It is generally accepted that hippocampal RSA depends on intact septo-hippocampal circuits. The experimental evidence is based on the fact that lesions of the septal area result in the disappearance of RSA from the hippocampus and other limbic cortical areas. Furthermore, it was shown that subpopulations of medial septal/diagonal band neurons, particularly those lying within the dorsal limb of the diagonal band and in the ventral part of the medial septal nucleus, discharge in phase with hippocampal RSA. This population of septal neurons is capable of sustaining burst firing within the RSA frequency range even when disconnected from the hippocampus. These experimental findings have led to the general idea that in the septal area some neuronal networks can work as pacemakers of RSA. However, it must be emphasized that the hippocampal neurons do not act as simple passive followers of the septal neurons. The neuronal networks of the hippocampus and of other cortical limbic areas also contribute to the characteristics of the local RSA. Indeed, even hippocampal slices kept *in vitro* are able to generate RSA-like rhythmic field potentials on the application of the cholinergic agonist carbachol in a large concentration. Theta frequency oscillations were also recorded in hippocampal neurons, maintained in *in vitro* slices, induced by depolarization by current injection of long duration. This cholinergic activation is mediated by muscarinic receptors since it is blocked by atropine, and RSA

elicited in hippocampal slices involves recurrent excitatory circuits of the CA3 region, mediated by glutamatergic (non-NMDA) synapses. It should be emphasized that this form of *in vitro* RSA mimicks the so-called atropine-sensitive RSA of behaving rats that appears during motionless behavior and REM sleep. However, the atropine-insensitive RSA that appears during motor activity certainly involves other processes and depends on other neuromodulating systems.

In addition to the rhythmic activity in the theta frequency range, one can also record from the paleo- and archicortex other EEG activities within the frequency range from 30 to 50 Hz (i.e., beta or gamma activities). An interesting feature of these rhythmic activities of the basal forebrain is that they have a relatively large value of coherence over a wide range of brain areas involved in olfaction. This coherent domain of beta activity reflects the fact that there is a rostrocaudal spread of this activity along the olfactory bulb, prepyriform, entorhinal cortices.

The cellular origin of the beta activity of the olfactory areas (paleocortex) has been revealed by many comprehensive investigations in which both single and multiple neuronal activity or LFPs were recorded, and their relationships were analyzed using signal analysis techniques by Walter Freeman. A conclusion of Freeman's studies is that the interactions at the neuronal population level are mediated by synaptic somadendritic mechanisms, involving electrotonic spread of activity and the transmission of action potentials, that have nonlinear dynamical behavior. It is also assumed that the oscillations result primarily from synaptic interactions among interconnected populations of neurons and not from intrinsic neuronal oscillations since the paleocortex isolated from extrinsic connections remains silent.

It is noteworthy that computer simulation studies of Walter Freeman and collaborators showed that the typical complex nonlinear (possibly chaotic) dynamics of the olfactory cortical areas appear to depend on the presence of interactions between the olfactory bulb, the anterior olfactory nucleus, and the prepyriform cortex, which are interconnected by short and long pathways with the corresponding time delays. This implies that the dynamical behavior of neuronal networks should not be assumed to be determined only by local properties but also to depend on the interactions between networks at different locations, through reentrant circuits, such that new emerging properties arise from these functional assemblies of corticocortical and subcorticocortical systems.

D. Beta/Gamma Activity of the Neocortex

The identification and characterization of high-frequency rhythms in the neocortex has been concentrated mainly in two neocortical areas—the visual cortex and the somatomotor cortex. Here, some of the properties of these beta/gamma rhythmic activities for these two areas are discussed.

Commonly, the EEG or LFP of the visual cortex is associated with the alpha rhythm, with typical reactivity with closing and opening of the eyes as described previously. However, other types of rhythmic activities can be present in the same cortical areas, namely within the beta frequency range. In the dog, it was shown that the EEG spectral density was characterized by peaks within the beta/gamma frequency range while the animal was looking attentively at a visual stimulus. These findings in the awake animal are in line with the demonstration in the bulbospinal transected preparation that brain stem electrical stimulation causes not only desynchronization of alpha spindles but also the appearance of fast rhythms in the cortical EEG. Recently, Walter Freeman and Bob van Dijk found in the visual cortex of a rhesus monkey that fast EEG rhythms (spectral peak of 30 ± 3.7 Hz) occurred during a conditioned task to a visual stimulus. A possibly related finding is the discovery by the group of Charles Gray and Wolf Singer and by Eckhorn and collaborators of oscillations within the beta/gamma frequency range (most commonly between 30 and 60 Hz) in the firing of individual neurons of the visual cortex in response to moving light bars. Using auto- and cross-correlation analyses, it was demonstrated that neurons tended to fire in synchrony, in an oscillatory mode, within cortical patches that could extend up to distances of about 7 mm. The oscillations in neuronal firing rate were correlated with those of the LFPs. The cortical oscillations are modulated by the activation of the mesencephalic reticular formation (MRF), but the stimulation of the MRF alone does not change the pattern of firing of the cortical neurons. However, MRF stimulation increases the amplitude and coherence of both the LFP and the multiunit responses when applied jointly with a visual stimulus.

In the somatomotor cortex, beta/gamma oscillations of both neuronal firing and LFPs were described in the awake cat by the group of Rougeul-Buser, particularly when the animal was in a state of enhanced vigilance while watching an unreachable mouse. Also, in monkey during a state of enhanced attention, fast oscillations were found in the somatomotor cortex. Oscillations of 25–35 Hz occurred in the sensorimotor

cortex of awake behaving monkeys both in LFPs and in single- /multi-unit recordings. They were particularly apparent during the performance of motor tasks that required fine finger movements and focused attention. These oscillations were coherent over cortical patches extending at least up to 14 mm that included the cortical representation of the arm. Synchronous oscillations were also found straddling the central sulcus, so they may reflect the integration of sensory and motor processes. The LFP reversed polarity at about 800 μm under the cortical surface, indicating that the source of the LFP is in the superficial cortical layers. It is noteworthy that at least some of the cortical beta/gamma rhythmic activities appear to depend on projecting dopaminergic fibers arising in the ventral tegmental area, but it is not clear to what extent the beta rhythms of the somatomotor cortex are related to thalamic or other subcortical activities.

It is relevant to correlate the characteristics of EEG beta/gamma activities found in experimental animals with those recorded from the scalp in man. Beta/gamma activity was reported by DeFrance and Sheer to occur over the parieto-temporo-occipital cortex in man, particularly in relation to the performance of motor tasks.

With respect to the origin of beta/gamma rhythmic activity, several experimental facts have led to the interpretation that these rhythmic activities are primarily generated in the cortex: (i) the fact that oscillations in the beta/gamma frequency range were easily recorded from different cortical sites but not from simultaneously obtained recordings from thalamic electrodes; (ii) the observation that in the visual cortex there are neurons that show oscillatory firing rates with a phase difference of about one-fourth of a cycle, indicating that a local recurrent feedback circuit can be responsible for the oscillations; and (iii) the finding of intrinsic oscillations in cortical neurons from layer IV of the frontal cortex of guinea pig *in vitro*. Nevertheless, it is possible that thalamic neuronal networks also contribute to the cortical beta/gamma rhythmic activity since about 40-Hz oscillatory behavior has been observed by Mircea Steriade and collaborators in neurons of the intralaminar centrolateral nucleus that projects widely to the cerebral cortex. The question cannot be stated as a simple alternative between a cortical versus a thalamic rhythmic process, both considered as exclusive mechanisms. As discussed in relation to other rhythmic activities of the mammalian brain, both network and membrane intrinsic properties cooperate in shaping the behavior of the population, including its rhythmic properties and its capability of synchronizing the neuronal elements.

VI. EVENT-RELATED PHENOMENA: EEG DESYNCHRONIZATION AND SYNCHRONIZATION

The electrical activity of the brain is ever changing, depending on both exogenous and endogenous factors. The spatiotemporal patterns of EEG/MEG activity reflect changes in brain functional states. These patterns are apparent as a sequence of maps of scalp activity that change at relatively short time intervals, on the order of seconds or even fractions of seconds. Dietrich Lehmann identified these series of maps as reflecting brain "microstates" and proposed that different modes of mentation are associated with different brain EEG microstates.

A classic phenomenon is the EEG/MEG activity that occurs in response to sensory events, the so-called sensory evoked potentials (EPs). In addition, another class of EEG phenomena of the same kind should be distinguished that consists of those changes of the ongoing EEG activity that precede motor acts, such as the readiness potential, or "bereitschafspotential" of Kornhuber and Deecke, and the premotor potentials. In order to detect EPs or, in more general terms, event-related potentials (ERPs), computer-averaging techniques are commonly used. The basic model underlying this approach is that the evoked activity is time and phase locked to a given event, or stimulus, while the ongoing EEG activity behaves as additive noise. Here, I do not consider this kind of phenomena in detail since this forms a specialized EEG field. Nevertheless, it should be noted that the discovery of evoked activity related to cognitive events has resulted in important contributions to neurocognitive research. One example is the contingent negative variation (CNV), first described by Grey Walter in 1964. The CNV is a slow potential shift with negative polarity at the cortical surface that precedes an expected stimulus and that is related to motivation and attention. Another example is a component of EPs that peaks at approximately 300 msec, with surface positivity, after infrequent but task-relevant stimuli that was discovered by Sutton, Zubin, and John in 1965. This component is called the P300, and it depends more on the meaning of the stimulus and the context of the task than on the physical properties of the stimulus. Still another EP phenomenon with relevant cognitive connotations is the so-called processing negativity

described by Näätänen that is a large surface negative wave that can begin as early as 60 msec and can last for 500 msec. It is a sign of selective attention. Neurocognitive studies using ERPs and, recently, event-related magnetic fields have been successfully carried out. Such investigations have benefited much from the approach developed by Alan Gevins and collaborators, the so-called EP covariance methodology, that has provided interesting results concerning the cortical processes involved in working memory and in planning of movement. In these studies, the recording of EPs at different brain sites during the sequential processing of cognitive tasks allowed researchers to follow sequential and/or parallel activation of different cortical areas as cognitive tasks evolved. This approach has been particularly successful in studies of brain processes underlying language functions, such as the seminal investigation of Riitta Salmelin and collaborators in Helsinki. Using a whole-head MEG and event-related magnetic fields, they were able to trace the progression of brain activity related to picture naming from Wernicke's area to the parietal-temporal and frontal areas of the cortex. Subsequent MEG studies of the same group in collaboration with that of Pim Levelt of Nijmegen revealed a more refined pattern of the dynamics of cortical activation associated with the successive stages of a psychological model of spoken word generation. These neurocognitive processes were approached using the novel methodology of combining fMRI and MEG in order to obtain high-resolution imaging, both in space and in time, of cortical activity during semantic processing of visually presented words. These studies confirmed that in general there is a wave of activity that spreads from the occipital cortex to parietal, temporal, and frontal areas within 185 msec during picture naming. Furthermore, they indicated that the effects of word repetition are widespread and occur only after the initial activation of the cortical network. This provides evidence for the involvement of feedback mechanisms in repetition priming (Fig. 5).

Since the focus of this article is the ongoing EEG/MEG activity, I consider in more detail a class of EEG/MEG phenomena that are time locked to an event but

Neuron
62

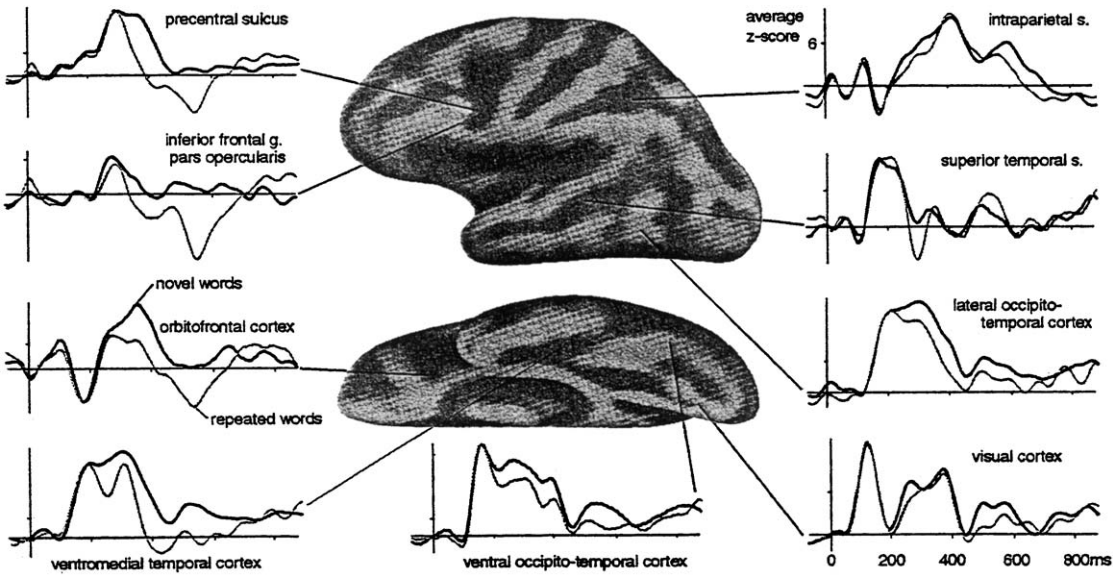

Figure 5 Estimated time courses of MEG signals corresponding to different cortical areas involved in processing of novel and repeated words. The MEG sources were estimated using noise normalization and were fMRI biased toward hemodynamically active cortical areas. The results represent averages across four subjects. Black lines show responses to novel words, and gray lines indicate the responses to repeated words. Waveforms are derived from single cortical locations (each representing 0.5 cm^2). Vertically, the z scores are shown: a score of 6 corresponds to a significance level of $p < 10^{-8}$ (reproduced with permission from Dale *et al.*, 2000).

not phase locked. These phenomena cannot be extracted by simple averaging but may be detected by spectral analysis. An event-related phenomenon may consist of either a decrease or an increase in synchrony of the underlying neuronal populations. The former is called event-related desynchronization (ERD), and the latter is called event-related synchronization (ERS) (Fig. 6). Gert Pfurtscheller and collaborators extensively studied these phenomena. When referring to ERD or ERS, one should specify the corresponding frequency band since, for example, there may be ERD of the alpha band and ERS of the beta band at the same time. The term ERD is only meaningful if the EEG activity during the baseline condition shows a clear spectral peak at the frequency band of interest, indicating the existence of a specific rhythmic activity. Complementarily, the term ERS has meaning only if the event results in the emergence of a rhythmic component, and therewith of a spectral peak that was not detectable under baseline conditions. In general, ERD/ERS reflect changes in the activity of neuronal networks that take place under the influence of specific and/or modulating inputs, which alter the parameters controlling the oscillatory behavior of the neuronal networks.

Even within the alpha frequency band, ERD is not a unitary phenomenon since we have to distinguish at least two patterns of alpha ERD: Lower alpha (7–10 Hz) desynchronization is found in response to almost any kind of task and appears to depend mainly on task complexity. Thus, it is unspecific and tends to be topographically widespread over the scalp. Upper alpha (10–12 Hz) desynchronization has a more restricted topographic distribution, particularly over the parieto-occipital areas, and it is most often elicited by events related to the processing of sensorisemantic information, as shown by the investigations of Wolfgang Klimesch. In general, many psychophysiological variables that cause ERD of rhythms within the alpha frequency range are related to perceptual and memory tasks, on the one hand, and voluntary motor actions, on the other hand. Voluntary movements can result in

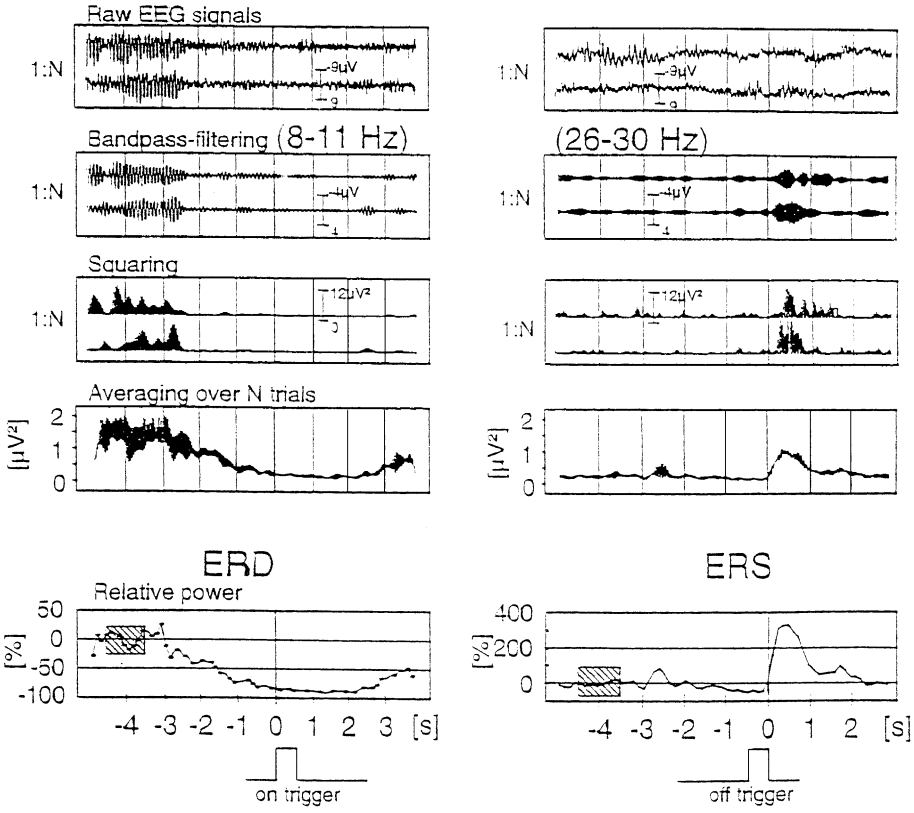

Figure 6 Principle of ERD (left) and ERS (right) EEG processing. A decrease of power within a given band (8–11 Hz) indicates ERD and an increase of band power (26–30 Hz) indicates ERS. Note that ERD precedes the trigger, a finger movement, and that ERS follows the trigger (i.e., it occurs at the cessation of the movement) (adapted with permission from Pfurtscheler and Lopes da Silva, 1999).

an ERD of the upper alpha (also called mu rhythm) and lower beta bands localized close to the sensorimotor areas. This desynchronization starts about 2 sec prior to movement onset, over the contralateral rolandic region in the case of a unilateral movement, and becomes bilaterally symmetrical immediately before movement execution. It is interesting to note that the ERDs for the different frequency bands have specific topographical distributions, indicating that different cortical populations are involved. For instance, in relation to a hand movement, the 10- to 11-Hz mu ERD and the 20- to 24-Hz beta ERD display different maxima over the scalp, although both activities are localized around the central sulcus. The mu rhythm ERD has maximal magnitude more posteriorly than the beta activity, indicating that it is generated mainly in the postrolandic somatosensory cortex, whereas the low beta activity is preferentially generated in the prerolandic motor area. In addition, after a voluntary movement the central region exhibits a localized beta ERS that becomes evident in the first second after cessation of the movement, at a time when the rolandic mu rhythm still presents a desynchronized pattern. The exact frequency of this rebound beta ERS can vary considerably with subject and type of movement. This beta ERS is observed not only after a real movement as shown in Fig. 6 but also after an imagined movement. Furthermore, ERS in the gamma frequency band (approximately around 36–40 Hz) can also be found over the central egions during the execution of a movement, in contrast with the beta ERS that has its maximum after the termination of the movement. A prerequisite for detecting this gamma ERS is that alpha ERD takes place at the same time.

A particular feature of ERD/ERS phenomena that we have recently analyzed is that under some conditions one can find a localized ERD at the same time as ERS in a neighboring region. This antagonistic ERD/ERS phenomenon can occur between two different modalities—for example, ERD of the alpha over the occipital region elicited by visual stimulation accompanied by ERS of the mu rhythm of the central somatosensory region—but it can also occur within the same modality. For example, a voluntary hand movement can result in an ERD over the cortical area representing the hand and simultaneously an ERS over the cortical area representing the leg/foot (Fig. 7). The opposite can be seen in the case of a voluntary foot movement. We interpret this ERD/ERS antagonistic phenomenon as indicating that at the level of the thalamic reticular nucleus, cross talk between the neuronal networks processing different inputs takes place. This may occur as follows: The specific movement would engage a focal attentional process that results in a desynchronization of a module of thalamocortical networks called the target module. This attentional signal is most likely mediated by the activation of modulating cholinergic inputs. These cholinergic inputs hyperpolarize the inhibitory neurons of the reticular neurons and depolarize the thalamocortical relay neurons of a given module. Consequently, the thalamocortical feedback loop responsible for the rhythmic activity becomes open, which is reflected in the ERD that is recorded over the corresponding cortical projection areas. At the same time, the neurons of the reticular nucleus that are adjacent to those of the target module become disinhibited. This results in an increase in the gain of the feedback loops to which the latter belong, thus resulting in an increase in the magnitude of the corresponding rhythmic activity that is reflected at the cortex by ERD. In this way, the analysis of ERD/ERS phenomena has led to the formulation of a hypothesis concerning the neurophysiological processes underlying the psychological phenomenon of focal attention/surround inhibition.

In short, ERD can be interpreted as an electrophysiolgical correlate of activated cortical areas involved in the processing of sensory, motor, or cognitive information. The mirror image of alpha ERD, of course, is alpha ERS (i.e., a pronounced rhythmic activity within the alpha frequency range), indicating that the corresponding neuronal networks are in a state of reduced activity. Thus, these rhythmic activities are sometimes called ''idling rhythms,'' although one should be cautious about the literal interpretation of this term since the underlying neuronal populations are not really ''idle''— they are always active but may display different dynamical properties. An important point is that ERD and ERS cannot be considered as global properties of the brain. Indeed, ERD and ERS phenomena can be found to coexist in neighboring areas and may affect specific EEG/MEG frequency components differently.

Understanding the significance of ERS of the beta frequency range that typically occurs after a movement has been aided by the observation that at the time that this form of ERS occurs the excitability of the corticospinal pathways decreases, as revealed by transcranial magnetic stimulation. This supports the hypothesis that the postmovement beta ERS corresponds to a deactivated state of the motor cortex. In contrast, the ERS in the gamma frequency band appears to reflect a state of active information

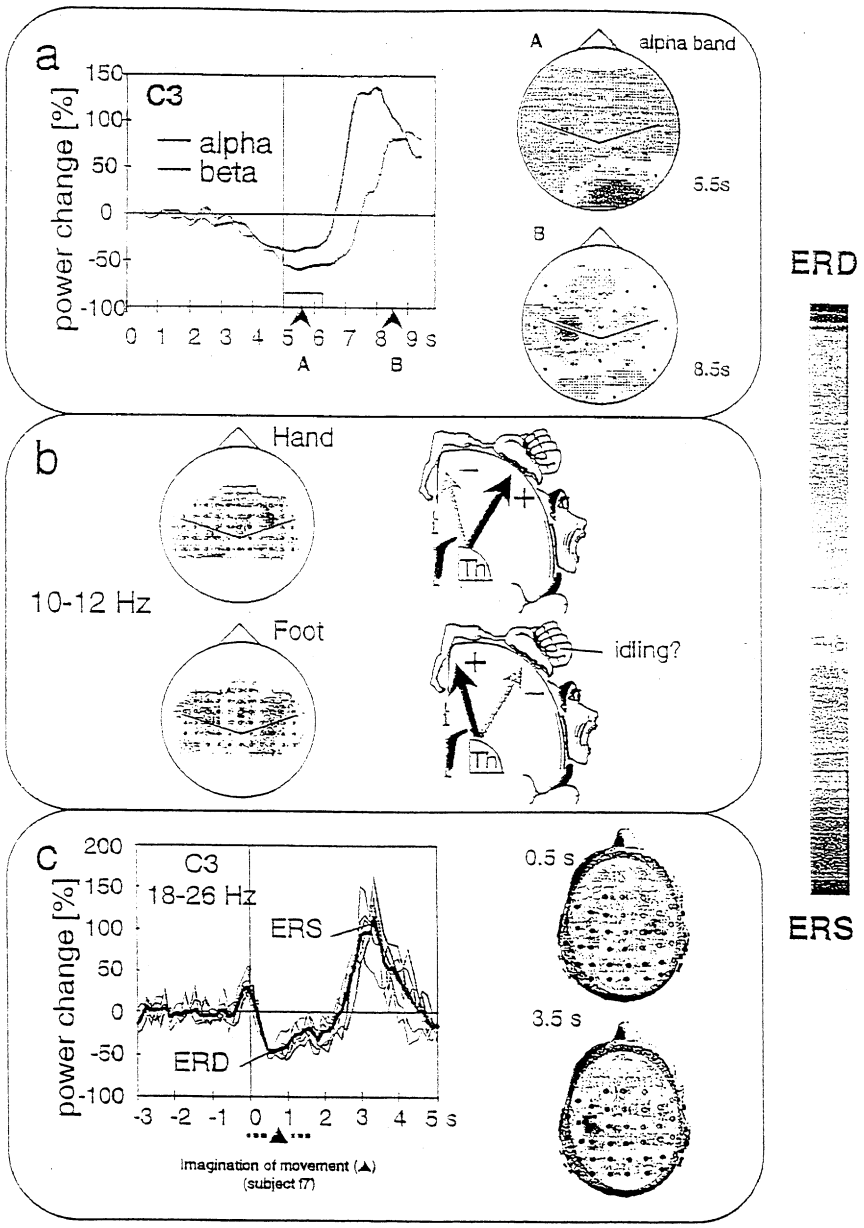

Figure 7 Event-related desynchronization (ERD) and event-related synchronization (ERS) in relation to movement. (a) Average ($n = 9$) of ERD curves calculated in the alpha and beta bands for a right-hand movement task; recording from C3 (left). The maps were calculated for a 125-msec interval during movement (A) and after movement offset in the recovery period (B). (b) Maps displaying ERD and ERS for an interval of 125 msec during voluntary movement of the hand and movement of the foot. The motor homunculus model is shown on the right-hand side to give an indication of the localization of the hand and the foot cortical areas. (c) (Left) Superimposed ERD curves and beta ERS rebound from eight sessions with right-hand motor imagery in one subject within the frequency band 18–26 Hz and for electrode C3. The average is superimposed. (Right) ERD maps displaying simultaneously occurring ERD (contralateral) and ERS (ipsilateral) during imagery and ERS (contralateral) after motor imagery. Color code: dark areas indicate power decrease (ERD) and light areas power increase (ERS) (reproduced with permission from Pfurtscheller and Lopes da Silva, 1999).

processing. Indeed, recordings by Bressler and collaborators from the monkey motor cortex during the performance of a visual-guided motor task showed increased neuronal activity at relatively high frequencies that corresponds in time to the gamma ERS found in human. Furthermore, these gamma band activities recorded from the striate and motor cortex were correlated when an appropriate motor response was

made but were uncorrelated when no response occurred. Similarly, the group of Pfurtscheller found that there was an increase in coherence between the EEG recorded from the sensorimotor and supplementary motor areas over one hemisphere, within the gamma range, during the performance of contralateral finger movements.

VII. WHAT ARE THE ROLES OF OSCILLATIONS IN THE PROCESSING OF NEURAL INFORMATION?

This question is sometimes answered in a negative way with the implication that brain oscillations are irrelevant for the functioning of the brain and should be considered simple epiphenomena. This point of view, however, is superficial since is does not take into account what is happening at the neuronal level during EEG oscillations. In order to answer the question, it is necessary to identify the specific neuronal processes underlying such oscillations. Only in this way we may reach an understanding of the functional implications of an EEG oscillation. In other words, we have to analyze the state of a neuronal population that displays an oscillatory mode in terms of the membrane potentials of the neurons that belong to the population. Of course, during an oscillation the membrane potentials of the constituting neurons vary in synchrony. Since the membrane potential controls the transfer of information of a neuron, we must analyze what happens to the membrane potential of the main neuronal population (i.e., the collective membrane potential) during specific oscillatory modes. Two essentially opposite states of the collective membrane potential may occur during an oscillatory state: The membrane potential of the main population changes in either a hyperpolarized or a depolarized direction with respect to the resting membrane potential.

The former case occurs during a sleep spindle or during a burst of alpha or mu waves since in these circumstances the mean membrane potential of the thalamocortical neurons is in a hyperpolarized state. The main neuronal population displays phased inhibitory potentials with only a few occasional action potentials. Consequently, the functional unit formed by this population is in an inhibitory mode and the transfer of information is blocked. In other words, a gate is closed for the transfer of information. Thus, the oscillatory mode of activity characterized by a dominant alpha frequency represents a ''closed gate'' functional state. In cases in which the mean membrane potential of the main neuronal population is hyperpolarized at still deeper levels, the population will present oscillations at lower frequency in the delta or ultra-delta frequency range, as it occurs during deep sleep.

In the opposite case, the mean membrane potential of the main neuronal population is displaced in a depolarized direction and it shows oscillations phased with the occurrence of action potentials, sometimes in the form of bursts. The implication is that the probability that series of action potentials of different sets of neurons are time locked increases. This can be the basic mechanism ensuring that neuronal firing becomes synchronized (i.e., that binding occurs). This form of oscillation is usually manifest at relatively high EEG frequencies in the beta/gamma band. Note that this does not imply that oscillations at about the same frequency will have the same functional connotation at the neuronal level. This can be illustrated with two examples that show that different types of beta oscillations may correspond to different functional states of corticospinal pathways. In one case, the beta burst that occurs over the central areas of the scalp at the end of a hand movement corresponds to a state of decreased excitability of the corticospinal pathways. In contrast, the MEG beta activity that occurs over the motor cortex during isometric contractions of the muscles of extremity is directly related to the EMG of the corresponding muscles. A common denominator of both cases, however, is that during the oscillatory mode the main neuronal population displays coherent activity. We may hypothesize that this coherent activity serves a goal in binding the neurons within the underlying population so that they may form a functional unit. The ultimate behavioral result corresponding to the EEG oscillatory mode will depend not only on the state of the membrane potentials of the neurons within the population but also on their connectivity with other networks. The complexity of the circuits that are involved in this process makes it difficult to assign a well-defined functional state to a given EEG/MEG oscillatory mode without precise knowledge of the related processes at the level of neurons and of interconnections between subsystems.

Nevertheless, two main functional connotations of brain oscillations can be put forward: (i) binding or linking of single neurons within a population such that they can form a functional unit of information processing, and (ii) gating the flow of information through given circuits. In addition, we should also consider the possibility that oscillatory modes of activity may contribute to other aspects of brain functions. One aspect is that neuronal networks in

general have frequency-dependent properties (e.g., they may show resonance behavior or frequency selectivity). This implies that the transfer of information between two neuronal networks coupled by way of anatomical pathways is likely to depend on the frequency of the sets of action potentials that are transferred between both. This means that oscillatory modes of activity can have another function, namely that of matching, which is the transfer of information between networks from distinct but related areas such that this transfer may be facilitated or optimized.

In this context, it has been demonstrated that in the hippocampus during the theta rhythmic mode of activity, the transmission of impulses through the synaptic path from the CA3 to the CA1 region is reduced. During the theta mode of activity, impulses arising in the entorhinal cortex may pass the two first synapses of the trisynaptic pathway (i.e., to the dentate gyrus and CA3 area) but cannot reach the CA1/subiculum areas. As a consequence, they will be rerouted and will be lead from the CA3 area to target structures of the forebrain, such as the septal area, instead of back to the entorhinal cortex through the subiculum.

Another functional implication of brain oscillatory modes of activity derives from the observation that the strength of synaptic transfer can change, either in the sense of potentiation or depression, depending on frequency of stimulation. This has been evidenced mainly in the case of the theta rhythm of the limbic cortex, particularly of the hippocampus, since it was shown that electrical stimulation at the theta frequency can induce long-term potentiation, whereas stimulation at much lower frequencies may lead to long-term depression. This implies that brain oscillatory activities may be associated with modulating processes of synaptic transmission and plasticity, even promoting the latter in specific synaptic systems.

One general principle of the functional organization of the brain is that it must keep track of different flows of information in the appropriate circuits while it establishes dynamical associations between several sets of processes through multiple reentrant pathways. This means that multiple neuronal networks, at both the cortical and the subcortical levels, are simultaneously active (i.e., that most cognitive processes involve the parallel activity of multiple cortical areas). In this way, different rhythmic activities may be present simultaneously in distinct brain areas or systems.

Another general principle is that processing of information takes place in populations of neurons organized in networks or assemblies of neurons and not just in single neurons. In this respect, evidence obtained recently from studies in which recordings of multiple neurons and LFPs in the visual cortex were obtained simultaneously is strongly indicative that coherent oscillations in a population of neurons could be the basic mechanism to ensure feature binding in the visual system. To underscore this finding, the concept of the linking or association field has been introduced, which is the equivalent—at the level of a neuronal population—of the classic receptive field of the single neuron. The linking field represents the area in visual space in which a stimulus can induce synchronized oscillations in assemblies of cortical neurons. In general, synchronized oscillations occur in different cortical populations if they have similar, or overlapping, receptive field properties and if the appropriate stimulus is present. Therefore, stimulus-induced synchronized oscillations in a given neuronal network may be the basic unit from which attentive percepts that require iterative processing between different neuronal groups are formed.

A third principle of organization, mentioned previously, is that the functional assemblies are interconnected by multiple reentrant connections. The experimental finding that the rhythmic firing of most neurons in an assembly tend to oscillate with zero-degree phase shift results from this property of multiple-level feedback and feedforward.

In summary, note that the change in the activity of a neuronal population from a random mode of activity to an oscillatory mode yields two important consequences for the functioning of the corresponding systems. First, it changes the value of the mean membrane potential in a relatively large group of neurons simultaneously: thus, it sets a bias on the activity of a neuronal population. Accordingly, the transfer function of the population can change in a dynamic way. It appears that the occurrence of synchronized oscillatory activities provides an efficient way to switch the behavior (i.e., to cause a qualitative bifurcation within an assembly of neurons) between different modes of information processing. In this way, neuronal groups with a similar dynamical functional state (linking fields) can be formed. Second, the oscillatory activity may have a frequency-specific role. This role is evidenced by two types of phenomena: (i) matching between interconnected neuronal networks in order to facilitate the transfer of information and (ii) modulation of synaptic plasticity. It is likely that this optimal transfer of information takes place bidirectionally between any two populations of neurons,

ensuring what Gearld Edelman called the reentry process. In this way, large groups of neurons can interact optimally. We may speculate that these processes of facilitating the transfer of information between populations of neurons distributed over different brain areas, such that they can form functional units (although with distinct patterns of local activity), could constitute the physiological basis of consciousness. Under specific conditions consciousness would be impaired, as occurs when these brain areas are recruited into a generalized oscillatory mode, such as the 3-Hz oscillations typical of an epileptic absence seizure.

Finally, the fact that neuronal networks tend to oscillate in a synchronized way, depending on local circuit properties and intrinsic membrane mechanisms, is gradually receiving more attention from physiologists and theoreticians. This is important since it is becoming apparent that the functional units of the brain, by means of which information is processed and transmitted, are dynamical assemblies of neurons. It is indeed necessary to determine how such functional networks are formed in order to be able to understand how the brain subserves cognitive functions. To reach these goals, it is clear that new techniques are necessary that combine the analysis of elementary physiological properties of neurons, *in vitro* and/or *in vivo*, with the study of groups of neurons working as dynamical systems in the intact brain.

VIII. CONCLUSIONS

Knowledge of the electrical and magnetic fields generated by local neuronal networks is of interest to neuroscientists because these signals can give relevant information about the mode of activity of neuronal populations. This is particularly relevant to understanding high-order brain functions, such as perception, action programming, and memory trace formation, because it is becoming increasingly clear that these functions are subserved by dynamical assemblies of neurons. In this respect, knowledge of the properties of the individual neurons is not sufficient. It is necessary to understand how populations of neurons interact and undergo self-organization processes to form dynamical assemblies. The latter constitute the functional substrate of complex brain functions. These neuronal assemblies generate patterns of dendritic currents and action potentials, but these patterns are usually difficult to evaluate experimentally due to the multitude of parameters and the complexity of the structures. Nevertheless, the concerted action of these assemblies can also be revealed in the local field potentials that may be recorded at the distance of the generators. However, extracting information from local field potentials about the functional state of a local neuronal network poses many nontrivial problems that have to be solved by combining anatomical/physiological with biophysical/mathematical concepts and tools. Indeed, given a certain local field potential, it is not possible to precisely reconstruct the behavior of the underlying neuronal elements since this inverse problem does not have a unique solution. Therefore, it is necessary to assume specific models of the neuronal elements and their interactions in dynamical assemblies in order to make sense of the local field potentials. This implies that it is necessary to construct models that incorporate knowledge about cellular/membrane properties with that of the local circuits, their spatial organization, and how they are modulated by different mechanisms.

I have presented many arguments and suggestions in line with the concept that the synchronized activity of populations of neurons in general, and the occurrence of rhythmic oscillatory behavior of different kinds in particular, is not an epiphenomenon of the functional organization of neuronal networks; rather, brain oscillatory activities can play essential functional roles within the brain.

Electroencephalography (EEG)

PAUL L. NUNEZ
Tulane University

GLOSSARY

cerebral cortex The outer layer of mammalian brains; in humans, approximately 2–5 mm thick with a surface area of approximately 1500–3000 cm^2.

coherence A squared correlation coefficient measuring the phase consistency between two signals, expressed as a function of signal frequency.

conductivity (ohm^{-1} mm^{-1}) The property of a material (e.g., living tissue) that determines the ease with which charges move through the medium to produce current.

current density ($\mu A/mm^2$) The flux of positive plus negative charge passing through a cross-sectional area.

electric potential (μV) The negative gradient of the local electric field vector.

electrocorticogram Electric potential recorded directly from the brain surface.

electroencephalography Electric potential generated by brain tissue, recorded from locations outside of nerve cells, either from scalp or from inside the cranium.

event related potential Brain electric potential produced by a combination of sensory stimulus and cognitive task.

evoked potential Brain electric potential produced as the direct result of a sensory stimulus.

Ohm's law for a volume conductor Vector current density equals the product of conductivity and vector electric field. Ohm's law simplifies to the usual scalar expression, voltage change = current × resistance, for current flow confined to one spatial direction, for example, in electric circuit wires.

The first recordings of electrical activity [electroencephalography (EEG)] from the human scalp were obtained in the mid-1920s. EEG provides functional, as opposed to structural, brain information and has important applications in medicine and cognitive science. The field of EEG encompasses evoked and event-related potentials and spontaneous EEG. This article focuses on spontaneous EEG recorded from human scalp.

I. WINDOW ON THE MIND

Human electroencephalography (EEG) provides a convenient but often opaque "window on the mind," allowing observations of electrical processes near the brain surface. The outer brain layer is the cerebral cortex, believed to be largely responsible for our individual thoughts, emotions, and behavior. Cortical processes involve electrical signals that change over times in the 0.01-sec range. EEG is the only widely available technology with sufficient temporal resolution to follow these quick dynamic changes. On the other hand, EEG spatial resolution is poor relative to that of modern brain structural imaging methods—computed tomography, positron emission tomography, and magnetic resonance imaging (MRI). Each scalp electrode records electrical activity at large scales, measuring electric currents (or potentials) generated in cortical tissue containing approximately 30–500 million neurons.

Electrodes may be placed inside the skull to study nonhuman mammals or human epilepsy patients. Such intracranial recordings provide measures of cortical dynamics at several small scales, with the specific scale dependent on electrode size. Intracranial EEG is often uncorrelated or only weakly correlated with cognition and behavior. Human "mind measures" are more easily obtained at the large scale of scalp recordings. The technical and ethical limitations of human intracranial recording force emphasis on scalp recordings. Luckily, these large-scale estimates provide important measures of brain dysfunction for clinical work and cognition or behavior for basic scientific studies.

EEG monitors the state of consciousness of patients in clinical work or experimental subjects in basic research. Oscillations of scalp voltage provide a very limited but important part of the story of brain functioning. For example, states of deep sleep are associated with slower EEG oscillations of larger amplitude. More sophisticated signal analyses allow for identification of distinct sleep stages, depth of anesthesia, epileptic seizures, and connections to more detailed cognitive events. A summary of clinical and research EEG is provided in Fig. 1. The arrows indicate common relations between subfields. Numbers in the boxes indicate the following:

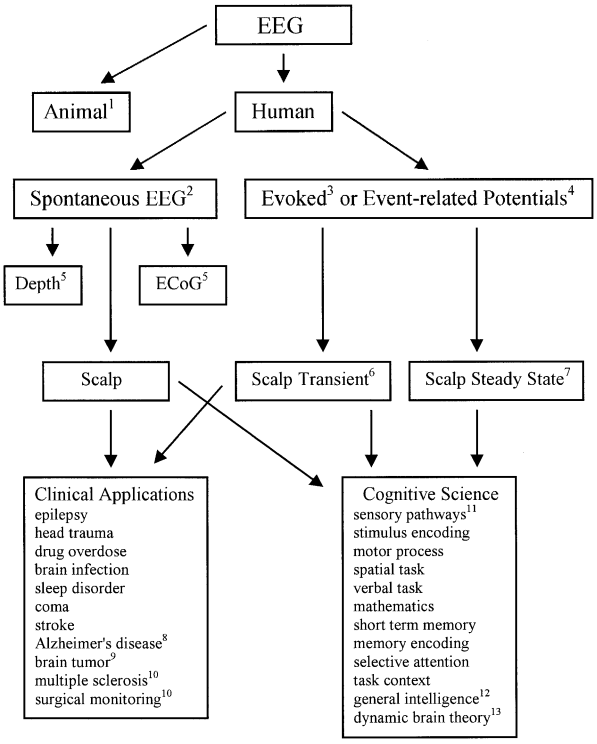

Figure 1 Common relationships between EEG subfields. Clinical applications are mostly related to neurological diseases. EEG research is carried out by neurologists, cognitive neuroscientists, physicists, and engineers who have a special interest in EEG.

1. Physiologists record EEG from inside skulls of animals using electrodes with diameters ranging from approximately 0.001 to 1 mm. Observed dynamic behavior generally depends on measurement scale, determined by electrode size for intracranial recordings. In contrast, scalp-recorded EEG dynamics is exclusively large scale and mostly independent of electrode size.
2. Human spontaneous EEG occurs in the absence of specific sensory stimuli but may easily be altered by such stimuli.
3. Averaged evoked potentials (EPs) are associated with specific sensory stimuli, such as repeated light flashes, auditory tones, finger pressure, or mild electric shocks. They are typically recorded by time averaging to remove effects of spontaneous EEG.
4. Event-related potentials (ERPs) are recorded in the same way as EPs but occur at longer latencies from the stimuli and are associated more with endogenous brain states.
5. Because of ethical considerations, EEG recorded in brain depth or on the brain surface [electrocorticogram (ECoG)] of humans is limited to patients, most of whom are candidates for epilepsy surgery.
6. With transient EPs or ERPs the stimuli consist of repeated short pulses. The number of pulses required to produce an average EP may range from approximately 10 to several thousand, depending on the application. The scalp response to each pulse is averaged over the individual pulses. The EP or ERP in any experiment consist of a waveform containing a series of characteristic component waveforms, typically occurring less than 0.5 sec after presentation of each stimulus. The amplitude, latency from the stimulus, or covariance (in the case of multiple electrode sites) of each component may be studied, in connection with a cognitive task (ERP) or with no task (EP).
7. Steady-state EPs use a continuous sinusoidally modulated stimulus (e.g., a flickering light) typically superimposed in front of a TV monitor showing the cognitive task. The brain response in a narrow frequency band containing the stimulus

frequency is measured. Magnitude, phase, and coherence (in the case of multiple electrode sites) may be related to different parts of the cognitive task.

8. Alzheimer's disease and other dementia typically cause substantial slowing of normal alpha rhythms. Traditional EEG has been of little use in dementia because EEG changes are often only evident late in the illness when other clinical signs are obvious. However, recent efforts to apply EEG to early detection of Alzheimer's disease have shown promise.
9. Cortical tumors that involve the white matter layer (just below neocortex) cause substantial low-frequency (delta) activity over the hemisphere with the tumor. Application of EEG to tumor diagnosis has been mostly replaced by MRI, which reveals structural abnormalities in tissue.
10. Most clinical work uses spontaneous EEG; however, multiple sclerosis and surgical monitoring are exceptions, often involving EPs.
11. Studies of sensory pathways involve early components of EPs (less than approximately 50 msec) since the transmission times for signals traveling between sense organ and brain are short compared to the duration of multiple feedback associated with cognition.
12. The study of general intelligence, often associated with IQ tests, is controversial. However, many studies have reported substantial correlation between scores on written tests and different quantitative EEG measures.
13. Mathematical models of large-scale brain function are used to explain or predict observed properties of EEG in terms of basic physiology and anatomy. Although such models represent vast oversimplifications of genuine brain function, they contribute to a general conceptual framework and may guide the design of new experiments to test this framework.

II. RECORDING METHODS

A. EEG Machines

Human EEG is recorded using electrodes with diameters typically in the 0.4- to 1-cm range, held in place on the scalp with special pastes, caps, or nets as illustrated in Fig. 2. EEG recording procedures are

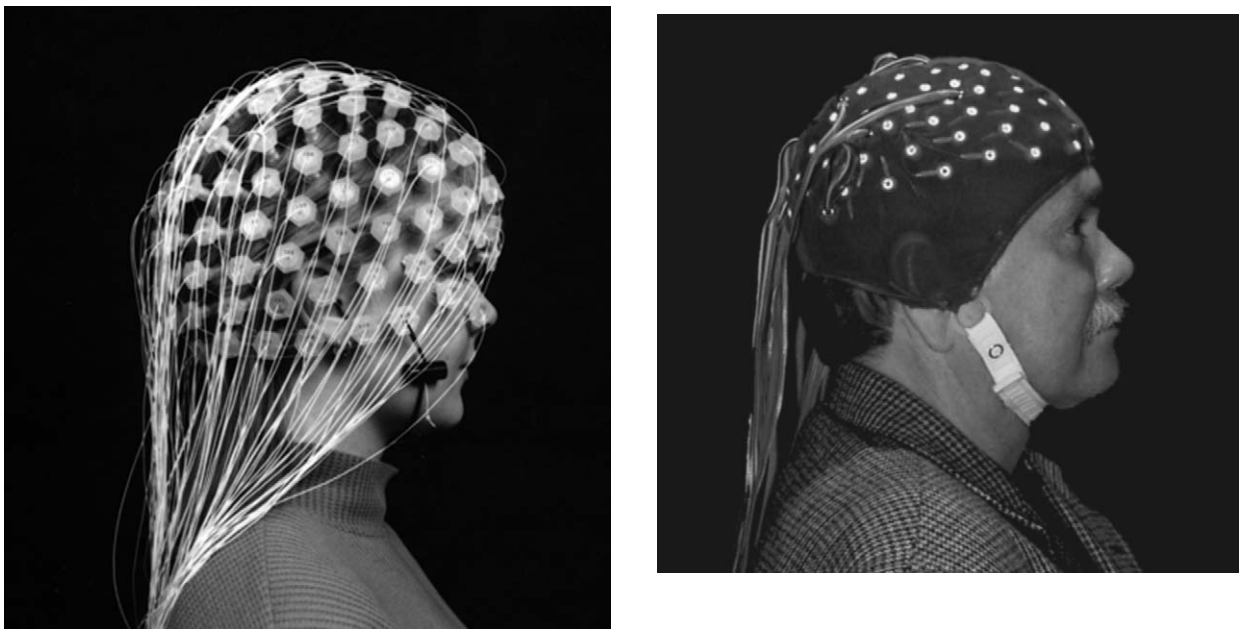

Figure 2 Two kinds of EEG scalp electrode placements are shown in which electrodes are held in place by tension in a supporting structure. (Left) A geodesic net with 128 electrodes making scalp contact with a sponge material (courtesy Electrical Geodesics, Inc.). (Right) An electrode cap containing 131 metal electrodes (courtesy Electro-Cap International, Inc., and the Brain Sciences Institute, Melbourne, Australia). Alternate methods use special pastes to attach electrodes.

noninvasive, safe, and painless. Experimental subjects used in research laboratories are often the same students or senior scientists conducting the research. Special gels are applied between electrodes and scalp to improve electrical contact. Wires from scalp electrodes connect to special EEG machines containing amplifiers to boost raw scalp signals, which are typically in the 5- to 200-μV range or approximately 100 times smaller than EKG (heart) signals. With older EEG machines, analog signals are displayed by rotating ink pens writing on chart paper that moves horizontally across machine surfaces. Modern machines typically replace such paper tracing with computer displays (*digital EEG*) and provide software packages to analyze unprocessed data.

B. Electrode Placement

In standard clinical practice, 19 recording electrodes are placed uniformly over the scalp (the *International 10–20 System*). In addition, one or two reference electrodes (often placed on ear lobes) and a ground electrode (often placed on the nose to provide amplifiers with reference voltages) are required. Potential differences between electrode pairs are recorded with EEG machines containing amplifiers, filters, and other hardware. In *referential recordings*, potentials between each recording electrode and a fixed reference are measured over time. The distinction between "recording" and "reference" electrodes is mostly artificial since both electrode categories involve potential differences between body sites, allowing closed current loops through tissue and EEG machine. *Bipolar recordings* measure potential differences between adjacent scalp electrodes. When such bipolar electrodes are placed close together (e.g., 1 or 2 cm), potential differences are estimates of tangential electric fields (or current densities) in the scalp between the electrodes. Electrode placements and the different ways of combining electrode pairs to measure potential differences on the head constitute the *electrode montage*.

Many research and some clinical laboratories use more than 21 electrodes to obtain more detailed information about brain sources. However, more electrodes may add very little useful information unless supplemented by sophisticated computer algorithms to reduce raw EEG data to a manageable form. Often, 48–131 recording electrodes are used in research; laboratories may soon use as many as 256 channels. The resulting multichannel data are submitted to computer algorithms that estimate potentials on the brain surface by accounting for distortions caused by intervening tissue and the physical separation of electrodes from brain. The combined use of high electrode density and computer algorithms providing such "inward continuation estimates" to the brain surface is called *high-resolution EEG*. Another approach using sophisticated computer methods is *dipole localization*. This method can estimate the location of source regions in the brain depths in a few specialized applications in which EEG is generated mainly in only one or two isolated source regions. However, in most applications, the sources are distributed over large regions of cerebral cortex and possibly deeper regions as well.

C. Artifact

Potentials recorded from the scalp are generated by brain sources, environmental and hardware system noise, and biological artifacts. Biological artifacts often contaminate EEG records and generally pose a more serious problem than environmental or system noise. Common artifact sources include whole body movement, heart, muscle, eyes, and tongue. EEG records containing large artifacts are often discarded. Artifact removal by computer is typically successful only for the largest artifacts. Such automated artifact editing is severely limited because the frequency bands of biological artifacts substantially overlap the important EEG bands, making distinctions between artifact and brain signal difficult.

III. TIME DEPENDENCE

A. Oscillatory Waveforms

Voltage traces of EEG signals recorded from each electrode pair oscillate with mixtures of component waveforms. Each component may be defined in terms of three parameters: its amplitude (A_{nm}), frequency (f_{nm}), and phase (ϕ_{nm}). The subscript n denotes the frequency component and the subscript m indicates the electrode pair. The electrical power associated with each frequency component is proportional to the square of the corresponding amplitude. One may express any physical waveform as a sum of components with different frequencies, amplitudes, and phases called a Fourier series. Fourier series are

analogous to expressions of music or other sounds as compositions of tones or of white light composed of many colors. The EEG voltage $V_m(t)$ recorded from any electrode pair m may be expressed generally as a sum over frequency components:

$$V_m(t) = \sum_{n=1}^{N} A_{nm} \sin(2\pi f_{nm} t - \phi_{nm}) \qquad (1)$$

Waveform frequencies f_{nm} are expressed in terms of the number of cycles per second (or Hz). EEG frequency ranges are categorized as *delta* (1–4 Hz), *theta* (4–8 Hz), *alpha* (8–13 Hz), and *beta* (>13 Hz). Very high frequencies (typically 30–40 Hz) are referred to as *gamma* activity. These distinctive labels correspond approximately to frequency ranges (or bands) that often dominate particular human brain states. For example, delta activity with frequencies lower than about 1 or 2 Hz provides the largest EEG amplitudes (or power) during deep sleep and in many coma and anesthesia states. Alpha, often mixed with low-amplitude delta, theta, and beta, is typically predominant in awake–resting states. It also occurs in *alpha coma* and is superimposed on delta activity during some sleep stages. Distinct rhythms can also occur in the same frequency range. Disparate rhythms may be associated with behavioral or cognitive state, brain location, or by other criteria. Thus, the plural terminology (alpha rhythms, beta rhythms, etc.) appropriately describes the wide variety of EEG phenomena.

B. Alpha Rhythms

Alpha rhythms provide an appropriate starting point for clinical EEG exams. The following are some initial clinical questions. Does the patient show an alpha rhythm, especially over posterior scalp? Are its spatial–temporal characteristics appropriate for the patient's age? How does it react to eyes opening, hyperventilation, drowsiness, etc.? For example, pathology is often associated with pronounced differences in EEG recorded over opposite hemispheres or with low alpha frequencies. A resting alpha frequency lower than about 8 Hz in adults is considered abnormal in all but the very old.

Alpha rhythms may be recorded in approximately 95% of healthy adults with closed eyes. The normal waking alpha rhythm usually has larger amplitudes over posterior regions, but it is typically recorded over widespread scalp regions. Posterior alpha amplitude in most normal adults is in the range 15–50 μV; alpha amplitudes recorded from frontal electrodes are lower. A posterior rhythm of approximately 4 Hz develops in babies in the first few months of age. Its amplitude increases with eye closure and is believed to be a precursor of mature alpha rhythms. Maturation of the alpha rhythms is characterized by increased frequency and reduced amplitude between ages of about 3 and 10.

Normal resting alpha rhythms may be substantially reduced in amplitude by eye opening, drowsiness, and, in some subjects, moderate to difficult mental tasks. Alpha rhythms, like most EEG phenomena, typically exhibit an inverse relationship between amplitude and frequency. For example, hyperventilation and some drugs (e.g., alcohol) may cause reductions of alpha frequencies together with increased amplitudes. Other drugs (e.g., barbiturates) are associated with increased amplitude of low-amplitude beta activity superimposed on scalp alpha rhythms. The physiological bases for the inverse relation between amplitude and frequency and most other properties of EEG are largely unknown, although physiologically based dynamic theories have provided several tentative explanations.

C. Spectral (or Fourier) Analysis

The modern methods of time series analysis are often used to simplify complicated waveforms such as EEG. Many industrial applications involve such methods as electric circuits, signal processing (television, radar, astronomy, etc.), and voice recognition. Most time series analyses are based on spectral (or Fourier) methods. Computers extract the amplitudes A_{nm} and phases ϕ_{nm} associated with each data channel (m) and frequency (n) from the often complicated EEG, represented by Eq. (1). The computer "unwraps" the waveform $V_{\mathrm{m}}(t)$ to reveal its individual components. Such spectral analysis is analogous to the physical process performed naturally by atmospheric water vapor to separate light into its component colors. Each color is composed of electromagnetic waves within a narrow frequency band, forming rainbows.

D. Alpha Spectra

Figure 3 shows a 4-sec period of alpha rhythm recorded from four scalp locations. The subject is a healthy waking adult, relaxed with eyes closed. Amplitude spectra recorded from left frontal (top left), right frontal (top right), left posterior (bottom left),

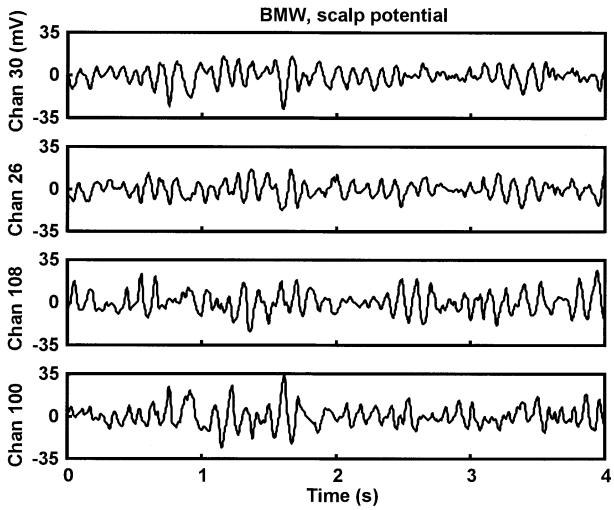

Figure 3 Alpha rhythm recorded from a healthy relaxed subject (age 25) with closed eyes using an electrode on the neck as reference. Four seconds of data are shown from four scalp locations (left frontal channel 30, right frontal channel 26, left posterior channel 108, and right posterior channel 100). The amplitude is given in microvolts. This EEG was recorded at the Brain Sciences Institute in Melbourne, Australia, using the electrode cap shown in Fig. 2 (right).

and right posterior (bottom right) scalp based on 5 min of EEG are shown in Fig. 4. The amplitude spectra show mixtures of frequencies that depend partly on scalp location; however, alpha rhythm is dominant at all locations in this typical example. This subject has two frequency peaks near 10 Hz, a relatively common finding. These two alpha oscillations are partly distinct phenomena as revealed by their separate distributions over the scalp and their distinct behaviors during mental calculations.

E. Alpha, Theta, Cognitive Tasks, and Working Memory

Two prominent features of human scalp EEG show especially robust correlation with mental effort. First, alpha band amplitude normally tends to decrease with increases in mental effort. Second, frontal theta band amplitude tends to increase as tasks require more focused attention. In addition to amplitude changes, tasks combining memory and calculations are associated with reductions in long-range coherence in narrow (1 or 2 Hz) alpha bands, whereas narrowband theta coherence increases. Large alpha coherence reductions at large scalp distances (e.g, >10 cm) can occur with no appreciable reduction in alpha amplitude and simultaneously with increases in short-range (<5 cm) alpha coherence.

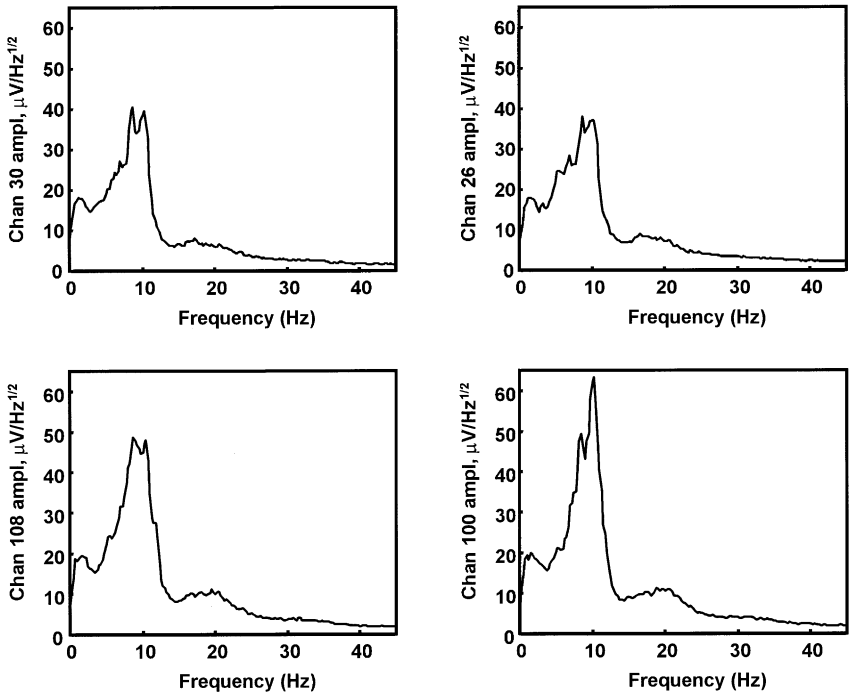

Figure 4 Amplitude spectra for the same alpha rhythms shown in Fig. 3 but based on the full 5-min record to obtain accurate spectra. Frequency resolution is 0.25 Hz. The double peak in the alpha band represents oscillations near 8.5 and 10.0 Hz.

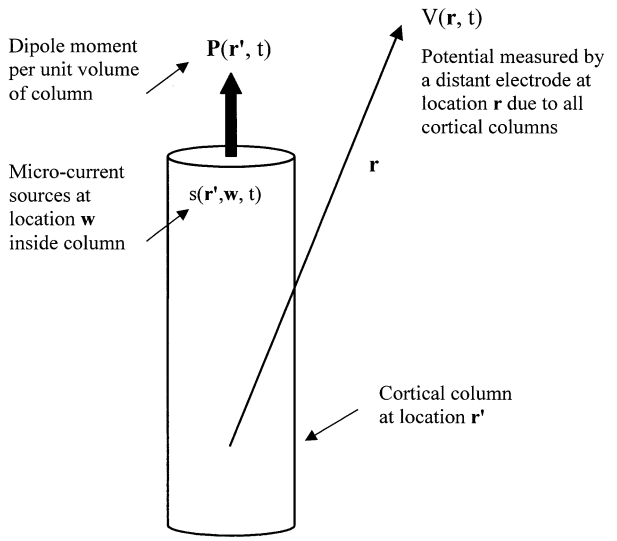

Figure 5 A single column of cerebral cortex with height equal to cortical thickness (2–4 mm) and diameter in the approximate range 0.03–1 mm (the mesoscopic scale). The volume microcurrent sources $s(\mathbf{r}', \mathbf{w}, t)$ ($\mu A/mm^3$) are generated by synaptic and action potentials at cell membrane surface elements, located by the vector $\mathbf{w}$ inside the column. A part of the column (e.g., the center) is located at $\mathbf{r}'$. The microcurrent sources integrated over the volume of the column produce a dipole moment per unit volume of the column $\mathbf{P}(\mathbf{r}', t)$, given by Eq. (2) and expressed in $\mu A/mm^2$. In Eq. (3), the electric potential $V(\mathbf{r}, t)$ at any tissue location $\mathbf{r}$ external to columns (including scalp) is due to the summed (cortical volume or surface integral) contributions from all column sources $\mathbf{P}(\mathbf{r}', t)$.

A common but oversimplified view of alpha rhythms is one of brain idling. However, upper and lower alpha band amplitudes may change independently, depending on scalp location and task. Some tasks cause lower alpha band amplitude to decrease while upper alpha band amplitude increases. Alpha amplitude reductions may be local cortical phenomena occurring in task-relevant brain areas, whereas task-irrelevant regions may be unchanged or even produce larger alpha amplitudes. Another (possibly complementary) hypothesis is that increases in higher frequency alpha amplitudes reflect a specific memory processing function and not simple idling.

Generally, intracerebral electrodes record a variety of alpha rhythms. Some intracerebral alpha rhythms are blocked by opening the eyes and some are not. Some respond in some way to mental activity and some do not. The alpha band rhythms recorded on the scalp represent spatial averages of many alpha components. For an alpha rhythm of a particular type to be observed on the scalp, it must be synchronized (roughly in phase) over a large cortical area.

F. The Rhythmic Zoo

Human EEG exhibits many waveforms, especially in the experience of clinical electroencephalographers (neurologists with specialized training). Some EEGs have known clinical significance and some do not. Any complicated waveform can be described as a mixture of oscillations with different frequencies and amplitudes, as indicated by Eq. (1). However, more picturesque descriptions are often preferred by electroencephalographers to characterized the "zoo" of EEG waveforms. Such labels include *paradoxical alpha*, *spike and wave*, *delta focus*, *sharp transient*, *sleep spindle*, *and nonspecific disrhythmia*.

Cortical EEG (ECoG) typically consists of complex waveforms composed of rhythms with different frequencies, locations, and spatial extent. This normal ECoG differentation between cortical areas is eliminated by anesthesia, suggesting a transition from more locally to more globally dominated brain dynamics. Highly localized cortical rhythms are not recorded on the scalp. Cortical beta rhythms are often strongly attenuated between cortex and scalp because they are more localized than some of the alpha band activity. EEG during sleep, coma, and anesthesia typically exhibits large scalp amplitudes, implying widely distributed cortical source activity.

IV. TOPOGRAPHY

A. Dynamic Measures that Depend on Spatial Location

EEG recorded from a single electrode pair is fully characterized by its time dependence, as in Eq. (1). In spatially extended systems, however, dynamic behavior generally depends on both time and spatial location, the usual independent variables of dynamical systems. Thus, multichannel recordings potentially introduce many new measures of brain dynamic behavior. Amplitude, phase, and frequency may vary with scalp or cortical spatial location, for example.

B. Spatial Distribution of Alpha Rhythms

Alpha rhythms have been recorded from nearly the entire upper cortical surface (ECoG), including frontal and prefrontal areas. High-resolution EEG scalp recordings also show widespread distribution of alpha rhythms over nearly the entire scalp in healthy, relaxed subjects. EEG clinical populations differ, typically

involving patients who are older, have neurological problems, and may be anxious during recording. These factors all tend to work against production of robust, widespread alpha rhythms. Second, the clinical definition of alpha is based on raw waveforms rather than spectra. Often, alpha is identified simply by counting the number of zero crossings of recorded waveforms. This can sometimes provide a misleading picture because raw EEG composed of broad frequency bands can appear very "non-alpha" to visual inspection, even though its amplitude spectrum shows substantial contribution from the alpha band. Such alpha rhythms may consist of mixtures of both localized and widely distributed activity.

Larger amplitude frontal alpha often occurs as subjects become more relaxed, for example, by employing relaxation or meditation techniques. Alpha rhythms of unusually large amplitude or exhibiting frontal dominance may be associated with mental retardation and some types of epilepsy. Large amplitude and dominant frontal alpha rhythm may also be recorded in some coma and anesthesia states. In summary, frontal alpha rhythms of moderate amplitude are common in healthy relaxed subjects with closed eyes, but very large frontal alpha is associated with disease or anesthesia. The physiological relationships between these disparate alpha phenomena are unknown, but they appear to share some underlying physiological mechanisms since their frequencies and widespread distributions are similar.

C. Coherence

Other dynamic measures involve a combination of location and time measures. For example, the (normalized) covariance of two signals is a correlation coefficient expressed as a function of time delay for characteristic waveforms recorded at the two locations. Covariance is used in ERP studies of cognition. A measure similar to covariance is the coherence of two signals, which is also a correlation coefficient (squared). It measures the phase consistency between pairs of signals in each frequency band. Scalp potential (with respect to a reference) recorded at many scalp locations, for example, over 1-min record may be represented by Eq. (1). Consider any two locations with time-dependent voltages $V_i(t)$ and $V_j(t)$. The methods of Fourier analysis may be used to determine the phases ϕ^p_{ni} and ϕ^p_{nj} associated with each 1-sec period or *epoch* (indicated by superscript p) of the full 60-sec record. The frequency component is indicated by subscript n and the two electrode locations are indicated by subscripts i and j. If the voltage phase difference $(\phi^p_{ni} - \phi^p_{nj})$ is fixed over successive epochs p (*phase locked*), the estimated EEG coherence between scalp locations i and j is equal to 1 at frequency n. On the other hand, if the phase difference varies randomly over epochs, estimated coherence will be small at this frequency.

An EEG record involving J recording electrodes will generally provide $J(J-1)/2$ coherence estimates for each frequency band. For example, with $J = 64$ electrodes and 1-sec epochs, coherence estimates may be obtained for all electrode pairs (2016) for each integer frequency between 1 and 15 Hz. The generally very complicated coherence picture may be called the *coherence structure of EEG*. This dynamic structure provides information about local versus global dynamic behavior. It provides one important measure of functional interactions between oscillating brain subsystems. EEG coherence is a different (but closely related) measure than EEG "synchrony," which refers to sources oscillating approximately in phase so that their individual contributions to EEG add by superposition. Thus, *desynchronization* is often associated with amplitude reduction. Sources that are *synchronous* (small phase differences) over substantial times will also tend to be coherent. However, the converse need not be true; coherent sources may remain approximately 180° out of phase so their individual contributions to EEG tend to cancel.

V. SOURCES OF SCALP POTENTIALS

The *generators* of scalp potentials are best described as microcurrent sources at cell membranes. Relationships between such very small-scale sources and macroscopic potentials at the scalp are made easier by employing an intermediate (*mesoscopic*) descriptive scale. This approach makes use of the columnar structure of neocortex, believed to contain the dominant sources of spontaneous scalp potentials. For macroscopic measurements, the "source strength" of a volume of tissue is defined by its electric dipole moment per unit volume:

$$\mathbf{P}(\mathbf{r}', t) = \frac{1}{W} \int \int_W \int \mathbf{w} s(\mathbf{r}', \mathbf{w}, t) dW(\mathbf{w}) \qquad (2)$$

Here, the three integral signs indicate integration over a small, local volume W of tissue, where $dW(\mathbf{w})$ is the tissue volume element. $s(\mathbf{r}', \mathbf{w}, t)$ is the local volume source current ($\mu A/mm^3$) near membrane surfaces inside a tissue volume with vector location $\mathbf{r}'$. $\mathbf{w}$ is the

vector location of sources within $dW(\mathbf{w})$ as indicated in Fig. 5. The current dipole moment per unit volume $\mathbf{P}(\mathbf{r}', t)$ in a conductive medium is fully analogous to charge polarization in a dielectric (insulator). Macroscopic tissue volumes satisfy the condition of electroneutrality at EEG frequencies. That is, current consists of movement of positive and negative ions in opposite directions, but the total charge in any mesoscopic tissue volume is essentially zero. Cortical morphology is characterized by its columnar structure with pyramidal cell axons aligned normal to the local cortical surface. Because of this layered structure, the volume elements $dW(\mathbf{w})$ may be viewed as cortical columns with height $\approx$2–5 mm, as shown in Fig. 5. For purposes of describing scalp potentials, the choice of basic cortical column diameter is somewhat arbitrary. Anything between the cortical *minicolumn* ($\approx$0.03 mm) and *macrocolumn* scales ($\approx$1 mm) may be used to describe scalp potentials.

The microsources $s(\mathbf{r}', \mathbf{w}, t)$ are generally mixed positive and negative due to local inhibitory and excitatory synapses, respectively. In addition to these active sources, the $s(\mathbf{r}', \mathbf{w}, t)$ include passive membrane (return) current required for current conservation. Dipole moment per unit volume $\mathbf{P}(\mathbf{r}', t)$ has units of current density ($\mu A/m^2$). For the idealized case of sources of one sign confined to a superficial cortical layer and sources of opposite sign confined to a deep layer, $\mathbf{P}(\mathbf{r}', t)$ is approximately the diffuse current density across the column. This corresponds to superficial inhibitory synapses and deep excitatory synapses, for example. However, more generally, column source strength $\mathbf{P}(\mathbf{r}', t)$ is reduced as excitatory and inhibitory synapses overlap along column axes.

