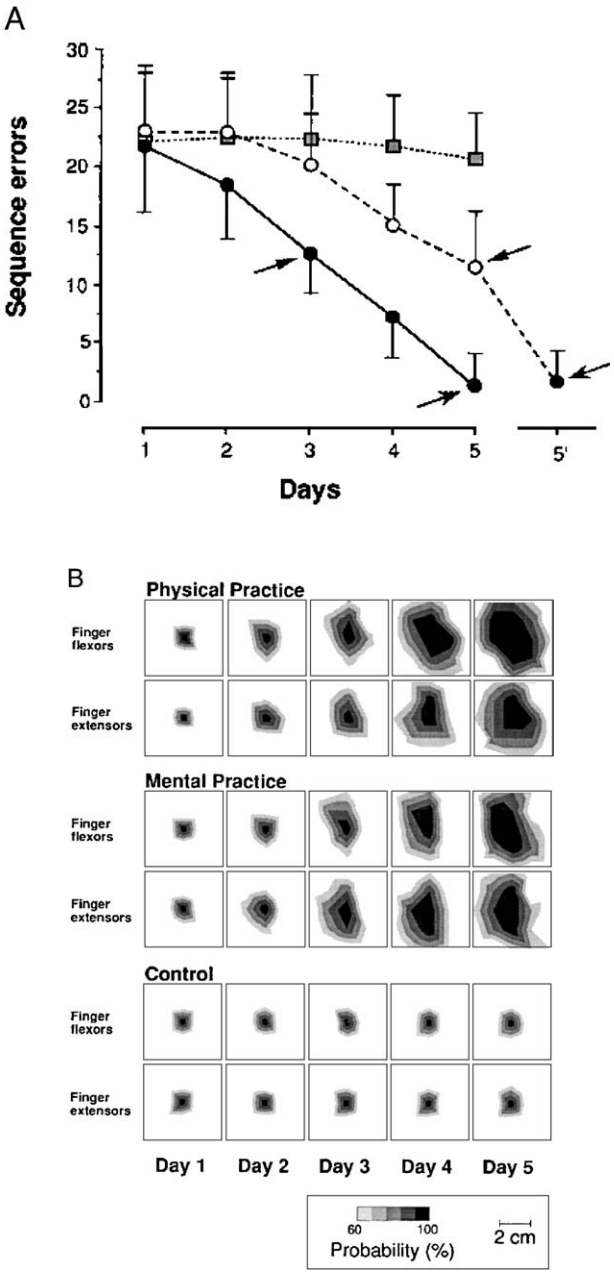

Figure 8 Piano exercise learning, physical vs mental practice. (A) Sequence errors: The number of errors in the order of notes on a posttest of 20 repetitions of the practiced exercise. ●, physical practice group; ○, mental practice group; ■, control group. 5′, in one physical practice session, the mental practice group attained the same performance level as that of the physical practice group. (B) Cortical motor output maps: Representative examples of cortical motor output maps for the long finger flexor and extensor muscles on Days 1–5 from a subject who practiced 2 hr/day, another who practiced mentally (i.e., sat in front of the piano for 2 hr and visualized the fingers performing the exercise while imaging the sound), and a control subject who played random sequences (all for the trained right hand). (reproduced with permission from Pascual-Leone *et al.*, 1995).

working memory systems. Thus, the song and imagery tasks described previously involve not only auditory imagery but also, at least implicitly, motoric simulation. Thus, all three tasks (imaging two-tone musical sequences, melodies, or songs) activated pre-SMA, in contrast to simple singing of a single note or imaging of an overlearned melody, which activated SMA proper.

The musical interval and melody imagery tasks also activated premotor cortex and the superior temporal gyrus—further evidence of simultaneous activity in the motoric and auditory working memory/imagery systems. Further work is needed in order to understand the functioning of each system in isolation as well as the mechanisms that allow their integration in melodic working memory and even in long-term melodic representations.

D. Sensorimotor Integration

One of the most defining characteristics of musical expression is that specific motoric actions produce specific musical sounds (i.e., that motor production and auditory feedback are tightly and, particularly for musical instruments, artificially integrated). Furthermore, somatosensory feedback must also be integrated, guiding motoric actions in order to produce the intended sounds. Finally, at least for playing musical instruments with eyes open, visuospatial feedback may also be closely integrated.

As discussed previously, simple singing of a single pitch or of musical intervals resulted in asymmetric activation of the right primary auditory region—activation that increased with the extent of pitch excursion. Thus, activation of primary auditory cortex in the right hemisphere appears to be particularly associated with auditory feedback from the pitch of one's own singing voice. Future studies, by manipulating feedback, could help to elucidate the neural mechanisms supporting auditory–motor integration in singing and instrument playing. Similar strategies may also shed light on the mechanisms of their further integration with visuospatial and somatosensory feedback.

V. MUSIC READING AND WRITING

Although not essential to musical behavior, many musical cultures have developed systems for graphically specifying musical sounds, intended to be read and studied by potential performers. Thus, musical reading and writing are learned behaviors that can be added to the musical functions described previously (much as linguistic reading and writing can be added to speaking). Like linguistic reading, writing, and speaking, these functions can be differentially affected by focal lesions.

A. Musical Lexical

One brain imaging study has addressed sight-reading. Justine Sargent and associates measured CBF during silent score reading of a Bach chorale and subtracted it from activation during perception of dots (and manual responses to their location). Activation during silent score reading was greater bilaterally in extrastriate visual cortex and in the left occipitoparietal junction. This suggests activity in the dorsal visual pathway, which is involved in spatial processing, as opposed to the ventral visual pathway, important for words. When score reading alone was subtracted from score reading while listening to a recorded rendition, activation was observed not only in auditory cortex bilaterally but also in the left supramarginal gyrus. However, the portion of the supramarginal gyrus activated was superior to that thought to be critical for verbal print-to-sound mapping.

Following brain damage, associations between musical and verbal alexia (or loss of reading ability) have frequently been reported, such as the cases of Bouillaud in 1865 and the French composer Maurice Ravel toward the end of his degenerative brain disorder. However, many cases of dissociation have been reported, including Ravel *earlier* in the course of his illness. Although some cases of selective musical alexia involve the right hemisphere, others involve the left hemisphere. Dissociations and associations may occur following left hemisphere damage, depending on whether adjacent but nonoverlapping critical areas are damaged together or separately.

B. Musical Graphic

Musical activation studies have not dealt with the problem of unraveling the neural substrates of music writing for obvious reasons, given the complexities involved (e.g., complex movement sequences, visual–spatial organization, and translation from auditory imagery working memory to notation). Our only other source of information is the sequelae of focal brain

damage, which again may result in dissociations between musical and verbal writing. Several musicians have become verbally agraphic but continued to write music. One, described by Signoret and colleagues, was an organist and composer who, following a left MCA stroke, became alexic and agraphic in Braille but continued to sight-read and compose music (in Braille). Thus, verbal and musical reading can be dissociated not only in their usual visual forms but also within the tactual modality.

VI. MUSICAL EMOTION

The neural substrates permitting the perception and expression of emotions through music are a relatively unexplored dimension of musical behaviour despite their obvious centrality to the enjoyment and importance of music. However, investigations into the perception of affect are under way.

Anne Blood, Robert Zatorre, and colleagues used PET to measure the correlation between CBF changes and the degree of dissonance or consonance (and unpleasantness or pleasantness) in musical excerpts constructed by altering the harmonic accompaniment of a novel tonal melody (Fig. 9A). Activation in the right parahippocampal gyrus and right inferior parietal lobe increased with increasing dissonance; that in portions of the orbitofrontal and subcallosal cingulate cortex increased with increasing consonance (Fig. 9B). Volunteers also rated the emotional quality of the excerpts along adjective pairs (e.g., pleasant vs unpleasant), two of which were known not to correlate with dissonance (happy vs sad). The fact that dissonance was associated with particular emotions (e.g., tense, unpleasant, irritated, and angry) and not others (Fig. 9A) suggests that the areas identified are involved in the perception of certain emotions, but not all.

The parahippocampal region is strongly and reciprocally connected with the amygdala, possibly involved in processing these emotions. CBF increases in the parahippocampal gyrus are also associated with unpleasant emotions in response to pictorial stimuli. Orbitofrontal and subcallosal cortex have been associated with emotional processing (e.g., the former with emotional disinhibition in monkeys following selective lesions, and deficits in emotional identification following subcallosal lesions in humans).

Blood and Zatorre measured the neural correlates of the experience of thrill during music perception. Though studied from a cognitive point of view by John Sloboda, this is probably the first study of the cortical and subcortical correlates of musical thrill. Subjects heard self-selected musical excerpts and made postscan ratings of subjective emotional intensity. Increased activity was associated with increasing intensity of thrill in the nucleus accumbens, midbrain, insula, thalamus, SMA, anterior cingulate, and orbitofrontal cortex. Decreasing activity was observed bilaterally in the amygdala and ventrolateral frontal cortex. These complex findings suggest the involvement of neural systems known to be associated with reward and arousal in the generation of musical thrill. Many of these areas have also been implicated in reward responses to other euphoria-inducing stimuli, both naturally occurring (e.g., food, sex) and artificial (e.g., cocaine, heroin). Thus music listening appears to serve some important biological function.

Peretz and colleagues noted that one of their auditory agnosia patients who no longer recognized any previously familiar melodies (''tune'' agnosia) and could not detect pitch or rhythmic variations within novel melodies, utilize melodic contour or interval information, or sing, nevertheless reported that she still enjoyed music. Tests of her ability to discriminate the happy vs sad emotional valence of musical excerpts revealed that this ability was entirely intact. When the stimuli were presented in computer-synthesized versions rather than as recordings of live performances, emotional discrimination was unaffected, indicating that at least for these stimuli, expressive variations in timing and intensity were not significantly contributing to their emotional processing. The judgments were demonstrated to rely primarily on the mode (major/minor) and tempo of the selection. This patient suffered sequential strokes affecting the left and right MCAs, which left extensive damage to almost the entirety of the left superior temporal gyrus (STG), the anterior third of the right STG, the middle and inferior temporal gyri, the left insula and frontal operculum, the right inferior and middle temporal gyri, and the left anterior parietal area. Though many hypotheses could be generated about the musical functions that might be impaired by such damage (e.g., singing and auditory–tonal working memory), it is interesting to note that most of the regions implicated by the PET studies of musical emotion described previously (with the exception of the left insula and left anterior parietal lobe) are spared. On the other hand, the emotional valence studied (happy vs sad) was not addressed by either of the activation studies. Clearly, much work remains to be done before the neural networks critical for the perception of specific categories of musically expressible emotions can be sorted out.

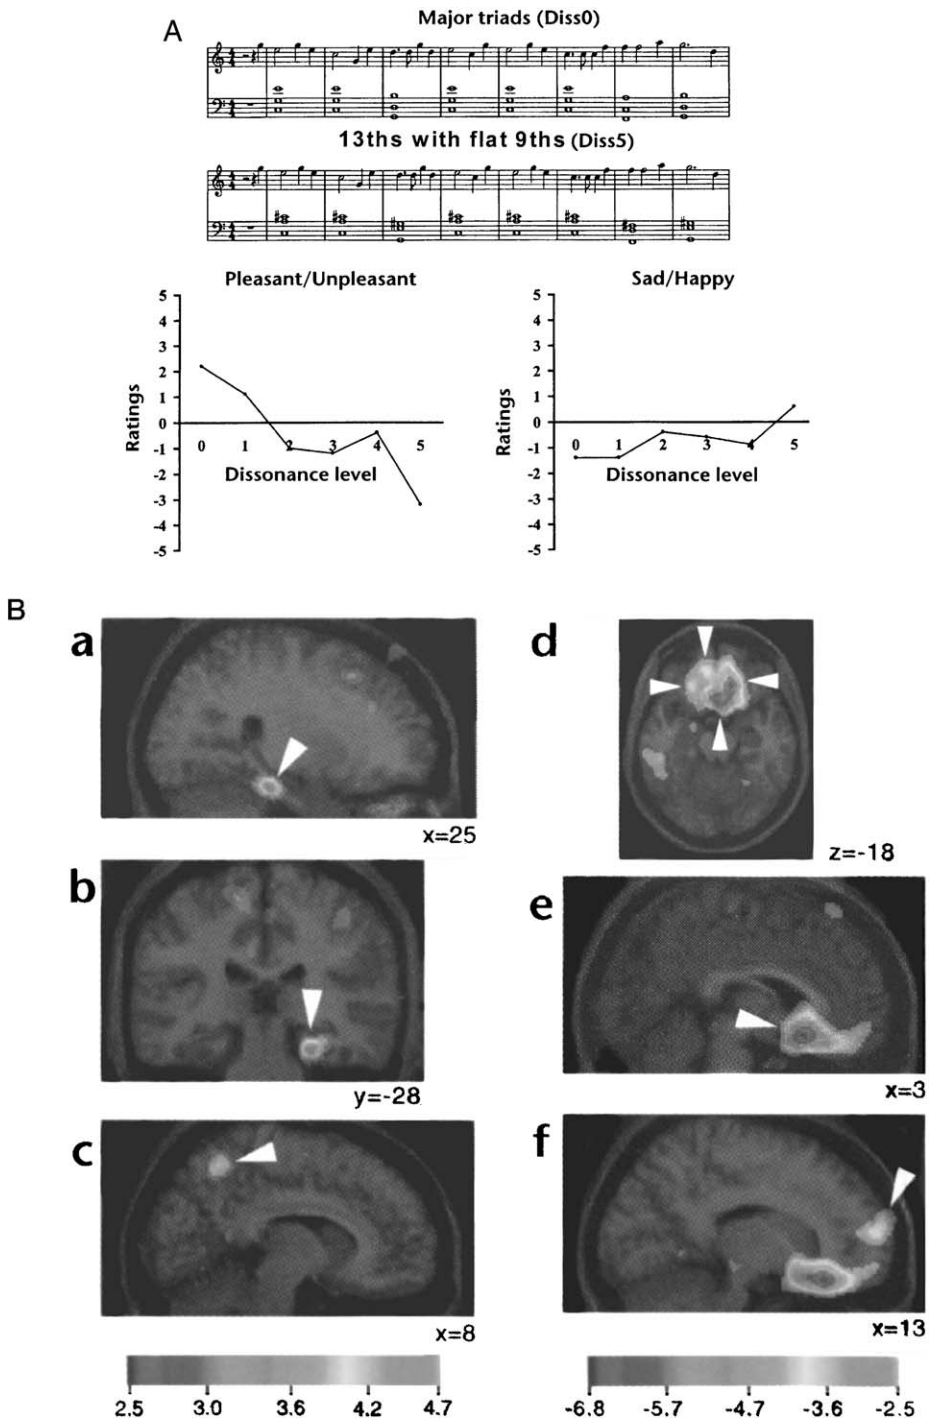

Figure 9 Consonant vs dissonant music perception. (A) (Top) Excerpts from the most consonant version (major triads; Diss0) and the most dissonant version (13ths with flat 9ths; Diss5) of the musical stimuli presented during PET scanning. (Bottom) Line graphs demonstrating averaged subject ratings following scans for each of the six versions Diss0–Diss5. Note that dissonance was related to judgments of pleasantness/unpleasantness but not happiness/sadness. (B) Regions demonstrating significant rCBF correlations with dissonance level, parametrically varied from consonant to most dissonant in five steps by altering the harmonic accompaniment to a novel tonal melody. Correlations are shown as *t*-statistic images superimposed on corresponding averaged MRI scans. (a–c) Positive correlations in rCBF with increasing dissonance in (a) right parahippocampal gyrus in saggital section and (b) coronal section and (c) right precuneus. (d–f) Negative correlations with increasing dissonance (equivalent to positive correlations with increasing consonance) in (d) bilateral orbitofrontal cortex, (e) medial subcallosal cingulate in sagittal section, and (f) right frontopolar cortex (reproduced with permission from Blood *et al.*, 1999).

Although in the context of Peretz's task of emotional classification, expressive microvariations in timing, intensity, or pitch did not play a significant role, clearly in other contexts they are manipulated by skillful musicians to effectively communicate musical emotion. Examples of masters in this musical domain include musicians such as Mahalia Jackson, Maria Callas, Nusrat Fateh Ali Khan, and Claudio Arrau. Future studies may help to determine the neural processing consequences of both the sensory characteristics used to convey particular emotions (e.g., consonance/dissonance, tempo, harmonic structure, and intensity) and the particular emotions (e.g., happiness/sadness, pleasantness/unpleasantness, and thrill).

Finally, the neural substrates supporting the *expression* of musical emotion have yet to be explored (i.e., the motor control of the actions producing these expressive variations in musical sound and the perceptual processing of the emotional content of one's own performance). Though complex, to the degree that these expressive parameters can be quantified, neural correlates of their motor control may be sought.

VII. SUNG LANGUAGE

A significant portion of the music we listen to contains words set to music (i.e., language in which the fundamental frequency pattern has become predominant, rather than providing an emotional background and semantic support as in the prosodic component of spoken language). The melodic component may be so predominant that it masks or distorts perception of the linguistic component.

A. Integrated Perception of Music and Language

The prototypical or simplest form of sung language is probably the song. In fact, the degree to which the linguistic context is attended varies from song to song, performance to performance, and listener to listener. Though complex, listening to and singing songs are clearly among the most basic and universal of musical behaviors.

The effects of unilateral cerebral excisions (for the relief of epilepsy) on a song memory task have been investigated by Samson and Zatorre. Subjects first listened to novel melodies sung to lyrics and then were asked if they recognized the original tune with new lyrics, the original lyrics with new tunes, or the original songs. Patients with left temporal lobectomies were impaired in recognition of the lyrics, and both groups were impaired in recognizing the original tune with new lyrics. In another experiment, they presented the same melodies and lyrics separately. Right temporal lobectomy impaired melody recognition, but left temporal lobectomy did not. It appears that the integration of tune with lyrics, once formed, may not be disassembled later without cost.

B. Integrated Production of Music and Language

In the act of singing (with words) there is a smooth integration of the neural systems producing speech and singing. We know that in terms of activation, these systems seem to exhibit a significant degree of overlap but also some opposite hemispheric asymmetries. These asymmetries may reflect complementary specializations that arose specifically to serve the simultaneous demands inherent in producing speech (words with prosodic intonation) or song (melody with lyrics). Regardless of its evolutionary origins, song production, like song perception, calls upon a combination of functions, some of whose components appear to exhibit opposite hemisphere asymmetries.

Numerous cases have been reported in the neurological literature of patients who were profoundly aphasic but could still sing songs with normal intonation and sometimes with perfect lyrics. The examples of combined loss of speaking and singing suggest damage at a shared level of the vocal motor control system, whereas dissociations suggest that higher levels are distinct, possibly due to opposite hemispheric specializations.

Although no brain imaging studies have examined the activity associated with song production, Zatorre, Halpern, and Perry investigated the perception and mental imagery of songs (see Section III.B). As with other nonverbal imagery tasks involving melodies or musical intervals, SMA was active during song imagery (Fig. 5.III). Since both speech and singing also activate SMA, its activation by song imagery is clearly expected.

Temporal lobe areas were activated bilaterally during song imagery, consistent with the integrated nature of melody and lyrics in song representations. During actual singing, temporal lobe activation would be predominantly driven by the processing of auditory feedback. It remains to be demonstrated whether song singing will result in strongly right hemisphere asymmetric activation, as does simple singing without words, or in significant activation of left temporal lobe areas associated with language comprehension.

VIII. MUSIC AND NEURAL PLASTICITY

In previous sections we discussed changes in the organization and responses of neurons in response to both auditory sequence and motor sequence learning, particularly within tonotopically and somatotopically organizaed cortical areas. For such learning, the concomitant neural changes formed for any given sequence may be to some extent unique. Here, we discuss changes in the brain that are more general and result from long-term exposure to musical perception or production. Considerable interest has been generated in recent years regarding the possibility of more generalized benefits of both music listening and training in musical performance.

A. Plasticity in Response to Music Production

One approach to investigating how long-term experience in music performance may result in lasting changes in the brain involves measuring the size of particular structures from high-resolution MRI images. Differences between musicians and individuals who do not engage in music performance may be the direct results of musical experience, though one can usually not rule out the alternative explanation that these morphometric differences result from innate differences in ability.

Gottfried Schlaug and associates measured the midsaggital areas of the corpus callosum, the bundle of interhemispheric corticocortical fibers. The anterior half of the corpus callosum was significantly larger in musicians, with most of the effect coming from the subgroup of musicians who began training before age 7. Since the fibers connecting the sensorimotor cortices in the two hemispheres are contained in this portion of the corpus callosum, the increase in interhemispheric connections may be related to sensorimotor cortical development in response to musical practice, especially during the first decade of life.

They also measured the intrasulcal length of the posterior bank of the precentral gyrus as an index of primary motor cortex. They found a significantly longer sulcus in the right hemisphere of musicians in comparison to nonmusicians. Furthermore, both right and left sulcal length were positively correlated with the age at which music training commenced.

Finally, Schlaug and associates used MRI morphometry to investigate the specialized ability of absolute pitch perception. The surface area of the planum temporale, or the superior temporal plane posterior to Heschl's gyrus, showed an exaggeration of the normal leftward asymmetry in musicians with perfect pitch. Zatorre and colleagues measured the cortical volume of the same region and found that it was slightly larger on the left for absolute pitch possessors than for musicians without absolute pitch. Furthermore, pitch naming performance was correlated with size of the left planum temporale, such that larger volume was associated with lower error scores. Although studies suggest a critical period early in life for the development of absolute pitch, it is not clear if these asymmetries are innate or result from musical training. In the monkey the majority of projections from the superior temporal gyrus to the frontal area analogous to that activated in absolute pitch musicians while listening to musical tones (the posterior dorsolateral frontal cortex) originate in the planum temporale.

Pantev and associates used MEG to measure the responses of large ensembles of neurons in auditory cortex to tones. Yoshihiro Hirata, Shinya Kuriki, and Pantev contrasted such responses from a group of musicians with absolute pitch to a group of nonmusicians. The best fitting single equivalent current dipoles, representing the sources of these auditory-evoked magnetic responses, were located significantly more posteriorly within the left hemisphere for the absolute pitch possessors. These results are consistent with morphometric data indicating a larger planum temporale.

Pantev and associates also measured the magnetic fields evoked by piano tones and by pure tones matched for hearing level and fundamental frequency. The strength of the primary auditory evoked response (dipole moment of the M100) in the left hemisphere to piano tones was about 25% greater than that to matched pure tones for musicians but not significantly different for nonmusicians. Moreover, the strength of cortical activation correlated linearly with the age at which musicians began playing (Fig. 10) and did not vary with absolute pitch ability. It was maximal for musicians who began to play before the age of 9. Thus, it is plausible that this increase results from cortical reorganization induced by the sensory input coincident with musical production—reorganization that results in the recruitment of a larger ensemble of auditory cortical neurons and/or an increased synchrony of neural firing.

Approximately half of the musicians in the previous study were pianists and half were string or wind instrument players, although almost all reported the piano as at least a secondary instrument. Therefore, it is not clear whether reorganization may have been

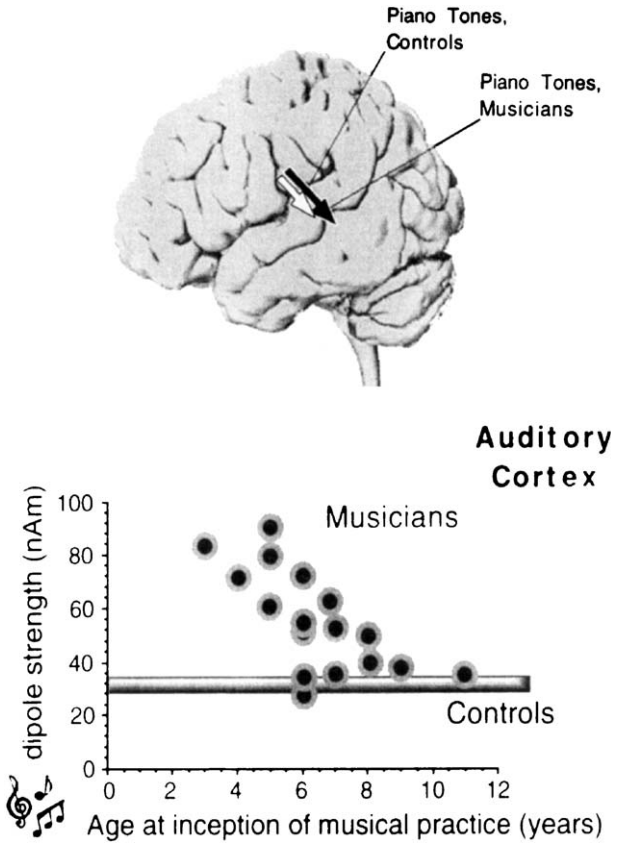

Figure 10 Enhanced auditory representation of piano tones in musicians. (Top) Mean values for the strength of the magnetic field evoked in response to piano tones (single equivalent dipole moment of the M100), plotted as arrow length, from musicians (black arrow) and nonmuscician controls (white arrow). (Bottom) ●, average dipole strength across all piano tones tested from each musician, plotted as a function of the age at which musical training began. The line indicates the average dipole strength across all piano tones and control subjects. Note that dipole strengths tend to increase with earlier training, but only for musicians who began playing before the age of 9 (reproduced with permission from Pantev *et al.*, 2001a; modified from Pantev *et al.*, 1998).

specific to the sounds produced by one's own instrument or to spectrally rich harmonic tones in general. To investigate the instrument specificity of this effect, Pantev and colleagues compared the auditory responses evoked by trumpet and violin notes (of the same fundamental frequency) in groups of trumpeters and violinists (none of whom played both instruments). The amplitude of the M100 was greater for a musician's own instrument and was greater overall for the trumpeters (Fig. 11). Although these results do not rule out generalized enhancement of neuronal responses for spectrally rich harmonic tones among musicians, they do indicate at least an additional enhancement in response to one's own instrument. The instrument-specific response enhancement may result from long-term exposure to feedback from one's own instrumental performance.

Plasticity in somatosensory cortex is also suggested by a study carried out by Thomas Elbert, Pantev, and colleagues, who used MEG to measure and compare the cortical representation of the digits of string players to those of nonmusicians. They found that

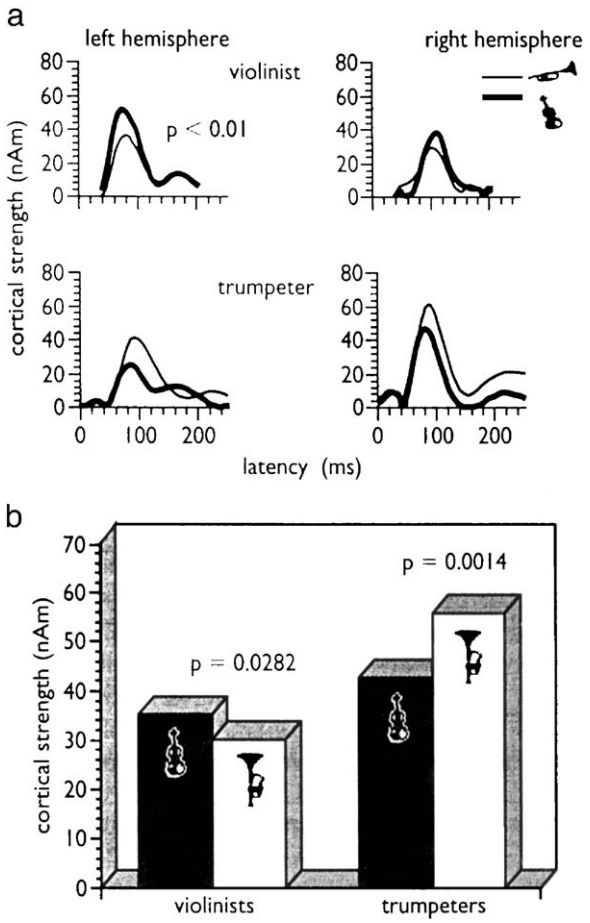

Figure 11 Enhanced auditory representation of tones played on one's own instrument (violin or trumpet). (a) Time courses of the strength of the magnetic field (as dipole moment) by hemisphere from one violinist and one trumpeter, evoked in response to trumpet tones (fine lines) and violin tones (heavy lines). Note that peak responses at ~100 msec (M100) are greater for one's own instrument. (b) Average dipole strengths across both hemispheres for all violinists and all trumpeters in response to violin tones (black bars) and trumpet tones (white bars). The interaction of stimulus type with instrument group was significant, and response strength was reliably greater for the timbre of the instrument of training within both groups (reproduced with permission from Pantev *et al.*, 2001b).

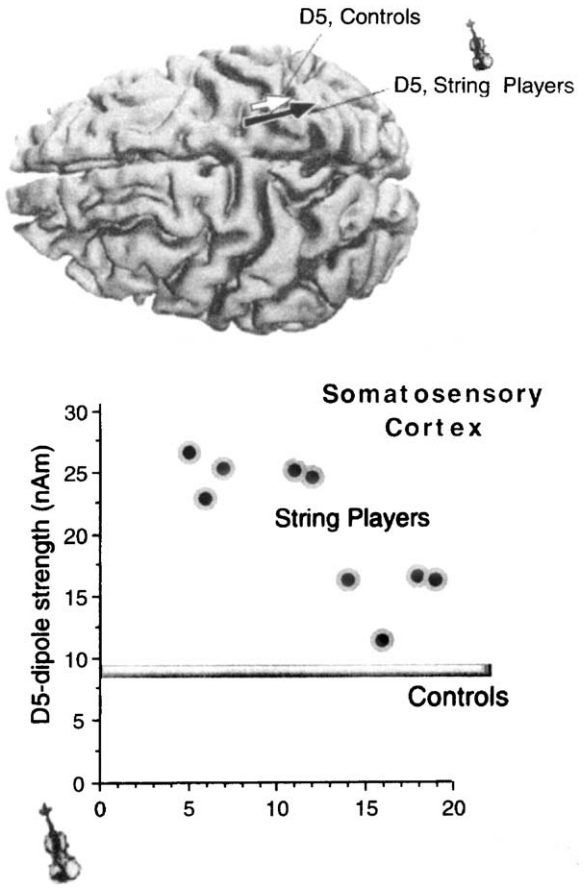

Figure 12 Enhanced somatosensory representation of left-hand digits in string players. (Top) Equivalent current dipoles (ECDs) elicited by stimulation of the little finger (D5) superimposed onto an MRI reconstruction of the cortical surface from one control subject. The arrows indicate the location, orientation, and moment (length) of the modeled dipoles averaged across sting players (black arrow) and nonmusician controls (white arrow) (Bottom) ●, magnitude of the dipole moment of D5 somatosensory-evoked responses from each string player, plotted as a function of the age at which musical training began. The line is the mean of the same response across all nonmusician subjects. Note that dipole strengths are particularly enhanced for those who began training at ≤ 12 years (reproduced with permission from Pantev *et al.*, 2001a; modified from Elbert *et al.*, 1995).

the cortical representation of the digits of the left hand was greater for string players (smallest for the thumb) but equivalent for the right hand. The magnitude of the effect correlated negatively with the age at which training began (Fig. 12). These results suggest cortical reorganization in response to somatosensory feedback from one's own instrumental performance since violinists typically use the four digits of the left hand to manipulate the strings. The results are consistent with direct mapping of somatosensory cortex in monkeys before and after tactile discrimination training. Greg Recanzone, Michael Merzenich, and colleagues found that the area of somatosensory cortex representing the portion of the skin of a trained digit increased up to threefold.

Focal hand dystonia, the loss of motor control of one or more digits, is a serious occupational hazard for those engaged in rapid, finely coordinated hand movements such as pianists. Robert Schumann may have suffered from focal hand dystonia beginning in his twenties. Its cause is controversial, but some theories suggest it is caused by maladaptive cortical plasticity, particularly an overlap of receptive fields within somatosensory cortex. Using MEG, Elbert, Pantev, and colleagues found that the single equivalent current dipoles representing somatosensory-evoked responses to individual digits were closer together for the affected hand of dystonic musicians than for nonmusician controls. These results are consistent with the hypothesis of maladaptive, overlapping somatosensory receptive fields.

Jesus Pujol, Pascual-Leone, and colleagues used functional MRI to measure brain activity while guitarists played a simple finger exercise (arpeggios) on a computer-interfaced guitar. When not experiencing dystonia, the pattern of motor cortical activation within contralateral sensorimotor cortex and SMA was the same for dystonic and nondystonic musicians. When dystonic symptoms were provoked by guitar playing, activity in sensorimotor cortex became elevated and motor cortex activity declined.

Further brain imaging studies during the active expression of dystonic symptoms will help to reconcile findings of disordered and hyperactive somatosensory functioning associated with focal hand dystonia, and it is hoped that they will lead to successful treatments for this all-too-common affliction.

Finally, we consider the most generalized claims of changes in the brain as a result of exposure to music production. M. Gardiner studied the effects of music training during childhood on development of other cognitive abilities. He found that children who participated in an intensive, active music training program (Kodaly method) also showed large improvements in math and reading. However, a causal link has not been established, nor have the mechanisms by which musical training might result in changes that could enhance other cognitive functions been determined. Continuing developmental research may help to provide new insights into very old controversies concerning the place of music within general education.

B. Plasticity in Response to Music Perception

In the previous section, I discussed changes that may occur in auditory cortex as a result of long-term exposure to auditory feedback during music production. Generalized changes within the brain may also result simply from exposure to music perception. The duration of exposure varies significantly across studies. In an influential study, Greg Recanzone, Christoph Schreiner, and Michael Merzenich trained monkeys to make pitch discriminations within particular frequency ranges over several weeks. After training, a frequency map of the primary auditory region was derived from multi-unit recordings. The cortical representation of the trained frequency band and its area correlated positively with performance.

Hans Menning, Larry Roberts, and Pantev carried out a related experiment in humans using MEG. Volunteers were trained to make increasingly fine pitch discriminations referenced to 1000-Hz pure tones over a period of 3 weeks. The M100 in response to the frequencies trained increased in amplitude during training. After 3 weeks without training, it decreased. Increased amplitude of the M100 could indicate that more neurons are firing, and it is consistent with the increased area of cortical representation seen in the analogous monkey experiments.

Pantev and colleagues asked volunteers to listen to music from which a narrow band of frequencies centered at 1 kHz had been removed by a "notch" filter. Magnetic fields evoked by a bandpassed noise corresponding to the notch filter and a similar control stimulus centered at 0.5 kHz were recorded before and after 3 hr of listening on 3 consecutive days. The amplitude of the response to the 1-kHz centered stimulus decreased after listening to the notched music,

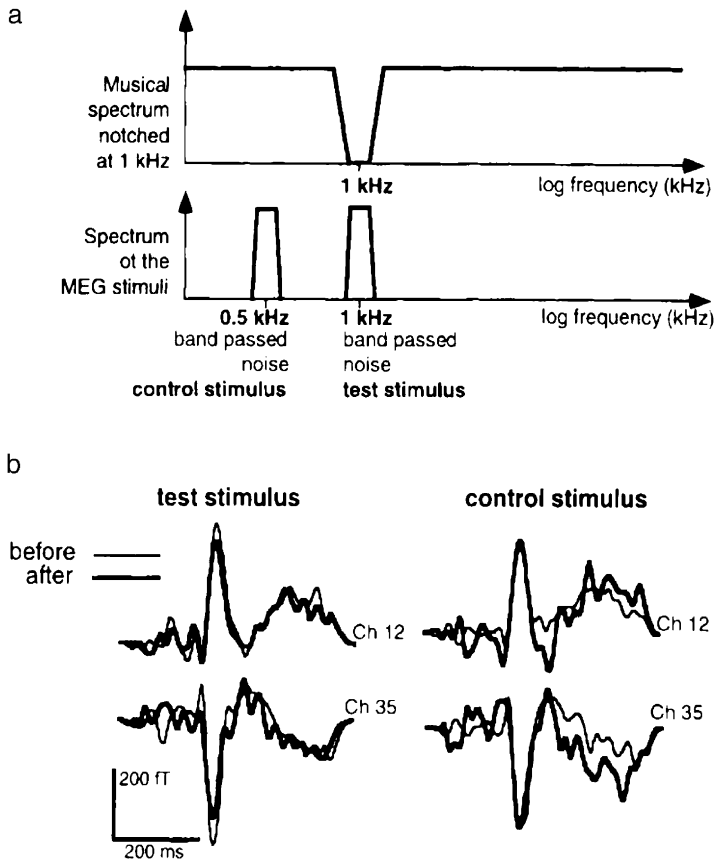

Figure 13 Short-term reduction of neural response to a specific frequency range after listening to "notched" music. (a) Spectrum of the notch filter centered at 1 kHz that was applied to self-selected music. Spectrum of the two stimuli, band-passed noise bursts centered at 1 and 0.5 kHz, used to measure the evoked magnetic response. (b) Auditory evoked fields from one representative subject in response to the two bandpassed noise bursts immediately before and after 3 hr of attentive listening to notched music on 3 consecutive days. Note that response magnitude is diminished afterwards only for the test stimulus (1 kHz), corresponding to the removed frequencies. This effect was not present 24 hr later (i.e., at the beginning of the next session), suggesting that auditory cortical neurons reverted to their initial frequency tuning (reproduced with permission from Pantev *et al.*, 2001a, modified from Pantev *et al.*, 1999).

but the response to the control stimulus was unaffected (Fig. 13). The 1-kHz response rebounded by the beginning of the next session. These findings point to the existence of more rapid and transient changes that may take place in response to changes in one's acoustic environment.

Finally, I consider claims regarding more generalized effects of music perception on the brain. In particular, much attention has been drawn recently to the so-called "Mozart" effect, or modest gains in cognitive test performance following 10 min of listening to a Mozart sonata (primarily in tests requiring visual–spatial manipulation). First, the effect is not specific to Mozart, and it has been reported by Glenn Schellenberg in response to Schubert, or even listening to a passage from a story. For a given individual it appears to be maximal for the preferred stimulus. Its persistence across time has not been demonstrated.

The Mozart effect appeals to the popular imagination in that it appears to promise a passive route to cognitive enhancement (much as the passive exercise machines of the 1950s did for physical improvement). Though considerable controversy still exists, perhaps the moral is that effort and time are required before long-lasting changes can be induced in the brain. Regardless, human beings will continue to make and listen to music, primarily for noncognitive reasons and without any goals for self-improvement.