Increased membrane capacity tends to confine the microsources $s(\mathbf{r}', \mathbf{w}, t)$ within each column to produce smaller effective pole separations—that is, smaller strengths $\mathbf{P}(\mathbf{r}', t)$. However, capacitive effects at macroscopic scales are negligible in normal EEG frequency bands. Also, tissue conductivity is only very weakly dependent on frequency. As a result of these two properties, a single dipole source implanted in the brain generates a time dependence of scalp potential that is identical (except for amplitude attenuation) to that of the source. Amplitude attenuation is independent of source frequency in the EEG range if the sources are equally distributed in location. The selective attenuation of different EEG frequency bands occurs as an indirect result of distinct spatial distributions of the sources.

Human neocortical sources may be viewed as forming a large *dipole sheet* (or *layer*) of perhaps 1500–3000 cm^2 over which the function $\mathbf{P}(\mathbf{r}', t)$ varies continuously with cortical location $\mathbf{r}'$, measured in and out of cortical folds. In limiting cases, this dipole layer might consist of only a few discrete regions where $\mathbf{P}(\mathbf{r}', t)$ is large, consisting of localized or *focal sources*. However, more generally, $\mathbf{P}(\mathbf{r}', t)$ is distributed over the entire folded surface. The question of whether $\mathbf{P}(\mathbf{r}', t)$ is distributed or localized in particular brain states is often controversial. The averaging of EPs over trials substantially alters the nature of this issue. Such time averaging strongly biases EPs toward (trial-to-trial) time stationary sources (e.g., sources confined to primary sensory cortex).

VI. VOLUME CONDUCTION OF HEAD CURRENTS

Scalp potential may be expressed as a volume integral of dipole moment per unit volume over the entire brain provided $\mathbf{P}(\mathbf{r}', t)$ is defined generally rather than in columnar terms. For the important case of dominant cortical sources, scalp potential may be approximated by the following integral of dipole moment over the cortical volume Θ:

$$V(\mathbf{r}, t) = \int_{\Theta} \int \int \mathbf{G}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{P}(\mathbf{r}', t) d\Theta(\mathbf{r}') \qquad (3)$$

If the volume element $d\Theta(\mathbf{r}')$ is defined in terms of cortical columns, the volume integral may be reduced to an integral over the folded cortical surface. Equation (3) indicates that the time dependence of scalp potential is the weighted sum (or integral) of all dipole time variations in the brain, although deep dipole volumes typically make negligible contributions. The weighting function is called the vector Green's function, $\mathbf{G}(\mathbf{r}, \mathbf{r}')$. It contains all geometric and conductive information about the head volume conductor. For the idealized case of sources in an infinite medium of scalar conductivity, σ, the Green's function is

$$\mathbf{G}(\mathbf{r}, \mathbf{r}') = \frac{\mathbf{r} - \mathbf{r}'}{4\pi\sigma/\mathbf{r} - \mathbf{r}'/} \qquad (4)$$

The vector $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ is directed from each column (located at $\mathbf{r}'$) to scalp location $\mathbf{r}$, as shown in Fig. 5. The numerator contains the vector difference between locations $\mathbf{r}$ and $\mathbf{r}'$. The denominator contains the (scalar) magnitude of this same difference. The dot product of the two vectors in Eq. (3) indicates that only the dipole component along this direction contributes to scalp potential. In genuine heads, $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ is much more complicated. The most common head models consist of three or four concentric spherical shells,

representing brain, cerebrospinal fluid, skull, and scalp tissue with different electrical conductivities σ. More complicated numerical methods may also be used to estimate $\mathbf{G}(\mathbf{r}, \mathbf{r}')$, sometime employing MRI to determine tissue boundaries. The accuracy of both analytic and numerical methods is limited by incomplete knowledge of tissue conductivities. MRI has also been suggested as a future means of estimating tissue conductivities.

Despite these limitations preventing highly accurate estimates of the function $\mathbf{G}(\mathbf{r}, \mathbf{r}')$, a variety of studies using concentric spheres or numerical methods have provided reasonable quantitative agreement with experiment. The cells generating scalp EEG are believed to have the following properties: First, in the case of potentials recorded without averaging, cells generating EEG are mostly close to the scalp surface. Potentials fall off with distance from source regions as demonstrated by Eq. (4). In genuine heads, tissue inhomogeneity (location-dependent properties) and anisotropy (direction-dependent properties) complicate this issue. For example, the low-conductivity skull tends to spread currents (and potentials) in directions tangent to its surface. Brain ventricles, the subskull cerebrospinal fluid layer, and skull holes (or local reductions in resisitance per unit area) may provide current shunting. Generally, however, sources closest to electrodes are expected to make the largest contributions to scalp potentials.

Second, the large *pyramidal cells* in cerebral cortex are aligned in parallel, perpendicular to local surface. This geometric arrangement encourages large extracranial electric fields due to linear superposition of contributions by individual current sources. Columnar sources $\mathbf{P}(\mathbf{r}', t)$ aligned in parallel and synchronously active make the largest contribution to the scalp potential integral in Eq. (3). For example, a 1-cm^2 crown of cortical gyrus contains about 110,000 minicolumns, approximately aligned. Over this small region, the angle between $\mathbf{P}(\mathbf{r}', t)$ and $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ in Eq. (3) exhibits relatively small changes. By ''synchronous'' sources, it is meant that the time dependence of $\mathbf{P}(\mathbf{r}', t)$ is approximately consistent (phase locked) over the area in question. In this case, Eq. (3) implies that individual synchronous column sources add by linear superposition. In contrast, scalp potentials due to asynchronous sources are due only to statistical fluctuations—that is, imperfect cancellation of positive and negative contributions to the integral in Eq. (3). Scalp potential may be estimated as approximately proportional to the number of synchronous columns plus the square root of the number of asynchronous columns. For example, suppose 1% ($s_1 \approx 10^3$) of the gyrial minicolumns produce synchronous sources $\mathbf{P}(\mathbf{r}', t)$ and the other 99% of minicolumns ($s_2 \approx 10^5$) produce sources with random time variations. The 1% synchronous minicolumn sources are expected to contribute approximately $s_1/\sqrt{s_2}$ or about three times as much to scalp potential measurements as the 99% random minicolumn sources.

Third, the observed ratio of brain surface (dura) potential magnitude to scalp potential magnitude for widespread cortical activity such as alpha rhythm is approximately in the 2–6 range. In contrast, this attenuation factor for very localized cortical epileptic spikes can be 100 or more. A general clinical observation is that a spike area of at least 6 cm^2 of cortical surface must be synchronously active in order to be identified on the scalp. Such area contains about 700,000 minicolumns or 70 million neurons forming a dipole layer. These experimental observations are correctly predicted by Eq. (3).

Finally, for dipole layers partly in fissures and sulci, larger areas are required to produce measurable scalp potentials. First, the maximum scalp potential due to a cortical dipole oriented tangent to the scalp surface is estimated to be about one-third to one-fifth of the maximum scalp potential due to a dipole of the same strength and depth but orientated normal to the surface. Second, tangential dipoles tend to be located more in fissures and (deeper) sulci and may also tend to cancel due to opposing directions on opposite sides of the fissures and sulci. Third, and most important, synchronous dipole layers of sources with normal orientation covering multiple adjacent gyri can form, leading to large scalp potentials due to the product $\mathbf{P}(\mathbf{r}', t) \cdot \mathbf{G}(\mathbf{r}, \mathbf{r}')$ having constant sign over the integral in Eq. (3).

VII. DYNAMIC BEHAVIOR OF SOURCES

EEG waveforms recorded on the scalp are due to a linear superposition of contributions from billions of microcurrent sources or, expressed another way, by thousands to millions of columnar sources $\mathbf{P}(\mathbf{r}', t)$ located in cerebral cortex, as indicted by Eq. (3). However, the underlying physiological bases for the dynamic behavior of the sources are mostly unknown. The 10-Hz range oscillations of alpha rhythm, the 1-Hz range oscillations of deep sleep, and other waveforms in the EEG zoo must be based on some sort of characteristic time delays produced at smaller scales. Such delays can evidently be developed in *neural networks* that cover a wide range of spatial scales.

Locally generated activity in small networks and more globally generated activity involving spatially extensive networks up to the global scale of the entire cerebral cortex may be reasonably assumed. The local network category includes so-called *thalamic pacemakers* that could possibly impose oscillations in specific frequency ranges on cortex (*local resonances*). Other possible mechanisms occur at intermediate scales between local and global. These involve feedback between cortex and thalamus or between specific cortical locations. Preferred frequencies generated at intermediate scales may be termed *regional resonances*. At the global scale, the generation of resonant frequencies (*global resonances*) due to *standing waves* of synaptic action has been proposed.

Delays in local networks are believed due mainly to *rise and decay times of postsynaptic potentials*. In contrast, global delays occur as a result of *propagation of action potentials* along axons connecting distant cortical regions (*corticocortical fibers*). Delays in regional networks may involve both local and global mechanisms. A working conjecture is that local, regional, and global resonant phenomena all potentially contribute to source dynamics. However, the relative contributions of networks with different sizes may be quite different in different brain states. The transition from awake to anesthesia states is an example of a local to global change. The ECoG changes from rhythms depending strongly on location to rhythms that look similar over widespread cortical locations. Another example is desynchronization (amplitude reduction) of alpha rhythms that occurs with eye opening and certain mental tasks.

Several mathematical theories have been developed since the early 1970s to explain the physiological bases for source dynamics—that is, the underlying reasons for specific time-dependent behaviors of the source function $\mathbf{P}(\mathbf{r}',t)$. Distinct theories may compete, complement each other, or both. Some common EEG properties for which plausible quantitative explanations have emerged naturally from mathematical theories include the following observed relations: frequency ranges, amplitude versus frequency, spatial versus temporal frequency, maturation of alpha rhythm, alpha frequency–brain size correlation, frequency versus corticocortical propagation speed, frequency versus scalp propagation speed, frequency dependence on neurotransmitter action, and mechanisms for cross-scale interactions between hierarchical networks. Because the brain is so complex, such theories must involve many approximations to genuine physiology and anatomy. As a result, verification or falsification of specific theories for the physiological bases for EEG is difficult. However, such mathematical theories can profoundly influence our general conceptual framework of brain processes and suggest new studies to test these ideas.

Emotion

RALPH ADOLPHS and ANDREA S. HEBERLEIN
University of Iowa College of Medicine

GLOSSARY

amygdala (from Greek *amygdala* = "almond"). A collection of nuclei located deep in the medial temporal lobe bilaterally. Extensively connected with cerebral cortex, it projects also to hypothalamus and brain stem nuclei.

basic emotions A limited set (usually six) of emotions thought to be primary; exhibited and recognized cross-culturally and observed early in human development. The standard list of basic emotions is anger, fear, sadness, happiness, disgust, and surprise.

emotional reaction The physiological components of an emotion, including but not limited to changes in heart rate, blood pressure, and piloerection.

feeling The subjective experience of emotion.

orbitofrontal cortex (used interchangeably here with ventromedial frontal cortex). The area of cerebral cortex on the ventral and medial side of the frontal lobes. This area is heavily connected to the amygdala.

periaqueductal gray matter Several columns of cells in the midbrain, surrounding the aqueduct.

social emotions A set of emotions thought to exist only in social species, in which emotional states are elicited by specific social situations and require some awareness of other individuals. Social emotions include embarrassment, pride, and guilt.

valence The pleasant or unpleasant aspect of an emotional feeling.

ventral striatum Components of the basal ganglia, including the nucleus accumbens septi and ventral parts of the caudate nucleus. These structures receive input from areas including amygdala and orbitofrontal cortex and project to the ventral globus pallidus (which projects via other structures back to amygdala and orbitofrontal cortex).

Emotions are internal states of higher organisms that serve to regulate in a flexible manner an organism's interaction with its environment, especially its social environment. Emotions can be divided into three functionally distinct but interacting sets of processes: (i) the evaluation of a stimulus or event with respect to its value to the organism, (ii) the subsequent triggering of an emotional reaction and behavior, and (iii) the representation of (i) and (ii) in the organism's brain, which constitutes emotional feeling. On the one hand, emotions are continuous with more basic motivational behaviors, such as responses to reward and punishment; on the other hand, emotions are continuous with complex social behavior. The former serve to regulate an organism's interaction and homeostasis with its physical environment, whereas the latter serves an analogous role in regard to the social environment. Studies in animals have focused on the first of the two previously mentioned aspects of emotion and have investigated the neural systems whereby behavior is guided by the reinforcing properties of stimuli. Structures such as the amygdala, orbitofrontal cortex, and ventral striatum have been shown to play critical roles in this regard. In humans, these same structures have been shown to also participate in more complex aspects of social behavior; additionally, there are structures in the right hemisphere that may play a special role in the social aspects of emotion. Emotions influence nearly all aspects of cognition, including attention, memory, and reasoning.

I. INTRODUCTION

In order to interact flexibly with a changing environment, complex organisms have evolved brains that construct an internal model of the world. Two necessary components of such a model are (i) a representation of the internal environment (i.e., a self-model) and (ii) representations of the external environment, including the other individuals constituting the social environment. An organism must continuously map self and external environment as the two interact in time. Emotion refers to a variety of different aspects of nervous system function that relate representations of the external environment to the value and significance these have for the organism. Such a value mapping encompasses several interrelated steps: evaluation of the external event or situation with which an organism is confronted, changes in brain and body of the organism in response to the situation, behavior of the organism, and a mapping of all the changes occurring in the organism that can generate a feeling of the emotion.

A. Historical Overview

William James, writing in the middle of the 19th century, made the somewhat counterintuitive claim that the subjective experience, or feeling, of emotion is caused by and follows the bodily changes of emotion. Thus, for example, one sees an angry animal approaching quickly, and one's gut tenses, one's heartbeat rises, and one's hair stands on end, all *before* one feels afraid. In fact, James argued, we depend on these physiological changes *in order* to have a feeling of an emotion.

Charles Darwin focused on emotional expressions and described similarities between human emotional expressions, such as smiles and frowns, and nonhuman animal reactions to positive and negative situations. These similarities supported his claim that human emotional expressions were innate and had evolved from once-adaptive muscle movements. Darwin also emphasized the social communicative function of emotional expressions—for example, between mother and infant or between fighting conspecifics.

These historical viewpoints have counterparts in our commonsense, or folk-psychological, concepts of emotion: Important components of emotion include observable expressions of emotion and perceptions of our own feelings, both of which follow the perception and evaluation of an emotionally salient stimulus. These components are also important in most modern theories of emotion, which share the view that emotions are adaptations sculpted by evolution, and that emotions in humans are on a continuum with emotions in animals.

B. The Functional Structure of Emotion

Emotion can be broadly viewed as a relation between an organism and its environment, pertaining both to the evaluation of external stimuli and to the organism's dispositional and actual action on the environment in response to such evaluation. To analyze this view in more detail, we can identify three components of emotion: (i) recognition/evaluation/appraisal of emotionally salient stimuli; (ii) response/reaction/expression of the emotion (including endocrine, autonomic, and motor changes); and (iii) feeling (the conscious experience of emotion). These components, and some of the neural structures that participate in them, are schematized in Fig. 1.

However, it is important to keep in mind that emotion is a broadly integrative function for which recognition (appraisal), experience (feeling), and response (expression) typically all overlap and influence one another. Several lines of evidence point to a correlation between the experience and expression of emotion, at least in many circumstances. For example, production of emotional facial expressions and other somatovisceral responses directly causes changes in emotional experience, brain activity, and autonomic state. Additionally, viewing emotional expressions on others' faces can cause systematic changes in one's own facial expression and emotional experience.

C. Basic Emotions and Facial Expression

It is widely thought that a small number of emotions are basic or primary. Data suggest that there are six basic emotional expressions: happiness, surprise, fear, anger, disgust, and sadness. However, these categories are without clearly demarcated boundaries and show some overlap (e.g., facial expressions can be members of more than one category). The conceptual structure of emotions may thus bear some similarity to the conceptual structure of colors. As with primary colors, there are basic emotions, and, like colors, an emotion can be a blend of other emotions. Basic emotions correspond closely to the emotions signaled from human facial expressions. The basic emotional expressions are recognized easily by normal subjects and are recognized consistently across very different cultures, as shown in the work of the psychologist Paul Ekman.

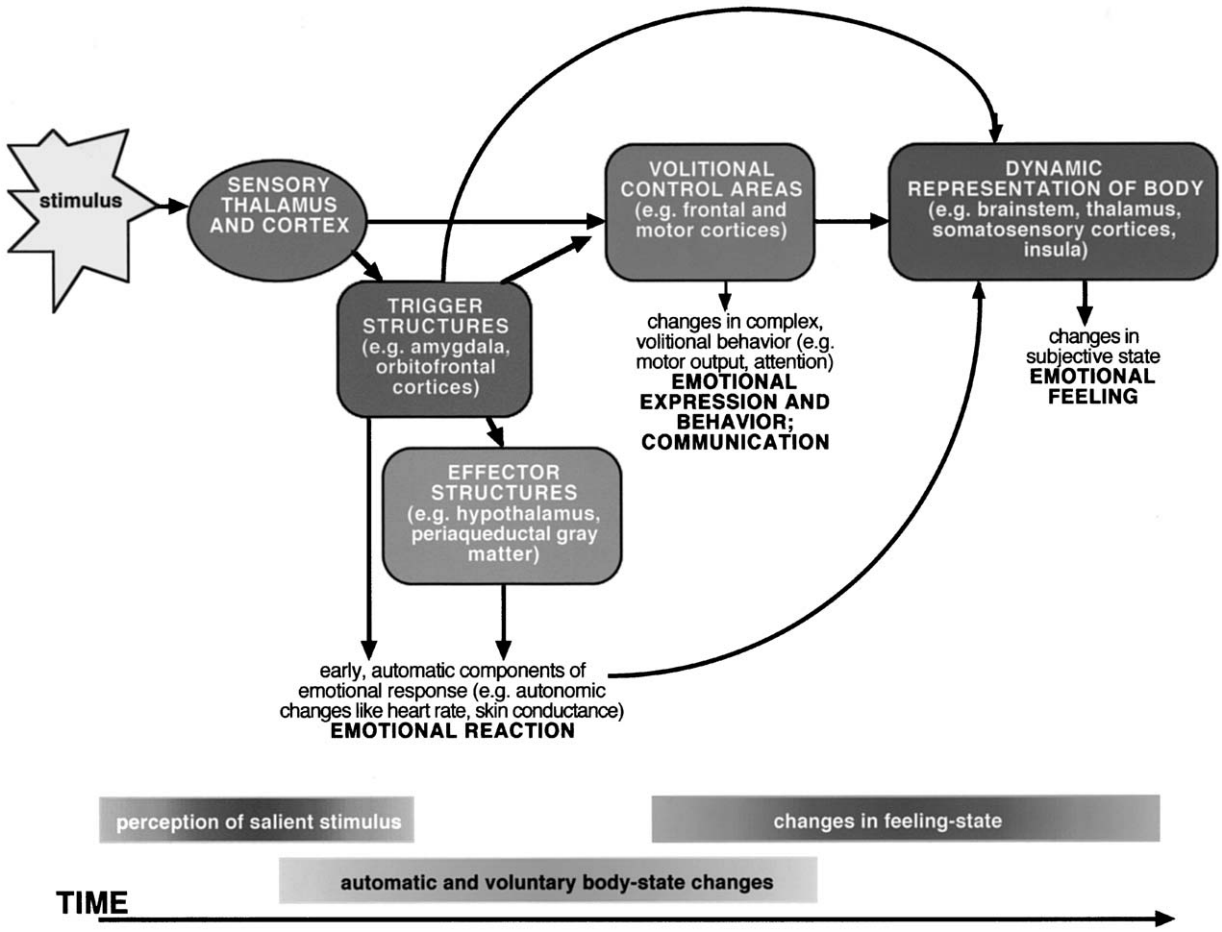

Figure 1 Time line relating the different components of emotion. A stimulus is perceived via a sensory organ, in most cases relayed through the thalamus to sensory cortex. The amygdala and other trigger structures receive projections from thalamus and from sensory cortex at many different levels. These trigger structures then project both to effector structures, such as hypothalamus, that effect changes in autonomic and endocrine activity and to volitional control areas, which are responsible for motor behavior and higher order cognition. All of these areas also project to areas which represent the body state and contribute to the subjective experience, or feeling, of emotion.

Although basic emotions may rely on largely innate factors, they do not appear immediately in infancy. Rather, like the development of language, emotions mature in a complex interplay between an infant's inborn urge to seek out and to learn certain things and the particular environment in which this learning takes place. Considerable learning important to emotion takes place between an infant and its mother. Some emotions that are present very early on, such as disgust, can be elaborated and applied metaphorically to a very large number of situations in the adult. For instance, all infants make a stereotyped face of disgust (as will most mammals) when they have ingested an unpalatable food. In adulthood, both the lexical term ''disgust'' and the facial expression are applied more broadly, for example to include responses to other people whom one finds distasteful. Although the circumstances in which an emotional expression may be elicited can be complex and can depend on the culture, a basic core set of emotional reactions are likely shared across different cultures.

Each of the basic emotions is distinct at the level of concept, experience, and expression, but psychological studies have also examined the possibility that there might be factors shared by these emotions. There is evidence from both cognitive psychology and psychophysiology that valence (pleasantness/unpleasantness) and arousal are two orthogonal factors that may capture the entire spectrum of basic emotions. Data from normal subjects show that emotions, as depicted both in facial expressions and in verbal labels, can be represented on a two-dimensional grid with valence

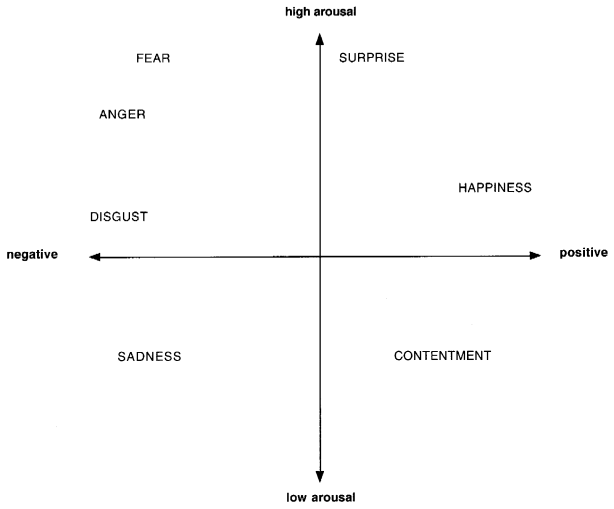

Figure 2 Valence and arousal emotion coordinates. Basic emotions can be placed on this two-dimensional grid.

and arousal as orthogonal axes (Fig. 2). Although such a representation makes sense intuitively, one need not conclude that emotions are analyzed completely in terms of their valence and arousal. A more pragmatic view might treat valence and arousal as two attributes of emotions that are useful for investigation but that may not exhaust all there is to know about emotion.

In addition to the previously mentioned ways of conceptualizing emotions, there are also the terms in our language by which we describe emotions. Certainly, these are much more numerous than just terms for basic emotions, and these include many combinations between emotions and varying shades of intensity of an emotion. Furthermore, we include so-called social emotions, such as guilt, embarrassment, and shame, which may be found only in very social animals and which may be distinct from basic emotions. Table I provides a summary of some of the different schemes used to classify different emotions. It remains an open question how these different schemes are related to one another. Currently, there is no clear classification scheme that stands out as uniquely suited for scientific investigation: In all likelihood, we will have to use different schemes for different purposes, and we will have to be able to translate research findings from one scheme to provide answers to questions posed under a different scheme. This issue becomes especially pressing when we are using data obtained from studies in nonhuman animals, which often investigate emotion at the level of reward and punishment, to provide insights into emotion at the psychological level in humans. Here, we provide an overview of research findings from both animals and humans that considers some of these issues.

II. ANIMALS

A. Historical Research Findings in Animals

Early studies of the neural substrates of emotion-related behavior in nonhuman animals used both lesion and stimulation methods. In the 1920s, Philip Bard and Walter Cannon observed behaviors in decorticate cats that appeared similar to extreme anger or rage. Brain transections produced increased autonomic activity and behaviors including tail lashing, limb jerking, biting, and clawing. They termed this *sham rage* because they thought it occurred without

Table I
Some Schemes Used to Classify Emotions

Classification schemes	Theory/function
Reward/punishment, approach/withdrawal, and positive/negative valence and high/low arousal	All emotions are reducible to and/or based on basic and opposing principles
Basic emotions: happiness, sadness, anger, fear, disgust, and surprise (sometimes others)	Evolved for adaptive value relative to commonly encountered situations
Basic/primary emotions: desire, anger, fear, sadness, sexual lust, joy, and maternal acceptance/nurturance	Come from subcortical brain mechanisms; evolved for adaptive value; there are several categories of emotions involving progressively greater levels of higher cognitive involvement
Social emotions: guilt, embarrassment/shame, and pride (possibly flirtation)	Occur in addition to basic emotions; elicited only in social situations
All the emotions we have words for in our language	Probably many more distinctions made in language than there are separable brain systems subserving emotions

conscious emotional experience and because it was elicited by very mild stimuli, such as light touches. Further research showed that when the lateral hypothalamus was included in the transected region, sham rage was not observed. More focal lesions of the lateral hypothalamus were found to result in placidity and lesions of medial hypothalamus to result in irritability. This observation correlated with the results of stimulation experiments performed at approximately the same time by Walter Hess. Hess implanted electrodes into different areas of the hypothalamus and observed different constellations of behaviors depending on electrode placement. Stimulation of the lateral hypothalamus in cats resulted in increased blood pressure, arching of the back, and other autonomic and somatic responses associated with anger. These results led to a concept of the hypothalamus as an organizer and integrator of the autonomic and behavioral components of emotional responses.

A second key neuroanatomical finding in animals was that by Klüver and Bucy in 1937, who showed that large bilateral lesions of the temporal lobe, including amygdala, produced a syndrome in monkeys such that the animals appeared unable to recognize the emotional significance of stimuli. For instance, the monkeys would be unusually tame, and would approach and handle stimuli, such as snakes, of which normal monkeys are afraid.

On the basis of these animal findings, as well as on the basis of findings in humans, early theorists proposed several neural structures as important components of a system that processes emotion. One of the most influential of these, put forth by Paul MacLean in the 1940s and 1950s, was the notion of a so-called "limbic system" encompassing amygdala, septal nuclei, and orbitofrontal and cingulate cortices. This system was interposed between, and mediated between, neocortical systems concerned with perceiving, recognizing, and thinking, on the one hand, and brain stem and hypothalamic structures concerned with emotional reaction and homeostasis, on the other hand.

Although the concept of a specific limbic system is debated, the idea is useful to distinguish some of the functional components of emotion, as we have done previously. A key insight is the need for specific structures that can link sensory processing (e.g., the perception of a stimulus) to autonomic, endocrine, and somatomotor effector structures in hypothalamus, periaqueductal gray, and other midbrain and brain stem nuclei. In the next section, we discuss various structures that play a role in either linking sensory processing to emotional behavior or effecting the body state changes of emotion.

B. Brain Structures Studied in Emotional Behavior in Animals

1. Amygdala

The amygdala is a collection of nuclei deep in the anterior temporal lobe which receives highly processed sensory information and which has extensive, reciprocal connections with a large number of other brain structures whose function can be modulated by emotion. Specifically, the amygdala has massive connections, both directly and via the thalamus, with the orbitofrontal cortices, which are known to play a key role in planning and decision making. The amygdala connects with hippocampus, basal ganglia, and basal forebrain—all structures that participate in various aspects of memory and attention. In addition, the amygdala projects to structures such as the hypothalamus that are involved in controlling homeostasis and visceral and neuroendocrine output. Consequently, the amygdala is situated so as to link information about external stimuli conveyed by sensory cortices, on the one hand, with modulation of decision-making, memory, and attention as well as somatic, visceral, and endocrine processes, on the other hand.

Although the work of Klüver and Bucy implicated the amygdala in mediating behaviors triggered by the emotional and social relevance of stimuli, by far the majority of studies of the amygdala in animals have investigated emotion not at the level of social behavior but at the level of responses to reward and punishment. These studies have demonstrated the amygdala's role in one type of associative memory—the association between a stimulus and the survival-related value that the stimulus has for the organism. The amygdala is essential to link initially innocuous stimuli with emotional responses on the basis of the apparent causal contingencies between the stimulus and a reinforcer. Although such a mechanism is in principle consistent with the amygdala's broad role in real-life social and emotional behaviors, it has been best studied in the laboratory as "fear conditioning." Fear conditioning uses the innate response to danger, which is similar in many mammals and includes freezing, increase in blood pressure and heart rate, and release of stress hormones. This response is elicited in fear conditioning by a noxious stimulus such as an electric shock to the foot. If this shock is preceded

by an innocuous stimulus such as a bell, the bell comes to be associated with the shock, and eventually the subject will exhibit the fear response to the bell. Joseph LeDoux and colleagues used this paradigm to study the neural substrates of conditioned fear responses in rats. By using anatomical tracing techniques to determine candidate structures and then lesioning these to observe changes in conditioning behavior, LeDoux determined that two nuclei in the amygdala are vital for associating an auditory stimulus with a fear response. The lateral nucleus receives projections from the auditory thalamus and cortex, and the central nucleus coordinates the response in various effector systems (freezing, increase in blood pressure, etc.).

The amygdala's role in associating sensory stimuli with emotional behaviors is also supported by findings at the single cell level. Neurons within the amygdala modulate their responses on the basis of the rewarding or punishing contingencies of a stimulus, as shown in the work of Edmund Rolls and others. Likewise, the responses of neurons in primate amygdala are modulated by socially relevant visual stimuli, such as faces and videos of complex social interactions. Again, it is important to realize that the amygdala is but one component of a distributed neural system that links stimuli with emotional response. There are several other structures, all intimately connected with the amygdala, that subserve similar roles (Fig. 1).

2. Orbitofrontal Cortex

Lesions of the orbitofrontal cortex (discussed in more detail later in regard to humans) produce impairments very similar to those seen following amygdala damage. As in the amygdala, single-neuron responses in the orbitofrontal cortex are modulated by the emotional significance of stimuli, such as their rewarding and punishing contingencies, although the role of the orbitofrontal cortex may be more general and less stimulus bound than that of the amygdala. Amygdala and orbitofrontal cortex are bidirectionally connected, and lesion studies have shown that disconnecting the two structures results in impairments similar to those following lesions of either structure, providing further support that they function as components of a densely connected network.

3. Ventral Striatum

Structures such as the nucleus accumbens also receive input from the amygdala and appear to be especially important for processing rewarding stimuli and for engaging the behaviors that cause an organism to seek stimuli that predict reward. Amygdala, ventral striatum, and orbitofrontal cortex all participate jointly in guiding an organism's expectation of reward on the basis of prior experience. Recent elegant single-unit studies by Wolfram Schultz and colleagues dissect some of the specific component processes. An important neurochemical system subserves the functional connectivity between ventral striatum and frontal cortex: the neurotransmitter dopamine. This system and the specific neurotransmitters involved are currently being intensively investigated as models of drug addiction.

4. Other Trigger Structures

There are several other structures that link stimulus perception to emotional response. Work by Michael Davis and colleagues has highlighted nuclei situated very close to the amygdala, such as the bed nucleus of the stria terminalis, and emphasized their role in anxiety. Other structures in the vicinity, such as nuclei in the septum, are also important and may mediate their effects through the neurotransmitter acetylcholine.

There are a collection of nuclei in the brain stem that can modulate brain function in a global fashion by virtue of very diverse projections. The locus ceruleus, a very small set of nuclei, provides the brain with its sole source of noradrenergic innervation. Similarly, the Raphe nuclei provide a broad innervation of serotonergic terminals. These neuromodulatory nuclei, together with the dopaminergic and cholinergic nuclei mentioned previously, are thus in a position to alter information processing globally in the brain. It is important to emphasize that these changes in the brain's information processing mode are just as important as the somatic components of an emotional reaction —and just as noticeable when we feel the emotion.

5. Effector Structures

The structures involved in emotional reaction and behavior include essentially all those that control motor, autonomic, and endocrine output. Some of these structures have further internal organization that permits them to trigger a coordinated set of responses. For instance, motor structures in the basal ganglia control some of the somatic components of emotional response (facial expressions in humans), and distinct regions in the hypothalamus trigger concerted emotional reactions of fear or aggression, as mentioned previously. Another important structure

is the periaqueductal gray matter (PAG), which consists of multiple columns of cells surrounding the aqueduct in the midbrain. Stimulation of these areas has long been known to produce panic-like behavioral and autonomic changes in nonhuman animals as well as reports of panic-like feelings in humans. Moreover, different columns within the PAG appear to be important for different components of emotional response. In a recent functional imaging study, structures in brain stem and hypothalamus were active when human subjects were experiencing emotions, further supporting the roles of brain stem and hypothalamic structures in the coordination of emotional reaction and behavior.

III. HUMANS

Not surprisingly, the neural structures that are important for emotional behavior in nonhuman animals are also important for emotional behavior in humans (Fig. 3). Again, these can be divided into (i) structures important for homeostatic regulation and emotional reaction, such as the hypothalamus and PAG, and (ii) structures for linking perceptual representation to regulation and reaction, such as the amygdala and orbitofrontal cortex. We will discuss the role of frontal and parietal regions in representing the organism's own changes in body state, focusing on right frontoparietal cortex as well as other somatosensory structures such as the insula. It is again important to remember, however, that all these structures are heavily interconnected, and that most play at least some role in multiple components of emotion. Next we discuss those structures for which the most data are available from humans: the amygdala, the orbitofrontal cortex, and right somatosensory-related cortices.

A. The Human Amygdala

Data on the amygdala in humans have come primarily from lesion studies and from functional imaging studies [e.g., positron emission tomography (PET) or functional magnetic resonance imaging] that image brain activity in neurologically normal individuals. These studies have provided evidence that the amygdala responds to emotionally salient stimuli in the visual, auditory, olfactory, and gustatory modalities. Lesion studies involve patients who have had amygdala damage because of encephalitis (such as Herpes simplex encephalitis) or other rare diseases or who have had neurosurgical resection of the amygdala on one side of the brain to ameliorate epilepsy.

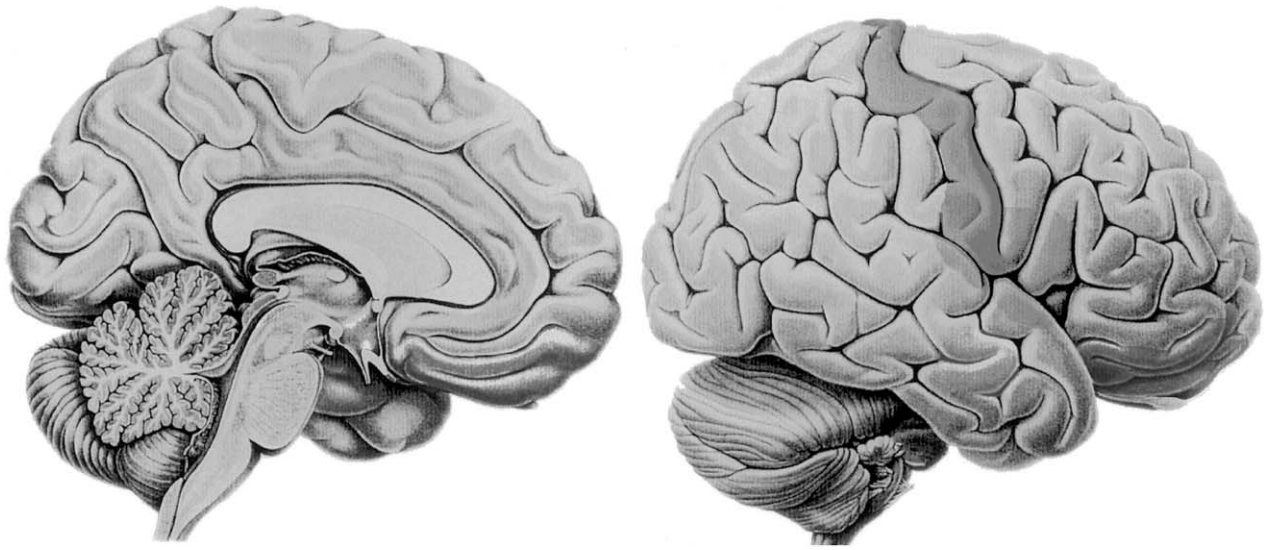

Figure 3 Some of the human brain areas important for emotion. (Left) Medial view of left hemisphere showing orbitofrontal cortex and, deep within the temporal lobe, amygdala, as well as hypothalamus and periaqueductal gray. (Right) Lateral view of the right hemisphere showing orbitofrontal cortex and, buried in temporal cortex, amygdala and also somatosensory cortex and, buried under overlying cortex, insula. As shown schematically in Fig. 1, amygdala and orbitofrontal cortex receive perceptual information and project to effector structures including, principally, hypothalamus and periaqueductal gray. These latter structures effect automatic changes in body state, including blood pressure and heart rate etc. The representation of body state (feeling) depends critically on somatosensory areas, including somatosensory cortex and insula. (See color insert in Volume 1).

As in animals, the human amygdala appears to be important for fear conditioning—for associating conditioned sensory stimuli with an aversive unconditioned stimulus. A variety of neuropsychological tasks have been used in humans to investigate in more detail both the recognition of emotion from stimuli (such as the recognition of emotions from viewing facial expressions of other people) and the experience of emotion triggered by emotional stimuli or emotional memories. Studies of the amygdala's role in emotion recognition have primarily used photographs of emotional facial expression (such as those developed by Paul Ekman). One subject with selective bilateral amygdala damage has been studied extensively with regard to her recognition of emotion in these photographs of facial expressions. This subject, SM046, has been shown in several different tasks to be specifically and severely impaired in regard to faces of fear. When rating the intensity of emotions in facial expressions, SM046 consistently failed to rate the emotions surprise, fear, and anger as very intense. She was particularly impaired in rating the intensity of fear, on several occasions failing to recognize any fear whatsoever in prototypical facial expressions of fear.

SM046's spontaneous naming of the emotions shown in faces in a labeling experiment using identical stimuli was impaired relative to normal controls: She virtually never used the label "fear," typically mislabeling such faces as surprised, angry, or disgusted. Thus, subject SM046's impairment in recognizing emotional facial expressions is disproportionately severe with respect to fear. However, she also has lesser impairments in recognition of highly arousing emotions that are similar to fear, such as anger. This is consistent with a more general impairment in recognition of negative emotions observed in other subjects with bilateral amygdala damage, and it leads to the question of how specific the amygdala's role is in recognition of certain emotions. Interestingly, SM046 is also impaired in her ratings of the degree of arousal present in facial expressions of emotion. When asked to place photographs of emotional facial expressions on a grid with valence (positive/negative) and arousal (low/high) as orthogonal axes, SM046 was normal in her valence ratings but abnormal in the level of arousal that she assigned to negative facial expressions. Thus, it is not the case that bilateral amygdala damage impairs all knowledge regarding fear; rather, it impairs the knowledge that fear is highly arousing.

A likely interpretation of the previous results from SM046, in conjunction with results from other subjects with bilateral amygdala damage, is that the amygdala is part of a more general neural system for recognizing highly arousing, unpleasant emotions—in other words, emotions that signal potential harm to the organism—and rapidly triggering physiological states related to these stimuli. Such physiological states involve both specific sets of behavioral responses and the modulation of cognitive processes, including those involved in knowledge retrieval necessary for normal performance on the previously mentioned tasks. In animals, the amygdala may trigger predominantly behavioral reactions; in humans, it may trigger both behavior and conscious knowledge that the stimulus predicts something "bad." How it is that conceptual knowledge about the arousal component of emotions comes to depend on the amygdala, in addition to emotional arousal itself depending on the amygdala, is a key issue for future research.

Functional imaging studies in normal individuals have corroborated the lesion studies implicating the amygdala in recognition of signals of unpleasant and arousing emotions. Visual, auditory, olfactory, and gustatory stimuli all appear to engage the amygdala when signaling unpleasant and arousing emotions. These studies have examined the encoding and recognition of emotional stimuli, as well as emotional experience and emotional response, but it has been exceedingly difficult to disentangle all these different components. Although there is now clear evidence of amygdala activation during encoding of emotional material, it is less clear whether the amygdala is also activated during retrieval. Two findings suggest that the amygdala's role may be specific to linking external sensory stimuli to emotion and not for triggering emotional responses that are internally driven. First, subjects with bilateral amygdala lesions can volitionally make facial expressions of fear. Second, when normal subjects induced a subjective experience of fear in themselves while undergoing a PET scan, no activation of the amygdala was observed.

Further insight has come from studies that used stimuli that could not be consciously perceived. Amygdala activation was observed when subjects viewed facial expressions of fear that were presented so briefly they could not be consciously recognized, showing that the amygdala plays a role in nonconscious processing of emotional stimuli. In summary, an important function of the amygdala may be to trigger responses and to allocate processing resources to stimuli that may be of special importance or threat to the organism, and ecological considerations as well as

the data summarized here all appear to argue for such a role especially in regard to rapid responses that need not involve conscious awareness.

B. Orbitofrontal Cortex

The importance of the frontal lobes in social and emotional behavior was demonstrated in the mid-1800s by the famous case of Phineas Gage. Gage, a railroad construction foreman, was injured in an accident in which a metal tamping rod shot under his cheekbone and through his brain, exiting through the top of his head. Whereas Gage had been a diligent, reliable, polite, and socially adept person before his accident, he subsequently became uncaring, profane, and socially inappropriate in his conduct. Extensive study of modern-day patients with similar anatomical profiles (i.e., bilateral damage to the ventromedial frontal lobes), has shed more light on this fascinating historical case. These patients show a severely impaired ability to function in society, even with normal IQ, language, perception, and memory. The work of Antonio Damasio and others has illuminated the importance of ventromedial frontal cortices (VMF; we use ventromedial frontal cortex and orbitofrontal cortex interchangeably here) in linking stimuli with their emotional and social significance. This function bears some resemblance to that of the amygdala outlined previously but with two important differences. First, it is clear that the ventromedial frontal cortices play an equally important role in processing stimuli with either rewarding or aversive contingencies, whereas the amygdala's role, at least in humans, is clearest for aversive contingencies. Second, reward-related representations in VMF cortex are less stimulus driven than in the amygdala and thus can play a role in more flexible computations regarding punishing or rewarding contingencies.

Antonio Damasio and colleagues tested VMF-lesioned patients on several types of tasks involving the relation of body states of emotion to behavioral responses. When patients with bilateral VMF damage were shown slides of emotionally significant stimuli such as mutilation or nudity, they did not show a change in skin conductance (indicative of autonomic activation). Control groups showed larger skin conductance responses to emotionally significant stimuli, compared to neutral stimuli, suggesting that VMF patients are defective in their ability to trigger somatic responses to stimuli with emotional meaning. In a gambling task in which subjects must develop hunches about certain decks of cards in order to win money, VMF-lesioned patients made poor card choices and also acquired neither subjective feeling regarding their choices nor any anticipatory autonomic changes before making these poor choices. All these findings support the idea that the VMF cortices are a critical component of the neural systems by which we acquire, represent, and retrieve the values of our actions, and they emphasize the close link between emotion and other aspects of cognitive function, such as reasoning and decision making. Damasio presented a specific neuroanatomical theory of how emotions play a critical role in reasoning and decision making—the *somatic marker hypothesis*. According to this hypothesis, our deliberation of choices and planning of the future depend critically on how we feel about the different possibilities with which we are faced. The construction of some of the components of an emotional state and the feeling that this engenders serve to tag response options with value and serve to bias behavior toward those choices associated with positive emotions. This set of processes may operate either under considerable volitional guidance, and as such may be accessible to conscious awareness, or it may play out in a more automatic and covert fashion.

Both the amygdala and the orbitofrontal cortex function as components of a neural system that can trigger emotional responses. The structure of such a physiological emotional response may also participate in attempts to reconstruct what it would feel like to be in a certain dispositional (emotional or social) state and hence to simulate the internal state of another person. In the case of the amygdala, the evidence thus far points toward such a role specifically in regard to states associated with threat and danger; in the case of the orbitofrontal cortex, this role may be somewhat more general.

C. The Right Hemisphere

One generally defined neural area whose importance in emotional behavior and perception has been explored in primates much more than in other animals is the right hemisphere. Both clinical and experimental studies have suggested that the right hemisphere is preferentially involved in processing emotion in humans and other primates. Lesions in right temporal and parietal cortices have been shown to impair emotional experience, arousal, and imagery. It has been proposed that the right hemisphere contains systems specialized for computing affect from

nonverbal information; these may have evolved to subserve aspects of social cognition.

Recent lesion and functional imaging studies have corroborated the role of the right hemisphere in emotion recognition from facial expressions and from prosody. There is currently controversy regarding the extent to which the right hemisphere participates in emotion: Is it specialized to process all emotions (the *right hemisphere hypothesis*), or is it specialized only for processing emotions of negative valence while the left hemisphere is specialized for processing emotions of positive valence (the *valence hypothesis*)? It may well be that an answer to this question will depend on more precise specification of which components of emotion are under consideration.

Recognition of emotional facial expressions can be selectively impaired following damage to right temporoparietal areas, and both PET and neuronal recordings corroborate the importance of this region for processing facial expressions of emotion. For example, lesions restricted to right somatosensory cortex result in impaired recognition of emotion from visual presentation of face stimuli. These findings are consistent with a model that proposes that we internally simulate body states in order to recognize emotions.

In contrast to recognition of emotional stimuli, emotional experience appears to be lateralized in a pattern supporting the valence hypothesis, in which the left hemisphere is more involved in positive emotions and the right hemisphere is more involved in negative emotions. Richard Davidson posited an approach/withdrawal dimension, correlating increased right hemisphere activity with increases in withdrawal behaviors (including feelings such as fear or sadness, as well as depressive tendencies) and left hemisphere with increases in approach behaviors (including feelings such as happiness).

D. Neuropsychiatric Implications

Emotion is a topic of paramount importance to the diagnosis, treatment, and theoretical understanding of many neuropsychiatric disorders. The amygdala has received considerable attention in this regard and has been shown to be involved in disorders that feature fear and anxiety. Moreover, specific neurotransmitters, acting within the amygdala and surrounding structures, have been shown to contribute importantly to fear and anxiety. Anxiolytic drugs such as valium bind to GABA-A receptor subtypes in the amygdala and alter the neuronal excitability. Corticotropin-releasing factor is an anxiogenic peptide that appears to act in the amygdala and adjacent nuclei. Several functional imaging studies have demonstrated that phobic and depressive symptoms rely on abnormal activity within the amygdala, together with abnormalities in other brain structures.

With regard to depression, the frontal lobes have also been investigated for their contribution to emotional dysfunction in psychiatric disorders. Evoked potential recordings and functional imaging studies have revealed their participation in depression, which may engage regions below the frontal end of the corpus callosum. Moreover, individual differences in affective style, independent of any overt pathology, may rely on hemispherically asymmetric processing within the frontal lobes.

IV. DEVELOPMENT AND EVOLUTION OF EMOTION

Both the developmental and the evolutionary aspects of emotion remain important issues for further research. A large body of findings, primarily from developmental psychology, has shown that the highly differentiated sets of emotions seen in adult humans develop over an extended time course that requires extensive interactions between an infant, its parents, and its cultural environment. The importance of many of the structures discussed previously in the development of emotional behavior is underscored by findings that damage to these structures relatively early in development causes more severe impairments than damage during adulthood. Although newborns do show some relatively undifferentiated emotional responses (such as general distress), and although they have an innate predisposition to respond to emotionally salient stimuli (such as the mother's face), the subsequent development of emotion depends both on the presence of critical neural structures and, crucially, on the child's environment. As with language, humans are predisposed to have a rich and complex set of emotional processes, but the precise details require maturation and learning in a socially rich environment.

Phylogenetically, human emotion depends on the more basic sets of emotions and motivational processes that we share in common with other animals. Clearly, the neural circuitry that subserves

the processing of reward and punishment must be in place before more differentiated emotions can evolve. However, higher mammals, and especially highly social mammals such as primates, did evolve additional circuitry in order to permit them to respond in a more flexible and adaptive manner to environments that change rapidly in time. The most dynamic environment of all, of course, is the social environment, and keeping track of and responding rapidly and appropriately to numerous conspecifics requires a rich repertoire of emotional regulation.

The comparative and developmental investigations of emotion raise important questions about how emotion contributes to behavior and about how emotion contributes to other aspects of cognition. A point of fundamental importance is that more complex behavior, and more complex cognition, requires more complex and differentiated emotions.

V. THE FUTURE

Emotion is now a hot topic in cognitive science in general and in neuroscience in particular. Future directions can be classified under two general topics: (i) development of a theoretical framework for thinking about emotion and for generating hypotheses regarding its component processes and (ii) further empirical investigations using new methods and using new combinations of methods and species. Especially important will be studies that combine different techniques, such as functional imaging and lesion methods, and studies that combine the same paradigms in different species, such as infant humans and monkeys. Such a multifaceted approach to investigating emotion is in fact being pursued by many laboratories. Currently, neuroscientists, psychologists, and anthropologists are collaborating on several of these issues.

A very difficult, but very important, problem to address in the future is the relation between emotion and consciousness. Recent proposals, for instance, by Antonio Damasio and Jaak Panksepp, have stressed that a proper understanding of emotion may in fact provide the key to understanding one particular feature of conscious experience: the fact that consciousness is always experienced from the particular point of view of the subject. The subjectivity of conscious experience shares in common with the feeling of an emotion that it requires a neural instantiation of a subject; that is, both require a set of structures in the brain that map and represent the organism and its ongoing state changes as the organism interacts with its environment. This proposal is in line with findings that damage to right hemisphere structures involved in self-representation also impairs the ability to experience emotions. The further investigation of the neural basis of such a mechanism, and of its enormous elaboration in humans, may provide us with a better understanding not only of emotion but also of the nature of conscious experience and its role in human cognition.

Endorphins and Their Receptors

CATHERINE ABBADIE and GAVRIL W. PASTERNAK
Memorial Sloan–Kettering Cancer Center

GLOSSARY

alternative splicing A way in which different portions of a gene are put together to yield more than a single protein.

analgesic A substance capable of relieving pain without interfering with other sensations.

endorphins Peptides naturally present in the brain with morphine-like actions. They function by activating a family of opioid receptors, which are also responsible for the effects of drugs such as morphine, methadone, and heroin.

opiates Compounds acting on the opioid receptors. Initially defined by their pharmacological similarity to morphine and other analgesic alkaloids present in opium, a product of the poppy plant.

respiratory depression A decrease in breathing.

The opiates, initially derived from opium obtained from the poppy plant, have opened new insights into many aspects of functioning of the brain. The opiates have been used since ancient times and represent one of the most important classes of medications currently in use. In ancient times, opium and extracts of opium were primarily used, although opium also was smoked. Morphine and codeine were isolated and purified from opium in the 1800s, providing physicians with a pure drug with a constant level of activity. Since then, thousands of analogs have been developed in an effort avoid side effects. The structures of these agents vary greatly: however, they share many pharmacological properties.

I. INTRODUCTION

The opiates have a wide range of actions. The opiates remain the most widely used drugs for the relief of moderate to severe pain (Fig. 1). Their actions on pain perception are unique. Rather than blocking the transmission of pain impulses into the central nervous system, like local anesthetics, or working on the sensitization of pain fibers, like the antiinflammatory drugs, opiates relieve the ''suffering component'' of pain. Patients often report that the pain is still there, but it just does not hurt anymore. This ability to relieve the pain without interfering with other aspects of sensation provides a major advantage. Furthermore, opiates do not display a ''ceiling effect,'' implying that even very severe pain can be successfully relieved at sufficiently high drug doses. Unfortunately, side effects become increasingly troublesome as the dose is increased and the ability of the patient to tolerate these unwanted actions may interfere with the ability to administer adequate doses of the drug.

The actions of the opiates are not limited to pain. The additional actions most often encountered when treating patients are constipation, sedation, and respiratory depression. All these actions are mediated through opioid receptors and can be reversed by opioid antagonists, although evidence is mounting that they may be produced by different opioid receptor subtypes. Opiates influence gastrointestinal transit both centrally and peripherally. Although this action can be troublesome in pain management, it is valuable in the treatment of conditions associated with increased gastrointestinal motility, such as diarrhea.

Respiratory depression is another important opioid action. Opiates such as morphine depress respiratory

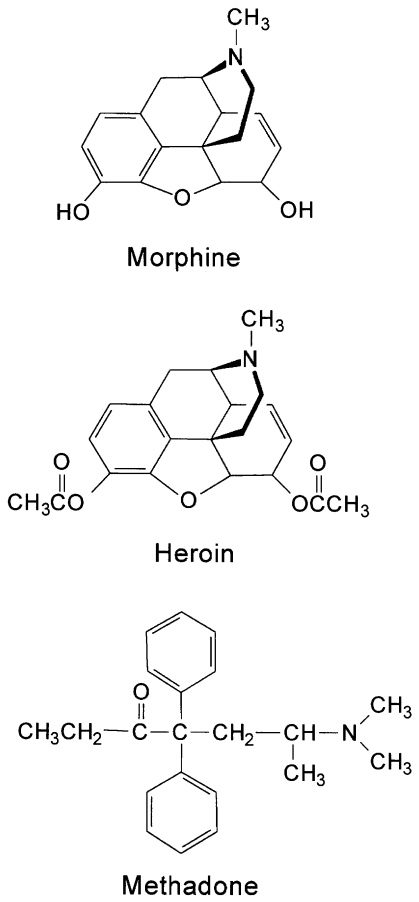

Figure 1 Structures of selected opiates.

depression in a dose-dependent manner and at sufficiently high doses breathing stops. The potential of respiratory arrest is a concern with very high doses of the drugs in naive patients, but typically it is not an issue with patients chronically on the drugs due to the development of tolerance to the action.

Sedation is also a common effect of morphine and related drugs. Indeed, morphine was initially named for Morpheus, the god of sleep. Like other opioid actions, tolerance will develop to sedation, but it may develop more slowly and to a lesser degree than tolerance to the analgesic actions of the drug. Opioids have many other actions. Their effects on the endocrine system are extensive and recent studies have also implicated them in immune function.

Morphine and related opiates produce their actions by activating receptors in the brain, mimicking a family of peptides with similar actions that are naturally occurring within the nervous system, termed the endorphins (Table I). The concept of peptide neurotransmitters has expanded dramatically, the endorphins are now only one family of many active endogenous peptides. This article discusses the four major groupings of opioid and opioid-like peptides and their receptors and also their physiological and pharmacological importance.

II. THE OPIOID AND RELATED PEPTIDES

Soon after the initial description of opioid binding sites using morphine-like radioligands, several laboratories identified endogenous peptides within the brain that bind to these opiate receptors (Table I). These peptides were then termed "endorphins," connotating their endogenous morphine-like character. Although their actions are likely to be very diverse, the only ones examined in detail involve analgesia and all the opioid peptides are active analgesics.

A. Enkephalins

The first peptides identified were the two enkephalins (Table I). These pentapeptides shared the same first four amino acids, differing only by a leucine or methionine at the fifth position. They are the endogenous ligand for the delta opioid receptor. The enkephalins are present throughout the brain and have been implicated in many actions. It is interesting that the enkephalins are present at high concentrations in the adrenal medulla, where they are colocalized with adrenalin. They also have been identified in other, nonneuronal tissues, including immune cells and the testis.

B. Dynorphins

Additional peptides with opioid-like actions were subsequently isolated. Dynorphin A is a heptadecapeptide that contains the sequence of [Leu^5]enkephalin at its amino terminus (Table I). Dynorphin A is the endogenous ligand for the kappa$_1$ receptor, although it retains high affinity for mu and delta receptors as well. Its actions were difficult to evaluate until highly selective, stable drugs were synthesized. These agents have established an important role for dynorphin A and its receptors in pain perception.

Table I
Opioid and Related Peptides

[Leu^5]enkephalin	**Tyr-Gly-Gly-Phe-Leu**
[Met^5]enkephalin	**Tyr-Gly-Gly-Phe-Met**
Peptide E (amidorphin)	**Tyr-Gly-Gly-Phe-Met-**Lys-Lys-Met-Asp-Glu-Leu-Tyr-Pro-Leu-Glu-Val-Glu-Glu-Glu-Ala-Asn-Gly-Gly-Glu-Val-Leu
BAM 22	**Tyr-Gly-Gly-Phe-Met-**Lys-Lys-Met-Asp-Glu-Leu-Tyr-Pro-Leu-Glu-Val-Glu-Glu-Glu-Ala-Asn-Gly-Gly
BAM 20	**Tyr-Gly-Gly-Phe-Met-**Lys-Lys-Met-Asp-Glu-Leu-Tyr-Pro-Leu-Glu-Val-Glu-Glu-Glu-Ala-Asn
BAM 18	**Tyr-Gly-Gly-Phe-Met-**Lys-Lys-Met-Asp-Glu-Leu-Tyr-Pro-Leu-Glu-Val-Glu-Glu-Glu
BAM 12	**Tyr-Gly-Gly-Phe-Met-**Lys-Lys-Met-Asp-Glu-Leu-Tyr
Metorphamide	**Tyr-Gly-Gly-Phe-Met-Arg-Val**
Dynorphin A	**Tyr-Gly-Gly-Phe-Leu-**Arg-Arg-Ile-Arg–Pro-Lys–Leu-Lys-Trp-Asp-Asn-Gln
Dynorphin B	**Tyr-Gly-Gly-Phe-Leu-**Arg-Arg-Gln-Phe-Lys-Val-Val-Thr
α-Neoendorphin	**Tyr-Gly-Gly-Phe-Leu-**Arg-Lys-Tyr-Pro-Lys
β-Neoendorphin	**Tyr-Gly-Gly-Phe-Leu-**Arg-Lys-Tyr-Pro
β_h-Endorphin	**Tyr-Gly-Gly-Phe-Met-**Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-Tyr-Lys-Lys-Gly-Glu
Endomorphin-1	Tyr-Pro-Trp-Phe-NH_2
Endomorphin-2	Tyr-Pro-Phe-Phe-NH_2
Orphanin FQ/nociceptin	**Phe-Gly-Gly-Phe-**Thr-Gly-Ala-Arg-Lys-Ser-Ala-Arg-Lys-Leu-Ala-Asp-Glu
Orphanin FQ2	Phe-Ser-Glu-Phe-Met-Arg-Gln-Tyr-Leu-Val-Leu-Ser-Met-Gln-Ser-Ser-Gln
Nocistatin	Thr-Glu-Pro-Gly-Leu-Glu-Glu-Val-Gly-Glu-Ile-Glu-Gln-Lys-Gln-Leu-Gln

C. β-Endorphin

The third member of the endogenous opioid family is β-endorphin, a 31-amino acid peptide that is localized primarily in the pituitary and the cells of the arcuate nucleus within the brain. The initial amino terminus of β-endorphin is identical to that of [Met^5]enkephalin, raising the question as to whether the enkephalins might simply be degradation products of longer peptides. However, this is not the case, as clearly demonstrated with the cloning of the peptide precursors.

The enkephalins and dynorphins are rapidly broken down by peptidases. Their extreme lability leads to very short durations of action, hampering early work on their pharmacology. However, substituting the glycine at the second position with a D-amino acid stabilizes the enkephalins and many stable derivatives have now been synthesized. The selectivity of these synthetic peptides for the opioid receptor classes can also be dramatically affected by their amino acid sequences. β-Endorphin, on the other hand, is more stable with a more prolonged duration of action. When steps are taken to minimize degradation, all three families of peptides share many actions, including the ability to produce analgesia. These actions are reversed by opioid-selective antagonists, confirming an opioid mechanism of action for the peptides.

D. Processing of Opioid Peptide Precursors

All these opioid peptides are generated by processing longer precursor proteins, which have been subsequently cloned. There are three distinct genes responsible for generating these peptides (Fig. 2).

1. Pre-Proenkephalin

The pre-proenkephalin gene contains four copies of Met-enkephalin and one copy each of Leu-enkephalin, the heptapeptide Met-enkephalin-Arg-Phe, and the octapeptide Met-Enkephalin-Arg-Gly-Leu (Fig. 2A). No dynorphin sequences are present within this precursor. However, the sequence of the gene predicts many additional putative peptides that also contain the sequence of met-enkephalin as the N terminus and thus might have opioid activity and be physiologically important. For example, peptide F contains [Met^5]enkephalin sequences at both its N terminus and its C terminus. The carboxy-terminally amidated peptide

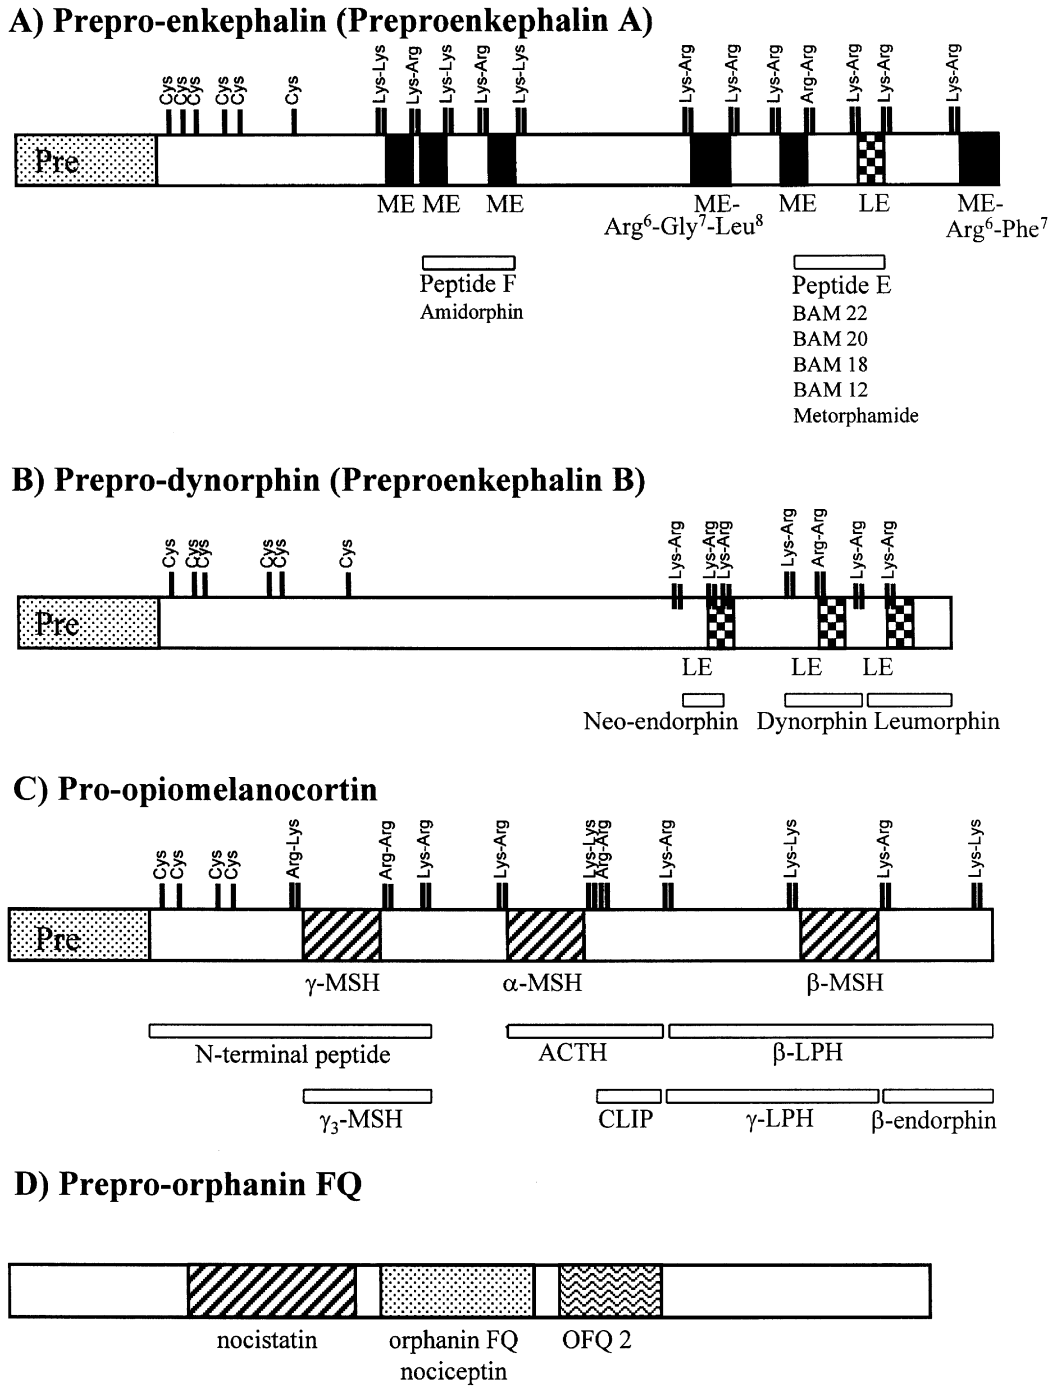

Figure 2 Structures of the precursors of the opioid peptides. Schematics of the precursor proteins for (A) the enkephalins, (B) the dynorphins, (C) β-endorphin, and (D) orphanin FQ/nociceptin.

comprising the first 26 amino acids of peptide F is named amidorphin. Peptide E has a [Met^5]enkephalin sequence at its N terminus and that of [Leu^5]enkephalin at its C terminus. Several peptides in which peptide E has been truncated at the C terminus have also been isolated: BAM 22, BAM 20, BAM 18, BAM 12, as well as an amidated octapeptide corresponding to the first 8 amino acids of peptide E termed metorphamide or

adrenorphin. The physiological significance of these additional peptides remains unclear. They may represent distinct neuropeptides with their own actions. However, the presence of dibasic amino acids following the enkephalin sequence in most of them raises the possibility that they might simply be further processed to the enkephalins. Although they were described many years ago, little work has been reported on these compounds for many years.

2. Pre-Prodynorphin

The pre-prodynorphin gene encodes a larger precursor that has many additional putative opioid peptides (Fig. 2B). The dynorphin precursor is quite distinct from the enkephalin precursor. It contains three [Leu^5]enkephalin sequences, each flanked by pairs of basic amino acids. If Lys–Arg pairs were the only processing signals, pre-prodynorphin would be cleaved into three larger opioid peptides: β-neoendorphin, dynorphin A, and leumorphine. However, several other peptides derived from pre-prodynorphin have been identified. Thus, the formation of dynorphin B results from the cleavage of leumorphin, whereas dynorphin A (1–8) is generated from dynorphin A. In addition, several larger peptides have been identified as putative processing products: a peptide containing dynorphin A at the N terminus and dynorphin B at the C-terminal end have been isolated. Dynorphin 24 contains dynorphin A with a C-terminal extension of Lys–Arg and the sequence of Leu–Enk. There is also evidence for a peptide comprising dynorphin A and leumorphin. In addition to dynorphin A (1–17), the truncated dynorphin A (1–8), and dynorphin B, this precursor also generates α-neoendorphin and β-neoendorphin. Again, the significance of these different peptides remains uncertain. Pharmacologically, they have opiate-like actions, but their physiologically relevance has not been proven.

3. Pre-Opiomelanocortin

β-Endorphin has the most interesting precursor peptide, pre-opiomelanocortin (Fig. 2C). Unlike the other opioid precursor peptides, the β-endorphin precursor makes many important, biologically active peptides that are not related to the opioid family. The precursor for β-endorphin also generates ACTH, an important stress hormone, α-melanocyte-stimulating hormone (MSH), and β-MSH. The association of β-endorphin with stress hormones is intriguing in view of the many associations between stress and a diminished perception of pain. In the pituitary, stimuli that release ACTH also release β-endorphin.

E. Endomorphins

For many years, the endogenous ligand for the mu opioid receptor was unknown. The recent identification of two tetrapeptides, endomorphin 1 and endomorphin 2, has resolved this issue. These peptides have a very interesting pharmacology and display the selectivity expected of a morphine-like, or mu, opioid peptide. It is assumed that the two peptides are also generated from a larger precursor, but this protein has not been identified. Although the evidence supporting the endomorphins is quite strong, the identification of its precursor is needed to fully establish its importance pharmacologically.

F. Orphanin FQ/Nociceptin

Recently, an opioid-related peptide has been identified termed orphanin FQ or nociceptin (OFQ/N). OFQ/N is the endogenous ligand for the fourth member of the opioid receptor gene family, ORL-1. Although it has some similarities to the traditional opioid peptides, it also has many significant differences. Like dynorphin A, OFQ/N is a heptadecapeptide (Table I) and its first four amino acids (Phe-Gly-Gly-Phe-) are similar to those of the traditional opioid peptides (Tyr-Gly-Gly-Phe-). However, OFQ/N has very poor affinity for the traditional opioid receptors, whereas the opioid peptides show no appreciable affinity for the ORL-1 receptor. Functionally, OFQ/N is also quite distinct from the opioid peptides. Although high doses of OFQ/N can elicit analgesia, low doses given supraspinally functionally reverse the opioid analgesia. The precursor for OFQ/N has been cloned, and it too contains additional putative neuropeptides, including nocistatin and OFQ2 (Fig. 2D).

III. OPIOID RECEPTORS

The opioid receptors were first demonstrated in 1973 with the binding of radiolabeled opiates to brain membranes. To date, three distinct families of opioid receptors have been identified that share many features. On the molecular level, they all are members of the G protein-coupled receptor family, which is a large

family of receptors located within membranes. Members of this receptor family span the membrane seven times, providing both intracellular and extracellular domains (Fig. 3). The opioids and opioid peptides bind to the extracellular component of the receptor and activate G proteins inside the cell. The opioid receptors are almost exclusively coupled to inhibitory systems, primarily G_o and G_i. Each receptor is encoded by a separate gene, but there is high homology between them.

A. Mu Receptors

Morphine and most clinical drugs act though the mu opiate receptors, making these receptors particularly important. Morphine has many actions, including analgesia, respiratory depression, and constipation. Early studies raised the possibility that these actions may be mediated though different subtypes of mu opioid receptors based on results using highly selective opioid antagonists. Antagonists have been developed that selectively block morphine analgesia without influencing respiratory depression and the inhibition of gastrointestinal transit. Another antagonist has also been reported that can reverse the actions of heroin without interfering with those of morphine. Thus, there is extensive pharmacological evidence for multiple subtypes of mu receptors.

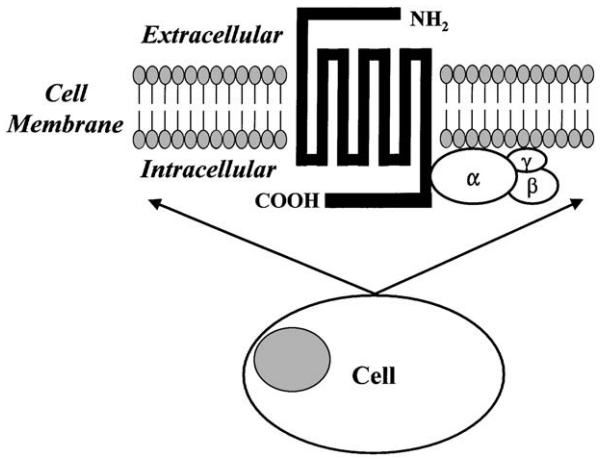

Figure 3 Structure of G protein receptors. G protein-coupled receptors span the cell membrane seven times, with the amino terminus located extracellularly and the carboxy terminus inside the cell. They are coupled to G proteins, which are composed of three subunits (α, β, and γ) and located on the inside surface of the cell. When the receptor is activated, it changes the G proteins, which then influence transduction systems.

Recently, a mu opioid receptor gene has been identified, *MOR-1* (Fig. 4). Additional cloning work has isolated seven different splice variants of this gene, implying the existence of at least seven different mu opioid receptor subtypes at the molecular level. Thus, the molecular biological approaches have uncovered far more mu receptor subtypes than even suggested from pharmacological studies. Correlating these variants with specific opioid actions is not simple. We know that a major disruption of the *MOR-1* gene eliminates all mu analgesia. However, more subtle disruptions of the gene leading to the elimination of only some *MOR-1* variants block the analgesic actions of some, but not all, mu analgesics. At this point, it appears that most mu analgesics will activate more than one mu receptor subtype. Thus, differences among the mu analgesics may reflect differences in their pattern of receptor activation.

B. Delta Receptors

Delta receptors were first found following the discovery of the enkephalins, their endogenous ligand. Early attempts to define the pharmacology of the delta receptors were limited by the lability of the enkephalins and their limited selectivity. The development of highly selective delta peptides, and recently organic compounds, has revealed important actions. Like mu receptors, activation of delta receptors produces analgesia but with far less respiratory depression and constipation. There is evidence for subtypes of delta receptors based on a series of antagonists, but functional splice variants have not been reported. The full functional significance of delta receptor systems is not entirely established.

C. Kappa$_1$ Receptors

Kappa receptors were first proposed from detailed pharmacological studies using a series of opiates long before the identification of its endogenous ligand, dynorphin A. Like the delta receptor, efforts to define kappa receptor pharmacology have been difficult due to the stability and selectivity of dynorphin A. The synthesis of highly selective ligands has helped to define the kappa$_1$ receptor, both biochemically and pharmacologically. Kappa$_1$ receptors can produce analgesia, but they do so through mechanisms different from those of the other receptor classes. However, kappa receptor ligands have also been associated with

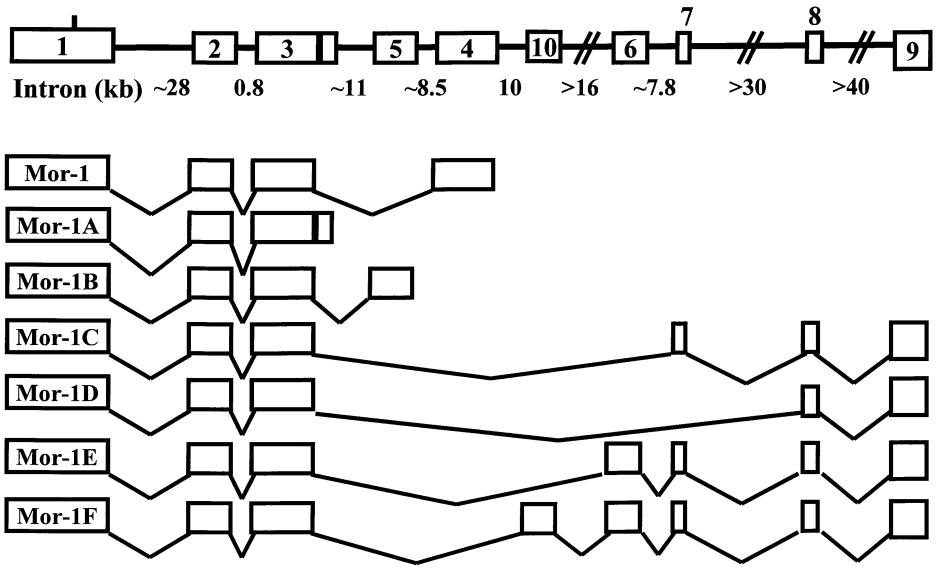

Figure 4 The murine *MOR-1* gene has been extensively studied. Ten different exons, the DNA sequences that end up in mRNA, are spliced together in different patterns to make seven different mu receptor variants. Although the human gene has not been explored as completely, there is little reason to believe that it differs significantly.

a variety of psychomimetic effects, making their clinical utility somewhat limited.

A kappa receptor with the appropriate pharmacological profile has been cloned, KOR-1. It has high homology with the other receptors and is localized within the brain. However, $kappa_1$ receptors also appear to be present in a variety of immune cells, as demonstrated by binding and molecular biological approaches.

D. The Opioid Receptor-like Receptor

A fourth member of the opiate receptor family has been cloned that is highly selective for OFQ/N. As noted previously, OFQ/N has many similarities to the opioid peptides, but it has very poor affinity for the traditional opioid receptors. Similarly, the opioid peptides do not label the ORL-1 receptor. ORL-1 has an interesting pharmacology. Evidence from both binding and pharmacological studies has suggested multiple subtypes of receptors.

The relationship of ORL-1 to the opiate family is unusual. Although there is high homology at the molecular level, traditional opiates do not bind to this site, and its endogenous ligand, OFQ/N, has poor affinity for all the opiate sites as well. It is interesting, however, that OFQ/N is also a heptadecapeptide. Functionally, the ORL-1 receptor has some unusual actions. Depending on the dose and the site of administration, OFQ/N can be a potent antiopioid peptide, functionally reversing the actions of morphine and other opioid analgesics. However, at higher doses the peptide is analgesic. Antisense mapping studies have suggested that the $kappa_3$ receptor is related to the ORL-1 receptor, but they are not identical. Thus, the pharmacology of OFQ/N and its receptor is quite complex and many issues remain to be evaluated.

E. $Kappa_2$ and $Kappa_3$ Receptors

Several other kappa receptor classes have been proposed. U50,488H is a potent and highly selective $kappa_1$ receptor agonist. Binding studies revealed additional kappa receptor binding sites insensitive to U50,488H. The first site was termed $kappa_2$ to distinguish it from the U50,488H-sensitive $kappa_1$ site. The difficulty with defining this site pharmacologically resulted from the lack of highly selective ligands. Recently, it has been suggested that the $kappa_2$ receptor may actually represent a dimer consisting of a $kappa_1$ and a delta receptor. Together, the receptors display binding characteristics quite distinct from either $kappa_1$ or delta receptors alone and may correspond to the $kappa_2$ receptor originally observed in binding studies.

The kappa$_3$ receptor was originally proposed using naloxone benzoylhydrazone (NalBzoH), which is a potent analgesic. Its actions are not reversed by highly selective mu, delta or kappa$_1$ receptor antagonists, giving it a very unique selectivity profile. Recently, its actions have been associated with the ORL-1 receptor. Antisense mapping studies revealed that KOR-3, the cloned mouse homolog of the ORL-1 receptor, and the kappa$_3$ receptor are both encoded by the same gene but are not identical and may be splice variants of the *KOR-3*/*ORL-1* gene. The exact relationship between the kappa$_3$ receptor and the *KOR-3*/*ORL-1* gene has not been completely defined.

IV. CONCLUSION

The opioid system, composed of a family of receptors and their endogenous peptide ligands, is quite important within the central nervous system. It has many functions, some of which are readily demonstrated. However, the complexity of the system is quite extensive and a full understanding is not available. Many questions remain, including the role of the many unexplored opioid peptides postulated to be generated within the brain. Furthermore, splicing appears to play a major role in generating multiple subtypes of the various opiate receptor families. Although our knowledge of this system is growing, many unknowns remain.

Epilepsy

BETTINA SCHMITZ
Humboldt University, Berlin

GLOSSARY

antiepileptic drugs (anticonvulsants) Drugs with different modes of action that prevent epileptic seizures.

epilepsy surgery A surgical treatment that includes the removal or disconnection of epileptogenic tissue and that aims at complete seizure control.

focal (partial) seizures Epileptic seizures with clinical or electroencephalographic changes indicating initial activation of neurons limited to one part of one cerebral hemisphere.

generalized seizures Epileptic seizures in which the first clinical changes indicate involvement of both hemispheres.

hippocampal sclerosis Typical pathology in mesial temporal lobe epilepsy characterized by loss of neurons in the CA1 region and endfolium (CA3/4) but with relative sparing of the C2 region.

Epilepsy is a heterogeneous condition characterized by recurrent seizures. Because the epileptic seizure is a nonspecific neurological symptom, it is important to distinguish epilepsy from isolated seizures and acute symptomatic seizures provoked by acute systemic or cerebral disorders. Epilepsy is one of the most common neurological disorders, with peak prevalence rates in early childhood and old age. Two international classification systems are used to differentiate seizure types and epileptic syndromes. The major distinction is between localization-related and generalized seizures. The former are most often symptomatic and caused by a circumscribed lesion, and the latter are typically idiopathic and associated with an inherited imbalance in excitatory and inhibitory mechanisms. There may be an association with learning disability or other neurological problems, particularly in symptomatic epilepsies. Idiopathic epilepsies are characterized by a specific age of onset, a good response to drug treatment, and a relatively benign course. The genes responsible for some rare syndromes have recently been identified; however, the suspected genetic background of the more common idiopathic epilepsies is complex and likely involves multiple susceptibility genes. The differential diagnosis of epilepsy includes a large spectrum of medical, neurological, and psychiatric disorders. The diagnosis of epilepsy is primarily based on history. Technical investigations include electroencephalography, functional and structural imaging techniques, and neuropsychological assessments. Treatment of epilepsies involves anticonvulsant drugs and behavioral recommendations and also surgery in suitable patients who are resistant to conservative strategies. Anticonvulsant drugs can be categorized into three groups according to their mode of action: GABAergic drugs, antiglutamatergic drugs, and membrane-stabilizing drugs that act through the modulation of the sodium channel. The choice of antiepiletic drugs depends on the type of epilepsy. The aim of drug treatment is complete seizure control without causing any clinical side effects.

Complications of active epilepsy are not only injuries but also psychiatric disorders such as depression. The social impact of epilepsy is more significant than with most other neurological disorders because of stigmatization and discrimination of seizure disorders. Professional training and employment are further limited by restrictions with respect to driver's licenses, working night shifts, and handling potentially dangerous machines.

I. CLASSIFICATION

How best to classify epileptic seizures and epileptic syndromes has occupied epileptologists for centuries. In the middle of the 19th century the epilepsy literature was dominated by psychiatrists who tried to systematize epilepsy based on their experiences with chronic patients in asylums. They spent more time on the psychopathological classification of psychiatric symptoms in epilepsy than on describing epileptic seizures. Specific psychiatric syndromes, especially short-lasting episodic psychoses and mood disorders, were regarded as being of equal diagnostic significance for epilepsy as convulsions.

With the introduction of electroencephalography (EEG) in the 1930s many episodic psychiatric states were identified as nonepileptic in origin. Epileptic seizures, however, showed very different ictal EEG patterns. Since then, epileptologists have concentrated on the electroclinical differentiation of epileptic seizures. Problems of terminology became obvious with increasing communication between international epileptologists in the middle of the 20th century. The first outlines of international classifications of epileptic seizures and epileptic syndromes were published in 1970. The proposed classifications by the Commission on Classification and Terminology of the International League against Epilepsy (ILAE) from 1981 and 1989 (Tables I and II) are based on agreements among international epileptologists and compromises between various viewpoints. They must not be regarded as definitive; a revision is currently being developed.

A. Classification of Seizures

Most authors in the 19th century simply differentiated seizures according to severity ("petit mal" and "grand mal"). Hughlings Jackson was the first to recognize the need for an anatomical description, physiological delineation of disturbance of function, and pathological confirmation. In the 20th century clinical events could be linked to ictal electroencephalographic findings. More detailed analysis of seizures became possible with simultaneous EEG video monitoring and ictal neuropsychological testing. In the former, patients are monitored by video cameras and continuous EEG recordings for prolonged periods. The data can be simultaneously displayed on a split-screen television monitor (Fig. 1).

The International Classification of Epileptic Seizures (ICES) from 1981 is based on this improved monitoring capability, which has permitted more accurate recognition of seizure symptoms and their longitudinal evolution. The current classification of seizures is clinically weighted and gives no clear definitions in terms of seizure origin. The ICES does not reflect our most recent understanding of the localizing significance of specific seizure symptoms, which has grown significantly since 1981 due to increased data from intensive monitoring and epilepsy surgery. Some parts of the ICES are therefore outdated and in need of revision. Complex focal seizure types, for example, are not yet distinguished according to a probable origin in the frontal or the temporal lobe.

The principal feature of the ICES is the distinction between seizures that are generalized from the beginning and those that are partial or focal at onset and may or may not evolve to secondary generalized seizures (Table I). In generalized seizures there is initial involvement of both hemispheres, reflecting an epileptogenic generator in subcortical structures. Consciousness may be impaired and this impairment may be the initial manifestation. Motor manifestations are bilateral. The ictal EEG patterns are initially bilateral. Spikes, spike–wave complexes, and polyspike–wave complexes are all typical (Fig. 2).

Focal seizures are those in which the first clinical and EEG changes indicate initial activation of a system of neurons limited to a part of one cerebral hemisphere. The other important feature of the ICES is the separation between simple and complex partial seizures depending on whether there is preservation or impairment of consciousness.

B. Classification of Syndromes

"Epilepsy is the name for occasional sudden, excessive, rapid, and local discharges of the gray matter." This simple definition was formulated by Jackson in 1866

Table I
International Classification of Epileptic Seizures[a]

Clinical seizure type	Ictal EEG
Focal (partial, local) seizures	
A. Simple partial seizures	Local contralateral discharge starting over corresponding area of cortical representation (not always recorded on the scalp)
1. With motor symptoms	
a. Focal motor without march	
b. Focal motor with march (Jacksonian)	
c. Versive	
d. Postural	
e. Phonatory (vocalization or arrest of speech)	
2. With somatosensory or special sensory symptoms (simple hallucinations, e.g., tingling, light flashes, and buzzing)	
a. Somatosensory	
b. Visual	
c. Auditory	
d. Olfactory	
e. Gustatory	
f. Vertiginous	
3. With autonomic symptoms or signs (including epigastric sensation, pallor, sweating, flushing, piloerection, and pupillary dilatation)	
4. With psychic symptoms (disturbance of higher cortical function); these symptoms rarely occur without impairment of consciousness and are much more commonly experienced as complex partial seizures.	
a. Dysphasic	
b. Dysmnesic (e.g., déja vu)	
c. Cognitive (e.g., dreamy states and distortions of time sense)	
d. Affective (fear, anger, etc.)	
e. Illusions (e.g., macropsia)	
f. Structured hallucinations (e.g., music and scenes)	
B. Complex focal seizures (with impairment of consciousness; may sometimes begin with simple symptomatology)	Unilateral or frequently bilateral discharge; diffuse or focal in temporal or frontotemporal regions
1. Simple partial onset followed by impairment of consciousness	
a. With simple partial features (as in A, 1–4) followed by impaired consciousness	
b. With automatisms	
2. With impairment of consciousness at onset	
a. With impairment of consciousness only	
b. With automatisms	
C. Focal seizures evolving to secondarily generalized seizures (this may be generalized tonic–clonic, tonic, or clonic)	Above discharge becomes secondarily and rapidly generalized
1. Simple partial seizures (A) evolving to generalized seizures	
2. Complex partial seizures (B) evolving to generalized seizures	
3. Simple focal seizures evolving to complex focal seizures evolving to generalized seizures	

(continues)

Table I *(continued)*

Clinical seizure type	Ictal EEG
Generalized seizures	
A. Absence seizures	Usually regular and symmetrical 3-Hz but may be 2–4 Hz spike and slow-wave complexes and may have multiple spike and slow-wave complexes; abnormalities are bilateral
1. Absence seizures	
a. Impairment of consciousness only	
b. With mild clonic components	
c. With atonic components	
d. With tonic components	
e. With automatisms	
f. With autonomic components	
2. Atypical absence a. Changes in tone that are more pronounced than in A.1 b. Onset and/or cessation that is not abrupt	EEG more heterogeneous; may include irregular spike and slow-wave complexes, fast activity, or other paroxysmal activity; abnormalities are bilateral but often irregular and asymmetric
B. Myoclonic seizures, myoclonic jerks (single or multiple)	Polyspike and wave, or sometimes spike and wave or sharp and slow waves
C. Clonic seizures	Fast activity (10 c/sec or more) and slow waves; occasional spike and wave patterns
D. Tonic seizures	Low-voltage, fast activity or a fast rhythm of 9–10 c/sec or more, decreasing in frequency and increasing in amplitude
E. Tonic–clonic seizures	Rhythm at 10 or more c/sec decreasing in frequency and increasing in amplitude during tonic phase, interrupted by slow waves during the clonic phase
F. Atonic seizures	Polyspikes and wave or flattering or low–voltage fast activity

[a]From the Commission on Classification and Terminology of the International League against Epilepsy (1981).

long before the introduction of electroencephalography. It has not lost its justification today. Recurrent epileptic seizures are pathognomonic for all types of epilepsies. The clinical spectrum of epilepsy, however, is much more complex and an epileptic syndrome is characterized by a cluster of signs and syndromes customarily occurring together; these include such features as type of seizure, etiology, structural lesions, precipitating factors, family history, age of onset, severity, chronicity, diurnal and circadian cycling, and prognosis.

In contrast to a syndrome, a disease is characterized by a specific etiology and prognosis. Some recognized entities in the International Classification of Epilepsies and Epileptic Syndromes (ICEES) are diseases and others are syndromes, some of which may turn out to be diseases—a specific etiology may still be discovered.

The ICEES distinguishes generalized and localization-related (focal, local, and partial) epilepsies. Generalized epilepsies are syndromes characterized by generalized seizures in which there is involvement of both hemispheres from the beginning of the seizure. Seizures in localization-related epilepsies start in a circumscribed region of the brain. The other important classification criterion refers to etiology. The ICEES distinguishes idiopathic, symptomatic, and cryptogenic epilepsies. Idiopathic means that a disease is not preceded or occasioned by another. The major pathogenetic mechanism is genetic predisposition. Symptomatic epilepsies and syndromes are considered the consequence of a known or suspected disorder of the central nervous system. In cryptogenic disorders, a cause is suspected but remains obscure, often due to limited sensitivity of diagnostic techniques.

Table II
International Classification of Epilepsies and Epileptic Syndromes[a]

- Localization-related (focal, local, and partial) epilepsies and syndromes
  - Idiopathic (with age-related onset)
  - Currently, the following syndromes are established, but more may be identified in the future:
    - Benign childhood epilepsy with centrotemporal spikes
    - Childhood epilepsy with occipital paroxysms
    - Primary reading epilepsy
  - Symptomatic
    - Chronic progressive epilepsia partialis continua of childhood (Kozhevnikov's syndrome)
    - Syndromes characterized by seizures with specific modes of precipitation
    - Temporal lobe epilepsy
      - With amygdala–hippocampal seizures
      - With lateral temporal seizures
    - Frontal lobe epilepsy
      - With supplementary motor seizures
      - With cingulate seizures
      - With seizures of the anterior frontopolar region
      - With orbitofrontal seizures
      - With dorsolateral seizures
      - With opercular seizures
      - With seizures of the motor cortex
    - Parietal lobe epilepsies
    - Occipital lobe epilepsies
- Generalized epilepsies and syndromes
  - Idiopathic, with age-related onset, listed in order of age
    - Benign neonatal familial convulsions
    - Benign neonatal convulsions
    - Benign myoclonic epilepsy in infancy
    - Childhood absence epilepsy (pyknolepsy)
    - Juvenile absence epilepsy
    - Juvenile myoclonic epilepsy (impulsive petit mal)
    - Epilepsy with grand mal seizures (GTCS) on awakening
    - Other generalized idiopathic epilepsies not defined previously
    - Epilepsies precipitated by specific modes of activation
  - Cryptogenic or symptomatic (in order of age)
    - West syndrome (infantile spasms, Blitz–Nick–Salaam Krämpfe)
    - Lennox–Gastaut syndrome
    - Epilepsy with myoclonic–astatic seizures
    - Epilepsy with myoclonic absences
  - Symptomatic
    - Nonspecific etiology
    - Early myoclonic encephalopathy
    - Early infantile epileptic encephalopathy with suppression burst
    - Other symptomatic generalized epilepsies not defined previously
  - Specific syndromes
    - Epileptic seizures may complicate many disease states. Under this heading are included diseases in which seizures are a presenting or predominant feature.
- Epilepsies and syndromes undetermined as to whether they are focal or generalized
  - With both generalized and focal seizures
    - Neonatal seizures
    - Severe myoclonic epilepsy in infancy
    - Epilepsy with continuous spike waves during slow-wave sleep
    - Acquired epileptic aphasia (Landau–Kleffner syndrome)
    - Other undetermined epilepsies not defined previously
  - Without unequivocal generalized or focal features

[a]From the Commission on Classification and Terminology of the International League against Epilepsy (1989).

1. Localization-Related Epilepsies and Syndromes

Seizure symptomatology and ictal EEG findings are the most important criteria for anatomical classification of localization-related epilepsies. As mentioned, the 1981 version of the ICES, with its emphasis on the formal structure of seizures, is of limited help in the detailed localization of seizures required in the ICEES from 1989. The 1989 classification has been criticized because reliable localization often requires invasive EEG techniques. It is hoped that with more data from taxonomic studies, clinical symptoms or symptom clusters will be identified that eventually will allow classification on clinical grounds in most cases.

Temporal lobe epilepsies are classified as those with lateral temporal seizures with auditory hallucinations, language disorders (in the case of dominant hemisphere focus) or visual illusions, and those with amygdala–hippocampal (mesiobasal limbic or rhinencephalic) seizures. The latter are characterized by simple seizure symptoms, such as increasing epigastric discomfort, nausea, marked autonomic signs, and other symptoms including borborygmi, belching, pallor, fullness of the face, flushing of the face, arrest of respiration, pupillary dilatation, fear, panic, and

Figure 1 Video recording of a complex partial seizure with secondary generalization (frontal lobe epilepsy): (a) interictal normal behavior; (b) patient pushes alarm button; (c) patient describes aura of fear; (d) automatisms: hand rubbing; (e) alternating tapping of legs; (f) patient does not respond when asked to name a pair of glasses; (g) tonic elevation of right arm; (h) generalized myoclonic movements; (i) reorientation; (j) end of seizure, patient answers adequately.

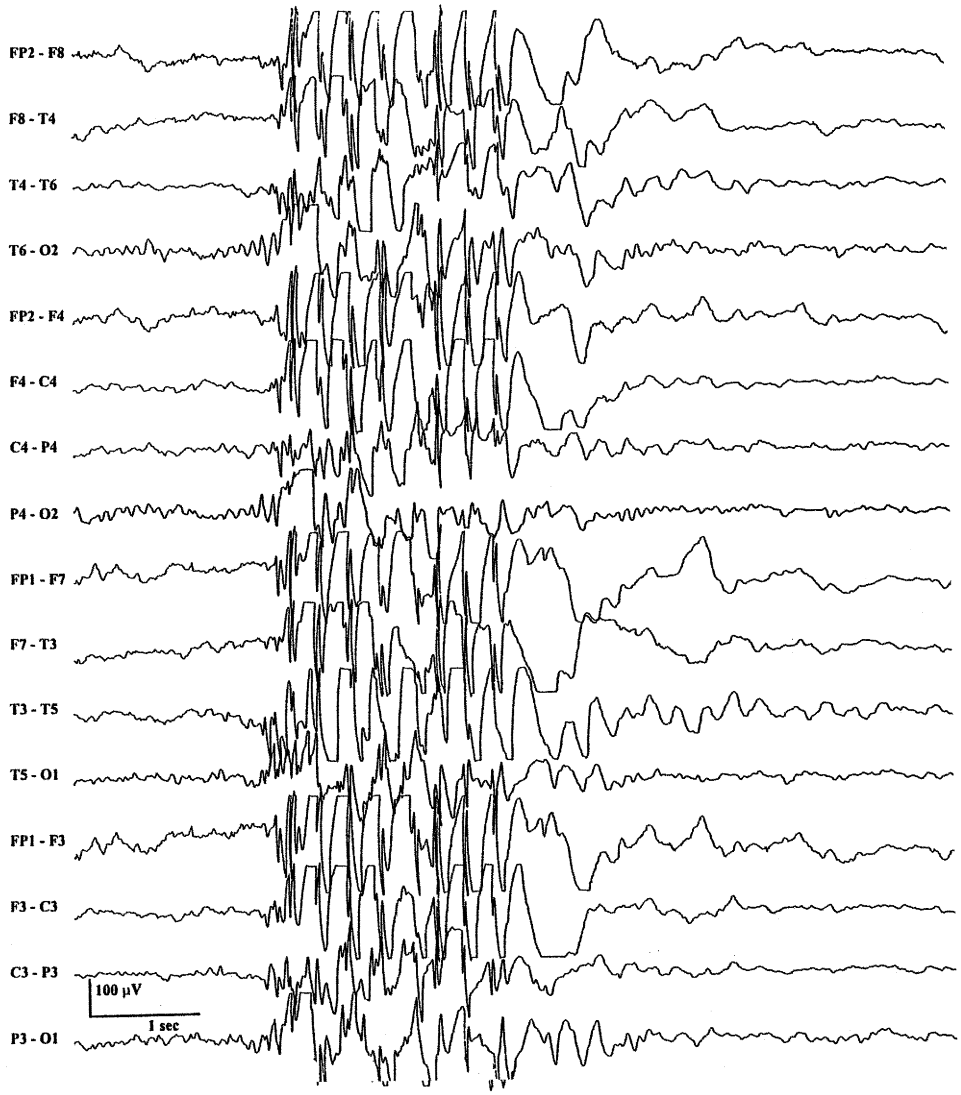

Figure 2 EEG in idiopathic generalized epilepsy (juvenile myoclonic epilepsy) with generalized polyspike–wave pattern.

olfactory hallucinations. Complex focal seizures often begin with a motor arrest, typically followed by oroalimentary automatisms. The duration is typically more than 1 min and consciousness recovers gradually.

Frontal lobe epilepsies are characterized by seizures of short duration, minimal or no postictal confusion, rapid secondary generalization, vocalization, prominent motor manifestations that are tonic or postural, complex gestural automatisms, and nocturnal clustering. Ictal scalp EEGs may show bilateral or multilobar discharges or are often normal. Accurate localization of frontal lobe epilepsies may therefore be difficult.

2. Generalized Epilepsies and Syndromes

Idiopathic generalized epilepsies are characterized by an age-related onset that reflects the ability of the brain to produce certain seizure types depending on cerebral maturation. In general, patients are asymptomatic between seizures. Radiological investigations are negative. Frequently, there is an overlap of idiopathic generalized epilepsies, especially of those manifesting in later childhood and adolescence. Response to antiepileptic drug treatment and psychosocial prognosis are good.

Symptomatic generalized epilepsies and syndromes usually start in infancy or early childhood. In most children several seizure types occur. EEG discharges are less rhythmical and less synchronous than in idiopathic generalized epilepsies. There are neurological, neuropsychological, and radiological signs of diffuse cerebral disease. The only difference between cryptogenic and symptomatic syndromes is that in cryptogenic syndromes the presumed cause cannot be identified.

3. Epilepsies and Syndromes Undetermined as to Whether They Are Focal or Generalized

There are two groups of patients who cannot be classified as focal or generalized. The first group consists of patients with both generalized and focal seizures (e.g., patients with both focal seizures and absence seizures). The second group comprises patients without unequivocal generalized or focal features (e.g., patients with nocturnal generalized tonic–clonic seizures).

4. Specific Syndromes

These are isolated seizures and situation-related syndromes, such as febrile seizures and seizures occurring only when there is an acute metabolic or toxic event due to factors such as alcohol, drugs, eclampsia, or hyperglycemia.

II. EPIDEMIOLOGY

A. Prevalence and Incidence

Epidemiological studies of epilepsy are often difficult to compare because of different study designs and definitions of epilepsy. Calculated incidence rates of epilepsy range between 20 and 70/100,000 per year. The incidence is age dependent, with a maximum in early childhood and lowest rates in early adulthood. Incidence rates rise again in older age groups, probably due to the higher prevalence of cerebrovascular disease. The overall risk for epilepsy is slightly higher in males than in females. The point prevalence of active epilepsy is of the order of 3–5/1000. The cumulative lifetime prevalence has been estimated to be 3.5%.

There is thus a 10-fold difference between the point prevalence and the lifetime prevalence, suggesting that the disease remains active in only a small proportion of cases. The prevalence of epilepsy is higher in third world countries, with rates of up to 37/1000 in Africa. This is probably related to a higher frequency of infectious diseases of the nervous system diseases such as neurocysticercosis and the higher risk of perinatal complications.

B. Relative Frequency of Epileptic Syndromes

Studies of the distribution of epileptic syndromes and epileptic seizures in the population have had conflicting results. In population-based studies, epilepsies with complex focal and focal seizures secondarily evolving to tonic–clonic seizures are most frequent, occurring in 69% of all patients. This is followed by primary generalized tonic–clonic seizures in 30% and absence or myoclonic seizures in less than 5%. In hospital-based studies, the numbers of subtle generalized seizures (absences and myoclonic seizures) are generally higher, almost certainly related to the increased accuracy and sensitivity of diagnosis.

C. Etiology

In most patients with epilepsy, the etiology remains unclear. According to an epidemiological survey in Rochester, New York, 65% of cases are idiopathic or cryptogenic. The most frequent cause of epilepsy is vascular disorder (10%), followed by congenital complications (8%), brain trauma (6%), tumor (4%), degenerative disorders (4%), and infectious diseases (3%). The etiology of epilepsy is largely dependent on the age of onset, with congenital disorders dominating in childhood epilepsies, trauma and tumors being most common in early adulthood, and cerebrovascular and degenerative disorders becoming more frequent with older age. Recent studies using advanced imaging techniques have revealed a high number of patients with subtle cortical dysgenesis or hippocampal sclerosis—patients who were formerly classified as cryptogenic.

III. PROGNOSIS

A. The Natural Course of Epilepsy

The natural course of untreated epilepsy is unknown. For obvious ethical reasons no one has ever conducted

a controlled study, and there are no systematic data from the days before antiepileptic drugs were introduced. Nineteenth century epileptologists emphasized the poor prognosis in epilepsy, but their experience was limited to institutionalized patients. Gowers (1885) believed that seizures may beget more seizures: "The tendency of the disease is to self-perpetuation, each attack facilitates the occurrence of another, by increasing the instability of nerve elements." Gowers studied the recurrence of seizures in 160 cases. A second seizure followed the first within 1 month in one-third of patients and within 1 year in two-thirds.

B. Recurrence Risk after a First Seizure

In an unselected sample of the population, isolated seizures occur in 20–40% of people with one or more seizures. It is methodologically extremely difficult to investigate the recurrence risk after an initial epileptic seizure. Estimates in the literature range between 27 and 71%, depending on inclusion criteria, duration of follow-up, and whether or not patients are treated after a first seizure. The most important source of error has been the exclusion of patients with early recurrences of seizures before presentation. The longer the interval between first seizure and inclusion into the study, the lower the recurrence rate.

The recurrence risk within 24 months of a first seizure calculated from a meta-analysis of 14 studies was 42%, with a higher risk in the group of patients with symptomatic seizures and pathological EEG findings (65%) compared to those patients with idiopathic seizures and a normal EEG (24%).

C. Prognostic Studies

Recent prospective and population-based studies have challenged previous views that epilepsy is likely to be a chronic disease in as many as 80% of cases. In a population-based survey in Rochester, 20 years after the initial diagnosis of epilepsy 70% of patients were in 5 years of remission and 50% of patients had successfully withdrawn medication. In an English study, 15 years after diagnosis 81% of patients were seizure free for at least 1 year. In another study of 104 patients who were followed up after onset of treatment, 60% were in 1-year remission after a follow-up period of 24 months. By 8 years of follow-up, 92% had achieved a 1-year remission. It is recommended that antiepileptic drugs be withdrawn after a minimum seizure-free period of 2 years or 5 years in severe cases. Relapses occur in 12–72% of patients after a 2-year remission and in 11–53% after a 3-year remission.

Approximately 5–10% of all patients with epilepsy eventually have intractable seizures despite optimal medication; most of these patients have complex partial seizures. Despite the overall favorable prognosis of epilepsy and the good response to treatment, the mortality rate of epilepsy is 2.3-fold higher than that in the general population, and it is 3.8-fold higher in the first years of the illness. The incidence of sudden unexpected death in epilepsy was estimated to be in the order of 1/525.

The prognosis of epilepsy largely depends on the syndromatic diagnosis. Idiopathic localization-related epilepsies such as Rolandic epilepsy have an excellent prognosis in all respects. Prognosis in terms of seizure remission, social adjustment, and life expectancy, on the other hand, is extremely poor in symptomatic generalized epilepsies such as West syndrome and in progressive myoclonic epilepsies.

Several studies have examined prognostic factors independent of the syndromatic diagnosis. Most studies have consistently shown that diffuse cerebral damage and neurological and cognitive deficits are associated with a poor outcome. There has been less agreement on the significance of other possible risk factors for poor prognosis, such as EEG features and positive family history of epilepsy. Whether early treatment and medical prevention of seizures improves the long-term prognosis as suggested by Gowers and indicated by experimental data from animal epilepsy models is not clear and subject to controversy. A recent Italian study showed that the treatment prognosis risk after a first seizure is not lower in patients treated with antiepiletic drugs (AEDs) compared to patients not treated after a first seizure.

IV. BASIC MECHANISMS

Epileptic syndromes are characterized by a tendency to paroxysmal regional or generalized hyperexcitability of the cerebral cortex. Because of the phenomenological diversity and the etiological heterogeneity of epilepsies, it is likely that there are multiple underlying cellular and molecular mechanisms.

The mechanisms responsible for the occurrence of seizures (ictogenesis) and the development of epilepsy (epileptogenesis) have been studied in animal models and by *in vitro* studies of surgical human brain tissue. The exact mechanisms remain to be clarified. They

represent complex changes of normal brain function on multiple levels, involving anatomy, physiology, and pharmacology. There are categorical differences in the pathophysiology of idiopathic generalized and symptomatic focal seizures. The latter are caused by a regional cortical hyperexcitation due to local disturbances in neuronal connectivity. Synaptic reorganization may be caused by any acquired injury or congenital abnormalities, such as in the many subforms of cortical dysplasia. Some areas of the brain seem more susceptible than others, the most vulnerable being mesial temporal lobe structures. The pathophysiology of hippocampal sclerosis, the most common etiology of temporal lobe epilepsy, has been a topic of much controversy. It is most likely that the hippocampal structures are damaged by an early trauma, typically prolonged febrile seizures. The process of hippocampal sclerosis involves a synaptic reorganization with excitotoxic neuronal loss, loss of interneurons, and GABA deficit.

Epileptic neurons in an epileptogenic focus may produce bursts of action potentials that represent isolated spikes in the EEG as long as they remain locally restricted. Depending on the failure of local inhibitory mechanisms, these bursts may lead to ongoing and repetitive discharges. If larger neuronal networks are recruited in this hypersynchronous activity, this leads to an epileptic seizure that is either focal or secondary generalized depending on the extent of seizure spread. The local seizure threshold is regulated by influences on excitatory and inhibitory postsynaptic potentials. The membrane excitability is regulated by ion channels that are modulated by excitatory transmitters, particularly glutamate and aspartate, and the inhibitory transmitter GABA. These three levels are the major targets for antiepileptic drugs (Table III).

Primary generalized seizures are accompanied by a bilateral synchronous epileptic activity. Therefore, they cannot be explained by cortical dysfunction alone. They are caused by an imbalance of pathways between the thalamus and the cerebral cortex. These thalamocortical circuits are modulated by reticular nuclei. Excessive GABAergic inhibition and dysfunction of thalamic calcium channels also play a role in the pathogenesis, at least in the pathogenesis of absence seizures. These cortical–subcortical circuits are also responsible for circadian rhythms, which may explain the increased seizure risk after awakening and following sleep withdrawal in idiopathic generalized epilepsies. The appearance and disappearance of primary generalized seizures is strongly age dependent, a phenomenon that has been explained by disturbances in brain maturation processes.

V. GENETICS

Genetic factors play a major role in the etiology of idiopathic epilepsies. Progress in molecular genetics has revealed several susceptibility loci and causative gene mutations in many rare human epilepsies with monogenic inheritance, such as the progressive myoclonus epilepsies. Mutations in the gene encoding the α_4 subunit of the neuronal nicotinic acetylcholine receptor gene have been identified as predisposing to autosomal-dominant nocturnal frontal lobe epilepsy. Mutations of two genes encoding potassium channels cause benign neonatal familial convulsions. A gene encoding the β subunit of the voltage-gated sodium channel has been identified in a rare syndrome called generalized epilepsy with febrile seizures plus. These findings suggest that at least some epilepsies are related to ion channel dysfunction.

Table III
Mode of Action of Old and New Antiepileptic Drugs

	Sodium channel[a]	GABA[b]	Glutamate[c]	Calcium channel[d]
Old AED				
Benzodiazepines	+	+ +	0	0
Carbamazepine	+ +	±	±	?
Ethosuximide	0	0	0	+
Phenobarbitone	+	+	+	0
Phenytoin	+ +	±	±	0
Valproate	+ +	+	±	0
New AED				
Felbamate	+	+	+ +	?
Gabapentin	±	+	±	0
Lamotrigine	+ +	0	±	0
Levetirazetam	0	0	0	0
Oxcarbazepine	+ +	0	?	?
Tiagabine	?	+ +	?	?
Topiramate	+	+	+	?
Vigabatrin	0	+ +	?	?
Zonisamide	+	±	?	?

[a]Blockade of voltage-gated sodium channels.
[b]Potentiation of GABAergic mechanisms.
[c]Blockade of glutamatergic mechanisms.
[d]Blockade of thalamic calcium channels.

In the common idiopathic generalized epilepsies, positional cloning of susceptibility genes was less successful due to the underlying complex genetic disposition. Many chromosomal regions (on chromosomes 6 and 15) are thought to harbor susceptibility genes for generalized seizures associated with juvenile myoclonic epilepsy.

In the genetic counseling of patients with epilepsies with complex modes of inheritance, empirical risk estimates are used. The recurrence risk for the offspring of probands with idiopathic generalized epilepsies is on the order of 5–10%.

VI. DIAGNOSIS

A. Clinical Diagnosis and Differential Diagnosis

Epilepsy is a clinical diagnosis, defined by recurrent epileptic seizures. The most important tool for the accurate classification and optimal diagnosis is the clinical interview. This should cover seizure-related information, such as subjective and objective ictal symptomatology, precipitation and frequency of seizures, history of seizures in first-degree relatives, and also information relevant for etiology, such as complications during pregnancy and birth, early psychomotor development, and history of brain injuries and other disorders of the central nervous system. Other important information that should be obtained refers to doses, side effects, and efficacy of previous medical or nonmedical treatment; evidence of psychiatric complications in the past; and psychosocial parameters, including educational and professional status, social independence, and psychosexual history.

The neurological examination may reveal signs of localized or diffuse brain damage. One should also look for skin abnormalities and minor stigmata suggestive of genetic diseases and neurodevelopmental malformations. There may be signs of injuries due to epileptic seizures, such as scars from recurrent falls, burns, and tongue biting. Hirsutism, gingival hyperplasia or acne vulgaris are indicative of side effects of long-term antiepileptic medication.

The clinical interview and the neurological examination are often sufficient to distinguish between epilepsy and its wide spectrum of differential diagnoses (Table IV) in most cases. However, there is a substantial problem with pseudoseizures.

For the correct interpretation of functional and structural diagnostic techniques it is important to understand that in focal epilepsies different concepts of pathological cerebral regions have to be distinguished. The epileptogenic zone is defined as the region of the brain from which the patient's habitual seizures arise. Closely related but not necessarily anatomically identical are the irritative zone, defined as the region of cortex that generates interictal epileptiform discharges in the EEG; the pacemaker zone, defined as the region of cortex from which the clinical seizures originate; the epileptogenic lesion, defined as the structural lesion that is usually related to epilepsy; the ictal symptomatic zone, defined as the region of cortex that

Metabolic disorders (e.g., hypoglycemia)
Hypertensive crisis
Endocrine disorders (e.g., pheochromocytoma)

Table V
Localization of Pathological Zones in Focal Epilepsies[a]

Epileptogenic zone	Ictal EEG with special electrode placements
Irritative zone	Interictal EEG, MEG
Pacemaker zone	Ictal EEG with special electrode placements
Ictal symptomatic zone	Ictal EEG with special electrode placements
Epileptogenic lesion	CCT, MRI
Functional deficit zone	Functional imaging, neurological examination, neuropsychological testing, nonepileptiform interictal EEG abnormalities

[a]From Lüders and Awad (1991).

generates the ictal seizure symptomatology; and the functional deficit zone, defined as the region of cortex that in the interictal period is functioning abnormally. The diagnostic techniques applied in epilepsy are characterized by a selective specificity for these various pathological regions (Table V).

B. EEG

The interictal surface EEG is still the most important method in the diagnosis and assessment of all types of epilepsy. A routine EEG is recorded over 30 min during a relaxed condition, including photic stimulation procedures and 5 min of hyperventilation. Paroxysmal discharges strongly suggestive of epilepsy are spikes, spike waves, and sharp waves. These epileptiform patterns, however, are not specific for epilepsy. They may be observed in patients suffering from nonepileptic neurological diseases and even in a small proportion of normal subjects.

The sensitivity of the routine EEG is limited by restrictions of spatial and temporal sampling. About 50% of patients with epilepsy do not show paroxysmal epileptiform discharges on a single EEG recording. Their detection depends on the epileptic syndrome and the therapeutic status of the patient. In untreated childhood absence epilepsy the EEG almost always shows generalized spike–wave complexes either occurring spontaneously or provoked by hyperventilation. In mild cryptogenic focal epilepsies, on the other hand, the interictal EEG is often negative. The temporal sensitivity can be increased by repeating the EEG or by carrying out long-term recordings with mobile EEGs. Paroxysmal discharges may also be identified by performing an EEG after sleep deprivation while the subject is asleep (Table VI).

Simultaneous video EEG recordings of seizures are useful for differentiating between different types of epileptic seizures and nonepileptic seizures. Ictal EEGs are also required for exact localization of the epileptogenic focus when epilepsy surgery is considered.

Surface EEGs record only a portion of the underlying brain activity. Discharges that are restricted to deep structures or to small cortical regions may not be detected. The spatial resolution of the EEG can be improved by special electrode placements, such as pharyngeal and sphenoidal electrodes.

Invasive EEG methods with chronic intracranial electrode placement are necessary for complex analysis in cases in which there are discordant or multifocal results of the ictal surface EEG and imaging techniques. These include foramen ovale electrodes positioned in the subdural space along the amygdala–hippocampal formation, epidural and subdural strip electrodes, and grids to study larger brain areas. Stereotactic depth electrodes provide excellent sensitivity for the detection of small areas of potentially epileptogenic tissue. The definition of exact location and boundaries of the epileptogenic region, however, is limited by the location and number of electrodes placed. Because of the limited coverage of implanted electrodes it may be difficult to distinguish whether a seizure discharge originates from a pacemaker zone or represents spread from a distant focus. Complications, the most severe being intracerebral hemorrhages, occur in 4% of patients.

Table VI
EEG Methods in the Diagnosis of Epilepsy

Interictal EEGs
Routine surface EEG
EEG after sleep withdrawal, during sleep
Mobile long-term EEG
Ictal EEG
Long-term video EEG
Special electrode placements (in increasing order of invasiveness)
Nasopharyngeal electrodes
Sphenoidal electrodes
Foramen ovale electrodes
Epidural electrodes (strips, grids)
Subdural electrodes (strips, grids)
Depth electrodes

C. Magnetoencephalography

Multichannel magnetoencephalography (MEG) is in some centers used in the presurgical assessment as a supplementary method to EEG. The electrical activity that can be measured by EEG produces a magnetic field perpendicular to the electric flow. This magnetic signal can be measured by MEG. In contrast to EEG, MEG is not influenced by intervening tissues, with the advantage of noninvasive localization of deep electric sources. Disadvantages are high costs and the susceptibility to movement artifacts, which makes it almost impossible to perform ictal studies.

D. Structural Imaging

Imaging studies should always be performed when a symptomatic etiology is suspected. Cranial computed tomography (CCT) is a quick, easy, and relatively cheap technique. The sensitivity can be improved by scanning in the axis of the temporal lobe (in cases of Temporal Lobe Epilepsy) and by using intravenous contrast enhancement. Except for a few pathologies such as calcifications, magnetic resonance imaging (MRI) is superior to CCT in terms of sensitivity and specificity in detecting epilepsy-related lesions such as malformations, gliosis, and tumors. With optimized MRI techniques, including T2-weighted images, inverse recovery sequences, and coronal images perpendicular to the hippocampus and thin sections, the sensitivity in depicting mesial temporal sclerosis reaches 90% (Fig. 3). Diagnosis of hippocampal pathology can be improved by quantitative MRI techniques such as T2 relaxometry and volumetric studies.

MR spectroscopy (MRS) is a noninvasive method for measuring chemicals in the body. MRS does not produce images but instead generates numerical values for chemicals. With phosphate spectroscopy it is possible to study energy metabolism in relation to seizure activity. Proton MRS is a technique that measures neuronal density, which has been found to be significantly decreased in the mesial temporal lobe of patients with mesial temporal sclerosis. MRS is a time-consuming procedure and therefore not routine.

E. Functional Imaging

Single photon emission computed tomography (SPECT) in epilepsy has mainly been confined to the imaging of cerebral blood flow in focal epilepsy. The tracer most widely used is ^{99}Tc-HMPAO. Interictally, there is localized hypoperfusion in an area extending beyond the epileptogenic region. Initially, there was considerable skepticism about the clinical value of the technique because the early studies were of low resolution and the correlations with electroencephalographic findings were imprecise. The sensitivity of interictal focus detection of SPECT in the literature ranges from 40 to 80%. In recent years there have been major technical developments in instrumentation. Using brain-dedicated multiheaded camera systems, the sensitivity of SPECT is similar to that of [^{18}F] fluorodeoxyglucose (FDG) positron emission tomography (PET).

^{99}Tc-HMPAO is distributed within a few minutes after injection in the brain, where it remains fixed for about 2 hr. If the radioisotope is injected during or shortly after an epileptic seizure, scanning can be carried out postictally without problems due to involuntary movements. Postictal and ictal SPECT is more sensitive than interictal SPECT and typically shows hyperperfusion ipsilateral to the epileptogenic

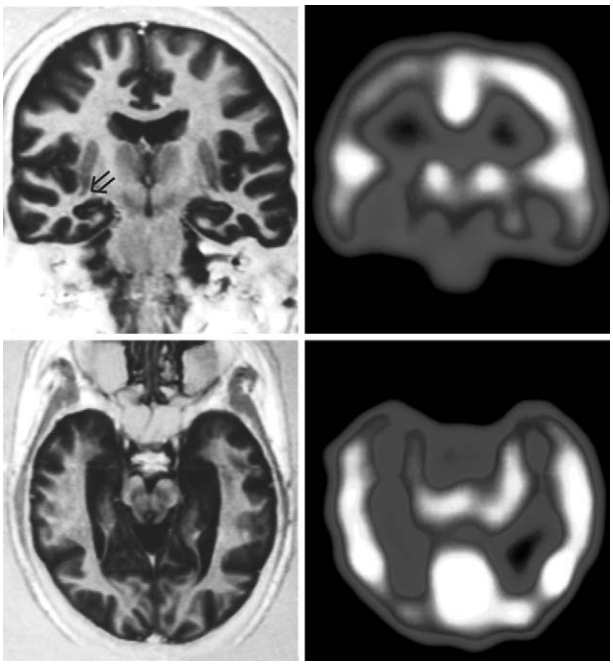

Figure 3 Imaging findings in temporal lobe epilepsy with hippocampal sclerosis. Left: MRI coronal (top) and horizontal (bottom), inversion recovery sequence. Hippocampal sclerosis (arrow). Right: Interictal HMPAO SPECT shows extensive ipsilateral hypoperfusion.

focus. Another ligand used for SPECT is ^{123}I-iomazenile, which is used to demonstrate benzodiazepine receptor binding, which is decreased in the epileptogenic region.

Compared to SPECT, PET is superior with respect to spatial and contrast resolution. PET, however, is expensive and requires an on-site medical cyclotron. Ictal studies are difficult with PET because of the short half-life of positron emitting radioisotopes. PET has mainly been used to study interictal blood flow with nitrogen-13-labeled ammonia and oxygen-15 and also glucose metabolism with FDG in focal epilepsy. Localized hypoperfusion and hypometabolism in the epileptogenic area as shown by PET are seen as a reliable confirmatory finding in the presurgical assessment of temporal lobe epilepsy. PET has also been used for imaging of benzodiazepine receptor binding and opiate receptor binding in epilepsy.

The major application of functional MRI in epilepsy is the noninvasive mapping of eloquent cortex in the presurgical evaluation of patients based on activation studies. The clear advantage over PET is the superior spatial resolution, which is on the order of 3 mm. The coregistration of a high-resolution MRI allows excellent localization of activated regions.

F. Neuropsychology

Identification of neuropsychological deficits is important for optimizing education, professional training, and rehabilitation in patients with epilepsy. Another aim of neuropsychological testing is to establish cognitive effects of antiepileptic drugs, seizure frequency, and ''subclinical'' EEG activity.

In the presurgical assessment neuropsychological evaluation is used to identify localizable deficits that can be related to the epileptogenic lesion. Crucial for lateralizing temporal lobe epilepsies is the function of verbal and nonverbal memory. Another neuropsychological task in the presurgical assessment is forecasting postsurgical cognitive outcome, which sometimes requires the intracarotid sodium amylobarbital procedure (Wada test).

G. Magnetic Cerebral Stimulation

Recently, magnetic cerebral stimulation has been used to lateralize the epileptogenic region in focal epilepsies. The technique of repetitive stimulation is also being evaluated for antiepileptic properties.

VII. TREATMENT

Once a diagnosis of epilepsy has been made and the decision to treat has been taken, many options are available. Pharmacological, surgical, and behavioral approaches may be taken. The majority of patients with epilepsy are treated with anticonvulsants. Recently, there has also been renewed interest in attempts at behavioral and nonpharmacological approaches to the management of seizures. A minority of patients with drug-resistant epilepsy may proceed to have surgery.

These strategies should not be viewed as being mutually exclusive. Hence, although in the following section, these treatments will be described separately, in practice they may be combined. Indeed, if surgery is pursued it is very likely that patients will receive antiepileptic medication both before and after the operation.

A. Antiepileptic Drugs

Ideally, patients should be managed on a single drug that leads to complete seizure freedom without causing any side effects. Approximately 75% of patients with epilepsy can be fully controlled on monotherapy (50% with initial monotherapy and 25% with second monotherapy), with the choice of agent determined by the epilepsy syndrome and seizure type (Table VII). Carbamazepine and valproate are the recommended substances for simple, complex partial, and secondary generalized tonic–clonic seizures. For most generalized seizures, sodium valproate is the most useful treatment. These drugs are generally thought of as the first-line treatments. Of the remaining patients not controlled on monotherapy, addition of another first-line drug will gain control in 15%. However, some patients will develop chronic seizures unrelieved by these treatments. In such circumstances, alternative monotherapies or adjunctive therapies will be considered. Many of the recently introduced anticonvulsants, often considered as second-line treatments, may be introduced, either alone or in combination with a first-line agent.

In Europe and the United States, nine novel anticonvulsants have been introduced in the past decade: vigabatrin, lamotrigine, felbamate, tiagabine, gabapentin, oxcarbazepine, topiramate, levetiracetam, and zonisamide. Because of serious side effects, two of these drugs are used only in a highly selected group of patients. Felbamate has caused fatal hepatotoxic and

Table VII
Selection of Antiepileptic Drugs According to the Epileptic Syndrome

Type of syndrome	First-line drugs	Second-line drugs
	Focal epilepsies	
All seizure types	Carbamazepine	Lamotrigine
	Valproic acid	
		Gabapentin
		Topiramate
		Tiagabine
		Levetiracetam
		Oxcarbazepine
		Phenytoin
		Clobazam
		Primidone
		Acetazolamide
		Vigabatrin
		Felbamate
	Generalized epilepsies	
Idiopathic		
Absences	Ethosuximide	Lamotrigine
	Valproic acid	
Myoclonic	Valproic acid	Lamotrigine
		Primidone
		Levetirazetam
Awakening grand mal	Valproic acid	Lamotrigine
		Primidone
		Topiramate
Symptomatic		
West syndrome	Vigabatrin	Clobazam
	ACTH	
	Valproate	
Lennox–Gastaut syndrome	Valproic acid	
		Lamotrigine
		Clobazam
		Topiramate
		Felbamate

hematotoxic adverse events, and vigabatrin leads to irreversible visual field constriction in 30% of patients.

An important feature in the clinical use of the first-line treatments is therapeutic drug monitoring (TDM). This should not be done as a routine procedure, but it may be useful in certain circumstances (e.g., to detect noncompliance and to explore changes in pharmacokinetics). There are significant interindividual variations in the relationship between drug levels and clinical side effects. Therefore, the measurement of serum concentrations should not be used for the optimization of treatment (with few exceptions); decisions to alter dosages should be based on efficacy and tolerability of AEDs. For appropriate agents, indications for TDM may include drug initiation or dose change, investigation of the absence of or change in therapeutic response, investigation of suspected toxicity, and situations in which pharmacokinetics may change such as during pregnancy and related to renal or hepatic disease. Sampling should occur once steady state has been achieved, four to six half-lives after treatment has been modified or introduced. TDM is particularly important for phenytoin because its hepatic metabolism is saturable and therefore a small increase in dose can result in a disproportionate and unpredictable increase in serum concentration.

B. Behavioral Treatment

Pharmacological treatments of epilepsy are not uniformly successful. Even if good seizure control is obtained, many patients experience troublesome side effects of treatments that must often be continued for many years. The need to take medication on a long-term basis has obvious implications for women wishing to become pregnant. In addition, many individuals describe feelings of oppression and an increased fear of being labeled as ill because of their ongoing need for regular drug taking. Surgical treatment is only an option for a minority of patients and is also not without physical and psychological sequelae. That alternative treatment approaches should be sought is therefore not surprising.

It has been suggested that many patients with epilepsy have a mental mechanism that they use in an attempt to inhibit their seizures. In one study of 70 patients, 36% claimed that they could sometimes stop their seizures. A behavioral approach to the treatment of epilepsy is based on observations that epilepsy can be manipulated in a systematic way through environmental, psychological, and physical changes. The initial stage in this approach is a behavioral analysis of the ways in which environmental and behavioral factors interact with seizure occurrence.

It has been demonstrated that significant reductions in seizure frequency may be achieved by teaching patients a specific contingent relaxation technique that they must be able to employ rapidly when they identify

a situation in which they are at high risk of having a seizure. In a subsequent study of three children with intractable seizures it was found that contingent relaxation alone did not significantly reduce seizures but that such a reduction was obtained following the addition of specific countermeasures aimed at changing the arousal level relevant to and contingent on early seizure cues—for instance, suddenly jerking the head to the right when it would habitually move to the left with a feeling of drowsiness at the onset of a seizure.

Some patients suffer from reflex seizures in that their seizures are precipitated by external stimuli. A proportion of people can identify specific environmental or affective triggers and may be able to develop specific strategies to abort or delay a seizure. These methods may involve motor or sensory activity or they may be purely mental. However, in one study it was found that 50% of patients who inhibited their seizures at times had to "pay the price in subsequent discomfort."

Primary seizure inhibition describes the direct inhibition of seizures by an act of will; for instance, a man whose seizures were precipitated by a feeling of unsteadiness dealt with this by keeping his gaze fixed on a point when walking down an incline. The nature of the successful act varies from person to person, and if this treatment approach is to be pursued then it must be tailored to each individual, based on an analysis of their seizures and of any actions they may already have noticed modify their seizures.

The term secondary inhibition is employed by Fenwick to describe behavioral techniques that are thought to act by changing cortical activity in the partially damaged group 2 neurons around the focus without deliberately intending to do so, thereby reducing the risk both of a partial seizure discharge and of a generalized seizure discharge that may otherwise follow recruitment of surrounding normal brain by group 2 neurons firing abnormally. An example of this is the act of maintaining alertness by a patient whose seizures appear in a state of drowsiness. Treatment in this case starts with trying to identify situations in which the subject reliably tends to have seizures or, alternatively, to be free of them.

In addition to these seizure-related approaches, more general psychological strategies have also been investigated. Several anecdotal reports have been published demonstrating benefit from reward programs that aim to reward seizure-free periods. Based on the observation that some patients with olfactory auras can prevent progression of the seizure by applying a sudden, usually unpleasant olfactory counterstimulus, "aromatherapy" techniques have been studied in the control of epilepsy. Currently, it is not clear what the relative contributions of specific olfactory stimuli and the general relaxation that is a part of the treatment are to any clinical benefit that might be observed.

Specific biofeedback techniques have also been explored. Measurement of scalp electrical activity has demonstrated that there is an increase in surface-negative slow cortical potentials (SCPs) in the seconds before a seizure occurs. These SCPs represent the extent to which apical dendrites of cortical pyramidal cells are depolarized and hence indicate neuronal excitability. Studies using visual feedback of this effect have demonstrated that some patients are able to modulate cortical electrical activity with an associated decrease in seizure frequency. However, it appears that patients with epilepsy are less able than normal controls to regulate their cortical excitability. This impairment can be minimized by extending the amount of training received by those with epilepsy. In a study that gave 28 1-hr training sessions to 18 patients followed up for at least 1 year, 6 became seizure-free. However, not every patient who achieved reliable SCP control experienced a reduction in seizure frequency.

It has been noted that the teaching of any of these methods of self-control of seizures may increase morale not only by reducing seizures but also by providing patients with a sense of control over their epilepsy. An important aspect of many "nonmedical" treatments of epilepsy is that although still of very limited proven benefit, they aim to consider seizures in the wider setting of the patient's life. In mainstream clinical management it is sometimes easier to focus purely on seizure response to the latest change in anticonvulsant therapy.

C. Surgical Treatment

In all patients with persistent epilepsy unrelieved by AED treatment, it is appropriate to consider surgical intervention. The aim of epilepsy surgery is the removal of the epileptogenic brain tissue in order to achieve seizure control without causing additional iatrogenic deficits. Only in rare cases, such as those with diffuse pathology and catastrophic seizures, are palliative surgical procedures performed. Approximately one-third of patients with refractory epilepsy are suitable for epilepsy surgery. The prerequisites of surgery are frequent epileptic seizures and a minimum

of 3–5 years of unsuccessful AED treatment including at least two first-line AEDs in monotherapy and combination. This is a minimal condition that only applies to patients who are ideal candidates for epilepsy surgery. These are patients with unilateral mesial temporal lobe epilepsy and hippocampal sclerosis, extratemporal epilepsies with localized structural lesions, and some types of catastrophic epilepsies in childhood. The poorer the individual prognosis of surgery, the longer the requested presurgical attempts to achieve seizure control with AEDs and complimentary nonsurgical treatments.

1. Presurgical Assessment

Treatment centers that engage in routine surgical management of epilepsy generally have a standardized assessment process for patients being considered for such treatment. Although the program may vary between centers, the general procedure is similar. A first hypothesis with respect to the suspected epileptogenic region is based on clinical history, neurological examination, and interictal EEG. These procedures focus particularly on searching for etiological factors, evidence of localizing signs and symptoms, and a witnessed description of the seizures. In addition, psychosocial information must be gathered relating to education, employment, social support, and past and present mental state findings. In a second step of presurgical assessment, all patients undergo more specific investigations. In general, these include several days of continuous video telemetry using surface electrodes. The aim of telemetry is to obtain multiple ictal recordings, which give more valuable localizing information than interictal records. Often, patients will reduce their AED prior to telemetry in order to facilitate the occurrence of seizures. Recent advances in structural and functional neuroimaging have made invasive EEG recording less necessary. MRI using optimized techniques has increased the sensitivity for the detection of subtle structural lesions not seen on CCT and standard MRI and is now used routinely. Functional imaging techniques using SPECT and PET are used to further delineate the epileptogenic region. If results from all investigations are concordant, patients will have surgery. If results are discordant, invasive EEG recordings using subdural grid electrodes or intracerebral depth electrodes may be applied in order to identify the critical epileptogenic region.

All patients being considered for epilepsy surgery should have a neuropsychological assessment. This is important both to detect focal brain dysfunction and to predict the results of surgery, especially temporal lobe surgery. The intelligence quotient may be measured using the Wechsler Adult Intelligence Scale. In some centers a score of less than 75 has been taken as evidence of diffuse neurological disorder and, hence, as a relative contraindication to surgery. It is important before proceeding to surgery to investigate the hemispheric localization of language and memory. This is generally performed using the Wada test. Sodium amylobarbitone is injected into one internal carotid artery, and while that hemisphere is briefly suppressed language and memory tests are performed. The procedure is then repeated for the other hemisphere.

2. Surgical Procedures

Many surgical procedures have been developed. Most patients who undergo surgery suffer from temporal lobe epilepsy. Most of these patients undergo one of two standard procedures: two-thirds anterior resection or amygdala hippocampectomy. In extratemporal epilepsies, lobectomies, lesionectomies, or individually "tailored" topectomies are performed. The latter techniques may involve preoperative stimulation in order to identify eloquent brain tissue that should be preserved from resection. A palliative method that can be applied in functionally crucial cortical regions is multiple subpial resections, which interrupt intracortical connections without destroying the neuronal columns that are necessary for normal cerebral function. Another palliative method that is performed mainly in patients with epileptic falls is anterior or total callosotomy.

3. Prognosis and Complications

The outcome of epilepsy surgery is classified according to four categories: class 1, no disabling seizures; class 2, almost seizure free; class 3, clinical improvement; and class 4, no significant improvement. According to a meta-analysis of 30 surgical series with a total of 1651 patients, seizure outcome is as follows: class 1, 59%; class 2, 14%; class 3, 15%; and class 4, 12%. In this study, predictors of a good surgical outcome were febrile seizures, complex partial seizures, low preoperative seizure frequency, lateralized interictal EEG findings, unilateral hippocampal pathology on MRI, and neuropathological diagnosis of hippocampal sclerosis. Predictors for a poor outcome were generalized seizures, diffuse pathology on MRI, normal histology of removed tissue, and early postoperative seizures.

Relative contraindications for temporal lobe resections are extensive or multiple lesions, bilateral

hippocampal sclerosis or dual pathology within one temporal lobe, significant cognitive deficits, interictal psychosis, multiple seizure types, extratemporal foci in the interictal EEG, and normal MRI. The ideal patient has mesial temporal lobe epilepsy due to unilateral hippocampal sclerosis of the nondominant hemisphere. A negative MRI decreases the chances of surgery for seizure control and a focus in the dominant hemisphere increases the risk of postoperative neuropsychological deficits.

The nature of potential perioperative complications and postsurgical neurological, cognitive, and psychiatric sequelae depends in part on the site of surgery. Operative complications occur in less than 5% of patients. In two-thirds of patients who undergo temporal resection of the dominant hemisphere, verbal memory is impaired. Another possible complication of epilepsy surgery is psychiatric disorder. Only rarely does this manifest as *de novo* psychosis. Many patients, however, will go through a phase of depression and increased anxiety following surgery. Therefore, most surgery centers include a psychiatric assessment in the preoperative phase and also a psychiatric follow-up in order to avoid catastrophic reactions (including suicide) to either the failure of surgery or the success of surgery, which requires far-reaching psychosocial adjustment.

4. Vagal Nerve Stimulation

A different surgical approach is that of vagal nerve stimulation (VNS) using an implanted stimulator. This approach has the drawback that while the nerve is being stimulated, usually for 30 sec every 5–10 min, the voice changes. More intense stimulation may be associated with throat pain or coughing. Nevertheless, in one series of 130 patients, mean seizure frequency decreased by 30% after 3 months and by 50% after 1 year of therapy. Altogether, 60–70% of the patients showed some response, but seizure freedom has rarely been achieved. Therefore, VNS is only indicated in patients who are pharmacoresistant and who are not suitable for resective epilepsy surgery.

VIII. STATUS EPILEPTICUS

Status epilepticus (SE) is defined as a condition in which a patient has a prolonged seizure or has recurrent seizures without fully recovering in the interval. With respect to the most severe seizure type (primary or generalized tonic–clonic) a duration of 5 min is sufficient for diagnosis of status epilepticus. SE may occur in a person with chronic epilepsy (the most frequent cause being noncompliance) or in a person with an acute systemic or brain disease (such as hypoglycemia or stroke). The classification of SE follows the international classification of epileptic seizures. In clinical praxis, often only two major types are distinguished: convulsive and nonconvulsive status epilepticus. SE, particularly convulsive SE, is a life-threatening condition that requires emergency treatment. Prolonged seizure activity causes systemic complications and brain damage.

The incidence of SE is 50/100,000. In all studies the convulsive type is most common (80%). However, nonconvulsive SE is difficult to recognize and may therefore be underrepresented in epidemiological studies. Mortality of SE is on the order of 20%. Prognosis and response to treatment largely depend on the etiology of SE. SE occurring in the context of chronic epilepsy has a much better outcome than SE complicating acute processes (such as hopoxemia). SE should always be managed on an emergency ward. Traditionally, drug treatment of SE includes the immediate intravenous administration of a fast-acting benzodiazepine such as diazepam plus phenytoin. Alternatively, lorazepam may be used alone because its pharmacokinteics are such that the medium-term control is comparable to that of phenytoin. If SE persists, phenobarbitone is an alternative, with the next step being a general anesthesia using pentobarbital or propofol .

IX. PSYCHIATRIC AND SOCIAL ASPECTS OF EPILEPSY

A person with epilepsy, particularly if seizures are not immediately controlled, carries an increased risk of developing psychiatric complications. These may be related to the psychological burden of a disorder that is characterized by unpredictable loss of control and is often stigmatized in modern societies. Other risk factors are biological and include the consequences of recurrent epileptic cerebral dysfunction as well as the potentially negative psychotropic effects of AEDs. Psychoses in epilepsy can occur in direct relationship to seizure activity, most often triggered by a series of seizures. They may also occur when seizures are controlled—so-called "alternative psychoses" due to "forced normalization." More common than psychoses are depressive syndromes, and suicide accounts for about 10% of all deaths in persons with epilepsy. Other psychiatric disorders that are common in

epilepsy are anxiety disorders and the coexistence of epileptic and nonepileptic pseudoseizures.

Epileptic seizures have a significant impact on the social life of a person with epilepsy. Depending on the type and frequency of seizures, patients are restricted in terms of their professional options as well as their leisure time activities. In all countries there are restrictions on driving. Patients and relatives often have false ideas about the nature and course of epilepsy and therefore need to be informed about individual dangers, restrictions, and liberties. Therefore, optimal treatment of epilepsy is a multidisciplinary and enduring task, in which not only the doctor but also the social worker and the psychologist play a significant role.

Event-Related Electromagnetic Responses

JOHN S. GEORGE
Los Alamos National Laboratory

GLOSSARY

electroencephalography (EEG) The noninvasive measurement of electrophysiological activity of the brain using electrodes attached to the scalp surface.

endogenous response An event-related response associated with voluntary movement, decision-making, or cognitive or other neural activity associated with internal processes of the experimental subject.

event-related potential (ERP) A spatiotemporal pattern in EEG data associated with a discernible event such as delivery of a stimulus or voluntary motion. The MEG analogs of these responses are sometimes called event-related fields.

event-related synchronization–event-related desynchronization (ERS–ERD) Neural population responses apparent as a resetting or reorganization of ongoing oscillatory activity.

evoked response An event-related response associated with sensory information processing of an external stimulus.

forward problem Computation of the physical consequences (e.g., an observable magnetic field or potential distribution at the head surface) associated with an assumed pattern of neural activation and a model of the properties of the head.

inverse problem Estimation of patterns of neural activation that can account for an observed pattern of experimental measures.

latency The timing of a response component or other feature relative to a defining event. Originally used to denote the period before any response was apparent (i.e., the latent phase of the response), in present usage often used to identify the peak of a response component.

magnetoencephalography (MEG) The magnetic analog of EEG, measuring magnetic fields associated with neural currents using ultrasensitive superconducting instrumentation.

response components Reproducible features in an event-related response. Typically identified on the basis of peaks and valleys in the response waveform in early work, components may be discriminated on the basis of response field topographies, consequences of stimulus properties, effects of behavioral modulations, or other criteria.

source localization Identification of the regions of neural activation that give rise to externally observable electromagnetic responses or other evidence of neural activation.

Event-related responses are spatial–temporal patterns of physiological responses associated with neural population activity, elicited by external stimuli or internal imperatives. Because these signals typically are much smaller than the ongoing activity, signal averaging, correlation, or related signal processing strategies are employed to recover the response.

I. INTRODUCTION

The function of neural systems, from the feeding and avoidance behaviors of the simplest multicellular organisms to the highest cognitive functions of the human brain, depends on dynamic spatial and temporal patterns of activation within linked networks of excitable cells. In the human brain, most purposeful function is mediated by correlated activity in substantial populations of neurons. The physical

and physiological consequences of this activity can be detected with noninvasive measurement techniques, including electroencephalography (EEG) and magnetoencephalography (MEG). These techniques measure the integrated activity of thousands to hundreds of thousands of neurons. Many cells operating in synchrony are required to generate fields that can be detected centimeters away from the source. Fortunately, neural activation typically involves large clusters of neurons with similar response properties.

The information processing activities of individual neurons depend on a chain of biophysical processes: the integration of synaptic input (both excitatory and inhibitory) throughout the dendritic tree; electrical excitation mediated by the biophysical properties of ionic channel proteins in the cell membrane; transmission mediated by active and passive physical processes in the neuronal axon; and chemical or electrical relay of activation at the synapses on target cells. By linking together collections of excitable cells, networks can achieve complex behaviors beyond the capacity of individual cells.