As this article makes clear, music, even when only perceived, engages and activates the human brain at many levels: auditory, cognitive, emotional, and, when working memory or imagery are involved, motoric. Across a lifetime of exposure, musical experience, both active and passive, has the potential to leave lasting traces in our brains, not only through the formation of memories for specific musical sounds and gestures (a musical "lexicon") but also in more general ways.

Like language, music is an accumulated product of humankind that is continually being passed on and added to. Questions regarding how (and why) the human brain produces and responds to music will continue to occupy researchers and philosophers for many years to come and touch upon many of the brain's most complex and integrative abilities.

Nausea and Vomiting

ROBERT J. NAYLOR
University of Bradford

GLOSSARY

area prostrema Located on the ventral surface of the brain stem and contains chemoreceptors; synonymous with the chemoreceptor trigger zone (CTZ).

emetic stimuli Arise from the stimulation of mechanoreceptors or chemoreceptors in the gastrointestinal tract, other body tissues, and the brain or from pain, psychogenic stimulation, or vestibular–visual conflict.

nausea A distinctive and unpleasant feeling of malaise and drowsiness, accompanied by autonomic changes.

nucleus tractus solitarius Lies close to the area postrema and receives emetic stimuli and autonomic connections; a crucial structure in the emetic reflex.

retching and vomiting (or emesis) Rhythmic contractions of the abdominal muscles and contraction of the diaphragm compressing the stomach to expel its contents through the mouth.

vestibular nuclei Receive information concerning body and head movements.

vomiting center A useful concept to explain the still undetermined coordination of the emetic reflex.

The act of vomiting has been considered one of the most primitive functions in animals and humans. There are pictorial representations of vomiting from Roman times, with the first recorded experimental work associating changes in stomach function with emesis being performed in the seventeenth century. By the late nineteenth century, a ''vomiting center'' in the brain had been hypothesized, the importance of the vagus nerve was established, and certain hindbrain areas had been shown to be more relevant than others to mediate drug-induced emesis. Little further progress was made until the 1950s when Borison and colleagues, using brain lesion and electrical stimulation techniques, substantiated and clarified earlier findings to demonstrate a functional and anatomical distinction between a ''chemoreceptor trigger zone'' and a ''vomiting center.'' This was again followed by little serious medical or research interest: nausea and vomiting were rarely a medical problem, more a difficulty for the patient, family, or nursing staff. Yet the introduction of aggressive and severely emetogenic chemotherapy in the 1980s stimulated medical concern to discover effective antiemetic treatments for the cancer patient. This was realized with the discovery of the antiemetic action of the 5-HT_3 receptor antagonists. These advances complemented the continuing efforts of the military and other researchers to investigate the mechanisms involved in the sickness of motion and space travel and the problems inherent in their treatment. This article indicates how an understanding of the stimuli, pathways, and structures within the brain and gut has begun to allow control of the emetic reflex and the therapeutic successes that have revolutionized treatments and caused a renaissance in emesis research.

I. THE PHYSIOLOGY OF NAUSEA AND VOMITING

Nausea is a highly subjective and peculiarly unpleasant sensation, quite distinct from other feelings. It is ''felt''

in the throat or stomach or as a ''sinking'' sensation in the epigastrium; the symptoms may include malaise, drowsiness, anxiety, and reduced vigilance. It is invariably accompanied by autonomic changes including vasomotor disturbances, causing vasoconstriction–pallor and pupil dilation, tachycardia, salivation and sweating, and a relaxation of the lower part of esophagus and abdominal muscles. The latter tends to increase tension of the gastric and esophageal muscles, which may directly contribute to the sensation of nausea. In the acute stage it is perceived as an unpleasant and temporary effect that precludes other mental and physical activity. It frequently precedes vomiting (although either may occur alone) and usually is relieved by an emetic episode, which the subject or patient may welcome. The presence of chronic nausea severely reduces the quality of life.

Following the relaxation of the lower part of the esophagus and abdominal muscles, a contraction of the upper small intestine occurs closely followed by contraction of the pyloric sphincter and the pyloric portion of the stomach. These changes will empty the contents of the upper jejunum, doudenum, and pyloric portion of the stomach into the fundus and body of the stomach, which are relaxed. Also relaxed are the cardiac sphincter, esophagus, and esophageal sphincter. In this manner the system is prepared for retching and vomiting, which are reflex in origin and serve to remove the contents of the upper gastrointestinal tract.

This involves a series of highly coordinated changes in gastrointestinal motility, respiratory movements, and posture. Emesis, which is initiated by a deep and sharp inspiration, is immediately followed by reflex closure of the glottis and raising of the soft palate, which prevent the passage of vomitus into the lungs and nasal cavity. The abdominal muscles then contract in the rhythmic manner of ''retching'' movements, which compress the stomach between the contracted diaphragm and abdominal organs. The inevitable increase in intragastric pressure causes evacuation of the stomach contents through the relaxed esophagus; definite antiperistalsis in the stomach itself is rarely observed. These events and pressure changes are shown in Fig. 1. This profile of activities can vary somewhat between species and also in the human infant. In the latter, the abdominal muscles or diaphragm apparently does not play a role in, for example, the regurgitation of an oversized meal; the reverse peristalsis occurs by contraction of the stomach muscle alone.

The feelings of nausea followed by retching or vomiting are the expression of a precisely controlled reflex, albeit of an extraordinarily complex nature. Almost irrespective of the causes of nausea and emesis, the autonomic and somatic patterns of motor activities are the same. Also, because the presence of the emetic reflex occurs in so many species, it would have been predicted that the actual function of nausea and

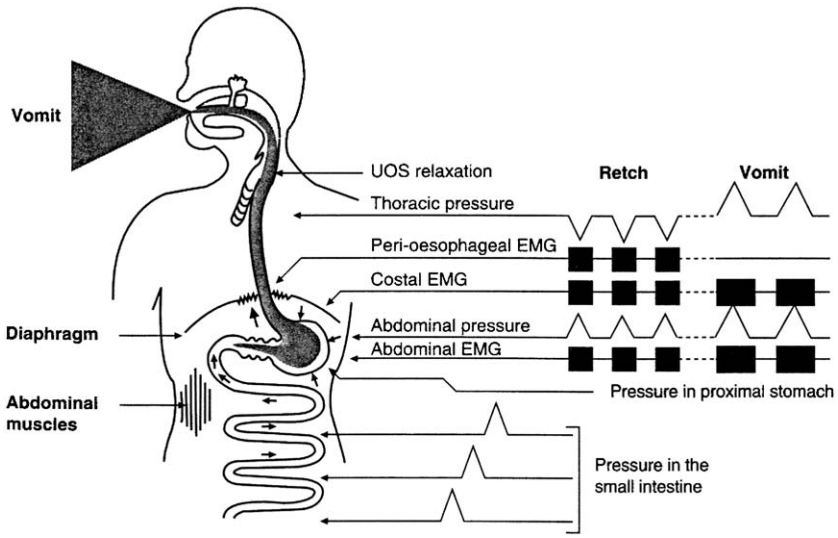

Figure 1 The major mechanomotor components of retching and vomiting. Abbreviations: EMG, electromyogram; UOS, upper esophageal sphincter. Andrews, P. L. R., and Davis, C. J. (1995). The physiology of emesis induced by anticancer therapy. In *Serotonin and the Scientific Basis of Antiemetic Therapy* (D. J. M. Reynolds, P. L. R. Andrews, and C. J. Davis, Eds.), pp. 25–49. Oxford Clinical Communications, Oxford. Reproduced by permission of Oxford Clinical Communications.

vomiting should be well-established. But this has not occurred. The physiological "value" of nausea and vomiting is usually described as a "defense mechanism" to protect the host against a toxic challenge. Thus, the activation of smell or taste receptors causing nausea could warn the organism of a noxious or poisonous substance in order to avoid its ingestion. Similarly, if toxins are actually ingested, the chemoreceptors in the stomach would warn of the presence of danger at an early stage and emesis would promptly expel the threat. However, such explanations remain unconvincing.

First, there are numerous toxins that do not cause nausea or emesis and simply kill the host; the defense mechanism is inadequate at best. More important, the defense theory fails to provide any reasonable explanation for the induction of nausea or emesis caused by nontoxins and, therefore, all other emetic stimuli, e.g., changes in blood pressure, irritation of the throat, pain, psychogenic stimuli, increased intracranial pressure, and motion. It is concluded that we have no satisfactory explanation for the phylogenetic persistence of the emetic reflex: its value appears extraordinarily limited. The absence of an emetic reflex in rats, mice, and other species confirms its nonessential role.

II. THE STIMULI GIVING RISE TO NAUSEA AND VOMITING

A classification of the stimuli giving rise to nausea or emesis is the essential precursor to an understanding of the mechanisms and systems mediating nausea and emesis. However, the reductionist approach has had an inevitable effect of "individualizing" stimuli to a particular "sickness." For example, the stimulus of motion sickness has generally been restricted to motion, travel, or space sickness and its potential importance to medically related conditions has been generally ignored. This limitation should be carefully considered in the delineation of the stimuli causing nausea and emesis.

A. Stimuli Arising from the Alimentary Canal

For many years it was the opinion of physiologists that the autonomic nervous system was composed mainly of motor (efferent) fibers. However, more recent observations in both animals and human, based on morphological and electrophysiological techniques, have clearly shown that sensory fibers are much more numerous than motor fibers in the physiological regulation of gut homeostasis, visceral motility, and alimentery behavior. Their normal function is related to events accompanying digestion. They signal events related to the mechanical state of the digestive tract (i.e., mechanoreceptors measuring contraction or distension) or the physicochemical properties of the gut contents (i.e., chemoreceptors measuring chemical composition, concentration of nutrients, osmotic pressure, acid and alkaline sensitivity, general chemosensitivity). Other polymodal receptors may respond to a broad range of stimuli, and digestive nerve endings appear to exhibit a general sensitivity to neurotransmitters, hormones, and other agents. A disturbance of this control can trigger changes in peristaltic contractions, the coordination of gastrointestinal activity, gastric emptying, and food intake.

These receptors can be stimulated by a diverse range of foreign stimuli of varying intensity. For example, simple overeating or serious obstruction can both cause distension and induce nausea and vomiting by mechanoreceptor stimulation. Similarly, the oral administration of a moderately innocuous solution of sodium chloride or a severe gut infection with staphylotoxin enterotoxin will both stimulate chemoreceptors to induce nausea and vomiting (see Fig. 2). Stimulation of receptors within the alimentary canal is the single most important cause of the induction of nausea and emesis in the normal population (Fig. 3). The vagus nerve is particularly important in sensory viscerotopic organization. Its afferent components contain general somatic, special visceral (taste), and general visceral sensory fibers, which carry both mechano– and chemoreceptive information from the gut to terminate in the nucleus tractus solitarius. The splanchnic nerves also relay sensory information from the gut. The efferent components of the vagus nerve contain both general and special visceral motor fibers arising in the dorsal motor nucleus of the vagus (DMV) and the nucleus ambiguous, respectively. These medullary systems comprise a final common pathway from the brain to control the activity of the gastrointestinal tract.

B. Stimuli Arising from the Area Postrema–Related Areas

It was established nearly 100 years ago that the application of chemicals to the dorsal surface of the brainstem or the ventricular system could induce emesis. In these early studies it was assumed that this

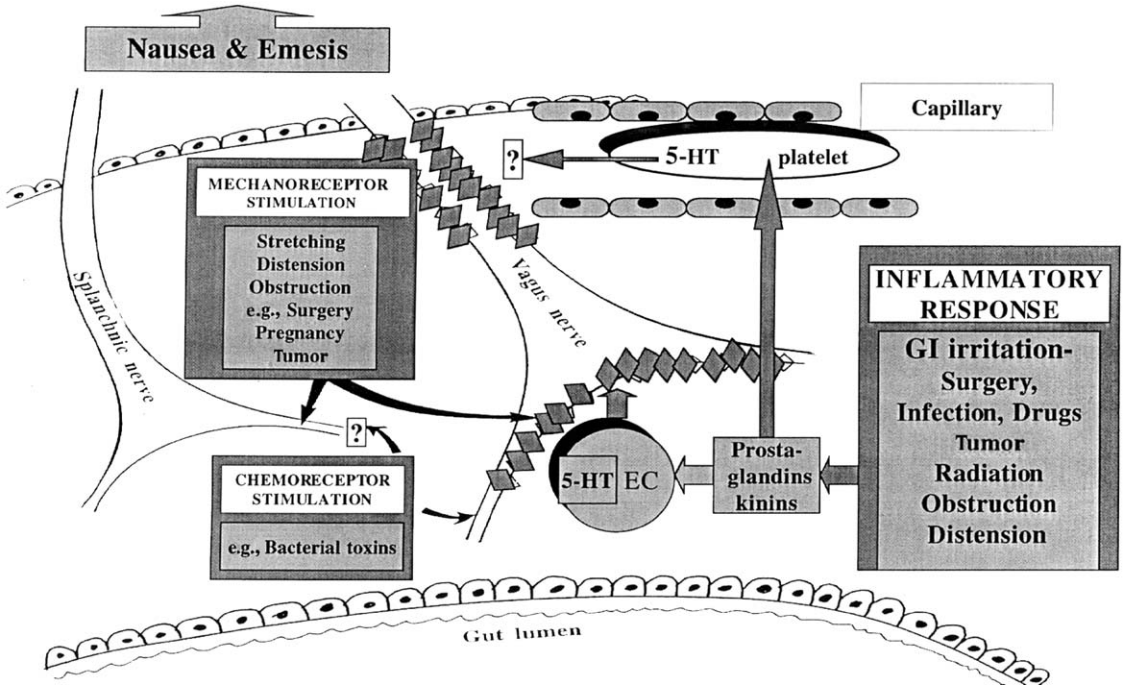

Figure 2 The stimuli causing chemo- and mechanoreceptors for stimulation of the vagus and splanchnic nerves in the gut wall to induce nausea and emesis. An inflammatory response may damage cellular elements leading to the release of prostaglandins and kinins which may stimulate the enterochromaoffin cells (EC) or possibly platelets. This will cause the release of serotonin, which may activate 5-HT_3 receptors located on the vagus nerve to trigger the emetic reflex.

occurred through a "vomiting center" in the brain stem. Again, it was the studies of Borison and colleagues that showed that a number of stimuli were actually detected by cells in the caudal part of the floor of the fourth ventricle, the area postrema, which was termed a "chemoreceptor trigger zone" for emesis. The area postrema is a circumventricular organ of the brain outside the blood–brain barrier, with the capillaries within the area lacking endothelial occluding junctions. Also, the ventricular ependymal cells lack occluding junctions, making the structure permeable to molecules in the blood or ventricles to provide an efficient chemoreceptor sensor for numerous chemicals and endogenous substances (Fig. 4).

C. Chemicals as Emetogenic Stimuli

Very few drugs or chemicals are administered to humans to purposefully induce emesis. However, chemoreceptor stimulation caused by concentrated saline solutions taken orally have a nauseous taste and may be given in an attempt to cause emesis and remove toxic substances from the stomach. (The insertion of a finger down the throat has a similar effect, irritating the mechanoreceptors in the pharynx.) The alkaloid ipecacuanha has well-known emetic effects and acts by stimulating chemoreceptors in the area postrema. It has also been used in subemetic doses in some paracetamol tablets to prevent self-poisoning; a person taking an excessive number of tablets would finally receive an emetic dose of ipecacuanha, which would expel the paracetamol from the stomach. A different use was found for disulfiram in the treatment of alcoholism. If taken with alcohol, it leads to an accumulation of acetaldehyde, which induces nausea and sickness. It was used as an aversion therapy for drug abuse; apomorphine was used as an alternative treatment. With these exceptions, drug-induced emesis is unwanted but occurs with many different types of medical treatments. It can vary from a transient effect of little consequence to a persistent and chronic effect to severely reduce the quality of life.

The nausea and emesis induced by cancer chemotherapy (and radiation) are correctly perceived as the most severe emetogenic stimulus induced by any drug treatment. However, it is emphasized that the potential emetogenicity of chemotherapy is rated as absent, low,

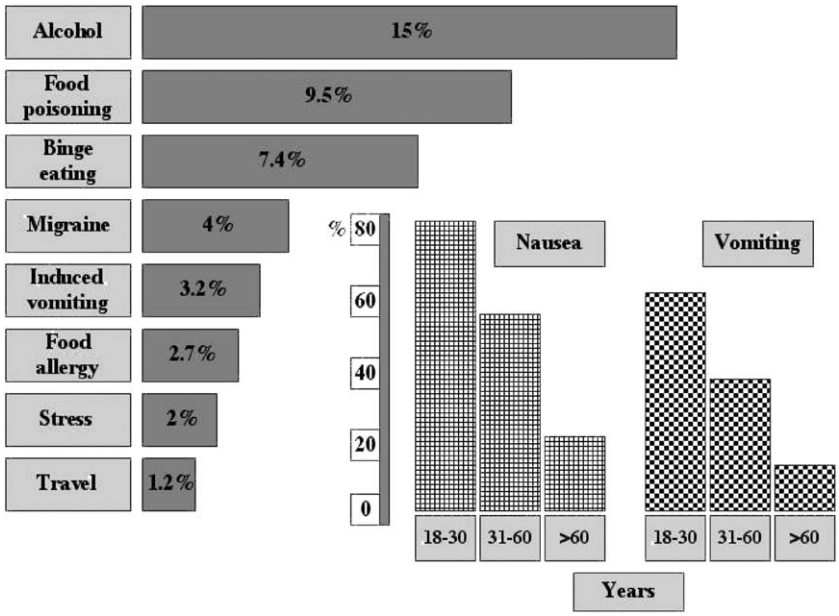

Figure 3 The causes and incidence of nausea and vomiting from an otherwise healthy population in the United Kingdom. The percentage of respondents in each group who reported nausea and vomiting at least once during the previous 12-month period.

moderate, or severe, depending on the drug used, regime of drug administration, dose, and patient variables. For example, all patients receiving cisplatin would be predicted to be very sick, whereas methotrexate causes little if any effect. Nausea and vomiting induced by radiation are also related to the dose used and to the area and extent of the body irradiated. Both the cytotoxic therapy and radiation treatment frequently cause tissue disruption to the gastrointestinal tract. This damage may cause the release of toxic products from the tissue destruction and may induce a local inflammatory response influencing vagal afferent nerve endings within the gut to trigger the emetic reflex. This will depolarize the vagus nerve, and this chemically induced response mimics the effects of electrical stimulation of the vagus nerve, which is known to cause vomiting. The release of 5-hydroxytryptamine from damaged enterochromaffin cells within the gut provides just one important example whereby an endogenous substance may stimulate the 5-HT_3 receptor subtype located on the vagal nerve (see Fig. 2). Additionally, substances such as 5-HT or other agents released as a consequence of cell damage may be transported in the blood system (with cytotoxic agents themselves and also the products of tumor breakdown) to directly stimulate the central components mediating the emetic reflex within the area postrema and perhaps the nucleus tractus solitarius.

A second group of therapeutic agents that inevitably cause nausea as the dose is increased is the dopamine agonist anti-Parkinson drugs, apomorphine, L-dopa, and the ergot derivatives. A major effect is to directly stimulate the dopamine receptors located in the central chemoreceptor mechanisms, with a lesser action to induce gastric stasis.

A third group of drugs that invariably induce nausea or emesis is the opiate analgesics. The acute administration of morphine and related drugs to opioid-naive patients frequently induces nausea and sometimes vomiting. However, tolerance rapidly develops to such effects, and indeed the first treatment may antagonize the emetic effects to a second opioid injection or other emetogens. The emetic effect may be mediated in the chemoreceptor trigger zone, whereas the antiemetic effect may be mediated closer to the vomiting center. The antiemetic effect may relate to an endogenous inhibitory tone exerted by opioids from the enkephalin or related series. The ability of narcotic antagonists such as naloxone to precipitate nausea or vomiting would support this hypothesis.

A fourth group of drugs is those enhancing 5-HT function, for example, 5-hydroxytryptophan, the precursor of 5-HT, or 5-HT re-uptake inhibitors, e.g., fluoxetine and paroxetine, which have been reported to induce nausea and occasionally vomiting as a side

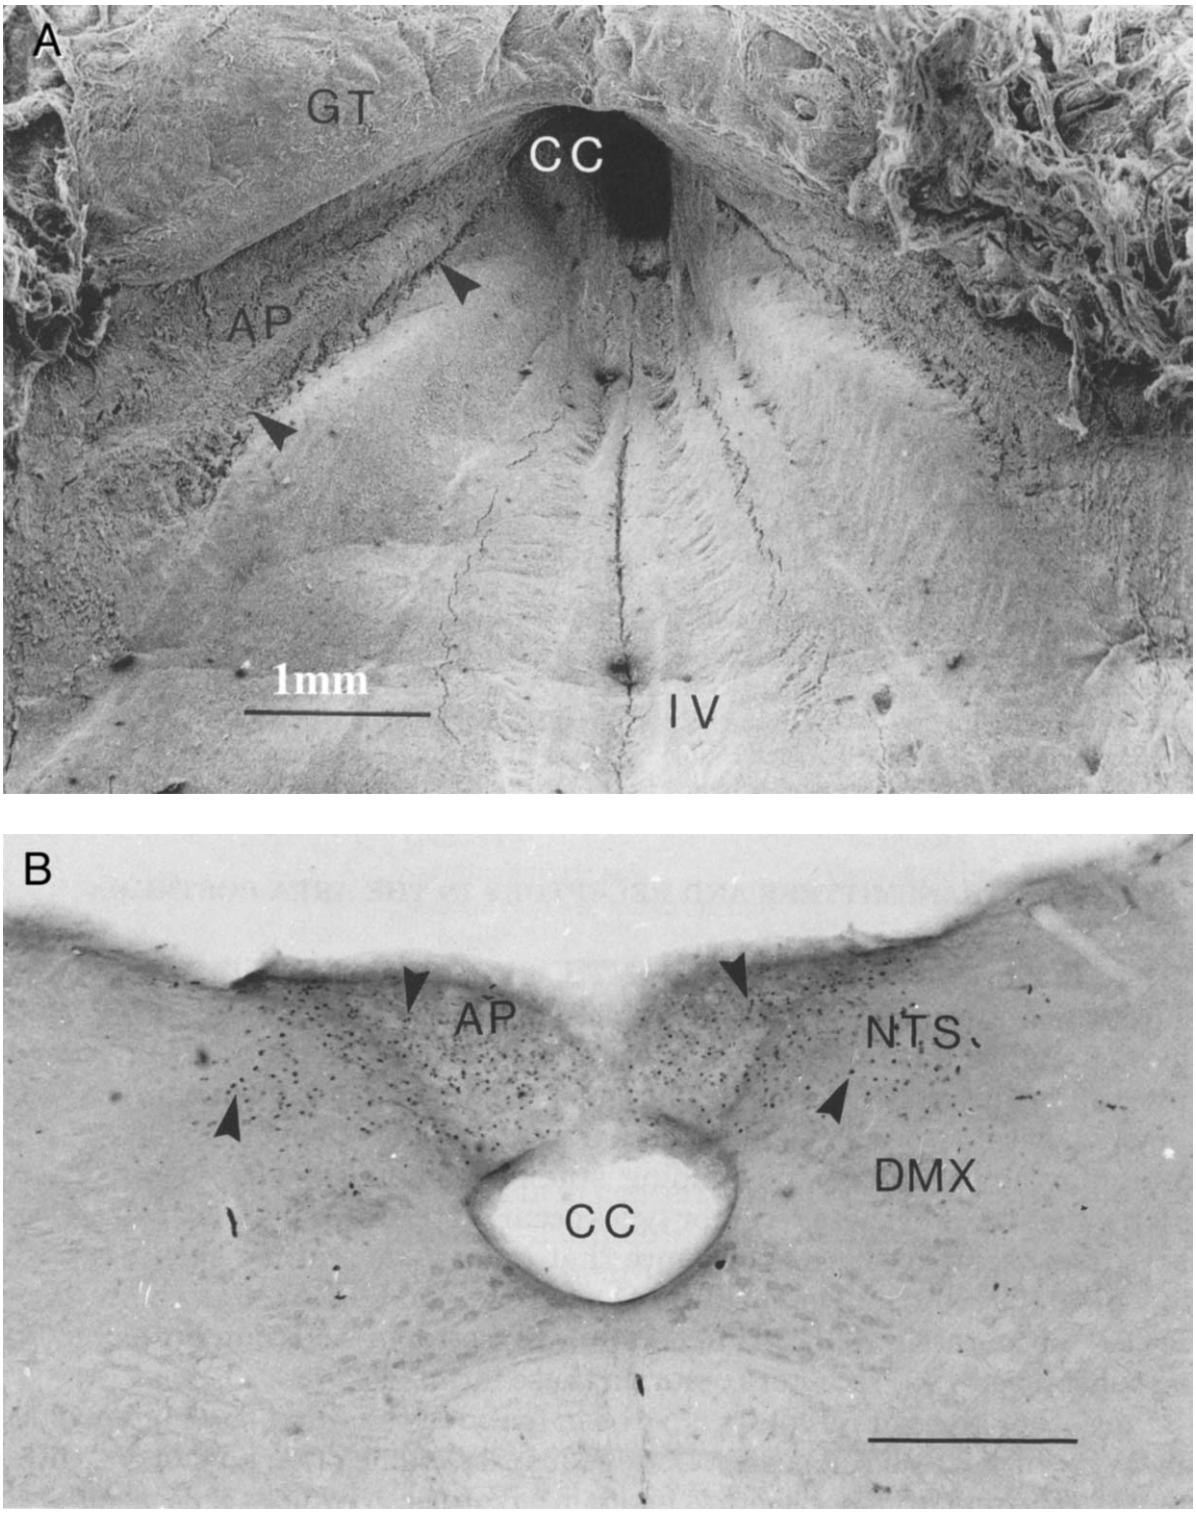

Figure 4 (A) A scanning electron micrograph showing the human area postrema (AP) on the caudal floor of the fourth ventricle (IV) looking toward the central canal (CC; GT, gracile tubercle). The arrowheads indicate the abrupt transition between the area postrema and underlying cells. (B) Section through the medulla oblongata of a ferret that had been given cisplatin to reveal an increase in cellular activity using Fos-like immunoreactivity. This appears as dark dots (indicated by the arrowheads) is visible throughout the area postrema, and extends into the nucleus tractus solitarius (NTS; DMX, dorsal motor nucleus of the vagus nerve).

effect. This may relate to an increased 5-HT activity in both central and gut tissues.

Numerous other drugs also induce nausea and emesis. For example, cardiac glycosides such as digoxin, at doses only slightly greater than the therapeutic dose, induced abdominal pains, nausea, and vomiting. This probably relates to a central action at the chemoreceptor trigger zone and an irritant action within the gastrointestinal tract, which may be exacerbated by cardiac dysrhythmia. Also, the gastrointestinal irritation caused by antibiotic treatment or nonsteroidal anti-inflammatory agents frequently causes gastrointestinal distress, nausea, or vomiting, triggering the emetic reflex via the vagal and splanchnic nerves.

D. Stimuli Arising from the Vestibular Labyrinth and Visual System

All animals that move must remain oriented to their surroundings, and for most movements this requires maintenance of balance and posture, measurement of the changes of bodily position, and the adjustment of eye position when the head is moving. This is also important for the maintenance of homeostasis upon a change of posture; compensation must be rapid to maximize respiratory requirements and direct blood flow to the areas of need. However, unlike most sensations, orientation, movement sensation, and associated autonomic changes never enter the awareness; we are not conscious of this level of control. However, unusual disturbing conditions of orientation or movement, of either the body or environment, exist that certainly enter the conscious domain, which can induce reliable and intense feelings of dizziness, vertigo, nausea, and vomiting. This occurs when the orienting response that has been configured to normal terrestrial movement for each species has been subject to an alien stimulation. In humans, the major orienting detectors are the vestibular organs and the eyes.

1. Vestibular Organs

These comprise the saccule, utricle, and semicircular canals, which in humans are designed to measure changes in gravity, linear movements, and rotary acceleration. Hair cells present in the fluid-filled membranous sacs of the saccule and utricle are bent by the free moving otoliths (calcium carbonate crystals) depending on the extent and direction of linear displacement, i.e., linear acceleration or changes in the rate of motion. The saccule and utricle are positioned to respond to vertical and horizontal movements, respectively; both respond to gravity. The three semicircular canals are fluid-filled and widen at the base to form the ampulla, which contains sensory hair cells fixed to the cupula and the base called the crista. Each of the three canals lies at approximately right angles to each other and to a major plane of the body; the cupula is bent by the pressure of fluid movement in the canal to stimulate the hair cells, which relays the nature of rotary acceleration to the head.

The orienting system has evolved in each species to meet the movements that are normally required. In humans, this is usually active movements and brief passive (imposed) movements and measures best acceleration or deceleration rather than constant velocity. For example, on a plane or train having attained constant speed with the constant passive movement of fluid, otoliths and receptors soon move at the same speed and there is no relative movement between the various components of the vestibular mechanism and, therefore, no stimulation.

2. Vestibular Stimulation and Occular Function

In response to rotation of the head, the stimulation of the semicircular canals transmits information to many body systems, including the occular muscles, which creates reflexive eye movement. The eyes move slowly opposite, the movement of rotation and then quickly return. The reflex that coordinates the eye and head positions is known as vestibular nystagmus, which facilitates the perception of a stable visual environment. In other words, the visual image of a fixed object remains stabilized on the retina.

3. Incidence and Susceptibility to Disorienting Stimuli

All individuals or animals with a normal vestibular system are susceptible to the sickness induced by an unusual movement or visual scene, and this is best known with respect to motion sickness. It is observed in numerous species, e.g., cows, sheep, dogs, birds, and monkeys, in addition to humans. It is not reliably demonstrated in children less than 2 years old; susceptibility is highest between 3 and the early teenage years and usually decreases thereafter. Parents who suffer from motion sickness report a greater incidence of susceptible children. Women are also generally believed to be more susceptible than men.

People may feel ill or nauseous and 1 or 2% may actually vomit during normal travelling by boat, coach, car, train, or airplane, which can all precipitate motion sickness. The problem has been studied intensively for pilots with increasingly serious implications for private license, commercial airline, and military pilots. The problem can be most intense and disabling during space travel, with some 75% of all astronauts being affected for 3–4 days. The occurrence of drowsiness (the Sopite syndrome) can also be significant.

A number of tests have been developed to assess individual susceptibility to motion sickness and to assess the mechanisms involved. One of the most common is the Coriolis Sickness Susceptibility Index, in which subjects are required to make a series of head movement in the pitch (sagittal) and roll (frontal) planes while undergoing body rotation in the yaw (horizontal) plane.

4. The Sensory Conflict Theory

Disorientation-induced sickness is generally considered to result from a sensory conflict between the data presented from the vestibular and visual systems against those that are expected on the basis of past experience. For example, reading a book in a moving car or train can be provocative; the constant visual image is at variance with the movement recorded by the vestibular system. In contrast, looking out of the car or train window with a fixed horizon presents a moving image that is in harmony with the input from the vestibular nuclei.

The importance of visual perception is shown dramatically by the sensory conflict imposed by the presence of a changing visual image but static vestibular input. For example, a subject sits quietly on a chair with no movement but is made to watch motion pictures shot from a moving vehicle or is placed inside an optokinetic drum or rotating room. In brief, the subject is stationary while the environment is moving. An alternative would be for the subject to operate a vehicle training device (a stimulator sickness) equipped with a moving visual display. In both cases, the ''visual sickness'' created by the visual record of movement in the absence of body movement creates a conflict sufficient to induce sickness. A most impressive demonstration of the power of visual input to influence vestibular function is shown by postural sway experiments. In these experiments, a stationary, standing observer is placed in a special room whose walls and ceiling can move backward and forward. The subject, who is unaware of the swaying of the room, begins to sway in synchrony with the swaying environment. The postural (vestibular) adjustment occurs only in response to the changing visual scene. These examples provide convincing evidence that visually induced sensations of motion appear equivalent to those produced by actual body motion.

E. Psychogenic Stimuli

Fear or disgust at the sight, smell, or taste of something intensely disagreeable can precipitate nausea or even vomiting. The stimuli arising in the visual, olfactory, or gustatory receptors are finally relayed to the cortical and limbic systems, which interpret and give meaning to the experience. In addition, anxiety itself is well-known to predispose one to nausea and vomiting. Also, higher functions in the brain can learn or be conditioned to respond with emesis to specific triggers. This involuntary or Pavlovian response, seen in cancer patients whose previous nausea and emesis to cytotoxic treatments had been poorly controlled, can be precipitated by even the sight or smell of the hospital where or the medical or nursing staff from whom they had received treatment.

F. Pain

The specific stimulus of intense and acute pain, caused by distension of intestinal, bile, or urethral ducts, or severe somatic or cardiac pain can induce nausea and vomiting.

III. THE CENTRAL AND PERIPHERAL SYSTEMS MEDIATING NAUSEA AND EMESIS

The stimuli influencing the emetic reflex provide important clues as to the brain circuitry mediating nausea and vomiting. Concepts based on results obtained mainly from animals using central and peripheral nerve lesions, from intracerebral injection of drugs into and electrophysiological stimulation from discrete brain regions, and more recently from human brain imaging have begun to establish key structures and pathways. Pharmacology, in discovering new antiemetic treatments, is establishing the relevance of specific neurotransmitters within these pathways.

A. The Area Postrema: The "Chemoreceptor Trigger Zone"

An important structure is the "chemoreceptor trigger zone" (CTZ) in the area postrema, which has numerous afferent and efferent connections with underlying structures, the subnucleus gelatinosus and nucleus tractus solitarius, and the vagus nerve.

B. The Nucleus of the Solitary Tract

The nucleus of the solitary tract consists of medial and lateral divisions, which are innervated in a highly selective manner by the terminals of the vagal sensory neurons; this provides the basis for a central sensory viscerotopy. The solitary nucleus is a complex integration center subserving many functions and also receives information from the parvocellular vasopressin containing neurons in the hypothalamus; increased levels of vasopressin are associated with nausea. Further, the amygdala innervates the solitary nucleus and has been implicated in the integration of autonomic and somatic components of emotional behavior. Its influence on cardiovascular and respiratory functions, together with cortical input, may contribute to the nausea and emesis induced by psychogenic stimuli. The aortic and carotid sinus afferents also relay chemo– and baroreceptor information to the solitary nucleus, and hypotension is a known factor to induce nausea and emesis (Fig. 5).

The nucleus tractus solitarius may also serve a chemoreceptor function. For example, the injection of the ∂_2 adrenoceptor agonist clonidine into the solitary complex induces bradycardia and hypotension; the reduction in blood pressure in humans may be related to the actions of clonidine to induce an intensity of nausea and dizziness that will cause at least 10% of patients to discontinue the treatment.

It is possible that psychogenic stimuli mediated via the amygdala on the solitary nucleus may modify cardiovascular and respiratory functions to reduce blood pressure; this may then trigger a lowering of the threshold for nausea and vomiting. It is possible that projections from the area postrema to the solitary nucleus may also interact with the visceral and other afferent terminals to modulate interoceptive information relevant to nausea and vomiting.

The solitary tract is a substantial structure and located close to the area postrema and vestibular nucleus. The solitary nucleus sends a major projection to the medullary reticular formation, has direct projections to the limbic and other forebrain regions,

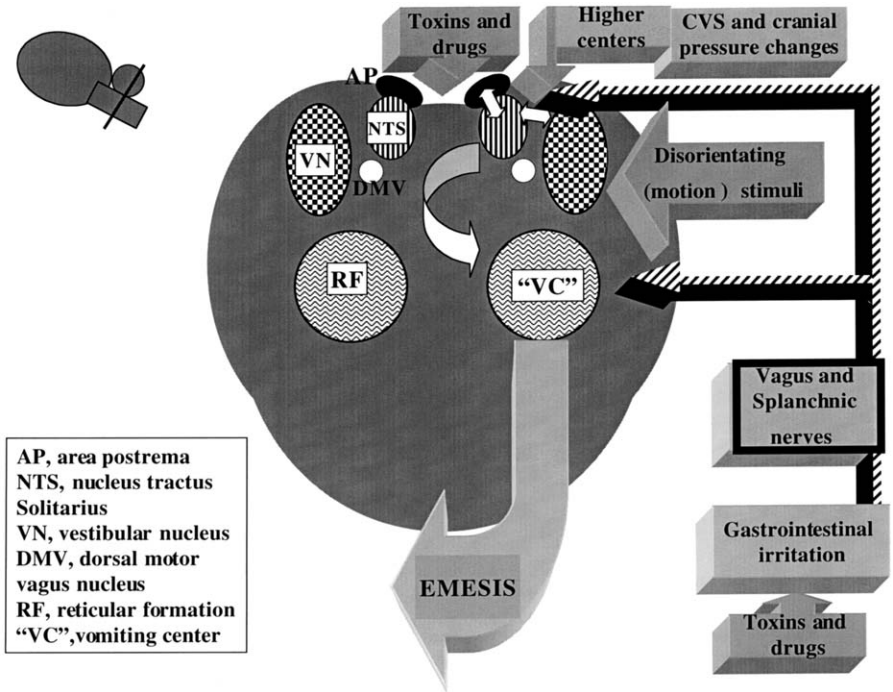

Figure 5 The major medullary structures and stimuli that contribute to the induction of emesis. CVS, cardiovascular.

and has indirect connections to the cortex. This may allow the interoceptive information generated in the solitary nucleus to influence both higher and lower brain centers relevant to nausea and emesis.

C. The Vestibular System

The vestibular pathways that begin in the hair cells of the christae and maculae have their cells bodies in the vestibular ganglion and their axon terminals in the vestibular nuclei of the medulla and cerebellum. It is well-established that impulses are then relayed to a number of sites, including cranial nerves III, IV, and VI to control head movements with eye movements and motor neurons to control posture and balance.