MEG and EEG are not the only methods that can be employed with event-related and evoked response techniques. Essentially any technique that records a consistent transient response to neural activation can be used. Optical imaging methods employing sensitive video cameras have been used to record event-related responses from exposed brain tissue in experimental animals and in humans undergoing neurosurgery. With small animals such as rats or mice, it is possible to acquire images of reasonable quality though the skull. Most studies to date have exploited changes in blood flow and oxygenation associated with neural activation—the same processes that serve as the basis of fMRI. Studies have shown that it is possible to image fast intrinsic responses of neural tissue with high-performance video technology *in vivo*. Fast optical responses tightly coupled with the electrophysiological processes of neural activation were described at least 30 years ago, and the roots of such work go back much farther.

Other investigators have recorded optical evoked responses from human subjects using noninvasive methods, i.e., by injecting and recording light at the head surface to detect changes in the optical properties of tissue buried deep beneath the skull. Impedance tomography techniques have been used in a similar way to detect transient changes in tissue conductivity associated with neural activity. Even sensitive temperature measurement techniques, based on thermal emission of infrared photons, or, more recently, MRI-based methods have been used to record event-related responses associated with neural activation.

Event-related experimental paradigms have been demonstrated with functional MRI (fMRI), in spite of the facts that the earliest detectable hemodynamic responses require several hundred milliseconds and that the response peaks several seconds after neural electrophysiological activation. It is possible to use sophisticated selective averaging or correlation techniques to identify fMRI evoked responses that are highly overlapping due to rapid stimulation rates.

MRI has other important and unique roles in functional neuroimaging. MRI is used to identify and visualize the anatomical substrate of functional activation through coregistration with other imaging modalities. MRI can be used to define the computational geometries required to model the physics of techniques such as MEG and EEG, facilitating three-dimensional (3D) source localization on the basis of data that is surface-based and, thus, topographic. By defining the geometry of cortex, MRI provides useful constraints on ill-posed source localization procedures. Functional MRI provides an alternative measure of neural activation that can increase confidence in the results of comparative or integrated analysis based on multiple imaging modalities. Event-related fMRI techniques allow the same experimental paradigms to be used for NEM and fMRI experiments, a useful feature for most purposes and a prerequisite for simultaneous measurements, for example, combining EEG and fMRI.

We will consider a range of methods within this article, but the major focus will be on neural electromagnetic measurement (NEM) techniques (MEG and EEG) and noninvasive measurements of neural population responses. These methods have challenges and limitations for localizing the source of neural responses, but the excellent temporal resolution of these responses can be exploited by clever experimental paradigms to probe the dynamic interactions between multiple cortical regions. These interactions serve as the basis of information processing and control by the human brain.

II. PHYSIOLOGICAL AND PHYSICAL BASIS OF NEM RESPONSES

A. Single-Unit Electrophysiological Responses

Much of our understanding of neural function stems from electrophysiological studies of single neurons. By

placing microelectrodes made of wire or drawn glass capillary tubing into or next to neurons, it is possible to record signals generated by one or a few cells. Because of the stereotypical shape and amplitude of action potentials (spikes) recorded from a given cell in a given recording configuration, it is often possible to sort a complex record into contributions from a small set of cells. The intensity of neuronal activation is typically assessed on the basis of firing rate; in sensory systems, the intensity of a stimulus is often encoded logarithmically in the firing rate within the sensory nerve. The response properties of neurons are often defined in terms of the *receptive field*, the region of sensory parameter space (e.g., location on the retina or stimulus properties of an auditory or visual stimulus) that can influence the firing rate of a particular neuron. A growing body of evidence shows that the temporal pattern of firing may also encode information. For example, in measurements across an ensemble of auditory nerve fibers in response to a pure tone stimulus below 1 kHz or so, spikes tend to occur in phase with the stimulus, i.e., a temporal code captures the temporal structure of the stimulus. In the visual system, phase-locked oscillatory activity in widely spaced cells appears to encode higher order features, such as coherent motion, beyond the spatial limits of the conventional receptive field.

B. Multiple Areas, Discrete Sources

Macroscopic electrophysiological techniques can resolve the course of neural population activation with sub-millisecond temporal resolution. This is adequate to detect the synchronous volley of action potentials that can result from electrical stimulation or sharp physiological activation and allows the characterization of oscillatory activity that can emerge within a network or by interactions between brain regions. In practice, most responses measured noninvasively do not disclose significant structure at time scales below a few milliseconds. A few specialized methods such as auditory brain stem evoked responses or electrical stimulation of the median nerve elicit a tightly correlated volley of action potentials that can be measured externally. However, most NEM evoked responses are a few milliseconds to tens of milliseconds wide and occur tens of milliseconds to hundreds of milliseconds after a stimulus event.

Dynamic responses of neural tissue involve a number of distinct processes. In response to upstream neural activity (or by endogenous processes in certain specialized sensor neurons, such as retinal photoreceptors or hair cells of the auditory system), the neuron generates an electrical response. This response is typically initiated by the flow of ionic currents though transmembrane protein channels in the plasma membranes of the neuronal dendritic tree. These currents produce a change in the standing potential across the membrane and produce potential gradients along the neuron. These potential gradients give rise to passive currents that flow along dendritic processes to rapidly equilibrate the membrane potential. Most neurons contain other channel proteins whose properties are voltage-sensitive; an excursion of the membrane potential from its typical resting value across some threshold produces a conformational change that opens an ion-specific conductance. This transient conductance change gives rise to an action potential or spike. Subsequent responses by other voltage-sensitive channels within the neuronal membrane shut down the action potential and allow recovery of the membrane potential to resting levels.

C. Propagation and Transmission

Unlike the passive conduction processes of the dendrites, action potentials are active processes that are essentially regenerated locally as the response moves across the cell body and along the axon. This allows the action potential to propagate for long distances without significant degradation of response amplitude. In some neurons the axons are sheathed with an insulating material called myelin. The sheath is interrupted periodically at nodes where membrane proteins responsible for excitation are concentrated. Excitation in myelinated axons appears to hop from node to node at rates considerably faster than transmission in uninsulated axons.

Because a patch of membrane is insensitive or refractory for a period after firing and given the stereotyped spatial pattern of dendritic integration, action potentials normally propagate in one direction from the cell body to the far reaches of the axon. Electrical simulation can elicit backward—antidromic—transmission, and there is evidence that similar processes may operate in the recovery of dendrites. Electrophysiological transmission in some specialized neural tissue is mediated by direct conductive interconnections (gap junctions), but most interneuron transmission is mediated by electrochemical transmission at specialized sites known as synapses. At the presynaptic terminal, the arrival of an action potential

causes ionic changes (including an influx of calcium) that lead to the release of a chemical neurotransmitter into the synaptic cleft. The neurotransmitter molecules diffuse across the synapse to bind to receptor proteins at the postsynaptic terminal. These receptors in turn activate ionic channels, which alter the local ionic composition and/or membrane potential within the postsynaptic dendrite, leading to another cycle of integration, excitation, and transmission.

D. Neural Population Responses

These processes are the basis of information processing by neural networks. The patterns of connectivity between cells define which cells can influence which other cells and, thus, define the architecture of information processing. Spikes signal the generation of a response by a single neuron and trigger the transmission of that information to the next cell in the chain. However, most neurons are interconnected in such a way that a spike in a single presynaptic neuron is not sufficient to elicit a response. Given the transient nature of postsynaptic responses, the efficacy of excitation within any particular neuron is critically dependent on the detailed temporal dynamics of activity within the population of neurons that converge on it.

Macroscopic electrophysiological responses depend on the activation of a significant population of neurons activating in concert. This is primarily a consequence of the distance separating the neuronal current generators and the electrodes or magnetic field detectors at the head surface. Electric and magnetic fields drop off

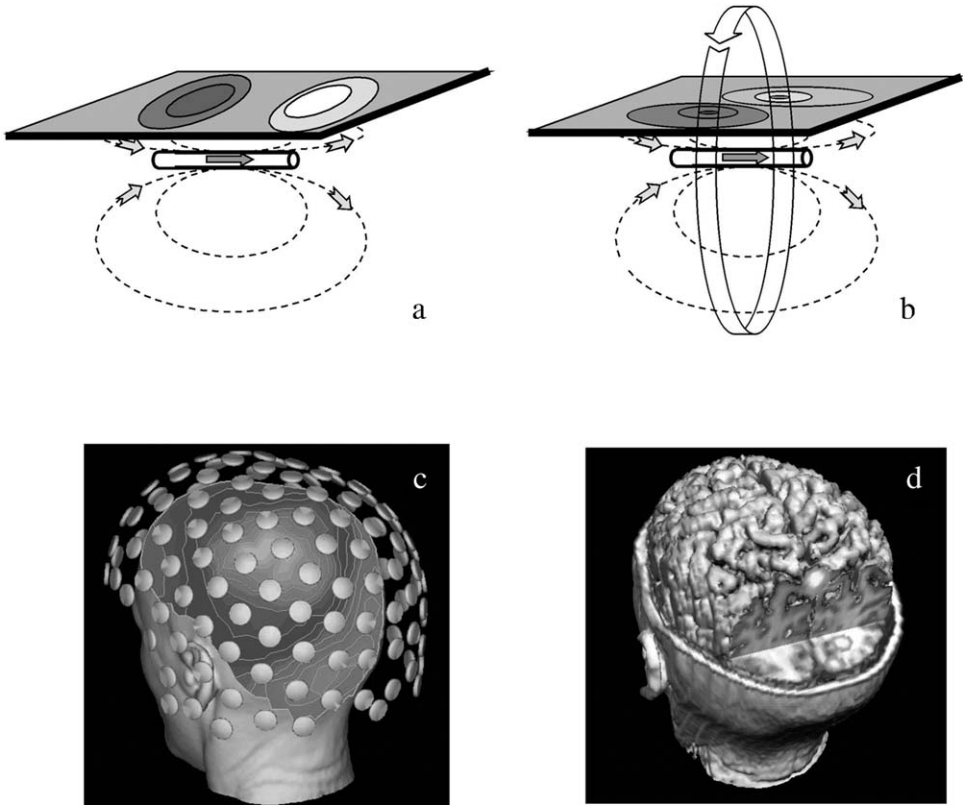

Figure 1 The physical basis of neural electromagnetic source localization. (a) Intracellular currents in tangential neural processes (parallel to the head surface) give rise to extracellular volume return currents. These currents interact with the head volume conductivity to set up a potential distribution, with surface extrema aligned with the current. (b) A detectable magnetic field is associated with the intracellular current. Extracellular currents tend to cancel in a spherical conducting volume. The extrema of the observed magnetic field distribution straddle and are orthogonal to the source current element. (c) An array of electrodes or SQUID-based magnetic field detectors are positioned on or over the surface of the head. Potential and field distributions consistent with one or more simple dipole-like sources are often observed. (d) Source localization based on a time-varying set of equivalent current dipoles. A simple source model is fit to the observed field distribution using nonlinear optimization techniques. In this figure, the uncertainty of source localization due to noise was estimated using Monte Carlo techniques, and a 3D histogram of dipole location was constructed.

rapidly with distance. EEG is further compromised by the insulating properties of the skull, which attenuate and diffuse the potential distributions that can be measured at the surface of the brain. Magnetic measurements are much less sensitive to the conductivity properties of the head, but the sensitivity of the method is reduced by the use of gradiometer sensors. Measurement of field gradients makes MEG less sensitive to interference from environmental influences, such as electric equipment, passing vehicles, or moving metal objects such as gurneys, at the expense of absolute sensitivity to neural responses.

E. Neural Electromagnetics

NEM responses are governed by the same physical processes that give rise to electric and magnetic fields in other systems. The vector currents set up by potential differences along cellular processes give rise to an electric field aligned with the current and an orthogonal magnetic field that encircles the current element. The sense (polarity) of the magnetic flux is predicted by the right-hand rule, which also predicts the direction of current flow induced in a coil penetrated by the flux. In a simple medium, charge is neither created nor destroyed; thus, all currents flow in closed loops. These relationships are summarized in Fig. 1.

Longitudinal, intracellular current flowing in the neuron during activation is matched by return current flowing through the extracellular space. These currents flow passively throughout the entire volume conductor, driven by the spatial potential gradient and limited by the resistance of the medium. In a spherical volume conductor, the magnetic contributions of these volume return currents integrate to zero, so that the measurement is dominated by the coherent currents flowing within neurons. The magnetic field is not strongly affected by the properties of biological tissue. EEG depends on the measurement of potential distributions set up by charge migration within the electric field and are critically dependent on the properties of the volume conductor. The potentials observed at the head surface arise from volume or capacitance currents that penetrate the highly resistive skull.

F. Spikes and Dendritic Responses

Although many investigators consider action potentials to be the most relevant observable consequence of neuronal activation, a number of factors limit their contribution to field and potential distributions measured at the head surface. The transmembrane currents that generate the action potential are radially symmetrical. The field cancellation associated with such distributions prevents their observation at a distance. The action potential itself is biphasic in both time and space: a depolarizing current flows along the axon, ahead of the region of excitation, and a repolarizing current flows in the opposite direction. This so-called quadrupolar current pattern is not readily detected in field measurements at a distance. Finally, the biphasic, temporally transient nature and stochastic timing of action potentials may limit their contribution to time-locked averages typically used in event-related or evoked response paradigms.

A number of lines of evidence suggest that electrophysiological responses observed at the head surface are dominated by postsynaptic dendritic currents. Such currents are typically gated by neurotransmitters, although they may have voltage-dependent characteristics. These channels often have a defined ionic specificity; some ions such as calcium may have powerful and specific effects on the response characteristics of the cell. Potentials set up by postsynaptic ion channels drive passive (i.e., ohmic) conduction along the dendrites.

G. Superposition and Integration

Electric and magnetic fields and the associated potential distributions obey the principle of superposition: the field distribution associated with a complex 3D pattern of currents is the integral over the contributions of all of the source currents flowing within the conducting volume. Within a small volume element (voxel), the distribution of cellular and volume currents can be modeled adequately by an equivalent point current with some orientation and magnitude, and the field of the entire volume can be computed as the sum over the contributions of all of the voxel currents.

Although the dendritic tree of a single neuron is often contained within a single voxel of an anatomical magnetic resonance image, each segment of current within the dendritic processes makes a contribution to the observed magnetic field and potential distributions. If the dendritic tree has a radially symmetrical geometry, the contributions may cancel and produce no effect observable at a distance. Cells of this configuration have been termed ''closed field''

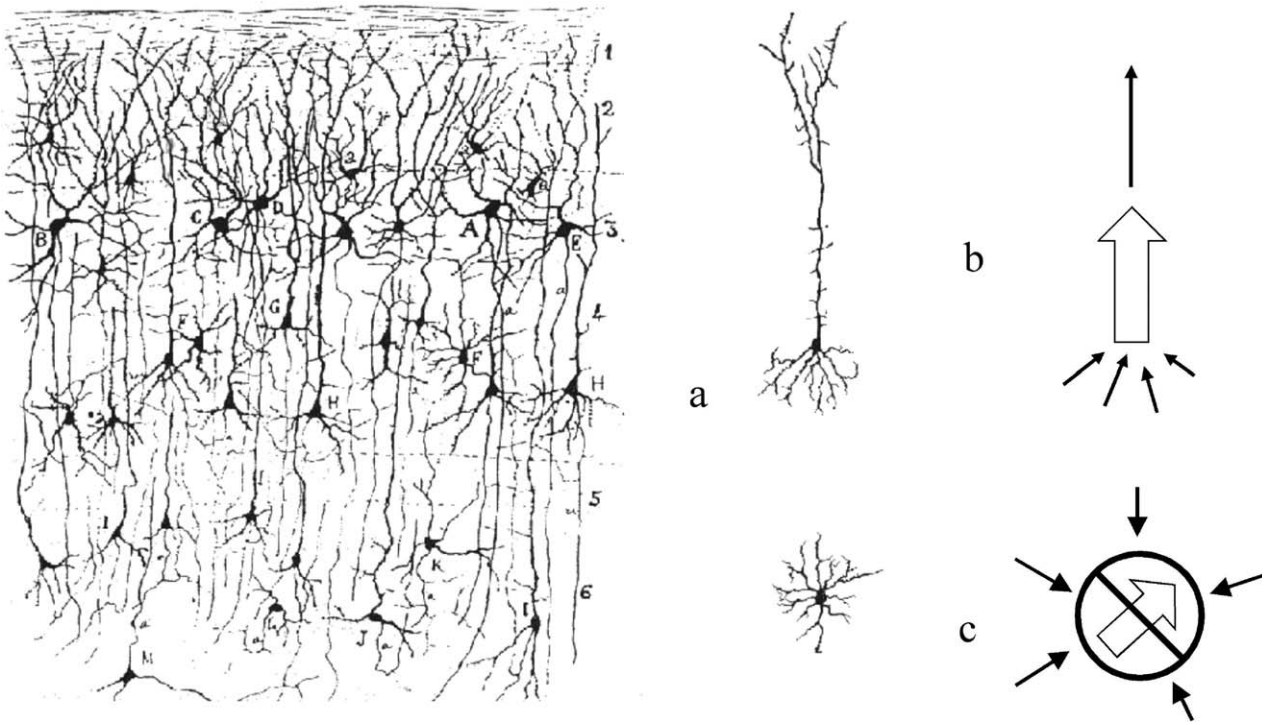

Figure 2 Vector summation of neuronal intracellular currents. (a) The regular array of cortical neurons is evident in this classic drawing of Golgi-stained neural tissue. (b) The partial symmetry of an open-field neuron (pyramidal cell) gives rise to a net intracellular current vector aligned normal to the cortical surface. (c) The radial symmetry of a closed-field interneuron produces current cancellation resulting in no net intracellular current vector.

neurons. Neurons with an asymmetric dendritic arborization have a net current vector and are termed "open field." These configurations are illustrated in Fig. 2. The neurons of neocortex have a net asymmetry that is normal (i.e., perpendicular) to the local cortical surface. Experimental validation of this prediction comes from experimental observations from linear arrays of microelectrodes penetrating the cortex. Such measurements find layered distributions of current sources and sinks across the thickness of cortex, whereas tangential potential differences are small within an extended area of activation. This basic prediction also is consistent with NEM measurements of responses from systematically arrayed sources in somatosensory or primary visual cortex.

III. THE METHODS

A. Measurement Technologies

Both MEG and EEG are passive technologies; they use sensitive instrumentation to detect the tiny electrical and magnetic perturbations associated with neural activity. Although some aspects of biological electricity can be measured directly even with primitive galvanometers, the practical application of EEG required the development of sensitive amplifiers. In particular, amplifiers with high input impedance [such as devices incorporating field effect transistors (FETs) on the front end] allow precise potential measurements without drawing significant current. This strategy has a number of advantages, including reduced sensitivity to high impedance electrodes or connections to the scalp.

EEG techniques traditionally employ a modest number of electrodes that are applied individually by hand. The most commonly used system (particularly for clinical practice) is the international 10–20 system —a montage of around 20 electrodes placed over the surface of the scalp with reference to anatomical landmarks. Electrodes are affixed to the scalp with conductive gel or other adhesives after preparation of the surface, typically by mild abrasion. This procedure produces lower contact resistance but is labor-intensive. Advances in source localization techniques, to

some extent driven by MEG, have provided motivation to increase the density of potential sampling across the scalp surface. Over the past decade typical research systems have grown from 32 channels to 128 channels or more. The development of electrode arrays based on caps or mechanical tension structures (see Fig. 3) has made the application of such arrays considerably more practical, requiring minutes instead of the hours required to apply dense arrays using conventional techniques. Although it is not yet clear how many electrodes are required to capture the nuances of the scalp potential map, studies of the spatial Nyquist frequency for EEG suggest that useful new details are available using 128-channel electrode arrays and perhaps even larger arrays.

MEG is based on ultrasensitive magnetic field measurement technology, incorporating superconducting quantum interference devices (SQUIDs). The field sensors are typically superconducting pickup coils consisting of multiple loops configured for sensitivity to field gradients. Both SQUIDs and gradiometers can be constructed from high-temperature superconductors. In designs to date, the increase in noise associated with higher temperatures has proven unacceptable for brain measurements, although such systems are adequate for cardiac applications. From early in the history of MEG, it has been clear that sensor arrays of 256 channels or more would be required to adequately sample field distributions associated with superficial cortical sources. However, the first systems consisted of detector arrays of limited extent. Mapping studies involved multiple placements of the sensor array in the context of event-related or evoked response paradigms. Most current MEG and EEG systems still sacrifice spatial sampling in order to provide whole-head coverage with a practical and more affordable number of sensor channels.

MEG sensor arrays are housed in a dewar, essentially a double-walled, vacuum-insulated flask, designed to hold cryogenic fluids such as helium. The dewar limits the proximity of sensors to the head surface; most superconducting sensor arrays are separated from the outside world by 1 cm or more. With advanced designs and considerable care, this distance can be reduced to closer to 1 mm for some applications. The standoff distance produces a significant loss of sensitivity, but this is not the limiting factor for most human brain measurements. Sensor arrays must be constructed with a rigid housing designed to accommodate the majority of heads, and smaller heads will involve greater separations over at least portions of the sensor array. Even the most superficial areas of cortex are on the order of 1 cm below the head surface, and some subcortical structures of interest may be

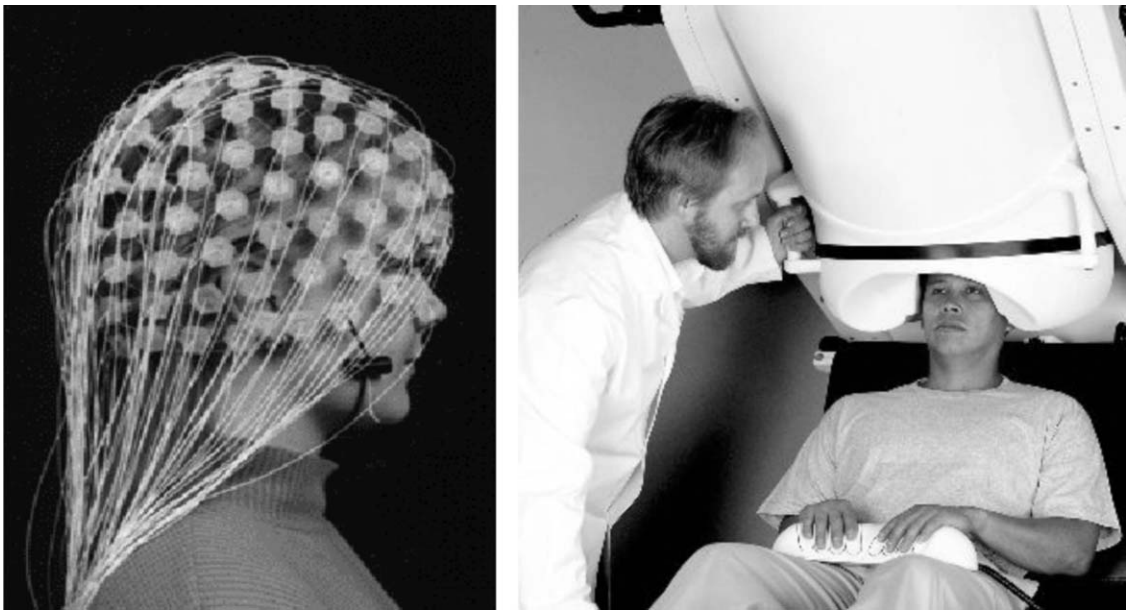

Figure 3 NEM measurement technologies. (Left) An EEG electrode array based on a mechanical tension structure (figure courtesy Electrical Geodesics, Inc.). (Right) A whole-head MEG system showing the helmet-shaped dewar that contains cryogenic fluids (figure courtesy of 4D Neuroimaging).

5–10 cm below the scalp. The fixed geometry of the MEG sensor array, the noncontact nature (and associated efficiency of subject preparation), and the relative insensitivity of MEG to head conductivity properties are all practical advantages of MEG for brain mapping applications. However, MEG sensor arrays providing full head coverage together with the magnetically shielded room used by most existing systems can cost as much as or more than a typical clinical MRI system with capabilities for functional neuroimaging.

B. Experimental Methodologies

Ongoing spontaneous activity can be recorded at the surface of the human head using MEG or EEG. Such activity typically is characterized by regions of relatively large amplitude oscillatory patterns that vary as a function of position on the head and state of the subject. Pathological responses such as certain forms of slow oscillation or the spikes and waves associated with epileptic activity often can be clearly resolved in the ongoing EEG record. The signals associated with responses to individual stimuli or other punctate cognitive or control processes typically are much smaller and require specialized experimental paradigms and signal processing techniques to pull the signals out of the noise.

1. Stimulus Evoked Responses

Brief presentations of sensory stimuli elicit a sequence of responses in the chain of specialized cortical and subcortical areas that process sensory information. In the primate visual system, over three dozen areas have been identified that are involved in the processing of visual information. Other sensory modalities such as auditory and somatosensory systems involve smaller numbers of areas and less cortical real estate but still employ distributed processing strategies.

In order to enhance the consistent aspects of the sensory response while suppressing the contribution of other physiological processes or environmental noise, most investigators employ averaging of temporal sequences time-locked to the stimulus. In this sort of *evoked response* paradigm, individual stimuli are typically presented in isolation. Different examples of a class of stimuli are often presented in a random sequence. The interstimulus interval typically is varied within some limits to minimize habituation and thwart the generation of temporal expectations by the subject; such effects can influence the amplitude and timing of certain components of the response. The time course of the electrophysiological response to a single stimulus ranges from tens of milliseconds to a few hundred. Thus, by presenting stimuli at intervals of 500 msec or more, it is possible to examine the entire time course of the response with little or no overlap from preceding or subsequent responses. Figure 4 illustrates an example of some of the techniques used for visualizing a somatosensory evoked response.

2. Steady-State Paradigms

An alternative approach for evoked response paradigms is to present stimuli at high rates, accepting the response overlap. Instead of discrete stimulus presentations, such paradigms often impose rapid changes on an ongoing stimulus, such as amplitude modulation of a continuous tone or contrast reversal of a patterned video display. Because the response does not return to baseline between stimuli (i.e., residual activation is maintained between trials), this class of techniques is referred to as *steady-state* methods. However, when using typical AC-coupled recording methods, the response must be modulated in order to be detectable. The time-locked response is typically isolated using Fourier transform techniques. The amplitude at the stimulation frequency is taken as a measure of the evoked response, whereas the phase is taken as a measure of the temporal delay (or latency) of the response.

The primary advantage of this strategy is speed; steady-state methods provide an efficient way of collecting and analyzing topographic data produced by MEG or EEG. However, such methods also have disadvantages. Fast stimulus presentations produce a measure of sensory overload, often leading to habituation or reduced levels of attention to stimuli. Steady-state methods may also introduce phase ambiguities. For example, visual evoked responses show evidence of an initial activation in layer 4 of the primary cortical visual area, V1, followed by activation in other layers and eventually by feedback activation in V1 from higher visual areas. At high stimulation rates the temporal relationship between various phases of the V1 cortical response may be obscured. Further, the subsequent activation of other visual processing areas may produce field or potential topographies that overlap with the responses of earlier areas. The loss of timing information removes an important tool for the identification of sources and for studies of the dynamics of information processing.

Experimental studies employing MEG have demonstrated a clever application of high-frequency stimulation techniques. By modulating the stimulus at frequencies that may be too high to consciously perceive, it is possible to frequency-tag the downstream response. Such methods can be used to tag the hemifield of stimulation in a wide-field visual stimulus or to identify the stimulated ear in a dichotic listening paradigm. Residual modulation at the tag frequency can be used to identify the origin of a response even after the arrival of the signal at a higher sensory processing area with convergent bilateral inputs.

By presenting fast pseudo-random sequences of individual stimuli, it is possible to achieve much of the efficiency of steady-state techniques while avoiding several of the problems. For example, a video display can be divided into elements that are turned on and off in an apparently random sequence, such as an m-sequence. The temporal activation sequences are designed to be orthogonal, i.e., each element has its own unique activation sequence. This allows correlation techniques to be used to extract the spatial and temporal patterns of response to each element of the display. This method can be very efficient because many stimulus elements can be presented simultaneously. However, this leads to stimuli that are decidedly nonphysiological and may be a bit disconcerting. At present, the method appears to be more useful for rapid mapping of the systematic parametric organization of primary sensory areas (i.e., retinotopic, tonotopic, or somatotopic projections) than as a tool for probing higher cognitive processes.

Sensory evoked response paradigms provide a powerful and robust tool for probing the functional architecture and dynamics of the neural systems devoted to the processing of sensory information. However, this is only one of several classes of functional activity within the human brain.

3. Motor Control

The control of voluntary movement is another critical capability of higher organisms. Although the coordination and fine-tuning of movement appear to be distributed through several brain centers, the initiation of movement is a function of the motor cortex, located adjacent to primary somatosensory areas in humans. Some investigators have used cued trials to study motor function, hoping that the temporal jitter in the reaction time does not wash out the targeted motor response. This strategy also produces a time-locked response to the sensory cue, which can interfere with the analysis of the motor response. An alternative strategy is to use self-paced tasks and to time-lock averaging to the motor response. For simplicity, the response can be a button press or similar action that is readily converted into an electronic timing signal. A bit more sophisticated strategy is to base experimental timing on a measured physiological response. For example, it is possible to record an electromyogram signaling the activation of specific muscle groups by using the same basic technology as EEG. These are large, robust responses that can be detected in a continuous recording, often using simple threshold techniques. This sort of activity, which may not be evoked directly by external stimulation but is associated with externally observable consequences, is referred to as an *event-related response*. In addition to motor processes or simple behavioral trials such as reaction time detection tasks, event-related experimental designs are often used to probe high order cognitive processing activity. In some cases, the "event" is only apparent as an internal state, e.g., conjunction of a particular stimulus with a specific behavioral or cognitive task.

4. Cognitive Processes

The general strategy for event-related cognitive studies is to employ a set of tasks designed to isolate and contrast the processes of interest. Measures derived from MEG or EEG are used as an index of activation and, thus, of the underlying cognitive processes. Such studies often employ well-balanced control trials, which account for sensory or motor components of a response while manipulating the relevance or difficulty of the cognitive component. Such strategies have been used to isolate and probe various aspects of selective attention. For example, many designs used for attention studies employ a cue stimulus presented before the probe trial to direct attention to one region of the visual field or another. The subject might be instructed to respond to a particular type of stimulus only when presented at the attended site. Thus, in the same experiment, a given physical stimulus might serve as the response target, an inappropriate stimulus at the attended site, or an irrelevant stimulus that can be ignored.

Other designs tap the endogenous cognitive skills of the subject. For example, a list of real words might be presented visually along with interspersed pseudowords (i.e., pronouncible constructs that look like words but have no meaning) or nonwords. The nature of the observed response varies as a function of the

lexical class of stimulus. A spoken sentence might be presented in which the final word either completes a reasonable semantic construct or renders the sentence nonsensical. Such paradigms can tap the mechanisms by which we comprehend language.

C. Signal Processing

Event-related and evoked responses in MEG and EEG are typically quite small compared to ongoing neural activity or other physiological activity or environmental noise. Effective signal processing strategies are essential for isolating the desired signals from other observed signals not of interest.

Temporal filtering is a ubiquitous initial step in the signal processing chain. Virtually all MEG and EEG systems employ some sort of analog filtering on the front end to reduce the signal bandwidth to avoid aliasing in digitization, if for no other reason. Many conventional EEG systems provide an extensive set of analog filtering capabilities, including high-pass and low-pass filters as well as notch filters (often tuned to the 50- or 60-Hz frequency of the power grid), to eliminate major sources of environmental interference. If the frequency content of the targeted signal is known or can be determined empirically, reduction of the bandwidth of the measurement reduces noise and can increase the efficiency of signal acquisition. However, as high-density sensor systems and digital acquisition

and processing become more standard, instruments are increasingly designed with fixed analog front ends. Signal processing is increasingly performed by digital signal processing subsystems, general purpose computers embedded in the data system, or workstations used by investigators for subsequent analysis.

Digital filtering is cheaper and in many respects technically superior to the use of analog filters. Methods based on the fast Fourier transform (FFT) greatly simplify the algorithms required to implement digital temporal filters. Related techniques are used for the frequency domain analysis of the major rhythms characteristic of spontaneous EEG or MEG recording or for the extraction of steady-state responses at the stimulation frequency. Short time base analyses based on wavelets or special FFT algorithms may be used to identify periods of transient synchronization (or desynchronization) that are associated with (but not time-locked to) external stimuli or perceptual states. Such analyses are often based on trial by trial analysis of continuously acquired data. The averaging techniques used for most event-related response work would attenuate or eliminate such responses because they are not time-locked to the stimulus and may vary in time and phase from one response to another.

Eye blinks or other movements of facial muscles can produce strong signals in MEG or EEG. The startup of an electric motor or power-hungry instrument in the vicinity (or sharing a power circuit) can also introduce large artifacts. A single large-amplitude transient may leave significant residue in an averaged event-related response even after many trials. For this reason, *artifact rejection* is another common step applied in the analysis of MEG and EEG data. The digital data stream is monitored for values that exceed some criterion threshold. If the threshold is exceeded, the offending channels or, more commonly, the entire trial is excluded from further analysis. For some clinical applications, artifact rejection is typically accomplished by visual inspection. In epilepsy, the pathophysiological responses of interest may exceed the size of signals considered artifacts under other circumstances, and inspection by a trained clinician may be the most efficient and effective way to identify both artifacts and epileptiform activity. However, as data streams become more dense and algorithms become more sophisticated, there is increasing reliance on software that can categorize events in the experimental record on the basis of temporal waveforms, spatial topographies, or both. Such systems are often used to preprocess an extensive record, bringing interesting or suspicious events to the attention of the reviewer.

Time-locked selective averaging is the mainstay of most existing work with event-related or evoked responses. As a first step, epochs in the data are identified and characterized according to the nature of the stimulus, the response, or the task and its performance. Averaging can even be undertaken relative to a reproducible endogenous transient, such as an epileptiform spike. Segments of the waveform data across all channels are selected relative to the timing event, and within each channel the corresponding time points in the segment are averaged. In general, averages are segregated according to the particulars of the trial, e.g., the identity of the stimulus or the accuracy of task performance, although in many cases averages are collapsed across conditions that are considered irrelevant for a particular experimental question. Many studies report "grand averages" constructed by averaging responses across many subjects in order to increase the power of statistical inference, although this practice probably precludes reliable source localization.

The construction of *difference waves*, by subtracting a control condition from a particular response, is another time-honored method for the analysis of event-related response data. For example, such methods clearly disclose the increase in response amplitude associated with selective attention to a particular location in the visual field and isolate responses associated with certain endogenous cognitive responses. In many cases such records are reduced to a single response waveform, for example, by averaging (or summing power) across all channels or a selected subset. However, an increasing number of investigators construct difference topographies by subtracting control responses from the corresponding signal channels. These distributions are often analyzed in the same way as the underlying event-related signals, for example, subjected to source localization procedures.

Such analyses should be approached with caution. The methods will work, in principle, if the only differences between conditions are due to the strength of the underlying sources or the appearance of a new source under particular experimental conditions. Unlike PET and fMRI, which in effect produce an estimate of the distribution of source activity, EEG and MEG produce topographic maps with a complex relationship to source activity, driven by the physical properties of the measurement instrument and the system under study. Minor changes in the location or extent of activation (especially in cortical regions of high curvature) can produce big changes in the

observed field topography and, thus, significant changes in computed difference fields.

Single-pass analytical methodologies are increasingly applied to the analysis of event-related response data. Frequency decomposition techniques (described previously) have been used to explore the putative role of transient phase-locking of oscillatory activity in certain perceptual processes. Correlation techniques can be applied to continuous evoked response data to identify consistent features in a manner analogous to signal averaging. Spatial filtering techniques compute a linear transform (based on a computed or assumed source model) that can be applied to the data to estimate the activation time course of the source. Several investigators suggest that techniques in this class (such as minimum variance beam-forming) are most useful if applied to single trial data rather than averaged responses. Some new methods such as independent component analysis (ICA), synthetic aperture magnetometry, or magnetic field tomography by the nature of the algorithm are most effectively applied to the analysis of single trial data.

IV. RESPONSE DYNAMICS

The principal strengths of neural electromagnetic methods stem from their capacity to define the dynamics of neural population activity. Even a single electrode pasted to the scalp may disclose a complex temporal waveform consisting of a series of peaks and valleys. In some cases, a peak in a waveform at a particular latency is observed across a large subset of the channels in a whole-head sensor array, even though the amplitude or the polarity of the peak changes. This pattern is characteristic of a single anatomical source or a set of sources acting in synchrony. In some cases, a close examination of the waveform montage collected from a sensor array discloses that what appears as a single peak in one waveform can be resolved as multiple overlapping temporal peaks observed at other locations. In such cases, the topographic map of the evoked response typically has apparent features that appear to shift systematically over the course of the response. A simple-minded analysis may suggest that the source is a single focus of activity moving through the brain volume. A more sophisticated source model may allow the same response to be decomposed into two or more component sources with stable NEM topographies and distinct but overlapping time courses.

In the absence of effective source localization techniques, there was a tendency in early work to focus on the peaks in the waveform as the unitary building blocks—the components from which complex event-related responses were built. Components were given names on the basis of the polarity and latency of the waveform peaks: e.g., the N100 (a negative-going response component peaking around 100 msec poststimulus) or the P300 (or P3, a positive peak in the response waveform around 300 msec poststimulus). As the characterization of response components proceeded, descriptions of the component scalp topography were sometimes added to aid identification and discrimination of named components. For endogenous cognitive response components, identifying criteria often included the nature of experimental manipulations required to elicit or enhance a particular peak in the waveform. Whereas such information is critical for investigators attempting to reproduce or extend a particular observation, it complicates the business of component quantification.

In an effort to address this concern, some investigators turned to blind decomposition techniques such as *principal components analysis* (PCA). PCA is a linear technique based on eigen analysis and singular value decomposition. The method attempts to find a set of basis functions—in this case, field or potential topographies—that can be used to reconstruct the original experimental data. In order to make the decomposition unique, principal components are constrained to be mutually orthogonal. Each principal component has an associated weighting vector that quantifies the representation in the data of each component as a function of time. In some well-behaved cases, principal components correspond to response components identified by other criteria. However, in general, the requirement for orthogonality precludes the proper identification of more than a few components. An alternative decomposition strategy has been developed that appears to hold an alternative decomposition strategy that appears to hold significant promise for functional neuroimaging applications. Independent component analysis identifies a basis set in which components are statistically independent though not necessarily orthogonal. Initial results with the algorithm are promising, although it will certainly be possible to find pathological cases that cause the algorithm to fail. It is not yet clear how effectively the algorithm will identify proper components in routine applications to event-related response data.

In a few cases, the idea that components reflect the successive activation of links in a processing chain

appears basically correct. For example, in the *auditory brain stem evoked response* (ABER), the peaks in the waveform are associated with specific structures in the early auditory pathways, and the waveform morphology can be used to assess the integrity of the relay and processing circuitry. Similarly, the earliest components of somatosensory responses evoked by electrical stimulation appear to be associated with specific anatomical loci. In contrast, for visual evoked responses the situation is considerably more complex. Although some investigators have reported an early, relatively small EEG component (N70) that was identified as the initial activation of cortical V1, most analyses have focused on the more robust P100 component. A variety of source analysis techniques indicate that this component is a complex consisting of temporally overlapping responses from several distinct though nearby visual areas. Although there is an element of sequential processing in the early visual system as activation spreads through the information processing tree, there is also considerable parallel processing. There are also forward and feedback links that skip over portions of the schematic processing hierarchy and delays within areas that can further complicate the simple orderly picture of temporal response dynamics.

V. SOURCE LOCALIZATION

The existence of detectable magnetic fields and electric potential distributions at the head surface is a consequence of the physics of electromagnetism. Given an adequate description of the source currents and the conductivity properties of the medium, it is possible to compute the anticipated field topographies. Calculations to solve this so-called *forward problem* can employ models of greater or lesser detail, depending on the complexity of the system and the required degree of accuracy. Computation of the forward problem for more complex source distributions—extended regions of activation or multiple active sources—is more time-consuming, but not significantly more difficult. The principle of superposition tells us that the contributions for multiple source currents will sum linearly.

In principle, it may be feasible to invert the process—to compute the currents that give rise to an observed field or potential distribution at the head surface. Unfortunately, this *inverse problem* is not well-behaved. In general, many different current distributions can produce the same set of surface measurements. To appreciate the problem intuitively, consider a homogeneous spherical volume that is conductive. It is possible to account for any given potential or magnetic field distribution measured at or above the surface, with a suitable collection of currents limited to the surface of the sphere. However, we can define another spherical shell 1 cm below the surface and derive another current distribution to account for the same set of observations. Given this fundamental ambiguity, how can we hope to reconstruct the proper set of current sources buried deep in the brain from the data available at the head surface?

The general strategy is to build a model of the sources that might produce the observed responses. The source model defines the structure of the solution. Model parameters define the details. In some cases, source models are very restrictive, so that a single, best-fitting set of model parameters can be found. In such cases, the accuracy of the solution depends on the applicability of the source model. As the complexity of the source model increases, generally the number of parameters also increases. This allows more complex source distributions to be modeled, but tends to increase the ambiguity of the reconstruction problem. By defining the criteria that we prefer in an acceptable solution it is generally possible to find a solution, but again, the accuracy of the solution depends on the validity of the assumptions.

A. Model-Based Approaches

Thus, source localization depends on the use of nested computational models that describe the distribution of neural currents and that predict the observable consequences of those currents. These models are based on implicit or explicit knowledge and assumptions about the nature of the system. The first 50 years of work with EEG involved little quantitative effort to localize the sources of observed topographies in the surface potential data. The development of MEG and the recognition that many observed field distributions could be explained by a simple forward model led to advances in procedures that have subsequently been applied to EEG data.

B. Forward Modeling

For electrical or magnetic measurements at a distance significantly larger than the extent of the source, the spatial fine structure of the field distribution is not

detected, and the dominant contribution is the dipole associated with longitudinal intracellular currents. In MEG, the effects of ohmic currents through the head volume are minimal, and a reasonable analytical solution can be derived by treating the head as a homogeneous conducting sphere. The radius of the sphere is chosen to approximate the inner surface of the skull, based on individual anatomical images or external measures of head shape coupled with a knowledge of average anatomy. Unlike MEG, EEG signal topographies are strongly influenced by the conductivity properties of the head. Even simple models of elemental EEG signals must take into account the presence of multiple tissue layers of differing conductivity. Dipole response topographies for EEG can be computed in a volume model consisting of multiple spherical shells, with layers corresponding to brain, cerebral–spinal fluid, skull, and scalp, using a truncated series of Legendre polynomials. Many researchers in the field have argued that this class of model is more than adequate for source localization, given the uncertainties associated with the inverse problem. However, as inverse procedures have improved, a number of studies have underscored the value of more sophisticated forward models for source localization accuracy. Some of these approaches are summarized in Fig. 5.

A significant improvement in the accuracy of the forward calculation can be achieved by *boundary element* calculations incorporating the geometry of the major tissue classes within the head. Surface meshes are constructed to approximate conductivity boundaries. Because the conductivity of the skull is significantly lower than that of other tissues in the head, it is particularly important to capture the geometry of the skull near sensors. Most calculations of this sort are limited to simple topologies, e.g., nested compartments without intersections or penetrations. Conductivity values are typically taken from the literature and correspond to measurements originally made in cadaver tissue. Because there is no basis for further subdivision, conductivity is taken as homogeneous within a compartment. Although the boundary element method employs simple geometries, the calculations are relatively time-consuming, because the solution matrix typically contains terms for the interactions between every pair of nodes in the mesh. Numerical studies have demonstrated that it is possible to achieve accuracy approaching that of the boundary element methods at much lower computational cost by approximating the skull boundary with local spheres selected for each sensor.

3D methods provide an alternative strategy for high-resolution forward calculations. In *finite difference* (FD) or *finite element* (FE) forward calculations, the head volume is divided into a collection of volume elements that form the computational mesh. Potentials are computed at nodes, typically associated with boundaries or vertices of the volume elements. These calculations assume a current source that generates the potential and account for the conductivity properties of the volume elements that strongly influence the spread of potential. FE methods typically employ an irregular mesh composed of tetrahedral elements. This allows the mesh to closely match conductivity boundaries within the medium that may give rise to sharp gradients in the potential distribution, providing greater accuracy with a smaller number of volume elements. However, most present methods for mesh generation and refinement require considerable human intervention. FD methods typically employ a regular (e.g., rectangular) mesh. Segmentation or voxel classification schemes can be applied to regular volumetric data such as MRI to produce a data volume that can be used for calculations without constructing specialized meshes.

3D methods are most useful if we have access to external information that can be used to define the geometry or electrical properties of the conductive medium. MRI provides the most accessible and flexible measure of tissue properties, although X-ray CT provides a better definition of the geometry and microstructure of the skull. New and evolving MRI techniques will eventually provide even more useful information for forward modeling. *Current density MRI* operates by applying external currents at the head surface and measuring the perturbation of the image by local volume currents. This allows an estimation of head conductivity on a voxel by voxel basis. *Diffusion tensor MRI* measures the magnitude and characterizes the direction of diffusion of water within tissue. Structures such as white matter tracts give rise to anisotropic physical properties that can be described by a tensor, e.g., the apparent diffusion coefficient of water and the measured conductivity are much higher along a fiber tract than transverse to it. MRI can be used to estimate the anisotropic conductivity of such tissue. FE and FD methods can accommodate anistropic conductivity (though again the FD application is simpler). By passing currents through pairs of surface electrodes and estimating the induced potentials at other electrodes in the array, electrical impedance tomography (EIT) allows an estimation of the bulk properties of major tissue

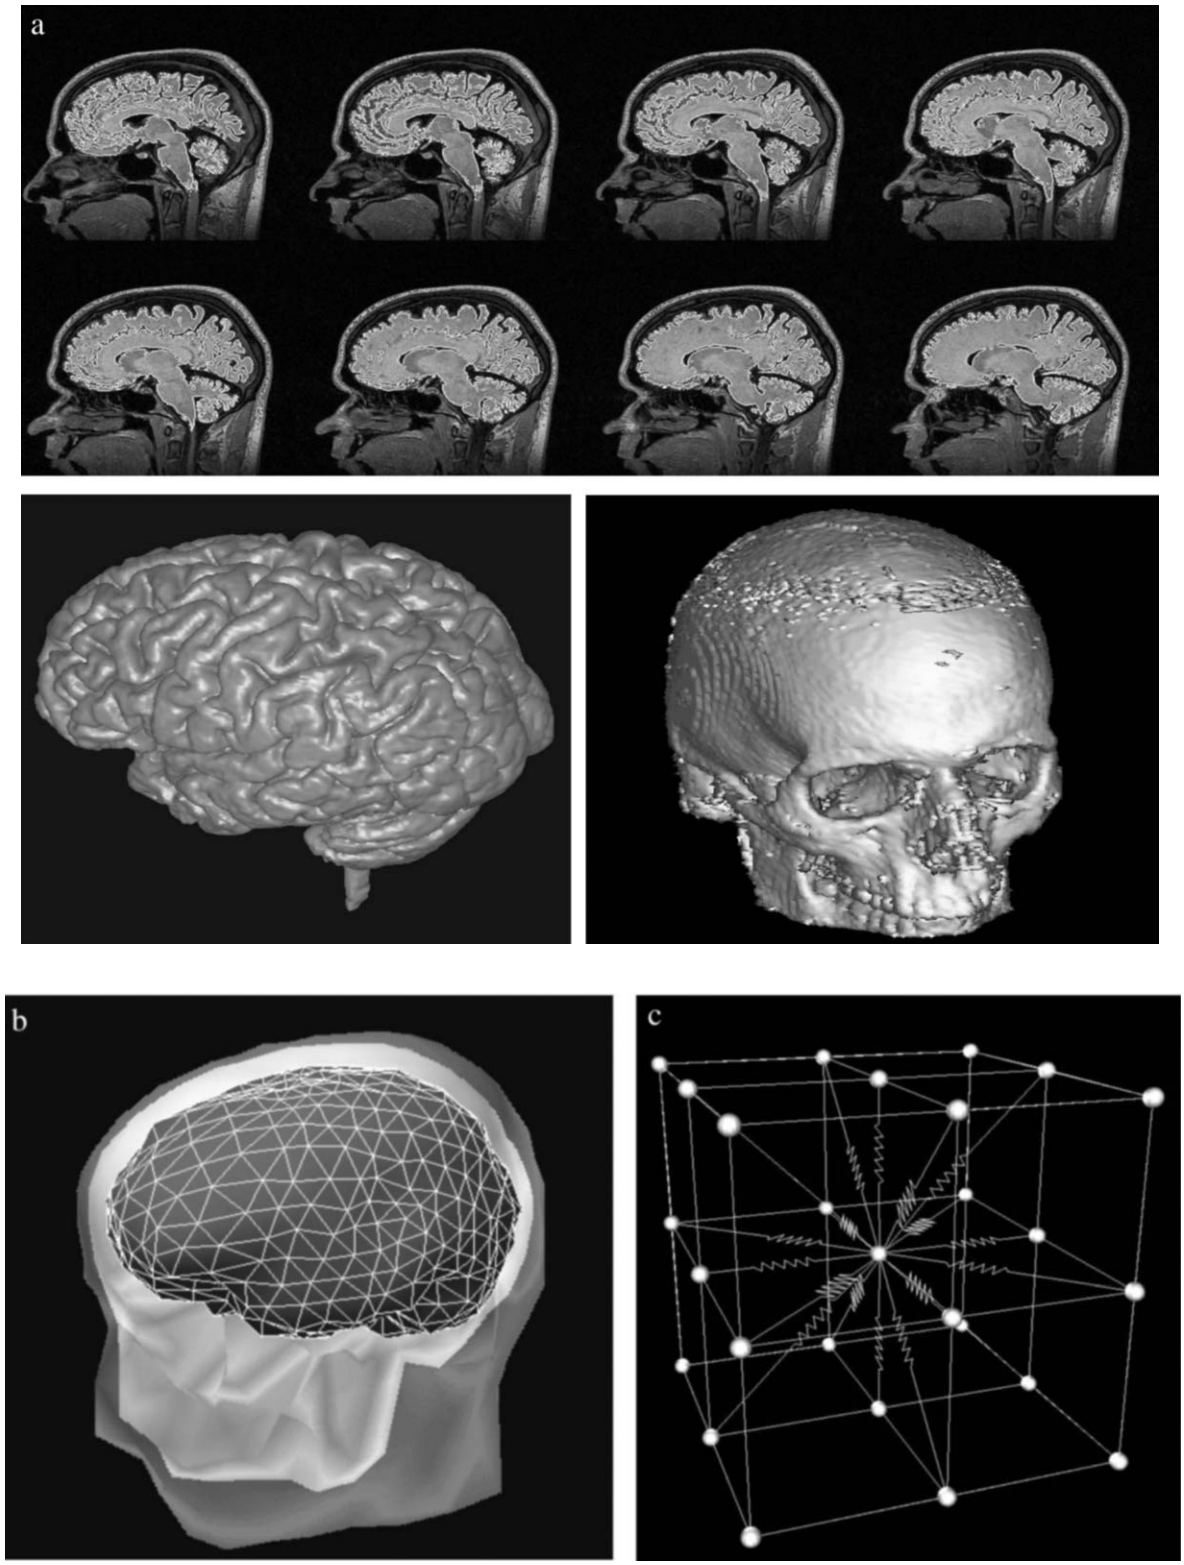

Figure 5a–c

Upper panel: Region-growing algorithms with adaptive criteria perform segmentation of white matter and identification of gray matter by dilation. Lower left: 3D rendering of the cortical surface identified by an automatic algorithm. Lower right: Rendering of the skull segmented by region-growing techniques from 3D MRI data. (b) Boundary element mesh based on simplified skull and scalp geometry derived from MRI volume imagery. (c) The regular computational mesh employed for finite difference computations in anisotropic media. The nodes for potential computation are at the corners of the spatial volume elements. (d) Finite difference calculation of potential distribution, using a detailed computational geometry derived from MRI. The current source is located within the temporal lobe, with a posterior to anterior orientation. The slices from the computed potential distribution show evidence of current leakage through the skull penetrations of the optic nerve.

classes within the head and even a measure of 3D reconstruction. Tomographic reconstruction of head conductivity requires 3D computational techniques and is greatly facilitated by accurate geometrical information drawn from MRI.

C. Source Model Estimation

Source localization from EEG and MEG began with educated inspection of surface field topographies. In EEG, a radially oriented current will produce a potential extremum over the source. In MEG, a radial current source produces little externally detectable magnetic field, but the tangential component of a neural source produces a field distribution with extrema that straddle the source. The distance separating the field extrema allows an estimation of the source depth, given assumptions regarding the nature of the current source. In both EEG and MEG, many observed response topographies can be explained by an *equivalent current dipole* (ECD) source, i.e., an isolated point current with a given location, orientation, and amplitude. Theory suggests that such a model provides a reasonable estimate of the field or potential distributions due to a small cluster of oriented neurons measured at a distance. Even extended patches of activated cortex often produce a dipole-like distribution, although the estimated location and strength of the ECD will contain systematic errors. An extended patch of parallel current elements produces an ECD estimate that is deeper and stronger than the center of mass and integral current estimated from the actual source distribution.

Because field topographies are typically diffuse, source estimation by eye is a rather inexact process. Some investigators have employed image processing techniques to allow for easier detection of features in the field topography. For example, computation of the spatial derivative (the Laplacean) of the observed magnetic field or potential topography tends to place maxima over the current sources. Indeed, one form of MEG sensor—a first-order planar gradiometer—effectively implements this transform in the detector coil configuration.

Although *inspection of response topographies* is a useful starting point for finding NEM sources, model-based parameter estimation procedures provide a more objective strategy that allows quantitative assessment of the goodness of fit. Nonlinear optimization procedures such as simplex or gradient descent allow the estimation of a dipole source; current orientation and strength are linear parameters that can be optimized separately. If a single focal current source is active in a simple medium, such procedures can localize it very precisely. However, at any given

instant in time, many sources may contribute to a given response topography. Because of superposition, a combination of several sources may give rise to a distribution that is adequately modeled by a single source at an entirely different location. Knowledge of the number and nature of active sources can reduce the ambiguity of the source localization problem. Spatiotemporal source localization techniques attempt to find a minimal set of sources, each with an associated time course, that explains the observed distribution across a defined interval within an event-related response. If the sources are activated asynchrously, this strategy can be very effective for decomposing and localizing the contributions of individual sources.

Nonlinear optimization methods can be used to find locations for a collection of simple current sources that might explain changing field topographies observed across time. Because the time course is an estimate of the source current amplitude as a function of time, linear methods can be used to optimize the estimates between iterative nonlinear optimization steps. This general strategy has been the most widely used approach for NEM source localization for over a decade, but modifications, extensions, or alternatives to the method can provide enhanced performance. A common problem with nonlinear methods is that they require a starting estimate of model parameters. This may be provided by an informed analyst or by a stochastic process. If the starting estimate is close enough, an optimization procedure that follows the error gradient can find the best-fitting model. If the starting estimates are far off and the error surface is complex (often the case with multiple-source models), the procedure may fall into a local minimum that is not globally optimal. A conscientious analysis can combat this problem by running the optimization procedure with multiple sets of starting parameters. *Multistart* procedures automate this process, employing a numerical algorithm to generate random starting parameter estimates. Such methods often find a consistent set of best-fitting source models that are globally optimal. Other methods such as *simulated annealing* or *genetic algorithms* employ alternative strategies to address the problem of local minima within the model parameter error space. Examples of these approaches are illustrated in Fig. 6.

The multiple signal classification (MUSIC) algorithm operates within the same framework (i.e., a multiple-dipole spatiotemporal model) but employs a more systematic strategy for finding sources. The array of measured potential or field values at any given instant in time is treated as a multidimensional vector in the space of possible measurements. Similarly, the topography associated with any given dipole is another vector in the same space. The algorithm operates by systematically stepping through a set of possible sources (e.g., a grid of locations within the brain) and evaluates the match between the source field vector and the collection of signal vectors across time. The sources that most closely match the observed signals across time are considered the most likely. The method is very effective and can be exhaustive, avoiding problems of local minima seen with nonlinear optimization techniques. Multiple sources with highly correlated time courses create problems for the algorithm, but enhanced methods such as recursively applied (RAP) MUSIC address this and other concerns.

A second general strategy is to use *linear inverse techniques* to solve a large and general source model. The reconstruction space is defined by a regular grid, a collection of voxels, or vertices from a computational mesh. One to three current elements are associated with each possible source location. The reconstruction procedure employs the Moore–Penrose pseudo-inverse to assign a current value to each model element. This procedure, based on singular value decomposition, estimates a source distribution with minimum power over the collection of driving currents. A number of variants on this *minimum norm* procedure have been described, mostly based on different strategies for weighting the lead field basis matrix in order to select a solution with desired properties. Anatomical constraints based on cortical geometry can improve accuracy and efficiency. However, even with substantial reductions in the source space based on anatomy, the inverse is a highly underdetermined problem. There are many more source model parameters to estimate than the number of independent measures available from MEG or EEG.

The major problem with minimum norm procedures is that there is no guarantee that the solution of minimum Euclidean norm (i.e., the sum of squared currents) will be representative of the true solution. Because of the strong dependence of measured magnetic field on distance from the source, the basic minimum norm procedure tends to produce diffuse, superficial current reconstructions, even when the reconstruction space is constrained to the cortical surface. Currents closer to the sensor array can account for more power in the field map with less current and therefore are favored by the method. However, more current elements are required to account for the shape of a field distribution that may actually arise from a more focal but deeper source.

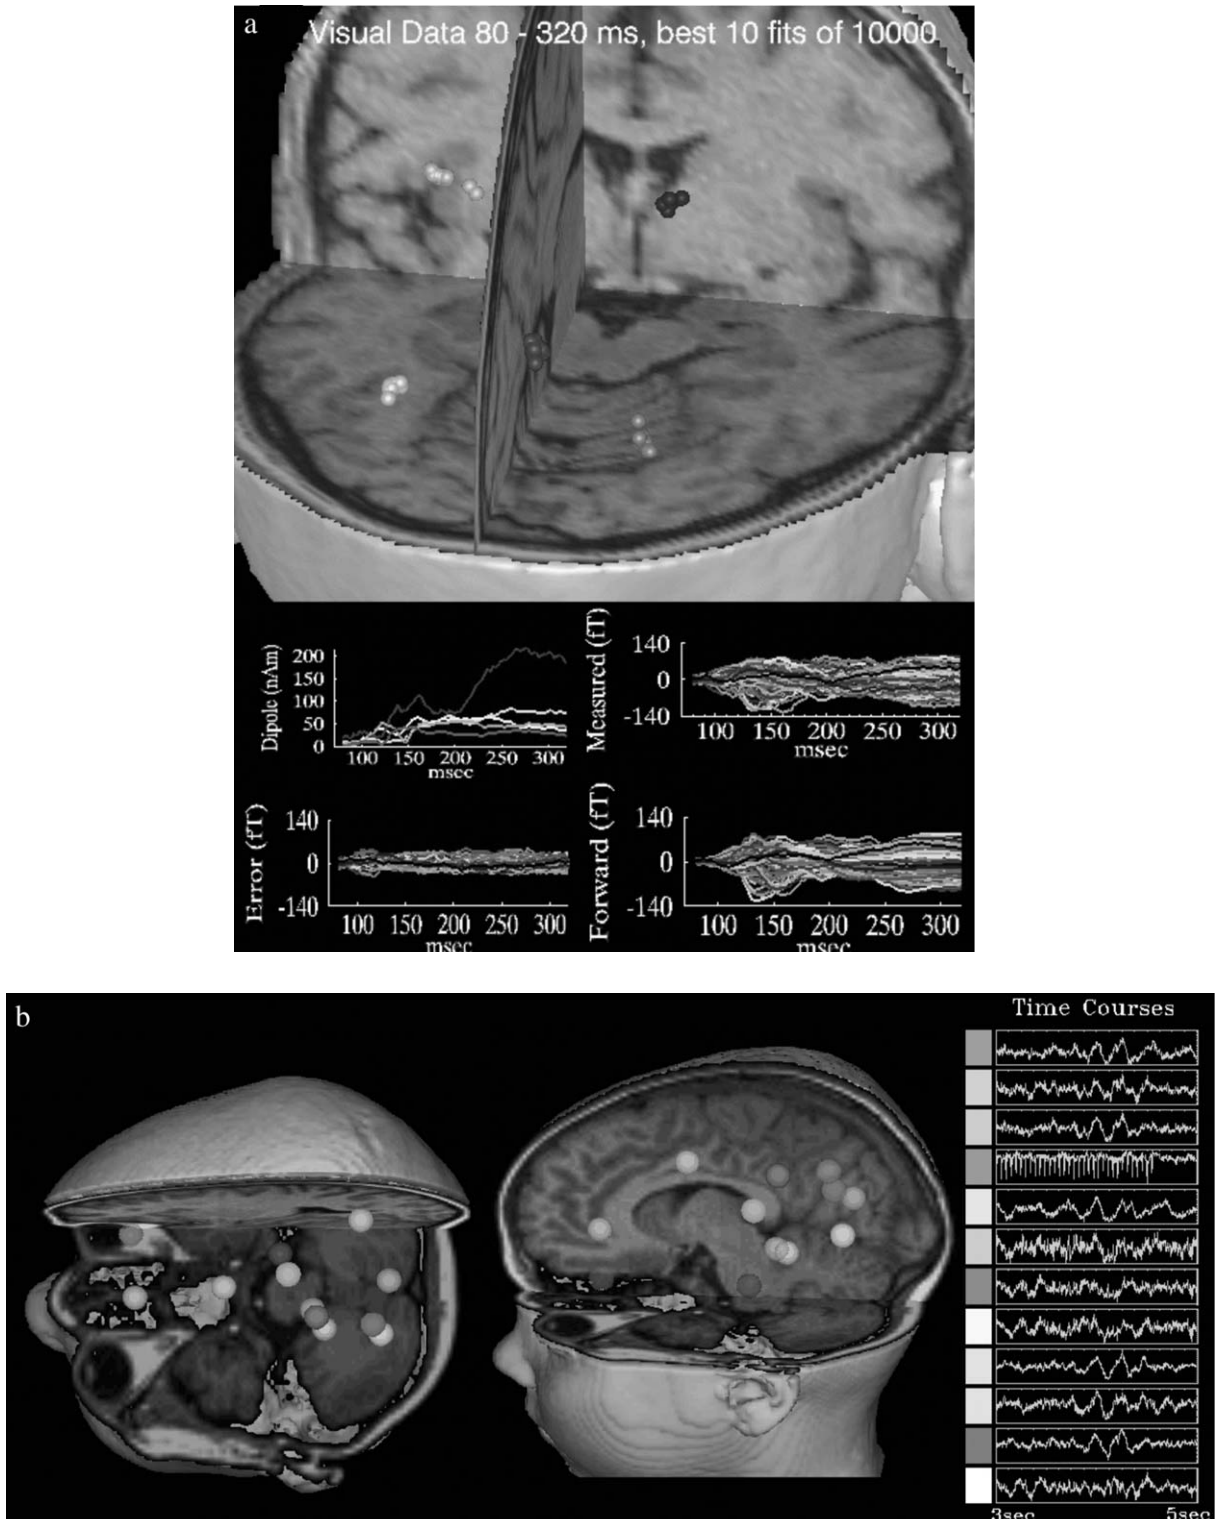

Figure 6 Source localization by multiple dipole spatiotemporal estimation procedures. (a) Dipole source locations and time courses estimated from visual evoked response data. This analysis used a multistart algorithm; the best 10 solutions from 10,000 generated are tightly clustered, suggesting that the algorithm has found a global best fit. (b) Dipole locations and time courses associated with an epileptic response from a photosensitive child. Dipole locations were estimated with a genetic algorithm. Note that the magnetic response of the eye contains evidence of the strobe flashes that triggered the response.

In order to combat this tendency, it is possible to scale the field distributions (or, alternatively, the strength of the unit currents) in order to normalize the field power associated with each elemental source. Pseudo-inverse procedures based on a normalized basis matrix offer some improvement in the fidelity of reconstructions. Explicit or implicit basis matrix weighting procedures have proven to be a useful general strategy for modifying the properties of reconstruction algorithms. The FOCUSS algorithm employs an iterative reweighting procedure to derive sparse reconstructions based on focal activated patches. The LORETA algorithm uses an alternative weighting scheme to find current reconstructions that are maximally smooth.

Given the fundamental ambiguity of the inverse problem and the complex error surface associated with the parameter space, there is no guarantee that the proper form of source model (e.g., the number of active sources) can be determined or that a single global minimum will be found. The estimated parameter values critically depend on model assumptions and may vary widely as a function of small amounts of noise in the data.

D. Bayesian Methods

Bayesian analysis techniques provide a formal method for integration of prior knowledge drawn from other imaging methods. In pure form, Bayesian techniques estimate a posterior probability distribution (a form of solution) based on the experimental data and prior knowledge expressed in the form of a probability distribution. In additional to providing a flexible mechanism for multimodality integration, these techniques allow rigorous assessment of the consequences of prior knowledge or assumptions about the nature of the preferred solution. Several investigators have explored traditional Bayesian methods, seeking a single "best" solution that satisfies some criterion, such as maximum likelihood, maximum *a posteriori* (MAP), or maximum entropy solution. However, any given single solution is effectively guaranteed to be inaccurate, at least in its details.

A technique for Bayesian inference has been developed that addresses this concern by explicitly sampling the posterior probability distribution. The strategy is essentially to conduct a series of numerical experiments and determine which solutions best account for the data. To make the method efficient, a Markov chain Monte Carlo (MCMC) technique is employed. After the algorithm identifies regions of the source model parameter space that account for the data by a stochastic process, the algorithm effectively concentrates its sampling in that region. Thus, in the end, samples are distributed according to the posterior probability distribution—a probability distribution of solutions upon which subsequent inferences are based. The Bayesian inference method does not employ optimization procedures and does not produce an estimate of the best-fitting solution. Instead, it attempts to build a probability map of activation. This distribution provides a means of identifying and estimating probable current sources from surface measurements while explicitly emphasizing multiple solutions that can account for any set of surface EEG–MEG measurements.

This method for Bayesian inference uses a general neural activation model that can incorporate prior information on neural currents, including location, orientation, strength, and spatial smoothness. Instead of equivalent current dipoles, the method uses an extended parametric model to define sources. An active region is assumed to consist of a set of voxels identified as part of cortex and located within a sphere centered on cortex or a patch generated by a series of dilation operations about some point on cortex. In a typical analysis, 10,000 samples are drawn from the posterior distribution using the MCMC algorithm. Despite the variability among the samples, several sources common to (nearly) all are often apparent. Features such as these are associated with a high degree of probability. By keeping track of the number of times each voxel is involved in an active source over the set of samples, it is possible to build a probability map for neural activation and to quantify confidence intervals. In addition to information about the locations of probable sources, the Bayesian inference approach also estimates probabilistic information about the number and size of active regions. Figure 7 illustrates several aspects of this approach to Bayesian inference.

VI. MULTIMODALITY TECHNIQUES

A growing body of evidence suggests that there is a good if imperfect correspondence between neural electrical activation and the fMRI BOLD response and that convergent information can be used to improve the reliability of macroscopic electrophysiological techniques. Because of the ambiguity associated with the neural electromagnetic inverse problem,

a number of investigators have pursued the strategy of using fMRI to define the locations of activation while using MEG or EEG to estimate time courses. Although this approach may have considerable value, it also has its pitfalls. In general, there is no guarantee that activation seen in one modality will be apparent in the other. The relationship between the precise areas of increased bloodflow and electrophysiological activation is not certain. If we assume that anatomical MRI constrains the location and orientations of possible source currents and that fMRI provides an estimate of the identity and relative strengths of active voxels, it is possible to compute the field topography associated with an extended source of arbitrary shape and size. Alternatively, fMRI can be employed as a method to *seed* dipole source estimates, which are optimized subsequently by using standard nonlinear procedures. This strategy provides a measure of flexibility to account for mismatches between assumptions and source model.

Other investigators have employed a form of weighted minimum norm to combine fMRI and NEM data. The inverse solution is constrained to lie within the cortical surface, and source current orientation may be constrained to lie normal to the local surface. By weighting the reconstruction according to the spatial pattern of apparent activation disclosed by fMRI, it is possible to guide the minimum norm reconstruction to preferentially place current in those regions. Because Bayesian methods explicitly employ prior knowledge to help solve the inverse problem, they provide a natural and formal method to integrate multiple forms of image data. The simplest strategy is to use fMRI data as a prior. This method can profitably employ strategies for the analysis of fMRI data that quantify the probability of activation in any particular voxel on the basis of fMRI data. Bayesian methods will also benefit from the efforts to develop probabilistic databases of functional organization. Figure 8 illustrates two approaches employed for the integration of MEG and fMRI data.

VII. TYPES OF EVENT-RELATED POTENTIALS

Model-based source localization, computational decomposition of complex responses, and quantitative estimates of the activation time courses of identified brain regions are all relatively new tools for the analysis of event-related neural electromagnetic data. However, 50 years of macroscopic electrophysiological study of neurological, psychological, cognitive, and behavioral processes of the human brain have produced a rich legacy of experimental observations and interpretation. Many of these results are based on the analysis of features in the response waveform, often averaged across many sensor locations and sometimes across many individual subjects. A comprehensive summary of such results is well beyond the scope of this article. Excellent review articles and even entire volumes have been devoted to small corners of the field. We will briefly review some of the major classes of event-related responses that have been identified and characterized.

A. Evoked Responses

Evoked responses are elicited by sensory stimulation and are usually recovered by signal averaging time-locked to stimulus delivery. Response waveforms consist of a stereotypical series of peaks and valleys observed between 2 and 250 msec poststimulus. Such features reflect the sequential and parallel activation of multiple specialized processing waystations within the targeted sensory pathway, although individual response components may represent simultaneous activity in several distinct areas. The responses are a product of the network architecture and the dynamics of participating neurons and are reasonably robust. Sensory evoked activity can often be recorded even under anesthesia.

Evoked responses have been used to probe the architecture and the information processing activities of sensory systems. Such work has provided evidence for specialized processing modules, corresponding to the discrete areas identified through invasive physiology, and has disclosed systematic projection of the sensory parameter space onto cortex. Other studies have provided evidence for early modulation of sensory responses by selective attention and demonstrated dynamic plastic changes in the functional organization of cortex, based on patterns of sensory coactivation or neglect.