However, more recently, like the vestibulo–ocular and vestibular spinal circuits, pathways have been established that appear to integrate vestibular and autonomic information. These may be relevant to the autonomic manifestations of vestibular dysfunction, gastrointestinal discomfort, nausea, and vomiting and complement the cerebellar complexes that influence the somatic motor system. The pathways are shown in Fig. 6. Both physiological and anatomical evidence indicates a convergence of descending vestibular and visceral information on neurons in the solitary tract and the rostroventral medullary reticular formation. An ascending projection to the parabrachial nucleus may integrate vestibular and autonomic influences via limbic (affective), cortical (cognitive), and hypothalamic (neuroendocrine) pathways. This may provide a substrate for the interactions between affective (e.g., anxiety) and cognitive (e.g., learned behavior) factors to predispose one to motion sickness and psychiatric disorders. The model provides a useful working hypothesis to further establish the autonomic changes that can be shown to occur following vestibular stimulation.

D. The "Vomiting Center"

The vomiting center was an area originally discovered by electrically stimulating brain stem medullary structures to induce emesis. However, it is now more

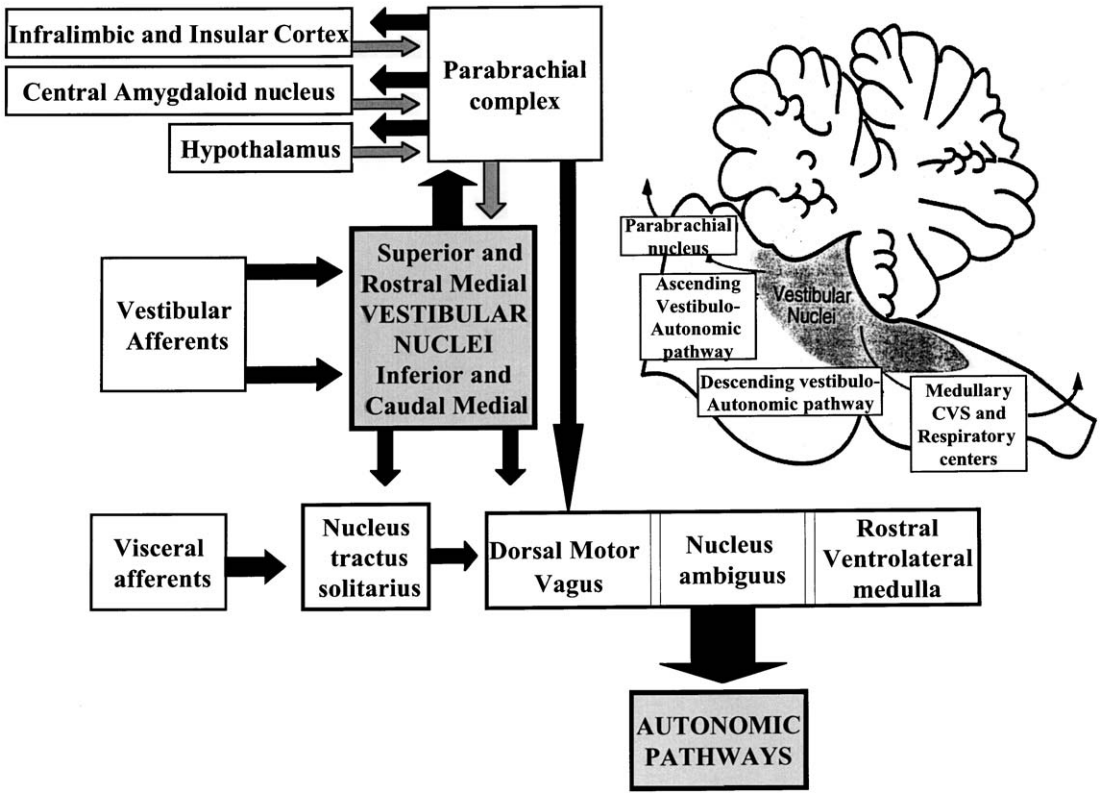

Figure 6 Diagram of the vestibuloautonomic pathways and the interactions with higher brain function relevant to emesis. Adapted from Babalan and Porter (1998) and Furman *et al.*(1998). Clinical evidence that the vestibular system participates in autonomic control. *J. Vestibular Res.* **8**(1), 27–34. Reproduced by permission of Elsevier Science.

accurately described as a collection of effector nuclei rather than a discrete brain area. The vomiting center receives major inputs from the chemoreceptor trigger zone, the nucleus tractus solitarius, the vestibular nucleus, a vagal and sympathetic input from the gut, and input from the cardiovascular system and a number of limbic brain nuclei, e.g., the olfactory tubercle, amygdala, hypothalamus, and ventral thalamic nucleus. Electrical stimulation of all of these structures can induce emesis. The latter nuclei may be involved in olfactory, emotional–anticipatory, hormonal–stress, and pain–induced vomiting, respectively.

E. Brain Mechanisms and Nausea

Finally, the brain regions that produce the sensation of nausea have been difficult to assess; nausea is a subjective human experience, and reliable animal models are not available. However, noninvasive magnetic source imaging in humans has revealed that neuronal activation occurs in the cortex in the inferior frontal gyrus in volunteers made nauseous with ipecacuanha or vestibular stimulation: the activation caused by ipecacuanha (but not vestibular) was antagonized by ondansetron. This brain area may be important in the perception or sensation of nausea (Fig. 7).

IV. THE PATHOLOGY OF NAUSEA AND VOMITING

A. Gastrointestinal Irritation

A summary of the major stimuli of the chemoreceptors and mechanoreceptors in the gut have been provided in Fig. 2. Gastrointestinal trauma following the accidental or deliberate injestion of toxic materials such as alcohol is the single most common cause of nausea and emesis in Certain chemotherapeutic agents such as cisplatin or radiation used in the treatment of

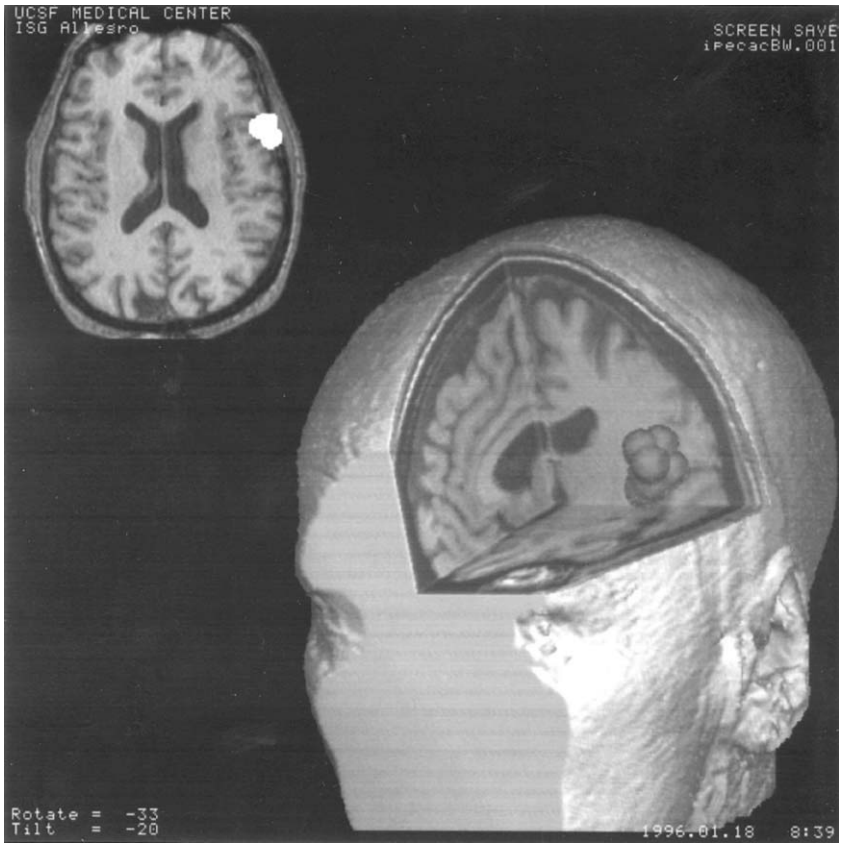

Figure 7 Location of current dipoles, indicative of neuronal activation, in the inferior frontal gyrus in a subject made nauseous by the oral ingestion of ipecacuahna syrup. The dipoles reflect magnetic source imaging of only one side of the head during a recording session.

cancer cause considerable damage to gut tissue, including the enterochromaffin cells. These contain 5-HT and it is hypothesized that damage causes the release of 5-HT to stimulate 5-HT_3 receptor located on the vagus afferent nerve fibers. This will depolarize the vagus nerve and trigger the emetic reflex.

B. Vestibular Pathology

The importance of the labyrinth to motion sickness is shown in labyrinthectomized monkeys and labyrinthine-defective human subjects; they are immune to motion sickness and probably visually induced sickness. Interestingly, chronic labyrinthectomy in dogs also impairs their ability to vomit in response certain poisons. However, in the presence of a defective vestibular function as is found in Ménières disease, the patient experiences sudden episodes of violent vestibular activity causing nystagmic eye movements, extreme vertigo, severe nausea, and distortions of hearing.

C. Intracranial Pathology

A sudden bout of vomiting associated with a severe headache may be the consequence of raised intracranial pressure caused by intracranial hemorrhage or a severe inflammatory response. A severe headache is also frequently observed following lumber puncture, which alters pressure within the cerebral ventricular system. This may be due to a direct influence on the central structures coordinating the vomiting reflex, with additional input from nociceptors present in the vascular smooth muscle. Migraine provides a less dramatic pathology and is the most common neurological disorder, presenting as the classical unilateral pulsating headache with gastrointestinal effects and nausea and vomiting. There is a little understood link between the susceptibility to migraine attacks and motion sickness.

D. Cyclic Vomiting Syndrome

The cyclic vomiting syndrome is an uncommon and unexplained disorder in children (and some adults), with an onset usually between 3 and 7 years and persisting for months to decades, with episodes occurring several times per month or year. It is characterized by recurrent attacks of severe and relentless nausea, vomiting (5–10 times an hour at peak effect) with prostration for hours to days; gastrointestinal disorders and intense abdominal pain, diarrhea, and fever also occur. The dehydration and electrolyte imbalance cause intense thirst and may be life-threatening. The child generally is well between attacks. Frequently, there is a familial history of migraine.

E. Hyperemesis Gravidarum

Nausea occurs in over 80% and vomiting in over 50% of pregnant women during the first trimester. The "morning sickness," which can actually occur at any time, then declines. Only a small number, possibly 1 in 1000, show the continued vomiting of hyperemesis gravidarum. The cause is not known but may involve changes in hormonal function, intraabdominal pressure, gastric emptying, metabolism, and pyschogenic influences.

F. Metabolic Disorders

A wide variety of metabolic disorders may induce nausea and vomiting, e.g., hypoglycemia due to over dosage with insulin and uremia following kidney damage.

G. Psychogenic Nausea and Retching or Vomiting

A raised level of anxiety predisposes one to nausea and emesis:

1. Chronic "psychogenic vomiting" (or usually retching) usually occurs upon getting up or just after breakfast; it may persist for years.
2. "Nervous dyspepsia" is used to describe symptoms of a feeling of satiety, abdominal discomfort, nausea, and vomiting associated with psychoneurotic features such as anxiety, irritability, and loss of weight.
3. Anorexia nervosa and bulimia have a well-established psychopathology in which retching–vomiting is a symptom of serious psychiatric illness.

H. Post-Operative Nausea and Vomiting (PONV)

General anesthetics were first administered in 1846 and were immediately associated with a very high incidence of postoperative nausea and vomiting. After 100 years the introduction of halothane caused a fall in the

incidence of PONV, but this remained at some 25–30%. Whereas PONV is generally is self-limiting and rarely is of medical or surgical importance, for many patients it remains the most distressing part of the operation.

PONV is multifactorial and may be triggered by any or all of the following factors:

1. Inhaled agents are variably associated with PONV, nitrous oxide being noteworthy. However, intravenous anesthetics and spinal anesthesia are also potentially emetogenic.
2. Stimulation of the oropharynx.
3. The nature of the surgery, e.g., gynecological and pediatric strabismus surgery have a high incidence of nausea and vomiting. Also, abdominal surgery may cause stretching, distention, or tissue damage, i.e., gastrointestinal irritation.
4. Pain resulting from surgery or disease.
5. Hypoxia, hypotension, and carbon dioxide retention.
6. Clumsy movement of the patient in the recovery room or ward or following day-case surgery, causing labyrinthine disturbance.
7. The nature of any pre- or postoperative drug treatments, e.g., opioid analgesics.
8. Psychogenic factors such as anxiety.
9. An increase in body weight increases the prevalence of PONV.
10. Adult females have three times more risk than adult males of developing PONV, and children are twice as susceptible as adults.

V. NEUROCHEMICAL COMMUNICATION WITHIN THE EMETIC REFLEX

An understanding of the neurotransmitters within the pathways of the emetic reflex is essential to the design of rational pharmacological antiemetic treatments. Neurochemical and immunocytochemical analyses of medullary nuclei have revealed a wealth of neuroactive substances that may contribute to a neurotransmitter, neurohumoral, and neuromodulatory role: e.g., serotonin, noradrenaline, γ-aminobutyric acid, acetylcholine, substance P, enkephalin, oxytocin, vasopressin, neurotensin, and thyrotropin releasing hormone. The identification of receptor binding sites within the medullary nuclei has further identified the potential loci of drug action. However, it is not yet possible to characterize the precise neurotransmitter pathways that exist between the nuclei of the emetic reflex. Also, the presence of a neurotransmitter or its receptors provides no guidance as to its functional relevance. This can only be undertaken by local and discrete injections of transmitters and receptor agonists and antagonists into the medullary nuclei. Such studies, relevant to emesis, remain to be performed.

VI. THE PREVENTION OR TREATMENT OF NAUSEA AND VOMITING

A. Overview

Nausea and vomiting are symptoms of a cause that may require investigation and treatment. A transient bout of emesis induced by a single psychogenic stimulus is unpredictable, by definition untreatable, and only of interest to the sufferer. Similarly, a brief bout of nausea and vomiting during travelling is essentially a social inconvenience of little consequence to anyone other than the afflicted and fellow passengers. However, when motion sickness interferes with the awareness, emotional, and cognitive competence of a professional or military pilot, the consequences are profound and will require careful investigation. The devastating nausea and vomiting induced by highly emetogenic chemotherapy or the relentless nausea and vomiting observed in the cyclical vomiting syndrome are of serious medical concern and require treatment. Finally, retching, vomiting, or regurgitation occasionally constitutes a medical or surgical emergency, which requires immediate treatment when it is induced

1. by major intracranial pathology or intestinal obstruction.
2. by in infants, where fluid loss may cause dehydration.
3. by postoperatively where the force of retching or vomiting may tear esophageal tissue or damage delicate surgical repair.
4. by in an emergency, when the patient has recently had a meal and therefore has a high risk of developing aspiration pneumonia.
5. by hyperemesis gravidarum.

It remains clear that, to a patient, either a brief or a persistent period of nausea and vomiting is always of concern. Persistent nausea will incapacitate the patient, and persistent vomiting may result in the loss of fluid and hydrochloric acid, leading to dehydration, alkalosis, reduced food intake, malnutrition, and serious debilitation, severely reducing the quality of life.

B. The Preferred Treatment of Nausea and Vomiting Is Removal of the Cause

Persistent nausea or vomiting may be indicative of gastrointestinal, neurologic, or metabolic disorders that require direct treatment, and it may be desirable to withhold antiemetic therapy until a diagnosis has been made. However, it remains clear that the treatment of a cardiovascular pathology such as migraine with sumatriptan will relieve the neurologic manifestations, headache, gastrointestinal effects, nausea, and vomiting. Yet sumatriptan has no direct effect on the emetic reflex. However, for most causes of nausea and emesis, e.g., motion sickness, cancer chemotherapy, and antiparkinsonian medication, removal of the cause is not an option. Also, there is a marked variation between individuals in their response to nausea–emetic stimuli, although previous sensitivity to a nausea–emetic stimulus is indicative of future sensitivity. For example, patients who have had nausea and vomiting following previous surgery are likely to experience it again. Also, women who experience pregnancy sickness are much more likely to develop nausea and vomiting in response to any hormonal disturbance (e.g., the contraceptive pill) or travelling and with a migraine. People who have an emetic response to a first drug challenge are likely to show a similar response to a subsequent challenge, i.e., an individual tends to have a consistent response. A simple enquiry therefore may identify people at greater risk, i.e., those who have a lower emetic threshold. These people are particularly likely to develop nausea and vomiting under emotional strain as occasioned by illness.

It should also be considered that many presentations of nausea and vomiting may be induced by a combination of different stimuli. This has remained the single most unexplored territory in the treatment of nausea and emesis.

There are now at least five major groups of compounds with defined pharmacological profiles to control nausea and emesis. These include the following:

- Dopamine receptor antagonists
- Muscarinic receptor antagonists
- Histamine H_1 receptor antagonists
- 5-HT_3 receptor antagonists
- NK_1 receptor antagonists
- Sedatives and hypnotics
- Phenothiazines

Procedures and treatments that alleviate retching and vomiting generally prevent nausea.

1. Dopamine Receptor Antagonists

Apomorphine induces intense nausea and vomiting and has a high affinity for the dopamine receptor. Dopamine receptors are found in high concentrations in the area postrema, the dorsal motor nucleus of the vagus nerve, and the nucleus tractus solitarius. The traditional view has been that apomorphine, levodopa (via dopamine), lergotrile, bromocriptine, and other dopamine agonists used in the treatment of Parkinson's disease induce nausea and vomiting by stimulating dopamine receptors in the CTZ. Highly potent dopamine receptor antagonists such as haloperidol block such receptors and thereby prevent nausea and emesis. However, the use of these drugs is limited in two ways:

- First, they generally do not inhibit nausea and emesis induced by stimuli other than dopamine agonists (although droperidol is used in PONV).
- Second, they have major adverse effects of motor impairment, severe akinesia and muscle rigidity, and dystonias (muscle spasm) caused by striatal dopamine receptor blockade, particularly in young people.

The adverse effects are less with the dopamine receptor antagonists domperidone and sulpiride because they are less able to penetrate the blood–brain barrier in the striatal areas but can easily access structures such as the area postrema, which lacks a blood–brain barrier.

Metroclopramide is also a dopamine receptor antagonist that has been widely used as an antinauseant–antiemetic for gastrointestinal disorders and migraines and, in much higher doses, for cancer chemotherapy and radiation-induced sickness. Its unusual and established ability to facilitate gastric emptying and intestinal activity may contribute directly to its antinauseant–antiemetic actions in gastrointestinal disorders and migraines. However, such actions reflect not a dopamine receptor blockade but more probably an agonist action at the 5-HT_4 receptor. Furthermore, its ability to prevent chemotherapy–radiation-induced emesis, when used in exceptionally high doses, is more readily attributed to its low-potency 5-HT_3 receptor antagonism.

2. Muscarinic Receptor Antagonists

Scopalamine is the most effective remedy for motion sickness of all types, although nausea and vomiting induced by extreme changes in motion and space travel

remain an intractable problem and scopalamine fails to control all types of movement sickness (e.g., due to severe vestibular disturbance). Scopalamine has a greater central depressant effect than atropine, and its antiemetic action is attributed to a blockade of muscarinic cholinergic receptors in the area postrema or associated nuclei of the dorsal vagal complex. Scopalamine is also a potent inhibitor of gastrointestinal movements and relaxes the gastrointestinal tract. These effects may make a modest contribution to the antiemetic action.

Adverse effects of scopalamine include sedation and predictable autonomic effects with increasing dose (e.g., blurred vision, urinary retention, decreased salivation). The sedation and blurred vision preclude its use in airline pilots, train, bus, and car drivers, and those operating machinery.

3. Histamine H_1 Receptor Antagonists

Antihistamines used for motion sickness include buclizine, cyclizine, dimenhydrinate, meclizine, and promethazine. Their antiemetic actions are attributed to a central blockade of H_1 receptors in the area postrema and possibly underlying structures. However, most antihistamines are also potent muscarinic receptor antagonists, and this behavior may make an important contribution to their antiemetic actions. Indeed, chlorpheniramine, which is an H_1 receptor antagonist that fails to block centrally mediated cholinergic effects, does not inhibit motion sickness. Whatever the contribution of an H_1 and ACh receptor blockade to the antiemetic potential, a sedative potential may also contribute to the effect, although this is less or absent for cinnarizine. However, some antihistamines that cause sedation are not antiemetic. The H_1 receptor antagonists may play some role in the treatment of PONV and pregnancy sickness.

4. 5-HT_3 Receptor Antagonists

Ondansetron, granisetron, and tropisetron were introduced 10 years ago as antiemetic agents. Their ability to antagonize chemotherapy- and radiation-induced emesis was first established in animal models in 1986. Their efficacy relates to the blockade of 5-HT_3 receptors, which are located in high density in the area postrema and nucleus tractus solitarius and on vagal afferent nerve endings in the gut.

It is hypothesized that severely emetogenic regimens such as cisplatin cause gastrointestinal tissue disruption, which initiates the release of 5-HT from the enterochromaffin cells within the mucosa to trigger vagus nerve firing to initiate the emetic reflex. The 5-HT_3 receptors within the area postrema–nucleus tractus solitarius lie on the vagus nerve terminals, because they disappear if the vagus nerve is cut.

Ondansetron and the other 5-HT_3 receptor antagonists control nausea, retching, and vomiting in patients with cancer receiving emetogenic treatments, especially during the acute phase (i.e., day 1 of treatment): the symptoms are completely controlled in 70% of patients and there is reduced vomiting in the others. However, on the second and subsequent days (i.e., a delayed phase) the antimetic effects are less pronounced and the addition of a glucocorticosteroid is needed to produce a maximally efficacious antiemetic regimen. Dexamethasone or methylprednisolone is now used frequently in combination with ondansetron or other 5-HT_3 receptor antagonists to secure optimal control, even on the first day of treatment. This is vitally important for the patient with cancer, because the development of nausea and vomiting during treatment can lead to learned anticipatory nausea and vomiting. Such anticipatory nausea–vomiting is resistant to all drug treatments, including the 5-HT_3 receptor antagonists.

The 5-HT_3 receptor antagonists have no effect on motion sickness or apomorphine-induced vomiting. They will, however, block the nausea and vomiting induced by ipecacuanha, which has been used as a tool in animals and humans to determine the dose regimens of 5-HT_3 receptor antagonists that will be required to block nausea and emesis in the cancer patient. Ondansetron has also been shown to antagonize the nausea induced by morphine and the nausea and adverse gastrointestinal effects of SSRIs. The lack of interaction between 5-HT_3 receptor antagonists and other drugs also prompted the use of ondansetron in the treatment of PONV, for which it is as efficacious as any of the existing remedies (e.g., cyclizine, droperidol) but does not produce their adverse effects. Its use in the treatment of other causes of gastrointestinal irritation and pregnancy sickness is being investigated.

5. Sedatives and Hypnotics

Vomiting is blocked by anesthesia and lesser degrees of CNS depression, which may attenuate a low emetic threshold that normally would trigger intractable nausea and vomiting. Barbiturates and chloral hydrate have been used, but benzodiazepines are a more contemporary treatment and have the advantage of causing amnesia to prevent recall of a highly

distressing event. However, caution is needed as the potential for vomiting or aspiration in the presence of reduced consciousness is a serious hazzard.

6. Phenothiazines

Agents such as chlorpromazine, promethazine, prochlorperazine, and trimeprazine have a mixed pharmacology as antagonists at muscarinic, histaminergic, dopaminergic, adrenergic, and serotonergic receptors. Nausea and vomiting that fail to respond to specific pharmacologic treatments may sometimes respond to this multireceptor blockade (e.g., pregnancy sickness, PONV). Because the mechanisms mediating most types of nausea and vomiting are not clear but there may be many different contributory stimuli, the use of a mixed pharmacologic approach is logical. This may account for the extensive use of trimeprazine in palliative care.

7. NK_1 Receptor Antagonists

Antagonists acting at the substance P NK_1 receptor subtype have the most interesting antiemetic spectrum of action recorded so far. In many animal species they have consistent actions to inhibit emesis induced by many different drugs and also motion sickness. They appear to be broad spectrum antiemetic agents, where the breadth of antiemetic activities may be revealing of an inhibitory effect on the final pathways of the emetic reflex, although this remains to be proven. The only action against which they have not yet been tested is psychogenic induced or anticipatory emesis.

In humans the NK_1 receptor antagonists have been tested in the cancer patient and show considerable potential to antagonie chemotherapy-induced emesis and nausea, although this remains to be proven. In any event, these agents undoubtedly will receive intensive clinical testing to clearly establish their full potential and limitations.

8. Ancillary Treatments of Nausea and Vomiting

Movement disturbances and visual, olfactory, and emotional or psychogenic factors are potent but variable emetic stimuli and can be expected to contribute to the development of nausea and vomiting in many, and perhaps most, patients. For example, the sight, sound, or smell of just one traveller or patient who is vomiting may be sufficient to trigger the same response in others. Thus, it could be questioned whether the residual vomiting of patients with cancer placed on an open ward after 5-HT_3 receptor antagonism could be partly psychogenic rather than exclusively chemotherapy-induced. Incautious movement of a patient postoperatively, during pregnancy, or during other nausea- and emesis-inducing procedures may also contribute to observed symptoms.

Nonpharmacological remedies for nausea and emesis that are available for all individuals, and not specifically motion sickness, include restricting head movements, lying in a supine position, and closing the eyes. There are reports that acupuncture at P6 is effective to relieve nausea and vomiting in the cancer patient and during pregnancy. Electrical stimulation of P6 is also being investigated. Specialized procedures of vestibular desensitization and biofeedback prior to flight and space travel aid susceptible fliers in overcoming sickness; the success of many of these programs is excellent.

9. Future Drug Treatments

Dexamethasone has antiemetic activity in its own right and is being investigated in motion sickness. The anticonvulsants carbamazepine and phenytoin, the calcium channel blocker flunarizine, the herbal product ginger and the 5-HT_{1A} receptor agonists are all being investigated in animal models and in the clinic. Their value remains to be determined.

10. Summary of Treatment for Nausea and Emesis

1. The subject or patient should, as far as possible, be provided with an environment that will minimize noxious visual, vestibular, olfactory, and emotional precipitants of nausea and vomiting.
2. Psychological procedures to offer relaxation and reassurance and relieve anxiety are important.
3. Advice should be given about eating habits.
4. Medical, surgical, acupuncture, psychological, or psychiatric procedures are used to alleviate the cause or symptoms.

Neocortex

JON H. KAAS
Vanderbilt University

GLOSSARY

area A major subdivision of neocortex. Each area performs a specific set of functions. classically, areas have been called the organs of the brain.

column or module Subdivisions of areas that mediate a function or functions that are repeated many times within other modules of the same type within the area. Areas may have two or more types of intermixed modules.

cortical magnification The greater representation of important parts of sensory surfaces in cortical areas.

representation Areas are said to represent a sensory surface, such as the retina, skin, or cochlea, when stimulation in different parts of the sensory surface activates neurons in different parts of the area in a matching or isomorphic pattern. Muscles and movements are also represented in areas of motor cortex. Some areas may have more abstract, higher order representations. In each case, the representation is based on a spatial pattern of neural activity.

Neocortex is the part of the outer shell or "bark" of the forebrain that was thought to be new with the evolution of mammals. The cerebral cortex or pallidum covers the deeper parts of the forebrain or telencephalon, and it is generally divided into three parts: the lateral paleocortex or olfactory cortex, the medial archicortex or hippocampus and subiculum, and the neocortex lying in between. The archicortex and paleocortex are easily recognized in reptiles, and therefore they have terms that reflect the early belief that they are phylogenically old parts of the brain. Whereas all mammals have an obvious neocortex, nothing quite like neocortex exists in reptiles. Hence, early investigators coined the term "neocortex" to refer to this seemingly new part of the brain. Nevertheless, neocortex is not really new with the advent of mammals. Rather, neocortex is homologous with the dorsal cortex of reptiles, a rather small and unimpressively thin sheet of tissue with hardly more than a single row of neurons, a marked contrast to the thick neocortex with several layers of neurons. Because neocortex really did not originate with mammals, some investigators prefer to call the structure isocortex, using an early term that refers to the relatively uniform structure or appearance of neocortex throughout. However, most investigators continue to use the term neocortex, and it is accurate to say that its thick, laminated form is new with mammals. No reptile has a dorsal cortex that looks like neocortex, and no mammal has a neocortex that looks like dorsal cortex. Thus, a simple, stable, and functionally limited structure that has been retained from early to present-day reptiles has been transformed into a more complex, highly variable, and remarkably flexible structure in mammals. No living vertebrates have a cortex that is intermediate between dorsal cortex and neocortex. Thus, mammals are characterized by neocortex as much as by mammary glands. Whereas

neocortex has a somewhat uniform appearance, being easily recognizable as neocortex throughout and across species, its variability in size and organization is what allows mammals to be so different in behavior and abilities. Neocortex allows us to be human and rats to be rats. To understand how this is possible, we need to identify the common features of neocortex, as well as how it varies from mammal to mammal.

I. LAMINAR ORGANIZATION

The basic design of neocortex is similar in all mammals. Neocortex is a thick (compared to dorsal cortex) sheet of tissue of varying size but usually 1–3 mm in depth. The thickness of cortex results from a proliferation of neurons, such that the cell bodies of over 100 would be encountered by a pin stuck through its surface to the underlying axon fibers that shuttle information to and from the cortex. This contrasts to the one or two neurons that would be encountered by a pin stuck through the dorsal cortex of reptiles. Whereas the thin row of neurons in dorsal cortex both receives input from other parts of the brain and provides output, the thicker neocortex provides a more complex and fundamentally different type of processing. First, the neurons across the thickness of cortex are of different morphological types and they have different connections and functions. Second, neurons of similar appearance and connections are grouped according to depth in the cortex so that groups of cells form a stack of layers. Early investigators numbered and named the layers in various ways, but a scheme of six basic layers, stemming from the publications of Korbinian Brodmann around 100 years ago, has become a nearly universal standard (Fig. 1). Some of the layers of other early investigators are now considered to be sublayers within the standard scheme.

Layer 4, a middle layer of neurons, is the main receiving layer of neocortex (Fig. 2). Neurons in this layer receive most of the activating input from other structures, including nuclei of the dorsal thalamus and other subdivisions of the cortex. The connections of neurons in layer 4 are predominantly local within layer 4 and with neurons immediately above or below in adjoining layers. There, the information that is received in layer 4 rapidly spreads in a narrow focus across the layers. These and similar vertical connections of neurons in other layers form vertical columns of coactive neurons in neocortex. This is a highly characteristic feature of cortical organization.

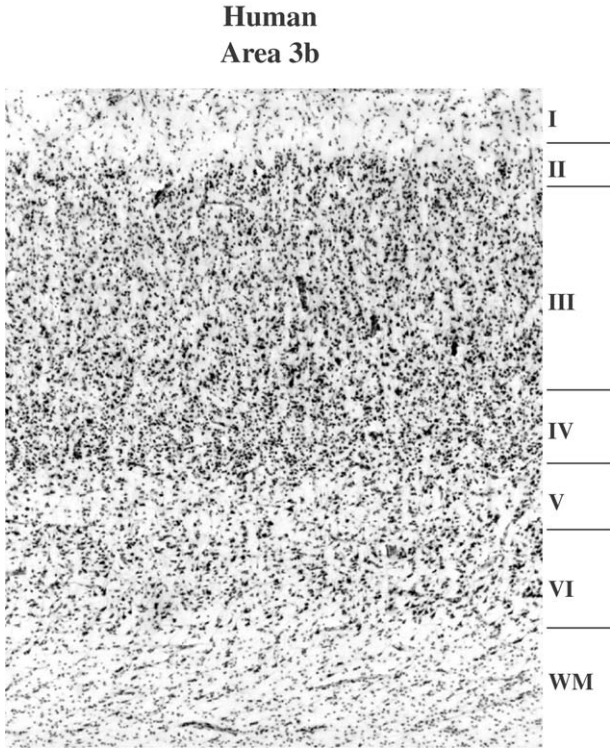

Figure 1 The laminar organization of the neocortex. Part of the neocortex was cut into thin slices across its thickness, and the sections were stained to reveal cell bodies (dark ovals) but not axons and dendrites. The cell bodies vary in size, shape, and packing density across the thickness of neocortex in a laminar pattern. It is now usual to divide the neocortex into six main layers (I–VI; for historical reasons, Roman numerals are usually used to number layers) from the surface to the underlying connecting axons or white matter (WM). Sublayers are also commonly distinguished. Layers play different functional roles in the processing that goes on in the neocortex (see text). Different areas of the neocortex are specialized for different functional tasks, and such specialization may be reflected in variations in the appearance and relative thickness of the layers. The section of cortex shown here is from the primary somatosensory cortex of a human, commonly referred to as area 3b after a numbering scheme devised for cortical areas by Korbinian Brodmann over 100 years ago. This cortex is just over 2 mm thick. Area 3b and other sensory areas of neocortex are characterized by a relatively thick layer IV that is densely packed with neurons having small cell bodies. Layer III is especially thick in the large brains of humans.

For activation, layer 4 neurons depend on focused synapses from only a few axons from another structure, and they spread this information to only a few nearby neurons that are immediately deeper or more superficial in the cortex. Thus, layer 4 neurons are rather small, with radial dendrites spreading around the cell body and a restricted and local axon arbor contacting adjacent neurons in layer 4 and neurons

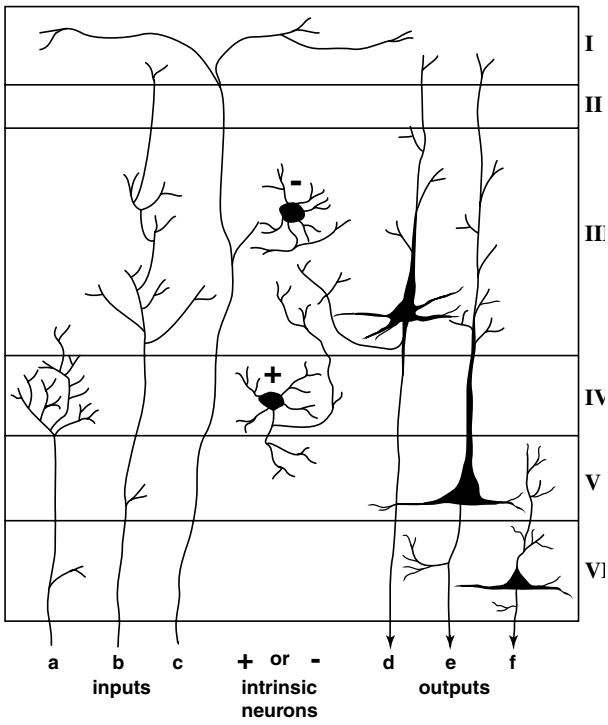

Figure 2 Major input axons, output neurons, and intrinsic neurons of the neocortex. Input to cortex includes (a) the major activating input from the thalamus or other areas of cortex that terminates largely in layer IV; (b) the feedback activating connections from other areas of cortex that terminate more diffusely above and below layer IV; and (c) the diffusely distributed modulating input that terminates above layer IV. Intrinsic neurons include excitatory (+) stellate or granular cells in layer IV with local dendrites and a local axon arbor and an inhibitory (−), nonspiny class of stellate cells or local circuit neurons of various types in all layers. Output neurons include (d) layer III pyramidal cells that project to other areas of the cortex and to subcortical targets; (e) larger layer V pyramidal cells that project mainly to subcortical targets including the spinal cord; and (f) pyramidal-like neurons of several types in layer VI that provide feedback connections to the

above and below layer 4. The small neurons in layer 4 are typically called stellate cells because their short dendrites protrude in all directions like the rays of a star. Because layer 4 cells are often so small as to appear to be no more than grains of sand, they are also called granule cells. Layer 4 is sometimes called a granular layer.

Layer 5 neurons, just under layer 4, are activated by layer 4 and other neurons in the superficial layers. The major neuron type is the large pyramidal neuron (Fig. 2). The cell body is triangular in shape with the apex pointing outward as it gives rise to a long apical dendrite that ascends toward or to the surface of layer 1. The base of the triangular cell body also gives rise to basilar dendrites that are much shorter and spread out horizontally away from the vertical cell column and ascending apical dendrite. The dendrites are covered with synaptic contacts from other neurons. The arrangement of the dendrites indicates that layer 5 pyramidal cells are designed to gather information somewhat horizontally in layer 5 via the basilar dendrites, and more locally from the more superficial layers via the long ascending apical dendrite, which has short radiating branches along its ascending stem. Thus, layer 5 pyramidal neurons have access to input from a vertical array of neurons, including those of a vertical row along the apical dendrite and those in adjacent rows contacted by the basilar dendrites or the branches of the apical dendrite. The layer 5 neuron sums all this information, and it provides the major output of the neocortex. In addition to forming a local axonal arbor, most layer 5 pyramidal neurons project over quite long axons to nuclei in the dorsal thalamus, structures in the subcortical basal ganglia, the midbrain, and other brain stem structures, and even the spinal cord. Thus, the output of neocortex that most directly affects behavior and performance stems from layer 5 pyramidal neurons. Some layer 5 neurons also send information to more distant locations in the neocortex, either in the same cerebral hemisphere or in the opposite cerebral hemisphere via the corpus callosum. Thus, layer 5 neurons help to inform other areas of neocortex about ongoing computations. In brief, a major function of layer 5 neurons is to send information to other parts of the brain. Because these targets can be relatively far from the neocortex and distance is time for the nervous system, layer 5 neurons have long, thick axons. Because thicker axons have faster conduction rates, the transfer of information is speeded up. Neurons with long, thick axons and long, branching dendrites need large cell bodies to maintain these structures, and layer 5 pyramidal cells are large. They also vary in size according to axon length and thickness, so that the large Betz cells of the motor cortex project all the way to the lower spinal cord, whereas the large Meynert cells of the visual cortex project to the opposite hemisphere, to a distant visual area in the neocortex, and to the brain stem.

The other main output layer of the neocortex is layer 3, and it also contains pyramidal cells with basilar and apical dendrites (Fig. 2). However, layer 3 pyramidal cells generally are not as large as layer 5 pyramidal cells, because their apical dendrites are shorter and, more importantly, their axons are shorter, traveling to other areas of cortex rather than to more distant subcortical structures. Thus, neurons in any part of the

neocortex send information to other parts of the neocortex, and this is done largely by layer 3 pyramidal neurons. In a manner comparable to layer 5 pyramidal neurons, layer 3 pyramidal neurons receive local input along the vertical apical dendrite extending and branching throughout the depth of layer 3 and the basilar dendrites extending horizontally, sometimes to adjacent cell columns. In general, deeper layer 3 pyramidal cells are larger than more superficial layer 3 pyramidal cells. Layer 3 often has obvious sublayers. Layer 3 neurons send information to layer 4 neurons of other regions of the cortex or directly to other layer 3 neurons. The great computational power of the neocortex stems from these layer 3 pyramidal cells because they transmit information from one region of neocortex to another. Each local group or column of neurons performs a similar and somewhat simple operation or computation, but it is the consequence of a series of simple computations that gives the cortex its great computational power, a power beyond that of the input–output operations of the dorsal cortex of reptiles.

Other layers add to the functional complexity of neocortex. Feedback about computational outcomes is important in information processing systems, and neocortex is designed to provide feedback both to the subcortical thalamic nuclei that provide all sensory information to the neocortex and to other cortical areas that provide information for further processing. Layer 6 is the main feedback layer (Fig. 2). Neurons in layer 6 typically provide feedback projections to the same structure that provides the major activating input to a cortical area or region. If, for example, the major activating input for a subdivision of visual cortex is from a nucleus in the visual thalamus, then layer 6 neurons project back to that same nucleus. If layer 3 neurons in one area of cortex provide the major activating input to layer 4 of another area of cortex, then layer 6 neurons from the target area typically project back to the activating region. Other neurons in other layers may also participate in providing some feedback. The layer 6 neurons receive rather direct information from upper layers, especially layer 4, and they even receive a small amount of direct input from branches or collaterals of axons terminating in layer 4. Thus, input from the visual thalamus to the visual cortex terminates largely in layer 4, but it also provides a few direct branches to layer 6. Layer 6 neurons in turn project back to the sending neurons in the visual thalamus to inform these neurons about the state of the cortex and to influence the next burst of information being sent to the cortex. Layer 6 neurons, by concentrating on responding to local layer 6 connections and input from more superficial neurons, have basilar dendrites and a variable but often long apical dendrite. Thus, they are considered to be pyramidal cells or modified pyramidal cells, although layer 6 is sometimes referred to as the internal granular layer, with layer 4 being the external granular layer. However, layer 6 neurons differ from layer 4 neurons by projecting to distant structures, and thus layer 6 neurons generally are larger. Besides having projections to thalamic nuclei and other cortical areas, layer 6 neurons project to a subcortical structure, the claustrum, which in turn projects back to layer 6. This reciprocal pattern of connections functions to modify the response properties of layer 6 neurons.

The other two layers of neocortex are layers 1 and 2. Layer 2 is a thin layer of densely packed small neurons with local connections and a role in modifying local processing via contacts on apical dendrites of deeper pyramidal cells. Layer 1 is a fiber layer with few neurons that largely consists of the ends of apical dendrites and axons that course along the brain surface and contact these dendrites. Thus, layer 1 is reminiscent of the outer fiber layer of the dorsal cortex of reptiles where input contacts dendrites. Some of the input to layer 1 is modulating input from brain stem neurons. Other input is feedback connections from other cortical areas.

II. LOCAL CIRCUIT FUNCTIONS

Whereas the basic structure of neocortex involves five layers of neurons and one layer of fibers that differ in functional role, neuron types, and connections, the functioning of the cortex cannot be fully understood from this framework alone. It is also important to consider several additional features of cortical organization. First, all layers of cortex contain populations of two fundamentally different types of neurons. The ones discussed so far excite each other and use the excitatory neurotransmitters. The release of an excitatory neurotransmitter at each synaptic contact tends to depolarize the contacted neuron and increase the probability of an action potential and the transmission of information. These excitatory pyramidal and spiny stellate cells constitute roughly 80% of the total number of neurons. The other 20% of neurons, distributed across the layers, are nonspiny stellate cells that release the inhibitory neurotransmitter, GABA, which hyperpolarizes the contacted neuron and

decreases the probability of an action potential. The GABAergic or inhibitory neurons in the cortex all have short axons that distribute locally, and thus they are considered to be interneurons or local circuit neurons (Fig. 2). Inhibitory and excitatory neurons interact to produce important outcomes within the circuitry of neocortex. First, circuits tend to respond briefly to changes in input. Input to layer 4 excites both excitatory and inhibitory neurons. The excitatory neurons transmit excitation to other excitatory and inhibitory neurons. The inhibitory neurons inhibit excitatory neurons and other inhibitory neurons. The immediate result is to limit the duration times of a cortical response to any input. The initial excitation gets through to activate the neuron, but later arriving inhibition dampens subsequent activity. Thus, the system selectively responds to what is new and changing in time. Response to temporal changes in the environment is usually what is significant for adaptive behavior and survival. Second, circuits compare and contrast adjacent inputs. The synaptic contacts of inhibitory neurons are local, and they tend to distribute horizontally to adjacent neurons. Thus, when adjacent vertical arrays of neurons respond to the same stimuli, they tend to inhibit each other and overall excitation decreases. In contrast, if input to adjacent neurons is activated by different stimuli so they do not respond at the same time, less lateral inhibition occurs to dampen local excitation. The circuits of neurons are most excited by local differences in activating input that is often related to spatial contrast in the stimuli falling on the retina, skin, or cochlea. Spatial antagonism between a core of neurons and a surround of neurons provides a neural mechanism for emphasizing spatial differences over uniformity, again something that is very useful biologically. A fly on a sheet of paper, for example, activates cortical neurons more than any comparable location on the uniformly white sheet of paper, and we easily detect the fly. By repeating neural computations in a series of successive circuits, the temporal and spatial contrast detection features of circuits can progress from local to global features and from mediating simple and "mindless" abilities to the complex and astonishing.

What else is important about neural circuits in the neocortex? Local circuits in vertical arrays in neocortex interact with each other within each area over short, lateral, or horizontal connections. Excitatory neurons, especially in layer 3, often have horizontal connections extending for several millimeters within the layer. The existence of these connections, which are relatively sparse, has long been known, but their significance is only now beginning to be understood. Basically, it appears that these sparse and relatively weak connections correlate the ongoing activities of separate groups of neurons. If the neurons are already responding to something, it does not take much in the way of interconnections to shift the times of neuronal action potentials or spikes so that the spikes occur in the separated neurons at the same time. If some of these neurons project to the same group of neurons in another structure, the arrival of these spikes from different groups of coactive neurons at the same time will have a powerful activating effect on the target neurons. There may be many uses for such correlated firing of neurons. One suggestion is that such correlation mediates "perceptual binding." All of the neurons firing at once, being activated by different aspects of the same stimulus object, signal by their correlation that they are responding to the same object. The object is thereby seen as one whole, rather than as fragments.

Another feature of neocortex that makes it so biologically useful is that the circuits are adjustable, rather than fixed. They are adjusted by "experience" in the way they respond to stimuli and other neurons so that they function in more useful and productive ways. This is largely because neurons have two types of membrane receptors for the excitatory neurotransmitter, glutamate. One type of receptor, the non-NMDA receptor functions as an excitatory channel that tends to generate neuronal spikes. The other receptor, the *N*-methyl-D-aspartate or NMDA receptor, is often blocked by a magnesium ion at resting membrane potentials so that glutamate release has no effect and the NMDA receptor fails to participate in the neuron's response. However, when the neuron has been depolarized by the activation of the non-NMDA receptors, the magnesium ion is released and the NMDA receptors can be activated and pass calcium ions by glutamate release, but only for a small fraction of a second. In some sense, the receptors function as "coincidence" detectors, because they are active when two sources of excitation are closely timed. The activation of NMDA receptors then provokes internal alterations in the neuron that strengthen the effectiveness of the synapses that were just active. Thus, some connections in the circuit are made more powerful. This change is often called long-term potentiation or LTP because synapses are potentiated or strengthened for up to weeks at a time. Other activity patterns weaken synapses. This change is called long-term depression or LTD. Thus, local circuits of neurons are always being altered in activity-dependent ways. These alterations are important in shaping brain circuits

during development and throughout life. They adjust the performance of local circuits and are necessary responsible for learning from sensory experience.

Neocortex has another way of adjusting its performance. Besides excitatory and inhibitory connections input exists that releases more long-lasting neurotransmitters that alter the probability of neurons producing spikes. Neural circuits in the neocortex do not always function at the same level of excitability. When we are drowsy or sleeping, the circuits may be harder to activate. When we are alert and motivated, the circuits may respond more readily. When we focus our attention, some groups of circuits become more responsive and others less responsive. These adjustments need not be spatially nor temporally precise, and they are mediated by neuromodulatory systems that project from the brain stem to the cortex in a widespread but regionally variable manner. When they are activated, these fiber systems release such transmitters as norepinephrine, dopamine, serotonin, or acetylcholine. Such releases generally alter the responsiveness of cortical neurons to create greater outputs. These increases in neural activity patterns also promote longer lasting alterations of neural circuits. Acetylcholine release, for example, is associated with arousal, and it promotes LTP and allows circuits to be modified more easily, thus improving learning during arousal.

In addition to these brain stem modulating projections that distribute broadly especially to the outer layers of cortex, some of the thalamic input also appears to be of the modulating type in that it avoids layer 4 neurons and instead terminates in the outer cortical layers, including layer 1. Such terminations, often on the distal dendrites of neurons, have only minor excitatory effects that add to the major sources of activation. The functions of such modulation are not well-understood, but they certainly add to the functional flexibility of the cortex.

III. AREAS OF NEOCORTEX

The basic organization of the neocortex helps explain how it can be such a powerful and flexible computing machine, but it does not explain the great variability in cortical function that occurs in different species of mammals, making one mammal a mouse in performance and capability and another a man. Whether you are a ''man or a mouse'' largely depends on your neocortex. A major difference in the neocortex of humans and mice is in the size of the cortical sheet. Mice have about 2 cm^2 of neocortical surface per cerebral hemisphere, whereas humans have 800 cm^2 or roughly 400 times as much. Human cortex is also 2–3 times as thick. Simply put, we expect a computer that is about 800 times larger to be better, and it is. A mouse will never speak or perform higher mathematics.

But as we know, size is not everything. Otherwise, mammals with brains of the same size would perform in similar manners. Instead, the neocortex can be quite different in internal organization from species to species. In addition, acquired differences in cortical organization exist in each individual. The cortex of a great tennis player is organized differently from that of the great scholar, largely as a consequence of experience-related modifications in the neocortex.

How does neocortex differ from species to species, other than in size? The most conspicuous ways are in numbers and types of cortical areas. Early investigators such as Korbinian Brodmann proposed that neocortex is subdivided into a number of functionally distinct regions or areas. For Brodmann, the cortical areas were the ''organs of the brain,'' each with a set of specific functions. The existence of such organs was suggested by the impairments produced by damage to different regions of the neocortex. As a well-known example, in 1861 Pierre Broca proposed that a speech area, now known as Broca's area, is located in the left frontal lobe after he noted that speech production problems followed lesions in the ventral part of the left frontal lobe. But working approximately 100 years ago, Brodmann had only one way to delimit and define areas of the cortex: he stained thinly cut sections from the brain for the cell bodies of neurons and used the slight differences in appearance that he noted from one region of cortex to another to define areas. The major or primary sensory areas, for example, have a thicker layer 4 that is more densely packed with small neurons (Fig. 1). This feature reflects the fact that layer 4 is the major receiving layer, and sensory areas are specialized for receiving input from the thalamus. In contrast, primary motor cortex is specialized for sending motor commands to the brain stem and spinal cord, and the major output layer 5 is especially thick, with large pyramidal neurons. Because the sensory role of the motor cortex is reduced, it does not have an obvious layer 4, also known as the external granular cell layer. Thus, primary motor cortex is sometimes called agranular cortex. Brodmann both named and numbered his cortical areas. Thus, primary visual cortex was named the calcarine type for its location in the calcarine sulcus of the occipital lobe and given a number, 17, as the seventeenth area described in an

arbitrary order. Area 1, just on the crest of the postcentral gyrus in the middle of the cerebral hemisphere, is a subdivision of somatosensory cortex, whereas the primary motor cortex was labeled area 4 by Brodmann.

Brodmann's approach was to study brain sections stained for cell bodies and look for distinctions that would suggest or indicate the boundaries between functional subdivisions. Boundaries between areas were usually or often assumed to be sharp, but Brodmann allowed for the possibility of gradual change between some areas. The method of study is known as cytoarchitectonics or the study of tissue structure from brain sections stained for cells. Soon, others used stains for myelin, the fatty substance around axons. The method of using regional differences in the myelination pattern to divide the neocortex into areas is called myeloarchitectonics. Currently, there are many ways of processing brain tissue for proteins and other substances in neurons, so that a field of chemoarchitectonics has emerged. Many new methods have proven to be very useful in defining cortical areas. Yet, the process has been and remains difficult. Often, architectonic results are difficult to interpret, and different investigators come to different conclusions.

Brodmann boldly defined over 50 areas in human neocortex and found fewer in other mammals such as monkeys and small-brained hedgehogs. Several of his general conclusions remain valid today. We now have considerable evidence that small-brained mammals such as hedgehogs have few areas, perhaps 15–20, monkeys have more, and humans have still more, probably many more than the 50 or so proposed by Brodmann. Moreover, the brains of all mammals share a few areas, as these areas emerged with the evolution of mammals and have been retained in most or all lines of evolution. In addition, as some mammals evolved larger brains, they added cortical areas. How cortical areas were added is unknown, but Brodmann believed that they emerged by existing areas gradually becoming differentiated into two or more areas.

Because only a few areas of the brain are so specialized that they could be easily seen in stained brain sections, Brodmann only correctly identified a few brain areas. Other investigators at that time came up with other proposals of how brains are divided into areas, but only Brodmann's numbering scheme remains in wide use. Unfortunately, the numbered areas largely mark locations in cortex rather than functionally distinct areas. Thus, many investigators are currently trying to determine how the cortex is divided into areas in humans and other mammals. The evidence that neocortex is subdivided into a patchwork of cortical areas in all mammals and that different species of mammals differ in number of areas is very strong, but the task of accurately locating and defining most of the areas has proven to be very difficult. Investigators now consider task-related neuronal activity patterns in the cortex and the ways in which cortical regions are connected with each other and other structures as additional sources of information. Of course, from the very beginning, investigators such as Pierre Broca used the relationship of different behavioral impairments to lesions of regions of cortex as a way of surmising the location and function of cortical areas.

Despite the lack of complete knowledge about cortical organization, it seems certain that a major reason that the human brain functions so well is that it has so many cortical areas. Studies of cortical organization in monkeys have given us some clear evidence for how the neocortex is organized in humans, and this evidence has provided some surprises. Most notably, many scientists once thought that most neocortex in humans and monkeys would be devoted to large regions of "association cortex" for associating the information from the different senses. Such large areas would deal with abstractions, so that they would be activated by visual, auditory, or somatosensory events. Thus, most neocortex was considered to be responsive to several senses or multimodal. We now believe that a great deal of the neocortex is devoted to processing information within a sense, and the creation of accurate, modality specific perceptions is not an easy task for the brain. Consider the inaccurate perceptions of a bird attacking its own reflection in a glass window, and the impact of limited processing becomes apparent. Monkeys have over 30 cortical areas for processing visual information, at least 15 for processing somatosensory information, and 15 or so for auditory information. Humans may have more. Why so many?

The reason for so many processing areas seems to be that each area performs a few rather simple computations. However, if the results are fed into another area for a second level of processing, roughly the same types of simple computations can add a level of complexity and sophistication. Complex abilities depend on a chain of processing events, simple at each step, but complex in the end. Of course, processing is not just in a series or chain, because feedback always (or nearly always) occurs between interconnected areas, cross-talk occurs between areas of roughly the same level, and much processing is over parallel chains of circuits.

Nevertheless, small-brained mammals are behaviorally limited compared to large-brained mammals, not only because they have less neocortex but also because they have fewer cortical areas.

All mammals appear to have primary visual, somatosensory, and auditory areas, as well as one or two associated secondary areas for each sense, and most mammals have one motor area or more (Fig. 3). Visual areas are located caudally in the occipital region or lobe, and they extend ventrally into the temporal lobe in mammals with more visual areas. Auditory areas are in temporal cortex or the temporal lobe, somatosensory areas are in parietal cortex, and motor areas are in the frontal lobe. In mammals with more areas, the visual, auditory, and somatosensory areas remain grouped. The grouping of areas for each sense in the same region of neocortex allows for more rapid processing over shorter interconnections.

IV. SENSORY REPRESENTATIONS (MAPS)

In all mammals, much of the neocortex consists of orderly representations or maps of receptor surfaces (see Fig. 3). Visual areas of each cerebral hemisphere represent the contralateral half of the visual field via the nasal hemiretina of the contralateral eye and the temporal hemiretina (actually a smaller and species variable portion that is less than half) of the ipsilateral eye. Somatosensory areas represent the receptors of the contralateral body surface. Auditory areas represent tones from high to low frequencies as they activate successive locations along a row of cochlear hair cell receptors in the contralateral and ipsilateral ears. Other cortical areas relate to taste and vestibular input. Smell is relayed to piriform cortex from the olfactory bulb. The cortical representations are activated from the thalamus via orderly, topographic projections from the receptor sheets to subcortical nuclei that relay to the thalamus, or to the thalamus directly, and then to cortex. The maps closely, but not precisely, reflect the order of the receptors on the receptor sheet. The maps might have disruptions so that receptors next to each other are represented in nonadjacent parts of the map, and the maps might have modular repetitions related to receptor class or eye or ear of origin (see later discussion). In addition, the receptive fields, the portion of the receptive sheet that activates a neuron, become larger for neurons in each successive level of a series of connected nuclei and areas, so that the maps in initial subcortical structures are the most detailed, the maps in primary sensory areas are somewhat less detailed, and secondary and higher order sensory areas contain progressively less detailed maps. These changes in receptive field size and the detail of map topography are compatible with the changing functions of neural circuits in representations that are early or late in a processing sequence. The number of topographic maps of a sensory surface in cortex varies with the number of sensory areas, with the early areas in sequences being most topographic and later areas often reflecting little of the order of the receptor sheet, but possibly representing in a systematic manner some product or feature that has been derived from other sensory areas. Topographic maps place neurons that most interact within the area close together and provide a suitable substrate for the common spatiotemporal computations of neural circuits.

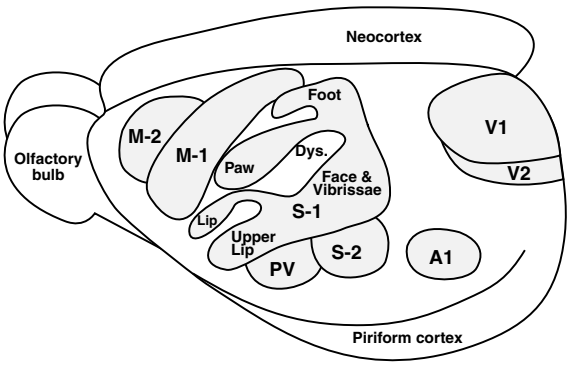

Figure 3 Some of the currently proposed areas of neocortex in rats. Like most other mammals, rats have a primary somatosensory area, S1, and a secondary somatosensory area, S2, a primary visual area, V1, and a secondary visual area, V2, a primary auditory area A1, and a primary motor area, M1. There is also evidence for a secondary or premotor area, M2, a dysgranular (Dys) somatosensory area with a less developed or "dysgranular" layer IV, and a parietal ventral (PV) somatosensory area. S1, S2, and PV each represent the receptors of the skin in an orderly manner. The locations of activating input relayed from major body parts are indicated for S1. Other areas of neocortex in rats have been proposed, but they are not indicated. Mammals, such as monkeys and humans, with larger brains and more neocortex have the same areas as those proposed here for rats, at least a few additional areas that they share with rats, and a number of additional areas that are not found in rats. Thus, species differ in numbers of cortical areas, as well as the proportional extent of neocortex. Piriform cortex and the olfactory bulb are indicated for reference.

V. MOTOR REPRESENTATIONS

Areas of neocortex also represent muscles and movements. Long before it was technically possible to

record the small changes in the electrical activity of neurons in neocortex, it was possible to generate and deliver an electrical current to the surface of neocortex and observe the effects. From quite early studies, it became apparent that the electrical stimulation of locations in the frontal lobe was especially effective in evoking movements of various parts of the body and that different sites in the frontal cortex related to different movements. Parts of the frontal cortex were seen to systematically represent body movements, and a primary motor area, M1, was defined first, followed by a supplementary motor area, SMA. M1 is a striplike area that extends mediolaterally along and in the central sulcus of the human brain just rostral to the somatosensory cortex, and it represents the body from foot, trunk, hand, face, and tongue in a mediolateral sequence. M1 largely, but not precisely, corresponds to cortex defined earlier by Brodmann as area 4, but many modern depictions make M1 coextensive with a redefined area 4. SMA is rostral to the more medial part of M1. The second motor area, M2, of rats (Fig. 3) might correspond to SMA, which is best known from studies in primates.

Detailed studies of the organization of M1 have used penetrating microelectrodes to more precisely activate small numbers of the large pyramidal cells of layer 5 at low levels of current, thereby evoking movements in only a few muscles and allowing the motor map to be seen in detail. As a result of microstimulation studies, it is now apparent that M1 and probably other motor representations are organized as a patchwork or mosaic of small regions of cortex that are devoted to specific movements, that of a single finger for example. Each type of patch of cortex typically occurs more than once but next to various other patches of motor cortex for other related movements. Such an organization may give the motor cortex great flexibility in the control of various combinations of movements.

Humans and other primates have additional motor areas in the frontal lobe that are collectively called premotor areas. They include the dorsal and ventral premotor areas just rostral to medial and lateral portions of M1, respectively, the supplementary motor area rostral to M1 on the medial wall of the cerebral hemisphere, and other motor areas on the medial wall and dorsolateral surface of the frontal lobe. Movements can be evoked by electrical stimulation from all of these areas, and each area represents the body in a sequence across the field. To evoke movements in these premotor areas takes higher levels of current than in M1, and the movements evoked are more complex. Movements also can be evoked by stimulating areas of the somatosensory cortex, but at high levels of current. Thus, a number of areas of cortex have motor functions. Motor and premotor areas also have sensory input, and they may also contain sensory maps.

VI. OTHER CORTICAL AREAS

Neocortex also has several types of areas that are not strictly sensory or perceptual in nature and not closely tied to motor behavior, although neurons in these areas may respond to sensory stimuli and the areas may be closely involved in behavior. One such region of neocortex in primates is dorsolateral prefrontal cortex, where neurons appear to briefly retain information and be involved in short-term or working memory. Areas of dorsolateral prefrontal cortex have not been defined completely, but several areas probably exist. The more ventral cortex of the frontal lobe has areas that appear to provide evaluative functions and emotional tones to experienced events. Cingulate cortex along the medial wall of each cerebral hemisphere has rostral divisions that are more motor in function and caudal divisions that are more sensory in function. Areas of the cingulate cortex appear to be involved in instinctive behavior and motivation. In humans, other areas, usually in the left cerebral hemisphere, are involved in processing language. Broca's area in the left frontal lobe, as a probable specialization of a ventral premotor area, is critically important for the production of speech. More caudal areas in the temporal lobe are used to extract meaning from speech and provide meaningful structure to speech. Part of the superior surface of the left temporal lobe is known as Wernicke's area after the description of Carl Wernicke in 1874 of defects in speech that result from lesions in this region. Such individuals easily produce words and phrases, but the speech has little meaning. Wernicke's area may actually contain several processing areas, as the organization of this cortex is not well-understood. Other areas appear to be more like the "association" cortex of early proposals and multimodal or polysensory in nature. Such a multimodal region, the superior temporal polysensory area (or region, because it probably contains several areas), has been described in the temporal lobe of monkeys. Whereas the functions of the superior temporal polysensory region are still largely unknown, neurons in the region respond to visual, auditory, and somatic

stimuli, and this cortex could be a site for integrating information across sensory modalities.

VII. SPECIES DIFFERENCES IN CORTICAL ORGANIZATION

As mentioned, species of mammals vary in amount of neocortex and in number of cortical areas. These differences obviously are important in mediating functional differences. In addition, neocortex and areas of neocortex differ from species to species in several other ways. These organizational differences are responsible for mediating many important variations in behavior and ability.

A. Cortical Magnification

Sensory areas, especially those early in the cortical processing sequence, are said to represent the receptor sheets. Thus, stimuli falling on different parts of the receptor sheet activate neurons in different parts of sensory areas in a pattern that is isomorphic with the receptor sheet. However, not all parts of the receptor sheet are equally important. For example, we only see well within a few degrees of central vision corresponding to the specialized center of the retina, the fovea, and the immediate surround, where receptor cells are very densely packed. In humans and monkeys, much of the visual cortex is devoted to processing information from the fovea. In part this is no more than a reflection of the greater receptor density of the fovea. However, the amount of cortex devoted to the fovea exceeds the proportional relationship to retinal receptors. Thus, there is a distortion within sensory representations in the neocortex that follows the variable density of receptors across the sensory surface (receptor-based cortical magnification) and a distortion that exceeds that dictated by receptor density (functionally based cortical magnification). Other mammals may distort sensory maps in other ways. For example, ground squirrels benefit from accurately seeing predators coming from the side as well as from the front. Their retinas have a horizontal strip of high receptor density, and their visual cortex is largely devoted to processing information from this strip of receptors. Rats devote most of their somatosensory cortex to processing information from the long whiskers on the sides of the face that they whisk forward to contact objects, whereas humans devote much of their somatosensory cortex to information coming from our sensitive finger tips. Thus, mammals vary in sensory and perceptual abilities, not only from specialization and alteration of the receptor surfaces but also by changes in the proportions of cortical areas that are devoted to different parts of the receptor sheet.

B. Laminar Differentiation

Neocortex varies in another way that also adds flexibility to its function. The laminar organization of neocortex has already been mentioned, as have the slight variations in the appearance and thickness of layers from cortical area to cortical area that reflect functional specialization. The same area can also vary across species in differentiation, so that the primary visual cortex in highly visual mammals, such as monkeys and humans, is more distinctively laminated than in poorly visual rats. Apparently, something is to be gained by tightly grouping cells in layers and sublayers of the same functional types and developing cells of different shapes to allow specialized functions, but there must also be some cost or loss for such differentiation or rats would have a highly differentiated visual cortex. Perhaps neurons in the primary visual cortex of rats, with poor vision and few visual areas, need to retain broad, general functions and thereby do not specialize. However, one of the sources of flexibility in the neocortex is in the degree to which specialized neurons and groups of neurons are tightly confined within layers and sublayers.

C. Modules or Columns

Another source of variability and specialization in the neocortex is in types of modular organization. Cortical areas are at least sometimes, and possibly always or often, divided into smaller, functionally distinct regions called columns or modules. The concept of the cortical column was introduced by the neurophysiologist, Vernon Mountcastle, who noted during recordings from the somatosensory cortex that neurons with similar response properties were grouped into territories or columns across the thickness of cortex that were less than one 1 mm in width. Investigators soon described "ocular dominance" columns in the visual cortex of cats and monkeys, where inputs to the primary visual cortex related to one eye or the other eye were found to be segregated into alternating bands of tissue in layer 4 of something close to 0.5 mm in width.

One set of bands was activated by input related to the ipsilateral eye and the other set by the contralateral eye. Neurons in other layers were activated less exclusively by one eye or the other, but they were said to be "dominated" by one eye. Whereas cats and ferrets also have ocular dominance columns, rats and apparently many other mammals do not.

Subsequent to the discovery of ocular dominance columns, the primary visual cortex of monkeys was found to have a dotlike pattern of clusters or "blobs" of neurons of high metabolic activity that appeared to be more related to processing color information, each surrounded by tissue devoted to other functions. Next, the second visual area, V2, of monkeys was found to contain repeating sequences of three types of bands crossing the field, with each type of band having input from functionally different types of neurons in V1 and each type of band having output to different targets. Soon thereafter, a visual area in the upper temporal lobe, the middle temporal visual area or MT, was found to contain a patchwork of small regions with neurons more sensitive to either global motion or local motion. In the somatosensory cortex of monkeys, area 3b or the primary somatosensory cortex was found to contain narrow regions of neurons responding to either slowly or rapidly adapting classes of cutaneous afferents. These and related findings suggest that many or even most cortical areas are subdivided into two or more types of smaller regions, the cortical columns or modules.

It was once thought that columns would all be of roughly the same shape, ovals of about 0.5 mm in diameter and extending columnlike from the brain surface to the fibers underlying cortex. Now it is apparent that columns come in a range of shapes, from a patchwork of small dotlike centers with large surrounds to bands. The shapes may depend in part on the ratio of neurons of one type or the other. Sizes also vary, but not by much, from widths of less than 0.5 mm to well over 1 mm. The differences in the shapes of the groups of neurons are more compatible with the term "module" than "column," although both terms are in use and are interchangeable. Modules allow areas to perform more specialized functions, with each area acting as two or three. By grouping neurons into processing units, the lengths of connections between neurons are reduced. Mammals not only differ in numbers of cortical areas and in how areas are differentiated into cell types and layers but also in how areas are divided into modules. Thus, areas can be highly specialized for the needs of a particular species or line of evolution.

D. Connections

Input and output obviously are important in mediating the functions of an area, and the same area in different species can have somewhat different connections. This aspect of variability has not been studied extensively, but clear examples of variability are known. One example might be the projections from the primary visual cortex in primates to the middle temporal visual area (MT) in the temporal lobe. All primates appear to have this direct projection, but MT has not been identified in any nonprimate mammal. Thus, the projections to MT appear to be a unique feature of the primary visual cortex in primates. As a related example, evidence exists that the primary visual cortex projects to the frontal lobe in some mammals, such as rats, but not in others such as monkeys. Across species, cortical areas vary as to with which other areas and subcortical structures they are connected, the density of these connections, and the distribution of connections of specific types within an area. Most primates have few connections between the primary visual areas in the opposite cerebral hemispheres, but prosimian primates and several other mammals have many such connections.

VIII. DEVELOPMENT AND EVOLUTION

The functional flexibility of the neocortex is related to its capacity to be altered in evolution and development. Neocortex develops from a thin sheet of germinal cells along the margin of the cerebral ventricle. The germinal cells undergo mitosis and divide to form more germinal cells, some of which ultimately differentiate into neurons or glial cells. A marginal zone of glial processes soon forms over the germinal cells, and neuron precursors migrate from the deeper germinal layer toward the surface to form a cortical plate and then cortical layers. Neurons reach the cortex largely by migrating along glial processes that extend radially from the inner ventricular surface to the outer margin of the developing hemisphere. Surprisingly, the neurons that arrive first form the deeper layers because later arriving neurons pass through the earlier arrivals to reach the surface. Most neurons pass from a specific location along the ventricle to a specific location in the cortex by migrating along the process of possibly a single radial glial cell. A row of neurons across the thickness of the cortex may largely originate from a single germinal cell

that has divided over and over again to produce a series of migrating offspring. Thus, the thickness of the cortex, constituting surface to white matter rows of roughly 100 or so neurons, may depend on roughly 100 cell divisions. Of course the number varies across cortical areas and the same cortical area across species, but not by that much. One of the reasons for the relative stability of the thickness of the cortex and the number of neurons across this thickness is the developmental process of repeatedly dividing the parent cell to produce offspring in series. Thus, a large change in the final number of neurons in a row would depend on a major change in the number of germinal cell divisions that produce neuronal precursors. Many of the inhibitory neurons of the neocortex do migrate in from a lateral location, but the major point to row migration pattern appears to provide some stability in one feature of cortical organization, the thickness. It may also be important that neurons migrate to specific regions of the cortex, because this might initiate the process of forming cortical areas.

In another way, the generation of cortex is a flexible process that easily allows increases in the size of the neocortical sheet. As neurobiologist Pasko Rakic has stressed, each symmetrical division of germinal cells doubles the number of germinal cells. When each germinal cell finally changes its role to produce a row of cortical neurons, then the number of rows and the size of the cortical sheet will be doubled by each of the previous doublings of the population of germinal cells. Whereas cortical thickness may be hard to change in development, increases in cortical size appear to depend on only a few more cell divisions in the early stages of development. Small genetic changes in the control of the number of cell divisions to form more germinal cells would have major consequences. Thus, we see great variability in the size of the neocortex, but little in the thickness.

Another important factor in the evolution of variability in the cortex is that developing cortical neurons are very sensitive to environmental influences. Developing neurons use information in neural activity patterns to form functional groups. As is sometimes stated, ''neurons that fire together wire together.'' Correlated activity in interconnected neurons maintains connections, whereas discorrelations remove those connections. This allows developing cortical neurons to respond in an adaptive way to variable features in the environment. The somatosensory cortex is normally subdivided so that groups of neurons process information from each finger or other subdivisions of the body surface. If a change in development alters the number of fingers or the number of sensory whiskers on the face, the areas of the cortex develop a matching number of modular subdivisions. In other words, brain regions develop to match each other in modular subdivisions that correspond to input from segregated groups of receptors. Each match is based on the transfer of information from one structure to another, rather than on the gradual selection for a long sequence of matches across nuclei and areas by the accumulation of changes in genetics. By using information from the environment, the rapid evolution of major alterations in the functional organization of the neocortex is possible. The monotreme mammal, the duck-billed platypus, has evolved a novel class of receptors on its bill, electroreceptors that are sensitive to weak electrical currents in water produced by the contracting muscles of swimming prey. The brain and neocortex adjusted to this new receptor by subdividing the primary sensory area, S1, into one set of modules related to tactile input and another set of modules related to electroreception. The developmental plasticity of the cortex allows useful adjustments for such changes in input, and the somatosensory system of monotremes was able to acquire new functions. The neocortex is designed not only to readily accommodate new or changed input originating from the receptor surfaces but also to accommodate input from functionally new classes of neurons that are created in the cortex by cortical circuits.

The ability of the neocortex to accommodate alterations in the nature of activating input by forming new circuits and modules may also relate to the evolution of new cortical areas. How the number of cortical areas increased in some lines of evolution is uncertain, but there are several logical possibilities. First, body parts sometimes duplicate in evolution so that suddenly extra parts emerge. A mutation in genes for some control mechanism could lead to the duplication of a cortical area. The two daughter areas could then be gradually differentiated by subsequent changes in genetic control, so that the two daughter areas come to mediate different functions. Another possibility is that new functions emerge as classes of modules are formed within areas. Gradually, over many generations, modules of each class could merge, reducing the lengths of the interconnections between modules. A full merger with complete separation of the two classes of modules would result in two areas emerging from one.

Whatever the mechanisms of cortical evolution, they work by modifying development. In order to

better understand the evolution of the neocortex, it will be productive to further investigate the great variability in neocortical organization that exists and the nature of the developmental changes that allow this variability.

Given the great potential for the neocortex to vary in size, accommodate changes in input, and subdivide into areas and modules specialized for functionally adaptive tasks, one might wonder why all mammals do not have expanded sheets of neocortex with many subdivisions. The major reasons for having less neocortex seem to be that the neocortex takes a long time to develop and mature and that the neocortex is metabolically costly. Other constraints undoubtedly also exist. For example, the weight of a large brain would be difficult to manage for bats as flying mammals, for whom all weight is costly. Mammals must be able to compensate for the metabolic and developmental costs of having more neocortex by having the gain in computational ability lead to getting better and more food and longer life spans, so that successful reproduction is improved or at least maintained. Humans, with exceptionally large sheets of neocortex, have used these sheets in ways that have allowed considerable reproductive success, with our species now exceeding 6 billion individuals, but most of this reproductive success has been exceedingly recent, over the last few hundred years. Great apes, as our closest relatives, have a large amount of neocortex, although much less than us. However, they have not done well and border on the verge of extinction. In contrast, small-brained rats and mice thrive over most parts of the earth. The rats and mice are not very bright and they make many mistakes, but they are able to replace themselves in large numbers very rapidly. However, mammals with little neocortex often specialized their small sheets of neocortex for particular functions. Thus, echolocating bats devote much of their small neocortex to auditory input and the sounds used for echolocating objects and prey. The large, costly sheets of neocortex that characterize the brains of higher primates remain unusual because they require long periods of safe development, long reproduction cycles, and consistently available foods of high metabolic value.

IX. SUMMARY

Although the neocortex is homologous with the dorsal cortex of reptiles, the neocortex is new with mammals as a thick, layered structure. The neocortex is an especially important part of the brain that varies greatly in structure and function across species. The neocortex can be changed in structure and function with training and experience so that members of the same species can become individuals. Several consistent features of the neocortex provide a framework with great structural and functional flexibility. These include the laminar organization of the neocortex with six basic layers of neurons with differing functional roles and patterns of connections, the existence of classes of neurons including small receptive neurons, large pyramidal output neurons, and local circuit inhibitory neurons, and the pronounced vertical connectivity of neurons across the depth of cortex. Species vary in amount of neocortex, types, numbers and sizes of areas, how areas disproportionately represent movements or sensory surfaces, modular organization within areas, laminar differentiation and specialization within areas, and patterns of connections within and across areas and with subcortical structures. The neocortex is a structure with great information-processing and -storing capacity. In humans and possibly other mammals, the neocortex mediates consciousness. Most importantly, the neural circuits in the neocortex are modifiable in development and throughout life, so that species become specialized for relevant perceptual and behavioral abilities, and individuals acquire individual skills, abilities, personalities, and memories.

Nerve Cells and Memory

PETER S. ERIKSSON
Sahlgrenska University Hospital

GLOSSARY

face agnosia The inability to recognize and remember faces.

neuronal stem cell A cell with the potential to give rise to all cell types found in the brain.

progenitor cell A cell with restricted potential to give rise to some cell types of the brain, e.g., astrocytes and oligodendrocytes.

prosopagnosia The inability to recognize and remember faces.

During the past century, neuroscientific research has generated a tremendous amount of knowledge on the function of the brain, but despite a substantial effort we still lack knowledge in such important areas as storage mechanisms for long-term memory, mechanisms responsible for higher intellectual functions such as reasoning, and decision-making processes based on judgment. There are, however, some areas in which it has been possible to localize behavior to small groups of neurons or even single nerve cells. Only a few mechanisms rely on spatially closely located neurons in the brain. Instead, many systems, such as the storage of long-term memories, seem to rely on diffuse, spatially nonlocalized circuitry throughout the brain. This article will focus on some examples for which the relationship between nerve cells and behavior has been partially unraveled.