1. Somatosensory Evoked Responses

The somatosensory system can be activated through tactile stimulation of almost any body surface. Particularly robust responses can be elicited by electrical stimulation, for example, of the median nerve of the forearm. The earliest responses to somatosensory

stimulation are observed from 9 to 15 msec poststimulus and represent responses generated in the spinal cord and brain stem. Initial responses in primary somatosensory cortex are observed around 20 msec poststimulus. An evolving complex of responses typically lasts over 150 msec. Source modeling studies identify at least 5–6 discrete regions of activation. Studies of the organization of the primary somatosensory area (S1) disclose a systematic projection of the body surface onto cortex adjacent to the central sulcus,

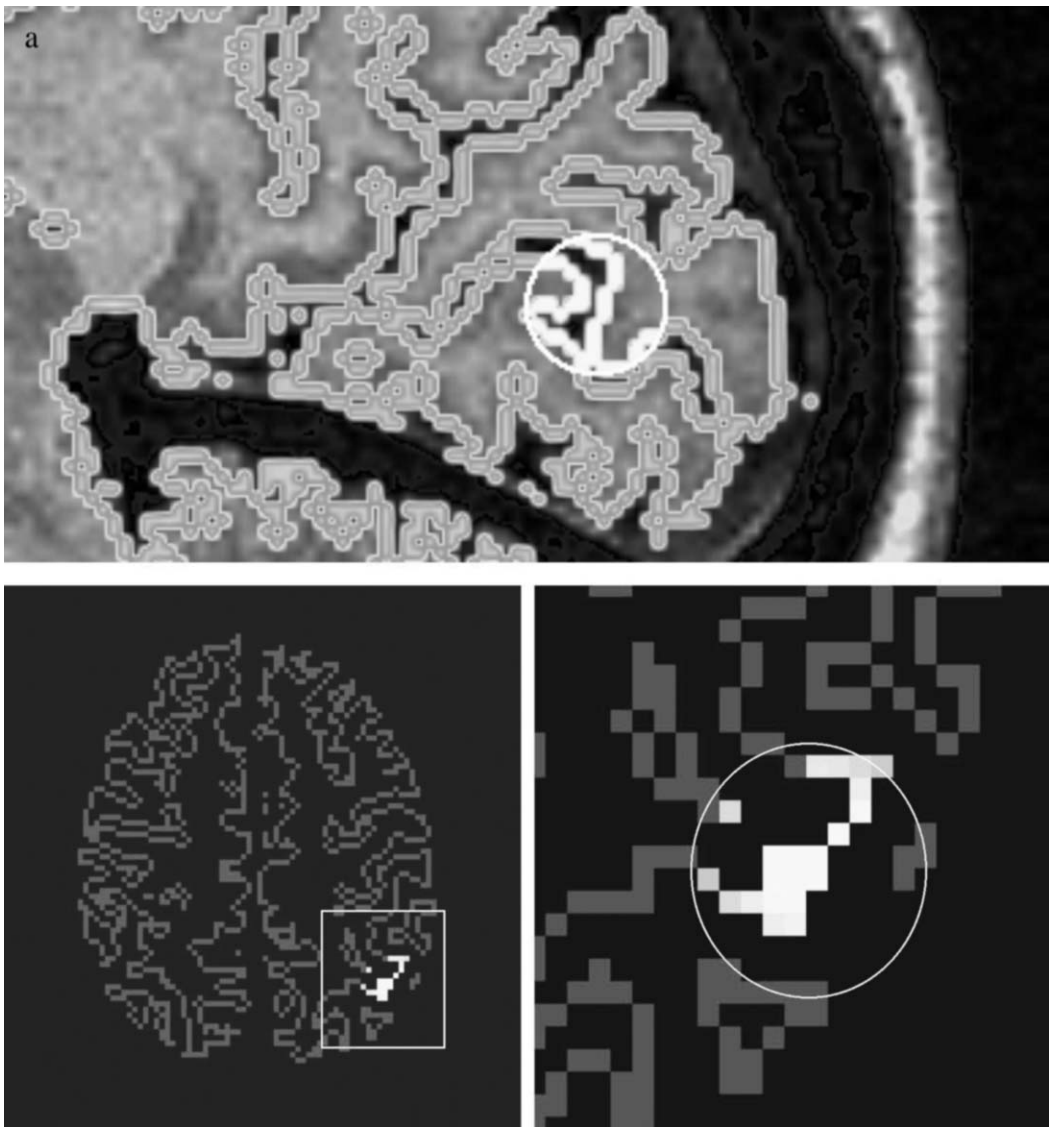

Figure 7 Analysis of MEG evoked responses by Bayesian inference. (a) Extended parametric source models used for Bayesian inference. Upper panel: A source defined by the intersection of cortex with a sphere centered on cortex. Note that adjacent sides of a sulcus or gyrus are often labeled together for extended sources. Lower panels: A source defined by a patch grown on the cortical surface. A location on cortex is seeded, and adjacent bands of voxels are labeled in a series of dilation operations. (b) A series of sample solutions from the posterior probability distribution. After 1000 iterations the MCMC algorithm found the same set of three sources in almost every sample, although additional extraneous sources also appear in some solutions. These data were simulated and thus known to contain three sources in the locations suggested by Bayesian inference. (c) Interactive visualization of spatial–temporal source probability maps coregistered with anatomical MRI for the same subject. The anatomical data set was used in the Bayesian inference procedure to constrain sources to lie in cortex. (d) Source probability maps estimated for visual evoked response data. Four views of a region found to contain activity at a 95% probability level. This example is for left visual field stimulation. For right field stimulation, the most probable source is lateralized to the calcarine fissure in the left hemisphere.

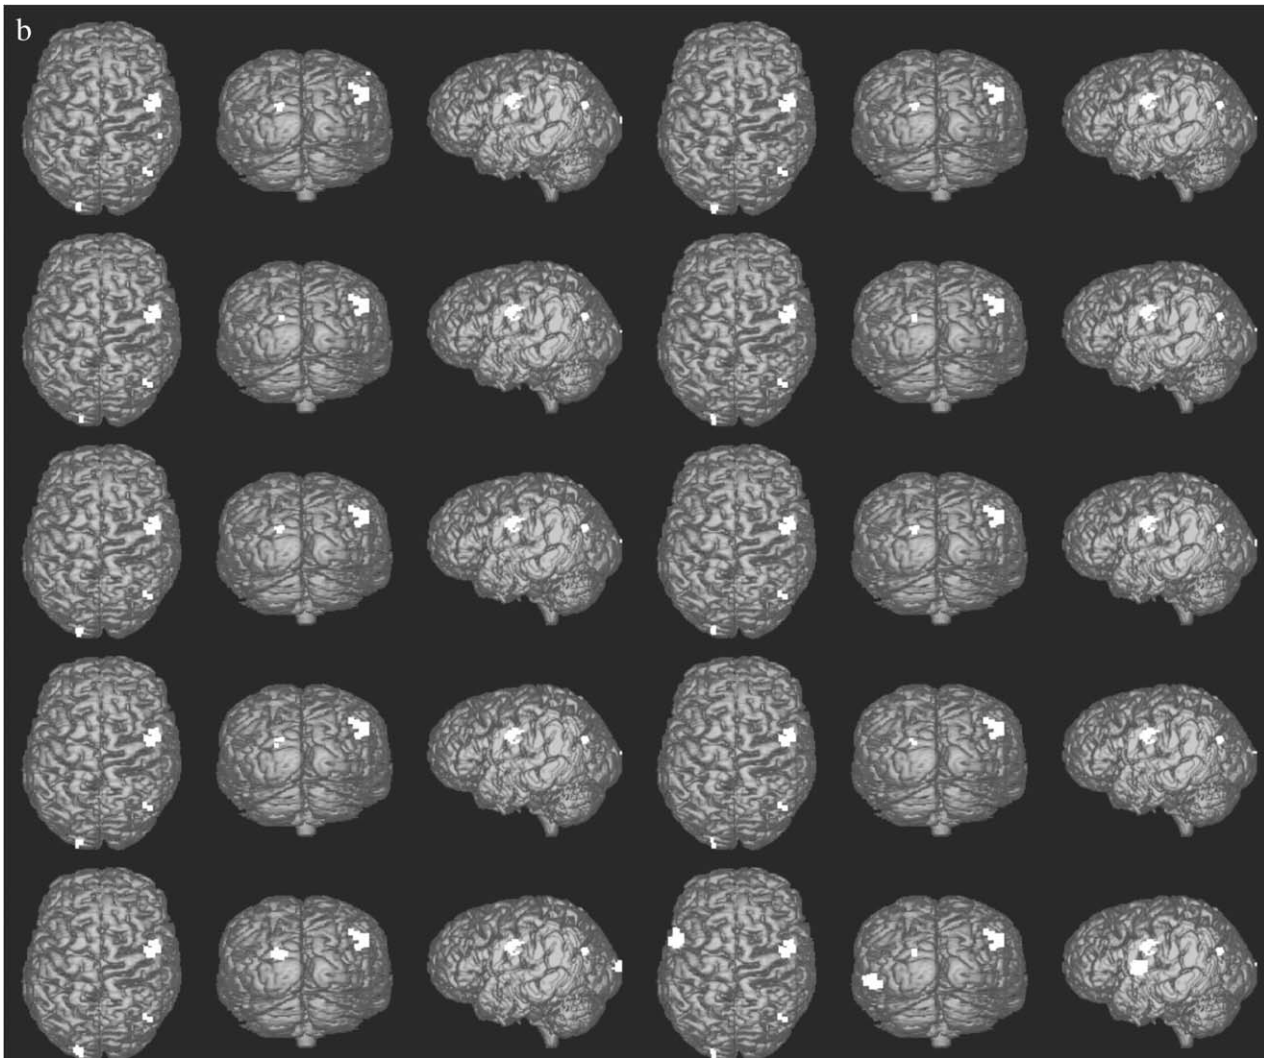

Figure 7b

generally consistent with the classic homunculus described by Penfield, based on intraoperative electrical stimulation.

2. Auditory Evoked Responses

Auditory evoked responses are typically elicited by clicks or tone bursts, which may be delivered to one or both ears. With appropriate electrode placement, it is possible to noninvasively measure electrical responses of the cochlea, including receptor potentials, and signals that reflect from neural encoding. From 1 to 12 msec poststimulus auditory brain stem responses can be measured. These responses consist of a series of mostly discrete waves labeled I–VII. Although the sources of these components are still a matter of some debate, there is general agreement that wave I is due to a compound action potential or graded dendritic potentials at the dictal (cochlear) end of the acoustic nerve. Waves III–V are generated in the brain stem. Waves V and VII are associated with higher brain stem structures—perhaps the medial geniculate body. Auditory brain stem responses are useful for hearing assessment in infants, uncooperative adults, and cases of functional deafness, as well as for evaluating brain stem function in suspected multiple sclerosis. The general temporal structure of auditory evoked responses is illustrated in Fig. 9.

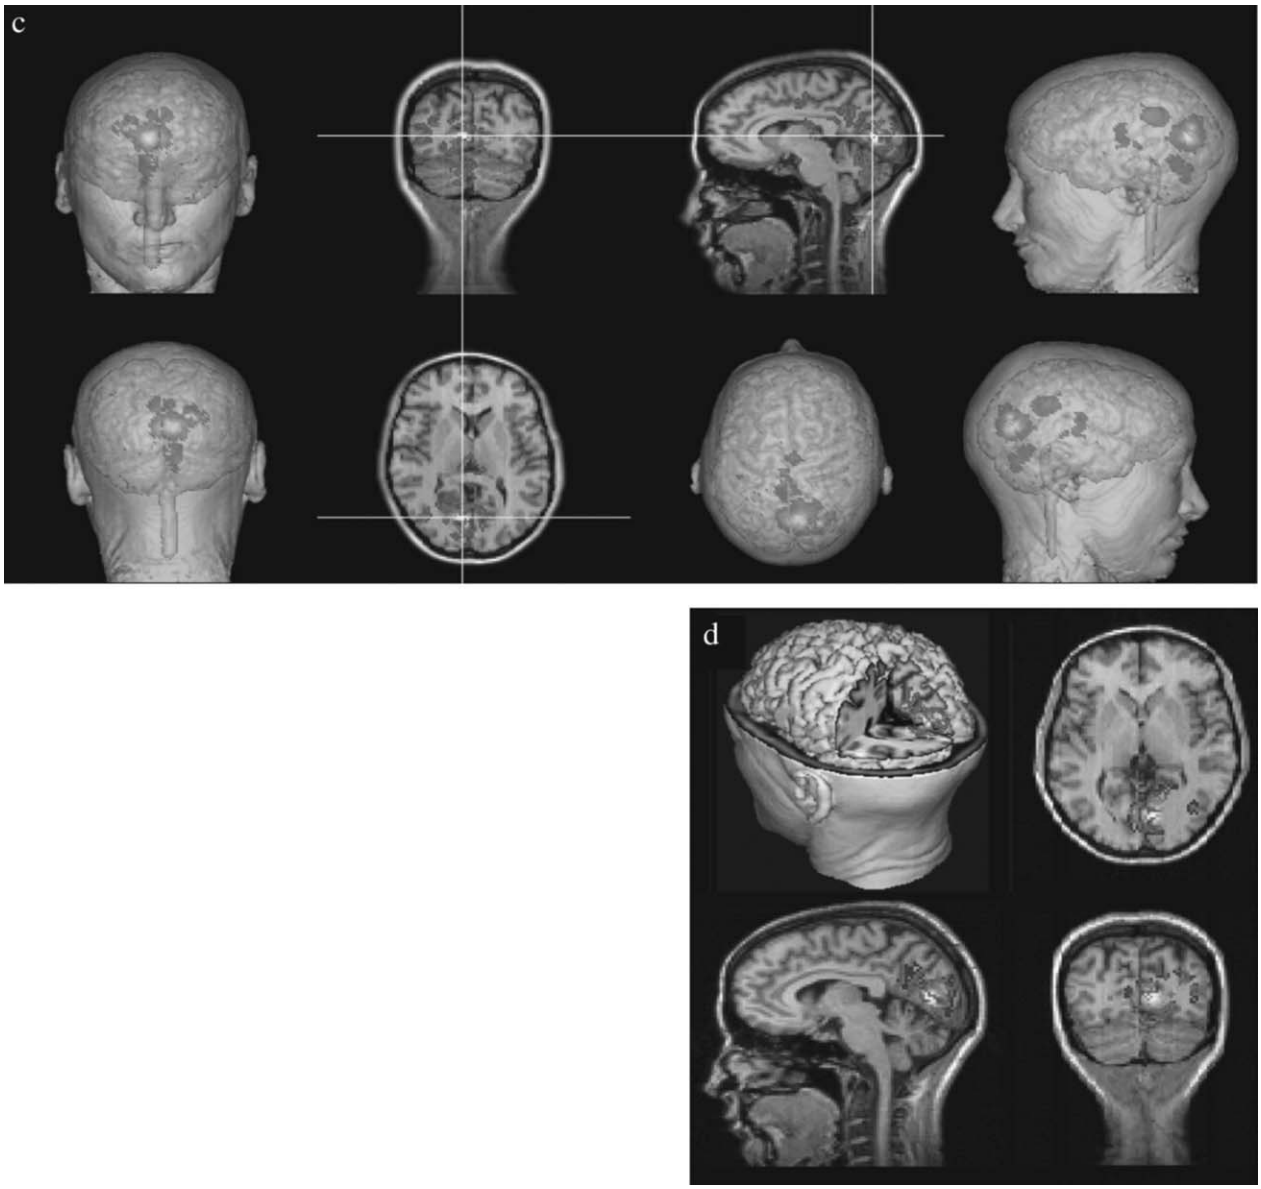

Figure 7c–d

Middle latency auditory evoked responses are typically observed from 12 to 50 msec poststimulus and are considered to represent subcortical activation.

Late auditory evoked responses (50 msec or more after the stimulus) are generally a product of neocortex. Such responses are best evoked by tone bursts and in EEG recordings show the highest amplitude over the vertex. MEG studies lave localized these responses to primary sensory areas along the Sylvian fissure and to nearby association areas. Such studies have also demonstrated clear tonotopic organization in primary cortical areas. With dipole localization techniques, very fine-grained discrimination of relative locations is possible. Auditory stimuli are often used for language studies, and in this role they may elicit an interesting array of endogenous responses that reflect the neural processing of language. However, at least one endogenous response appears purely acoustic: the mismatch negativity is observed when a repetitive auditory stimulus is briefly altered and may serve as an orienting response to cause a shift in the focus of attention.

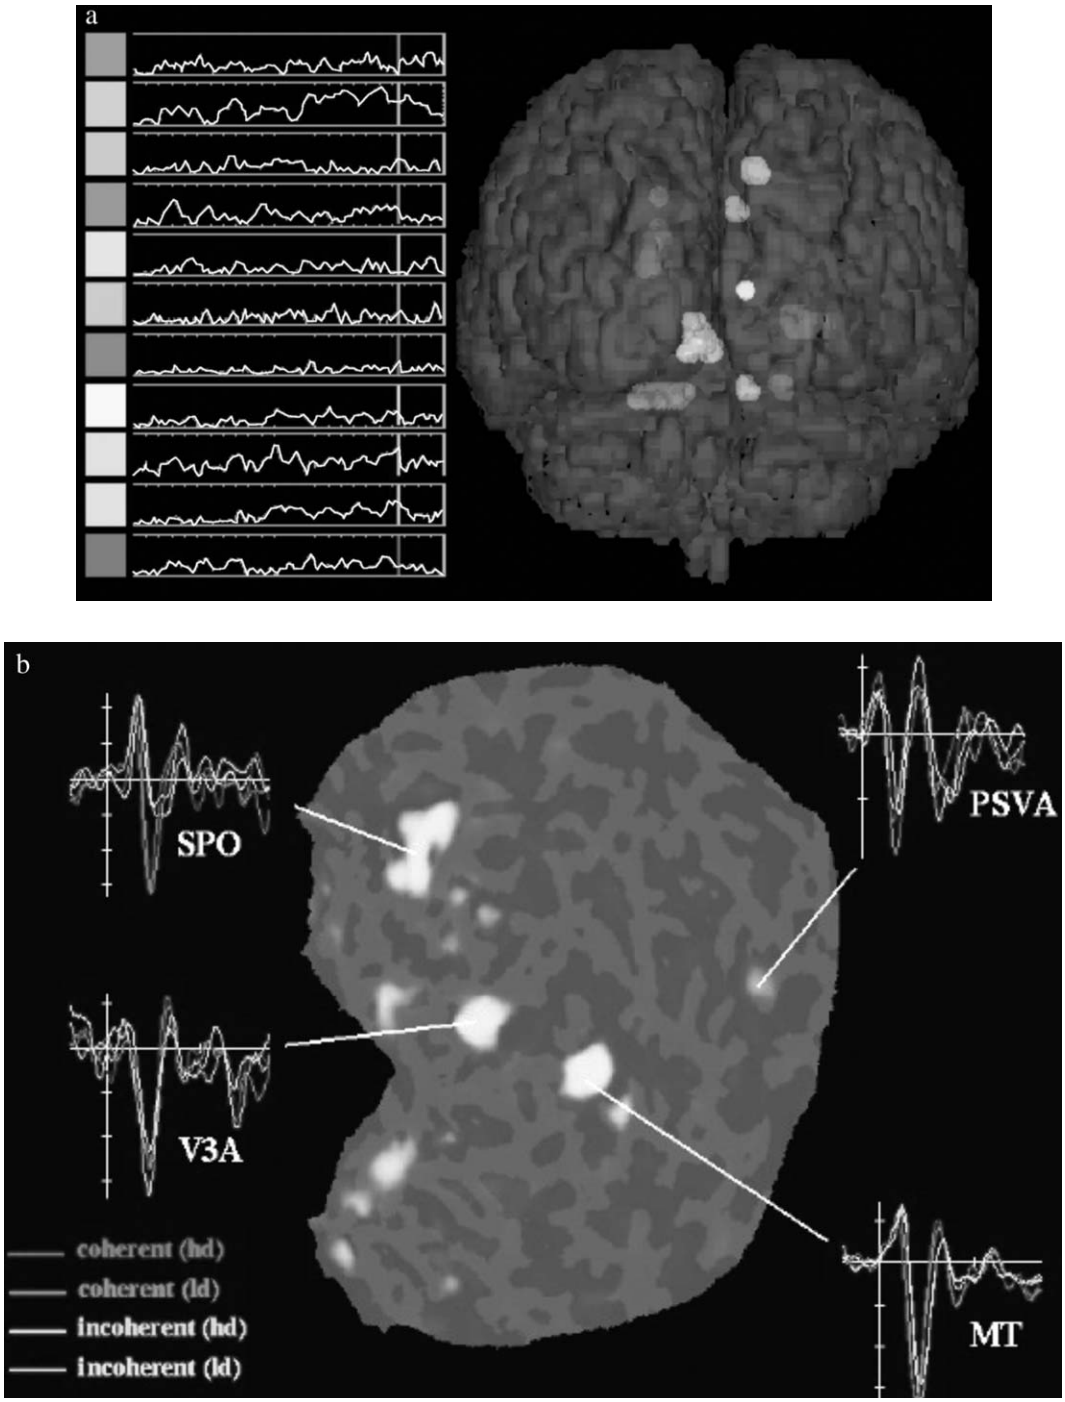

Figure 8 Integrated analysis of fMRI and MEG. (a) Time courses of fMRI equivalent sources estimated from MEG data. fMRI visual data were acquired using blocked steady-state stimulation, using the same video display from a previous MEG experiment. Currents were assumed to vary within the source according to the distribution of functional MRI activation. Currents were constrained to lie normal to cortex as indicated by anatomical MRI. Topographies were derived for each of the assumed sources and used as basis functions for a linear decomposition of the time-varying field maps. Estimated time courses for 11 areas are coded in color. (Figure courtesy of Dale *et al.*) (b) MEG time courses of fMRI sources using a weighted minimum norm procedure. Areas of activation from a visual fMRI experiment (involving visual motion) are shown on an unfolded cortex. A 0.9:0.1 weighted pseudo-inverse procedure was applied to field maps at each time point. Estimated time courses for activation in four identified visual areas are illustrated. Differences as a function of stimulus type are coded in color. (Figure courtesy of Dale *et al.*)

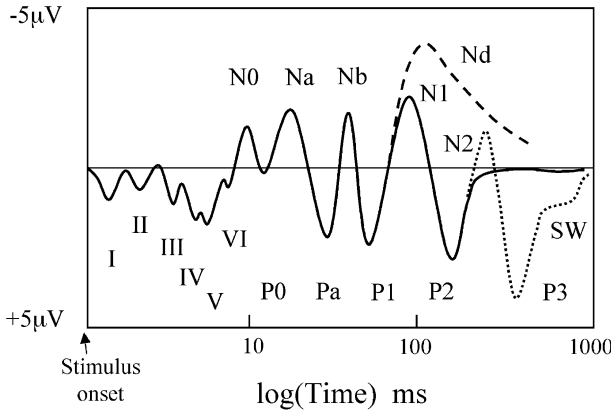

Figure 9 Component structure of the auditory event-related potential. The trace schematically represents the averaged evoked response of the auditory system to a brief stimulus such as a click or a tone. A logarithmic time scale allows visualization of the major response component peaks in a single trace. Components include auditory brain stem responses (I–VI), early positive (P) and negative (N) cortical components (Na, Nb, Pa, P1), and late cortical components (N1, P2). Other components that vary as a function of cognitive or attentive states are shown with dashed lines. (Figure courtesy of Hillyard and colleagues)

3. Visual Evoked Responses

In primates, the visual system is the largest and most distributed of the sensory modalities, consisting of over three dozen discrete areas and spanning at least one-third of the neocortical surface area. The system has been studied extensively with invasive electrophysiological techniques, as well as with MEG and EEG (and fMRI). The comparatively small signals and their dynamic complexity make this system a major challenge for sensory evoked response studies.

As in the auditory system, it is possible to measure the electrical response of the sensory organ—the eye. The electroretinogram (ERG) is typically measured using a contact lens electrode referred to a reference on the head surface. The response consists of receptor and neural components. Because the retina is a relatively accessible outpost of the brain, it has been the target of a number of studies of information processing by neural networks. In the future, optical techniques may allow noninvasive characterization of retinal network dynamics.

The visual evoked response observed with surface sensor arrays is dominated by primary cortical areas. The initial cortical activation in layer 4 of striate cortex probably occurs around 70–80 msec poststimulus, although this component is often small and difficult to detect. Other cortical responses are observed in striate and nearby areas from 90 to 120 msec poststimulus, and evoked activity often lasts through 250 msec. Source localization studies have demonstrated the anticipated retinotopic organization of primary visual cortex as well as extrastriate areas. The visual field is systematically projected onto striate cortex, mostly buried in the fissure between the hemispheres along the calcarine fissure. The central field representation is found near the posterior pole of occipital cortex and may extend onto the posterior surface. The lower quadrants of the visual field are mapped onto the upper banks of the contralateral calcarine and interhemispheric fissure; the upper field projects to the lower banks, and the horizontal meridian projects to the depths of the calacrine in a scheme summarized by the cruciform model (due to its appearance in coronal section). Noninvasive studies have confirmed the outlines of this model, although individual departures appear common. Such studies also support the idea of the cortical projection factor: the cortical area devoted to a given size patch of the visual field systematically decreases from the center to the periphery of the visual field.

Noninvasive techniques so far have largely been used to confirm in humans results suggested by invasive studies in animals. Thus, a number of specialized areas have been identified in humans analogous to those identified in electrophysiological studies in nonhuman primates, including areas specialized for processing visual motion, color, texture, and even faces. The visual system appears to be organized into two major processing chains or streams. The dorsal stream, arrayed mainly across occipital cortex and the upper surface of the parietal lobe, operates in low contrast and is involved in processing visual motion. The system is probably involved in orientation and allocation of attention and may interact with motor control. The ventral stream flows along the base of the occipital and temporal cortices, and is involved in the processing of color, texture, and other detailed attributes of visual information. This system probably interacts with language processing centers. Some investigators have dubbed these streams the *what* and *where* systems.

B. Motor Control

The control of voluntary movement can also be studied with event-related response techniques. In a typical experiment, the subject is instructed to perform a series of self-paced voluntary movements, and the

signal is averaged relative to the movement as registered by a button press or an electrical response recorded from muscle. The response appears as a slowly developing negative potential shift somatotopically arrayed along the central sulcus, starting approximately 1 sec before movement. This response is called *the readiness potential* and is taken as an index of motor preparation; the amplitude of the response is correlated with the complexity of the subsequent movement as well as the force and speed developed. The readiness potential preceding a lateralized response (such as a hand movement) is maximal over the contralateral hemisphere. Some investigators use signal subtraction techniques to remove the ipsilateral contribution to the signal. In addition to the readiness potential, other movement-related responses can be resolved, as well as somatosensory and proprioceptive feedback generated as a consequence of the movement.

C. Cognitive Event-Related Responses

The readiness potential is considered an *endogenous response* because no external (exogenous) stimulation is required to elicit it. Although motor cortex is certainly involved in responses that involve sensory processing, typical paradigms do not employ sensory cues because stimuli would elicit sensory evoked responses and trigger a set of cognitive processes that might complicate interpretation. Cognitive responses to assigned tasks involving search, discrimination, classification, or decision processes also have been studied extensively, often in the absence of any observable (behavioral) response.

1. CNV

Studies of the effects of classical conditioning led to the identification of the *contingent negative variation* (CNV), one of the first of the endogenous responses clearly linked to a cognitive process. In these experiments, an initial stimulus was delivered, followed by a delay and then a second stimulus. During the interval between the stimuli, a slowly growing negative potential was observed at the scalp. In many experiments the second stimulus was intended to cue a behavioral response, although a response is unnecessary and, as outlined above, would presumably elicit motor potentials that would complicate interpretation. Studies with variable intervals between the stimuli suggest that the CNV reflects at least two processes: an *orienting response* (o-wave) associated with the initial (warning) stimulus and an *expectancy response* (e-wave) that develops in anticipation of the imperative stimulus.

2. P300

One of the most extensively studied cognitive event-related responses is the P300 (or P3) complex, sometimes referred to as the family of late positive responses. The form of this response is relatively independent of the sensory modality used to elicit it. The generic paradigm associated with the response is an oddball discrimination task: for example, two or more stimuli are presented in a random series so that one occurs infrequently. This oddball elicits a response that begins around 300 msec poststimulus and may last 100 msec or more. Since the initial reports, the response has been resolved into at least two components that are differentiated on the basis of scalp topography and sensitivity to paradigm manipulation. The P3A is larger in amplitude over the central and frontal electrode sites. The response may be an alerting response arising in frontal cortex; in any case it is the component most strongly associated with the oddball response. The P3B appears to reflect subsequent allocation of attentional resources and encoding of stimulus memory. Some authors have argued that the response reflects information transfer via the corpus callosum with subsequent activation of hippocampal and parietal processes.

3. Selective Attention

The processing of information from the environment can be effectively suppressed or significantly enhanced depending on the state of attention. Event-related responses have been used extensively to study the time course and anatomical basis of *selective attention* in the human brain. Such experiments are typically conducted with contingencies that are manipulated within or between blocks of stimuli, so that the same physical stimulus may be the target of a discrimination task, may share some features with the target, or may be irrelevant. Data are typically analyzed by taking differences between responses to the same stimuli that differ in assigned task. The so-called negative difference or processing negativity is constructed by subtracting the response to an unattended stimulus from the response to the same stimulus while attended. In focused auditory attention, this effect may be observed as early as 20 msec poststimulus and is most apparent

around the latency of the N1; however, the time course does not reflect a simple scaling of the N1.

In visual evoked responses, tasks involving spatial selective attention, spatial cueing, or visual search produce enhanced P1 and N1 components, although controversy remains regarding whether the sources of the difference component are the same as for the underlying evoked response component. Visual selection on the basis of features such as shape, texture, or color elicits a difference signal termed the selection negativity and is observed from 150 to 250 msec poststimulus with a maximum over posterior electrodes. Taken together, these observations suggest that attention to location in the visual field is an early process, perhaps mediated by facilitation and/or suppression in prestriate relays such as the thalamus. Attention to other features or conjunction of features probably is mediated by specialized visual areas further along the processing chain.

4. ERN

In discrimination trials in which a fast choice is enforced by a reaction time task, an *error-related negativity* (ERN) is observed in trials in which the wrong response is performed. This response, predominantly observed over midline frontal areas, appears to reflect a process of rechecking that is initiated in parallel with the response. In many cases the ERN appears before the behavioral response; presumably when the response is optimized for speed, the motor system is committed before the decision–recheck cycle is complete.

5. Language-Related Responses

Event-related potential studies have been used to identify a number of responses associated with language processing. Word stimuli presented in spoken or written form elicit a response peaking around 280 msec (N280 or *lexical processing negativity*) typically characterized by a negative peak over left frontal regions of the scalp. This is considered to be a generic correlate of word processing, though in an experimental context the latency can be manipulated as a function of the frequency of the word. Another prominent response is elicited by semantic incongruity in written text or speech. The N400 is a right posterior scalp negativity the begins around 200 msec and peaks around 400 msec following the presentation of a word that violates semantic expectation. Because the response is associated with meaning and context, the N400 is considered an index of higher order language processing. A number of response components have been associated with processing of the form and structure of language. The *syntactic positive shift* (P600) is a late positive response elicited by certain types of grammatical errors (such as subject–verb agreement), even though the meaning of such a sentence may be clear. Figure 10 illustrates an example of a language-related ERP.

6. ERS–ERD

Event-related or evoked responses are generally considered to reflect transient, discrete processes associated with responses to external stimuli or internal imperatives. The time courses of many event-related response components look suggestively like the postsynaptic potentials that are recorded directly from neural tissue, perhaps reinforced by population activation and broadened by timing jitter. However, in some cases the response of neural populations appears to reflect a reorganization of ongoing activity; either an increase in synchronized oscillatory activity (*event-related synchronization*) or a decrease (*event-related desynchronization*). Although most authors consider these to be distinct phenomena, others have argued that all event-related responses might reflect transient phase locking of spontaneous activity. For example, the waveforms associated with some auditory evoked responses look like a damped oscillation. Perhaps the most interesting responses of this class are transient oscillatory population responses that may reflect phase locking within a network. Such processes are not phase-locked with respect to the stimulus and appear to reflect detection or "binding" of features such as coherent motion or a shared contour that may extend well beyond the receptive field of any individual neuron.

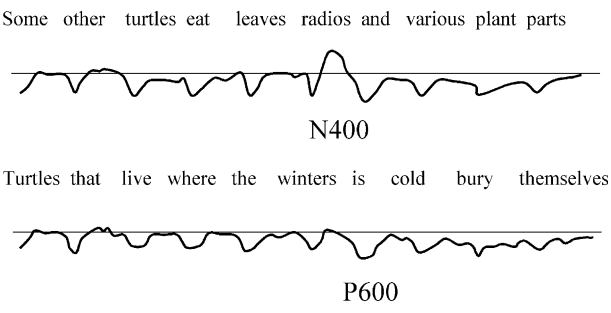

Figure 10 ERP effects elicited during language processing. Average ERP data from written sentences read one word at a time for comprehension. Upper trace: An N400 elicited by semantic violation. Lower trace: P600 elicited by grammatical violation. (Figure courtesy of Kutas and Dale.)

VIII. APPLICATIONS

A great deal of scientific effort has been devoted to the study of event-related neural responses: characterizing the spatial distribution and temporal structure of responses, probing the underlying physiology and biophysics, dissecting the consequences of cognitive and behavioral manipulations, and developing the analytical techniques and computational tools that allow more powerful inferences based on such measures. Event-related and evoked responses have recognized utility for a variety of applications in clinical and basic research.

A principal clinical application of evoked responses has been *for assessment of the patency of sensory information processing pathways*. Measurements of the ABR and early VEP have been used as objective diagnostics for the integrity and proper development of the auditory and visual pathways in infancy and childhood. The latency of the VEP has been used for the assessment of multiple sclerosis. Demyelination associated with this progressive degenerative disorder causes decreases in conduction velocity apparent as increases in the latency of cortical response components. Endogenous response components such as the P300 have been used as a generic probe of psychological and cognitive processes in disorders ranging from schizophrenia to Alzheimer's to alcoholism. In many cases the link between the diagnostic measure and the underlying pathology is tenuous, but statistical differences between normal and affected individuals can be observed.

The development of source localization techniques has led to applications for *presurgical mapping of eloquent cortex*. When neurosurgeons need to resect portions of brain tissue to remove a tumor or an epileptic focus, a principal requirement is that they spare the cortical tissue responsible for language and movement. Otherwise the pathology is often considered inoperable, even if life-threatening. The deleterious consequences for quality of life are considered too severe. MEG has been used to map the cortical regions responsible for these functions, in some cases even when the anatomical substrate has been distorted or displaced by the disease process. Such studies are typically undertaken as part of the process leading to a commitment to surgery; the conclusions are typically confirmed by conventional procedures during surgery. Because the questions are fundamentally issues of static functional architecture, fMRI is increasingly used for such purposes.

NEM techniques have clear advantages for *presurgical mapping of certain cortical pathology*. Disorders such as epilepsy are fundamentally disorders of dynamic neural function. Although the generator region is sometimes associated with an obvious lesion, sometimes the area appears normal on anatomical MRI. Typically, patterns of seizure and other epileptiform activity are first studied with EEG. MEG is used if available in an attempt to better localize the initial focus of the time-evolving response. In present practice, localization is usually confirmed by grids of electrodes placed over the surface of cortex or depth electrodes inserted in key locations. Many physicians believe that source localization based on noninvasive methods will eventually be accurate and reliable enough for surgical decisions.

Seizures can be triggered in some individuals, often children, by stroboscopic visual stimulation, providing a useful measure of experimental control. However, most epileptic seizures are not scheduled and may be relatively infrequent. Capture of an ictal event during an experimental session is, to some extent, a matter of chance. For practical reasons, many clinical researchers have studied interictal activity. Such studies suggest that interictal activity often arises at or near the locations that can trigger a seizure. Other researchers have noted a strong correlation between computed sources of slow waves with the margins of lesions that give rise to seizures. Slow waves are also associated with regions of closed head trauma. Abnormal low-frequency activity is sometimes seen in such cases even when the tissue appears normal in MRI and no significant cognitive or behavioral deficits can be detected.

NEM measures and event-related response methods have been used for other applications in *physiological and behavioral research*. EEG has been used extensively in human factors studies, for example, to assess the effects of workload, stress, and sustained effort on intellectual performance and attention. Although many of these studies have employed correlation or coherence analysis of ongoing EEG activity, others have employed sensory or cognitive probe tasks to assess neurological performance. Several investigators have explored the use of EEG to generate control signals for electromechanical systems. Prosthetic devices for amputees have been built with electronic control systems, although to date the most successful have employed control signals derived from remnant muscle. Proof of principle has been demonstrated for the use of EEG for the control of vehicles or mobility aids for patients with little or no voluntary control of muscle function.

Basic neuroscience and cognitive research have become major applications of event-related neural

response techniques. The advent of neural electromagnetic source modeling techniques has allowed localization of specialized sensory processing areas and disclosed interesting aspects of functional organization within areas. Such methods have disclosed evidence for neural plasticity in the form of use-dependent changes in the strength and extent of activation associated with stimulation. The greatest value of electromagnetic techniques is likely to come in studies of the dynamics of neural information processing within and between areas. To date, such studies have been largely qualitative and observational. However, by coupling the physical models used for electromagnetic source localization with computational neural network models, it should be possible to predict integrated responses of complex networks from the interaction dynamics of populations of model neurons. Such methods will allow us to frame and answer questions about the role of dynamic, spatiotemporal processes in the encoding and processing of information by neural systems.

Evolution of the Brain

HARRY J. JERISON
University of California, Los Angeles

GLOSSARY

allometry Measured comparisons of two organs or organ-systems. In brain-body allometry, usually the regression of brain size on body size. Size is scaled logarithmically, and the allometric equation is usually a power function.

encephalization The degree to which actual brain size in a species is greater or less than that expected according to an allometric analysis. It is often measured as an "encephalization quotient" (EQ), which is the residual of the regression of log brain size on log body size.

neocortex A characteristically layered portion of the cerebral cortex unique to mammals, usually six-layered.

There are about 50,000 species of vertebrates, each unique in many traits but sharing "primitive" traits with close and distant relatives. The pattern of unique traits defines each species, and the suite of shared (older, more primitive) traits, depending on the size of the suite, helps define them as members of a higher taxon: genus, family, etc. This is as true for neural traits as it is for other traits that differentiate animal species. All biologists accept the evolutionary dogma that the uniformities in traits across species are due either to common ancestry or to convergent evolution, and that the diversity of species should usually be explained by adaptations to specialized environmental niches.

This article is updated from one originally published in D. W. Zaidel, (Ed.), *Neuropsychology*. Academic Press, New York. (1994). For those with access to the Internet, an unusual collection of data is available for inspection and analysis at a site supported by the U.S. National Science Foundation, including photographs of brains and serial sections of brains in many living species of mammals. Fossil evidence is displayed at the same site and may be accessed at http://www.neurophys.wisc.edu/brain/paleoneurology.html.

I. GENERAL CONSIDERATIONS

This article emphasizes inferences from allometric analysis of brain/body relations and encephalization, the latter being a complex trait often attributable to convergent evolution. Although the diversity in organization of brains is at least as important, especially for understanding the phylogenetic trees, an adequate discussion of the evolution of diversified brain organization requires a more detailed review of comparative anatomy and physiology than is possible in a single article, and the conclusions, though important, are easily summarized for evolutionary neurobiology: Brain structure is appropriate to function, and specialized functions are appropriate to the environment (i.e., structure and function are adaptive). In short, the results are consistent with adaptation as a biological principle. Applied to the sizes (weight, volume, or surface area) of the subsystems in the brain, such as cortical projection areas and thalamic nuclei, this is the principle of proper mass.

Despite their simplicity, allometry and encephalization provide more unusual evolutionary insights. Allometry helps us understand the biological role of size; encephalization does the same for understanding neural information-processing capacity and its evolution. It will be enough to review the diversity of

organization by citing a few examples, the reports of which are extremely well documented.

The issues considered in this article are also relevant for the evolution of invertebrate nervous systems. The neuron, for example, probably appeared as a specialized cell early in metazoan evolution, more than 600 million years ago (Ma), and many of its features are identical in all instances in which it functions in a synaptic nervous system. This is evidently true for small networks of neurons as well as for isolated cells. Much of what is known about neural functions as single units and in small networks was learned from giant neurons of horseshoe crabs and from networks of cells in sea slugs and roundworms. The early appearance of the adaptation is deduced from a cladistic analysis of the time of divergence of species in which it is identifiable. It is most likely that the adaptation first appeared in a pre-Cambrian metazoan species that is the "common ancestor" of all the living species that share the adaptation. From an evolutionist's perspective, however, very complex behavior requiring integrated neural activity and involving more extensive neural circuitry that is common to vertebrates and invertebrates is as likely to be analogous ("homoplastic") rather than homologous. It may have evolved in independent evolutionary paths in the vertebrate and invertebrate groups in which it occurs.

A. Brain Structure and Function

Every vertebrate brain is hierarchically organized into forebrain, midbrain or mesencephalon, and hindbrain. The forebrain can be further divided into telencephalon and diencephalon, and hindbrain can be divided into rhombencephalon and myelencephalon. Brain tissue in all animals consists of neurons as information processing units and glia and other cells that are, in effect, supporting tissue. Neurons are often specialized with respect to neurotransmitters, shape, and size. Sizes, for example, range from the granule cells of the cerebellum (soma less than 10-μm diameter) to the giant Mauthner cells (soma about 100-μm diameter) that mediate startle responses in fish and in amphibian tadpoles. The full size of a nerve cell includes the arborization of axon and dendrites, which may account for 95% or more of the volume of a neuron and which varies enormously in pattern both within a brain and between species.

Underlying this diversity, there is surprising uniformity about principles of nerve action in the transmission of information, which makes it possible to use almost any neuron from any species as a model for neuronal action. There is, furthermore, a uniformity at the level of networks of cells in vertebrate brains, evident even in the neocortex in mammals, which encourages one to emphasize information-processing capacity for the brain as a whole as well as in its specialized component systems, such as those for color vision, binocular vision, sound localization, and olfaction.

B. Evolution

The facts of evolution are first, that it occurred and second, that it could occur because of the genotypic and phenotypic diversity both within species and between species. Charles Darwin's great contributions were to recognize the diversity and to explain it by the theory of natural selection. As currently understood, the theory is that given the variety of phenotypes in a species, some individuals will be more successful than others in surviving to produce offspring. Reproduction is the measure of success. The mean of the gene pool of the next generation shifts toward the mean of the successful phenotype. As the environment changes, the characteristics required to be successful change, and there is natural selection of individuals with those characteristics. This is a theory of the origin of species because there will eventually be enough change in the genotypic population to designate it as a new species.

There is so much support for the theory, in laboratory experiments and from field observations, that one might prefer a stronger word than "theory" to describe Darwin's integration. But there are disagreements among evolutionists, of course, which are sometimes taken incorrectly to be challenges to the credibility of the theory as a whole. The controversies are mainly about the relative importance of selection as opposed to random genetic drift, about the merits of various approaches to determining phylogenetic trees (cladistics), and about the rate of evolutionary change (gradualism versus punctuated equilibria). Despite their use and misuse in popular polemics, the controversies are on fairly technical questions and not on the fact of evolution.

II. THE EVIDENCE

A. Fossil Brains

The fossil record of the brain is from casts ("endocasts") that are molded by the cranial cavity of fossil

skulls. Natural endocasts are made by the replacement of soft tissue in the skull by sand and other debris that eventually fossilizes. Artificial endocasts can be made by cleaning the cavity and filling it with a molding compound such as latex, from which plaster casts can be made. Errors in identifying "brain" areas in endocasts of birds and mammals are likely to be about the same as in brains when superficial markings rather than histological or physiological evidence are the basis for the identification. Endocasts of some fossil animals are so brainlike in appearance (Fig. 1) that they are often referred to as fossil brains.

Figure 1 presents lateral views of the endocast and brain from the same domestic cat, *Felis catus* (Figs. 1A and 1B), and a copy of a natural endocast from a fossil sabretooth (Fig. 1C). The sabretooth is *Hoplophoneus primaevus*, which lived in the South Dakota Badlands during the Oligocene epoch of the Tertiary Period, about 30 Ma. Although no more than a piece of rock, its endocast is unmistakably a picture of its brain as it was in life; it was clearly appropriate to name its parts as brain areas in Fig. 1D following the nomenclature for cat brains.

There are several lessons to be learned from Fig. 1. First, an endocast can provide an excellent picture of the whole brain. This is evident when comparing Fig. 1A with Fig. 1B: The endocast of the domestic cat provides an excellent picture of external features of its brain and correctly estimates its size. (The estimation from the endocast is as "correct" as that from the brain, which is probably slightly shrunken by fixation.) Second, the convolutional pattern in an endocast may be fairly constant in related species. Thus, despite their separation by 30 million years of felid evolution, the endocasts of the living cat and of the sabretooth (Figs. 1A and 1C) are clearly similar. This lesson is especially important because convolutions map the way a brain is organized, at least in a general way. A third lesson, therefore, is that the felid brain of 30 Ma was probably organized in a way similar to that of living felids. Finally, as counterpoint to the lesson of uniformity of organization, there is a lesson of diversity: Two gyri, the coronal and sigmoid gyral complexes, are differentiated in living domestic cats but are undifferentiated in the sabretooth. Increases such as these in the apparent complexity of the brain in felid evolution may be related to increases in information processing in the expanded areas in later species compared to earlier species.

The quality of an endocast as a model of the brain differs in different taxa. Endocasts from fish, amphibians, and reptiles (except in very small specimens) are poor models, useful mainly to estimate total brain size after suitable corrections, because the brain fills only a

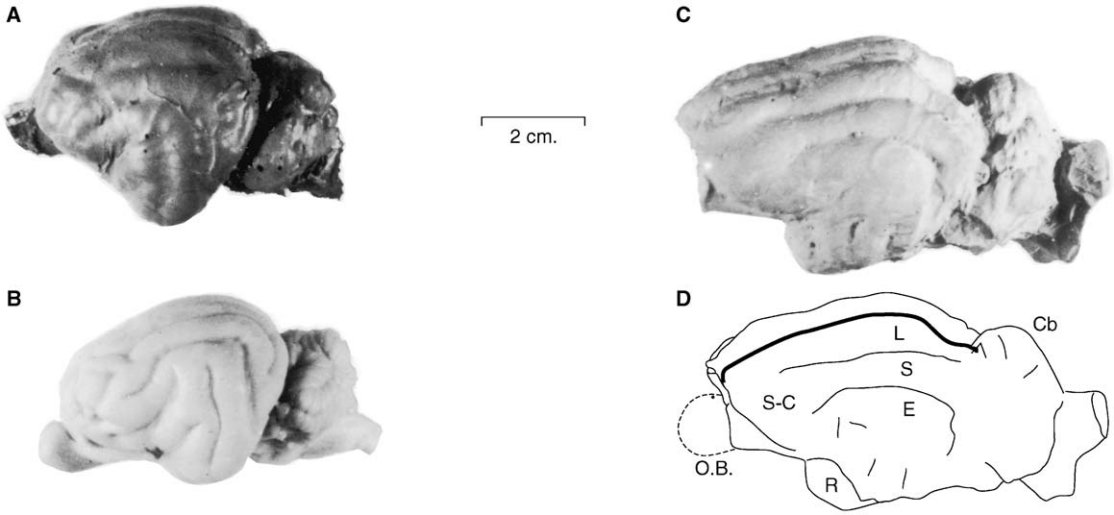

Figure 1 Brain and endocasts of felids. (A) Endocast of domestic cat (volume = 30 ml). (B) Brain of same cat (weight = 29.1 g). (C) Endocast of Oligocene sabretooth, *Hoplophoneus primaevus*, of 30 million years ago (volume = 50 ml; Specimen No. USNM 22538 at the United States National Museum, Smithsonian Institution). (D) Tracing of the endocast of Hoplophoneus with labels for several structures: Cb, cerebellum; E, ectosylvian gyrus; L, lateral gyrus; R, rhinal fissure; S, suprasylvian gyrus; S-C, sigmoid and coronal gyral complex (undifferentiated). Both endocasts are rotated about the anterior–posterior axis, exposing the longitudinal fissure (heavily inked in D). Olfactory bulbs (OB) are sketched in on the basis of more complete endocasts (e.g., AMNH 460 at the American Museum of Natural History). The unlabeled gyrus above the lateral gyrus is the lateral gyrus of the right hemisphere.

fraction of the cranial cavity. In mammals and birds, on the other hand, the brain actually helps shape the cranial cavity during development, and endocasts are usually excellent pictures of the outside of the brain. Olfactory bulbs, forebrain, and hindbrain are readily identifiable, as are most of the cortical gyri and sulci that are seen when a brain is first removed from the skull. Certain large-brained living mammals—namely, cetaceans, elephants, great apes, and humans—are exceptions to this rule, with little or no impression of their convolutions on their endocasts; even the boundary between cerebrum and cerebellum may be unclear.

Fossils provide other information for understanding brain evolution and for extrapolations to behavior. Body size, for example, estimated from postcranial skeletal data, is used to analyze encephalization of fossil vertebrates. Details of structure, such as the shape of teeth, forelimbs, and hindlimbs, can enable one to analyze feeding habits, gait, and other behavior. There is even fossil evidence on social behavior, for example, in dinosaurs, which has been reconstructed from the aggregation of fossils, their eggs, and their foot and tail prints. Perhaps most important for an analysis of brain evolution, there is a fossil record of sensory structures that is useful in reconstructing the information available to fossil animals. Olfactory bulbs, of course, are visible on the endocast, and their size is related to the evolution of the sense of smell. There are fossil middle ear bones and cochlea important for the analysis of the evolution of hearing; the orientation of the orbits of the eye provides evidence on the evolution of binocular vision, and the placement of the hyoid bones on fossil humans has been the basis for speculations on the evolution of the voice box and of articulated speech.

B. The Living Brain

Most of the evolutionary evidence on living brains is from anatomical and physiological studies of brain tracts and regions compared for unique and common features across species. There is growing interest in molecular evidence (e.g., on neurotransmitters), and one can anticipate increasing emphasis on that kind of information.

Braitenberg and Schüz have published a straightforward anatomical monograph, noteworthy for the quantitative analyses of the cerebral cortex of the mouse. Though not specifically concerned with evolutionary issues, they provided exemplars of data necessary for an evolutionary analysis. The most striking facts are on the amount of information processing machinery in the mouse, with some suggestions on the human brain. There are about 40,000,000 neurons in the 0.5-g brain of a mouse; more astonishing, there are about 80,000,000,000 synapses in its neocortex. Taking into account the packing density of neurons and synapses, they reached the conclusion that a particular volume of cortex processes the same amount of information, whether it is in a mouse or a man. This is an outstanding uniformity for evolutionary analysis since it validates the use of brain size as a "statistic" to estimate the total information processing capacity of a brain.

Uniformity is balanced by diversity. All species differ in the details of the organization of the component systems of their brains. The raccoons and their relatives (family Procyonidae) provide an outstanding example reported by W.I. Welker. The fish-handling raccoon has a much enlarged forepaw projection area in its somatosensory neocortex, with separate representation in the brain for each of the pads on the forepaw. The coati mundi, kinkajou, and most other procyonids obtain this kind of information by nosing about, exploring their environment by touching things with the sensory skin around the nostrils. Their neocortical projections from that region are comparably expanded and their forepaw projection areas are much less extensive and not as differentiated as in the raccoon. The conclusion is inescapable that reorganization of the brain, like the differentiation of the behavior that it controls, occurred as part of the speciation of procyonids as they evolved, and that raccoons branched away from the main line by their specialized adaptations in their use of forepaws. Data like these can be used for formal cladistic analyses. The mammalian phylogeny constructed from brain features is essentially the same as that based on a more complete suite of traits.

I depend on the comparative quantitative data laboriously accumulated by Stephan and his colleagues on the volumes of many brain structures in "primitive" species represented by insectivores and their relatives and in "advanced" species (primates) for many of my analyses of allometry and encephalization. Theirs are the most complete data of this sort currently available. In their sample of 76 species, there were 26 from the order Insectivora (shrews, moles, and hedgehogs), 2 Macroscelididae (elephant shrews), 3 Scandentia (tree shrews), and 45 primates, of which 18 are from the suborder Prosimii (lemur-like species) and 27 from the suborder Anthropoidea (simian species,

including humans). The brain structures are listed in Table I. These data are especially useful because of the large number of species that are in the sample and the good sample of brain structures on which measurements were taken.

III. QUALITATIVE ANALYSIS

There have been a number of outstanding evolutionary analyses of classic issues in neurobiology, and I describe three of these very briefly to suggest the topics and flavor: those by Ebbesson, by Karten, and by Killackey (complete citations for this discussion are in the chapter referred to in footnote on first page). Ebbesson provided a superb case history on the difficulties in interpreting and reasoning from available anatomical data on the brain. Ebbesson argued that connections are created by a process of "parcellation (segregation–isolation)" that occurs ontogenetically as well as phylogenetically, with originally diffuse and extravagantly proliferating neurons and connections eventually becoming reduced and segregated from one another during the course of development. Northcutt's commentary was noteworthy, pointing out not only the problems with the data used to support the position but also the semantic and philosophical difficulties: the need for rigorous specification of homologies and homoplasies in using comparative data for cladistic analysis.

Karten analyzed the origin of neocortex as a "uniquely" mammalian brain system, pointing out that neocortex is not functionally unique since its connections are comparable to those of the "neostriatum" in birds (and even in reptiles). The enlarged neostriatum in birds is homologous with mammalian neocortex. His microscopic analysis of these forebrain systems points to their comparability with respect to information processing, despite the very different ways that the brain is organized in these classes of vertebrates. This is in agreement with data that show birds and mammals to be comparable in "grade" of encephalization.

Killackey argued from ontogenetic data on the sequence of appearance of various neocortical regions, making the important point for evolutionists that the detailed organization of the neocortex is established to a significant extent by experience, and the evolution of its organization is therefore likely to be difficult to specify with standard genetic models.

Although informed by modern evolutionary theory, with the exception of Northcutt's commentary the discussion that I just reviewed was traditional in its evolutionary approach. The concern was to develop insight into the origin of neural systems and to the degree of specialization in different species. The analysis proceeded from data on morphology and development, and from educated intuition rather than from the rigorous application of cladistic methodology. All would agree that the nervous system parallels other systems in the body in reflecting adaptations to various environmental niches. Killackey and Ebbesson emphasized the lability of the fate of neural structures, and there is a consensus about the significant extent to which use determines fate for the circuitry of the brain—that brains can be normal only if they develop in a normal environment.

Comparative brain data have also been used for more formal analyses of relationships, either with the methods of modern cladistics or with other multivariate methods. The results of these analyses can be summarized in a few sentences. Performing a factor analysis on brain traits in fish helps to clarify issues on the classification of particular groups of fish. The most helpful traits were the size of the olfactory apparatus. The contribution, however, is primarily to taxonomic issues rather than to neurobiology. The cladistic analyses, using only data on brain traits in constructing a species-by-traits matrix, produce essentially the same phylogenetic tree as when a full suite of traits is used. The diversity of species as determined rigorously by a full suite of traits predicts the measured diversity as determined from brain traits. The similarity between *Hoplophoneus* and *F. catus* in Fig. 1 is the expected finding in any comparative analysis of mammalian brains and confirms the taxonomic conclusion that these are relatively closely related species despite their separation by 30 million years of evolution. The brain can serve as well as other organs of the body for evidence on phylogenetic relationships.

IV. QUANTITATIVE ANALYSIS: LIVING VERTEBRATES

Darwin's theory of natural selection emphasized evidence of selection as practiced by animal and plant breeders. The term natural selection implied that nature, like breeders, worked to select the "most fit" individuals relative to some criterion. In a breeder's case, the criterion might be plumpness, large size, docility, and so forth. Nature had other criteria, and animals well endowed on nature's criteria would be

more likely to survive to produce more offspring than would less well-endowed animals. The unnatural docility of domestic animals suggested some deficit in their brains.

Darwin could explore the relationship by comparing brain size in wild and domesticated populations of animals known to be related to one another. In what was probably his only contribution to neurobiology, Darwin was the first to observe that the brain in domesticated rabbits was smaller than that in their wild cousins. This is evidently a general principle on the effect of domestication on brain size. It may even be true for human brain evolution if we think of ourselves as domesticated and our ancestors as savage or feral, although the available sample size is too small for a clear test. The earliest *Homo sapiens* were the neandertals, and they were slightly larger brained, on average, compared to their living conspecifics.

A. Uniformities in Structure in Living Brains: Allometry

Darwin's publications inspired several generations of comparative neuroanatomists to provide detailed pictures of the diversity of brains. The effort included studies of brain size and of brain-body relations, some of which stand up under appropriate analysis today. In this tradition, Brodmann tabulated data on brain surface area in mammals, and his results are included as 33 of the 50 data points in Fig. 2A. The validity of his work is attested to by its consistency with data from more recent studies that used different methods of measurement. A single regression line fits the entire data set remarkably well. Both Fig. 2A and Fig. 2B are examples of uniformities of organization of the brain in mammals.

Analyses such as those in Fig. 2 are "allometric" in that they display the relationship between different morphological features, such as height and weight, as they can be measured in any animal. The relationships displayed in Fig. 2 transcend species and are so strong that they appear to reflect a fundamental feature of the body plan (*Bauplan*) of mammals. Evolutionists call shared ancestral features plesiomorphies, and although the term is not usually applied to functional relationships such as those shown in Fig. 2, the idea fits. The relationships should be thought of as representing a primitive feature in mammalian evolution.

Because of its unusually diverse sample of species, Fig. 2A provides important justification for using total brain size as a statistic that estimates the total neural information processing capacity of a brain, between species, in the mammals as a class. To understand this further, consider some candidates for the role of processing unit. A frequent candidate is the cortical column, and its cross sectional area appears to be relatively uniform across species. The neuron is another candidate, and the number of neurons under a given surface area of neocortex is more or less constant across species. Finally, the synapse is a candidate. Braitenberg and Schüz observed that the number of synapses per unit volume of cortical tissue is

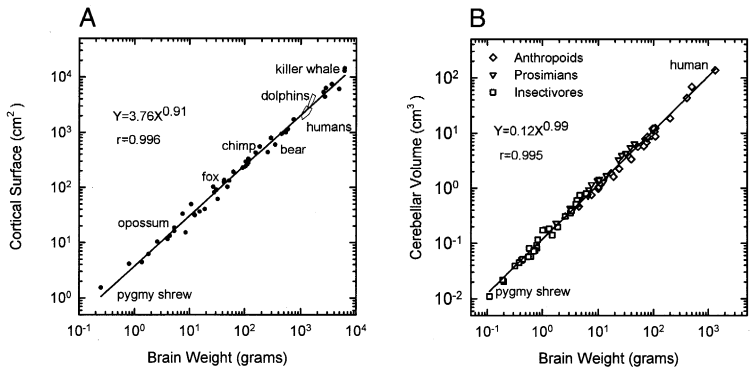

Figure 2 (A) Cortical surface area as a function of brain size in 50 species of mammals, including orders Monotremata, Marsupialia, Artiodactyla, Carnivora (including pinnipeds), Cetacea, Perissodactyla, Primates, and Xenarthra. Minimum convex polygons enclose individual human ($n = 20$) and dolphin (*Tursiops truncatus*: $n = 13$) data and indicate within-species variability. Some species are named to suggest the diversity of the sample. (B) Cerebellar volume as a function of brain size in 76 species of mammals (insectivores: 26 Insectivora, 2 Macroscelididae, and 3 Scandentia; primates: 18 Prosimii, 27 Anthropoidea (redrawn with permission from Jerison, 1991).

constant across species. There are qualifications to these generalizations, but they are reasonable first approximations. They reinforce the conclusion about the use of brain size as a statistic.

Figure 2B is another allometric analysis. It demonstrates the uniformity of cerebellar size in mammals—that, independent of species, if you know the size of the brain you can make a very good estimation of the size of the cerebellum. Although this analysis does not have the obvious theoretical significance of Fig. 2A, it demonstrates the fundamental orderliness of the construction of the brain. It validates the use of brain size as a statistic to estimate the size of other brain structures. To the extent that these other structures can be assigned special functional significance, one may be able to use quantitative data on brain size to assess the evolution of brain functions. This has been done by M.A. Hofman and by me for the analysis of the control of social behavior and of other neocortical functions. In general, anatomists emphasize the differences among the species that they examine, but I have been even more impressed by the uniformities. The example in Fig. 2B of the relationship between cerebellum and brain size is just one of these. Table I summarizes a multivariate analysis of an entire data set: 12 morphological measures in 76 species.

The most important fact in Table I is that just two factors were enough to account for all but 1.5% of the variance, and that 86% of the variance is explained by a single "size" factor. The size factor is a "general" factor in the sense that it is strongly represented in all the brain structures with the exception of the olfactory bulbs, and it is also represented in body weight. The loading of cerebellum on this factor (0.983, accounting for 97% of the variance in cerebellar volume) in conjunction with the even higher loading of total brain weight reflect the high correlation shown in Fig. 2B. All the measures with higher loadings would have produced bivariate graphs such as Fig. 2B. The mammalian brain hangs together well, and when one part is enlarged the rest of the brain tends to be correspondingly enlarged.

Perhaps the most surprising extension of this conclusion is the tentative discovery that even the size of prefrontal neocortex, the "executive organ" of the mammalian brain, appears to be determined by the size of the whole brain in mammals. The conclusion is tentative because it is based on evidence from only four primate species (marmoset, rhesus, orang, and human) and the laboratory rat, but there was an almost perfect correlation between neocortex volume and brain volume in these five species (logarithmic measures; $r = 0.999$). Developmental and morphological evidence obtained by B.L. Finlay and her associates, essentially supporting the conclusions of the factor analysis, has resulted in much more extensive additional evidence for the fundamental uniformity of structure in the mammalian brain, that is, for the extent to which it "hangs together."

Table I

Factor Loadings and Percentage Variance Explained by Two Principal Components (Factors) in Brain and Body in 76 Species of Mammals[a]

	Factor 1 (general brain size)	Factor 2 (olfactory bulbs)
Neocortex	0.991	0.059
Total brain weight	0.989	0.137
Diencephalon	0.987	0.144
Basal ganglia	0.987	0.133
Cerebellum	0.983	0.168
Mesencephalon	0.972	0.196
Medulla	0.966	0.224
Hippocampus	0.962	0.239
Schizocortex	0.954	0.274
Body weight	0.939	0.285
Piriform lobe	0.899	0.399
Olfactory bulbs	0.157	0.985
Percentage total variance	85.855	12.668

[a]Varimax rotation. Reproduced with permission from Jerison (1991).

The second factor in Table I, accounting for 12.7% of the variance, is an olfactory bulb factor. It is represented primarily by the olfactory bulbs, with a modest representation in the parts of the brain that are classic "rhinencephalon" (piriform lobes, schizocortex, and hippocampus) and in body weight. Factor analyses are notoriously susceptible to artifacts of sampling, and I believe that the high fraction of variance accounted for by the olfactory bulb factor is such an artifact. Simian primates have much reduced olfactory bulbs, whereas insectivores are normal mammals in this regard. The distribution of olfactory bulb size in the sample on which the factor analysis was performed is, therefore, seriously bimodal. This inflates the measured variance of the size of the olfactory bulbs and enlarges its fraction of the total variance compared to what would be expected in a more representative sample of mammals. In any case, the important feature of the multivariate analysis is the

almost uniformly heavy loadings of the other measures on the general size factor.

B. Diversity in Living Brains: Cladistics

Having emphasized uniformities so forcefully, I must warn against underestimating the importance of diversity. All brains are different, and there are major differences both within and between species. Differences in brains within species are often difficult to measure with conventional anatomical and physiological methods, but since the brain is the control system for behavior, behavioral differences are evidence of differences among brains. Differences among species, of course, are much more dramatic.

The qualitative differences among the procyonids described by Welker could be presented as quantitative differences as well by measuring the amount of tissue in, for example, forepaw and rhinarial projections to the neocortex of procyonids. Differences among orders of mammals or classes of vertebrates are even more striking, but they too have not been quantified, perhaps because they are so obvious. And even when differences are great, they may be surprisingly difficult to describe quantitatively. One recognizes in an instant that the human brain is an unusual primate brain, for example, but the analysis of the relative size of its major parts usually shows it to be a perfectly normal primate (or mammalian) brain. In Fig. 2 there is nothing other than gross size to distinguish the human data, which fell on or near the regression lines determined for all the mammals in each sample. Also, as mentioned earlier, even the size of the prefrontal neocortex, often assumed to be uniquely important in human performance, is exactly as large as expected for a mammalian brain the size of a human brain. The uniqueness of human behavior is related to the size of the entire neural control system, and the correct conclusion about prefrontal executive function is that its size is appropriate to the very large brain systems that it controls.

A rigorous, though not really quantitative, analysis of the diversity of organization of the brain has been in the application of cladistic methodology. As indicated earlier, the results of this kind of analysis with brain features are essentially the same as those when other morphological features are used in the traits-by-species matrix that provides primary data for the analysis.

A cladistic methodology was applied by P.S. Ulinski, who took as his goal the reconstruction of probable features of the internal anatomy of brains at nodal evolutionary points in the evolution of reptiles, birds, and mammals. He first used the results of cladistic classification to determine nodes at which branching occurred when an ancestral species split into two daughter species. Second, he examined the brains of living representatives of the daughter species (or higher taxa). Finally, he constructed a hypothetical ancestral brain as a kind of lowest common denominator of the brains of the daughter species. The approach can be applied only to nodes in which surviving species from both branches exist. For example, taking living turtles and crocodiles to represent surviving species from the node of the early reptilian branching that led to these species, the ancestral brain can be constructed as having only those features that turtles and crocodiles share. With this procedure Ulinski could suggest various details about the ancestral brain of birds, crocodiles, lizards, and turtles. (From a cladistic perspective birds may be thought of as specialized reptiles derived from dinosaurs.) The nodal point in the history of the mammals, unfortunately (for this approach), is late in a "reptilian" synapsid lineage, represented today only by mammals. The mammal–reptile transition brain could be reconstructed only if synapsids at a reptilian grade of brain evolution had survived; but none have. The reconstruction of the brain at the reptile–mammal transition is, therefore, impossible using his procedure.

It would be possible to temper this conclusion, which is based on qualitative internal features of the brain, by analyzing the superficial anatomy using data on fossil endocasts, although such data are sparse for synapsids. Where they exist, in therapsids, they suggest a size pattern comparable to that in living reptiles. The transition from mammal-like reptiles to mammals is documented in the endocasts, and at present it seems to be reflected primarily as both enlargement of the brain (encephalization) and a major reduction in body size.

In his analysis of mammalian brain evolution, particularly the diversity of organization of somatosensory neocortex, J.I. Johnson presents an impressive catalog of detail on differences but concludes that "a great many features are constant across all mammals, from platypus to monkey, rat, cat, and sheep." The major variations "include [amount of] multiplication of representations of certain body parts" and details of the representations. He also notes few general trends of organization but comments that the appearance of "association cortex" intercalated between somatosensory and visual neocortex is haphazard across species,

and that its appearance seems "to have something to do with the use of limbs as information-gathering and manipulating organs." Johnson's conclusions are consistent with the notion that the pattern of organization of the brain in a species that differentiates it from other species follows no general principles in the mammals but is part of the specialization of each species. In cladistic analyses, Johnson and his associates found that the phylogenetic tree in mammals deduced from 15 brain traits was essentially the same as that deduced from other traits.

The quantification of diversity depends on the measurement of size. The evolution of brain size in mammals has led to the diversification that was already evident in the data of Fig. 2, with species having brains as small as 0.1 g (pygmy shrew) and as large as 8 kg (killer whale). These all evolved from a single species of mammal (according to the monophyly accepted today) that lived more than 200 Ma. I outline the history later, but we must first understand how the diversity of size is analyzed.

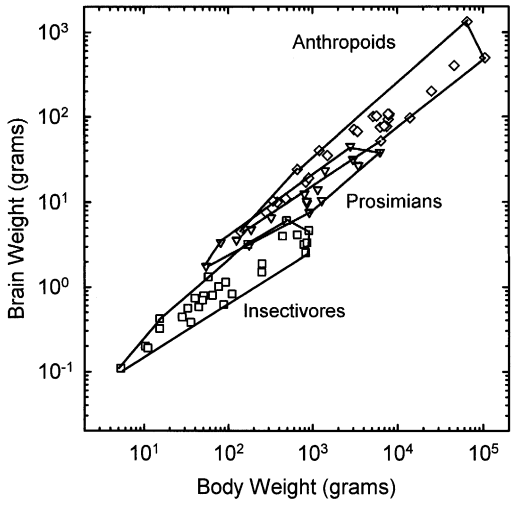

Figure 3 Convex polygons to differentiate insectivore, prosimian, and anthropoid data on brain weight and body weight (from a chapter for Zaidel; see footnote on first page).

C. Allometry and Encephalization

Body size accounts for 80–90% of the variance in brain size between species, a relationship described by an allometric equation: the regression of the logarithms of brain size on body size. The distance of a species from the regression line is a measure of its encephalization. Because the scales are logarithmic, this distance, or residual, is an encephalization quotient—the ratio of actual brain size to expected brain size. Encephalization is a characteristic of a species; it is usually meaningless to discuss differences within a species in encephalization.

Allometry and encephalization do not have to be defined by regression equations and residuals, but most recent work on brain evolution involving brain body allometry uses this approach, which might be called "parametric" since it involves the estimation of the parameters of a normal probability distribution. Instead of the regression, the data can be described with minimum convex polygons enclosing the data points of the groups to be compared, but there are currently no quantitative methods to analyze the polygons.

Minimum convex polygons described the location of human and dolphin data in Fig. 2A, and the brain/body data for the same insectivores, prosimians, and anthropoids as in Fig. 2B are graphed in Fig. 3, with polygons drawn around each group to compare them with respect to encephalization. (Recall that Fig. 2B related the size of the cerebellum to the size of the whole brain; in Fig. 3 the relationship is of the whole brain to the size of the body.) It is not difficult to distinguish relative brain size among the groups since there is little overlap. All the polygons are oriented upward. There is slight overlap between the insectivores and prosimians and a bit more overlap between prosimians and anthropoids. From Fig. 3, one would describe the order of encephalization of these groups as follows: insectivores are least encephalized; prosimians are intermediate, and anthropoids are most encephalized. These data are also described by regression equations in Fig. 4.