I. THE BRAIN AND BEHAVIOR

The brain relays an enormous number of incoming and outgoing impulses every second. Input may stem from any of our senses, such as hearing, seeing, or feeling. More profound, and considered by the brain to be more important, information may result in the perceptions being stored as memories. These memories may be retrieved and perhaps used while processing subsequent incoming impulses. The result of this processing may be either rather simplified and stereotypical actions, such as reflexes (the knee jerk reflex), or more complex output, such as decisions based on judgment. The more complex output can also be termed behavioral output, or behavior. Although we consider these two examples of elicited behavior to be fundamentally different, they have many features in common. It is widely recognized that the lowest common denominator in all processing, including both simple and extremely complex behavior, is the nerve cell or the neuron. Behavior is thought of as the concerted signaling of an enormous number of neurons. In fact, it has been estimated that the human brain contains about 10^{11} neurons, classified into as many as 10,000 different types. One can easily understand the complexity within a system consisting of this number of signaling units, especially considering the fact that each neuron can have connections with perhaps thousands of other neurons. Another intriguing feature of the brain is the presence of glial cells. Cell number estimations suggest that the human brain may

contain as many as 10 times more glial cells than neurons.

II. THE BRAIN CONSISTS OF TWO MAJOR CLASSES OF CELLS

As indicated earlier, two primary cell types exist in the brain: nerve cells (neurons) and glial cells. Nerve cells, which have been the focus of neuroscientific research during the past century, have a number of basic common features. A typical neuron consists of a cell body containing the nucleus with the genetic material; neurons generally are highly metabolically active and thus contain relatively large amounts of energy producing mitochondria. Finally, the neuron usually has two types of processes: dendrites and an axon. The dendrites branch out in a treelike fashion and are generally considered to be the receiving components for input from other cells. The axon, on the other hand, is considered to be the output apparatus for the neuron, conveying output signals to other neurons. The axon's diameter can range from 0.2 to 20 μm, and it can be up to 1 m long, as are, for example, the motor neurons located in the cerebral cortex whose axons end in the spinal cord. Perhaps their most important feature is the neurons' ability to initiate and propagate an all-or-nothing transient electrical signal. This feature is called the action potential and is normally generated from the cell soma either as an independently initiated signal or as a result of incoming impulses (excitation). The action potential is initiated once a critical threshold (membrane potential) is reached.

The function of glial cells, whose name is derived from the Greek word glia, meaning glue, is less well-known. Whereas glial cells traditionally have been considered mainly as passive supporting elements providing structure to the brain, they may also provide metabolic support to surrounding neurons. There are two major classes of glial cells: oligodendrocytes and astrocytes. The oligodendrocytes produce the insulation that covers most large axons within the central nervous system. The astrocytes, on the other hand, provide metabolic support, act as scavengers, and perhaps more importantly buffer K^+ ions in the extracellular space. Another very important feature of the astroglial cells is taking up and metabolizing transmitters released by neurons during synaptic transmission. Glial cells also participate in forming the so-called blood–brain barrier. Finally, some classes of glial cells guide the migration of neurons and direct the outgrowth of axons.

Glial cells may play a very important role in scar formation after injury to the brain. Gliosis, or proliferation of glial cells, is an almost universal response to brain injury. It has even been proposed that gliosis after brain injury actually inhibits the reparative processes in the brain, in which neurons try to reestablish connections with their normal target regions. It is possible though that, by so doing, astrocytes help seal off damaged brain tissue after injury, thus inhibiting abhorrent reorganization within a damaged brain region.

It has been established that astroglial cells provide an extra neural signaling network via so-called gap junctions. Gap junctions are pores between individual glial cells that provide communication between glial cells for small molecules, up to 1000 kDa. Calcium signaling spreading within the astroglial network has been described in various model systems, including preparations of the intact brain. Although very little is known about the function of glial signaling, one can easily imagine the potential importance of a signaling network consisting of 10 times more cells than there are neurons within the brain. At present, the neurons are generally considered the most important components in the processing of sensory information, eliciting motor and emotional responses, and in learning and memory function. Although a large number of different neural types can be described on the basis of the transmitters the neurons release, what receptors they have, etc., researchers have been forced to reduce the degree of complexity by viewing neurons as more simple units, with either stimulatory or inhibitory output. By so doing, and by focusing instead on the interconnection between nerve cells, researchers have begun to emulate theoretically some of the processing capabilities of the brain. The deployment of several neural clusters or pathways to convey the same information is called parallel processing. This phenomenon has a number of advantages, including increased processing speed, increased reliability, and, of course, increased processing capacity. Scientists attempting to construct computational models of brain function have adopted this particular aspect of neural connectivity. Computer scientists initially used a serial-processing model to simulate higher levels of cognitive functions in the brain, such as the formation of memory, motor performance, and pattern recognition. It was soon realized that parallel processing allowed for the performance of these and other complex and demanding tasks. Thus, it is generally

believed that complex processing does not rely on the contribution of individual components but instead consists of the results of the interconnection of many elements. In this way the wiring between neurons provides the cellular basis for higher brain functions, such as face recognition, learning, and memory. In the following sections, we will give some examples of complex behavior resulting from activity in a small group of nerve cells.

III. NERVE CELLS AND PATTERN RECOGNITION

Face agnosia, or prosopagnosia, is a selective deficit in recognizing familiar faces. There are numerous case reports on patients suffering from this condition. The patients are aware they are looking at a face, but are unable to identify or even sense any familiarity in the faces of family members, co-workers, or other previously well-known individuals. Typically, these patients have difficulties remembering new faces. Patients with this condition normally rely on recognizing individuals by their clothing or their voices. Patients suffering from isolated prosopagnosia have raised the question of whether this condition is in fact due to selective damage to dedicated neural circuitry. There are patterns of deficits in processing face material in prosopagnosia that suggest that a number of dissociable cognitive operations are involved in processing face information. For instance, some patients retain their ability to judge the age, gender, and emotional expressions of faces whose identity remains completely unrecognized. It has been suggested that this is due to an inability to connect the obviously intact perception of face information to the stored biographical memories associated with a given facial structure necessary for identification. Prosopagnosia has been associated with damage to the right posterior cortex, and therefore face recognition was thought to be associated exclusively with neural circuits within the right posterior hemisphere. Studies on autopsy material have also suggested that bilateral damage may be necessary to induce prosopagnosia. Still, the identity and location of neurons responsible for face recognition in humans have yet to be firmly established.

Primate models of prosopagnosia suggest that the superior temporal sulcus contains a great concentration of ''face-selective'' neurons. This area is, however, well-separated from the region one would suppose to be homologous to the site of damage revealed in humans with prosopagnosia. Furthermore, bilateral ablation of the superior temporal sulcus in monkeys clearly fails to produce more than a minor decrease in face recognition. Face-selective neurons located in more ventral portions of the temporal lobe in ablation experiments have been shown to play an important role in face recognition. Removal of this area of the cortex causes severe impairments in face perception. Furthermore, it also perturbs the perception and recognition of a large number of other classes of objects.

One possible explanation for the seemingly different ways in which monkeys and humans process face recognition is that the neural substrates for recognizing faces and other classes of stimuli are not segregated as completely in monkeys as in humans. Functional neuroimaging studies suggest that the ventral occipitotemporal cortex of the right hemisphere is primarily responsible for the perceptual analysis of faces. More anterior temporal regions are then activated for the association of face information with stored information about individuals. The frontal cortex appears to contribute both to the analysis of emotional facial expression and to the maintenance of faces within the short-term memory store. Interestingly, electrophysiological experiments on patients going through presurgical epilepsy investigation have shown that large potentials are generated by faces and not by other categories of stimuli at very small sites within the ventral occipitotemporal cortex. These small groups of ''face-activated'' neurons are thought to be the human counterparts to the face-selective neurons found in monkeys. The analyses of the brain's mechanisms for face recognition thus suggest that single or small groups of neurons may in fact be responsible for distinct aspects of face recognition. These neurons therefore might be considered discrete units, possibly providing singular perceptions of complex stimuli at the level of individual nerve cells.

IV. LEARNING AND MEMORY

One structure that has been associated with memory formation is the hippocampus. The hippocampus is an area of the allocortex hidden within the temporal lobe, where it resides in the medial portion. The hippocampus is connected to a number of adjacent cortical areas. The areas affiliated with the hippocampus include the perirhinal, entorhinal, and parahippocampal cortex. Hippocampal injury in humans results in deficits in episodic memory. Memories dependent on the hippocampus also include memories for spatial material. There are case reports on patients with hippocampal

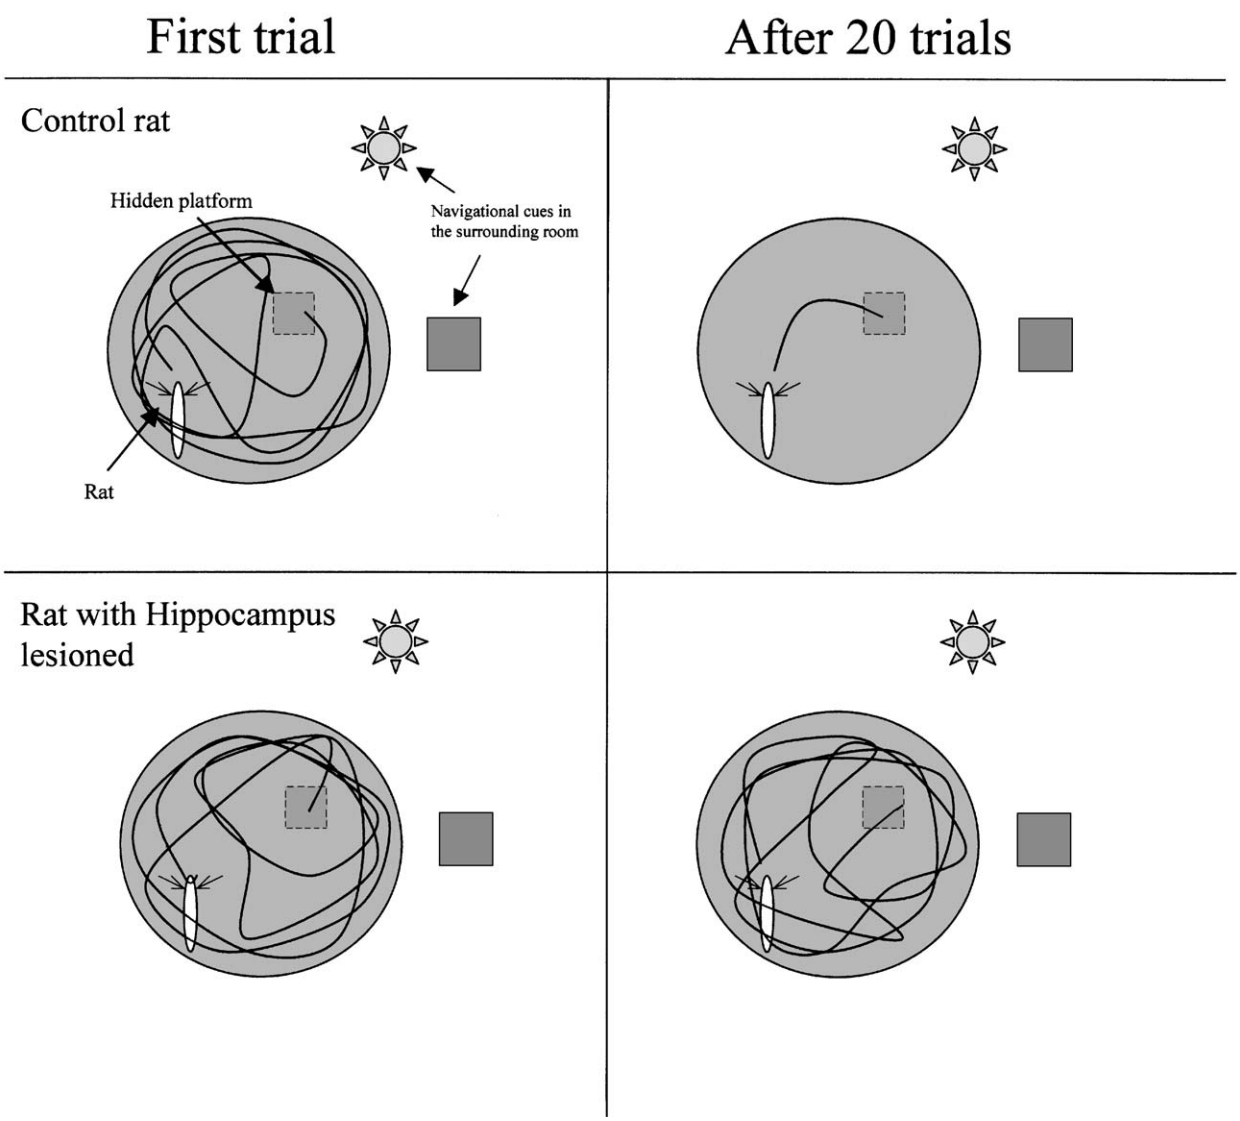

Figure 1 Spatial memory testing in rats. Rats are placed in a circular water pool filled with cloudy water. A small platform is placed at a fixed location just under the surface of the water. The pool has no any specific features but the surrounding environment usually contains a number of navigational cues (lamps, windows, doors, etc.). As the rats search for the platform, their swim path (and speed) is monitored by a video camera (indicated by the traces in the figure). After a number of trials normal rats swim directly to the platform. Rats with impaired spatial memory due to a lesion on the hippocampus fail to learn where to find the hidden platform.

injuries due to temporal lobe surgery, who suffer from an inability to learn how to find their way in unfamiliar neighborhoods (Fig. 1).

V. NERVE CELLS AND MEMORY

As mentioned earlier in this article, most aspects of memory are dissociable processes mediated by distinct and separate brain systems. Although we are still far from resolving all aspects of memory formation, converging evidence from psychology and neuroscience point to at least five major systems in humans. These are episodic memory, working memory, semantic memory, the perceptual representation system, and procedural memory (Fig. 2).

Episodic memory is the recollection of specific incidents that occurred at a particular time and place during a person's past. Researchers study episodic memory formation by asking questions about specific

Human memory formation

System:	Neuronal circuitry:
Episodic memory	Hippocampal formation Prefrontal cortex
Working memory	Hippocampal formation (possibly left temporal lobe)
Perceptual representation system	Extrastriate occipital cortex Temporal lobe and frontal cortex
Semantic memory	Lateral regions of the temporal lobe (left)
Procedural memory	Corticostriatal systems and possibly also the cerebellum

Figure 2 Converging evidence from psychology and neuroscience point to at least five major memory systems in humans with somewhat different anatomical locations.

information acquired at a certain time and place in the past. In this manner, it has been established that damage to the medial parts of the temporal lobes, especially the hippocampus, greatly impairs the acquisition of new episodic memories. Patients with acquired damage to the hippocampal formation invariably suffer impairment of episodic memory, only the degree of damage changes. This means that they have difficulty remembering events during their daily life. Bilateral hippocampal damage may also affect the ability to acquire new memories. Episodic memory also appears to rely on the prefrontal cortex, which seems to provide temporal information on episodic memories. Patients with damage to the prefrontal cortex may have severe difficulty in remembering when and even where recent events occurred. Frontal lobe damage also often produces what is known as source amnesia, which means that patients readily acquire new facts but fail to recollect where or when they learned them. Damage to the frontal lobes, which can, for instance, result from severe alcohol abuse, can also produce distortions of episodic memory in which patients may even claim to remember events that never occurred. Episodic memory studies have been performed while monitoring subjects with positron emission tomography (PET scanning) in order to measure regional cerebral blood flow. These studies confirm that the frontal lobe is activated during episodic memory tasks. Studies using PET scanning have also shown that the temporal lobe and the hippocampus are activated during both the encoding and retrieval of memories.

Working memory is a memory system used for short-term retention, operating over periods of seconds. Working memory is used during reasoning, problem solving, and comprehending. The concept of working memory emerged among other things from studies of patients suffering from amnesia due to bilateral hippocampal damage. Such patients may for instance be able to immediately remember small numbers of digits. Studies on patients with hippocampal damage therefore have revealed that a separate memory system for short-term memory exists. Case reports on patients with selective deficits in working memory have suggested that this memory system may rely on a small group of specific neurons situated in the supramarginal gyrus of the left temporal lobe.

The third memory system, semantic memory, refers to general knowledge of facts and concepts without any apparent connection to time or place. Semantic memory is important for knowing that Hawaii is in the Pacific Ocean, whereas episodic memory is used for remembering a certain visit to Hawaii. Semantic memory also relies on the function of the medial temporal lobes. The acquisition of new memories, both episodic and semantic, depends on the integrity of the medial temporal lobe and is collectively referred to as the declarative memory. The semantic and episodic elements composing declarative memories are thought of as dissociated from each other. Case reports indicate that patients with damage to the anterior part of the temporal lobe have relatively little difficulty remembering specific past episodes but more pronounced difficulties with knowledge of historic events. On the other hand, the study of patients with damage to the more lateral regions of the temporal lobe, particularly in the left hemisphere, suggests that these regions play important roles in the semantic memory system, thus implying that limited neural circuitry may in fact be responsible for the integrity of the declarative memory function.

Another memory system is generally called the perceptual representation system. This memory system plays an important role in the identification of words and objects based on their structure and form. The perceptual representation system operates at a presemantic level and is not involved in semantic memory. PET scanning studies have suggested that specific regions within the extrastriate occipital cortex

are involved in processing and representing the visual form of words, whereas regions within the temporal lobe and the frontal cortex process the meaning of words. The perceptual representation system plays an important role in the phenomenon called priming. In priming experiments, the subject studies a word or a picture and subsequently is presented with only a part of the same item. Priming means that the subject's ability to identify the partial items improves following recent exposure to the entire item. This phenomenon appears to operate unconsciously, because it can be observed in subjects who were primed under conditions resulting in their lack of explicit memory of having studied the object or the word. Amnesic patients (patients with bilateral temporal lobe damage) exhibit intact priming across a wide variety of paradigms. This suggests that the perceptual representation system does not rely on temporal structures. Functional imaging has suggested that posterior cortical regions may be responsible.

Procedural memory refers to the acquisition of skills, characterized by the ability to perform a specific task or habit. Such memories include, for instance, knowing how to ride a bike or more explicit knowledge of sequences or grammatical rules. Studies of amnesic patients have revealed that, although unable to explicitly remember past experiences, these patients can gradually acquire new perceptual, motor, or cognitive skills. These studies suggest that the acquisition of procedural knowledge is independent of the medial temporal lobe. Instead, procedural memory seems to depend heavily on corticostriatal systems, e.g., patients with Huntington's disease or Parkinson's disease may have difficulty in acquiring new motor skills without having any deficits in explicit memory. Functional imaging studies have suggested that both the motor cortex and the basal ganglia are involved in procedural learning. Interestingly, the cerebellum also appears to be involved in procedural memories, as demonstrated by the fact that patients with cerebellar damage may have difficulty learning to execute sequences of movements.

VI. MEMORY FUNCTION IN NORMAL AGING AND DEMENTIA

It has traditionally been accepted that moderate neural death occurs as an inevitable consequence of normal aging. Significant age-related neural loss has been reported in almost every region examined. Studies involving unbiased quantitative techniques for estimating cell numbers in tissue samples have led to a significant revision of traditional views on age-related neural loss. This is due to the fact that most investigators had been focusing their attention on cell density, measured as the number of neurons in a fixed volume of tissue within a brain region. The counting was typically accomplished using standard histological staining procedures to visualize and count cells microscopically. If a strategy like this is employed without taking into account the fact that gliosis within a brain region may actually alter the size of a brain structure, it can lead to the possibly erroneous conclusion that the total number of neurons is decreased. Instead, studies taking into account volumetric differences between young and aged brains have led to a reevaluation of the traditional view on age-related neural loss. Modern stereological tools have been widely used to investigate neural numbers in the aged hippocampus. Earlier studies had suggested that the hippocampus is especially susceptible to age-related cell death and that this may be the explanation for decreases in hippocampal-dependent learning and memory within aged subjects. Instead, investigations have revealed that the number of granule cells of the dentate gyrus and pyramidal neurons within fields CA2, CA3, and CA1 remain unaffected in the aged hippocampus (Fig. 3). Studies also suggest that the number of hippocampal neurons remains normal even among aged individuals with pronounced learning and memory deficits, which are normally associated with hippocampal dysfunction. Other studies have even suggested that granule cells within the dentagyrus are formed continuously throughout life. Instead, age-related neural loss associated with memory deficits preferentially targets subcortical brain systems. Aging does result in substantial subcortical cell loss, especially among neurons with ascending projections to cortical regions. The loss of cholinergic neurons in the basal forebrain has been studied extensively because of its assumed role in Alzheimer's disease. A hallmark of this degenerative condition is an accelerated degeneration of acetylcholine-containing neurons affecting cell groups that project to the hippocampus, the amygdala, and the neocortex. The loss of cholinergic cells might disrupt the circuitry responsible for information processing in these target regions. The number of remaining cholinergic neurons correlates with a magnitude of behavioral impairments in dementia patients and aged individuals. Although the loss of cholinergic neurons may not be directly responsible for the cognitive deficits seen in these patients, it probably indirectly affects other neurochemically specific

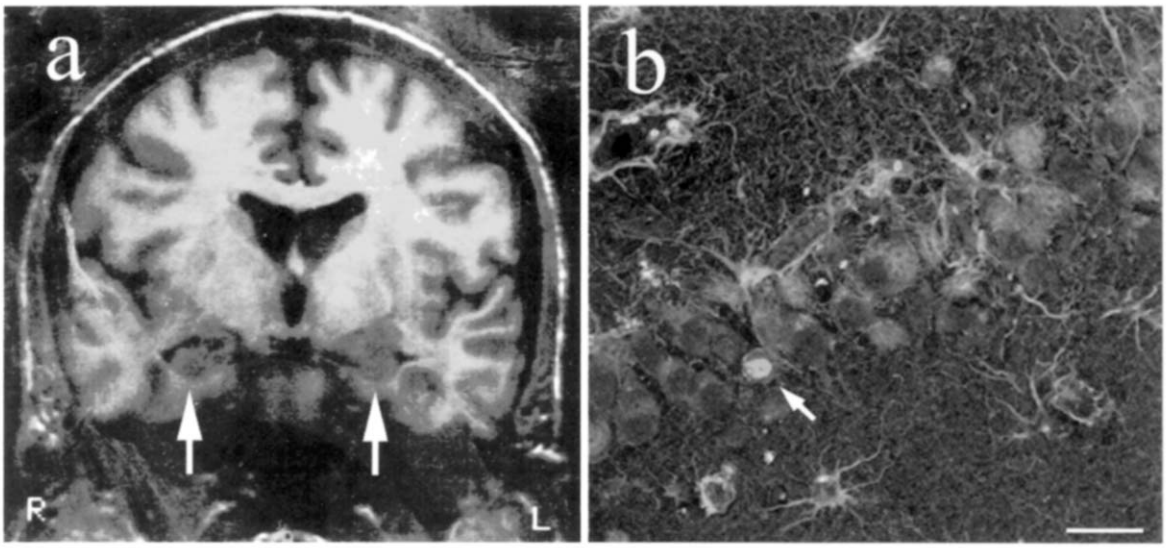

Figure 3 (a) MRI image of the human brain showing the location of the hippocampi (arrows) within the medial portions of the temporal lobe. (See color insert in Volume 1).

projection systems responsible for memory and learning. Thus, cholinergic neurons within the basal forebrain represent an example of a limited number of neurons that have a pronounced impact on behavior.

VII. MODELS FOR THE ANALYSIS OF NERVE CELLS AND SPATIAL MEMORY

In animal models using rodents, neural electrical activity can be monitored in the hippocampus while the test animal is running at arm radial mazes and performing tasks that require locomotion within a workplace. Experiments using this paradigm have revealed a remarkable degree of spatial selectivity. A surprisingly high number of neurons throughout the hippocampus have place fields. This means that a specific neuron within the hippocampus will fire most strongly while the rat is in a certain area of the workspace. In this way, it has been shown that different neurons within the hippocampus cover the workspace made up of the testing area. There are also some hippocampal neurons that are sensitive not only to the rat's location but also to the direction in which its head is pointing. This feature is most pronounced within the postsubiculum, an area closely linked to the hippocampus. Experiments have shown that these postsubicular neurons fire when the rat's head is pointing in the neuron's preferred direction and conversely decrease the firing rate as the orientation of the rat's head deviates from that direction.

Another example of a contribution from specific neural circuitry is new granule neurons formed during adulthood. Neuronal stem cells or progenitor cells residing within the dentate gyrus in the hippocampus continuously generate granule neurons throughout life. This phenomenon has been was shown to be under dynamic regulation. Increased hippocampal volume has been reported in birds and animals that engage in behavior requiring spatial memory, such as food storing. Another study demonstrated navigation-related structural changes in the hippocampus of taxi drivers, with an increased volume of the posterior hippocampus correlating to the time spent as a taxi driver. Laboratory animals housed in an enriched environment have an increased rate of neurogenesis within this region as compared to rats living in a standard environment. Furthermore, animals living in an enriched environment perform better on spatial memory tests. Running also induces this phenomenon and selectively enhances dentate gyrus long-term potentiation (LTP). Newborn granule cells within the adult rat hippocampus have been shown to project axons through the mossy fibers to their natural targets

within the CA3 region. It has, therefore, been speculated that newborn granular cells may contribute to the improvement in spatial memory test performance. The direct link between neurogenesis within the dentate gyrus and spatial memory performance, although compelling, still needs further investigation.

GLOSSARY

autonomic nervous system (ANS) Efferent part of the nervous system supplying motor innervation to the viscera. Has three divisions: sympathetic (thoracolumbar), parasympathetic (craniosacral), and enteric.

axon Usually a single, long, thin, and often branched process arising from the cell body or major dendrite of a neuron, conducting nerve impulses (action potentials) to other neurons, muscles, or glands.

cell body (soma) Plump, spherical part of the nerve cell; includes the nucleus and surrounding organelles. Indispensable, irreplaceable trophic (nutritive, sustaining) center, houses genetic history of the neuron, maintains integrity of the cell and all its far-reaching processes.

central nervous system (CNS) The brain and spinal cord; the neuraxis, consisting of seven bilaterally organized, largely symmetrical, functionally specialized regions: the cerebral hemispheres, diencephalon, midbrain, cerebellum, pons, medulla oblongata, and spinal cord.

cortex Extra gray matter external to white matter in the cerebral hemispheres, roof of the midbrain, and cerebellum. Nerve cell bodies are arrayed in distinct layers; nerve fibers (afferent, intrinsic, and efferent) are arranged in orderly, geometric ways that facilitate integrative, analytic, and comparative functions.

dendrites Short, highly branched, tapered, often spiny processes extending from the nerve cell body or, in sensory neurons, from the distal end of an interposed axon; chief receptive surface of the neuron.

ganglion Spherical or fusiform cluster of sensory nerve cell bodies in the PNS or of small motor nerve cell bodies in the ANS. Has connective tissue investments like those of adjoining nerves.

gray matter Inner core of CNS, containing nerve cell bodies (somata), dendrites, the proximal extents of axons, which distally enter white matter, neuroglial cells, and blood vessels (especially capillaries).

interneurons Originally defined as all neurons lying between sensory and motor neurons, comprising most neurons in the CNS; tiny or huge, linking neurons receiving stimuli from sense organs to those innervating muscle. Now used much more restrictively for neurons intrinsic to specific CNS regions.

motor neurons The ultimate neurons or "final common path" (Sherrington) over which neural activity passes to muscles and glands; the large multipolar anterior horn cells in spinal gray and similar cells in the brain stem (hypoglossal nucleus). Paltry in number (about 2 million), profound in importance.

nerve In the PNS, a bundle or bundles of myelinated and unmyelinated fibers with supportive, protective, and nutritive connective tissue investments (endoneurium, perineurium, epineurium). Like a CNS tract, but serving a wider range of functions (sensory and motor, somatic and visceral, etc.).

neuroglia Singular noun meaning "nerve glue." One of two types of cells intrinsic to the CNS, the other being neurons. The neuroglia (astrocytes, oligodendrocytes, ependymal cells, microglial cells) outnumbers neurons 10–50 times and makes up half the volume of the CNS. More than offering structural support, neuroglial cells surround, protect, nurture, and assist neurons in important ways as they perform their integrative and communicative functions.

neuron Nerve cell, highly diversified in size, shape, and chemical properties. The human nervous system has over 100 billion, perhaps 1 trillion neurons (25 billion in the cerebral cortex alone).

nucleus Functional cluster of nerve cell bodies in CNS gray matter (not the nucleus of a cell). Their axons and dendrites frequently

Dedicated to the memory of David Bodian and Walle J. H. Nauta.

extend beyond the arbitrary nuclear boundary and their component cells exhibit differences in size and other structural features, as well as in the functions served.

peripheral nervous system (PNS) The peripheral nerves (cranial and spinal) with their sensory and motor roots, sensory ganglia, and complicated nerve plexuses.

sensory (or primary sensory) neurons Initial neurons (about 20 million) in sequential sensory data processing. Derived chiefly from neural crest, their bipolar or pseudounipolar cell bodies lie outside the CNS in the sensory ganglia of craniospinal nerves and in the olfactory mucous membrane.

synapses Intimately apposed regions (10- to 20-nm gap; 10^{14} or more) of contact between neurons or between neurons and muscle fibers, which permit functional transactions and, by allowing one-way transmission only, help determine the forward impulse traffic in the nervous system as a whole.

tract Cablelike bundle of myelinated or unmyelinated axons in CNS white matter, running from place to place, often over long distances (up to 1 m in humans) and representing a functional group of nerve fibers. Named functionally (optic tract), descriptively (medial forebrain bundle), binomially as to origin and termination (spinocerebellar tract), or analogously (lemniscus, L. for ribbon).

white matter Outer zone of CNS, surrounding the ever-present gray core; contains vast numbers of axons of various caliber and myelination, derived from nerve cell bodies in subjacent gray or PNS sensory ganglia, neuroglial cells, capillaries (fewer than in gray matter), and larger blood vessels.

The human nervous system is a hierarchy, culminating in the brain, of 100 billion or more neurons of 10,000 types, 1–10 trillion neuroglial cells, 100 trillion chemical synapses, 160,000 km of neuronal processes, thousands of neuronal clusters and fiber tracts, hundreds of functional regions, dozens of functional subsystems, 7 central regions, and 3 main divisions. All of these parts form a coherent, bodily pervasive, diversified, complex *epithelium* with interdependent connectivity of neurons, mostly neither sensory nor motor but anatomically and functionally intermediate. The key organizing principles of the system are *centralization* and *integration*. The nervous system performs two roles: *regulation* and *initiation*. In the first, it *counteracts*: responsively and homeostatically, gathering stimuli from outside and inside the body (including the brain), assessing their short-term and long-range significance, generating activity from faster breathing to stock trading, even to functional plasticity in learning or after brain damage. In the other, it *acts*: endogenously, not so homeostatically, replacing one state of neural activity with another, generating activity from doing nothing at all to creative thinking and extraordinary achievement, even taking steps toward understanding how itself, the nervous system, works. Although the divisions and regions of the nervous system are identical in all normally developed humans, their genetic specification and personal history are unique, as are the permutations and combinations of their unified function. Each human nervous system is unprecedented. The work of each (expressed or hidden) is unpredictable, ever-different, surprising, startling, at times horrifying, but not infrequently magnificent.

I. PRINCIPAL DIVISIONS OF THE NERVOUS SYSTEM

A. Central Nervous System

The central nervous system (CNS) comprises the brain and spinal cord (Fig. 1). Derived from five vesicles in the cranial part of the embryonic neural tube, the brain has five bilaterally represented, largely symmetrical, functionally specialized regions: cerebral hemispheres, diencephalon, midbrain, pons, and medulla oblongata (Fig. 2, Table I). Each has a central hollow, large or small. All are interconnected as a four-chambered ventricular system (Fig. 3) with a connecting aqueduct. In its size and specialization, the cerebellum, inseparably a part of the pons, deserves status as a sixth region. Figure 4 illustrates the embryonic and fetal development of all these regions.

The spinal cord is a tubular structure (Fig. 1). Its central canal, a remnant of the lumen of the neural tube, is no longer patent (Fig. 18). Continuous with the medulla oblongata, it has 31 segments: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Segments are spinal regions served by a pair of spinal nerves. Reflecting the segmental development of the body, they are functionally and clinically important. No other demarcation of segments exists: an epigraph for the spinal cord is "continuity." Extending 43–45 cm from the base of the skull to the lumbar spine, the spinal cord mediates all sensations and movements of all parts of the human body, except those served by cranial nerves.

B. Peripheral Nervous System

The peripheral nervous system (PNS) comprises the cranial and spinal nerves (Fig. 1), with their associated roots and ganglia. Through these nerves, sensory impulses come to the CNS and motor impulses go to muscles and glands. Like the cranial structures they

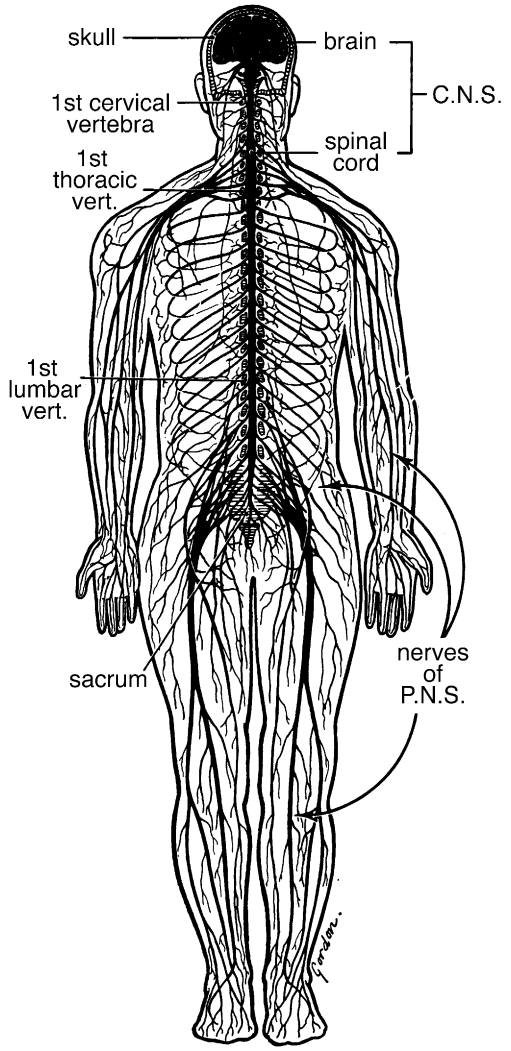

Figure 1 Basic subdivisions of adult nervous system: central nervous system (CNS) and peripheral nervous system (PNS). From Han, A. W., *Histology*, 5th ed., J. B. Lippincott, 1961 (illustration by Louise Miller).

innervate, most of the 12 cranial nerves are specialized. Some, like the optic nerve, are purely sensory, whereas others, like the abducens, are purely motor. Still others, like the vagus, are mixed sensory and motor (Fig. 5, Table II).

By contrast, the spinal nerves are much alike, providing a basic segmental pattern of sensory and motor innervation for the rest of the body, including the limbs. In the cervical, brachial, lumbar, and sacral regions, nerve plexuses interpose between the spinal cord and the nerves themselves. In these complex webs, nerve fibers leaving the spinal cord segmentally sort out and recombine into specific nerves. This involves a process of diverging and converging roots, trunks, divisions, cords, and branches, eventually combining in nerves, such as the phrenic, radial, femoral, and sciatic, to cite prominent nerves derived from each plexus in turn. These and other nerves continue to ramify.

C. Autonomic Nervous System

The autonomic nervous system (ANS) is an involuntary division for maintaining homeostasis (Fig. 6). It sends motor fibers to the viscera, blood vessels, sweat glands, arrector pili, pupillary smooth muscles, etc. and regulates heart rate. It features two small visceral motor neurons in tandem: a preganglionic neuron with its cell body in the CNS and a postganglionic neuron in an autonomic ganglion. Both have meager dendritic trees and thin, lightly myelinated, slow-conducting axons that travel in peripheral or autonomic nerves to smooth muscle in a viscus, blood vessel, or gland.

The ANS has three subdivisions: *sympathetic* (thoracolumbar), *parasympathetic* (craniosacral), and *enteric*. In the first, preganglionic nerve cell bodies lie in thoracic and upper lumbar segments of the spinal cord and postganglionic ones in the paravertebral sympathetic chain ganglia or the prevertebral ganglia (celiac, superior mesenteric, and inferior mesenteric). In the second subdivision, preganglionic nerve cell bodies lie in the brain stem (in cranial nerve nuclei III, VII, IX, and X; see Table II) and in sacral spinal cord segments 2–4, with postganglionic ones in or near the organs innervated. In the enteric component, postganglionic neurons lie in the alimentary wall in ganglia and intramural plexuses. These nets contain 100 million neurons. They function almost autonomously, subject to control and override by preganglionic parasympathetic and sympathetic neurons.

The CNS receives visceral sensory axons not included in the ANS as originally defined. Visceral afferents, from mechanoreceptors, chemoreceptors, and nociceptors, are poorly understood but important to homeostasis and behavior. The sympathetic part of the ANS forms a distinct pair of cords in the PNS: the sympathetic chain ganglia alongside the spinal cord. The parasympathetic part, by contrast, is less obvious as its fibers are components of cranial and sacral nerves.