The work by Stephan's group is especially relevant for evolutionary analysis because of the species they used. They worked with insectivores to represent a primitive grade of brain evolution and to provide an evolutionary perspective on the human brain. The issues are more complex, of course, but insectivores are reasonable models for the base group from which most placental species evolved. They resemble the earliest mammals both skeletally and in their endocasts. Although primates are currently a highly encephalized order of mammals, they are also a very ancient order, probably derived during the Late Cretaceous period from a species comparable to living insectivores or tree shrews. Comparisons between insectivores and primates are thus very appropriate for our topic.

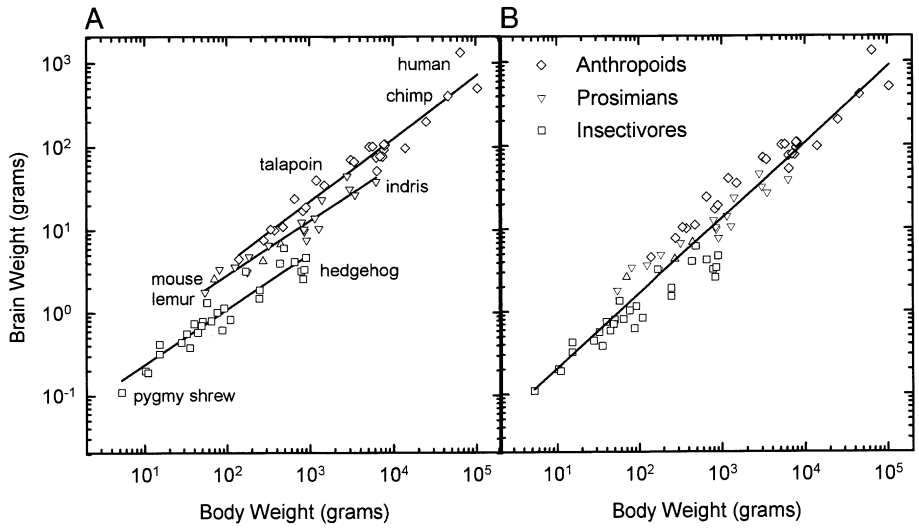

Figure 4 Regression analysis of the data shown in Fig. 3. Some species are named to indicate diversity of sample. (A) Separate regressions and correlation coefficients for the three groups: insectivores: $Y = 0.05\ X^{0.67}$, $r = 0.946$; prosimians: $Y = 0.14\ X^{0.66}$, $r = 0.960$; anthropoids: $Y = 0.13\ X^{0.75}$, $r = 0.972$. (B) Lumping the data for an overall regression for all 76 species: $Y = 0.05\ X^{0.91}$, $r = 0.966$. (redrawn with permission from Jerison, 1991).

D. A Bit of Theory

Issues in parametric quantification of encephalization as they apply to insectivores and primates are suggested in Fig. 4. The two graphs present the same data, fitted by straight lines in different ways. Fig. 4A shows the regression of log brain size on log body size computed separately for the three groups; Fig. 4B is a single regression for all 76 species. The three regression lines in Fig. 4A provide the same information as the polygons in Fig. 3. But if one is interested in curve fitting all the regression lines fit remarkably well ($r > 0.94$) despite their different slopes. These slopes on log–log axes are the exponents of the equations written as power functions, and the value of a "true exponent" has been the subject of considerable debate during the past decade. This is where a little theory may help.

The emerging consensus is that an exponent of 3/4 is the correct value. I have quarreled with this view, arguing in favor of a 2/3 exponent, which has theoretical significance for dimensional analysis of the brain's work in mapping information from the external environment. It is true that empirical analyses of large enough samples of species, or of properly sampled groups of species, lead to the 3/4 exponent when the fit is statistical, but I believe that the theoretical value of 2/3 is nevertheless correct. The point is that the 2/3 value is required by the dimensional problem in order to convert data about a surface into data about a volume (a "mapping"). It reflects the fact that our information about the external world is spread across a surface consisting of sensory cells distributed throughout the body (skin, retina, organ of corti, olfactory epithelium, etc.) and that information is pumped up to neurons distributed through a kind of conceptual surface in a brain. I have assumed a fixed cortical thickness as representing that brain surface, and that the measure of brain volume in brainbody allometry is converted into a measure of that surface area. However, since the conversion is by a physical system that takes up space, one has to take into account the thickness of the map formed by the cortical "surface." To explain the difference between a 2/3 exponent required for the mapping and the 3/4 exponent found empirically, I have argued that this thickness as estimated by the thickness of neocortex is known to be greater in larger brains, varying approximately with the 1/9 power of body size. The value 3/4 is approximately the sum of $2/3 + 1/9$. The theoretical value of 2/3, which is meaningful for the brain's mapping function, thus leads to an expected empirical value of 3/4.

E. Encephalization

The fact of encephalization is evident in the vertical displacement of the lines that are fitted to the three groups (Fig. 4A) or of the minimum convex polygons

(Fig. 3). Since the polygons do not require the dubious assumptions of statistical curve fitting, they may be preferred for describing encephalization. They are certainly preferred if they are adequate for answering questions about whether groups are equal or differ in encephalization.

The degree of encephalization in living vertebrates is summarized in Fig. 5. The polygons enclose all the available data on the indicated classes. The data were assembled from a variety of sources. The main inference from Fig. 5 is that one can characterize birds and mammals jointly as "higher" vertebrates, and reptiles, bony fish, and amphibians can be characterized as "lower" vertebrates. The polygons do an adequate job, although the addition of data on cartilaginous fish (sharks, rays, and skates), jawless fish (agnathans), and electric fish (bony fish: Mormyriformes) makes it difficult to distinguish the groups by inspection. The additions are of relatively few species. As mentioned previously, the present consensus recognizes about 50,000 vertebrate species. Of these, to the nearest thousand, about 25,000 are bony fish, 6000 are reptiles, 4000 are amphibians, 10,000 are birds, and 5000 are mammals. There are about 800 cartilaginous fish species and 70 agnathan species.

From the evidence presented earlier in Fig. 2A, it is appropriate to assume that the amount of encephalization measures the information processing capacity of a brain, adjusted for body size. It is therefore appropriate to consider the ecological requirements met by increments in processing capacity in different groups of species. Not much debate is required to see mammals and birds as higher vertebrates in this regard, given the normal complexity and plasticity of behavior observed in these groups. No reasonable speculations have been offered for the position of the cartilaginous fish as overlapping the higher and lower groups, but the place of electric fish reflects an unusually enlarged cerebellum in these species, related to processing information from their electric organs. It is unclear why that processing should require as great an investment in neural machinery. The position of jawless fish has been placed below the bony fish polygon, leading to speculations that there may have been a reduction in brain size related to the parasitic habits common in this group, particularly among lampreys. However, as evident from Fig. 5, agnathans, though relatively small-brained, fall more or less within the fish polygon, making such speculations unnecessary.

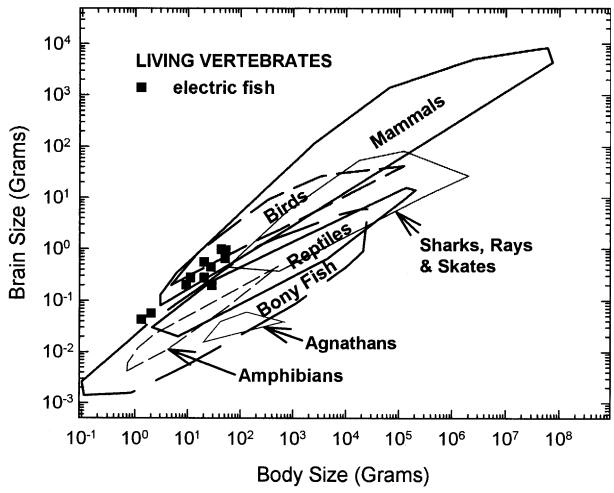

Figure 5 Brainbody relations in 2019 living vertebrate species enclosed in minimum convex polygons. The samples are 647 mammals, 180 birds, 1027 bony fish, 41 amphibians, 59 reptiles, 59 chondrichthyans (sharks, rays, and skates), and 6 agnathan fish (redrawn with permission from Jerison, Roth and Wulliman, 2001).

The approach signaled by Fig. 5 enables us to evaluate fossil endocasts with respect to encephalization, providing a direct evolutionary window to the patterns of change that led to the current diversity in brain size. I present such a nonparametric analysis as well as a parametric (regression) analysis of neocorticalization in the next section. In the analysis by convex polygons, I will be concerned with the evolution of birds and mammals from the reptiles and the utility of the method for some conclusions about dinosaur brains.

V. QUANTITATIVE ANALYSIS: FOSSILS

A. Vertebrate History

Vertebrates first appeared during the past 500 million years of the earth's 4.5 billion (4.5×10^9) year existence, and Table II provides a synopsis of their history. Here are some points to remember.

First, the world was very different in the distant past compared to the present. During the Paleozoic Era, there were times when there was only a single global continent (Pangea), but landmasses joined and separated with the passage of time. The global map was significantly different during the Mesozoic, with major masses (Gondwanaland and Laurasia) during the Paleozoic and Mesozoic Eras. There were warmer and more stable climates during the Mesozoic, and the continents were drifting toward their present loca-

Table II
Synopsis of Vertebrate Evolution

Era	Period and epoch	Age (years $\times 10^6$)	Fauna (first appearance)
Cenozoic	Quaternary		
	Holocene	0.01–	No new megafauna
	Pleistocene	1.8–0.01	*Homo erectus, H. sapiens*
	Tertiary		
	Pliocene	5–1.8	Hominids: *Australopithecus*, *Homo habilis*
	Miocene	25–5	Hominoids (apes)
	Oligocene	35–25	"Progressive" brains
	Eocene	55–35	Progressive ungulates, Anthropoids
	Paleocene	65–55	Primates[a] and carnivores
Mesozoic	Cretaceous	140–65	Marsupials, Placentals
	Jurassic	210–140	Birds, mammal endocast
	Triassic	250–210	Mammals
Paleozoic	Permian	285–250	Primitive dinosaurs
	Carboniferous	360–290	Reptiles
	Devonian	410–360	Bony fish and amphibians
	Silurian	440–410	Jawed fish
	Ordovician	500–440	Jawless fish
	Cambrian	550	First chordates

[a]Primate teeth reported in late Cretaceous deposits. Paleocene primate identification is controversial. There is consensus recognizing early Eocene tarsier-like species, middle Eocene lemur-like species, and recently discovered late Eocene simian species.

tions. The Cenozoic was more variable in every way, with more diverse and sometimes chilling climates and periods of major mountain building. A burgeoning animal and plant life is evident in fossils from sediments laid down during all of these periods.

Second, there were several mass extinctions, with the greatest, at the end of the Permian Era, signaling the beginning of the Mesozoic. The most famous extinction, attributed to impact by a small asteroid, occurred at the end of the Mesozoic (the K–T, or Cretaceous–Tertiary boundary) 65 million years ago. Niches, emptied of their otherwise well-adapted organisms that could not survive the environmental catastrophe, could then be filled by suitably adapted birds, mammals, teleost fish, and snakes.

Third, although mammals were present during much of the 185 million years of the Mesozoic Era, all were small-bodied, none larger than living cats. They were probably nocturnal in their habits. Only during the Cenozoic did very large mammal species appear, and even today the average mammalian species is about cat size and nocturnal. Humans are giant vertebrates, physically larger and heavier than 90% or more of living species. Anthropoid primates are an unusual group of mammals; species of the suborder Anthropoidea (monkeys, apes, and humans) are diurnal and are well-adapted for color vision.

Finally, a major environmental event in human history may have been the Pliocene drying of the Mediterranean about 5 million years ago, which probably contributed to natural selection among chimpanzee-like primates for a species that became the earliest hominid. Extensive glaciation characterized the Pleistocene Epoch and may have driven the evolution of the human species to its present grade.

B. Fossil Brains Revisited

From the history of the brain in fish, amphibians, and reptiles as available from the fossil record, the most unusual inference is that these can all be treated as lower vertebrates in encephalization (Fig. 5). The exceptions are sharks and, perhaps, the ostrich-like dinosaurs (ornithomimids). Here is a list of a few more outstanding discoveries.

First, from the evidence of small (<15 cm long) Carboniferous (350 Ma) fossil fish, the diversity in living teleosts was probably foreshadowed by some of the earliest bony fish. They had optic lobes enlarged in ways comparable to those of living fish, such as trout, that feed at or near the surface of the water and rely on visual information.

Second, although sharks and other cartilaginous fish are often considered primitive, they are not primitive with respect to their brains. Many sharks are big-brained, overlapping the distributions of relative brain size of the lower vertebrates, on the one hand, and of birds and mammals, on the other hand. There is one uncrushed endocast known in a Paleozoic shark, the earliest evidence of encephalization beyond the grade of living bony fish. The species was comparable in both brain and body size to the living horned shark (*Heterodontus*).

Third, dinosaurs continue to be libeled with the walnut-size brain label despite evidence to the contrary. Their brains were within the expected size range for reptiles. The Tyrannosaurus 404-ml endocast implies a brain in the size range of those of living deer—small for an elephant-sized mammal but impressive for a reptile. The basic data are shown in Fig. 6.

Fourth, the major transition from water to land in the amphibians more than 350 Ma was accomplished without enlargement of the brain, and there has been no enlargement since if one compares present amphibians with their fossil ancestors. Of course, there was and is, considerable diversity in relative brain size within each of the classes of living lower vertebrates, just as there is in birds and mammals, and there has been significant reorganization of the brain across species of lower vertebrates, especially between classes but also within classes. By any standard, one must recognize the brain in living reptiles as more specialized than that of fish or amphibians.

Finally, of the major lateralization of function in the living human brain, and the recognized lateralization in the brains of many other living species, there is little or no evidence at a gross level. There is no good fossil evidence for such lateralization, although some has been claimed and evidence may be forthcoming. The problem is that asymmetries are difficult to establish, even in living brains, and are almost impossible to establish in fossils, which are often asymmetrically distorted and partially crushed.

These statements sum up the evidence on brain evolution in about three-fourths of the vertebrate species. There remains the story of about 10,000

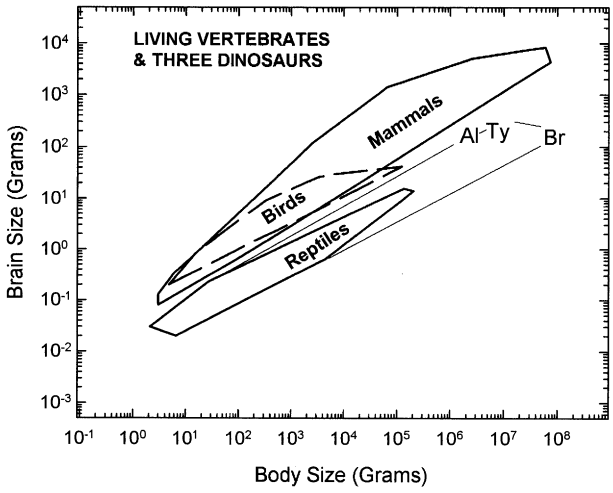

Figure 6 Data from Fig. 5 for mammals, birds, reptiles, and three dinosaurs (Al, *Allosaurus*; Ty, *Tyranosaurus*; and Br, *Brachiosaurus*), showing extension of reptilian minimum convex polygon by adding dinosaur data.

species of birds and 5000 species of mammals, in which encephalization is a major feature. As background, and for a better sense of the potential and limitations of the method, I discuss the relevant data from Fig. 5, namely, those on reptiles, birds, and mammals. These are presented in Fig. 6, in which distracting information from the three classes of fish were removed and to which I have added data on three dinosaurs.

The three added species are the large well-known carnivorous dinosaurs, *Tyrannosaurus* and *Allosaurus*, and the largest of all dinosaurs in which there are reliable body size estimates, *Brachiosaurus*. To illustrate the method and its use, I will review the status of the "ostrich dinosaurs" from this perspective. One of these is a relatively small late Cretaceous carnivorous dinosaur, *Troodon*, which has been described as encephalized as large living birds and in the range of encephalization of living mammals. The analysis depends on estimating body size as well as brain size. There is a reliable estimate of *Troodon*'s body size as about 45 kg. Its brain size was first estimated by inspection and by perceived similarity to an ostrich's brain size of 40 g. However, with the help of a computer program recently developed and a qunatitative analysis of its brain size, I now estimate its brain as about 20 ml in volume. This is somewhat smaller than the albatross's 27-ml brain as determined by the same computer analysis. If *Troodon* had a 20 ml brain in a 45 kg body, it would fit within the reptile polygon of Fig. 6. More analysis is needed, but it is evident that

reports of the past 30 years of these large-brained dinosaurs need to be reevaluated. Other dinosaur data, such as those in Fig. 6, appear to be reasonably reliable, and provide an acceptable basis for evaluating dinosaur brain evolution. The ostrich that provided data for Fig. 6 weighed 133 kg and had a 42 g brain. It is the end-point of the avian polygon, which falls somewhat below the corresponding point on the polygon for living mammals. I have not entered data points for albatross at a body size of 12 kg, but it would fit comfortably within the avian polygon. *Troodon* fits within the reptilian polygon as extended in Fig. 6 to include a few dinosaurs. *Troodon* was indeed among the larger brained dinosaurs, but it probably did not reach either the mammalian or avian polygon.

The analysis with convex polygons is, in short, based on inclusion or exclusion of a particular species within the taxon described by a particular polygon. In Fig. 5, it was this approach that demonstrated the anomalous situation for living electric fish and cartilaginous fish and the "normal" position for agnathans. In Fig. 6, it indicates that dinosaurs were reptilian rather than avian in relative brain size.

C. Birds and Mammals

The history of the bird brain is not as well-known as that of mammals, and the present diversity in brains in birds does not appear to be as dramatic. However, the brain of *Archaeopteryx* was bird-like primarily because it filled the cranial cavity and was larger than that in comparable reptiles. There was no Wulst—that is, the dorsal enlargement of the forebrain in living birds that functions equivalently to primary visual cortex in mammals. The next significant evidence in the history of birds is from an Eocene whimbril-like bird, *Numenius gypsorum*, in which the brain is somewhat smaller than in comparable living birds of its body size but, most dramatically, its forebrain is clearly much smaller so that its optic lobes are more fully exposed than in living birds. Endocasts of later birds are indistinguishable from those of their living relatives.

In their early history, the mammals were small, probably nocturnal insectivorous creatures. Their adaptation for life in nocturnal niches could have been the major selection pressure to explain the "advance" to a mammalian grade of brain morphology and encephalization. The characteristic morphological feature of the brain of living mammals is the presence of neocortex, the six-layered neuronally rich outer covering of the forebrain. Its presence can often be established on an endocast because a major fissure, the rhinal fissure, is its ventral boundary.

The earliest mammalian brain is known from an Upper Jurassic endocast of *Triconodon mordax* and is about 150 million years old. The lateral surface of this endocast is not preserved well enough to indicate whether or not there was a rhinal fissure; thus, positive evidence regarding the presence of neocortex is not available. In encephalization, however, its brain was comparable to that of small–brained living species such as opossums and hedgehogs, in which neocortex is present. It is therefore likely that neocortex appeared at least 150 Ma. The best assumption from available information is that neocortex is, in fact, part of the suite of traits that characterized the mammals from the beginning of their evolution, at least 50 million years earlier.

Mammals in which the endocasts are sufficiently complete to show a rhinal fissure, if present, are about 75 Ma. They are from a unique assemblage of Late Cretaceous mammals from the Gobi desert, which includes early placentals. The most common mammals of the time, the multituberculates, were unrelated to any living species. Superficially, multituberculates probably looked like living rodents or insectivores. Their life span as an order was about 120 million years, between about 150 and 30 Ma, a very long span for a mammalian group. The specimen in which the endocast is best known, *Chulsanbaatar*, weighed no more than about 15 g, a small mammal even for the Mesozoic and smaller than most living species of mice. There is a suggestion of a rhinal fissure in its endocast, although there is disagreement about where it is located. Whether or not one can see a rhinal fissure, from its grade of encephalization it is very likely that neocortex was present in its brain.

D. Neocorticalization

Neocorticalization is a concept in comparative neuroanatomy, based on comparisons among living species. For example, it describes the fact that primates have relatively and absolutely more neocortex than insectivores. One makes the statement: Primates are more neocorticalized than insectivores. Of course, living insectivores did not evolve to change into living primates under natural selection. But there is an evolutionary translation of the statement: The ancestors of living insectivores were members of an order (or other taxon) of mammals that probably included at least one species from which primates evolved. This

species has not been identified, but as evolutionists positing a relationship between insectivores and primates as "sister" groups, we have to assume that it existed. Neocorticalization is then understood as part of the differentiation of daughter species from parent species: One daughter species of a fossil insectivore, which had relatively more neocortex than the parent species, was the ancestral primate species. These statements are almost parodies of evolutionary analysis, but they approximate a correct analysis.

The concept of neocorticalization can also be used in another sense—as describing the history of a trait in successive populations of species. If we sample a broad range of species across geological time and determine that later species had relatively more neocortex than earlier species, we could state that neocorticalization had occurred, even though we would not be able to determine its phylogenetic history. Such a discovery would be enough to suggest that there was a selective advantage in an increase in neocortex. The analytic model to be applied might be an elaboration of simple models of phenotypic evolution within lineages. It would require theorizing about selective advantages above the species level—about broad evolutionary "landscapes" that are contexts for interaction among species.

Neocorticalization in this sense can be quantified as a feature of the history of the mammals. It is more or less evident from a simple inspection of endocasts, but the quantitative effect can only be demonstrated with the help of some statistical analysis. I present such an analysis in Fig. 7. For the analysis, I measured the planar projection of neocortex and olfactory bulbs in 59 species of living and fossil ungulates and carnivores. The sample included 38 Carnivora, 7 Creodonta, 4 Condylarthra, 5 species from extinct South American (neotropical) ungulate orders, 1 Eocene perissodactyl (*Hyrachyus*, an ancestral rhinoceros), and 4 progressive ungulates (artiodactyls). The complete sample consisted of 35 fossil species and 24 living species.

The results were analyzed as neocortical and olfactory bulb quotients, determined by partialling out the effect of body size much as in encephalization quotients. A quotient of 1.0 means that the size was as expected for a species at the centroid, 0.5 means it was half as big, and so on. As presented in Fig. 7, the results lead to four conclusions. There is first the fact of neocorticalization. Later species tended to have relatively more neocortex than did earlier species. This is the meaning of the significantly positive slope of the regression line of the neocortical quotient against geological time.

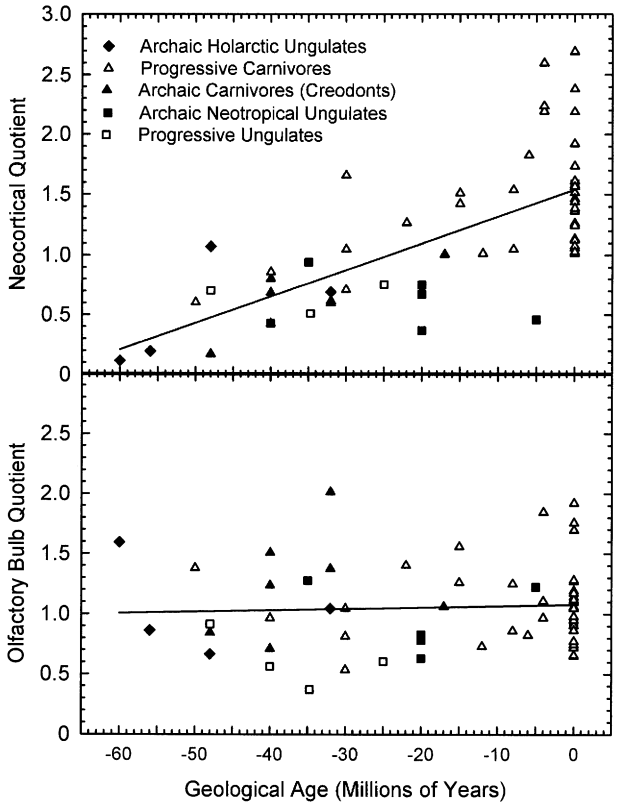

Figure 7 (Top) Change in relative neocortical surface area (neocortical quotient) as a function of geological age. "Progressive" change noted here (positive slope of regression line) indicates increased neocorticalization over time. Each point is a species. (Bottom) Absence of change in relative surface area of the olfactory bulbs as a function of geological age. (Redrawn with permission from Jerison, in Jones and Peters, 1990).

Second, species from archaic orders (Fig. 7, filled symbols) tended to have less neocortex than did species from progressive orders (Fig. 7, open symbols). Thus, 3 of the 4 archaic ungulate species, 5 of the 7 archaic carnivore (creodont) species, and 4 of the 5 Neotropical ungulate species (also archaic in that their orders are extinct) are below the regression line. Twelve of the 16 archaic species thus had less neocortex than would be predicted for their geological age by an unbiased regression analysis. For those who enjoy playing with statistics, a chi-square analysis contrasts this with an expected even split: $\chi^2 = 4$, $df = 1$, $p < 0.05$.

The third result in a comparison between progressive and archaic species limited to fossil Carnivora versus Creodonta. It is in two parts. First, the Carnivora points appear generally to be higher than those of the Creodonta. Second, the Carnivora points seem to show more "progress" over time than do those

of the Creodonta. It is not possible to test the first part properly, because the species are from different geological times, and there is no obvious way to control the time variable. The second part, however, can be tested by simple regression analysis. The correlation between age and neocortical quotient for 15 Carnivora species was $r = 0.72$ ($p < 0.01$). For seven Creodonta it was $r = 0.42$ ($p > 0.05$). Only the Carnivora were demonstrably progressively neocorticalized.

The result is important for evolutionary analysis of the relations between true carnivores and creodonts. The argument is summed up by R. L. Carroll as follows: "Romer (1966) and Jerison (1973) stigmatized the creodonts as archaic and small brained, but Radinsky (1977) demonstrated that relative brain size increased as rapidly among creodonts as it did in the early members of the Carnivora, together with an increase in the extent of the neocortex." The quantitative analysis supports Romer's view as mentioned by Carroll. (My contribution in 1973 was mainly to quote Romer and to provide very limited quantitative data. The current confirmation of our older view is possible because of the additional data collected by Radinsky, which permitted a statistical test.)

The final conclusion is that unlike neocortex, the olfactory bulbs did not change in relative size with the passage of time. The correlation between the olfactory bulb quotient and geological time was $r = 0.1$, which is not significantly different from zero. This is an important point because it shows that this approach is fine enough to discriminate between the presence and absence of change. It also helps quash a myth about what is "primitive" and "progressive" in brain evolution.

Although careful students do not make the error, some neurobiologists assume that having large olfactory bulbs is a primitive mammalian trait and that the olfactory bulbs became relatively smaller as the mammals evolved. Fig. 7 corrects this error by showing that olfactory bulbs have been a stable feature of the brain in Tertiary carnivores and ungulates. The misconception is a bit of primate chauvinism, as it were. Primates (at least the anthropoids) are neocortical specialists, but they are deficient mammals in olfactory development. A reduced role for olfaction is part of the adaptive mosaic of the adaptive zone of simian primates and is not a broad feature of mammalian evolution. (It also complicated the factor analysis presented earlier.) Neocorticalization, on the other hand, appeared as a general trend in many mammalian groups and its relative absence in the insectivores and many marsupials is correctly recognized as a primitive feature in these groups.

VI. CONCLUSIONS

First on neocorticalization. The fossil evidence indicates that there was neocorticalization in mammals and that it can be detected even in samples as small as 15 species of Carnivora. Evolution of the carnivores involved neocorticalization in another sense, in that the two great orders of Tertiary carnivores (Creodonta and Carnivora) differed in the extent of neocorticalization. This could have been a factor in the survival of true carnivores. In any event, the history of neocorticalization indicates that there was almost certainly some benefit derived from the expansion of neocortex. The fossil evidence therefore confirms conventional wisdom in neurobiology that it was a progressive thing for mammals to evolve neocortex and (perhaps within limits) more is better.

If the conclusions on neocortex are expected, those on the olfactory bulbs are not. These structures are surprisingly constant features in mammalian brains. There is no reason to have predicted that they would not evolve to large or small size relative to other parts of the brain, depending on the extent of olfactory specializations in particular species. But according to current evidence from fossil brains, the olfactory bulbs have been constant and relatively unchanging features that make a brain a mammal's brain. They are not unusually enlarged in any species; most mammals are olfactory specialists. Evolutionary changes in the olfactory bulbs occurred mainly in a negative way, by reduction. The reduced state of olfactory bulbs in humans and other primates (and their complete absence in some cetaceans) merely reflects the extremes of diversity that are possible as the brain evolved to control the activities of mammals in the variety of niches in which they function.

From these and related data it seems likely that encephalization in mammals was driven by neocorticalization. One mammalian trend was toward enlarged neocortex, and since neocortex is a fairly fixed fraction of total brain size the enlargement of the brain was presumably correlated with the increased size of neocortex. Because neocortical function is deeply involved with cognitive functions—knowledge of "reality," expanded neocortex would be associated with more elaborate cognition, a major suggestion about the evolution of mind.

It would be appropriate to look more closely at neocortical functions and assume that the evolutionary advantage conferred by these functions was the engine driving progressive brain evolution in mammals. However, it would be a mistake to make much of such an idea of progress. It is true that neocorticalized species are more prevalent now than in the distant past. It must also be true that some fitness is associated with this aspect of the brain's evolution. But there are many successful living species that are at a very ancient grade of mammalian neocorticalization. Hedgehogs in Europe and opossums in America are outstanding examples because they are very fit in the evolutionary sense. They may litter our highways because of their "stupidity" in refusing to yield the right of way to cars and trucks, but the litter is part of the evidence of their reproductive success. And they manage this at a grade of neocorticalization and encephalization that some mammalian species reached 150 Ma.

The analysis of neocorticalization suggests that comparable advances occurred in birds with the expansion of their forebrains. It is certainly true that the avian forebrain is much enlarged compared to that of reptiles, and the grade of encephalization in birds is probably related to forebrain enlargement. The optic lobes (midbrain, homologous to the superior colliculi in mammals) also seem much larger in birds than in reptiles, at least to an analysis by eye.

The final conclusion, however, must be that animals do not live by brains alone. The majority of living vertebrates get along with about as much brain as was present in their earliest ancestors. Adaptation to one's niche can be accomplished in many ways, and to adapt behaviorally by brain enlargement is expensive energetically. The brain is profligate in its use of energy, and almost any other solution to an adaptational problem is less costly. In those groups that adopted encephalization as an adaptive strategy, however, there was evidently a real gain in fitness. Encephalization appeared in many very distantly related species of birds and mammals. It is a general rather than specific adaptation for increased total information processing capacity. It is sometimes considered as the brain correlate of intelligence. If that is true, it must mean that there are many intelligences that evolved, since encephalization is an overall sum of enlargements of constituent regions within the brain. Because the different regional enlargements are correlated with different behavioral capacities, there would be different kinds of intelligences in different species.

Eye Movements

CHARLES J. BRUCE and HARRIET R. FRIEDMAN
Yale University School of Medicine

GLOSSARY

frontal eye field Motor cortex for eye movements. In man and monkey, the frontal eye field lies in premotor cortex, just rostral to the hand representation in motor cortex.

neural integrator Brain stem circuit that maintains the current position of the eye by integrating all eye velocity commands. Its tonically spiking output neurons (tonic neurons) are located in the nucleus prepositus hypoglossi, the interstitial nucleus of Cajal, and the medial vestibular nucleus.

nystagmus Any to-and-fro movement of the eyes. Nystagmus can be normal (e.g., continued optokinetic stimulation causes optokinetic nystagmus, such as watching a train go by) or pathological, both congenital and acquired. The waveform of pathological nystagmus often indicates the damaged structure (e.g., sawtooth nystagmus indicates vestibular system damage).

optokinetic reflex/nystagmus Smooth, relatively slow eye movements elicited by movement of the whole visual field. Prolonged optokinetic reflex becomes optokinetic nystagmus when the slow movement alternates with quick-phase movements in the opposite direction.

response field The spatial parameters for the sensory stimulation and/or motor behavior associated with the spiking (or maximal spiking) of a particular neuron.

saccade generator Circuitry in brain stem reticular formation that underlies all rapid eye movements. Its principal output cells are short-lead excitatory burst neurons (EBNs): Horizontal EBNs are in the caudal paramedian pontine reticular formation near the abducens nucleus, and vertical EBNs are in the midbrain near the oculomotor nucleus. Other key cell types are inhibitory burst neurons, long-lead excitatory burst neurons, and omnipause neurons.

saccades Short-duration, high-velocity (rapid) eye movements that quickly move the eyes to a new position; can include both voluntary saccades and the quick phase of vestibular or optokinetic nystagmus. Special saccade types include memory saccades, in which the eye movement is directed to the location of a remembered target not currently visible, and antisaccades, in which the movement is deliberately directed opposite to the target's location.

smooth pursuit Smooth, continuous eye movements used to track a moving target.

superior colliculus Midbrain visuomotor structure for triggering visually guided saccades.

vestibuloocular reflex Smooth, relatively slow eye movements elicited by the vestibular sense that serve to cancel movements of the visual stimulus on the retina (retinal slip) caused by head movements.

This article on the human brain's widely distributed circuitry for controlling the eyes stresses the functional significance of eye movements. It takes an evolutionary perspective by emphasizing the primacy of the image-stabilization system (vestibuloocular reflex, optokinetic reflex, and quick phases of nystagmus) and how the relatively new eye movements of primates (saccades, smooth pursuit, fixation, and vergence) serve the primate's high-resolution foveal vision by engaging the far older image-stabilization circuits. The anatomy and physiology of principal oculomotor structures are reviewed, with emphasis on the frontal eye field region of primate neocortex.

I. INTRODUCTION

Processing the visual sense is one of the most considerable endeavors of the human brain. One

measure of the complexity of this function is that more than 30 distinct "visual" brain regions have been identified as contributing to the visual percept. Although eye movements are not required for visual function, they immensely improve the ability of primates to gather relevant, high-quality visual data for processing by this large expanse of neocortex. Thus, it is not surprising that a sizeable complement of cortical and subcortical circuits of the human brain is concerned with moving the eyes, nor that eye movements are often closely related to cognitive behavior.

This article is organized around three fundamental questions:

Why move the eyes? (What are the functions of eye movements?)
How do the eyes move? (What is the phenomenology and kinematics of eye movements?)
What moves the eyes? (Which neural structures and circuits effect eye movements?)

Table I
Principal Functions of Eye Movements

Image stabilization: Keep the visual image stationary on the retina
Purpose: To prevent blurred vision caused by movements of the head and body
Movements
Vestibuloocular reflex in response to vestibular signals
Optokinetic reflex in response to whole-field visual motion
Quick phases of vestibuloocular and optokinetic nystagmus
Foveation: Capture and keep particular stimuli on the foveal part of retina
Purpose: To facilitate fine, detailed viewing and visual analysis of important objects
Movements
Saccades to rapidly foveate new of different stimuli
Smooth pursuit to track moving visual stimuli
Fixation to maintain foveation of stationary visual stimuli
Binocular alignment: Foveate the same object/point in both retina
Purpose: To facilitate single vision and steropsis in order to extract relative depth (3D) perception from fine disparities between the 2D images in the two eyes
Movements
Disjunctive eye movements, both convergent and divergent (other eye movements are conjugate/conjunctive, i.e., equal in the two eyes)

II. WHY MOVE THE EYES?

Eye movements serve vision in three principal ways (Table I): to stabilize images on the retina, especially against movements of the head and body (image-stabilization system); to image the important details of the visual world on the most sensitive part of the eye, the fovea (foveation system); and to align the retinal images in the two eyes in order to promote single vision and stereopsis (vergence-accommodation system). Eye contact and avoidance also have very important roles in interpersonal behavior.

A. The Image-Stabilization System

Ironically, one of the principal reasons for the eyes to move is to keep the direction of gaze stationary—that is, fixed in space. The underlying objective is to keep the visual image of the external world stationary on the retina despite movements of the head and body because even slight movements of this image across the retina (i.e., *retinal slip*) cause considerable visual blur. For this reason, seeing animals need image-stabilization strategies and reflexes, and for vertebrates this principally involves extraocular muscles that rotate the eyeball within its bony orbit so as to cancel or minimize the retinal slip consequent to movements of the head. Furthermore, the anatomical and physiological substrates of image-stabilization eye movements are remarkably similar across vertebrate species, from primitive fish to modern apes.

Three distinctive types of eye movements are associated with image stabilization: the vestibuloocular reflex (VOR), the optokinetic reflex (OKR), and the extremely high-speed resetting movements called the "quick phase" (of nystagmus). The VOR is a very short latency reflex instigated by the vestibular system in response to body/head rotation. The OKR, on the other hand, is triggered by visual motion. In the laboratory, VOR and OKR can be separately studied; however, in the real world both are activated whenever the head moves, and they synergistically sum to compensate for most head movements and thereby minimize movement of the visual image on the retina. In contrast, the quick phase is an anticompensatory movement that very rapidly returns the eye to a more central position whenever it is taken to eccentric orbital positions by the vestibulooptokinetic reflexes.

These image-stabilization eye movements are reflexive and automatic. From an evolutionary perspective, they are the most basic, primary eye movements. Indeed, for most vertebrate species VOR, OKR, and the quick-phase movements of nystagmus are the only eye movements.

B. The Foveation System

As in most primates, the human retina has a tremendously specialized central zone, the fovea, where visual acuity is 1000 times better than vision just 10° eccentric. Hence, to "look at" something is effectively to foveate it. However, the fovea subtends only 1° of visual angle (equivalent to the full moon's subtend). Therefore, the second principal function of eye movements is to foveate important parts of the visual scene.

Foveation is accomplished by a triad of voluntary eye movements: saccades, fixation, and smooth pursuit. Of these, saccades are the most conspicuous because humans incessantly make saccades in order to maximize retrieval of high-quality visual information by foveal viewing. Although the saccadic movement is ballistic and stereotyped, saccades are voluntary with regard to the choice of whether or not to make a saccadic movement (when to look) and what saccadic vector to program (where to look). For example, reading is accomplished with a succession of voluntary saccades that march across each line (Fig. 1), and during each fixation (between saccades) the reader processes the foveated word(s) while simultaneously programming the next saccade.

Smooth-pursuit eye movements, the third member of the foveation triad, assists the viewing of objects moving in space by matching eye velocity to target velocity, up to 50–100°/sec. A record of smooth pursuit is shown in Fig. 2. Pursuit is sometimes confused with the OKR; however, they are very different movements, as described later, and pursuit often must override the combined vestibulooptokinetic reflexes (e.g., during combined head–eye tracking of a moving stimulus). Instead, pursuit is more equivalent to the continued fixation of a target that happens to be moving.

Whereas image stabilization is effected by a largely reflexive brain stem system, the more voluntary, cognitive foveation system and its constituent eye movements (saccades, fixation, and pursuit) involve many areas of neocortex, most notably the frontal eye field (FEF) region of the frontal lobe.

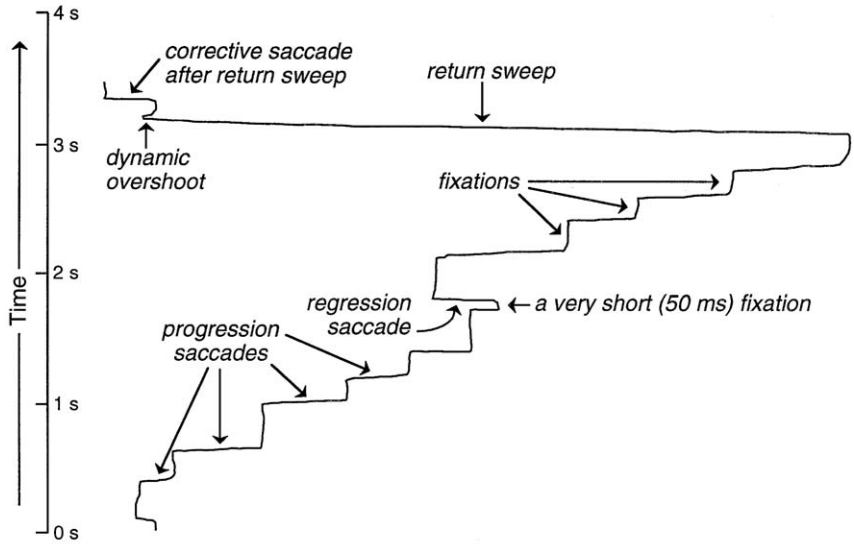

Figure 1 Eye movements during reading. Eye movement records showing the pattern of saccades and fixations made while reading the sentence shown in the abscissa. Records were obtained using the infrared photoelectric scleral reflection technique (at 100 Hz). Time increases along the ordinate; therefore, to recreate the eye's movement the traces should be read from bottom to top. Notice that the sentence/line was read with 10 progressive (rightward) saccades and one regressive (leftward saccade), and the majority of the time spent reading the line is during the 11 fixations between the saccades (adapted from J. K. O'Regan, *Eye Movements and Their Role in Visual and Cognitive Processes* (E. Kowler, Ed.), copyright 1990, with permission from Elsevier Science).

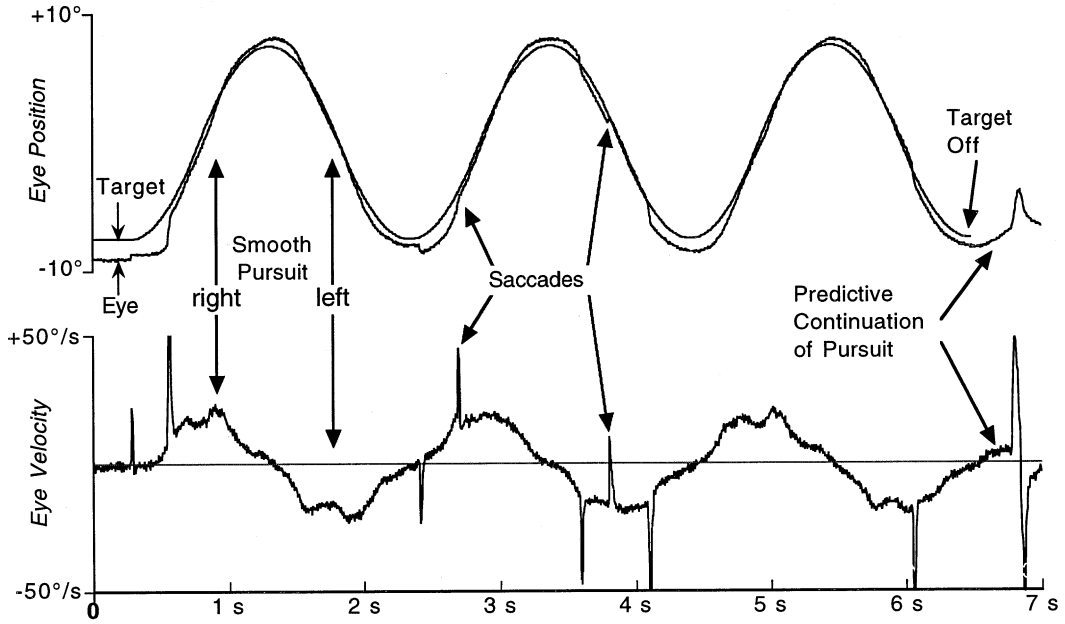

Figure 2 Smooth-pursuit eye movements. Horizontal eye position (top) and eye velocity (bottom) records of a monkey's smooth-pursuit tracking of a small spot with sinusoidal motion (amplitude $\pm 7.5^{\circ}$, frequency 0.5 Hz). Tracking sinusoidal motion is equivalent to tracking the bob of a pendulum, a classic pursuit test. Maximum target velocity is 23.6°/sec, and maximum pursuit velocity was $\sim 25^{\circ}$/sec. Saccades are easily identified by their spikes in the eye velocity traces. A total of seven saccades were made during the 6 sec of sinusoidal motion, starting with a large catch-up saccade shortly after the start of the target motion. At the end of the record smooth pursuit continued for part of a fourth cycle (predictive pursuit), even though the target was extinguished after three cycles (C. J. Bruce, unpublished data).

C. The Vergence-Accommodation System

As a consequence of frontally placed eyes (found in all primates and in predatory species of other vertebrate orders), the visual fields of the two eyes have considerable overlap. Stereoscopic depth can be extracted from the small differences in the these overlapping images, yielding detailed information about the three-dimensional (3D) structure of the visual world. However, good stereopsis requires that both eyes be directed at (i.e., foveate) the same object in visual space. Vergence (or disjunctive) eye movements provide such binocular alignment in response to changing fixation target distances, which necessitate that the two eyes point in different directions. In contrast, all of the aforementioned eye movement types are conjugate (or equivalently, conjunctive). Thus, the two eyes move as one during saccades, pursuit, VOR, etc. but not during vergence. The basic neural mechanisms of vergence and accommodation are in the brain stem, especially in midbrain regions immediately adjacent to the oculomotor nucleus (n. III). However, the vergence-accommodation system is also dependent on neocortex, especially primary visual (striate) cortex and the frontal lobe cortex.

III. HOW DO THE EYES MOVE? PHENOMENOLOGY OF EYE MOVEMENTS

The oculomotor response can be reduced to seven basic types of eye movements (Table I) that achieve the three principal functions of image stabilization, foveation, and binocular alignment. Although these movements differ in many regards (e.g., whether they are fast or slow, voluntary or reflexive, as well as which of the three functions is served), the kinematics of eye movements are generic. All eye movements share a common final path represented by three cranial nerve nuclei and the six pairs of eye muscles that they control. This section describes the basic mechanics of eye movements and the muscles, nerves, and motor nuclei involved.

A. Eye Movements Are Three-Dimensional Rotations of the Eye in the Orbit

Eye movements can generally be regarded as rotations of the eye about the center of the eyeball. Like a ball in a socket, the eyeball spins inside its bony orbit in the skull. As shown in Fig. 3, any particular eye position can logically be obtained by a combination of rotations about the three axes through the center of rotation.

B. Each Axis of Rotation Is Controlled by a Pair of Opposing Muscles

Eye rotations are effected by six extraocular muscles that are organized as three opposed pairs. Each of these muscles has a major action: The medial and lateral rectus muscles effect horizontal eye movements, with the lateral rectus pulling the eye temporally (abduction) and the medial rectus pulling nasally (adduction). The primary actions of the superior and inferior rectus muscles are elevation and depression, respectively. The primary actions of the superior and inferior oblique muscles are torsional rotations of the eye about the line of sight, with the superior oblique effecting intortion, and the inferior oblique effecting extorsion. However, the actions of the superior and inferior recti and the superior and inferior obliques are better regarded as "mixed" in that both pairs actually effect combined vertical and torsional eye movements. Vertical and torsional eye movements are further discussed later.

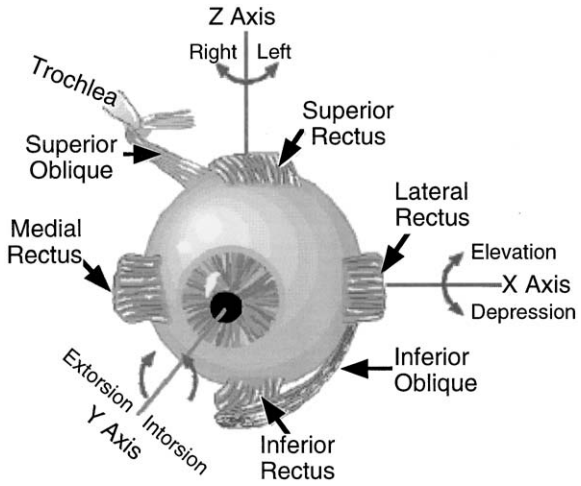

Figure 3 Axes of rotation and muscles of the eye. The eye rotates about three axes to effect horizontal, vertical, and torsional movements. These rotations are implemented via six extraocular muscles for each eye, as shown. Adduction and abduction about the z axis are accomplished by the lateral and medial rectus muscles. Raising and lowering the eyes (x axis rotations) are accomplished by the inferior and superior rectus muscles in association with the inferior and superior obliques. Likewise, torsional movements (y axis rotations) require the inferior and superior obliques together with the superior and inferior rectus muscles.

C. The Oculomotor Cranial Nerves and Their Brain Stem Nuclei

The six extraocular muscles are innervated by cranial nerves III (oculomotor), IV (trochlear), and VI (abducens). Nerve IV innervates the contralateral superior oblique, nerve VI the ipsilateral lateral rectus muscle, and nerve III the remaining four extraocular muscles as well as the eye lid. The neurons giving rise to these general somatic efferents are termed oculomotor neurons (OMNs). Their cell bodies are located in three eponymous nuclei that lie in pairs along the medial longitudinal fasciculus near the midline of the brain stem: the oculomotor, trochlear, and abducens nuclei, which are often grouped and simply termed the oculomotor nuclei.

D. Neural Activity in Oculomotor Neurons

In the early 1970s, several pioneering laboratories recorded the activity of single neurons in oculomotor nuclei while monitoring the eye movements of alert monkeys. They found that every OMN had the same characteristic firing pattern, organized about the eye's position and motion in the plane of its target extraocular muscle (Fig. 4). The clarity and constancy of the OMN responses galvanized sensorimotor neurophysiology, setting the stage for the analysis of circuits responsible for OMN responses and for tracing the antecedents of these activities further into the brain stem and then to the cerebral and cerebellar cortices.

1. Coding of Eye Position by Oculomotor Neurons

The relationship between the discharge rate of any OMN and the static position of the eye is a linear function of the eye's coordinate, θ, as measured along the pulling direction of the OMN's target muscle: $R_{OMN}=A\cdot(\theta-\theta_0)$, where R_{OMN} is spikes/sec, θ_0 is the

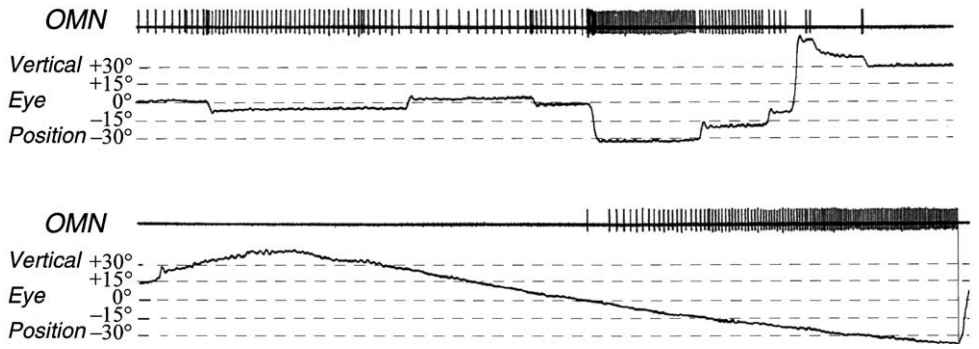

Figure 4 Discharge characteristics of a neuron in the oculomotor nucleus (OMN). The firing rate of this neuron increased in association with downward eye movement. The upper set of traces shows spontaneous saccadic eye movements with intervening periods of fixation. The lower set shows smooth pursuit brought about by moving an object in front of the monkey. In each part the top trace has the neuron's spikes during the eye movement; the **lower** trace (solid line) is the vertical eye position. The dashed lines represent degrees of deviation from straight-ahead gaze; upward deflection corresponds to elevation and downward deflection to depression of the eye (adapted with permission from P. H. Schiller, *Exp. Brain Res*. **10,** 347–362, 1970. copyright © 1970 by Springer-Verlag).

OMN's recruitment position, or threshold, and a typical value for factor A is 4 Hz/deg. Most θ_0 are more than 15° in the "off" direction (i.e., $\theta_0 \leq 15°$), meaning that most motor units are active during central fixation. Two nonlinear constraints on R_{OMN} are necessary, however: $R_{\mathrm{OMN}}=0$ for all $\theta \leq \theta_0$, because neurons cannot have a negative rate, and $R_{\mathrm{OMN}} \leq 500$ because OMNs typically saturate at 500 Hz.

This linear relation reflects the passive physical properties of the eyeball in the orbit, namely the elastic forces that are constantly pulling the eye toward its central position with a force proportional to its eccentricity. Thus, larger deviations from the central position require proportionally larger muscular forces, which in turn require larger rates in the agonist muscle's OMNs. Larger eccentricities also require more relaxation in the antagonist muscle; however, the same equation, with the direction of θ reversed, provides for relaxation of the antagonist OMNs as well.

2. Coding of Eye Velocity by Oculomotor Neurons

For the eye to be rotated at any appreciable velocity, its extraocular innervation must also overcome the viscous drag of the orbit, which is approximately proportional to rotational velocity. Indeed, OMNs have significantly higher or lower spike rates when crossing a given eye position as a function of tracking direction and velocity. Thus, a velocity factor must be added to the OMN equation, yielding $R_{\mathrm{OMN}}=A\cdot(\theta-\theta_0)+B\cdot(d\theta/dt)$. A typical value for velocity factor B is 1 Hz/deg/sec. The magnitude of this factor, like the threshold position (θ_0) and position factor (A), varies across the motor pool of each muscle; however, all OMNs require such a velocity term, as well as a position term, in their rate equation.

This basic equation holds for all OMNs during all types of eye movements. The velocity term has its most dramatic effect when the eyes move via saccades or quick phases (Fig. 4, top) because such rapid eye movements can approach 1000°/sec. Likewise, the nonlinear stipulation that $0 \leq R_{\mathrm{OMN}} \leq 500$ is very important in relation to rapid eye movements; in fact, most OMNs are saturated at their maximal rate during large saccades in their on direction, and most are briefly silenced during saccades in their off direction.

3. Causality

The rate equation for OMNs is instructive, but it is causally backwards because the data are from recordings in alert monkeys making natural eye movements, not from direct experimental manipulation of eyeballs. Presumably, the brain arrives at a goal for θ and $d\theta/dt$ and then provides appropriate rates for all OMNs, including the few from which neurophysiologists record. Consequently, the extraocular muscles contract and the eye moves to position θ at velocity $d\theta/dt$. In other words, the causal equation is $\theta(t)=F(R_{\mathrm{OMN}}(t-\tau))$, where τ is the $\sim$5-msec delay from OMN spikes to actual eye movement. The substantive questions are (i) how an appropriate eye position and velocity are reckoned by a hierarchy of oculomotor structures distributed across the brain and

then (ii) how the appropriate R_{OMN} for effecting that position and velocity are computed.

E. How the Eyes Are Coordinated and Constrained

The complexity of controlling 12 extraocular muscles is dramatically mitigated by several "laws" that reduce the degrees of freedom for controlling the eyes. These laws are implemented in the oculomotor anatomy near the output stage, and thus nearly all eye movements obey them.

1. Descartes–Sherrington's Law of Reciprocal Innervation

This law asserts that the six eye muscles of each eye act as three agonist/antagonist pairs (as discussed earlier), thus reducing the oculomotor system's degrees of freedom from 12 (the total number of extraocular muscles) to 6. Reciprocal innervation was implicit in the R_{OMN} equation because the agonist and antagonist muscles of each pair lie in the same plane with reversed sign.

2. Hering's Law of Motor Correspondence

Hering's law halves the oculomotor systems degrees of freedom from 6 to 3 because it asserts that the two eyes act in unison (conjugately) for all eye movements excepting vergence. Thus, the brain operates as if there is only one eye, a cyclopean retina. This motor correspondence is accomplished by yoking pairs of muscles in the two eyes. For example, the lateral rectus of the right eye and the medial rectus of the left eye comprise a yoked pair. They receive the same commands and both effect a rightward movement.

The brain stem circuits for both reciprocal innervation and motor correspondence in horizontal eye movements (medial and lateral rectus) are shown in Fig. 5 for rapid eye movements, such as saccades, and in Fig. 6 for smooth/slow eye movements, such as VOR. The yoking for horizontal movements is straightforward: Signals entering the right abducens nucleus not only innervate motor neurons of the right eye's lateral rectus but also innervate interneurons within the abducens nucleus. These interneurons relay this signal, via the medial longitudinal fasciculus, to the contralateral oculomotor nucleus, synapsing on OMNs of the left eye's medial rectus. For reciprocal innervation, an inhibitory copy of the command signal is routed to the contralateral abducens, which relaxes the contralateral lateral rectus and, by the yoking circuit, relaxes the ipsilateral medial rectus as well.

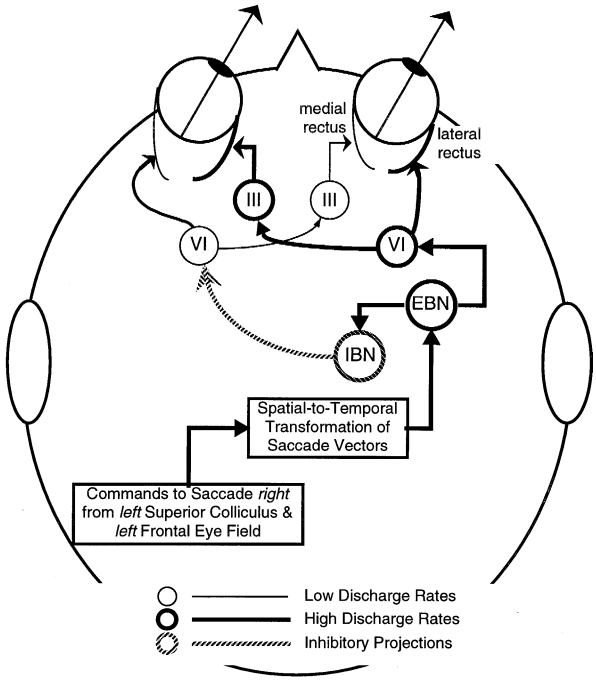

Figure 5 Neural circuit for a conjugate rightward eye movement. Making a conjugate eye movement, as in this figure, invokes activity in the diagrammed neural circuit that implements both Hering's law (motor correspondence) and Descartes–Sherrington's law (reciprocal innervation). For a rightward eye movement, the yoked agonist muscles contracted are the right lateral rectus and left medial rectus, and the antagonist muscles relaxed/inhibited are the left lateral rectus and right medial rectus. In the example shown, a signal to make a rightward saccade originates in the left hemisphere (cortex and colliculus) and is transmitted via the excitatory burst neurons (EBN) to the motoneurons of the right lateral rectus in n. VI (abducens). In order to also contract the yoked muscle in the left eye (the medial rectus), and thereby make the movement conjugate, a set of non-motor neurons in n. VI relay the movement signal to contralateral n. III (oculomotor). Reciprocal innervation (inhibition of the two antagonist muscles) is accomplished by inhibitory burst neurons (IBN) that project to the left n. VI and thereby both directly inhibit motoneurons of the left lateral rectus and indirectly diminish contraction in the right medial rectus via the n. VI to n. III projection. Similar circuits accomplish motor correspondence and reciprocal innervation for the other extraocular muscles in order to carry out conjugate vertical and torsional movements.

For the remaining eight muscles, yoking is less obvious. Each superior oblique and the opposite inferior rectus constitute one yoked pair, and each inferior oblique and opposite superior rectus another.

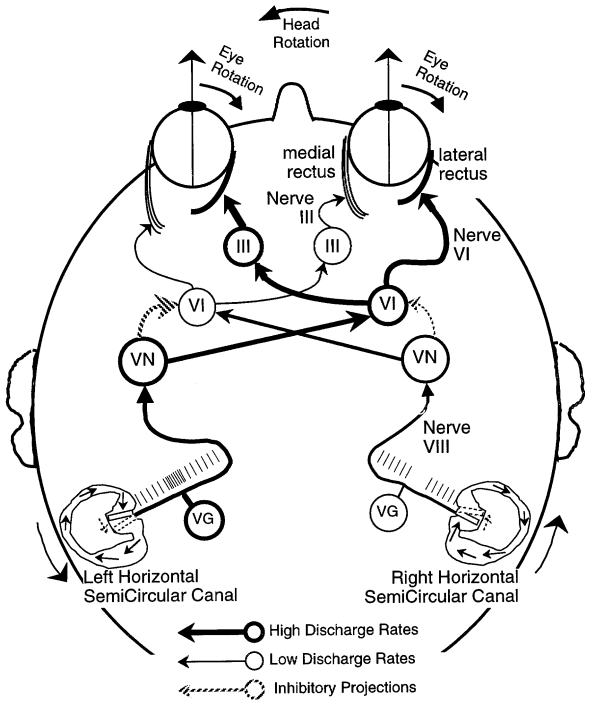

Figure 6 Neural circuit for the horizontal vestibuloocular reflex (VOR). The diagram depicts the rightward horizontal eye movements that compensate for leftward head rotation. The basic connectivity shown here serves all conjugate rightward eye movement (e.g., Fig. 5), regardless of the origin of the eye movement command signal. For the VOR, this signal originates in the semicircular canals and is communicated, via bipolar neurons in the vestibular ganglion (VG), to the vestibular nuclei (VN). The VN sends an excitatory projection to the contralateral oculomotor neurons in n. VI (abducens) and also sends an inhibitory projection to ipsilateral n. VI. The consequences of the increased activity from the left horizontal canal are reinforced by the decreased activity from the right horizontal canal, illustrating the push–pull operation of the canal pairs. An additional excitatory pathway (not illustrated) from the VN directly to the medial rectus motoneurons in ipsilateral n. III (oculomotor) gives the medial rectus its three-neuron VOR drive in addition to its four-neuron VOR drive via the contralateral n. VI.

These pairings reflect the true rotational axes of these muscles and their relation to the vestibular canals (Fig. 7).

3. Listing's and Donders' Laws and the Loss of Torsion

In primates torsional movements are severely constrained. For example, the human eye torts only a few degrees in response to a large sideways tilt (technically a "roll") of the head, whereas the rabbit eye torts up to 70°. The absence of significant torsional movement has an evolutionary advantage for stereoscopic vision.

Ocular torsion is classically summarized by the laws of Donders and Listing. Donders' law asserts that each eye direction (the combination of a particular azimuth and a particular elevation) has a unique torsion always associated with it, regardless of the sequence of eye movements used to achieve that particular azimuth/elevation. This has important implications. First, although it takes three coordinates to specify a general rotation, Donders' law means that the eye has only 2 degrees of freedom, and thus only two angles (azimuth and elevation) need be specified. This is analogous to navigation; longitude and latitude suffice, even though locations on the ocean surface have three coordinates in space. Second, whereas 3D rotations are not commutative, Donders' law stipulates that human eye movements effectively are commutative.

Listing's law asserts Donders' law and more because it specifies the particular torsion associated with any final eye direction, whereas Donders' law only ensured that this torsion is unique. To find the torsional position that the eye will always assume at a particular azimuth and elevation, Listing's law instructs to find the axis in the frontal plane through the center of the eye (Listing's plane) such that a single rotation about that axis takes the eye from the primary position to the particular azimuth and elevation in question. This single rotation will obtain the orientation that the eye will always have at that azimuth and elevation, no matter the sequence of eye movements actually used to get there. This means that the human eye has zero torsion following purely horizontal or purely vertical movements from the primary position (these are called "secondary" positions). However, for a typical oblique direction (a "tertiary" eye position) the eye appears to have undergone a torsional rotation because real-world vertical lines no longer fall along the vertical meridian of the retina when fixated. This is often called a "false torsion" because the eye did not have to make a true torsional movement about the line of sight but, rather, only a single rotation about an axis in Listing's plane, which is orthogonal to the torsional axis.

The role of the extraocular muscles in controlling ocular torsion is complex. The medial and lateral rectus have minimal torsional movements; however, as noted earlier, the four remaining muscles (inferior oblique, superior oblique, superior rectus, and inferior rectus) all have both vertical and torsional actions ("mixed" actions). Consequently, as Ewald Hering stated, elevation of gaze is effected "only by the cooperation of the superior rectus and the inferior

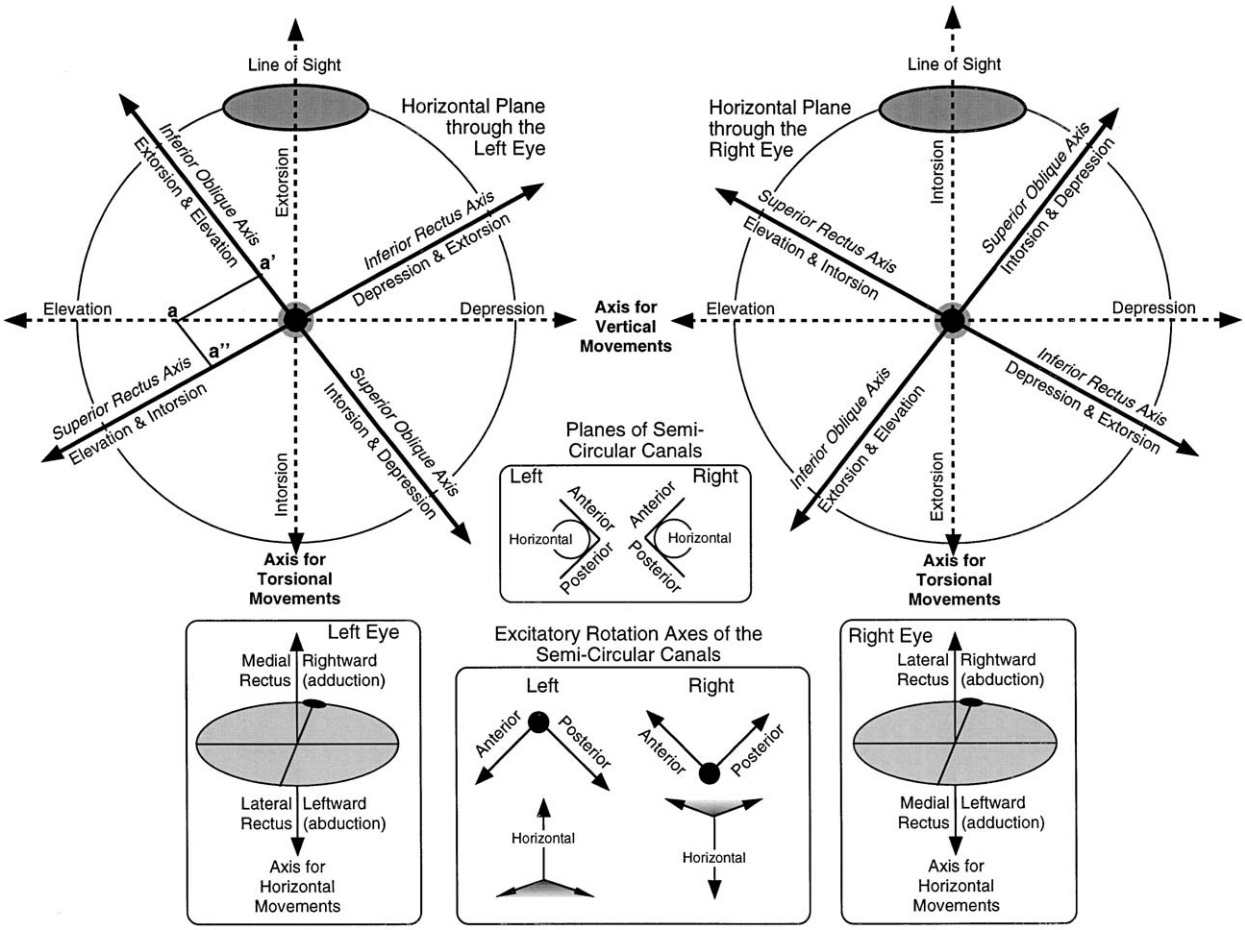

Figure 7 Rotational axes of the eye muscles and canals. (Top, left and right) The axis of rotation for all extraocular muscles, except for the medial and lateral rectus (bottom, left and right). For each muscle, the direction, or sign, of the eye rotation is given by the left-hand rule: Point the thumb along the arrow and the curve of the (slightly closed) fingers indicates the eye rotation. The rotation axes of the six semicircular canals (bottom middle) are perpendicular to the canal planes depicted above (upper middle) and show (by the left-hand rule) the eye rotation evoked by stimulation of individual canals. It is easy to see which muscle axis in each eye best aligns with each canal's axis; those muscles receive the three-neuron excitatory projection from that canal. Although in the primate, the eyes have migrated from the side of the head to the front, the canals are little changed, and the primate's extraocular muscles have maintained their rotation axes in correspondence with the canals axes. The figure also graphically depicts the rationale of yoking of the inferior oblique with the contralateral superior rectus and the superior oblique with the contralateral inferior rectus. The angular difference in both cases is far less than the difference between the left and right obliques axes or the left and right superior–inferior rectus axes. This figure was inspired by Fig. 51 in Hering (1942). His axis values, which were used here, have the axis of the superior–inferior rectus as being 29° off the axis for purely vertical movements and the axis of the superior–inferior obliques as being 38° off the torsional movement axis. The [a, a′, a″] parallelogram (top, left) is his geometrical construction of a pure elevation movement (with no torsion) from simultaneous contractions of the inferior oblique and superior rectus: Add the rotation axis vectors of these two muscles to obtain the axis for combined rotation.

oblique." Likewise, depression is effected by "cooperation of the inferior rectus with the superior oblique." This is analogous to lifting a barbell: If both arms lift with the same force, then the barbell will remain level, whereas if one arm exerts too much force then the barbell will tilt (tort) as it rises. Likewise, when the superior oblique and the inferior rectus are cocontracted, their downward forces are additive, but an extorsional force from increased tension in the superior oblique is canceled by an intorsional force from increased tension in the inferior oblique. Furthermore, the increased tension of the superior oblique and inferior rectus is always reciprocated by decreased tension of the inferior oblique and superior rectus, respectively. This results in a decrease in upward force, but with decreases in extorsion and intorsion canceling.

Thus, the eyes can move downward (or upward) with very little torsion, even though all four muscles involved have significant torsional actions.

Donders' and Listing's laws are not absolute or inherent in the passive properties of the eye. Large departures accompany convergence, head tilt, sleep, and certain neural pathologies. Torsional nystagmus, a clear violation of Donders' and Listing's laws, can be obtained with electrical stimulation of particular midbrain nuclei or individual canals and can also be a consequence of central disease.

IV. NEURAL CIRCUITS FOR EYE MOVEMENTS

A. Neural Circuitry of the Image-Stabilization System

The brain circuitry underlying image stabilization is organized around a vestibular apparatus in the temporal bone that can sense head rotations in any direction. The basic VOR is augmented by the OKR and several other specialized circuits, located in the brain stem and midline cerebellum, to become a very sophisticated system for minimizing retinal slip. These additional circuits are schematized in Fig. 8 and described next.

1. Circuit 1: The Three-Neuron Vestibuloocular Arc

How the brain fashions image-stabilization eye movements based on the vestibular sense has been extensively studied. Of prime importance is the vestibular sensory organ and the three-neuron arc composed of neurons in the vestibular ganglion, the vestibular nuclei, and the oculomotor nuclei.