The sympathetic subsystem is the "fight or flight" component. When energy must be burned, it acts

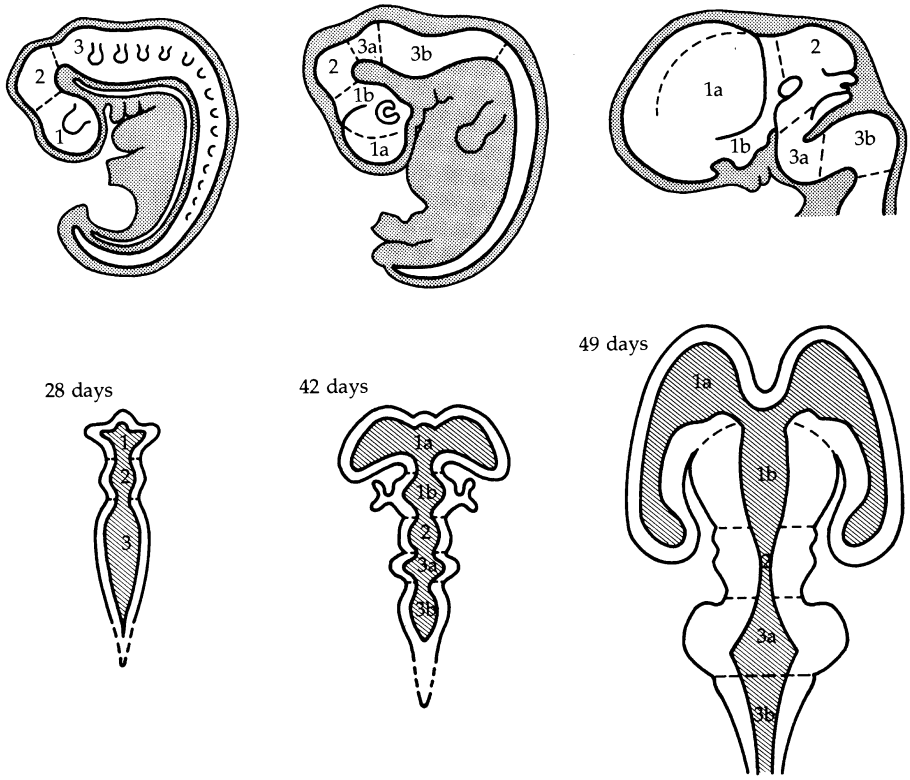

Figure 2 Basic subdivisions of embryonic nervous system: at 28 days, prosencephalon (1), mesencephalon (2), rhombencephalon (3). Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by Steven J. Harrison).

almost instantly in a concerted manner and over some duration. Heart rate goes up, blood vessels in skeletal muscles dilate, as do respiratory bronchioles and pupils, suprarenal glands kick in massive secretions of epinephrine and norepinephrine, hepatic glycogenolysis provides glucose for energy, hairs stand on end, and the mouth is suddenly very dry. The parasympathetic subsystem functions less dramatically. It is the

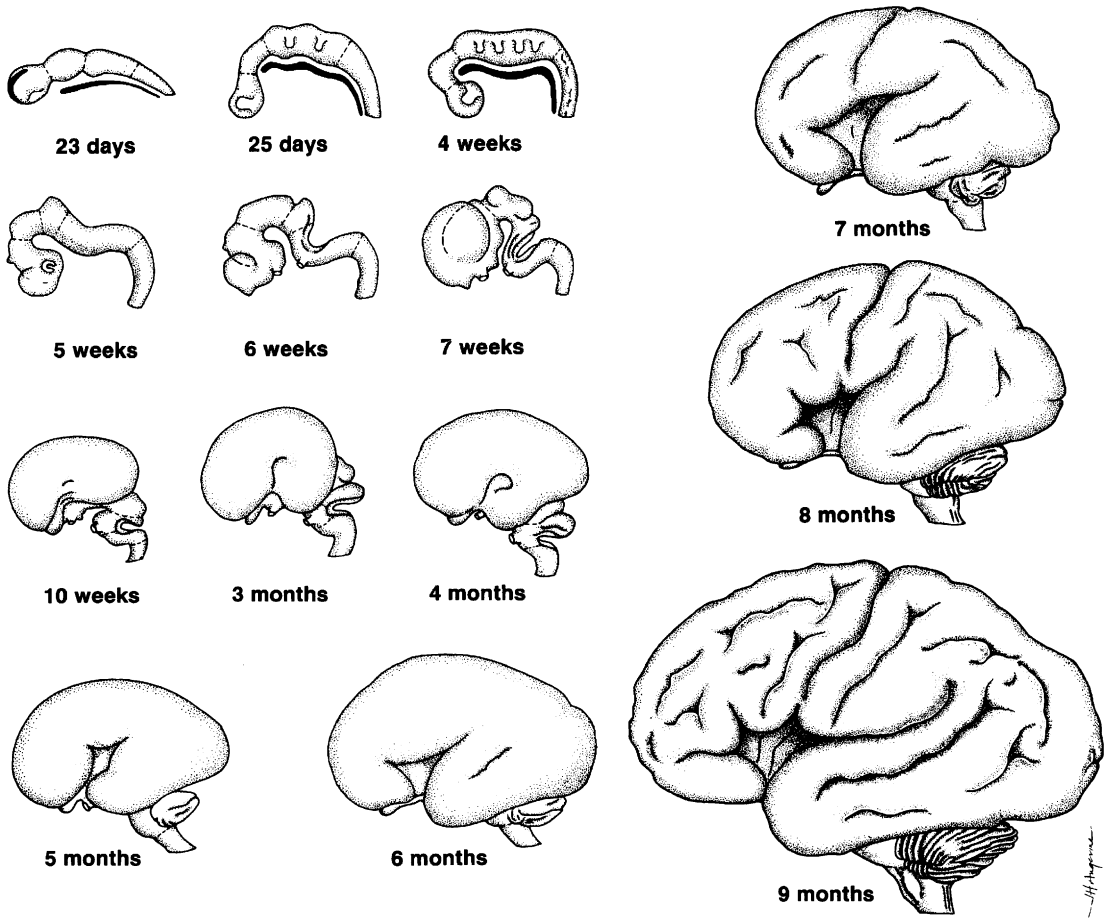

Figure 4 Embryonic and fetal brain development: flexures and differential expansion of its chambers, along with cerebral fissuration, bring about the definitive appearance of the brain. From J. B. Angevine, Jr., Morphogenesis of the Central Nervous System, *BNI Quarterly*, Vol. 5, No. 4, 1989 (illustration by Janice H. Angevine, modified from Carol Donner).

"rest and replenishment" component. When activity brings fatigue and energy must be restored, it goes about its business slowly, quietly, selectively. Heart rate goes down, blood vessels stay the same, bronchioles and pupils constrict to normal size, and digestive, urinary, and reproductive systems proceed with normal function.

Usually, sympathetic and parasympathetic divisions act separately and at times cooperatively. Sweat glands and blood vessels in the limbs have only sympathetic innervation; the pupil and bladder are dominated by parasympathetic fibers. Certain disparate domains see both divisions working together: in never-ending modulation (with neurohormonal assistance) of cardiac rhythmicity and intermittent assistance in male sexual function (erection is mediated mainly by parasympathetic fibers but ejaculation by sympathetic fibers). Visceral and somatic functions may also be performed cooperatively. This requires the interplay of many parts of the CNS: spinal cord, brain stem, limbic system, hypothalamus, basal ganglia, and others. Performances of respiratory, digestive, and sexual functions offer eloquent illustrations of concerted viscerosomatic activity.

Visceral sensations may intrude deeply upon thoughts and feelings. Often difficult to describe and localize, they are usually unpleasant and at times uncompromising. As biofeedback studies show, the ANS can be classically conditioned. Once activated, it plays a pivotal role in human decision making. It now receives major attention in studies of normal, abnormal, and criminal behavior, with benefit to informed family counseling, crisis mediation, law enforcement, corrections, and society at large.

Angevine, Jr., *The Human Brain. In Photography and Diagrams*, 2nd ed., Mosby, St. Louis, 2000 (photograph by Biomedical Communications, The University of Arizona College of Medicine).

II. MAJOR REGIONS OF THE CENTRAL NERVOUS SYSTEM

A. The Cerebral Hemispheres

The largest, most striking structure in the adult human nervous system is the *cerebrum*. It is almost completely divided into left and right cerebral hemispheres (Fig. 7), each containing a core region of *gray matter*, the *basal ganglia*, a domelike central mass of *white matter*, and an intricately and deeply infolded thin outer sheet (1.5–4.5 mm deep by 2200–2400 cm^2 in area) of additional gray matter comprising the *cerebral cortex*. It has six lobes: frontal, parietal, temporal, occipital, limbic, and central (hidden by opercular folds of the first three; see Fig. 4, 9 months).

1. The Cerebral Cortex

The term cortex (Latin: "bark") means an external layer, in this case of the endbrain. The cerebral cortex features six distinct *layers* of neurons (estimated at 25 billion) and intrinsic axonal plexuses (Fig. 8). Nerve cell bodies are neatly regimented in these horizontal planes as to size, type, and connectivity (3×10^{14} synapses). Nerve fibers (afferent, intrinsic, and efferent) are also arranged in orderly, geometric ways. Nerve cells are of two main types. *Pyramidal* or projection neurons, about 75–80% of the total, display dendritic spines and are generally glutamatergic and excitatory. *Nonpyramidal* or local-circuit neurons lack spines; they take many forms but are usually GABAergic and inhibitory. They dominate some areas (e.g., the visual), but overall are outnumbered by the former.

Superimposed on the laminar plan is a *columnar* mode of organization, featuring about 500 million small, vertical slabs or columns (50–500 μm wide), each containing some 100–300 neurons profusely interconnected in the vertical axis. The cellular make-up of a column is similar throughout the cortex, but the input and output vary according to function and

Table II
Names, Components, Constituent Neurons, and Functions of Cranial Nerves

Nerve	Name	Components[a]	Location of cell bodies[b]	Functions
I	Olfactory	SVA	Bipolar cells in nasal mucosa	Olfaction
II	Optic	SSA	Ganglion cells of the retina	Vision
III	Oculomotor	GSE	Principal oculomotor nucleus	Elevation, depression, adduction, extorsion of eye; elevation of lid
		GVE	Nucleus of Edinger–Westphal	Pupillary constriction, accommodation of lens
IV	Trochlear	GSE	Trochlear nucleus	Intorsion (also abduction, depression) of eye
V	Trigeminal	SVE	Motor nucleus of nerve V	Chewing, control of tensor tympani muscle
		GSA	Trigeminal ganglion	Anterior cranial sensation (face, nose, mouth, dura mater)
		GSA	Mesencephalic nucleus of V (primary sensory neurons)	Stretch input from chewing muscles, pressure from teeth
VI	Abducens	GSE	Abducens nucleus	Abduction of eye
VII	Facial	SVE	Facial nucleus	Facial expression, tensing stapedius muscle
		GVE	Superior salivatory nucleus	Lacrimation, salivation (glands of oral floor)
		GVA	Geniculate ganglion	Nasal and palatal sensation
		SVA	Geniculate ganglion	Taste (anterior two-thirds of tongue)
		GSA	Geniculate ganglion	Sensation from external ear
VIII	Cochlear	SSA	Spiral ganglion	Hearing
	Vestibular	SSA	Vestibular (Scarpa's) ganglion	Sense of stability, oculocephalogyric control
IX	Glossopha-ryngeal	SVE	Nucleus ambiguus	Swallowing movements
		GVE	Inferior salivatory nucleus	Salivation (parotid gland)
		GVA	Petrosal ganglion	Pharyngeal sensation
		SVA	Petrosal ganglion	Taste (posterior one-third of tongue)
		GSA	Superior ganglion	Sensation of skin behind ear
X	Vagus	SVE	Nucleus ambiguus	Swallowing and phonation
		GVE	Dorsal motor nucleus of X	Parasympathetic innervation of viscera
		GVA	Nodosal ganglion	General visceral sensation
		SVA	Nodosal ganglion	Taste (epiglottis)
		GSA	Jugular ganglion	Sensation of skin behind ear
		GVE	Nucleus ambiguus	Parasympathetic innervation of heart
XI	Spinal accessory	SVE	Spinal accessory nucleus	Head, neck, and shoulder movements
XII	Hypoglossal	GSE	Hypoglossal nucleus	Tongue movements

[a]GSA, general somatic afferent; GSE, general somatic efferent; GVA, general visceral afferent; GVE, general visceral efferent; SSA, special somatic afferent; SVA, special visceral afferent; SVE, special visceral efferent.

[b]Note: Input from stretch receptors in the extraoccular and facial muscles may be mediated by cells in the trigeminal ganglion and similar input from lingual muscles by inconstant ganglion cells along the hypoglossal rootlets.

location in the sheet. As to function, each column is stimulus-specific. All of the neurons in a given column respond preferentially to some stimulus parameter: sensory modality, stimulus orientation, ocular dominance, etc. Like the many floors and floorplans of a tall office building, the orderly laminar and columnar features of cortex facilitate integrative, progressive analytic, and comparative functions.

Beneath the cortex, in the white matter, lie millions of myelinated axons of varying caliber, so closely packed as to seem a solid mass of myelin. All of the axons are associated with the cortex. Some go to it,

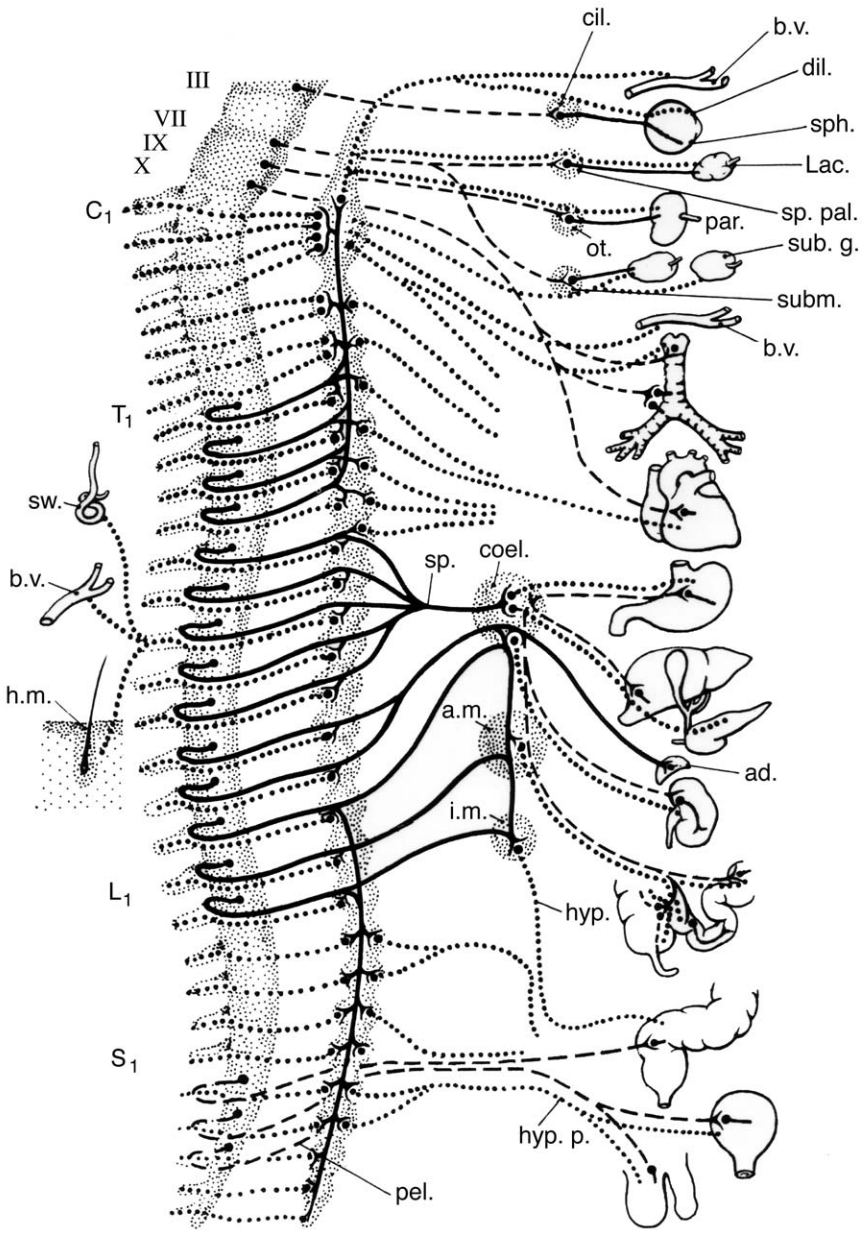

Figure 6 Autonomic nervous system (ANS) showing target organs: preganglionic sympathetic fibers (solid lines), postganglionic (dotted lines); preganglionic parasympathetic fibers (dashed lines), postganglionic (solid lines). From *The Life of Mammals*, copyright 1957 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (original painting by Frank Netter, modified by Jane deVere).

whereas others depart from it. The total length of axons involved in cortical connectivity is estimated at more than 100,000 km. These fibers are crucial to cortical function. They allow parts of the two cortical sheets to influence one another and parts of the underlying brain. Three types of fibers are found (see later discussion). For rapid communication, most are large, well-myelinated axons.

Association fibers interconnect cortical areas in one cerebral hemisphere. They are short, looping from one gyrus to the next, or long, extending the entire frontooccipital length of the hemisphere. They may pass from one cortical area to another in linear sequence or bypass areas, diverge, or converge in a selective manner. These cascades provide profound connectivity in the cortical sheet. Outward or

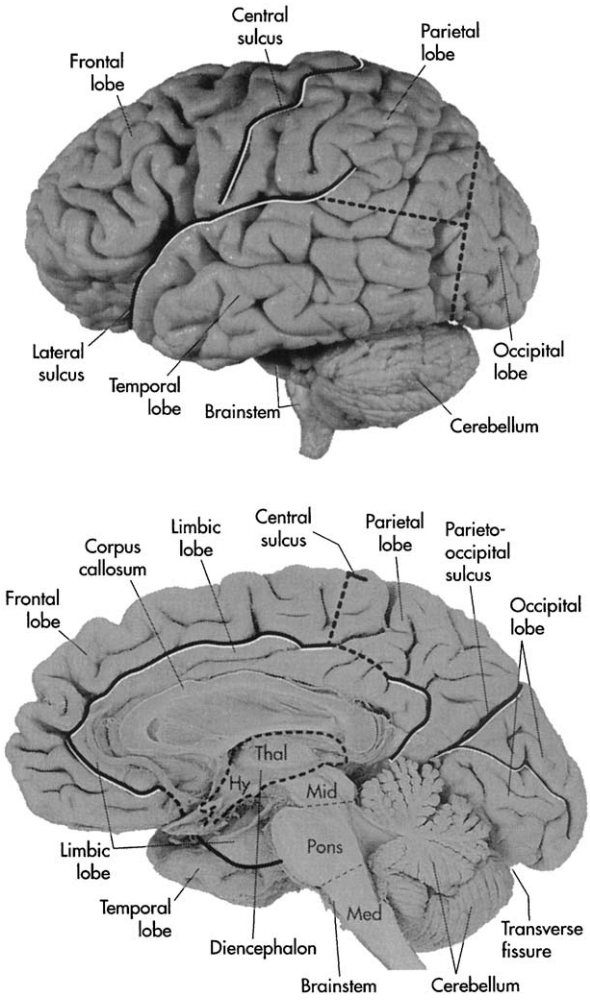

Figure 7 Lateral (top) and medial (bottom) aspects of brain, showing major fissures and lobes (except central lobe; see Fig. 4, 9 months) and principal regions of the brain stem. From J. Nolte and J. B. Angevine, Jr., *The Human Brain. In Photographs and Diagrams*, 2nd ed., Mosby, St. Louis, 2000 (photograph by Biomedical Communications, The University of Arizona College of Medicine).

feedforward connections originate and terminate in specified cortical layers. Backward or feedback connections begin and end in other specific cortical "landing strips." Wherever signals enter the network, they eventually filter through to the orbitofrontal cortex and limbic system, where emotional colorations and affect may be factored in. This network makes for unified cortical function: in analysis and integration, wherein multiple data are processed, coincidences detected, and sensory and motor data reduced and combined in schemes of reference, such as our world and ourselves within it.

Commissural fibers interconnect cortical areas across the midline. There they form a huge curvilinear bridge of white matter, the *corpus callosum* ("hard body"), the largest assembly of nerve fibers in the human brain at 700 mm long and 50–100 mm thick, comprising over 300 million well-myelinated axons (Fig. 7). Most of these make mirror-image connections between the two hemispheres, but some cross to areas different from the ones at which they arise. Much of the temporal lobe interconnects in the *anterior commissure* (Fig. 12; small oval structure just beneath the interventricular foramen).

The traditional concept is that the corpus callosum allows information sharing and teamplay between the two hemispheres. This idea is being reevaluated. Callosal connections involve a time lag (about 30 msec at 6.5 m/sec to travel the roughly 175 mm between origin and termination) that could interfere with cooperative feature analysis. Not excluding hemispheric cooperation, new ideas posit callosal connections permitting hemispheric competition. Callosal connections may effect largely inhibitory, not excitatory, influences and express true hemispheric dominance, albeit moment to moment.

Projection fibers lead to, or come from, subcortical structures. By analogy, they "cross state lines." They convey impulses between structures in different principal regions of the CNS (corticospinal, spinocerebellar, cerebellothalamic, etc.). The neocortex of mammals (as contrasted with the olfactory cortex of all vertebrates) is unique in its *direct lines* to every level of the neuraxis. Association and commissural fibers are direct lines too, from one part of the cortex to another, near or far. No region of the CNS is beyond the reach of the cerebral cortex (Table III). Cortical efferents modulate activity in all parts of sensory and motor neurons, visceral and somatic. Most cortical projections go to the thalamus, which reciprocates them. The work of the cortex would be impossible but for the thalamus. A concept of thalamocortical resonance may offer a better understanding of mechanisms of attention and perseverative thought processes.

Except for minor differences in sulcal pattern, the hemispheres look much alike, but show *functional asymmetry*. Each makes the same functional contributions, but more pronounced than those of the other side. For example, one hemisphere (usually the left) is better in speech and calculation and has a stronger link with consciousness and deliberate, analytical thought processes. The other (usually the right) is better at spatial relations, nonverbal ideation, and holistic

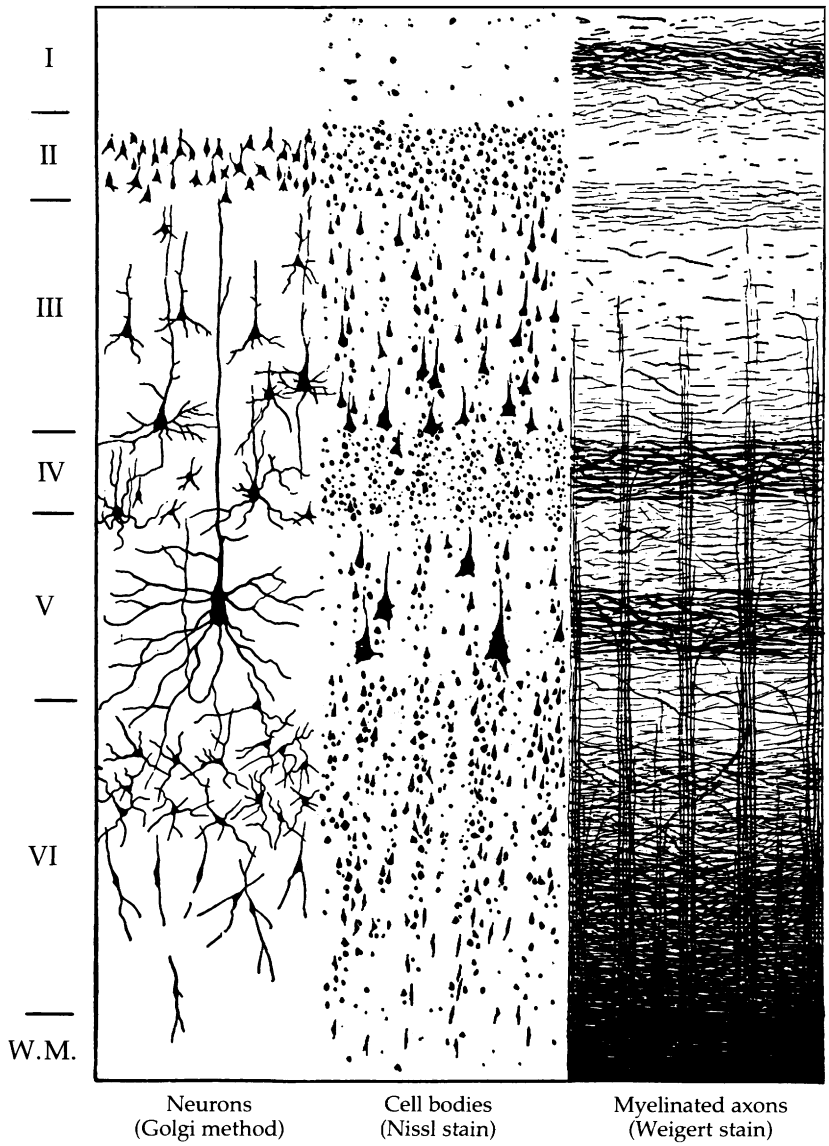

Figure 8 Cerebral cortex showing six principal layers, constituent neurons (pyramidal, stellate, multiform), and myelinated axons. Horizontal lamination is evident, but a vertical or columnar plan of organization is also prominent (see text). From *Principles of Neuroanatomy* by J. B. Angevine, Jr., and C. W. Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by Konstantin Brodmann).

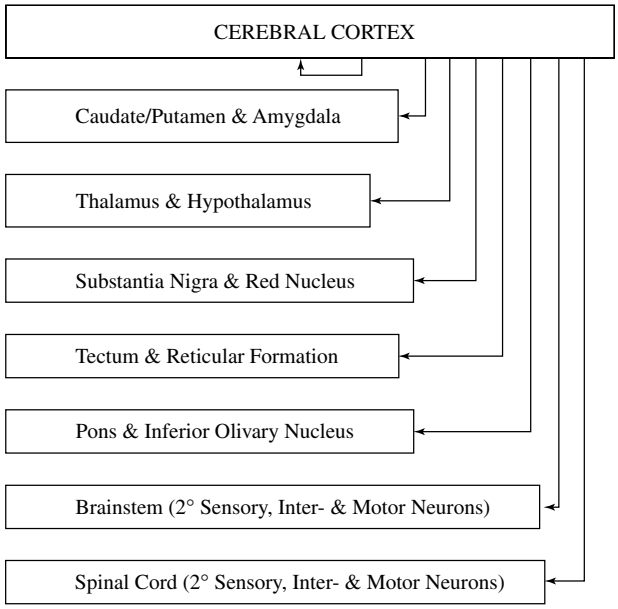
thinking. But in both hemispheres, all abilities are well-represented, and neural integration and pattern synthesis are equally profound.

2. The Basal Ganglia

The basal ganglia are large nuclei within each hemisphere, joined here and separated there, by cortical efferents. They contribute to motor control, cognition, motivation, selection and initiation of behavior, emotion, and perhaps other higher functions (Fig. 9). Only relatively recently have we begun to understand them.

A huge mass of gray matter, the striatum ("striped" by myelinated inputs), has four parts. A lateral, bulky part, the *putamen* ("a shell"), is separated by projection fibers from an inner, curving one, the *caudate nucleus* (with head, body, and tail). Below, in the

Table III



temporal lobe, is the *amygdala* (''almond''), now part of the limbic system. It mediates learning, expression, and the cognitive experience of emotion. A fourth part is the *nucleus accumbens* (not shown), also annexed by the limbic system.

Medial to the putamen is the *globus pallidus*, a major output center to the thalamus and midbrain. Two smaller centers are now considered basal ganglia: the *subthalamic nucleus* and the mesencephalic *substantia nigra*. The former provides an excitatory sidearm between the outer and inner segments of the globus pallidus (all other circuits of the basal ganglia are inhibitory). The lower *reticular part* of the nigra serves, like the inner pallidum, as an output center. Its upper *compact part* synthesizes and ships dopamine up to the caudate and putamen for use as a neurotransmitter in their activities.

The contributions of the basal ganglia have long eluded understanding. The results of their injury, however, are dramatic, expressing something terribly wrong with the teamwork of motor control. Examples include Parkinson's disease and Huntington's chorea. Great strides are now being made regarding the functions of the basal ganglia, the connections that underlie their interplay with the cortex, and the chemistry and molecular biology of their complex synaptic relationships.

The basal ganglia receive widespread cortical inputs and project back, via the thalamus, to motor cortex (Fig. 10). The circuit details are daunting, but the advantage is clear. Almost all of the cortex is involved in movements in the making. The same is true of the cerebellum. Projections from the basal ganglia and cerebellum to the motor cortex are integrated in the rostral thalamus en route.

3. The Limbic System

The limbic system (Fig. 11) is the most controversial subsystem of the human brain. It does not represent one sensory modality, nor one effector mode. Many disagree as to its components. Its functional contributions are not as defined as those of other subsystems or of new ones postulated. The system comprises closely interconnected structures with components in all brain regions, not just the forebrain as conceived. It has multimodal inputs: sensory and associative, and dual outputs: neural and endocrine. It is postulated to mediate memories, drives, and rewards underlying motivation, regulate visceral function and emotional expression, and influence and emotionally color high functions essential to perception and perhaps thoughts.

Nineteenth century neurosurgeon Paul Broca's limbic lobe (the cingulate and parahippocampal gyri, bordering the sulcus of the corpus callosum) gave the system its name. The hippocampus, fornix, mammillary body, and anterior thalamic nuclei projecting to the cingulate gyrus were key links in neuroanatomist James Papez's 1937 sulcal circuit. Then other structures were added: the septal area, temporoamygdaloid complex, habenula and its somatovisceral connections; preoptic area and hypothalamus with visceromotor and endocrine outputs; the striatal nucleus accumbens and ventral pallidum; and the ventral tegmental area and other brain stem nuclei serving visceral afferents energizing the system. Some include the orbitofrontal cortex and the thalamic medial dorsal nucleus projecting to it. This cortex has direct lines to most of the preceding places for cortical oversight and regulation.

B. The Diencephalon

1. The Thalamus

Analysis of detail and synthesis of effector patterns are carried out in the cerebral cortex to a degree unequalled by other parts of the CNS. A close competitor is the *thalamus*, a diencephalic structure between the

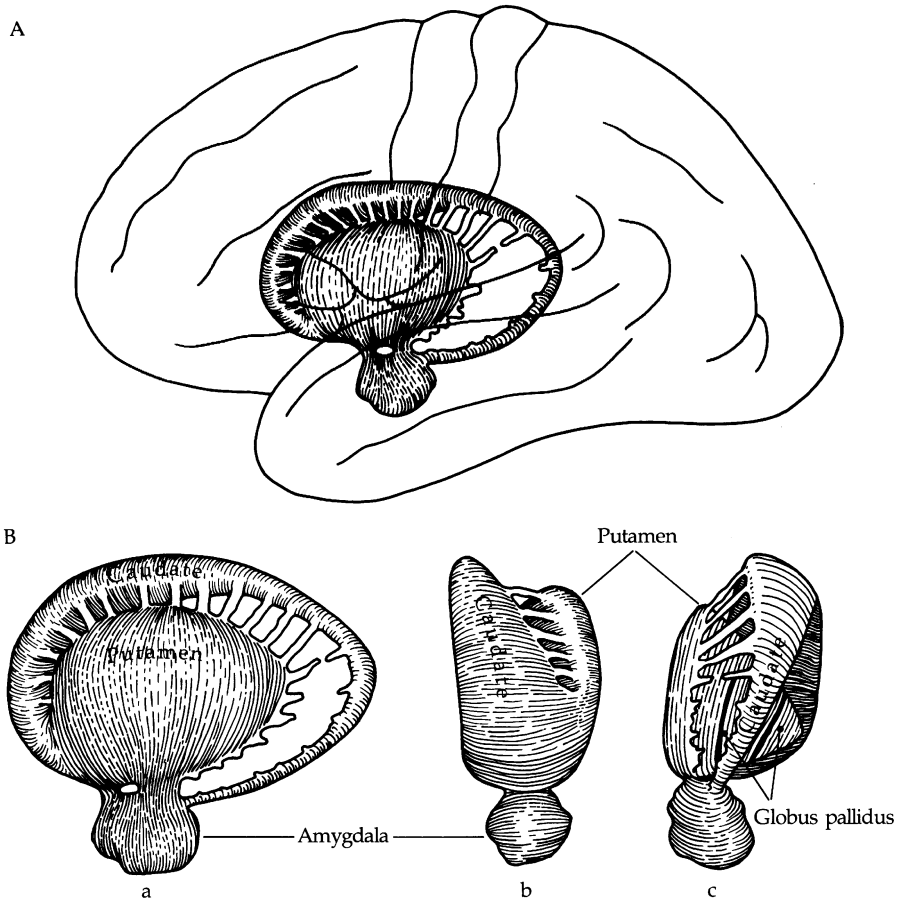


Figure 9 Basal ganglia: the massive putamen is continuous medially in many places with the fishlike caudate nucleus and inferiorly with the amygdala. Medial to the putamen and visible only in view c is the cone-shaped globus pallidus with its outer and inner divisions. From *Principles of Neuroanatomy* by J. B. Angevine, Jr., and C. W. Cotman, copyright 1981 by Oxford University Press Inc. Used by permission of Oxford University Press, Inc. (illustration by Emeline M. Angevine).

cerebral hemispheres, surrounded by them, and during development bound to them by thalamocortical fibers (Fig. 12). The thalamus thus is physically coherent with the cerebrum. It is a bilateral ovoid gray mass with a prominent pole (the pulvinar) facing posteriorly on each side. During development, its halves bulge to form a small interthalamic adhesion. In aging, this adhesion may atrophy and disappear. (Descriptively, "thalamus" often refers to one half-of the thalamus, "thalamic function" to both halves collectively. Such dual usage also applies to the hypothalamus.)

The intimate association with the optic tract is a metaphor of thalamic function. It is the portal of the cerebral cortex. All of the sensory tracts, and many nonsensory tracts, converge on the thalamus. It integrates this information, then passes it to the cortex for additional integration, correlation, and comparison. Olfaction is an exception. It is first processed in the olfactory bulb, a region of old cortex. This sensory information eventually reaches the thalamus after passing through other way stations.

Messages to the thalamus concern *discriminative* aspects of sensation (location, quality, intensity) and *affective* aspects (pleasant, unpleasant). Such inputs dominate the caudal part of the thalamus. Other messages, however, have but an indirect relation to sensation; they come from the basal ganglia, cerebellum, and limbic system. As noted, the basal ganglia and cerebellum act as consultants to the cortex in synthesizing movement patterns, the former offering complex programming of movements and the latter regulating their direction and force. Results of these consultations go to the rostral part of the thalamus (Fig. 10, VA, VL) and are projected to motor cortex,

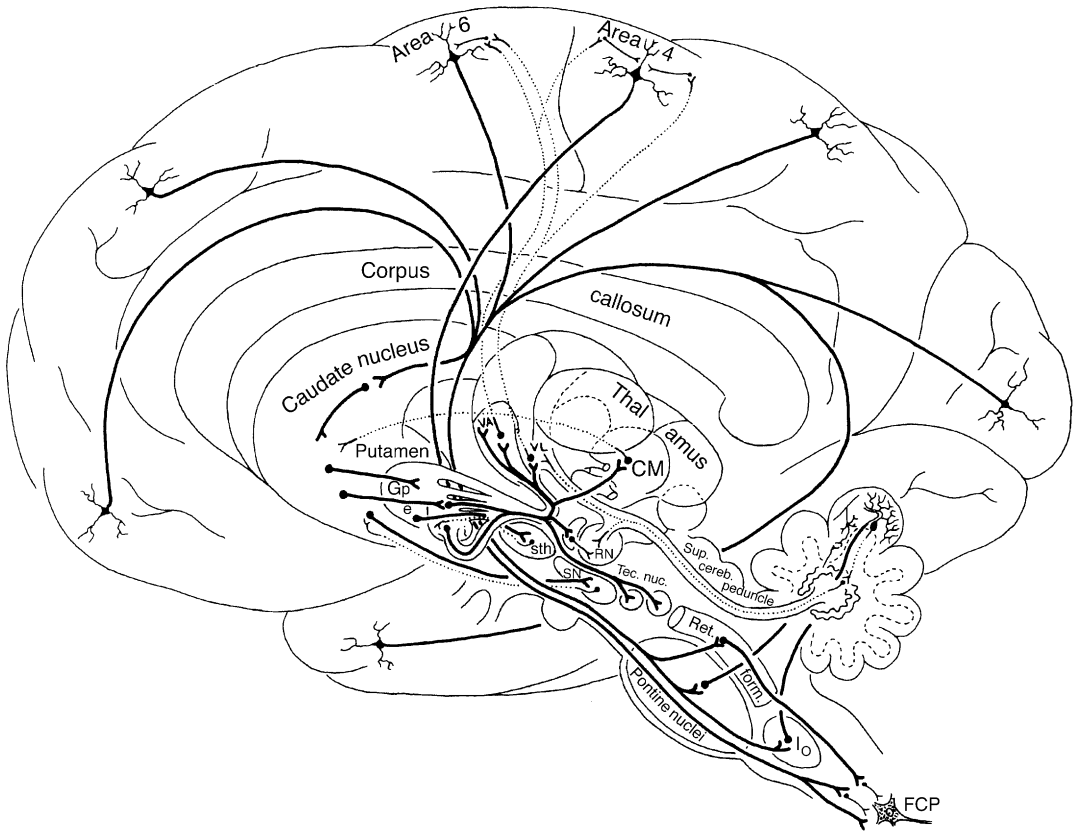

Figure 10 Motor system: an important feature of this complex circuitry is that the basal ganglia lie between the entire cerebral cortex and the motor cortex, by way of pallidothalamic feedback. The same is true for the cerebellum. Although the motor system includes many structures and connections, what emerges is refined motor control. From *Principles of Neuroanatomy* by J. B. Angevine, Jr., and C. W. Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by Jay B. Angevine, Jr.).

where movement patterns are synthesized. Limbic input comes from the hypothalamus and orbitofrontal cortex: visceral afferent data from the former, highly refined integration of the widest range of function imaginable from the latter. As before, thalamic projections to specific cortical areas permit the necessary cortical interplay.

The human thalamus comprises two egg-shaped halves containing some 15 major nuclei and many small cell clusters. Space constraints preclude their coverage, but the structural and functional unity of the thalamus is more important. Over the last 50 years, neurophysiology has shown five functional attributes of thalamocortical connections that are especially illuminating.