On each side of the head within the labyrinth of the inner ear lie three semicircular canals filled with endolymph. Sensory receptor cells project hairs into a gelatinous mass, the cupula, that extends across the canal. When the head moves the bony canals move with it, but the endolymph lags behind, bending the cupula and the hairs embedded in it. Deforming the hairs hyperpolarizes their receptor cells for one direction of head rotation and depolarizes them for the opposite direction, and the resting discharge rate of bipolar neurons of the vestibular ganglion that innervate the receptor cells is modulated up or down by the receptor polarization (Fig. 6).

The central course of the bipolar cells' axons is the vestibular component of nerve VIII. They synapse in the vestibular nuclei, located in the medulla. Each canal projects to both the medial and the superior vestibular nucleus, and some vestibular afferents go directly to the cerebellum.

The three semicircular canals (horizontal, anterior, and posterior) lie in three different planes at approximately right angles to each other so that rotations of the head about any axis can be sensed. The planes of the three semicircular canals approximately correspond to the planes of action of the three pairs of extraocular muscles (Fig. 7), and the three-neuron pathway connects each canal to the extraocular muscles that move the eye in the canal's plane. This pathway was illustrated for the horizontal plane in Fig. 6. Horizontal head rotation excites the three-neuron pathway leading from the horizontal canal to the medial and lateral rectus, thus effecting an appropriate horizontal counterrotation of the eyes. Each canal also has a three-neuron inhibitory pathway to the corresponding antagonist muscles via inhibitory relay neurons in the vestibular nucleus. There are left and right sets of canals, and the symmetry of the VOR circuitry effectively uses the difference of the opposing signals from the left–right canal pair in each plane to increase the sensitivity of the VOR response, as shown in Fig. 6 for the horizontal canals.

The same principles hold for the anterior and posterior canals and the remaining four extraocular muscles, but in a less straightforward manner. The anterior and posterior canals lie in approximately vertical planes that are midway between the sagittal and coronal planes (Fig. 7). Thus, they do not correspond to the x–y–z axes of eye rotations described previously. Each anterior canal is paired with the contralateral posterior canal because they are in approximately the same plane and have the opposite responses to rotations in that plane. Also, each anterior–posterior pair controls a yoked pair of extraocular muscles that comes closest to its plane. For example, as can be deduced from Fig. 7, the excitatory three-neuron pathway of each anterior canal leads to the ipsilateral superior rectus muscle and the contralateral inferior oblique.

2. Circuit 2. Position Holding Mechanism (the "Neural Integrator")

The first problem for the basic three-neuron VOR circuit occurs when the head stops moving after a brief

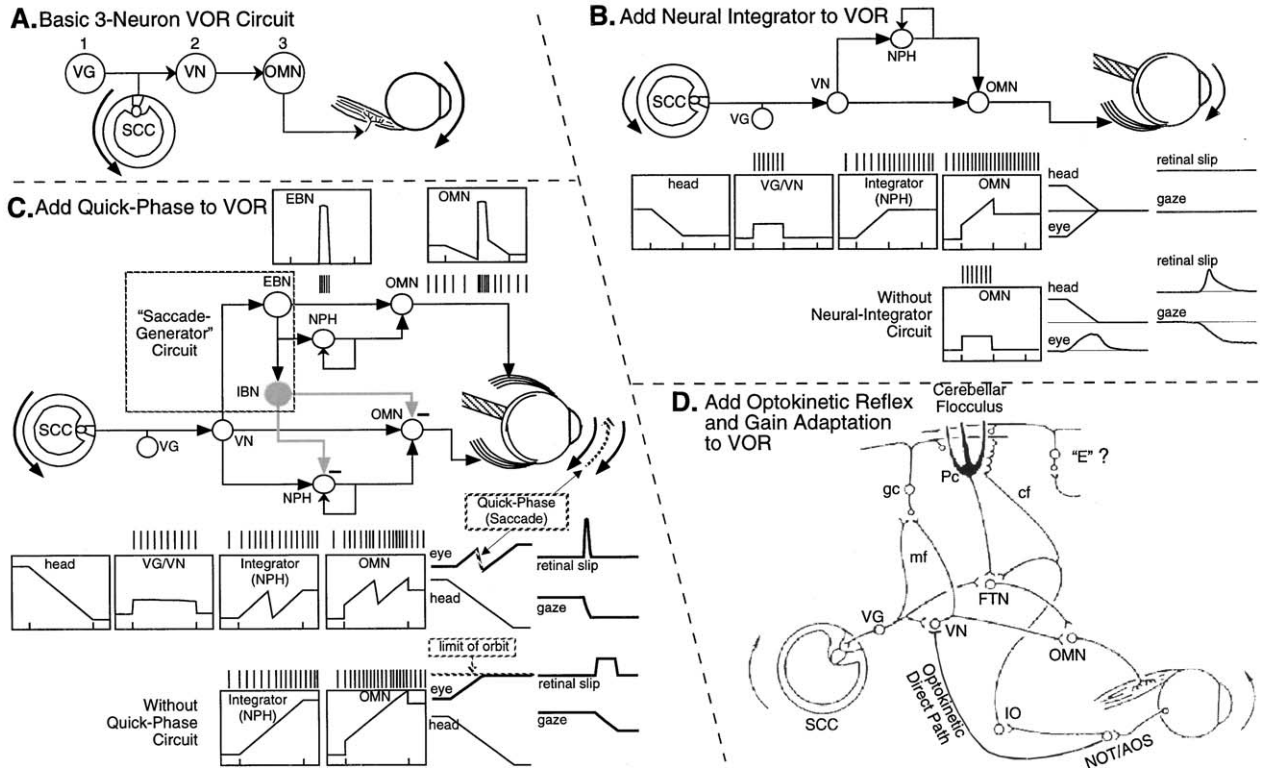

Figure 8 Neural circuits for image stabilization. (A) Basic three-neuron VOR circuit. Head rotations transduced by the semicircular canal (SCC) activate a three-neuron circuit that rotates the eye in the opposite direction. The circuit is as follows: neurons in the vestibular ganglion (VG) to neurons of the vestibular nuclei (VN) to oculomotor neurons (OMN) in one of the three oculomotor nuclei. (B) The VOR with the addition of a neural integrator. (Top) The neural integrator for horizontal eye movements is located in the n. prepositus hypoglossi (NPH) (and in the medial vestibular nucleus, which is not illustrated). Its integration function is symbolized by the recurrent connection of the NPH onto itself. (Middle) The plots show idealized spike rate functions for the components of this circuit, with idealized spikes above the plot boxes. With the neural integrator, retinal slip is minimal as gaze is held steady during and after the head movement. (Bottom) Without the integrator, the OMN does not cancel the elastic forces of the eye; thus, the eye slides back to the center of its orbit, both during and after the head movement, resulting in considerable retinal slip. (C) The quick-phase addition to the VOR. The quick-phase addition is symbolized by the inclusion of the saccade generator circuit with its excitatory (EBN) and inhibitory burst neurons (IBN) that enable the eye to be rapidly "reset" to the central position. Again, the plot boxes and spikes are hypothetical neural responses of the components of this circuit. (D) Addition of the optokinetic reflex (OKR) and a circuit for VOR gain adaptation. Visual motion signals from the nucleus of the optic tract (NOT) and the accessory optic system (AOS) go directly to the VN to add an OKR to the image-stabilization system. This OK signal is also sent to the inferior olivary nucleus (IO), and then to the cerebellar Purkinje cells (Pc) via their climbing fibers (cf). Likewise, the canal signal is relayed to the cerebellum's floccular Pc on mossy fibers (mf) that are axon collaterals of vestibular neurons via granule cells (gc) and their parallel T fibers. These inputs enable the flocculus to adaptively adjust VOR gain via its direct projections to the VN; the VN cells that receive this inhibitory projection are termed floccular target neurons (FTN). Pcs are also thought to receive a copy of the eye velocity signal, hence "E?" (adapted with permission from A. E. Luebke and D. A. Robinson, *Exp. Brain Res.* **98,** 379–390, 1994. Copyright © 1994 by Springer-Verlag).

turn. The canal signal quickly returns to baseline when the head stops moving because the cupula is no longer distended. However, if the innervation of the extraocular muscles also returns to its baseline level, then the elastic forces of the orbit would pull the eye back to the central position, thus negating the benefits of the VOR because vision would be blurred throughout this prolonged return.

Thus, for stable vision, the eye should not only stop rotating when the head stops turning but also must be held stationary at its current position and not slip back toward the central position. This is elegantly accomplished by the brain stem's neural integrator, a hypothesis of David Robinson, who reasoned that a command for eye position could be obtained by integrating eye velocity commands. Robinson's integrator now has a specific location, a neural signature (tonic activity coding static eye position), and distinctive neurological consequences of injury to it (e.g., gaze-evoked nystagmus).

The stabilization system, based on the VOR with the addition of the neural integrator, is shown in Fig. 8B, with the neural integrator represented by a local recurrent connection. Such a local recurrent connection was perhaps the earliest neural mechanism proposed for a short-term memory by Rafael Lorente de Nó and others. As the VOR "eye velocity signal" moves the eye, the integrator output grows, continually signaling where the eye should be held both during the VOR movement and after it. Thus, the neural integrator serves to exactly overcome the elastic force that accompanies increasingly eccentric eye rotations. Referring back to the equation $R_{OMN}=A\cdot(\theta-\theta_0)+B\cdot(d\theta/dt)$, the head velocity signal from the vestibular sensory nucleus is fed to the oculomotor nuclei as a command for eye velocity ($B\cdot(d\theta/dt)$) [where B is the synaptic strength] and the neural integrator obtains its eye position signal by integrating the eye velocity command, $d\theta/dt$, to obtain the $A\cdot(\theta-\theta_0)$ term for the OMN. This scheme is used for all types of eye movements: The command signal is formulated as a desired eye velocity (the velocity command hypothesis), and a common neural integrator integrates velocity commands of all types to continuously maintain the eye position signal.

3. Circuit 3. Quick Phases and Nystagmus

What if a large head rotation is made, or there are successive turns in the same direction? The eye can move only about 40–60° in any direction from its central position in the orbit. Thus, the VOR/neural integrator circuit will quickly drive the eye to the extreme of the orbit and the retinal image will begin to slip. Furthermore, in extreme orbital positions the eye's visual field is partially occluded.

Nature's solution is to periodically reset the eye back to the central position (usually slightly past it) during prolonged or large head rotations. Moving back to center results in considerable blur; however, the vertebrate solution is for the reset mechanism to recenter the eye as fast as possible in order to minimize the duration of the temporary blindness due to the high-velocity smearing of the retinal image. This requires near-maximal contraction of the agonist muscles coupled with complete relaxation of the antagonist muscles in order to produce eye movements approaching 1000°/sec and directed opposite the compensatory vestibuloocular movement.

The resets are obvious when prolonged rotation occurs, the resulting to-and-fro pattern of movement is called nystagmus (Fig. 9). In vestibular nystagmus, fast movements alternate with slow ones, yielding a characteristic sawtooth waveform. The slow phase is the compensatory reflex, and the rapid resets are called the quick phase. The quick-phase circuit is indicated by the addition of "burster" neurons in Fig. 8C. The excitatory burst neurons (EBNs), with their high spiking rate, project to the OMNs to realize the quick-phase movements. Actually, these EBNs are the output neurons of the "saccade generator" circuit, so labeled because it is appropriated by the foveation system to effect voluntary saccadic eye movements that are completely independent of the VOR. Moreover, the saccade generator is usually studied in the context of voluntary saccadic eye movements, in part because rotating subjects about different axes to achieve vestibular nystagmus can be a daunting experiment. Therefore, the saccade generator is further elaborated later in conjunction with voluntary saccades.

4. Circuit 4. The Optokinetic Reflex Complements the VOR

The VOR handles brief head movements very well, but it has trouble with prolonged rotation. This is because, with continued rotation of the head, the endolymph in the semicircular canals begins to catch up with the movement of the head, the cupula returns to its resting position, and hence the vestibular afferents return to their baseline rate, falsely indicating that the head is no longer rotating. Consequently, for continued rotation in the dark (or with the eyes closed) vestibular nystagmus will gradually slow down and completely stop after 30–60 sec. One solution to this problem of vestibular transducer adaptation is to let retinal slip help in driving this compensatory reflex. This is OKR, which is added to the basic VOR circuit in Fig. 8D. The principal sources of this retinal slip signal are two lesser known targets of the optic nerve: the nucleus of the optic tract (NOT) and the accessory optic system (AOS). Cells in these brain stem nuclei are tonically driven by the movement of large patterned visual stimuli, the best stimulus for eliciting OKR, with different neurons tuned to different directions of motion. In primates, the responses of these cells depends not only on their direct retinal inputs but also on pathways that involve neocortex, especially primary visual cortex and extrastriate motion areas. The direct and indirect projections of AOS/NOT to the vestibular nuclei complete the OKR circuit, which means that neurons in the vestibular nuclei also respond to visual (OK) stimuli. Moreover, despite

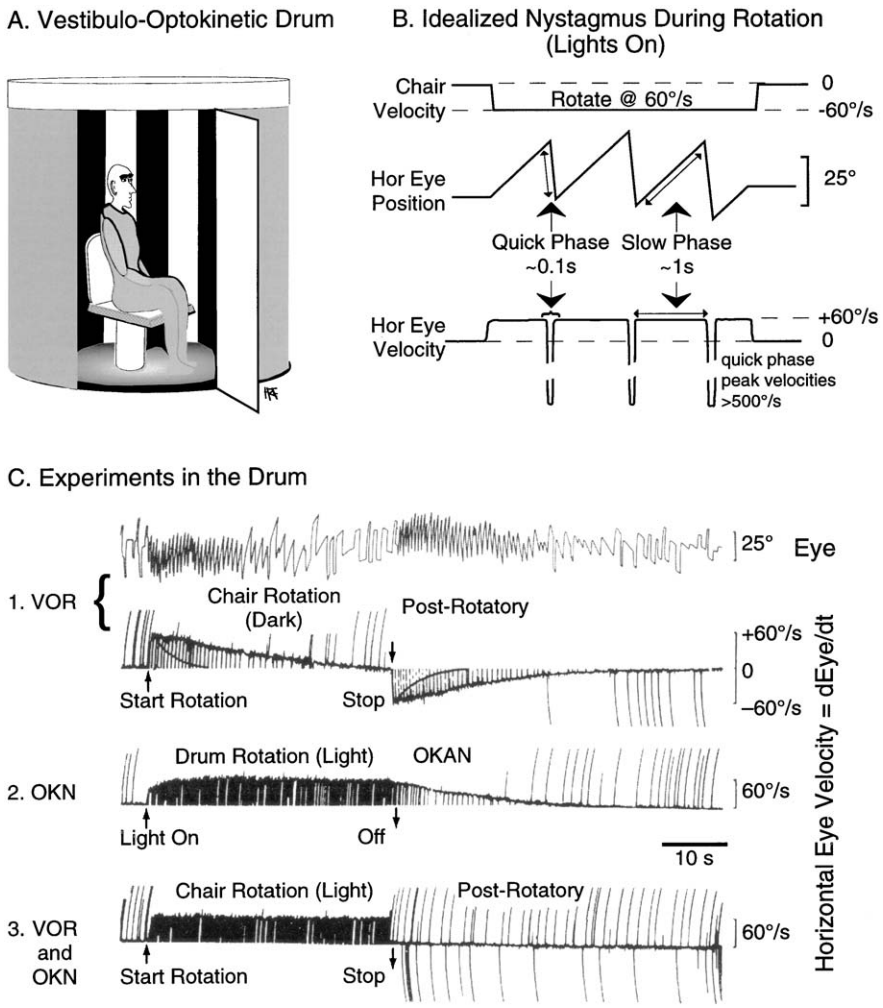

Figure 9 The optokinetic reflex and nystagmus. (A) A depiction of a rotating chair and drum (with striped inner walls) used for testing the vestibuloocular (VOR) and optokinetic reflexes (OKRs), together and separately. Rotation of the drum (surround) alone, with illumination, elicits the OKR in a stationary subject. Rotation of the chair in the dark elicits the VOR. Rotation of the chair in the light activates both reflexes. (B) Idealized nystagmus during chair rotation with full illumination. (Top) The chair velocity plot indicates leftward rotation. (Middle) The horizontal (HOR) eye position record shows slow-phase movements, directed opposite the chair rotation, which compensate for the chair rotation, combined with quick-phase movements in the direction of rotation that periodically reset the eyes toward their central positions in the orbit. (Bottom) The "envelope" of the velocity trace also shows the rightward direction of slow-phase motion, which is quite distinct from the brief, high-velocity leftward-moving quick phase of the nystagmus. (C) Experimental nystagmus data (1) (Top trace) Horizontal eye movement record showing vestibuloocular nystagmus elicited by chair rotation in the dark. (Bottom trace) Eye velocity record from the same trial (see Fig. 9B). The velocity envelope shows that slow-phase rightward movements are elicited with a very short latency after rotation begins but taper off as rotation continues (adaptation). Note that the postrotatory response is in the opposite direction. The exponential dark lines, in both the adaptation and the postrotatory epochs plot the theoretical strength of the vestibular canal signal, which adapts much faster than the slow-phase velocity adapts. (2) Eye velocity during drum rotation in the light. Optokinetic nystagmus (OKN) refers to the combination of the slow-phase OKR response and the quick-phase resets. The OKN velocity envelope during rotation is similar to that of the VOR except that (i) there is no diminution in the response to ongoing rotation in the light and (ii) there is a more gradual rise time to the maximal slow-phase velocity. Also notice that the optokinetic after nystagmus (OKAN) is in the same direction as the OKN, whereas the postrotatory response was opposite the VOR. (**3**) Chair rotation in the light elicits both VOR and OKN responses. There is a quick rise in slow-phase velocity because of the VOR, no adaptation because of the OKN, and no postrotatory nystagmus because the OKAN cancels the postrotatory nystagmus from the canals (Fig. 9C adapted with permission from T. Raphan, V. Matsuo, and B. Cohen, *Exp. Brain Res.* **35,** 229, 1979. Copyright © 1979 by Springer-Verlag).

the addition of many refinements to the VOR, and the addition of new types of eye movements, the vestibular nuclei remain the principal gateway to the oculomotor nuclei.

Since the OKR is indefatigable, why not dispense with the VOR and base image-stabilization eye movements solely on the OKR? The reason is that the OKR is much slower to react than the VOR. OKR latency is 50–100 msec (reflecting the slow pace of visual processing), whereas VOR latency is $\sim$10 msec. To demonstrate that OKR alone is poor, rotate the head left and right while reading. The text is legible because image stability is provided by the VOR. Now move the book left and right with the head still; the page will be blurred despite the OKR. This test hints at another reason the VOR is needed: Once a visual image is moving very fast across the retina, then it is blurred and hence is a poor stimulus for engaging the OKR in order to decrease its retinal slip and blur.

5. Circuit 5. Velocity Storage

VOR adaptation during prolonged rotation in the dark reflects the adaptation of the vestibular transducer in the semicircular canals. However, closer inspection of this phenomenon reveals that the vestibular apparatus adapts rapidly, with a time constant of $\sim$6 sec, but the reflexive eye movement adapts with a much longer time constant (15–30 sec) (Fig. 9C.1). The reason is that a central neural process stores up the vestibular signal, thereby providing a more veridical representation of head motion than is provided by the raw VIIIth nerve signal.

This velocity-storage circuit stores optokinetic as well as the vestibular velocity (because they are merged in the vestibular nucleus). Indeed, the OKR does not stop immediately with the cessation of OK stimulation but continues, in the same direction, for several seconds after the lights go off (Fig. 9C.2). This continuation is called optokinetic afternystagmus (OKAN). Thus, the OKR is like charging a battery: It takes several seconds of stimulation for the OKR to reach its asymptote velocity (Fig. 9C.2) and to ensure robust OKAN after the optokinetic stimulation ceases.

This velocity storage underlies another aspect of the symbiosis between the VOR and the OKR regarding cessation of prolonged head rotations. If the VOR is adapted when rotation stops, the canal endolymph continues to move and produces a strong VOR in the opposite direction, called "postrotatory nystagmus" (Fig. 9C.1). It is accompanied by a loss of balance and vertigo and lasts several seconds. However, postrotatory nystagmus is best demonstrated by rotation in the dark so there can be no optokinetic stimulation. Indeed, there is usually no problem after rotation in the light (Fig. 9C.3) because OKAN serves to cancel postrotatory nystagmus.

6. Circuit 6. Gain Adjustment Mechanism for the VOR

Whereas the OKR is a closed-loop system in that the response cancels its own input signal, the VOR is an open-loop system because the counterrotation of the eye has no direct effect on the semicircular canal head-rotation signal. Also, because it is an open-loop system, the VOR reflex strength is critical. Ideally, VOR gain is exactly 1.0; however, it would seem too much for the genome to so completely specify the VOR circuitry so as to yield this ideal gain. Instead, an adaptation circuit continually adjusts VOR reflex strength so as to minimize the retinal image slippage that accompanies head movements. For example, wearing 2 $\times$ magnifying goggles for a few days will drastically increase VOR gain because 2 $\times$ goggles require that the VOR gain be 2.0 to cancel retinal slip when the head moves. In real life, less drastic but nevertheless critical adjustments of VOR strength need to be made—for example, when the head changes size during development, when people don spectacles (which more modestly magnify or minify the visual world), or whenever vestibular hair cells die or extraocular muscles weaken because of old age or other factors.

The crucial brain structure for VOR gain adaptation is the cerebellum, specifically the flocculonodular lobe that is interconnected with the vestibular nuclei that mediate the VOR (Fig. 8D). Monkeys without a cerebellum still have a robust VOR; however, VOR gain does not adapt in response to experimental goggles and other manipulations that induce adaptation in normal subjects. Other structures critical for VOR gain adaptation include the NOT and AOS, which provide an optokinetic signal not only directly to the vestibular nuclei but also to cerebellar cortex via the dorsal cap of the inferior olive. The overall goal of the gain-adjustment circuit (Fig. 8D) is to minimize the optokinetic signal that the cerebellum "sees"; the better the VOR works, the less the OKR is needed. Thus, the optokinetic signal serves two important purposes: It effects the OKR to assist the VOR and it provides the error signal for continually fine-tuning VOR gain.

B. Neural Circuitry of the Foveation System

The image-stabilization system (ISS) functions to ensure that the visual image as a whole is stationary on the retina. This suffices for many species, but with the evolution of the fovea came the need to deliberately shift the direction of gaze, independent of the ISS, in order to purposively foveate different stimuli. Because the foveal specialization covers only $\sim 1/10{,}000$ of the visual field, the eyes must be moved accurately. Furthermore, they must be moved intelligently to selected targets because systematic scanning of the whole visual field (like radar or television) would require hours and mostly be a waste of time. Therefore, the foveation system (FS) orchestrates eye movements that provide the fovea with an endless succession of the most important, informative, and pleasing visual stimuli.

As mentioned earlier, the primate FS uses three distinct eye movements: saccades, smooth pursuit, and fixation. These eye movements are voluntary in that they are controlled by, or made in the service of, the subject's choice to foveate a particular stimulus. In contrast, the ISS reflexively responds to the aggregate of vestibular and visual motion sensations and requires only a state of wakeful alertness.

Although choosing to foveate a particular stimulus is a voluntary action, doing so automatically activates the appropriate foveation subsystem(s). For example, after choosing to fixate a particular stationary target, (i) if the target moves quickly to a new location (e.g., a "step" motion), then a saccadic movement will be made in order to foveate it at its new location; (ii) if the target begins to smoothly move (e.g., "ramp" motion), then smooth-pursuit movements will match the target velocity and thereby both maintain foveation and reduce retinal blur; and (iii) if the target remains stationary, then fixation continues.

The cerebral cortex has a large role in these foveating eye movements. This seems obvious considering that occipital, temporal, and parietal neocortex are all heavily engaged in visual processing. Nor is involvement of the frontal lobe surprising, because the FS concerns voluntary movement. Although saccadic and smooth-pursuit eye movements are represented in separate cortical areas that have different subcortical projections, it is still likely that a common network of cortical areas mediates the target choice decisions for the FS as a whole.

Despite their functional differences, the FS and ISS engage the same basic brain stem neural circuits to effect eye movements. More precisely, the FS engages OMNs only indirectly via the ISS circuits: Voluntary saccadic eye movements exploit the quick-phase generating circuitry in the midbrain and pontine reticular formation and smooth-pursuit eye movements target the vestibular nuclei where the vestibulooptokinetic velocity commands are assimilated. By engaging these established motor (as opposed to sensory) aspects of the ISS circuitry, foveating eye movements automatically achieve proper connectivity to the neural integrator in order to overcome elastic forces in the orbit and hold the eye steady wherever it has moved. Note that an important implication of this strategy is that the FS, like the ISS, ultimately formulates both its fast and slow eye movement objectives as eye velocity commands.

Usually the FS and the ISS work together; for example, while walking through a garden, saccades might foveate different flowers, with the VOR holding the image of each flower stationary on the retina despite movements of the head while walking. However, it is easy to pit the systems against each other, and in such situations the FS usually prevails. For example, given a small stationary spot in front of a background of moving stripes, one can elect to fixate the spot and thereby subdue the OKR ordinarily evoked by a large moving pattern. Conversely, given a moving spot on a stationary background of stripes, one can choose to pursue the spot smoothly across the stripes and the ensuing retinal slip of the pattern, caused by the pursuit eye movements, would be ignored. Finally, the FS can even suppress vestibular signals to move the eyes. For example, by looking at an object fixed relative to the head (e.g., the brim of a cap) and then rotating the head (like in Fig. 10), one can keep the brim fixated and thus keep the eye stationary in its orbit, despite the vestibular signals that indicate head rotation.

C. Neural Circuitry of Voluntary Saccades

The principal eye movement of the FS is the voluntary saccade. Humans average about two saccades/sec while awake, and thus most of the day is spent in brief fixations of different parts of the visual world, continually interrupted by saccades. This incessant visuomotor activity, the processing of foveal visual data during a fixation, as well as the planning and execution of the next saccade, occupies much of the human brain, as exemplified by the expansive zones of

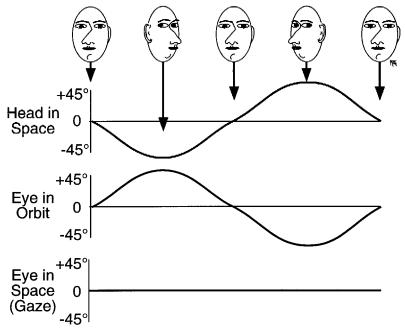

Figure 10 Retinal image stabilization during head rotation. As the head rotates about its vertical axis, the eyes reflexively rotate in the opposite direction to stabilize gaze, the direction of the eye in space. The two sinusoidal plots show the angular direction of the head in space (top) and the eye in its orbit (middle). The flat summation of these changes (bottom) signifies a steady gaze despite movements of the head.

cerebral activation revealed by functional magnetic resources imaging during simple and complex visuomotor tasks.

A few behavioral facts about saccades must be presented before considering their neural circuitry. First, saccades are open loop (i.e., ballistic and preprogrammed). As Gerald Westheimer stated, "once initiated, saccadic movements complete their predetermined course and cannot be modified or countermanded." In fact, 50–100 msec prior to its start, the saccade generally cannot be canceled or redirected on the basis of new sensory information. Second, saccades have long reaction times. Saccadic latency, the time from the appearance of an unpredictable visual target to the start of the movement, is 100–400 msec (200 msec being typical). Third, saccades have a long refractory period. It is usually difficult to initiate a second saccade for 100–200 ms after the previous saccadic movement ends. Fourth, saccades are highly stereotyped movements. Thus, the saccadic waveform and its parameters (duration, velocity, etc.) are almost completely determined by the dimensions of the movement vector being programmed. Finally, although saccades to foveate a stimulus can seem reflexive, and have been termed the visual grasp reflex, one can make accurate and advantageous predictive saccades that anticipate where a stimulus will appear. Thus, saccades can be guided by our experience, memories, guesses, purposes, and strategies as well as by overt visual stimulation.

1. The Saccade Generator

The first four properties mentioned previously reflect the fact that all saccades are ultimately "generated" or programmed in a very rigid, mechanistic fashion by a specialized circuit in the brain stem. This final common pathway for all rapid eye movements, called the saccade generator, is a network of several distinctive types of neurons embedded within the reticular formation near the oculomotor nuclei. This network originally evolved to generate the quick-phase movements of vestibulooptokinetic nystagmus. Thus, voluntary saccades of primates are accomplished by the relatively new FS triggering this ISS circuitry. If the saccade generator is damaged, then all rapid eye movements, both reflexive and voluntary, are disabled.

To accomplish a saccadic eye movement, the OMNs of the agonist muscle(s) need a special waveform of innervation: a pulse followed by a step. The pulse is a brief period of spiking at a very high rate, which is used to move the eye very quickly to its new location. The step is the new level of tonic discharge needed to hold the eye at its new location in the orbit. This pulse–step innervation is inherent in the OMN equation given earlier, and is illustrated in Fig. 11. Not shown is the fact that the pulse briefly but completely silences most OMNs of the antagonist muscles via inhibitory interneurons termed inhibitory burst neurons. This brief silence is also inherent in the basic OMN equation reviewed previously.

The pulse is provided by the principal output neuron of the saccade generator—the excitatory burst neuron (EBN). EBNs discharge with a high-frequency burst of spikes in conjunction with all saccadic eye movements and are silent between saccades. Their bursts begin $\sim$12 msec before the eye starts to move (they have also been called short-lead bursters) and end just before the eye completes the saccade. Horizontal EBNs are located in the caudal portion of the paramedian pontine reticular formation, conveniently near the abducens nucleus. Their spike counts during each burst determine the horizontal displacement of the saccade (in the ipsilateral direction). Vertical EBNs are located in the rostral interstitial nucleus of the medial longitudinal fasciculus, with separate sets of neurons for the upward and downward components. Other EBNs here also represent torsional saccadic eye movements.

The tonic "step" change in the OMN innervation is provided by the neural integrator that adds the pulse (EBN spikes) to its current value and then maintains that new value. Thus, when each saccade is made, the

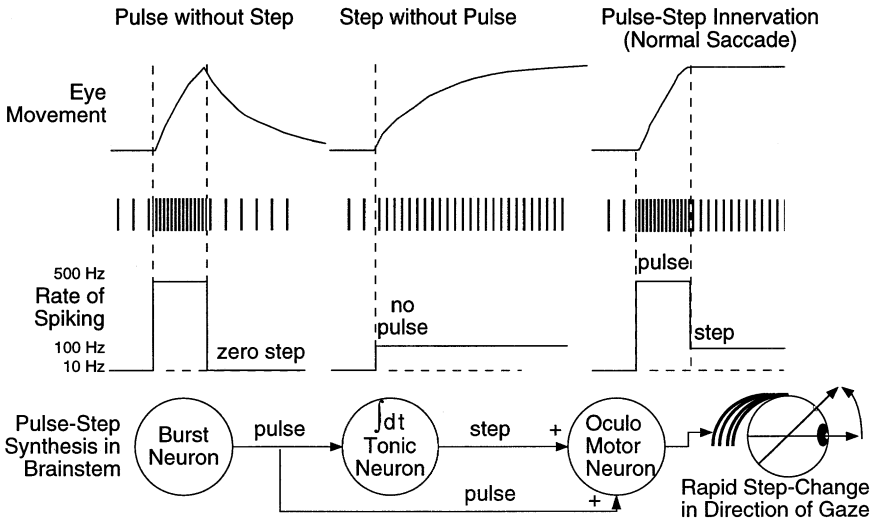

Figure 11 Pulse-step innervation of oculomotor neurons. A schematic showing eye position (top) and spike rates of burst and tonic neurons (middle) for real and hypothetical conditions producing abnormal and normal saccades. (Left) Given pulse activity but no tonic activity (step) to defend the new eye position, the eye slides back to its starting position (e.g., gaze-evoked nystagmus). (Middle) In the hypothetical case of a damaged pulse generator, the tonic/step activity alone causes very slow eye movements that "glide" exponentially to a target. (Bottom) Circuit diagram for pulse–step innervation of oculomotor neurons and the generation of saccades. The excitatory burst neurons are activated by signals from higher levels (e.g., the superior colliculus and frontal eye field). The activity of tonic neurons reflects ongoing integration of all eye velocity commands by neural integrator circuits in the pons and midbrain. Oculomotor neurons sum these phasic and tonic inputs to produce a high-velocity saccade and then to hold this new eye position.

neural integrator quickly "steps" from its old presaccadic level of activity to a new postsaccadic level. In contrast, the response of the neural integrator to a low-velocity long-duration signal from the VOR command is a "ramp" change in output rate. This short-term memory mechanism has been successfully modeled with recurrent neural networks and thus is schematized as a single recurrent feedback connection (Fig. 8C).

Several cell types antecedent to the EBNs have been identified. One of the most remarkable types is the omnipause neuron (OPN). The tonic activity of these inhibitory (glycine) neurons has the critical job of keeping all EBNs totally silent during the intervals between saccades. If EBNs had even a low spontaneous rate when not bursting, then the neural integrator would generate random "walks" between saccades instead of providing steady fixations. Only when OPNs temporarily stop spiking (which they briefly do in conjunction with all saccades, regardless of saccade size or direction) are EBNs given an opportunity to discharge. In fact, electrical stimulation at the OPN locus (nucleus raphe interpositus along the midline of the pons) during a saccadic eye movement will immediately brake the eye and (prematurely) end the saccade, and continuous stimulation there prevents all rapid eye movements, but not slow eye movements, such as the VOR or smooth pursuit. Detailed consideration of OPNs and the other cell types that complete the saccade generator circuit are beyond the scope of this article.

2. Visually Guided Saccades and the Superior Colliculus

How can the brain stem's saccade generator be activated to produce useful saccades in the absence of head movements and VO/OK stimulation? The exemplar structure for this function is the superior colliculus (SC), which forms the roof of the midbrain. The SC is the mammalian version of the optic tectum, which is the vertebrate brain's prototype sensorimotor structure. The SC receives a strong projection directly from the retina as well as afferents from most other senses (auditory, somatosensory, etc.), and its efferents to the brain stem and spinal cord serve to orient the head and body toward localized sensory inputs. In the primate, and other mammals with a foveation system, a major role of the SC is to move visual stimuli appearing in the visual periphery into the foveal region

of the retina by triggering a saccadic eye movement of the appropriate size and direction. This automatic, visually guided foveating saccade has been called the visual grasp reflex.

The functional anatomy of the primate SC that affords such visually guided foveation is forthright (Fig. 12): Neurons in the superficial layer of the primate SC constitute a topographic map of the contralateral visual hemifield (Fig. 12B; interestingly, this is only true of primates—for all other vertebrates each SC represents the entire contralateral eye). Neurons in the deeper, intermediate layer of the primate SC provide a topographic map of all contralaterally directed saccade vectors. These sensory and

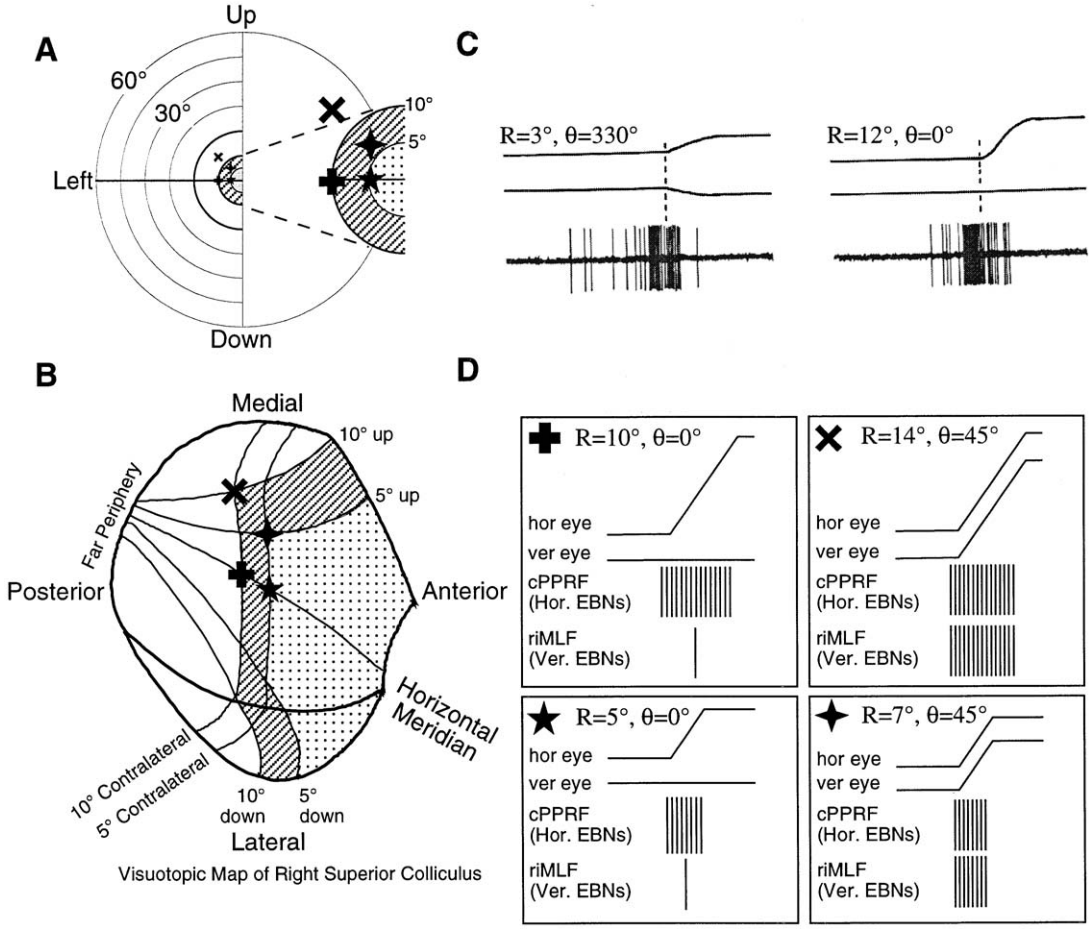

Figure 12 Spatial-to-temporal transformation of saccade vectors. Depiction of the necessity of a spatial-to-temporal transformation as saccade commands are relayed from the superior colliculus (SC) to the saccade generator, but the figure does not show how it is accomplished. (A) Spatial representation of four hypothetical visual stimuli. The stimuli are within the central-most 10° of the diagram and the dashed lines lead to enlargement of this region. (B) A visuotopic map of the SC showing the idealized representations of the visual stimuli depicted in A on the surface of the SC. Note that more than half the SC is used to map the central 10° (adapted with permission from M. Cynader and N. Berman, *J. Neurophysiol.* **35,** 187, 1972). (C) Saccade-related burst cells in the deeper SC layers code saccadic eye movements via their location in its spatial map of the contralateral visual hemifield. The top two traces are horizontal and vertical eye coordinates, and the bottom traces are spikes. These cells burst most robustly prior to a saccade matching their preferred vector (reprinted from D. L. Sparks, *Brain Res.* **156,** 1, copyright 1978, with permission from Elsevier Science). (D) Hypothetical response of the excitatory burst neurons (EBNs), the output stage of the saccade generator, to the visual stimuli shown in A and B. Top traces are eye position, and lower traces are the bursts of horizontal (Hor) EBNs [in the caudal paramedian pontine reticular formation (PPRF)] and vertical (Ver) EBNs [in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF)]. Saccade dimensions are a quasilinear function of the number of spikes in the bursts. Since EBNs usually burst at near-maximal rates, their spike count is largely a function of burst duration, just as saccade size is largely a function of saccade duration. In contrast, the burst duration of the saccade-related bursters in the SC is independent of saccade size or duration.

motor maps are in perfect register for making foveating saccades. For example, if recording from a superficial layer neuron located near the center of the left SC, the visual response field center would be 10° right of the fixation point (cross in Fig. 12B). If the microelectrode were then advanced into the underlying intermediate layer, it would record a "saccade-related burst neuron" that responds optimally (i.e., has the most spikes in its burst) immediately prior to 10° rightward saccades (Fig. 12C), exactly the saccade needed to foveate visual stimuli appearing in the superficial (layer) neuron's visual response field (RF). Moreover, electrical stimulation there would yield a 10° rightward saccade as well.

3. Transformation from Spatial Code to Temporal Code

Saccades are clearly "spatially" coded in the SC in that the saccade vector is determined by which part of collicular "space" has active saccade-related bursters. In contrast, the output cells of the saccade generator, the EBNs, use a "temporal" code for saccade metrics: Saccade size is coded by the spike counts in their bursts (Fig. 12D) and not by which (or where) EBNs are spiking most. Exactly how this spatial-to-temporal transformation is carried out is unclear. Moreover, the cortical eye field signals need the same spatial-to-temporal transformation, and neither the cortex nor the colliculus projects directly to the EBNs. Another class of saccade generator neurons, the long-lead burst neurons (LLBNs), seem to be an intermediate stage in this transformation. LLBNs do receive direct projections from the SC and FEF. Moreover, individual LLBNs often prefer saccades with specific oblique directions and amplitudes, like SC and FEF neurons but unlike EBNs.

D. Cortical Eye Fields and Saccades

1. Cortical Pathways for Visually Guided Saccades

In primates, the cerebral cortex is a very important part of the saccadic circuitry. Although the SC seems to be the premier structure for visually guided saccades, it is not a critical component of saccade generation because the effects of SC lesions are largely transient, whereas the saccade structures downstream are vital. Thus, lesions of the saccade generator structures in the pontine and midbrain reticular formation permanently eliminate all rapid eye movements, including visually guided saccades, whereas SC lesions do not eliminate visually guided saccades at all. Following an acute period of visual neglect, there are few lasting oculomotor deficits following SC lesions in monkeys and man, with the most consistent lasting deficit being a modest increase in latency of visually guided saccades.

Visually guided saccades survive SC lesions because the primate also has an elaborate neocortical network for visually guided saccades. The connectivity diagram of Fig. 13 summarizes these cortical pathways and helps explain most effects of experimental lesions. For example, the sparing of visually guided saccades following SC lesions is mediated by FEF projections to the brain stem saccade generator; however, the SC normally provides a shorter path via its direct retinal projections, which explains the increase in saccade latency after SC damage. FEF lesions alone also spare visually guided saccades; however, FEF lesions combined with SC lesions eliminate most visually guided saccades. Thus, the SC and FEF provide parallel pathways for visual stimuli to activate the brain stem saccade generator for the purpose of accurate, foveating saccades. It is also the case that visually guided saccades are spared following lesions of primary visual cortex (V1) even though conscious awareness of the visual world is lost. However, combined V1 and SC lesions eliminate visually guided saccades most likely because, as Fig. 13 indicates, V1 removal eliminates most visual inputs to FEF and, hence, renders FEF incapable of triggering visually guided saccades.

2. Frontal Eye Field Anatomy and Physiology

David Ferrier discovered ($\sim$1875) that electrical stimulation in the frontal lobe of macaque monkeys deviated the eyes toward the contralateral side, and it was soon confirmed that many primate species, including man, have such an FEF. These electrically elicited eye movements are indistinguishable from naturally occurring saccadic eye movements, and each site in FEF yields saccades of a characteristic direction and amplitude, with the set of all possible contralaterally directed saccades represented in each hemisphere's FEF. The macaque FEF lies primarily in the anterior bank of the arcuate sulcus; the human FEF lies in the precentral sulcus, behind the middle frontal gyrus and in front of the hand representation in the precentral gyrus (Fig. 14).

FEF is not the only cortex specialized for eye movements. There is also the parietal eye field (PEF),

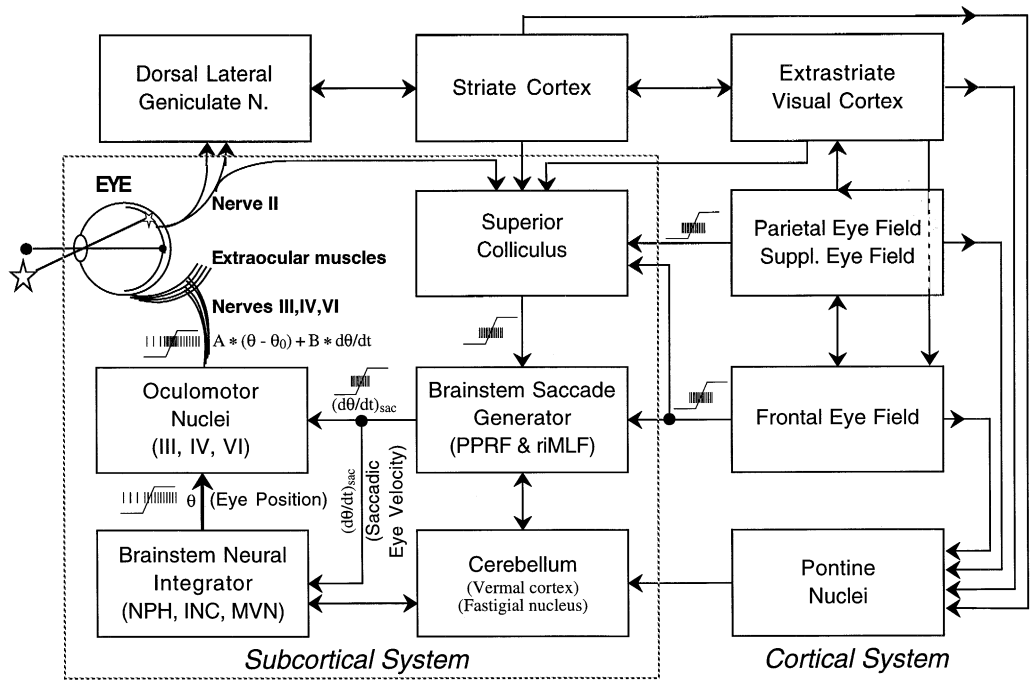

Figure 13 Pathways for visually guided saccades. Anatomical connections between cortical and subcortical structures involved in the control and generation of saccadic eye movements. The frontal eye field (FEF) receives visual information via pathways originating in the striate cortex, as does the parietal eye field (PEF) and the supplementary eye field (SEF). Notice that all these cortical areas project to the superior colliculus (SC), with FEF, PEF, and SEF all projecting primarily to its intermediate layers. In contrast, the superficial layers of SC receive direct visual projections from the retina and indirect visual projections from the striate and extrastriate cortices. The brain stem saccade generator is in the paramedian pontine reticular formation (PPRF) and in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). The brain stem neural integrator is in the medial vestibular nucleus (MVN), the adjacent nucleus prepositus hypoglossi (NPH), and the interstitial nucleus of Cajal (INC). Additional structures and pathways involved in saccades, such as the thalamus and basal ganglia, are omitted for simplicity.

located in the lateral bank of the intraparietal sulcus in the macaque, and the supplementary eye field (SEF), located in the frontal lobe near the midline. FEF, SEF, and PEF are reciprocally interconnected with each other; however, FEF seems to be the principal cortical eye field. FEF has the lowest thresholds for electrically elicited saccades, oculomotor behavior after FEF lesions is generally more impaired than after lesions of the other eye fields, and FEF is indispensable for visually guided saccades if the SC is damaged.

3. Effects of FEF Lesions

Gordon Holmes found that patients with frontal lesions had difficulty moving their eyes in response to verbal commands, even though they could follow visual objects and understood the verbal commands. In a 1938 lecture, he concluded that "the frontal centers make possible the turning of gaze in any desired direction and the exploration of space, but they also keep under control, or inhibit, reflexes that are not appropriate." In 1985, Daniel Guitton and colleagues used the antisaccade paradigm to demonstrate that "frontal lobe lesions in man cause difficulties in suppressing reflexive glances and in generating goal-directed saccades." In other words, their subjects could not launch saccades in the direction opposite the visual target (antisaccades), even though they understood that to be the task. Instead, they made inappropriate saccades toward the visual targets (prosaccades), exactly what they were instructed not to do. Similarly, subjects with FEF lesions have difficulty making memory saccades and in making predictive saccades to square-wave target motion. Thus, lesion studies show that FEF is important for "purposive" saccades, particularly when there is no visual target present to trigger the visual grasp reflex.

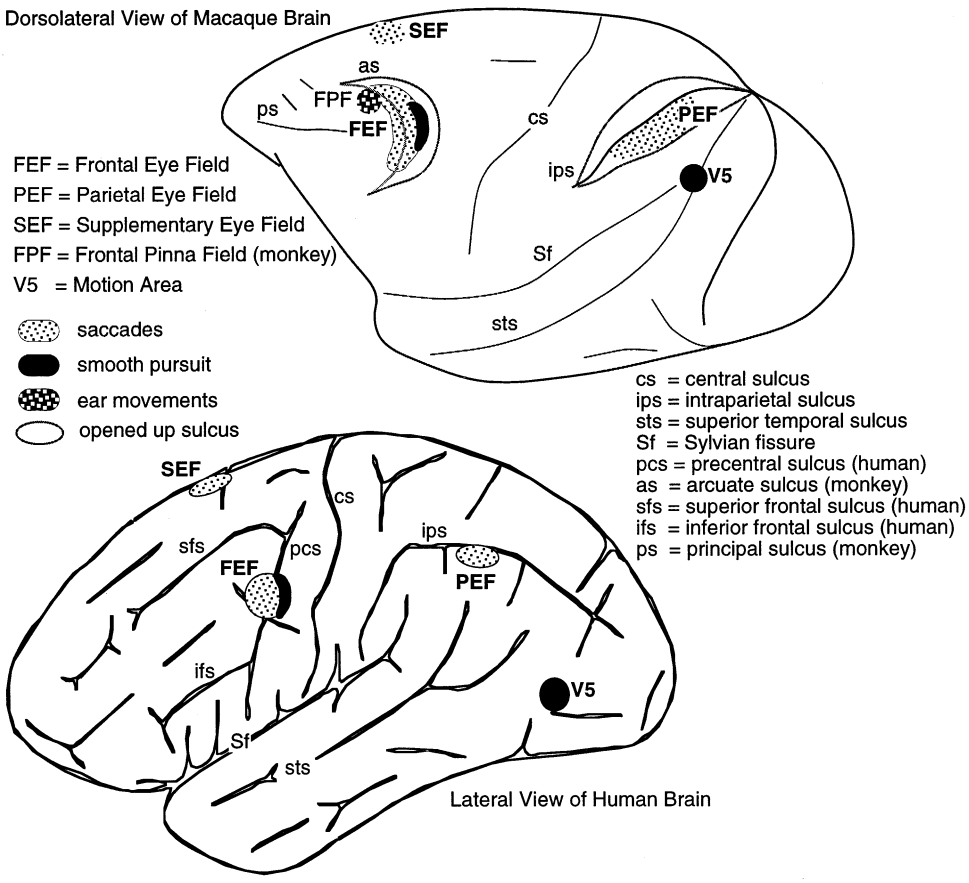

Figure 14 Cortex for eye movements in man and monkey. Cortical regions important for saccade and smooth-pursuit eye movements are highlighted on lateral views of a monkey brain (top) and human brain (bottom). In both monkey and man, FEF is in front of premotor cortex for the hand and neck and mostly lies within the sulcus marking the anterior limit of the precentral gyrus. In both species, the smooth-pursuit region of FEF is just posterior to the saccadic region of FEF. A dorsolateral view is used for the monkey brain in order to minimize distortion of the frontal lobe sulci.

4. FEF Bursts Precede All Types of Purposive Saccades

During the past three decades, single-neuron recordings in trained macaque monkeys have resulted in a detailed picture of FEF activity during all manner of voluntary oculomotor behavior. Presaccadic bursts are the signature activity of FEF and are manifest in more than 30% of FEF neurons. These bursts begin prior to saccade initiation, usually end sharply just after the saccade is completed, and are always tuned for particular saccade vectors, similar to saccade related bursters in the SC and vectorial LLBNs in the pons. Presaccadic bursts seem to constitute the FEF command to the saccade generator (both directly and through the SC), providing both an impetus to saccade and a saccade vector specification. Indeed, electrical stimulation through a recording microelectrode in FEF elicits natural-looking saccades that closely match the vector for the optimal presaccadic burst of nearby cells. Moreover, FEF-elicited saccades are very insistent and are still elicited with low currents even when subjects are intently fixating a stationary light.

a. Visually Guided Saccades FEF neurons have robust presaccadic bursts in conjunction with visually guided saccades. The average response of 51 FEF cells recorded in a single monkey during a "stable-target" type of saccade task is shown in Fig. 15A. This task was chosen to separate any phasic visual response to the appearance of the peripheral target from the presaccadic burst. This provides a baseline for assessing presaccadic bursts made without an overt target.

b. Memory Saccades Presaccadic bursts of FEF neurons in conjunction with saccades made to remembered targets are generally equivalent to bursts associated with visually guided saccades on the stable-target task. In this paradigm, as shown for a representative visuomovement neuron in Fig. 15B, a peripheral cue appears only briefly, and the saccade is made some time later and hence must be guided by a short-term memory of the cue.

c. Antisaccades FEF neurons also have robust presaccadic bursts in conjunction with antisaccades, as shown in Fig. 15C for another representative visuomovement neuron. The cell discharged preceding antisaccades into its visuomovement RF, even though the visual cue had been on the opposite side and thus not at all in the cell's RF.

d. Other Purposive Saccades FEF cells have also been demonstrated to reliably burst for some other types of purposive saccades (e.g., saccades made to the locations of sounds). It is interesting to speculate that FEF lesions might disrupt socially motivated saccades and that FEF cells would burst in conjunction with such saccades, but this has not been tested.

e. Spontaneous Saccades In contrast with most purposive saccades, FEF bursts are usually weaker in conjunction with spontaneous saccades made in the dark, presumably because such saccades are usually not purposive.

5. FEF Activities and Circuits

Just as the basic VOR reflex has a set of associated assisting circuits, a diverse set of functional activities and cortical circuits underlie FEF's programming of purposive saccades in the monkey. These serve to facilitate the generation of appropriate presaccadic bursts in diverse situations and paradigms.

a. Visual Activity More than half the neurons in FEF are visually responsive. Typically, they have large RFs centered in the contralateral hemifield and respond to the appearance of any stimulus within their RF, without much selectivity for color or form. Moreover, FEF visual responses do not require overt attention to the stimulus or the RF location or that the stimulus has functional significance to the monkey.

b. Alignment of Visual and Presaccadic Movement Fields Visuomovement FEF cells have both visual and presaccadic burst activities, and their visual RF generally corresponds with the optimal saccade vector for their burst (i.e., movement field) and also to the electrically elicited saccadic eye movement vector obtained at the cell's location. Thus, the FEF default is a foveating saccade. However, the presaccadic burst is independent of the location and/or the presence of RF stimulation as shown by the memory saccade and antisaccade tasks (Fig. 15B,C). Moreover, a minority of FEF cells are discordant with nonmatching, or even nonoverlapping, visual and movement fields.

c. Tonic Visual Activity The strongest aggregate visual response in FEF is to the initial appearance of visual targets, and many visual cells only respond to this appearance. However, other visual cells tonically respond as long as the target remains in their RF. Notice in Fig. 15A that the composite spike rate was elevated throughout the wait period (between the phasic visual response and the eventual presaccadic burst). Thus, FEF visual activity can guide saccades to old, "stable" visual targets as well as newly appearing targets.

d. Mnemonic Activity Usually tonic visual FEF activity is maintained even after the visual cue is extinguished, and this activity could provide a short-term memory of the visual cue location in the memory saccade test. Many individual FEF cells have robust mnemonic responses (Fig. 15B). However, when many FEF cells are averaged, the mnemonic signal is only a modest elevation of the overall spike rate, especially when compared to the size of the presaccadic burst. Tonic neural activity has a high metabolic cost; therefore, it is economical for overall tonic visual and tonic mnemonic activity to be minimal—just robust enough to inform spatially appropriate saccades whenever the go signal finally arrives.

e. Postsaccadic Activity Coding Executed Saccades (Efferent Copy) Postsaccadic activity in the FEF was first described by Emilio Bizzi, and $\sim$25% of FEF neurons are excited after particular saccadic eye movements. This postsaccadic activity seems to be an efferent copy of saccades actually executed because it reliably follows every saccade made into the cell's postsaccadic movement field, even spontaneous saccades made in the dark or rapid phases of nystagmus. A timely efferent copy of saccadic displacements, as coded by postsaccadic activity in FEF, is critical for several of the following circuits. Interestingly, many FEF cells with presaccadic (visual, movement, or

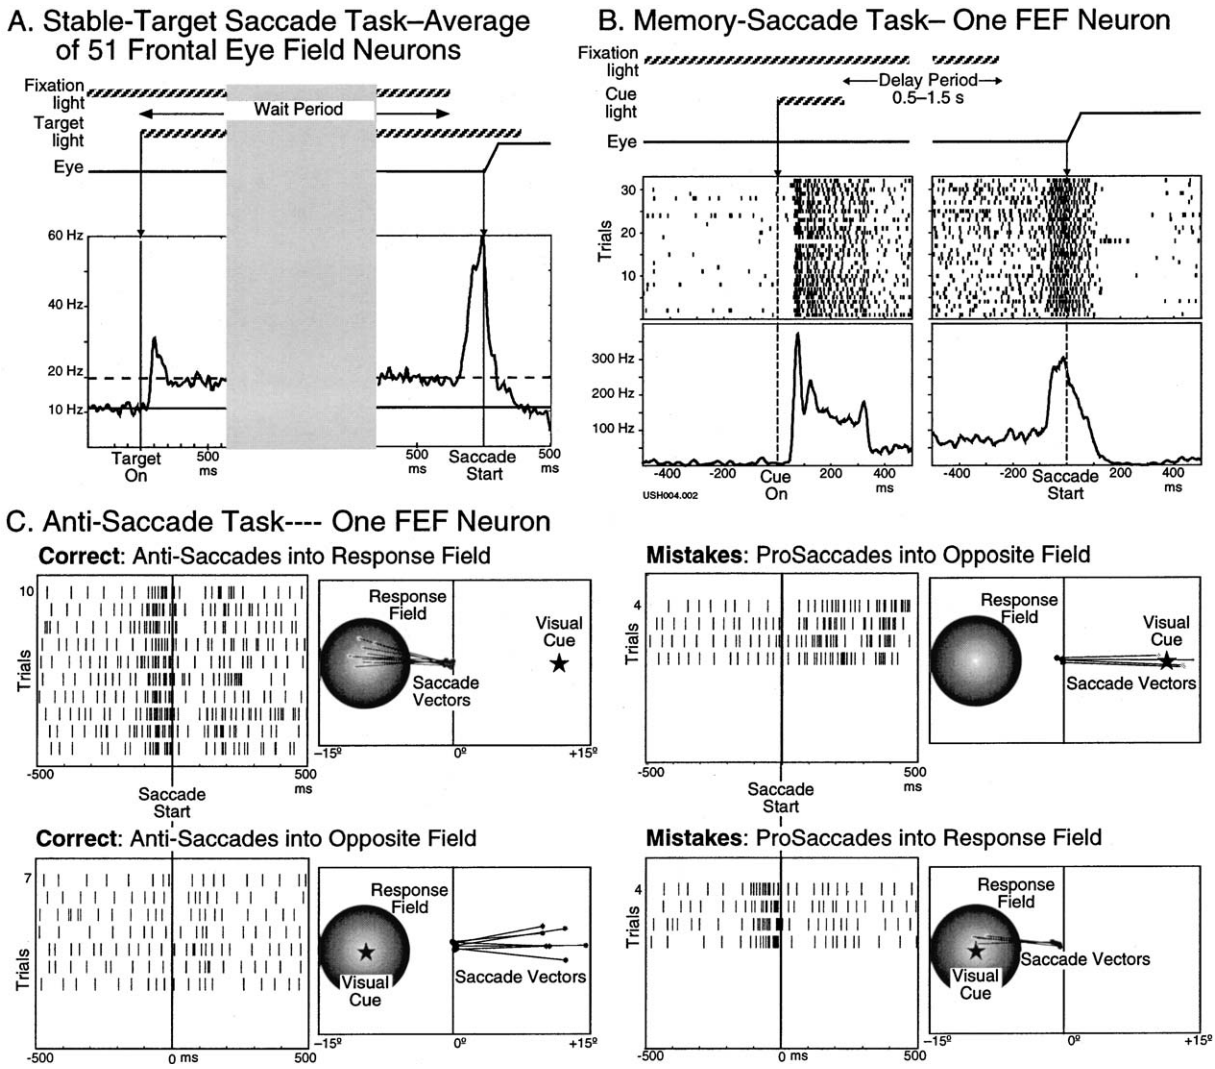

Figure 15 Frontal eye field activity for purposive saccades. (A) Aggregate activity of 51 FEF neurons recorded from one monkey during the stable-target type of visually guided saccade task. (Top) Task events: Shortly after the monkey fixates a central light, a peripheral target appears in the neuron's response field (RF). This target remains on for the remainder of the trial, but no saccade is permitted until the fixation light is extinguished at the end of the wait period. Thus, the target is a stable presence at the time of the saccade. (Bottom) The histogram aligned on the target appearance (left) shows the aggregate visual response. The histogram aligned on the saccade start (right) shows the large aggregate burst that starts just prior to the saccade. Thus, FEF activity manifests both visual (phasic and tonic) and movement activities (H. R. Friedman and C. J. Bruce, unpublished data). (B) Activity of a visuomovement FEF neuron from a second monkey tested on memory–saccade task. (Top) Task events: Shortly after the monkey fixates a central light, a peripheral cue briefly appears. Then, after a delay period, the fixation light is extinguished and the monkey must saccade to the location where the peripheral cue had been shown earlier. Thus, unlike in A, there is no visual target present at the time of the saccade. (Bottom) Rasters (by trial) and histograms of spike activity aligned on cue onset (left) show the burst of activity elicited by the visual stimulus and aligned on saccade onset (right) show the large burst of activity preceding the saccades. Note that the visual response has three components: a phasic high-rate burst to the initial appearance of the visual stimulus (with a latency of $\sim$50 msec), a robust tonic visual discharge while the cue remained on, and then, starting $\sim$50 msec after the cue was extinguished, a medium-level tonic mnemonic response that was maintained above the cell's baseline level of activity throughout the delay interval (M. S. Kraus, H. R. Friedman, and C. J. Bruce, unpublished data). (C) Activity of a visuomovement FEF neuron, from a third monkey, tested on an antisaccade task (memory version). As in B, the monkey must remember the position of a brief visual cue across a delay interval. However, unlike in B, the correct response (once the fixation light goes off) is a saccade to the location opposite to where the cue was shown. The visual RF of this cell was on the left when tested with conventional "prosaccade" tasks and its presaccadic bursts were maximal for leftward saccades. (Top, left) The cell discharged preceding leftward antisaccades, even though the visual cue had been in the right side and thus not in its RF. (Bottom, left) The neuron was silent before rightward antisaccades even though the visual cue had been in its RF. Interestingly, its bursts were completely predictive of erroneous prosaccades mistakenly made on some trials (right). (H. R. Friedman and C. J. Bruce, unpublished data).

both) activity also have postsaccadic activity for saccades directed opposite their presaccadic RF. This provides a mechanism for readily returning to the previous fixation (i.e., glances).

f. Suppression of Presaccadic Activities by Saccade Execution A striking aspect of FEF presaccadic activity of all types (e.g., anticipatory, visual, mnemonic, and movement) is that it quickly ceases upon the execution of a saccade into the RF. Notice in Fig. 15 that saccade execution actively suppresses both tonic visual (Fig. 15A) and mnemonic (Fig. 15B) activity as well as the presaccadic bursts.

This suppression could come from the postsaccadic coding of prior saccades (efferent copy) previously described. Such suppression is very important because visual or mnemonic activity coding a peripheral cue location becomes invalid once the monkey foveates the peripheral location. Without prompt suppression, persistent activity could lead to multiple triggering of the same saccade, much like the "staircase" of saccades evoked by continued electrical stimulation in FEF.

g. Fixation Status Signals (Tonic Foveation and Eye Position Activity) Some FEF cells provide tonic signals concerning the current fixation target rather than pertaining to possible saccade targets. One class is excited by fixation (foveal) stimulation; their activity could play a role in suppressing other saccade cells in FEF and elsewhere in the interest of maintaining fixation. Another class has the inverse activity, being suppressed by foveal stimulation and active thereafter, and thus signaling the extinction of the current fixation light. A small minority of cells tonically respond as a linear function of absolute eye position (e.g., elevation); they could be receiving an efferent copy from the common neural integrator, and some have foveal responses that are modulated by the current eye position.

h. Other Saccade-Related Activities and Responses Many FEF cells show anticipatory activity for predictable saccadic situations. This activity could decrease saccade latency by biasing FEF in favor of the predicted saccade dimensions. Sometimes, anticipatory activity is purely guessing. For example, in the "gap" paradigm, wherein the signal to saccade (e.g., fixation light off) precedes the peripheral target appearance by 100–200 msec, FEF neurons with presaccadic motor bursts will first discharge at an intermediate level in response to the fixation light extinction and then drastically accelerate or suppress their rate after the peripheral target comes in the neuron's RF or opposite it. Saccade latencies in the gap paradigm are typically shorter than in conventional saccade tasks and are termed express saccades.

Cells in and near the medial FEF have responses to sound. Their auditory RFs are partially remapped from a craniocentric to a retinocentric framework, which should facilitate FEF bursts known to precede aurally guided saccades. Moreover, there is a pinna movement region adjacent to the medial FEF of the monkey (Fig. 14).

Finally, saccades to moving targets are usually directed at a predicted target location, based on both retinal position and velocity. Visual and movement RFs of FEF neurons evidence this predictive process, indicating that target motion information is being utilized.

E. Neural Circuitry of Smooth Pursuit

1. Tracking with Pursuit and Saccades

Smooth-pursuit eye movements support scrutiny of objects moving in space by matching eye velocity to target velocity in order to both reduce retinal blur of the moving object and facilitate its continued foveation. Smooth pursuit occurs when the FS selects a moving target or when a previously selected stationary target starts to move. However, target selection for pursuit also activates the saccadic system; hence, moving targets are usually tracked with a combination of smooth pursuit and saccades, with these two eye movement systems operating independently but synergistically to track the same chosen target (Fig. 2). Their synergy reflects control by separate parameters of the target's trajectory. The principal impetus for smooth pursuit is target velocity (i.e., retinal slip), and the pursuit system continuously endeavors to eliminate retinal slip by matching eye velocity to target velocity. In contrast, the principal concern of the saccade system is target position (i.e., retinal error), and saccades are intermittently generated to eliminate retinal error by foveating the target.

However, this division of labor is not absolute. Smooth pursuit is modestly affected by positional errors: Ongoing pursuit accelerates in response to small retinal positional errors, and it is even possible to initiate smooth pursuit with an afterimage placed near the fovea (although eccentric afterimages are usually tracked with a succession of saccades). The pursuit system also responds to the rate of change in retinal slip

(i.e., acceleration). Thus, pursuit is a function of the zero-, first-, and second-order derivatives of the target's retinal image.

Conversely, the saccadic system attends to target velocity as well as location. Saccadic latency is shorter for targets moving centrifugally (away from the fixation point) and longer for targets moving centripetally. Moreover, saccades are usually directed to a predicted target location based on its position and velocity as acquired 100–200 msec before the saccadic movement starts.

Pursuit velocity ranges up to $\sim 100^{\circ}$/sec; however, pursuit gain (defined, like VO and OK gain, as eye velocity/target velocity) is generally poor for target velocities above 25°/sec. When the pursuit gain is low, the eye will persistently fall behind the target and frequent, large "catch-up" saccades will be made; however, if gain is high (~ 1.0), then only a few, small saccades may be needed.

Interestingly, low smooth-pursuit gain is the principal symptom of the eye tracking dysfunction (ETD) of schizophrenia. Subsequent research has shown a cluster of oculomotor impairments that covary across the schizophrenic patient population and are often also present in first-degree relatives of schizophrenic patients. On the basis of the ETD and other cognitive aspects of schizophrenia, it has been hypothesized that schizophrenia reflects diminished frontal lobe function in general, and that the ETD specifically reflects impaired function in both the saccadic and the smooth-pursuit regions of the FEF.

2. Smooth Pursuit versus Optokinetic Following

Smooth pursuit can be confused with the OKR because both provide smooth, nonsaccadic ocular following in response to visual motion. However, the OKR is an automatic response to motion of large parts of the visual world (e.g., watching a train go by), whereas pursuit is the voluntary tracking of a discrete moving object (e.g., a bird flying across the sky).

In typical situations, smooth pursuit is in direct opposition to the OKR (and often to the VOR as well), and we choose to maintain foveation of the pursued target stimulus and reduce its retinal slip at the expense of increasing retinal blur of the rest of the visual field. For example, pursuit will need to override the OKR whenever tracking a target moving across a patterned background because as soon as pursuit starts the background necessarily becomes a stimulus for OKR in the opposite direction. Similarly, during combined head–eye tracking of a moving stimulus, the combined vestibulooptokinetic reflex must be overcome.

3. The Neural Pathway for Pursuit

The major pathways of the smooth-pursuit system are shown in Fig. 16. On the sensory and decision-making side, smooth pursuit is very much a neocortical behavior. It begins with the high-quality visual map in V1 that sends visual motion information into area V5 and other immediate extrastriate areas. Motion information is relayed to several other areas in the parietal and temporal lobe and to the smooth-pursuit zone of FEF. These cortical areas relay their visual motion signals and commands to oculomotor parts of the cerebellum, principally by way of their projections to the dorsolateral and medial pontine nuclei.