Thalamic *overlap* and *fusion* blend modalities and submodalities of sensation, e.g., all sensations of the index finger are processed by neurons in a particular region of the thalamic somesthetic nucleus. *Orderly representations* of sensory or other functional domains form topographic maps of the retina, cochlear duct, and cutaneous surface, in tracts leading to the thalamus, and in certain thalamic nuclei. *Multiple representations* of venues are exemplified by the lateral geniculate nucleus (Fig. 12). It receives the fibers of the optic tract. Its six cell layers provide six tightly registered retinal maps of the contralateral half of the binocular visual field, the map in each layer representing the ipsilateral or contralateral hemiretina serving the half visual field in alternation. *Reciprocity* of function is evident in the equally numerous and precise thalamocortical and corticothalamic projections. These inhibit or facilitate thalamic neurons, perhaps for selective attention or further integration. Finally, *specificity* of thalamic neurons: David Hubel and Torsten Wiesel, Nobel laureates of 1981, showed that

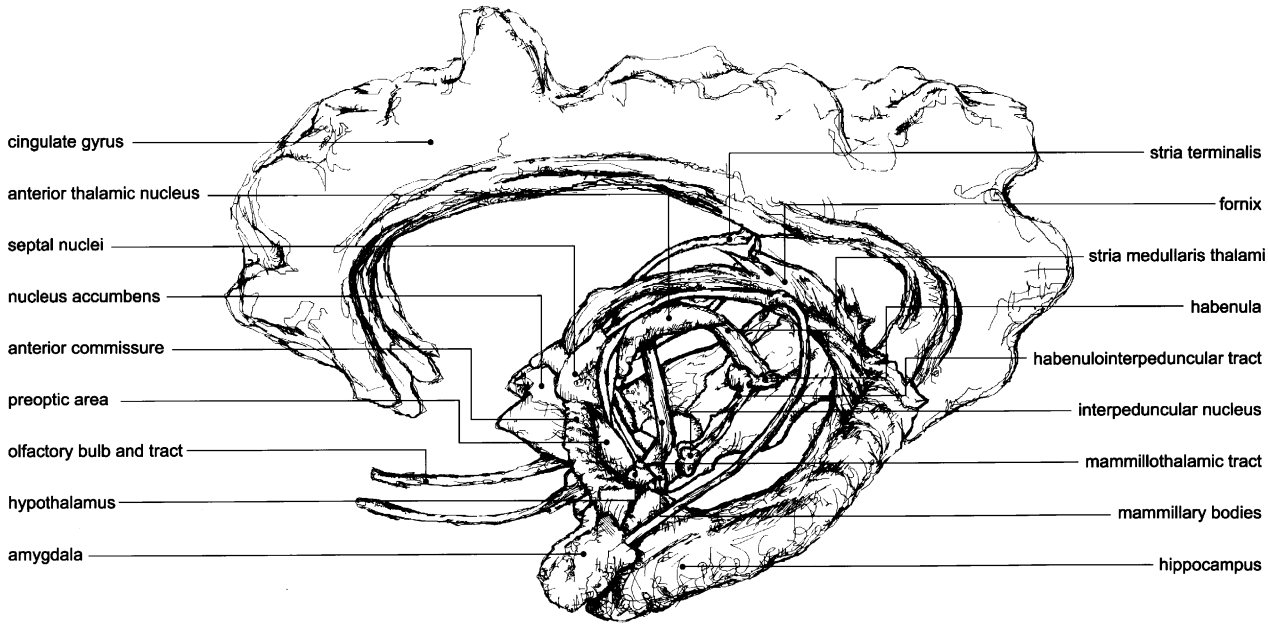

Figure 11 The limbic system: major limbic centers and connections, based on a computer reconstruction of limbic structures traced and digitized from whole brain serial sections. From Cheryl A. Cotman, Jay B. Angevine, Jr., and Kevin Head (illustration by Cheryl A. Cotman; commissioned for this article by the author). (See color insert in Volume 1).

nerve cells in the visual cortex respond to particular features of sensory information and only that feature.

2. The Hypothalamus

The hypothalamus (Fig. 13) lies at the heart of the limbic system. With dual outputs, it plays key roles in short-term and long-range homeostasis. Its neural output is effected by descending tracts in the core of the neuraxis and its endocrine output by pituitary hormones. It regulates vegetative functions: control of body temperature, caloric input, water–osmolar balance, and sleep–wakefulness. It selects and integrates autonomic responses. It controls the release of adenohypophyseal and neurohypophyseal hormones that exert far-ranging and, in some cases (growth hormone), enduring effects on the body.

The hypothalamus lies just below the thalamus. It is minute: about one-three hundredth to one four-hundredth of total brain weight (4 out of 1400 g). Yet it has over a dozen nuclei and receives, emits, or gives passage to as many tracts and to and from as many brain regions, both upstream and downstream. Neuroanatomist Walle Nauta saw it as the instrument panel or the "dashboard" of the brain. It monitors and regulates (not on dials or by switches but from receptors and via diverse connections) visceral and endocrine activities for homeostasis, offensive–defensive or trophic responses, and conative pursuits of long-range goals.

C. The Midbrain

The cylindrical midbrain (Fig. 7) separates the diencephalon and pons. Hardly more than 20 mm in diameter, its layout of structures reflects its embryonic tubular plan. Massive tracts run through it, some ascending from the spinal cord and cerebellum and others descending from the cerebral cortex. The cerebral aqueduct in its upper part is a vital, yet narrow, vulnerable conduit of cerebrospinal fluid (CSF) and a useful landmark. Above it, in the *tectum* (Latin: "roof"), lie two small hills of gray matter: the superior and inferior colliculi, which are visual and auditory way stations. They receive 10% of the fibers of the optic nerve and 100% of the auditory projection, respectively. They show cortical features of organization, perform multimodal integration, and mediate complex responses to sights and sounds.

Beneath the aqueduct is the *tegmentum* (Latin: "covering"). It covers *basal* parts of the midbrain, the cerebral peduncles, and substantia nigra. It houses

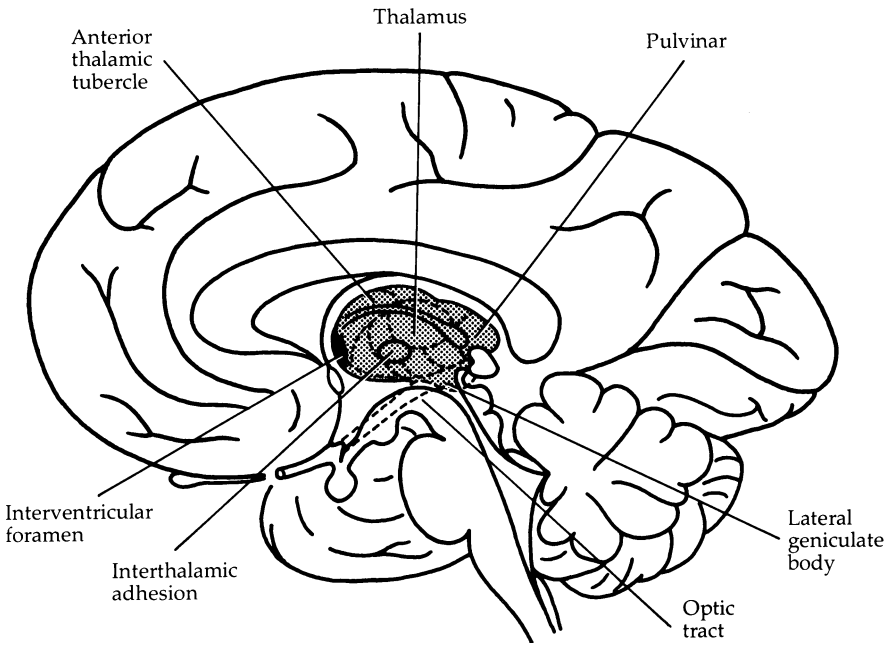

Figure 12 The thalamus, gateway to the cerebral cortex: a large mass of gray matter, comprising over a dozen recognizable nuclei, in the upper diencephalon, separated by the third ventricle into right and left halves. Its strategic central position permits a broad range of upstream input and cortical interconnections. From *Principles of Neuroanatomy* by J. B. Angevine, Jr., and C. W. Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by Jay B. Angevine, Jr.).

cranial nerve nuclei mediating eye movements and pupillary constriction and provides the rostral part of the brain stem reticular formation, a fabric of gray and white matter forming a continuous core of the midbrain, pons, and medulla oblongata. It exerts strong facilitatory and inhibitory influences on virtually all activities up and down the neuraxis. In the reticular formation on each side is a large round mass of neurons: the highly vascularized *red nucleus*, a motor center distributing cerebellar output to nuclei in the brain stem and thalamus.

Basal components are corticospinal and corticopontine fiber bundles surmounted by a gray cushion, the *substantia nigra*. Its compact upper part, where some neurons contain melanin pigment, makes dopamine and delivers it by axonal transport to the caudate nucleus and putamen for use in their complex neuronal interactions related to motor control. The lower layer of the nigra, as stated, serves as an output center of the basal ganglia, along with the inner segment of the globus pallidus.

Injuries to the midbrain have devastating results: almost total loss of sensation, paralysis, severe extensor spasms from the interruption of key connections of the motor system, and, from damage to the reticular formation, lasting coma if not death.

D. The Cerebellum

In humans, the cerebellum is half-hidden by the overlying occipitotemporal regions of the cerebral hemispheres (Fig. 7). It is bilobed, with a narrower median part, the vermis, connecting two large, ovoid hemispheres. These are gracefully fissurated in a curving way, a feature resulting in closely apposed, almost sinusoidal folia coated by cortical gray matter. The geometrical organization of this cortex, the self-evident design of its elegant neurons, and the swift, reliable contributions to motor control make it a natural wonder. The cerebellum is found in all vertebrate brains, with tremendous variations in size, shape, numbers of neurons, and neuronal idiosyncrasies. But the usual neuronal types are always there and the basic plan of cortical connectivity is instantly recognizable in all.

The cerebellum, like a computer, regulates the rate, range, and force of movements and contributes to muscle tone and posture. Like the basal ganglia, it works in concert with the cerebral cortex. It has ties to pontomedullary vestibular centers and also input from the spinal cord. Unlike the cerebrum, it does not play a major role in perception of sensation or initiation of volitional movement. With damage to the cerebellum,

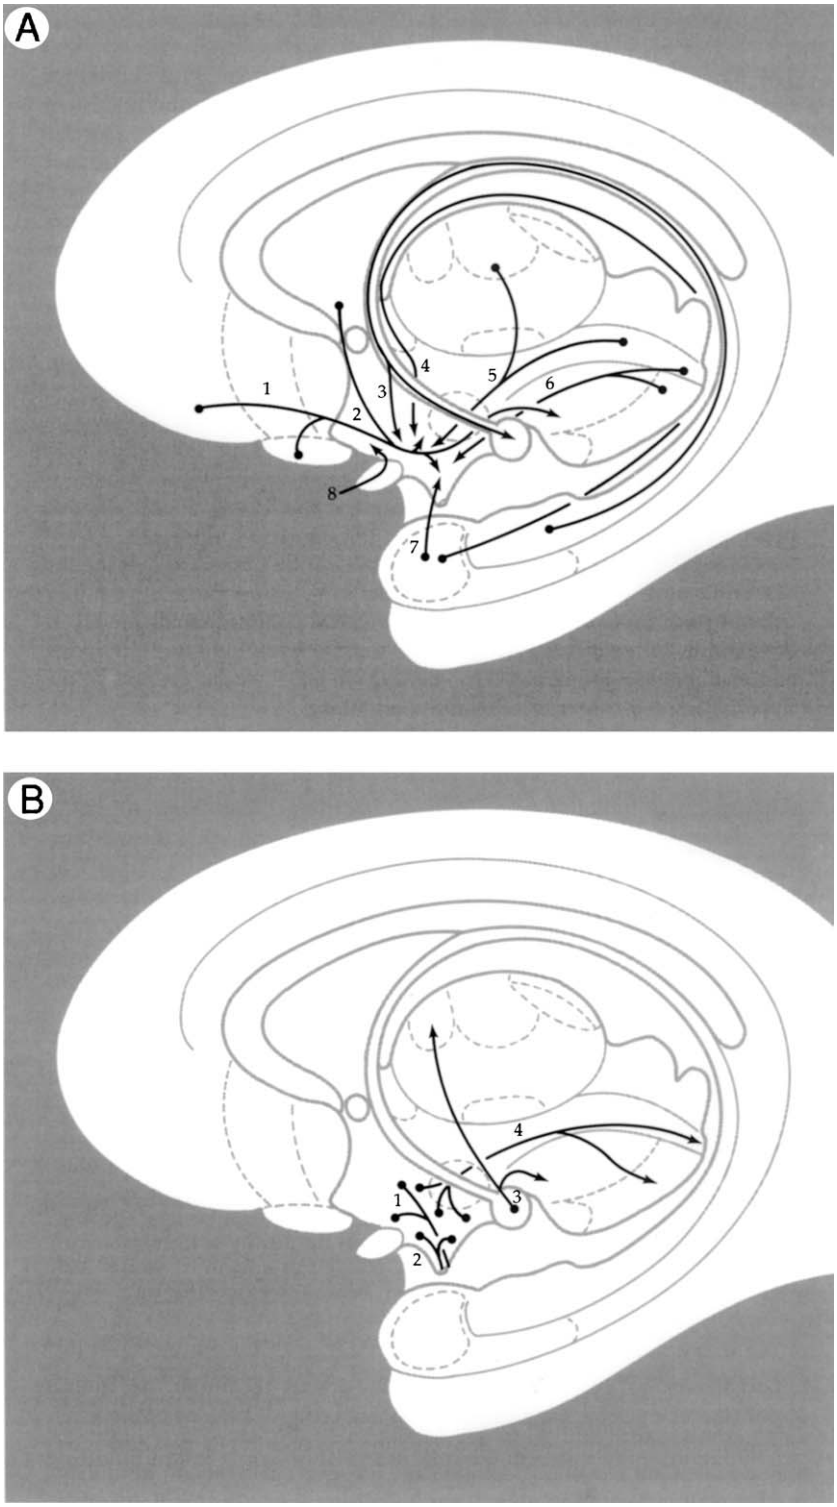

Figure 13 Hypothalamus: afferents (upper view) are corticohypothalamic fibers (1), medial forebrain bundle (2), fornix (3), stria terminalis (4) periventricular fiber system (5), mammillary peduncle (6), ventral amygdalofugal pathway (7), and retinohypothalamic fibers (8). Efferents (lower view) are the hypothalamohypophysial tract (1), tuberoinfundibular tract (2), principal mammillary fasciculus (including the mammillothalamic tract) (3), and dorsolateral fasciculus (4). These connections are largely reciprocal and form integral parts of the limbic and neuroendocrine systems of the brain. From *Principles of Neuroanatomy* by J. B. Angevine, Jr., and C. W. Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by W. J. H. Nauta and V. B. Domesick).

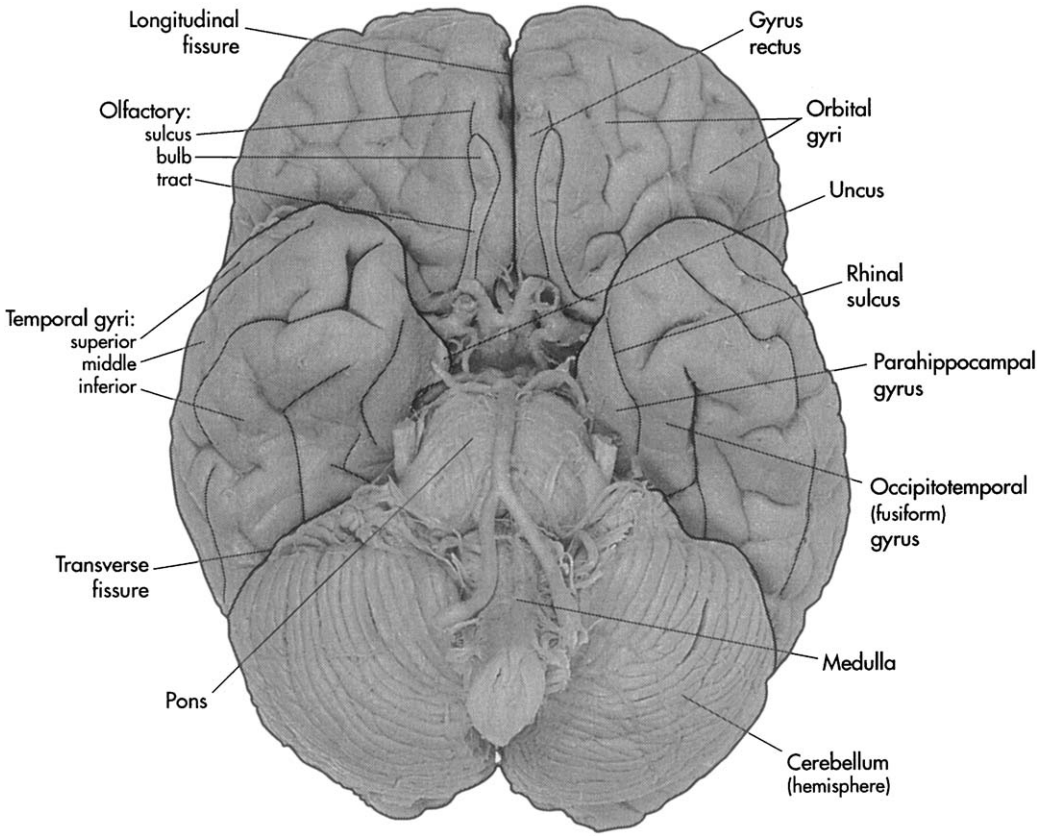

Figure 14 Base of the brain: low power view of same brain shown in Fig. 5 to show the inferior surface of the cerebellum, pons, and medulla oblongata, together with other structures. From J. Nolte and J. B. Angevine, Jr., *The Human Brain. In Photographs and Diagrams*, 2nd ed., Mosby, St. Louis, 2000 (photograph by Biomedical Communications, The University of Arizona College of Medicine).

conscious sensation is largely spared, but dexterity and smooth execution of movement (especially skilled movements of the upper extremities) are impaired, muscle tone and strength are diminished, and posture and equilibrium are deficient. The degree of deficits depends on the location, severity, and duration of the insult. In time, cerebellar circuitry often brings improvement, but damage to its outflow path, the superior cerebellar peduncle, usually effects lasting dysfunction.

E. The Pons

The pons (Fig. 14) is a thick bridge of nerve fibers, crossing the midline anteriorly. With a massive arm reaching into the cerebellum on either side, it binds that organ (its derivative) to the brain stem like a backpack strapped around one's waist. But it does more than hold the cerebellum in place. It provides a key link between the cerebral cortex and the cerebellum. The brachium pontis, or middle cerebellar peduncle, is a huge cable by which the contralateral cerebral cortex, through the liaison of 20 million pontine neurons, accesses the cerebellar movement computer. This cross-link in cerebral–cerebellar function enables movement to be performed in a smooth, coordinated, directed manner.

Caudal to the middle cerebellar peduncle is the inferior peduncle, in which sensory information from spinal cord and messages from the cortex sent through the inferior olivary nucleus of the medulla reach the cerebellum. Rostral to it is the superior peduncle. It distributes cerebellar output, via a thalamic nucleus, back to the contralateral motor cortex (thus completing a neural "double-cross"), as well as to various motor centers in the brain stem (red nucleus, reticular formation, and others).

F. The Medulla Oblongata

Protruding behind the pons (Fig. 14), the medulla oblongata tapers smoothly into the spinal cord. Like many regions of the CNS (see locus ceruleus), it is important out of proportion to its size. No bigger around than the last part of a little finger, it is vital. Even slight injury to it can swiftly lead to devastating or fatal consequences: hemianesthesia, hemi- or diplegia, and respiratory arrest. Through the medulla oblongata run all of the long ascending and descending tracts that connect the brain with the spinal cord and permit their interactions. In it are neuronal clusters of the lowermost five cranial nerves (Table II) and other nuclei that regulate breathing, heart rate, swallowing, caliber of small blood vessels, and indirectly blood pressure, waking, sleeping, and other vital functions. Some medullary neurons, like those of the brain stem serotonergic system, elicit profound effects by their neurotransmitters and through pervasive connections on general levels of activity elsewhere in the neuraxis. Consciousness and alertness depend on their upward influences, and spinal reflexes of posture, locomotion, and visceration rely on their downward effects.

G. The Spinal Cord

The caudal part of the CNS is the spinal cord (Fig. 1). Sensory impulses enter through its 31 paired spinal nerves, and sensory data processing begins. Messages flow up over modality-specific tracts, fast and direct or slow and indirect, to higher cord regions and the brain: to the medulla, pons, cerebellum, midbrain, and thalamus. The thalamus integrates this information with other input and in reciprocal association with the cerebral cortex. In due course, or on its own, commands from the cerebral cortex and certain brain stem regions flash down to spinal motor neurons and nearby local-circuit neurons. These small cells regulate the motor neurons and integrate their activity from one level to another and across the midline. Although its intrinsic spinal activity is monitored by higher centers, the spinal cord draws up swift and complex reflexes on its own, playing out movement programs (like walking or running) as if from a computer–numeric–control tape.

III. BASIC ORGANIZING PRINCIPLES OF THE NERVOUS SYSTEM

Breakthroughs have occurred in our understanding of these principles. Visual sensory processing, the task of the visual system, is a good example. Like other sensory analyses, it is far more complex than once surmised. At their first way station in the brain, the lateral geniculate nucleus (LGN), optic tract fibers end on neurons in one of two neuronal populations: a large-celled group in the lower two layers of the LGN and a more numerous small-celled group making up the upper four layers. When thalamic projections of these two types of cells reach the primary visual cortex in the occipital lobe, visual processing diverges into two distinct, only partly connected streams. The parvocellular system streams into inferior temporal cortex for analysis of color and form and the magnocellular system into posterior parietal cortex for analysis of location and movement. In brief, these ventral and dorsal streams are the "What?" and "Where?" systems. Taken together, they comprise (at last count) 32 distinctive cortical areas interconnected by association fibers in a complex, often nonlinear, reciprocal manner, affording divergence and convergence modes of data analysis.

Visual analysis draws upon other sensory systems and systems distant from visual processing: the motor system, core integrative systems (reticular formation, thalamus), the affect and drive-related limbic system, and the decision-making and memory-related frontal cortex. Perceptual meaning emerges and responses drafted as impulses diverge and converge in the network in domains of alertness, attention, comparison, affect, cognition, and conation. By feature analysis, integration, pattern synthesis, and data storage and retrieval, the nervous system may oversee activity inside and outside it, maintain homeostasis, and generate and monitor responses, all in a timely way, but not necessarily. We now consider eight attributes of the nervous system. They provide a context for its design and details.

A. Ubiquity

With 100,000 miles of nerve fibers (Fig. 1), the nervous system rivals the vascular system. Both pervade the body and function in harmony. By nerve impulses or circulating red and white blood cells, glucose, hormones, and immune principles, they integrate body activity, protect the body, enhance its performance to meet stress or demand, promote its growth and nutrition, and maintain its tone and vigor. The trunk and branches of both systems reflect body form. If either system and no other part of a person were visible, he or she would be recognizable. Density of

innervation varies as the value of parts to sensory discrimination or motor control. In well-innervated areas (lips, fingertips), stimuli are sharply discriminated as to modality, intensity, and location, but in sparsely innervated areas (flanks, legs) these are less defined. Similarly, muscles vary in the ratio of motor neurons to muscle fibers. The higher the ratio, the more precise the control of the muscle and the movements it serves (a motor neuron may excite 2000 muscle fibers in a limb muscle or as few as 5 in extrinsic ocular muscles).

B. Unity

As an epithelium, all parts of the nervous system are physically coherent and functionally linked by nerves, tracts, and specified cell-to-cell contacts. Potentially, each part communicates with all others. Some connections are direct (a two-neuron, monosynaptic reflex), whereas others involve myriad interposed neurons. Though complex, neural circuits offer total connectivity: fast, body-wide communication. Nerve impulses may originate in sensory nerve endings in any part of the body or anywhere in the system itself. *Responsive* activity complements *endogenous* activity, which is always evident in the human nervous system with its startling capacity to generate patterns of behavior and initiate events on its own. Sensory impulses, triggered by PNS primary sensory neurons, race over its nerves to the CNS, there diverging to clusters of secondary sensory neurons. Analysis begins. New impulses pass to central neurons on which related messages converge, which is a recombinant process providing *integration*. Other messages on stimulus modality, intensity, location, affective quality, body position and movement, visceral activity, fatigue, experience, and expectations are all integrated. Huge numbers of impulses are generated; untold numbers of synapses are activated. Almost instantly, nerve impulses that will elicit bodily responses stream out of the CNS to muscles and glands.

C. Centralization

The key feature of the nervous system is centralization. It offers few circuits for local interactions of body parts. The CNS is almost always involved even if the distance, as from thumb to index finger, is slight. Intercession of the brain and spinal cord ensures integrated and coordinated activity.

Exceptions are instructive. The local cutaneous response to irritating stimuli (raking a blunt probe over the skin) has three components: local reddening (vasodilation from injury), wheal formation (transient edema from tissue fluid extrusion), and ensuing widespread vasodilation (flare) with lowered threshold and increased sensitivity to pain (pinprick). The flare and hyperalgesia represent an *axon reflex*. Nociceptive (pain) nerve endings are activated by substances released by injured tissue cells, and nerve impulses are conducted a short way centrally along nociceptive axons and then distally over branches of these axons to nearby arterioles, causing them to dilate. Advanced or primitive (it is sluggish, starting in about 20 sec and developing fully in around 3 min), this reflex involves local nerve fibers only, not the CNS.

The "triple response" illustrates three concepts. Pain receptors sense chemical, as well as mechanical and thermal, stimuli. Their sensitivity is increased by substances accumulating in the damaged area. Their response includes a *neuroeffector* component. They release substances (peptides) that initiate further events, providing further protection and favoring local tissue repair.

Studies in invertebrate neural systems show extensive local control of visceral function. Exceptions to central control are also found in the mammalian ANS. Near-normal interaction of bowel segments persists in the absence of CNS innervation. Sensory fibers from the gut exert feedback in intramural autonomic ganglia on visceral motor neurons regulating smooth muscle in the intestinal wall. The nervous system has *pattern generators*, both central and peripheral: systems with cellular, synaptic, and network properties (cyclic firing rhythms, reciprocal inhibition of cell pairs, leader and follower cells) that provide automated mechanisms for generating rhythmic movements (breathing, walking) or periodic activities (sleeping, waking). Regulated by neural (sensory feedback, volitional override) or neuroendocrine influences, pattern generators are pithy examples of neural endogenous activity.

D. Specialization

Reflecting its diverse tasks, the nervous system is specialized, from the single neuron to each brain region. Specialized subsystems analyze sensations. They differ in some ways, but data processing is progressive and networked in all. Neurons and the neuroglia have special shapes and roles, but both enjoy

all criteria for cells and work in concert. Less obvious but equally specialized are subsystems for other functions: sleep–wakefulness, alertness, attention, affect, collating pages of a report, reading out loud from a book, self-awareness, brain damage control, and so on ad infinitum.

Ubiquitous specializations include those for high nerve conduction velocity (large axon diameter, thick myelin sheath), space-saving bundling (small axon diameter, thin myelin sheath, shared sheaths), short latency response (monosynaptic reflex), staggered, persistent latencies (parallel side chaining of long-axoned neurons), dependability (neuron redundancy), feature analysis (parallel processing), effect monitoring (feedback circuits), and force multiplication (feed-forward circuits). The neurons performing such tasks and the neuroglia backing them up are as specialized as these many diversified services. For neurons and the neuroglia, form indeed reflects function.

E. The Purposefulness of Neural Components

Every part of the nervous system has at least one function, often many more. Small parts of the CNS may play crucial roles, as in the extensive distribution and profound influence of axons from inconspicuous brain centers. The *locus ceruleus* (''blue spot'') on each side of the fourth ventricle contains about 12,000 large, melanin-pigmented neurons. These synthesize *norepinephrine* and release it in the cerebral cortex, cerebellum, and almost every other part of the CNS. Electrically, they are almost silent in sleep, hypoactive in wakefulness, and hyperactive in watchful or startling situations. They serve vigilance and attention to novel stimuli. They contribute, indirectly but no less crucially, to perceptual and cognitive functions. By contrast, immense structures make large but expensive contributions, as in the cognitive and motor abilities afforded us by the billions of neurons in our cerebral and cerebellar cortices.

F. Uniformity with Versatility

The vertebrate nervous system is accurately and reproducibly assembled. In animals of like genus and species it appears almost identical, although this is not absolute when genetic histories differ. Minor variations in the size of components and arrangements of cells are seen between species, striking ones between classes, orders, and families. Yet basic regions and properties, cells and circuits, and overall organization are sufficiently alike to permit instant recognition of the basic brain plan and insights as to what these parts and cells contribute to function. Humans show huge increases in brain size and regional elaboration, numbers of neurons and prominence of certain connections, variations in cerebral sulcation, hemispheric asymmetry, and long projections.

G. Plasticity

Highly reliable in a healthy person, the human nervous system has inherent modifiability, though in adulthood this attribute cannot approach that in invertebrates (moths and snails) or certain other vertebrates (teleosts and amphibians). In mammalian development, neural plasticity is striking. It continues postnatally. Abnormal visual experience at certain sensitive periods profoundly affects ocular dominance and orientation columns in the visual cortex. If an eye is closed at birth, ocular dominance columns for the other eye enlarge at the expense of adjacent blind eye columns, with thalamic fibers arriving in the cortex expanding terminal fields into them. If, shortly after birth, visual stimuli are restricted for a few weeks or even days to stripes of one orientation, cortical cells develop a response preference to lines of that orientation.

In humans, PET imaging studies of cortical blood flow show that tasks requiring tactile discrimination activate visual cortex in people blind at birth or having lost sight in childhood. This suggests that cortical connections reorganize after blindness: that afferent fibers to nearby cortical areas serving polymodal sensory integration usurp the bereft visual cortex. Such plasticity may explain the well-known tactile acuity of the blind.

In later development, neural plasticity operates on many levels, as in fine-tuning circuits to changing body dimensions. Depth perception is recalibrated as the skull enlarges and interpupillary distance increases. Even in adulthood, plasticity persists. Vilayanur Ramachandran has shown that a stroke with a cottonswab on the cheek of a young man who had accidentally lost his left arm led him to feel touch on his missing left hand. Later, the whole hand could be mapped on his face.The findings suggest that the deprived somatosensory cortical region for the hand becomes innervated by fibers from the adjacent face areas and that secondary input to a cortical neuron's broad receptive field becomes functional when primary input is lost.

After injury to the CNS, intact neurons form new terminals, by *axon sprouting*, to replace those of other neurons lost to trauma and thus reoccupy vacated synapses. Such *reactive synaptogenesis*, the clinically proven effectiveness of long-range regrowth of PNS axons, and the evident potential for axon regeneration in the CNS (as in teleosts and amphibia) hold promise for circuit restablishment. But in mammals, these factors are thwarted by myelin debris, glial scarring, usurpation of sprouts, unresponsive injured neurons, and complex central connections. Developmental neuroscience now focuses on the cerebral cortex. The human nervous system appears to learn very rapidly by using preconstructed circuits and by locking neurons into specific types and functions after cell origin.

H. Chemical Message Coding

The basic function of the nervous system, from which all others derive, is *communication*, performed (with unsung neuroglial support) by neurons. It depends on special electrical, structural, and chemical properties of these diversified cells with their long processes, on their exploitation and refinement of two basic protoplasmic properties, *irritability* and *conductivity*, on their external and internal neuronal morphology featuring multipolar shape and integrative design, almost infinite modes of dendritic and axonal branching, widespread, diversified connections, and specialized organelles, and on their use of chemical substances to encode, deliver, and decipher messages of their own and other neurons.

Neural circuits are chemically coded. Neuroanatomy encompasses interneuronal connections and also chemical mediators and transmitters. Neuroactive substances comprise neurotransmitters, neuromodulators, and neurohormones. Their definition in contexts other than site of action, postsynaptic neuronal activity, and corelease of one or more additional neuroactive substances can be misleading. Neurotransmittters are small molecules acting swiftly, locally, and briefly on target cells. Neuromodulators are very small (peptides), regulating but not effecting transmission, and neurohormones are also small, with intrinsic activity mediated by neuronal and other cells, exerting slow, widespread, and enduring influence via the extracellular fluid or bloodstream.

Neurons releasing hormones are quasi-endocrine cells, liberating secretory products from axonal endings into the perivascular space to be conveyed to blood vessels and thence to target organs. The provincial concerns of neurophysiology and endocrinology have fused into neuroendocrinology, as psychoneuroimmunology has united psychobiology, molecular neurobiology, and immunology.

IV. STRUCTURAL APPROACHES TO STUDY OF THE NERVOUS SYSTEM

Neurohistology is the study of nervous tissue per se, and neuroanatomy is the study of nervous tissue as a *communications system*. The concerns and methods of the two fields are different, but overlapping and interdependent. Both approaches shed light on the organization of the human nervous system.

A. Neurohistology

Like the microscopic anatomy of other tissues, this approach focuses on nerve cells: their types, internal and external features, structural, functional, and chemical properties, and interrelationships. But the great size, extent, and diversity of neurons, their interdependence, and their complex spatial relationships can be daunting to the histologist.

Let us examine a motor neuron. Figure 15 is a schematic illustration showing a motor neuron innervating a muscle just above the letter B. We begin with the cell body, noting its size, organelles, and inclusions, and then trace its dendrites (100 terminal ones), spines, and relationships to neuroglial processes and capillaries. We identify the axon, note its features (axon hillock, initial segment, side branches if any), and follow its course through the gray matter into the white matter (the two are not delineated), where it becomes myelinated by oligodendrocytes (OI) for rapid conduction and protection.

We follow the axon into the PNS. Here it is myelinated by Schwann cells (S_1), for the same reasons. Outside the myelin sheath, three connective tissue sheaths (endoneurium, perineurium, epineurium; not shown) provide vascular, isolating, and protective support for the delicate nerve fibers. We trace the axon for a meter or so to a skeletal muscle and inspect its preterminal branches and axon terminals on muscle fibers at the neuromuscular junction: the nerve–muscle synapse.

We cannot examine one motor neuron in all respects. For the total picture, we piece together these parts from many motor neurons. The hardest thing to grasp is the relative size of a neuron and its parts.

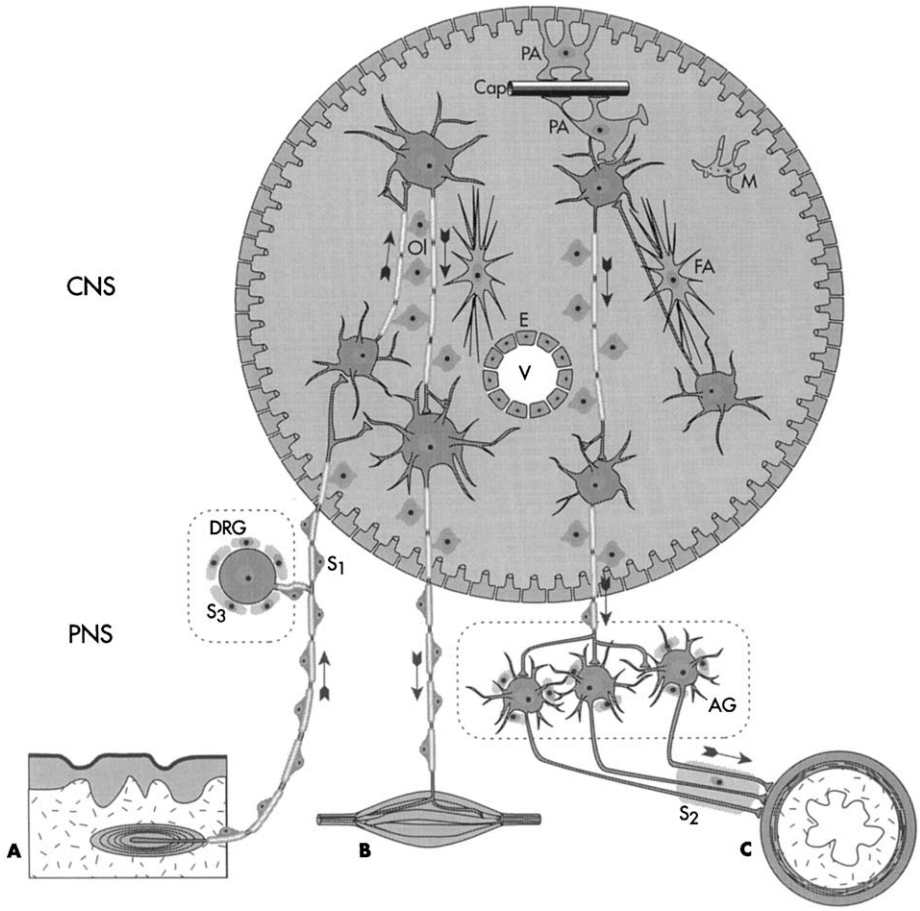

Figure 15 Neuronal and neuroglial cell types in the nervous system: the end feet of protoplasmic astrocytes (PA) form a leaky membrane around the CNS and others in the gray matter about either neurons (the dark cells) or capillaries (Cap). Fibrous astrocytes (FA) lie among axons in the white matter, many of which are myelinated by oligodendrocytes (Ol). Microglia (M) scavenge debris after injury, and ependymal cells (E) line the ventricles (V). Schwann cells are the glial cells of the PNS, myelinating peripheral nerve fibers (S_1), surrounding unmyelinated axons (S_2), and satelliting dorsal root and autonomic ganglion cells (S_3). Direction of impulses in various axons is indicated by arrows. Other abbreviations: skin (A), skeletal muscle (B), gastrointestinal tract, containing intramural smooth muscle and glands (C), autonomic ganglion (AG). See also text. From J. Nolte, *The Human Brain. An Introduction to Its Functional Anatomy*, 4th ed., Mosby, St. Louis, 2000 (illustration by Prof. Dr. Radivoj Krstic).

Neuroanatomist Jack Nolte offers this perspective: If the cell body of a motor neuron were the size of a tennis ball, its dendrites would fill a room and its axon would extend, like a 0.5-in. garden hose, nearly 0.5 mile.

B. Neuroanatomy

Here the emphasis is different. We look at a motor neuron as a part of the *motor subsystem* of the nervous system. From the number of axon terminals on its receptive surface (around 50,000, each signifying a synapse), we see that this large cell, final in the chain of communication from sensory periphery to muscles, has a vast range of inputs. This includes PNS primary afferents, spinal and brain stem connections, feedback and feedforward circuits from other motor neurons, self-directed inputs from recurrent axon collaterals of its own and neighboring local interneurons, and direct, express lines from the cerebral cortex 1 m upstream from this motor neuron. We recall that each input releases a chemical messenger eliciting excitation, inhibition, or modulation of the target cell, depending on the nature of receptor molecules and second messenger systems in it and other complex factors. We know that each input has a specified place on the

soma, dendrites, or axonal initial segment of the motor neuron and that this orderly display favors input identification and efficacy in control of this harried cell.

Moving peripherally, e.g., in the sciatic nerve, we find that the axon terminals in the muscular system end on muscle fibers in the gastrocnemius. With methods for tracing nerve fibers, we find that sensory axons supplying stretch receptors (*muscle spindles*) in this muscle lead back into the CNS over the dorsal roots of spinal nerves to synapse on our motor neuron and all its homonymous neighbors, thereby closing the external arc of a spinal neuromuscular control loop: the monosynaptic *stretch reflex*. We now see the place and role of the motor neuron in the human nervous system. Its inputs include large, well-myelinated, fast-conducting axons that excite it monosynaptically when the gastrocnemius is stretched. Its output to gastrocnemius fibers enable it, with the help of other motor neurons, to maintain our erect posture.

Our virtual excursion teaches us that neuroanatomy is less interested in cytological detail and more interested in the identity, interconnections, and interactions of neurons, in "wiring diagrams," in chemical colorations, and in the functional roles of neurons in networks.

C. Complementarity of Neurohistology and Neuroanatomy

The two approaches contrast with, yet complement each other. The study of neural circuits is enhanced by familiarity with neurons and the neuroglia, just as their study is enriched by knowledge of the uses to which these cells are put. Whatever the design and extent of its circuits, the work of the nervous system derives from neuronal activity, singly or in modular groups, within these circuits. Indeed, one neuron can be as complex as an integrated circuit, because it responds (when it does) partly in a *fractionated* manner as well as in the familiar "*all-or-none*" nerve impulse.

V. PROPERTIES OF NERVOUS TISSUE CRUCIAL TO THE NERVOUS SYSTEM

Six properties of nervous tissue are key to its communications functions. Among these, the first is cardinal, especially for the CNS. We revisit it after overviewing all six.

A. Epithelial Nature of Nervous Tissue

The nervous system is an *epithelium*, with cells close by and little space between. Far more complex than other epithelia, with flattened, cuboidal, or columnar cells in single or stratified sheets covering surfaces or lining spaces, the nervous system is a superepithelium: a huge, three-dimensional jigsaw puzzle with billions of pieces of varying size (1 to over 150 μm), length (1 μm to 1 m) and, in some cases, an extraordinarily complex and beautiful configuration. Electron micrographs show that its pieces fit together, precisely and intimately, with little space left over, an evident benefit for cell communication (Fig. 16).

B. Integrative Design of Cells and Processes

Neuronal or neuroglial, the pieces of the nervous system are of an integrative design, shaped to contact many other pieces at many places. Their integrative roles are expressed in their shapes as seen in electron micrographs: curling dendrites and thorny spines of neurons, sprawling processes of astrocytes, and fenced-in clusters of axons clearly delimit discrete territories in the puzzle (Fig. 16).

C. Interdependent Ordered Connections

Connections in the nervous system are highly ordered. In tracts and nuclei, maplike representations of functional domains are found: a sensory surface, a pattern of muscles or movements calling up particular muscles, and some part of the body, including the brain itself, that requires service. Sometimes, many maps of a venue are found in many places along many routes, allowing parallel processing of details (quality, intensity, and location of stimuli; steady-state, change of state, or affective nature).

D. Organized Display of Inputs on Neurons

Each neuron has its view of the world, a spatial arrangement on its receptive surface of the inputs (many or few) impinging on it. The location of each input (on the dendritic tree, cell body, or initial region of the axon) indicates its source and helps to determine its efficacy in bringing about excitation, inhibition, or modulation of target cell activity.

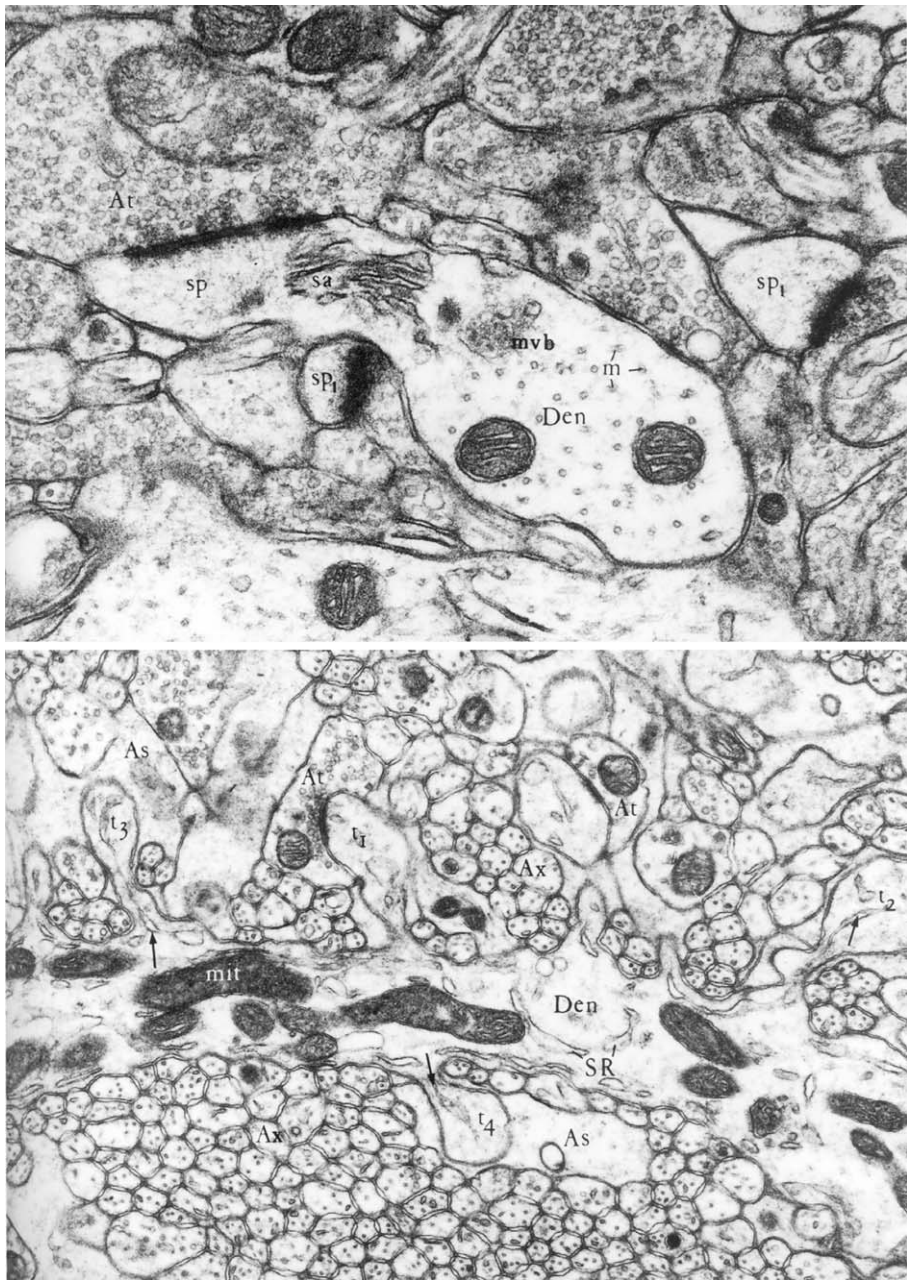

Figure 16 Dendrites: electron micrographs (EMs) show that the CNS is a hypercomplex epithelium, with billions of pieces fitting together precisely, intimately, and with evident benefit for cell-to-cell communication. Upper EM: dendrite (Den) of pyramidal cell from cerebral cortex with dendritic spine (sp) in synaptic contact with axon terminal (At) containing spherical synaptic vesicles. Lower EM: spiny branchlet of a Purkinje cell dendrite (Den) with spines (thorns; t1–t4) synapsing with axon terminals (At) of parallel fibers (Ax). See also text. From *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells*, 3rd ed., by Alan Peters, Sanford L. Palay, and Henry deF. Webster, copyright 1990 by Alan Peters. Used by permission of Oxford University Press, Inc. (upper EM by Katharine Harriman, lower EM from authors).

E. Graded and All-or-None Neuronal Responses

Nervous tissue shows fractionated, graded responses peculiar to the traditional receptive regions of neurons (mainly dendrites and somata) and all-or-nothing responses, which are properties of the impulse-triggering surface (initial axon segment and downstream axonal membrane at nodes of Ranvier).

F. Chemical Messengers

At a synapse, neurons use chemicals to deliver and receive impulses. Presynaptic substances are exocytosed into the synaptic cleft and received and acted upon by postsynaptic receptors. These rapidly open membrane ion channels or act via second messenger systems (the transmitter is the first messenger) to elicit changes in postynaptic activity. Such effects, with the many diverse mediators (biogenic amines, peptides, growth hormones, gases), fluctuating activity of neurons, and multiple modes of prolonging or stopping messages, permit many combinations of factors to be in play at any time. The synapse is thus a multifactorial, extremely versatile information transfer system. This type of system is physically difficult for the investigator to study and clearly more complex postsynaptically than described in many accounts.

VI. CELLULAR ELEMENTS OF THE NERVOUS SYSTEM

A. Neurons and the Neuron Doctrine

Although the neuroglia has far greater importance than we accord it, nerve cells are regarded as the fundamental genetic, anatomical, functional, and trophic (nutritive, sustaining) units of the nervous system. These attributes are the four tenets of the neuron doctrine, a once-controversial, ever-authoritative, and still-evolving restatement of the cell theory first applied to nervous tissue in 1891. Fifth and sixth tenets were quick to follow.

In 1890, the histologist Santiago Ramón y Cajal, considering neurons as separate cells and tirelessly delineating their connections, inferred that impulse traffic in a neuron flows one way: from dendrites and soma to axon and axon terminals or from receptor parts to effector parts. In 1897, the physiologist Charles Sherrington proposed the term *synapse* for the contact between nerve cells and suggested that the one-way sensorimotor traffic in spinal reflexes rested on a one-way valvelike action of the synapse. So a fifth tenet, Cajal's law of *dynamic polarization* (like neuron doctrine, strong words), was added and then a sixth, his law of *connectional specificity*: synapses are not random, but determined.

B. The Neuron Doctrine Revisited

Electron microscopy conclusively shows that nerve cells are separate, but the neuron doctrine needs careful revision. Indeed, this has gone forward. Four issues spurred its reevaluation.

1. Gap Junctions, Cell-to-Cell Influences, and Electrical Synapses

Small, roughly circular plaques (0.1 μm to many micrometers across) of intimate apposition (2–3 nm) unite the membranes of epithelial cells. Here, tiny membrane particles (connexons) with minute pores (<2 nm) in each membrane and in register permit the flow of ions and small molecules (amino acids, cyclic AMP, tracers) between cells. Such a contact is a *gap junction*, nexus, or communicating junction. The last term is definitive: they permit cell-to-cell percolation of nucleotides and peptides that may coordinate cellular activity. They also offer low-resistance electrical coupling of adjacent cells, as in embryonic tissues. In neural development, cell-to-cell communication by gap junctions in epithelial tissues plays a role in major events, as in gastrulation and neural plate closure.

For a time, gap junctions challenged the second tenet of the neuron doctrine. They allowed chemical commerce between neurons and united them electrically. But controversy subsided. Though present in a few neurons in a few places in the adult and more widely encountered in the early CNS, such areas of interaction between separate cells do not undermine the unitary nature of neurons.

2. Versatility of Neuronal Processes and Complexity of the Neuropil

An old problem in studying neurons (especially invertebrate ones) is identifying their extensions as dendrites or axons. Some processes play both roles. Such versatility violates the law of dynamic polarization tacked on to the neuron doctrine: that dendrites and cell body receive impulses and the axon and its terminals conduct them away and deliver them elsewhere. But the parts of neurons are adaptable. Dynamic polarization was based on a neuron considered to be typical: the motor neuron.

Today, we know that the neuronal surface is a *mosaic* of receptor and effector parts and that local circuits with different polarizations need no spikes but only graded potentials to function. Cajal's law must be viewed in perspective. It was a great step in

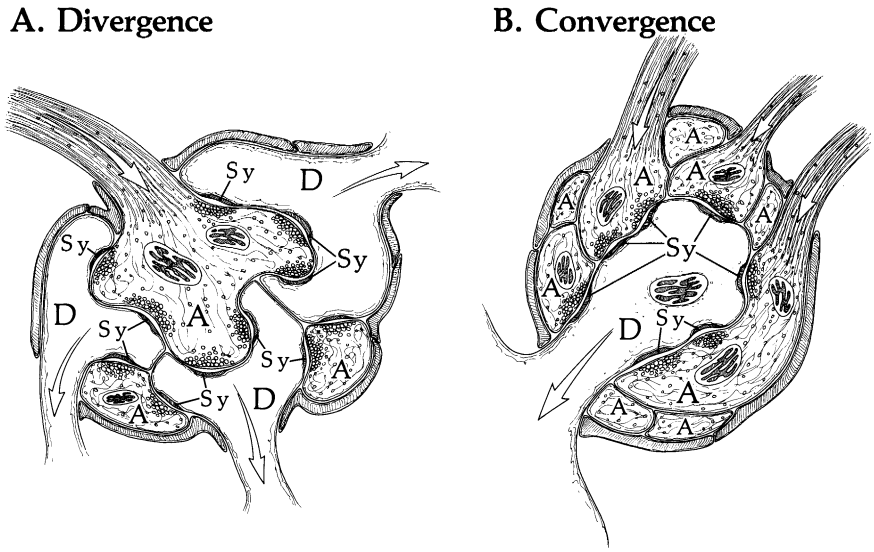

Figure 17 Glomeruli, resembling renal capillary glomeruli and long known in the cerebellum and olfactory bulb; many more complex tangles of intricately intertwined and synapsing neuronal processes of multiple origin are now recognized elsewhere. The interactions of processes in many of these knots are not known, but as shown in this schematic drawing, some provide for divergence or convergence of information. At left, a glomerulus in the cerebellar cortex centered on a single mossy fiber axon terminal; at right, a glomerulus in the thalamic pulvinar centered on a single departing dendrite. From Jay B. Angevine, Jr., (1988) Dendrites, axons and synapses, *BNI Quarterly* **4**(2), 9–19. after T. Bullock, R. D. Orkand, and A. D. Grinell (illustration by Steven J. Harrison) by permission of Barrow Neurological Institute.

understanding neuronal activity, but it cannot account for the almost limitless interactions between neurons.

Related problems are *glomeruli* (Fig. 17), which are knots of neuronal processes of diverse morphology and origin in which group synapses (rather than the familiar paradigm of one-on-one) are the rule and complex transactions of many cells, near and afar, are afoot. Here the independence of neurons is diminished, but not abrogated, by the complexity of the *neuropil*, the feltwork of neuronal and glial processes in which most synapses are found and most CNS business is transacted. Awareness of the epithelial nature of nervous tissue helps to explain these regions of multineuronal interaction.

3. Neuronal Teamwork and Distributed Systems

A critique of the functional tenet of the neuron doctrine comes from the growing awareness that the nervous system employs groups of neurons, not necessarily all in one place, to perform its tasks, and not single cells themselves. Striking examples are the progressive feature analyses by sensory systems of the CNS (notably the visual), the cooperative interplay of neurons at all levels of the motor system, and the communal organization and stepwise connections of the cerebral cortex. A fitting term for this team concept of neuronal function is *distributed system*. As a key principle that is crucial to understanding cognitive functions and disorders, it does not impugn the individuality of neurons in any respect. However, it lessens their individual importance as determinative functional or gnostic units.

4. Transneuronal Degeneration

Neuronal responses to axon interruption include degenerative changes in the severed axon and its investments, as well as reparative changes in the cell body. Undamaged neurons nearby do not react, nor does the degeneration usually involve the postsynaptic cell, with certain major exceptions: atrophy of skeletal muscle is a familiar consequence of denervation. These results illustrate tenets one and four: the anatomical individuality of neurons and the trophic importance of their cell bodies. But with a century gone by and better methods for evaluating and following up effects of injury upon neurons, the concept of a single neuron as *the* trophic unit is hardly tenable.

Transneuronal degeneration is now well-recognized. It was first noted in pathways in which a given neuron largely depends on another for its input. In the visual system, cells of the thalamic lateral geniculate nucleus degenerate after lesions to the retina, where the

ganglion cells that project to them lie. Transneuronal effects are now known in many neuronal sequences in the CNS and PNS. Even more remarkable is that transynaptic effects of injury or disuse may extend in either direction (retrograde and orthograde) and involve neurons one or more than one synapse removed (primary, secondary, tertiary, etc.). Neurons in circuits seem to depend on one another in ways that go beyond receipt and delivery of impulses. Their metabolic equilibrium may derive, in part and varied measure, from their interactions. These possibilities are relevant to interpreting experimental lesions or treating neurologic diseases. Insights on the factors underlying these trophisms may explain how the nervous system maintains itself and what it could do (with assistance) to compensate for injury or cell loss.

C. The Neuron Doctrine Today

As the *genetic unit*, the neuronal nucleus contains the chromosomal DNA, the human genome of 30–40,000 genes. A high percentage probably concern the nervous system, whereas the degree of alternate processing and the number of proteins expressed, though unknown, may be far greater.

As the *anatomical unit*, the picture proof by Sanford Palay and George Palade in 1954 that at the synapse the apposed neuronal membranes are separated by a 10 to 20-nm cleft was a triumph for electron microscopy. But for gap junctions (see previous discussion) and fine filaments seen in the EM crossing the gap between pre- and postsynaptic cytoplasm, doubts about the separateness of nerve cells were laid to rest.

As the *functional unit*, modification of the doctrine is mandatory: groups of cells are the working units of the nervous system, not single cells themselves.

As the *trophic unit*, evidence has accumulated over the last century (in neurology, neuropathology, and experimental biology) to show that the cell body of a neuron is vital to its *own* life. If its processes are severed or injured but the soma is left intact or little harmed, new ones may be formed, or at least the damage controlled. But if the soma is severely damaged, the nerve cell dies.

Still (to paraphrase neuroanatomist Alf Brodal), "The concept of a neuron as a trophic unit is scarcely acceptable as originally formulated. A single neuron is dependent on other neurons for its viability." In this regard, neurons and their processes exert nurturing and supporting effects on other tissues, but such trophic interactions have not been examined as fully in the nervous system itself.

Studies of *neurotrophisms* are numerous, and they continue. But trophic functions of neurons have not been investigated as intensively as their communicative and endocrine abilities. Less is known about them. Their clinical significance is profound, as in managing patients with spinal cord injury in which muscular atrophy and decubitus ulcers are secondary to even more debilitating problems.

Finally as to trophisms, the multitudinous, ubiquitous neuroglial cells deserve attention. The neuron doctrine was formulated a century ago for neurons and for good reasons. But, as it was for the laws of dynamic polarization and specified connections, a corollary for the neuroglia could be added. Its production, by astrocytes, of numerous *growth factors* supporting vital attributes of certain neurons merits mention in relation to the trophic tenet of the revised neuron doctrine.

D. Epithelial Design of Nervous Tissue

As stated, nervous tissue is a specialized epithelial tissue. Epithelia are sheets of cells that cover surfaces or line cavities of the body and in places grow into subjacent connective tissue to form hair follicles, glands, or other derivatives. Features of epithelia include close aggregation of functionally related cells, small amounts of intercellular substance, a basement membrane, a free surface, and utter avascularity. Nervous tissue, wherever encountered clearly shows the first two attributes and the free surface and basement membrane in the CNS as well. The presence of blood vessels might seem to depart from epithelial design, yet they are not part of the nervous tissue but only pass through it, ensheathed by basal lamina.

Nervous tissue meets all structural criteria of epithelial tissue. It arises from epithelium: the embryonic neural plate. As epithelial duties include sensory reception, protection of the body, and secretion of hormones, nervous tissue performs these functions to a fault, offering general body responsiveness, integration, and chemical transmission. It is thus properly and usefully classified as epithelial tissue. Where the resemblance of nervous tissue to epithelium ends is in the configurations of its cells. They have far more complex shapes than the squamous, cuboidal, columnar, and domelike cells of other epithelia. With its many wavy processes, a neuron looks like a medusa.

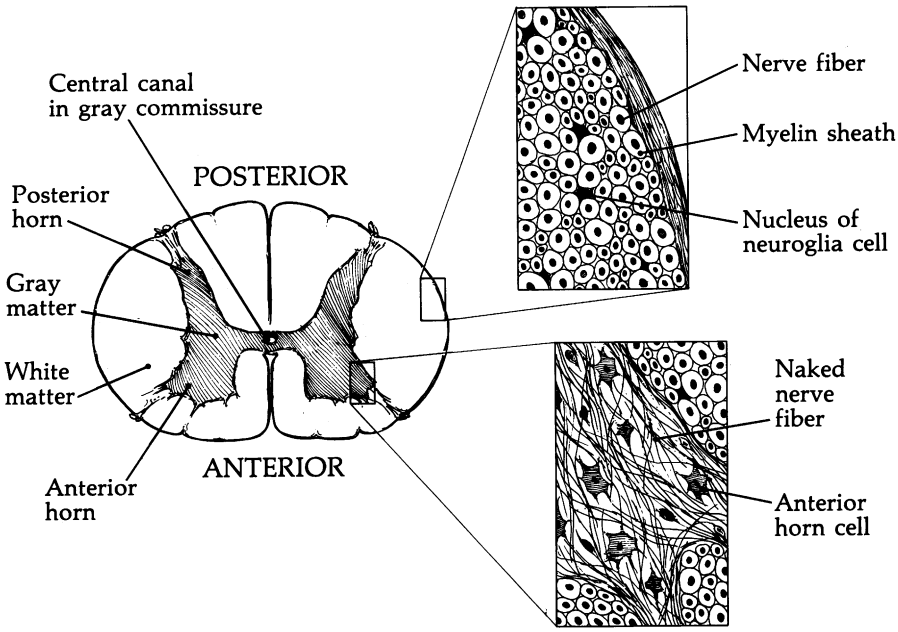

Figure 18 Gray and white matter: light micrographs (LMs) of the CNS fail to show its epithelial nature. Myelinated axons in the white matter resemble closely packed strands of spaghetti; nerve cell bodies in the gray seem to float in a watery matrix. At first glance in hematoxylin and eosin preparations, the CNS looks much like loose areolar connective tissue. From A. W. Ham, *Histology*, 6th ed., J. B. Lippincott, 1969 (illustration by Steven J. Harrison, from Dorothy Chubb).

Light micrographs of gray and white matter in the CNS (Fig. 18) convey a misleading impression, failing to show the epithelial design of the nervous system. Nerve fibers in the white matter resemble strands of spaghetti, and nerve cell bodies in the gray float here and there amid processes in a watery substance, like the fibroblasts and collagen fibers in the fluid extracellular matrix of connective tissue.

Yet nervous tissue is epithelial throughout. Little intercellular matrix exists, mainly cells and their processes. A schematic drawing (Fig. 19) shows this epithelial character. Two of the three meninges covering the CNS, the arachnoid and pia mater, separated by the subarachnoid space, lie externally. Beneath them, the CNS is bounded by a basement membrane (basal lamina). Such membranes separate each of the four basic tissues of the body, preventing contact and unregulated commerce between them and thereby serving tissue homeostasis. An excellent example is the basal lamina between axon terminals and muscle fibers at the intimate nerve–muscle synapse.

Internal to the basement membrane are three elements seen in CNS tissue: neurons, neuroglia, and blood vessels. As noted, epithelia are avascular. For oxygen and nutrients, they depend on vessels in nearby connective tissue. But in the CNS superepithelium, the volume of tissue and the never-ending demand for oxygen and glucose mandate their proximity. The blood vessels entering and exiting the CNS and their interposed capillary networks (so dense that neurons lie no more than 100 μm away) are *extrinsic* as stated, separated from nervous tissue by the basal lamina of the CNS and that of the vessels. Substances from the blood must traverse both laminae to enter the CNS and then an interposed astrocytic process before reaching a neuron.

The inner free surface of the CNS epithelium comprises a single layer of ciliated ependymal cells lining a brain ventricle. Nearby, in attenuated regions of the brain where the pia and ependyma are apposed, modified ependymal cells form the choroid epithelium, which produces the cerebrospinal fluid (CSF). Its cells are specialized for secretion, with basal infoldings, free surface microvilli, many mitochondria, and tight junctions to limit the passage of substances larger than ions.

Epithelial design is striking in electron micrographs of the CNS. Figure 20 shows the soma of a spinal motor neuron, replete with nucleus, nucleolus, and surrounding organelles. Proximal parts of three dendrites are visible, as well as other dendritic, axonal, and glial processes around the cell and two capillaries. The

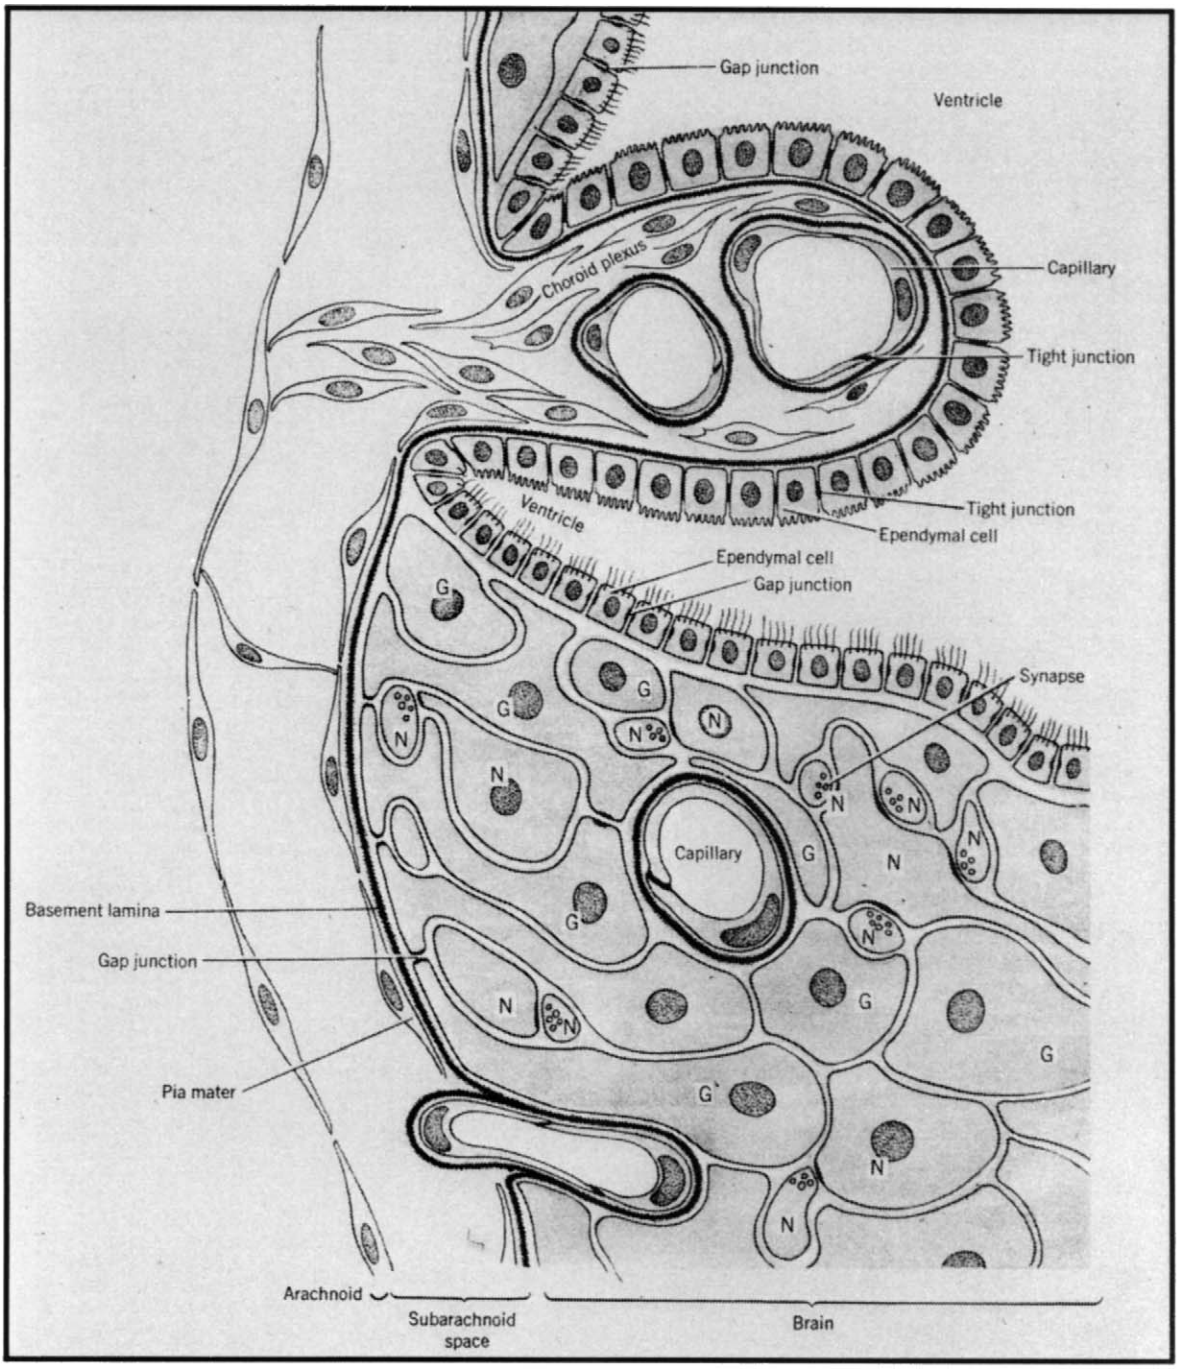

Figure 19 Epithelial nature of the CNS: neurons (N) and glial cells (G) lie within a basement lamina (basal lamina), like the diverse cells of conventional epithelia. Unlike other epithelia, however, is the presence of blood vessels; the volume of tissue and unceasing demand for oxygen and glucose mandate them, but they are separated from CNS parenchyma by their own basal lamina and that of the CNS. Blood-borne gases and substances must traverse both laminae to enter or exit the CNS. From C. R. Noback and R. J. Demarest, *The Human Nervous System. Basic Principles of Neurobiology*, 2nd ed., McGraw-Hill, New York, 1975 (illustration by Robert J. Demarest).

key point: everywhere the tissue is epithelial. Every nook and cranny is occupied, with the 2–4 nm of extracellular space invisible at this low magnification. The capillary basal lamina is barely apparent. The darkly encircled fibers in the field are small, myelinated axons of arriving input.

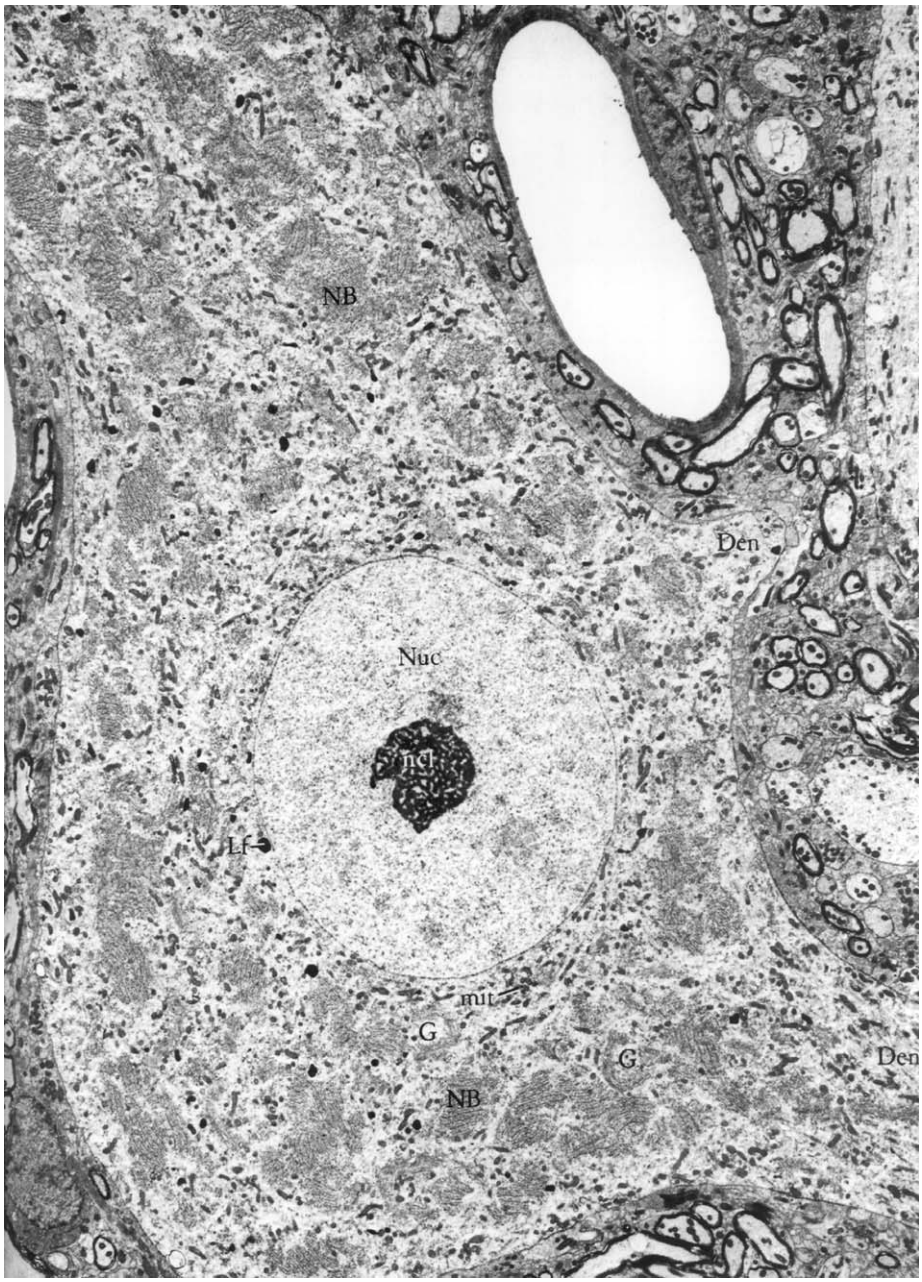

Figure 20 Neuronal cell body: low-magnification EM of a motor neuron. Nucleus (Nuc) is pale and contains a nucleolus (ncl). Perikaryon shows Nissl bodies (NB), Golgi apparatus (G), mitochondria (mit), and a few lipofuscin granules (Lf). Extending from the perikaryon are three dendrites. Other dendrites, as well as axonal and glial processes and two capillaries, lie nearby. See also text. From *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells*, 3rd ed., by Alan Peters, Sanford L. Palay, and Henry de F. Webster, copyright 1990 by Alan Peters. Used by permission of Oxford University Press, Inc. (EM from collections of authors).

E. Complexity and Individuality of Neurons

Neurons typically emit many highly branched, intermingling processes. This complexity, along with their sheer size, is a problem in studying them and a reason why the neuron doctrine was controversial. Many studies, experiments, and years of bitter debate took place before the idea that nerve cells were separate was

generally accepted. Even then, some doubted it. Only with the demonstration by electron microscopists in the mid-1950s of the minute cleft between neurons at the synapse was the physical individuality of neurons established.

F. Parts and Functional Dependencies of Neurons

1. The Cell Body

A neuron (Figs. 21E–21I) invariably has a *cell body* (soma) containing the cell *nucleus* and a more or less spherical mass of ambient cytoplasm, the *perikaryon*, filled with cell *organelles* and *inclusions*. During development, the soma is the first part of the neuron to arise, and throughout the life of the cell (with few exceptions, postmitotic and incapable of cell division) it is the irreplaceable trophic part that maintains the structural integrity and health of the neuron with its far-reaching processes.

2. Dendrites

Extending from the soma in most neurons are the *dendrites* (Figs. 21A–21B). These relatively short, initially tapering processes branch obliquely, like the limbs and branches of a tree. In varying proportions, they contain the organelles seen in the soma. In a few neurons, they arise at the end of an axon. A dorsal root ganglion cell (Fig. 15, DRG) has dendritic tufts or a specialized nerve ending (a free or an encapsulated axonal tip) in such an axon in the dermis, wall of a viscus, or other peripheral area.

Dendrites may branch elaborately (Fig. 27). They are the chief receptive processes of a neuron, even though the soma and certain proximal or distal axonal regions may also receive inputs. In their ramification, they signify the relationships of the neuron to other neurons and, hence, their integrative role. They offer points of contact (synapses) for axon terminals and for axons grazing them as they pass by (*fibers of passage*). They are the prime integrative components of neurons: receiving, combining, summing, or otherwise regulating their input.

In the multipolar neurons of the CNS (Fig. 15, the six dark cells), dendrites originate from the soma as one or more primary branches. These continue to ramify, becoming finer and finer, eventually forming branchlets or twigs. The surface area and volume of the dendrites may exceed those of the soma by many times. Incoming axons end on the dendritic shaft or on *spines* (Fig. 16, upper and lower plates), which are minute thorns, that if present in large numbers give dendrites a studded appearance.

The role of spines is not understood, but (as once surmised) they do not serve to increase the receptive surface area; intervening shaft regions may have but few synapses. Spine synapses are the major sites of excitation; each spine usually has one input, but may have several. One function spines seem to play is isolating such afferents. But it is premature to characterize them. They have electrical properties that may be modified by slight changes in the form of the spine neck, perhaps during learning or in aging, when they show deterioration early on. They seem to be specialized ports of entry for currents into the dendritic shaft. They may be bounded by *astrocytic processes* (Fig. 16, lower plate). By "spongelike" action, astrocytes serve vital roles in neural communication: taking up excess potassium ions that might interfere with local neuronal activity, localizing glutamate release for optimal elicitation of excitation in target cells, and preventing glutamate-induced toxicity, which is potentially life-threatening to neurons.

3. The Axon and Axonal Collaterals