On the efferent side of the pursuit pathway, smooth movements are created by engaging the brain stem substrate for the slow-phase, compensatory part of VOR, much as visually guided saccades are made by engaging the mechanism that generates the quick phases of vestibuloocular nystagmus. Specifically, pursuit uses the VOR adaptation circuit that was shown in Fig. 8D. The key neurons are the Purkinje

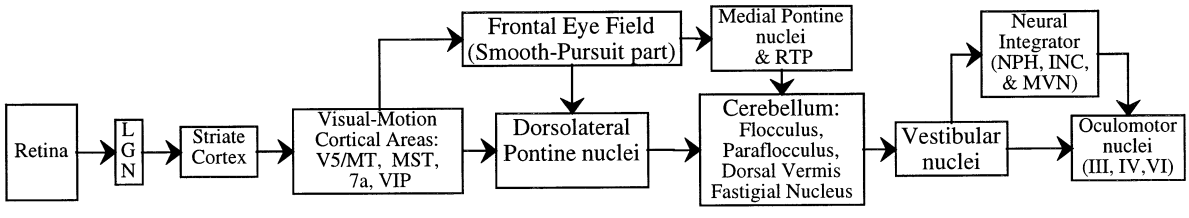

Figure 16 Pathways for smooth-pursuit eye movements. The flow-chart shows that the smooth-pursuit part of the frontal eye field receives visual motion information from extrastriate motion areas, e.g., from the middle temporal area (MT, V5) and the medial superior temporal area (MST) and from parietal regions such as 7a and the ventral intraparietal area (VIP). INC, interstitial nucleus of Cajal; LGN, lateral geniculate nucleus; MVN, medial vestibular nucleus; NPH, nucleus prepositus hypoglossi; RTP, nucleus reticularis tegmenti pontis.

cells in the floccular–nodular lobe and the paraflocculus regions of the cerebellar cortex. They carry a smooth-pursuit signal and effect pursuit by inhibiting vestibular nucleus neurons that in turn project to extraocular motoneurons. This pathway is both indirect, via the fastigial cerebellar deep nucleus, and direct from the Purkinje cells. In the context of the VOR, these projections from the cerebellum to the vestibular nuclei serve to adapt the VOR gain and offset. The smooth-pursuit system uses this pathway to temporarily create a vestibular imbalance in favor of desired pursuit direction, and thereby create a smooth eye movement. Cerebellar outputs may also aid pursuit by suppressing any opposing OKR evoked by the slip of the visual background once pursuit is underway as well as by suppressing any opposing VOR during combined head and eye pursuit.

4. Effects of Lesions in the Smooth-Pursuit Pathway

Neocortex is critical for smooth pursuit. Hemidecortication or large unilateral cortical lesions can cause a profound and permanent deficit of ipsilaterally directed pursuit in man and monkeys. Unilateral loss of V1 produces a permanent pandirectional loss of pursuit in response to motion in the contralateral hemifield. Discrete lesions in motion area V5 produce temporary pursuit deficits in restricted parts of the visual field (pursuit scotomas).

FEF lesions cause permanent ipsilateral pursuit deficits because each hemisphere's FEF is principally concerned with ipsilateral pursuit. Similar ipsiversive deficits, with profound reductions in both acceleration during pursuit initiation and steady-state pursuit velocity, follow lesions or temporary inactivation in the dorsolateral pontine nuclei. Finally, cerebellar lesions can cause severe and permanent pursuit deficits; in fact, smooth pursuit is the only eye movement type that is lost following cerebellectomy; other types of eye movements may be profoundly disturbed but are nevertheless still realized.

5. Sensory-to-Motor Transformation for Pursuit

Neurons throughout the pursuit pathway have been studied in the rhesus monkey. Similar to the saccadic system, neuronal activity in structures closer to the retina have obligatory responses to visual stimuli, but closer to the oculomotor nuclei the neural activity is more aligned to motor behavior. For example, neurons in V5 are highly selective for the direction of stimulus motion in their RFs. At the other end, the smooth eye velocity signal is elaborated in several pontocerebellar circuits, including the dorsolateral and the medial pontine nucleus and the nucleus reticularis tegmenti pontis, together with cerebellar pursuit areas (the flocculus, paraflocculus, and dorsal vermis). Many neurons in these structures respond as a function of pursuit velocity.

The critical step in this sensorimotor transformation underlying pursuit is provided by the neurons that respond to target motion, but only if it is selected for foveation/pursuit. The smooth-pursuit zone of FEF (Fig. 14) is a candidate site. It lies downstream from V5 and other areas that provide most of the visual motion information for smooth pursuit, but upstream from pontocerebellar and brain stem circuits that effect pursuit movements. Microstimulation in the pursuit FEF elicits smooth eye movements (usually ipsiversive), and many FEF pursuit cells discharge to the motion of a pursuit target over most of the visual field but discharge little to moving targets that are not pursued. An FEF pursuit cell is shown in Fig. 17; notice that it also discharged during predictive pursuit at the end of sinusoidal tracking and that reversible inactivation at this FEF site caused a immediate deficit in ipsilateral smooth pursuit.

F. Neural Circuitry of Fixation

When an interesting or important stimulus is foveated, it may be important to maintain its fixation and to temporarily suppress the generation of saccades to other stimuli. For example, during reading (Fig. 2), the average fixation time depends on the overall difficulty of the material, and individual fixation durations depend on the complexity of each word fixated. Thus, controlling fixation duration is an important component of eye movements.

The rostral end of the SC (adjacent to the representation of the smallest saccades) is specialized for fixation. Cells there project to the omnipauser region of the pons, and electrical stimulation at the rostral pole of the SC prevents saccades. Because most visually responsive neocortex projects strongly to the SC, this rostral fixation zone provides a pathway for cortical areas that process foveated stimuli to temporarily suppress saccades. Stimulation at some FEF sites can inhibit saccades as well, and foveally responsive FEF cells resemble cells at the SC rostral pole.

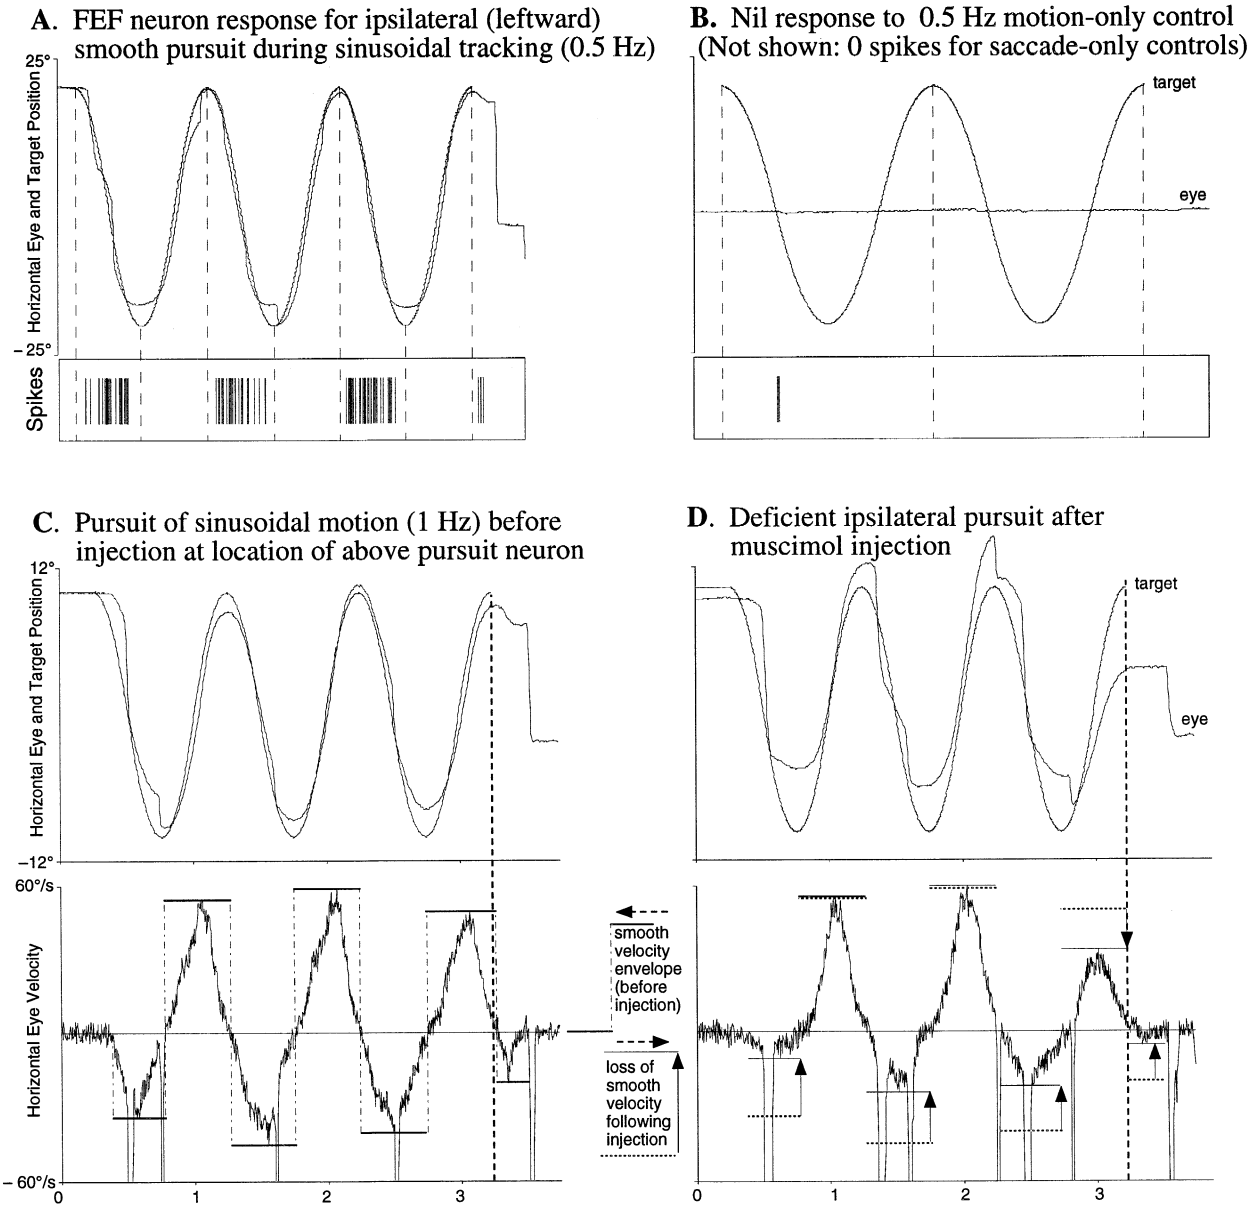

Figure 17 Activity of FEF pursuit neuron and pursuit deficits after FEF deactivation. (A) The pursuit neuron, recorded in the left hemisphere FEF, was active in conjunction with leftward (negative moving on the traces) smooth pursuit and responded throughout the leftward phase in all three cycles of sinusoidal motion (0.5 Hz, $\pm 20^{\circ}$A). Notice that it also discharged prior to leftward predictive pursuit that occurred at the end of sinusoidal tracking (see also Fig. 4). (B) The neuron responded very little to visual motion that was not pursued and was silent, except for three spikes on the initial cycle, when the monkey fixated a stationary point while viewing the same sinusoidally moving stimulus used in A. (C) Sinusoidal (1.0 Hz, $\pm 10^{\circ}$A) smooth pursuit of this monkey immediately before the injection. (D) Deficient smooth pursuit immediately following a small muscimol injection at the site of the pursuit neuron shown in A and B. Leftward smooth eye velocity was much less on every cycle, especially the first, and there was no longer predictive pursuit after the target was extinguished (adapted with permission from D. Shi, H. Friedman, and C. Bruce, *J. Neurophysiol.* **80,** 458–464, 1998).

G. Neural Circuitry of the Vergence-Accommodation System

The primate has frontally placed eyes with highly overlapping visual fields (i.e., a large binocular field). The two retinal images are combined (fused) in the cyclopean retina (effectively located in V1). Fusion, however, requires that both eyes look in approximately the same direction so that visual objects fall on corresponding points of the two retinae. Consequently, most eye movements are conjugate because both eyes move in synchrony during nystagmus, saccades, and pursuit in order to maintain fused vision and obtain stereopsis, the extraction of relative depth from slight differences in the images of the two eyes. As discussed earlier, conjugate movement is accomplished by equal innervation of yoked muscle pairs in the two eyes (Hering's law).

However, when the distance of the fixation object varies, adjustments are needed that involve converging or diverging the relative horizontal directions of the two eyes. Cells in a region immediately lateral to the oculomotor nucleus are active during such disjunctive eye movements. These cells bilaterally innervate the nearby OMNs of the medial rectus and thus add a convergence command to the conjugate eye movement signal that medial rectus OMNs receive from interneurons in the abducens nucleus.

The two principal cues for vergence movements are retinal disparity, which occurs when a fixation target is not on the fovea of both eyes, and retinal blur, which occurs when a target is not in focus (as well as when it has retinal slip). Because vergence is tightly linked to accommodation, either cue evokes both responses. The "near triad" is a popular term for the response to viewing a near object: (i) The lens is compressed to bring the object into focus (accommodation), (ii) the eyes converge to image the object on the fovea of both eyes, and (iii) the pupils constrict to increase the depth of field. As noted earlier, cranial nerve III also has the efferents (from the Edinger–Westphal nucleus) that effect the lens accommodation and pupillary reflex components of the triad.

Although the complete circuitry of vergence is not known, it is clear that cortical visual areas, especially V1, are critical for processing disparity and blur. Paul Gamlin finds that a small region of frontal cortex, located just anterior to the saccadic FEF in the monkey, has cells that respond specifically during vergence movements and electrical stimulation there can elicit vergence eye movements. Moreover, cells throughout FEF can be sensitive to the depth location (or binocular disparity) of visual targets as well as to their azimuth and elevation. This depth information may be critical in allowing changes in vergence to be made simultaneously with saccades to targets differing in depth as well as in visual direction. Vergence movements are generally very slow and can last nearly a second. This slowness reflects in part the difficult task of processing vergence cues; however, saccadic vergence is accomplished much faster than pure vergence movements. Vergence changes can also accompany smooth pursuit in depth, and vergence could even be considered as part of the FS rather than as a separate, third oculomotor system or function.

Forebrain

LUIS PUELLES* and JOHN RUBENSTEIN†

*University of Murcia, Spain and †University of California, San Francisco

GLOSSARY

prosencephalon Refers to the anteriormost major subdivision of the neural tube that gives rise to the forebrain. Consists of several major parts. The caudal part is the caudal diencephalon. The rostral part is the secondary prosencephalon; this region consists of the telencephalic and optic vesicles, and the rostral diencephalon.

prosomere Prosencephalic (forebrain) segment or neuromere. A transverse subdivision of the forebrain containing all the primary longitudinal subdivisions.

rostral diencephalon Unevaginated part of secondary prosencephalon, divided into hypothalamus proper (basal plate and floor plate) and prethalamus (alar plate).

telencephalon Large evaginated dorsal subdivision of the forebrain that contains primarily the cerebral cortex (pallium) and basal ganglia (subpallium).

The forebrain is the rostralmost portion of the central nervous system (CNS). It is an extremely complex assembly of structurally and functionally diverse structures that regulate most aspects of cognition, homeostasis, and behavior. In this brief overview, we describe the major components of the forebrain using a developmental viewpoint. Although the adult forebrain seems hopelessly complicated to most neuroanatomy students, a rudimentary understanding of its development provides a framework that simplifies its comprehension. Thus, we describe forebrain organization from a neuroembryological perspective. Most of the information that we will describe is valid for tetrapods (mammals, birds, reptiles, and amphibians). Available evidence supports the idea that the fundamental organization of the human forebrain differs little from that of less complex vertebrates. Most apparent differences are due to more extensive growth and larger morphogenetic deformation in the human brain of structures already found in other vertebrate brains. These differential aspects will be noted whenever this is appropriate.

I. EARLY DEVELOPMENT

The forebrain is derived from the anteriormost transverse domain of the neural plate that is generated during gastrulation (Fig. 1). Tissues adjacent to and within the neural plate produce molecules that regulate regional specification and morphogenesis of the CNS. Prospective subdivisions of the brain are specified through several mechanisms. Anteroposterior patterning generates transverse subdivisions: forebrain, midbrain, hindbrain, and spinal cord (Fig. 1A). Dorsoventral patterning generates longitudinally aligned domains, called floor plate, basal plate, alar plate, and roof plate (Fig. 1B). Within the forebrain, neuromeric theories postulate that there are further transverse subdivisions, which will be discussed later. Finally, regionally distinct molecular properties of the neuroepithelium and local signals from adjacent

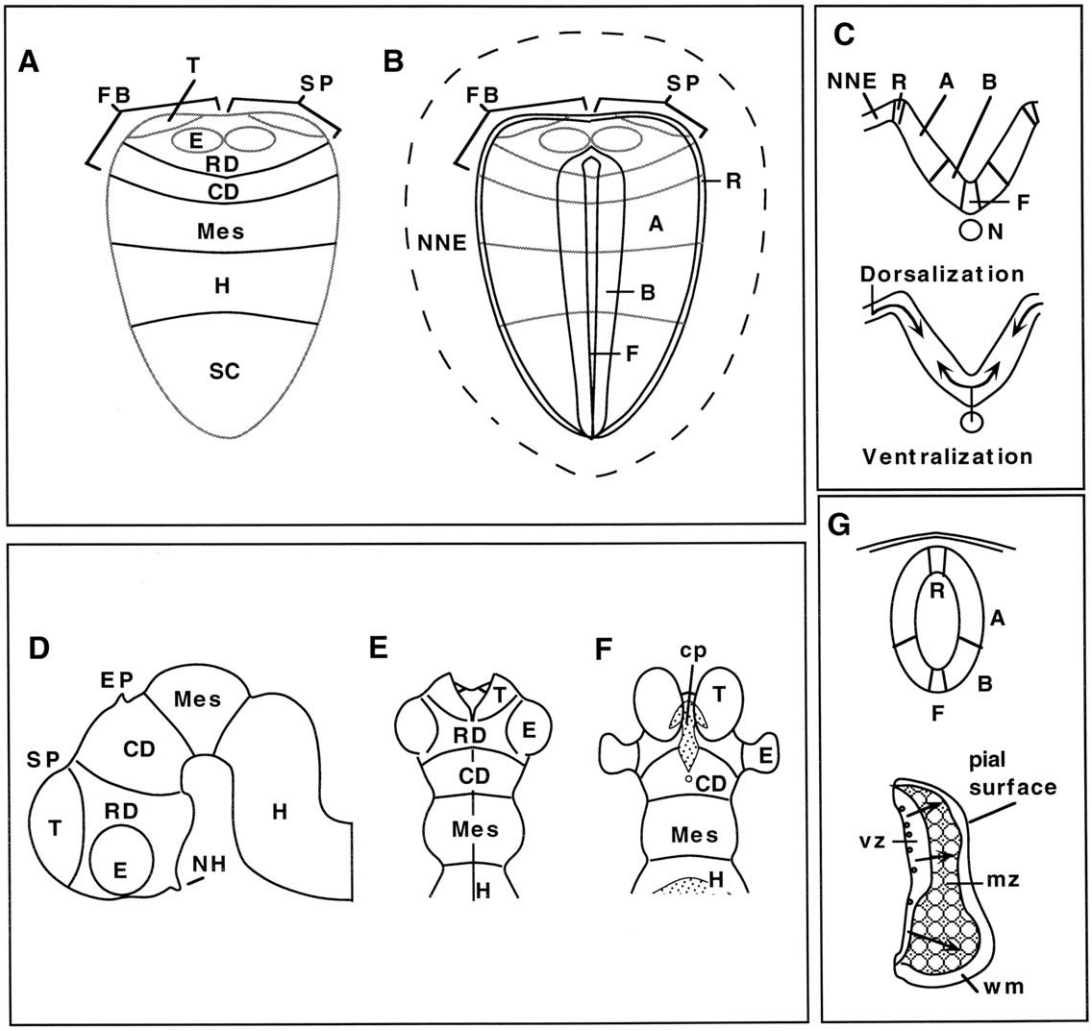

Figure 1 Early development of the forebrain. (A) Schema of transverse domains specified at the neural plate stage; the transverse boundaries are represented by black lines. Note that telencephalic and eye vesicles are separate outgrowths. (B) Schema of longitudinal domains at the same stage (boundaries in black; transverse and other limits in gray). (C) Schema of cross section through the neural plate showing the longitudinal domains and the relative position of the main tissues that regulate dorsoventral patterning, the notochord and the nonneural ectoderm. These exert ventralization and dorsalization effects, respectively, which are symbolized below. (D) Side view of the closed neural tube. The forebrain appears rostral to the mesencephalon and is composed of the caudal diencephalon, rostral diencephalon, eye vesicle, and telencephalon; the latter is shown as it starts to evaginate. (E) Dorsal view of the same stage as in D showing unfinished anterior closure of the neural tube and the bulging eye vesicles. (F). At a later stage, a dorsal view illustrates the stalks of the eye vesicles, the bilateral telencephalic vesicles, and the choroidal plexus primordium at the forebrain roof (cp; stippled area). (G) Schema of the closed neural tube in cross section and its longitudinal domains. Development of its wall is schematized below; a proliferating ventricular zone, a differentiating mantle zone, and a subpial layer of white matter (growing axons) can be distinguished.

tissues regulate the outgrowth of vesicles from the forebrain, such as the bilateral eye and telencephalic vesicles (secondarily also the olfactory bulbs), the neurohypophysis, and the epiphysis (pineal gland) (Figs. 1D–1F).

Dorsoventral patterning is regulated by nonneural tissues flanking the neural plate [the dorsalizing nonneural ectoderm (NNE) in Figs. 1B and C] and below the neural plate midline (the ventralizing notochord and prechordal mesendoderm) (N; Fig. 1C). Anteroposterior patterning is less fully understood, but it involves tissues underlying the neural plate, tissues at the anterior and posterior limits of the neural plate, as well as a later-appearing patterning

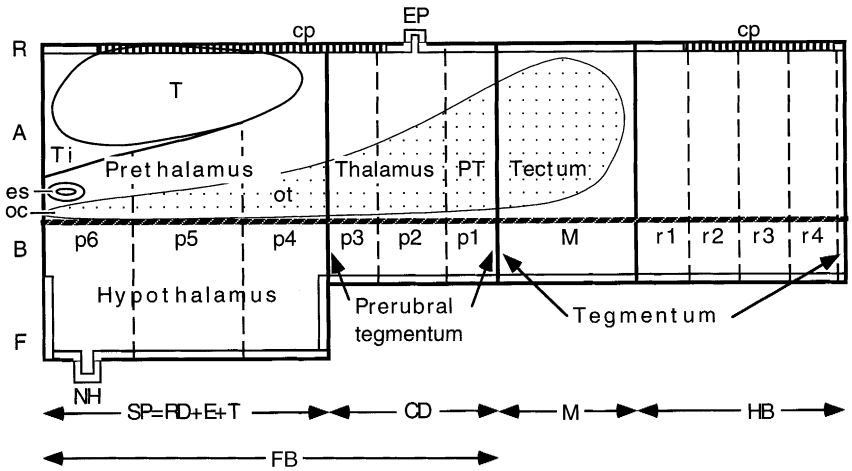

Figure 2 Topological schema of transverse and longitudinal subdivisions of the vertebrate forebrain (FB), midbrain (MB), and rostral hindbrain (HB). The longitudinal zones are indicated at the far left (R, roof plate; A, alar plate; B, basal plate; F, floor plate); the alar/basal boundary is represented by the thick black line with oblique white stripes. The transverse boundaries are vertical lines; black lines separate the main brain vesicles (identified underneath) and dashed lines separate the neuromeric subdivisions (prosomeres p1–p6), which are identified under the alar/basal boundary line. Various other specific names for different alar or basal territories are indicated. The choroidal plexi (cp) are marked by vertical stripes at the top. Note the position of the evaginated telencephalic vesicle (T) and the unevaginated telencephalon impar (Ti). The optic tract (ot) is schematized as a longitudinal domain extending from the optic chiasm (oc) to the optic tectum. See Table I for other abbreviations.

center at the midbrain–hindbrain junction. These stepwise processes generate a two-dimensionally regionalized specification map of prospective forebrain subdivisions (Fig. 2) Table I.

During the patterning stage, morphogenetic processes start to generate the shape of the forebrain. Neurulation folds the neural plate into the neural tube (Figs. 1C and G) and rapid cell divisions expand its surface area. The position-specific production of neurons and glia increases the thickness of the neural tube along the ventriculopial axis, which is the third dimension of the brain (Fig. 1G, arrows). Note that the internal, fluid-filled cavity of the neural tube and adult brain is called ventricular space, which is lined by the pseudostratified neuroepithelium; the outside of the neural tube contacts through a basement membrane the surrounding mesenchyme, which matures into a thin meningeal sheet called the "pia." Thus, the term "pial" means superficial, whereas "ventricular" means internal; most cell divisions occur in the "ventricular zone" (vz) of the neuroepithelium (Fig. 1G). Cell-type specification and differentiation processes generate postmitotic cells that migrate away from their site of origin in the vz toward the pial surface, under which they form the mantle zone (mz; Fig. 1G). Here, nuclei and laminar structures are gradually assembled. Many neurons and some glia cells only undergo radial migrations to the mz (Fig. 1G, arrows), thus maintaining a fixed position relative to their site of origin. This is probably essential for the generation of topographic connectivity maps between different brain regions. On the other hand, some neurons and oligodendrocytes undergo tangential migrations away from their primary sites of entrance in the mantle layer, frequently into specific target loci. Tangential migrations enable certain cell types that can only be formed in specific neural tube areas to become functionally integrated in local circuitry elsewhere.

II. PRINCIPAL COMPONENTS

In this section, we describe the major components of the forebrain in the context of their developmental origins and following the framework of the prosomeric model of Puelles and Rubenstein (Fig. 2). Although this model is still changing as new data accrue (in fact, we introduce some changes here), we suggest that it provides a useful conceptual format to integrate developmental mechanisms with the complex morphology of the forebrain. It is important to note that other morphological models of the forebrain have been postulated, including neuromeric and nonneuromeric

Table I
Anatomical Abbreviations

Abbreviation	Definition
A	Alar plate
Ac	Accoustic cortex
ac	Anterior commissure
Ac1-2	Primary and secondary accoustic cortical areas
ACC	Accumbens nucleus
AEP	Anterior entopeduncular area
AH	Anterior hypothalamus
AM	Amygdala (subpallial part)
B	Basal plate
BL	Basolateral amygdala
BM	Basomedial amygdala
BST	Bed nucleus of the stria terminalis
CAU	Caudate nucleus
cc	Corpus callosum
CD	Caudal diencephalon
Ce	Central amygdala
CLdl	Claustrum, dorsolateral part
CLvm	Claustrum, ventromedial part
cp	Choroid plexus tissue
DP	Dorsal pallium
DT	Dorsal thalamus
E	Eye vesicle
EMT	Eminentia thalami
EP	Epiphysis
es	Eye stalk
ET	Epithalamus
F	Floorplate
FB	Forebrain
FP	Frontal pole of telencephalon
GP	Globus pallidus
H	Hindbrain
hc	Habenular commissure
hic	Hippocampal commissure
iml	Internal medullary lamina
INS	Insular cortex
L	Lateral amygdala
LOT	Lateral olfactory tract
Lp	Lateral pallium
Mes	Midbrain
M	Motor cortex
M1–M3	Primary and secondary motor cortical areas
MAM	Mammillary region
Me	Medial amygdala
MP	Medial pallium
mz	Mantle zone
N	Notochord
NH	Neurohypophysis
NNE	Non-neural ectoderm
OB	Olfactory bulb
oc	Optic chiasm
OP	Occipital pole of telencephalon
OT	Olfactory tuberculum
ot	Optic tract
p1–p6	Prosomeres 1–6
p1c	Floor commissure of p1
p3c	Floor commissure of p3
Pal	Pallium
pc	Posterior commissure
PEP	Posterior entopeduncular nucleus
PIR	Piriform (olfactory) cortex
POA	Anterior (telencephalic) preoptic area
poc	Postoptic (supraoptic) commissure
POP	Posterior (prethalamic) preoptic area
PT	Pretectum
PUT	Putamen nucleus
PV–SO	Paraventricular-supraoptic nucleus
R	Roof plate
r1–r4	Rhombomeres 1–4
RD	Rostral diencephalon
RM	Retromammillary area
rt	Retroflex tract
S	Somatosensory cortex
S1–S3	Primary and secondary somatosensory cortical areas
SC	Spinal cord
SCH	Suprachiasmatic nucleus
Se	Septum
SIA	Subincertal area
sm	Stria medullaris
SP	Secondary prosencephalon
Sp	Subpallium
ST	Striatum
T	Telencephalon
Ti	Telencephalon impar
TM	Tuberomammillary region
TP	Temporal pole of telencephalon

(continues)

(continues)

Table I *(continued)*

Abbreviation	Definition
TU	Tuberal region
V	Visual cortex
V1–V4	Primary and secondary visual cortical areas
VP	Ventral pallium
VPA	Ventral pallidum
VST	Ventral striatum
VT	Ventral thalamus
vz	Ventricular zone
wm	White matter
zl	Zona limitans

ones of Herrick and Kuhlenbeck. The primary prosencephalon, or early forebrain vesicle, soon divides into two principal transverse subdivisions: caudally, the caudal diencephalon, and rostrally, the secondary prosencephalon (sum of rostral diencephalon and telencephalon; Figs. 1D–1F, 2). In our description, the conventional hypothalamus is constituted exclusively by parts of the rostral diencephalon and is independent from the caudal diencephalon.

The caudal diencephalon abuts caudally the midbrain; it has three transverse subdivisions, postulated to be prosencephalic neuromeres (prosomeres p1–p3) (Figs. 2 and 3). These contain the pretectal (p1), dorsal thalamic/epithalamic (p2), and ventral thalamic (p3) regions. Each prosomere has alar (dorsal) and basal (ventral) components; the aforementioned three large regions are the respective alar components of p1–p3 (Fig. 3). The basal components jointly form the prerubral tegmentum.

The transverse organization of the secondary prosencephalon (SP) is more hypothetical, but it has been postulated to contain three prosomeres as well (p4–p6), which are readily distinguishable in the rostral diencephalon, though it is not clear how they relate to the overlying telencephalon (Fig. 2). The telencephalon is a dorsal evaginated region within the SP (T in Figs. 1D–1F), and lies strictly dorsal to the rostral diencephalon. The latter also appears divided into alar and basal plates, like its caudal counterpart. The alar plate extends from the telencephalon down to approximately the ventral limit of the optic tract. Thus, the optic stalk and the optic tract lie in a longitudinal alar plate domain that traverses the rostral diencephalon, thalamus, pretectum, and midbrain (Fig. 2). The alar rostral diencephalon consists of three prosomeric subregions labeled caudal (p4), intermediate (p5), and rostral (p6) prethalamic areas (Fig. 4). The optic vesicles evaginate out of the rostral area at early neurulation stages (Figs. 1A–1F). Part of the prethalamus, particularly the rostral part, has been attributed to the hypothalamus, but it is convenient to restrict the term ''hypothalamus'' to the basal part of the rostral diencephalon. This includes mammillary/subthalamic (p4), tuberomammillary (p5), and tuberal hypophyseal regions (p6) (Fig. 4). In this way, the rostral diencephalon divides into optic vesicles and prethalamus (alar plate) and hypothalamus (basal and floor plates).

III. THE CAUDAL DIENCEPHALON

The pretectum (alar p1) is the caudalmost forebrain region. It is characterized by the posterior commissure, whose fibers cross the pretectal dorsal midline and then course transversally through the alar plate, just in front of the diencephalomesencephalic limit, before spreading longitudinally in the basal plate (pc in Fig. 3). The function of the posterior commissure is unclear. This region contains various pretectal nuclei involved in visual processing, including the centers for the pupillary and optokinetic eye reflexes. The subcommissural organ is a dorsal midline specialization that secretes glycoprotein (Reissner's fiber) into the ventricular fluid. The basal plate has dopamine-containing neurons that form part of the substantia nigra in addition to diverse reticular cell populations involved in motor circuits, like the parvocellular nucleus ruber (origin of the rubroolivary tract) and the interstitial nucleus of Cajal. The latter is a rostral source of descending preoculomotor axons in the medial longitudinal fasciculus, a tract that coordinates eye movements.

Anterior of the pretectum lies the dorsal thalamus and epithalamus complex (alar p2). Its dorsal midline includes the epiphysis (pineal gland), the habenular commissure, and choroid plexus rostrally. The epithalamus (ET or habenula) is the most dorsal nuclear complex; these neurons relate to the longitudinal stria medullaris tract (sm), which crosses the dorsal midline in the habenular commissure (hc in Fig. 3). The habenular nuclei produce the retroflex tract (habenulointerpeduncular tract). This compact transverse fascicle is a landmark that remains just anterior to the p1/p2 boundary throughout its dorsoventral extent; near the diencephalic floor it bends caudally (retroflects), continuing longitudinally across p1 and

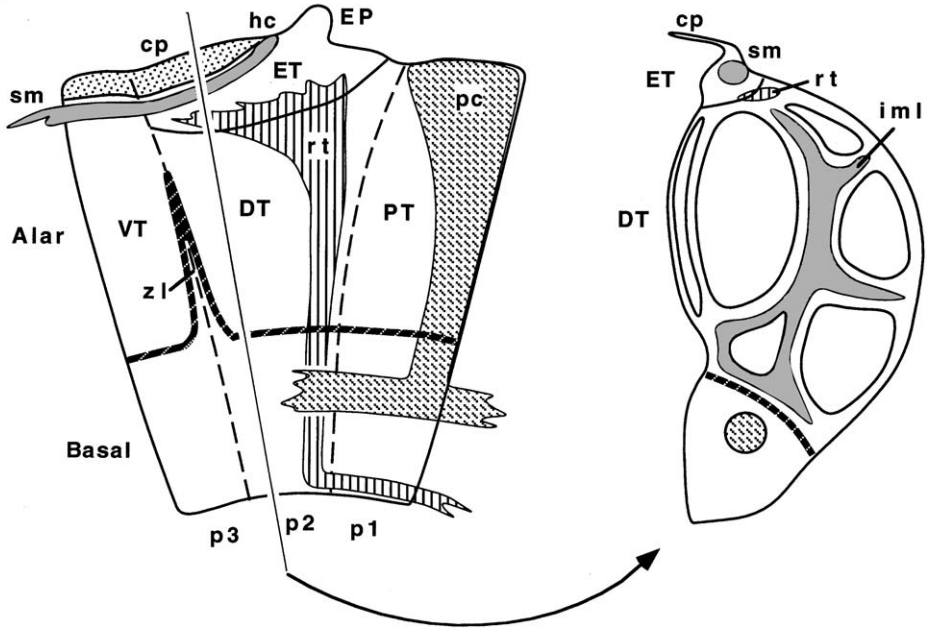

Figure 3 Schema of subdivisions of the caudal diencephalon and relevant anatomical landmarks in lateral view (rostral to the left; alar/basal limit as in Fig. 2): The pretectum (PT) in alar p1 contains the posterior commissure (pc); the dorsal thalamus (DT) and epithalamus (ET) in alar p2 contain to the retroflex tract (rt). The zona limitans (zl) separates dorsal and ventral thalami (VT) and seems to contain an expansion of the basal plate (according to gene expression data). The stria medullaris tract (sm) courses longitudinally near the roof choroidal plexus (cp). (Right) A schematic cross section through the dorsal thalamus, whose section level is indicated in the schema on the left, shows various nuclear groups (each of them is further subdivided into several nuclei), separated by the axon-rich internal medullary lamina (iml). See Table I for other abbreviations.

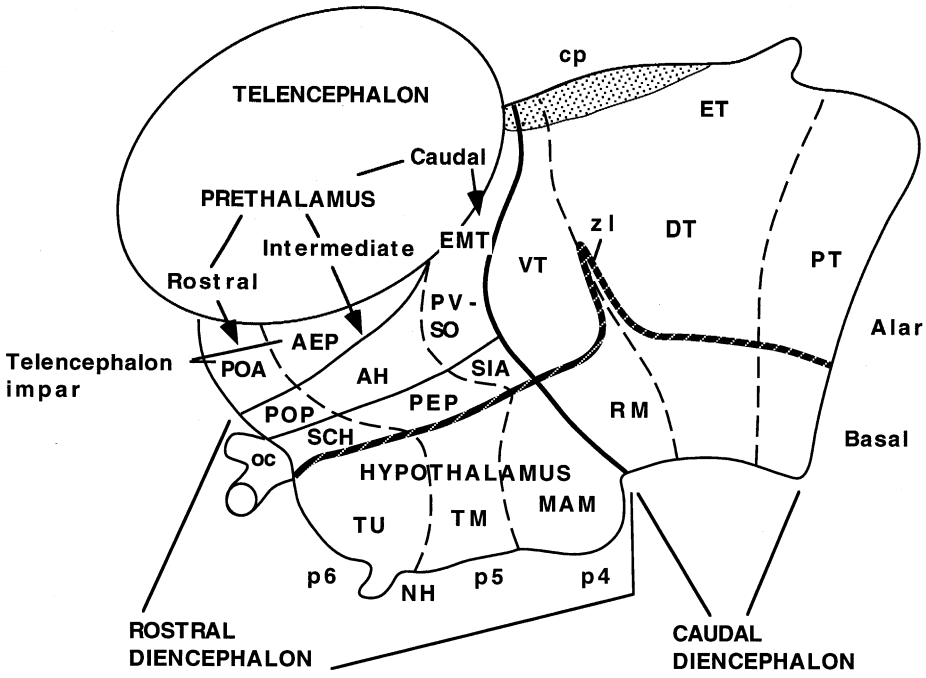

Figure 4 This schema highlights subdivisions in the rostral diencephalon in the context of the overlying telencephalon and caudal diencephalon. We call "hypothalamus" the basal part of the rostral diencephalon and "prethalamus" the alar part. These are both divided into three prosomeres (p4–p6) and various smaller areas. See Table I for abbreviations.

the midbrain into the interpeduncular nuclear complex in the isthmic floor plate (rt in Fig. 3).

The dorsal thalamus (DT) lies ventral to the epithalamus and consists of an elaborate complex of nuclei that generally project to the telencephalon (targeting both subcortical and cortical structures) (Fig. 3 and arrow 11 in Fig. 5A). These nuclei serve as relay centers for numerous telencephalopetal pathways with diverse functional implications. The telencephalic cortex sends topographically ordered projections to the respective thalamic relay centers. The main subdivisions of the DT contain groups of related nuclei. The *intralaminar* nuclei lie within the fiber-rich internal medullary lamina, which separates the other nuclear groups (iml in Fig. 3). These intralaminar nuclei form a separate projecting system with a modulatory role over the cortex and basal ganglia (embodying the final stage of the ascending activating system for mental arousal). The *sensory* nuclei process somatosensory and viscerosensory information (ventrobasal complex), visual input (dorsal lateral geniculate nucleus), and auditory input (medial geniculate nucleus), which are then relayed by these nuclei to the primary sensory areas of the isocortex via axons in the internal capsule (telencephalic peduncle; arrow 11 in Fig. 5A). Other thalamic nuclei are part of the *motor control* system (ventral anterior and ventrolateral nuclei); these process inputs from the globus pallidus and the cerebellar dentate nucleus and send efferents to the motor and premotor cerebral cortex. The anterior and periventricular thalamic nuclei are the *limbic* part of the thalamus, receiving hypothalamic (mammillary and other) projections and projecting to the limbic cingulate cortex, hippocampus, septum, and amygdala. Another important group of dorsal thalamic nuclei is conceived as the *associative* group (lateral dorsal, lateral posterior, pulvinar, and medial nuclei). These nuclei receive their major inputs from parts of the secondary sensorimotor, limbic, and associative cortex and project again into higher order cortical areas of the frontal, parietal, and temporal lobes. The associative nuclei are particularly developed and become secondarily subdivided and specialized in man.

The basal plate of p2 is poorly understood; it resembles that of p1 in that it contains a part of the dopaminergic neurons of the substantia nigra and of the median ventral tegmental area, in addition to some reticular populations participating in preoculomotor functions (i.e., the rostral interstitial nucleus).

The transition from p2 to p3 is characterized by several major changes in molecular and developmental properties. The p2/p3 limit appears as a fiber-rich gap between dorsal and ventral thalami; it is known as the zona limitans intrathalamica, or external medullary lamina (zl in Figs. 3 and 4).

Alar p3 is also known as the ventral thalamus for historical reasons, even though it is anterior to the dorsal thalamus (VT in Figs. 2 and 3; compare resulting position in bent forebrain, as in Fig. 1D). The choroid plexus of p2 extends through p3 and p4 into the telencephalon (cp; dotted roof domain in Figs. 1F, and 3 and 4; striped roof in Fig. 2). A choroid plexus is a neuroepithelial specialization where blood plasma is filtered into the brain ventricles as cerebral spinal fluid, which circulates and then flows out from holes in the hindbrain roof. Alar p3 consists of the ventral lateral geniculate nucleus (a superficial reflex visual center), the reticular thalamic nucleus (traversed by the thalamocortical fiber bundles), and a periventricular zona incerta. The latter two nuclei contain many inhibitory neurons, whose projections spread widely ipsi- and contralaterally in the alar and basal plates of the caudal and rostral diencephalon, perhaps reaching the midbrain. Inhibition exerted by the reticular nucleus on the dorsal thalamus organizes rhythmic electrical activity characteristic of sleep.

The basal plate of p3 consists of the so-called posterior hypothalamic area and the retromammillary area, which is frequently named the "supramammillary area." The latter is characterized by some dopaminergic neurons and other reticular cell populations.

IV. THE ROSTRAL DIENCEPHALON

As outlined previously, we use the term rostral diencephalon to refer to the extratelencephalic part of the secondary prosencephalon. We hypothesize that it is divided in basal and alar plates across three prosomeres (p4–p6), with its alar plate forming the prethalamus and its basal/floor plates representing the hypothalamus, as originally defined for human embryos by His in 1890 (Figs. 2 and 4). Although the diencephalic prosomeres p1–p3 represent the part of the extratelencephalic forebrain machinery that regulates information processing (and subsequent motor output) of signals coming in from the external world, the rostral diencephalic prosomeres p4–p6 attend mainly to the inner world of viscera, neurohumoral functions, and internal homeostasis. They also provide ascending (motivating) input into the limbic parts of

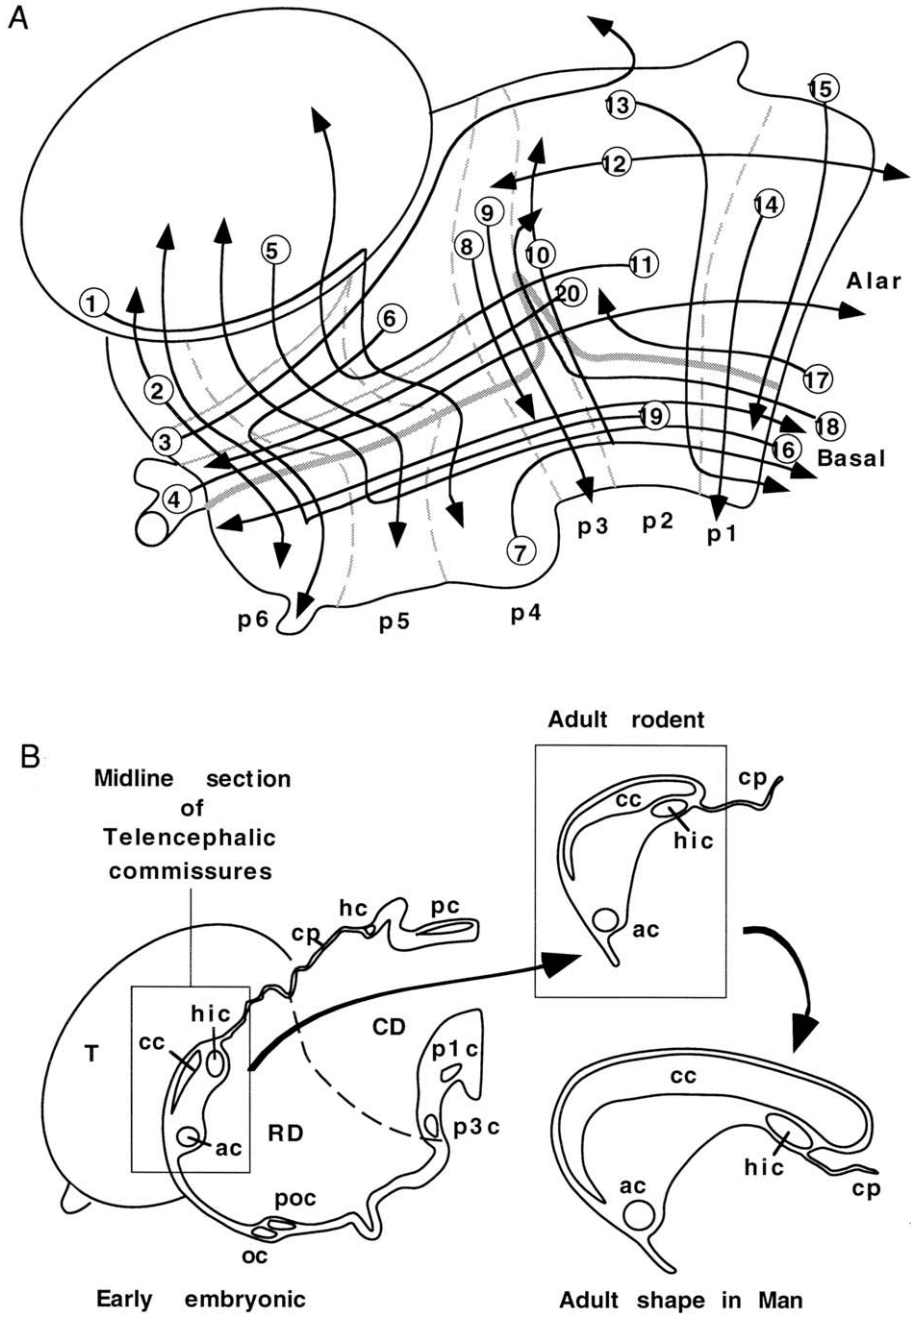

Figure 5 Schema of connectivity in the rostral and caudal diencephalon. (A) In general, tracts can be mapped within the prosomeric model as aligned with the transverse or longitudinal dimensions of the forebrain components. There are thus basically transverse tracts or tract portions and longitudinal tracts or tract portions. Individual tracts may change direction at specific decision points. This schema does not describe all the tracts present in the forebrain. It only exemplifies the previous general principle by illustrating 20 assorted tracts: 1, Fornix (hippocampomammillary) tract; 2, septohypothalamic tract; 3, stria medullaris (into habenular commissure); 4, optic tract; 5, amygdalohypothalamic tract; 6, supraoptohypophyseal tract; 7, mammillotegmental tract; 8, incertotegmental tract; 9, commissural ventral thalamic tract; 10, mammillothalamic tract; 11, thalamotelencephalic tract; 12, longitudinal alar interconnections; 13, retroflex tract; 14, commissural anterior pretectal tract; 15, posterior commissure; 16, nigrostriatal tract; 17, medial lemniscus; 18, superior cerebellar peduncle; 19, medial forebrain bundle; 20, intergeniculate–suprachiasmatic tract. (B) The various commissures present in the forebrain are illustrated in a median sagittal section. Emphasis is placed in the area where the telencephalic commissures develop, showing in the two schemas on the right the progressive relative increase in size of the corpus callosum over developmental time and from adult rodent to adult man. See Table I for abbreviations.

the telencephalon through the medial forebrain bundle, whereas the caudal diencephalon is connected to the telencephalon via the lateral forebrain bundle (internal capsule). The prethalamus and hypothalamus accordingly are a collection of neural centers that are involved in regulation of homeostasis, reproduction, the autonomic nervous system, and emotional states.

The caudal part of the hypothalamus (p4) includes the mammillary region, the subthalamic nucleus, the lateral hypothalamic area, and part of the posterior hypothalamus (MAM in Fig. 4). The prethalamic (alar) region of p4 reaches dorsally the forebrain roof (choroidal plexus) via the eminentia thalami at the caudal end of the telencephalic stalk (EMT in Fig. 4); this area possibly extends into the telencephalon through the medial amygdala. The p4 alar plate probably includes among its derivatives the subincertal area, the paraventricular and supraoptic nuclei (SIA and PV–SO in Fig. 4), and the perireticular nucleus (not shown), with the latter lying just in front of the ventral thalamic reticular nucleus. The eminentia thalami received its name due to its protrusion at the back of the interventricular foramen (tight passage interconnecting the prethalamic ventricular space with that of the telencephalic vesicle, or lateral ventricle) and the idea that it belongs to the thalamus. Its neuronal derivatives participate in the bed nuclei of the stria terminalis (posterior, or medial, parts) and the stria medullaris. This domain is characteristically traversed superficially by the telencephalic peduncle as it exits the telencephalon, incorporating as well the thalamotelencephalic projections. The fornix tract —hippocampal fibers passing from the caudal aspect of the commissural septum to the mammillary region —follows the dorsoventral dimension of p4 at an intermediate depth (arrow 1 in Fig. 5A).

The intermediate hypothalamus (p5) is represented by the tuberomammillary region, which also contains the premammillary nuclei and the dorsomedial hypothalamic nucleus (TM in Fig. 4). The corresponding alar or prethalamic area extends through the posterior entopeduncular area, the conventional 'anterior hypothalamus,' and anterior entopeduncular area into the telencephalic stalk (PEP, AH, and AEP in Fig. 4).

The rostral hypothalamus (p6) starts ventrally with the neurohypophysis, median eminence, and arcuate nucleus (floor plate derivatives) and includes the basal plate tuberal area, with the ventromedial hypothalamic nucleus and the anterobasal nucleus (retrochiasmatic area) (NH and TU in Fig. 4). The rostral prethalamic alar plate continues through the suprachiasmatic and posterior/anterior preoptic regions into the telencephalic stalk (SCH, POP and POA in Fig. 4).

The mammillary area is a complex of nuclei with a variety of inputs, including the fornix fibers from the hippocampus, as a part of the limbic circuit of Papez. These nuclei send their major outputs through the basal plate of p3, p2, and p1 to the brain stem tegmental nuclei (mammillotegmental tract), with a collateral projection to the anterior dorsal thalamus, via the mammillothalamic tract (arrows 7 and 10 in Fig. 5A); these are also part of the Papez limbic circuit, which returns from there to cingulate and hippocampal cortex.

The tuberal/infundibular region and pituitary stalk are traversed by neuroendocrine fibers carrying vasopressin and oxytocin from magnocellular secretory cells in the overlying alar plate (supraoptic and paraventricular nuclei) to the neurohypophysis (arrow 6 in Fig. 5A); the neurohypophysis liberates these substances into the bloodstream. The median eminence contains a profusion of nerve terminals that secrete the proteins that regulate the release of various hormones from the anterior pituitary (corticotropin, thyrotropin, gonadotrophin, and growth hormone) into the hypophyseal portal capillaries. These regulator proteins arise from discrete groups of parvocellular neurosecretory neurons in the anterior hypothalamus and preoptic area. Other modulation of the pituitary occurs directly via axon terminals of dopamine neurons in the arcuate nucleus. The anterobasal nucleus bridges the retrochiasmatic midline area as a bed nucleus of the postoptic (supraoptic) commissures (poc in Fig. 5B) and is the rostralmost component of the basal plate.

The prethalamus can be subdivided into two superposed longitudinal tiers across prosomeres p4–p6. The lower tier coincides with the subpial course of the optic tract and the optic chiasm (Figs. 2 and 5A). It contains the suprachiasmatic nucleus (p6; involved in the control of circadian rhythms in homeostatic functions), the posterior entopeduncular area (including the migrated posterior entopeduncular nucleus; p5) and the subincertal area (p4). Little is known about the functions of the more caudal area. The upper tier is the so-called optoeminential domain, which lies just under the telencephalic stalk and telencephalon impar (unevaginated parts continuous with telencephalic structures, such as the telencephalic preoptic and median septal areas; Ti in Fig. 2). The optoeminential domain starts rostrally (p6), with a prethalamic preoptic area found around the optic stalk recess (POP in Fig. 4). It

includes the anterior hypothalamic area (p5), dorsal to the PEP, and the supraoptic and paraventricular nuclei, together with the derivatives of the eminentia thalami (p4; posterior bed nucleus striae terminalis and bed nucleus striae medullaris). At the boundary with the telencephalic stalk, this domain is traversed longitudinally by the stria medullaris, which continues caudalwards into the diencephalic roof (epithalamus) (arrow 3 in Fig. 5A). The overlying telencephalic stalk domain (telencephalon impar) consists of cell groups found at the peduncular transition into the evaginated telencephalic vesicles. From caudal to rostral, these contribute to the amygdala, the extrapyramidal system [entopeduncular nucleus (or internal segment of globus pallidus in highly evolved mammals), substantia innominata, and basal nucleus of Meynert], the anterior preoptic area/diagonal band formation, and the telencephalic preoptic area.

V. BASIC CIRCUITRY IN THE EXTRATELENCEPHALIC FOREBRAIN

The whole lateral wall of the rostral and caudal diencephalon is traversed by numerous transverse, longitudinal, and commissural fibers that interconnect the diverse prosomeric centers into interactive circuitry (Figs. 5A and 5B). These interconnecting fiber systems often reach the midbrain alar and basal plates (and extend from there into the rest of the brain stem), and they converge rostrally at the postoptic (so-called supraoptic) commissure or diverge into the telencephalic stalk. The commissures allow the left and right halves of the brain to interact for coordination of both analytical (alar) and motor/neurovegetative/neurohumoral (basal) functions.

Another pervasive fiber system, the optic tract, is subpial and is found largely in the alar plate (there is also an accessory basal optic tract targeting specific terminal centers in the basal and alar parts of p1). The main optic tract courses longitudinally from the optic chiasm, where half of its fibers decussate (in man), through the prethalamus, thalamus, and pretectum and up to the midbrain roof (tectum)—the superior colliculus. Along its way, the optic tract gives out collaterals or terminal fibers to prethalamic areas (such as the suprachiasmatic nucleus) and to thalamic (ventral and lateral geniculate nuclei, intergeniculate leaflet, and pulvinar nucleus) and various pretectal centers receiving topographically ordered (retinotopic) projections (anterior pretectal nucleus and nucleus of the optic tract) or nonordered retinal projections (olivary pretectal nucleus). The retinorecipient posterior pretectal nucleus lies in the midbrain.

There are also many characteristic transverse fiber tracts normally coursing close to a given interprosomeric boundary (Fig. 5A), although other systems of transverse fibers course sheet-like throughout a given portion of the wall. Most of these fibers change course (i.e., become longitudinal) at a given decision point, generally coinciding with entrance into the basal plate; a few proceed into commissures across the roof or floor plate (mainly in p1 and p3; Fig. 5B).

Given the specialization of alar centers in analytic signal decoding/locating and associated relay functions, and the specialization of the basal centers in motor patterns, longitudinal alar or basal fibers crossing diverse neuromeres tend to integrate separately such functions (bilaterally, due to the commissures). Conversely, fiber tracts coursing transversally convey the diverse segmentally analyzed (and longitudinally cross-correlated) alar outputs into the responding basal plate net of reticular and motor neurons. Much of our subconscious brain activity and reflex behavior depend on this subtle multimodal neuronal machinery for its precise situation- and aim-dependent adaptations. Note that this system, which is able to respond in a large extent to external and/or internal multimodal stimuli autonomously, is also controlled by the telencephalon for a higher degree of contextual integration, or volitional control, as indicated by separate descending telencephalic projections to many alar and basal plate centers.

VI. THE TELENCEPHALON: BASIC PARTS AND MORPHOGENESIS

The telencephalic hemispheres evaginate bilaterally from the dorsalmost alar plate of the secondary prosencephalon (Fig. 1). This process includes within each vesicle a portion of the roof plate choroidal tissue, which later builds the choroidal plexi of the lateral ventricles (Figs. 1 and 2F). Rostrally, a thick median wall portion is the site where the telencephalic commissures develop (fibers interconnecting both vesicles; there are three major commissural pathways in mammals—anterior commissure, hippocampal commissure, and corpus callosum; Fig. 5B).

There are two principal subdivisions of the telencephalic vesicle: the roof, or pallium, and the basis, or subpallium (Fig. 6A). The subpallium consists

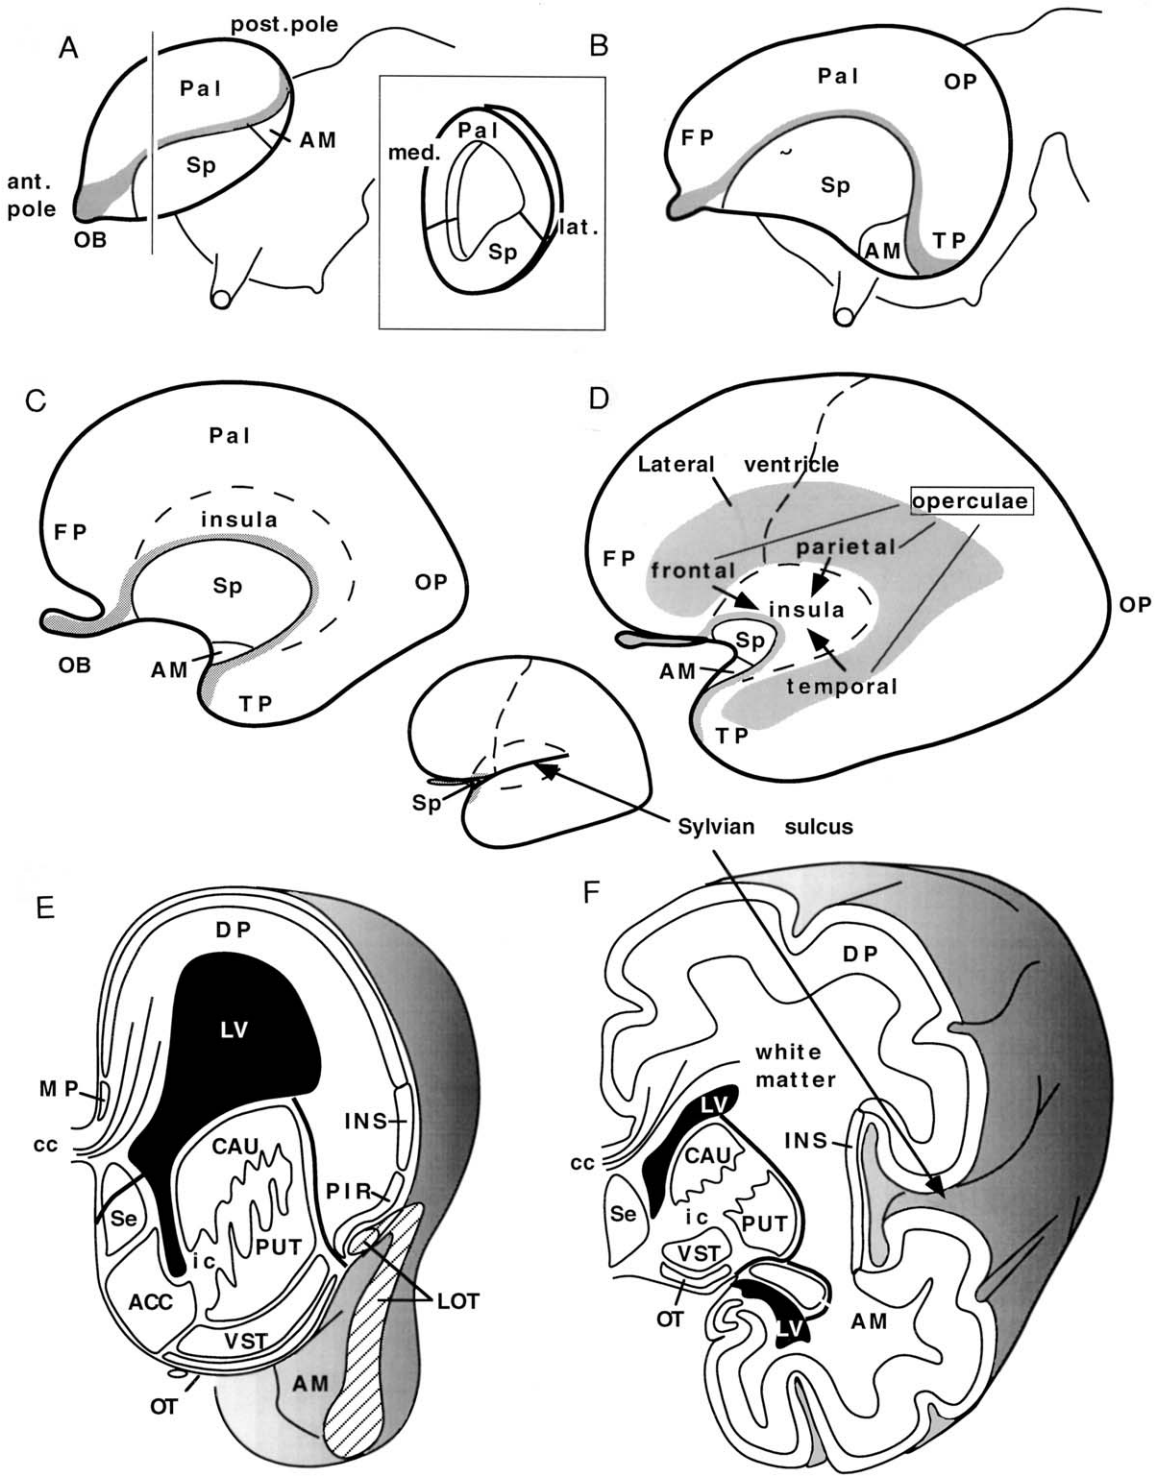

Figure 6 Morphological development of the telencephalon. (A–D) These drawings show lateral views of the left telencephalon at four developmental stages (see text). The inset in A shows a cross section and internal division into pallium (Pal) and subpallium (Sp). The olfactory tract is shaded in gray and helps to visualize the enormous growth of the pallium relative to the subpallium. (E) This drawing represents a section through the frontal part of the telencephalon, seen from the front; it shows in perspective the more caudal parts and the position of the temporal lobe. Within the section, the thick black lines mark the palliosubpallial boundary. Many subdivisions are indicated, as well as the lateral olfactory tract (LOT). (F) Similar to the drawing in E, representing a later stage in which further cortical expansions have introduced gyrification, internment of the insular cortex in the Sylvian sulcus (arrows) under the opercular overgrowths (compare with D and inset), and entrance of the temporal lobe (including its ventricular cavity) into the section plane (compare full shape in D). See Table I for abbreviations.

primarily of nuclei, the so-called basal ganglia (Figs. 7 and 8; note that use of the term "basal" here, or with regard to the amygdala, does not mean an embryological origin in the neural tube basal plate but, rather, a rough topographic indication of intratelencephalic position; all telencephalic parts are alar). The pallium contains primarily cortical structures but also some pallial nuclei (Fig. 8).

The area occupied by the basal ganglia in the hemisphere differentiates early and then its growth slows, whereas the overlying pallium is capable of prolonged surface growth. The increasing disproportion between these two parts leads to a characteristic morphogenetic deformation that in highly evolved mammals consists of a progressive incurvation and relative diminution in size of the subpallium, forced by anteroposterior and mediolateral expansion of the pallium (Fig. 6). The early forming posterior pole of the vesicle is converted into the temporal pole, which protrudes laterally and rostralwards (TP in Figs. 6B–6E). New anterior and posterior poles appear in parallel, forming the definitive frontal and occipital poles of the hemisphere (FP and OP in Figs. 6A–6E). An outgrowth at the early forming anterior pole forms the olfactory bulb, which gradually becomes displaced under the new frontal pole or orbitofrontal cortex (OB in Figs. 6A–6D). The lateral olfactory tract projecting from the olfactory bulb to the primitive posterior pole (gray in Fig. 6A) is transiently visible at the surface along the whole telencephalon, always just lateral to the palliosubpallial boundary (gray in Figs. 6C and 6D).

Internally, the subpallium forms an intraventricular bulge that affects the shape of the lateral ventricle

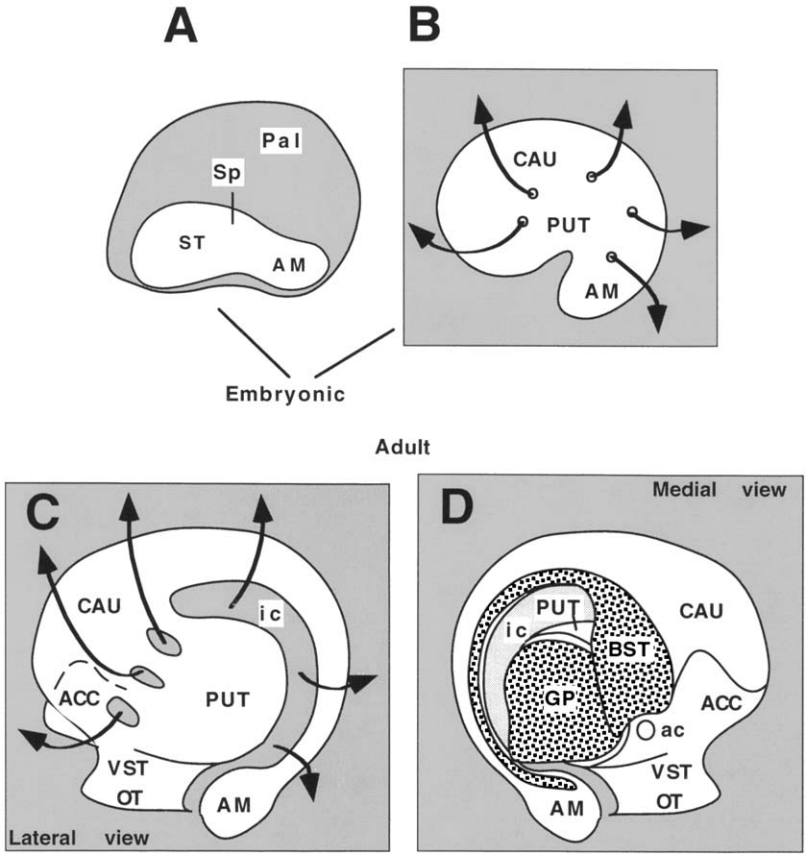

Figure 7 Development and subdivisions of the basal ganglia. (A). The common mass of subpallial formations is shown under the pallium. Its caudal part contains prospective subpallial amygdala (AM) and its rostral part the striatum (and pallidum, internally). (B). Early passage of fibers from the internal capsule (arrows) starts to divide the subpallial nuclei. (C, D). At the final stage, external (C) and internal (D) views show the different main portions that are distinguished. The stippled formations in D represent the pallidal components. See Table I for abbreviations.

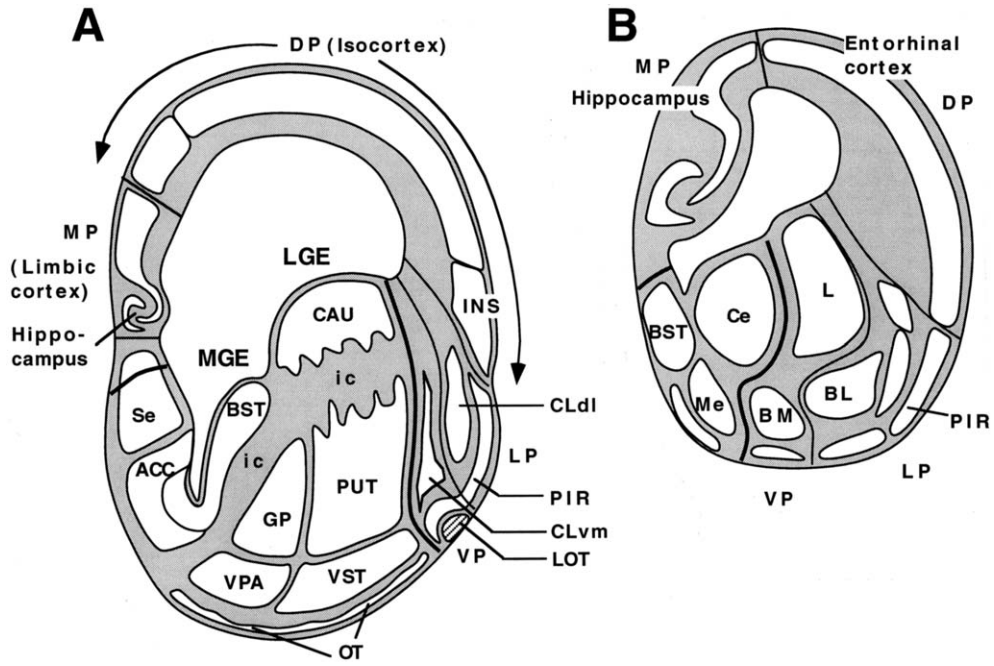

Figure 8 Pallial and subpallial subdivisions shown in schematic cross sections through the middle sector of an undeformed telencephalon (A) and through the amygdaloid complex at the temporal pole (B). The thick black line represents the palliosubpallial boundary. Note the pallium is subdivided into ventral, lateral, dorsal, and medial portions. See Table I for abbreviations.

(Sp in Figs. 6A, 6E and 6F, 7, and 8). The basal ganglia are traversed by the radiating fibers of the internal capsule (bidirectional thalamocortical axons) and become secondarily subdivided into several portions (Figs. 6E and 6F, 7B–D, 8A, and 8B). Pallial overgrowth also occurs mediolaterally, both in the main frontooccipital body of the hemisphere and in the temporal horn. This leads to the formation of the Sylvian (lateral) fissure and the progressive internment under the frontoparietal and temporal operculae of the piriform (olfactory) and insular cortexes (these are the earliest formed cortical parts, covering laterally the basal ganglia) (Figs. 6D–6F).

Additional adjustments of the pallial surface to more localized bouts of final surface growth lead to the partial or total burial of the oldest formed cortex (anchored by its more advanced connections) in the depth of other fissures (hippocampal, collateral, internal parietooccipital, and calcarine) and constant or variable sulci (central, frontal, parietal, temporal, cingulate, and rhinal). The intervening gyri protrude superficially in interlocked shapes, adapting to available space in the cranium (Fig. 6F). The main sulcal formations serve to separate the frontal, parietal, occipital, temporal, insular, and cingulate/entorhinal lobes; the latter includes the hippocampus. The relative amount of gyrification increases in evolutionarily more advanced mammals. The increase in cortical surface that is found in complex mammals is thought to occur without fundamental changes in the radial organization of the cortex, which is divided into columnar modules of constant dimensions and cell density across mammals. Thus, one evolutionary trend tends to increase the number of cortical columnar modules (presumably improving the analytical capacity of the animal). At the interhemispheric surface, gyrencephalic animals also show a correlatively larger corpus callosum, the main interhemispheric commissure (Fig. 5B).

VII. TELENCEPHALIC COMPONENTS

A. The Pallium

Recently, the pallial cover of the telencephalic vesicle has been shown to be divided molecularly and structurally into four pallial territories, that are common to all vertebrates: the medial, dorsal, lateral,

and ventral pallial domains (Fig. 8). The medial and dorsal pallial parts mature structurally into purely cortical centers. The medial pallium primarily forms the hippocampal cortex (allocortex; three-layered), although parts of the surrounding transitional cingulate/entorhinal cortex (mesocortex; four- or five-layered) may have the same origin. This functionally connected complex is subsumed under the term "limbic lobe" and is important in the evaluation of experiences, motivation of behavior, emotions and memory.

The dorsal pallium forms the isocortex (six- or seven-layered; predominant in relative surface extent). This domain specializes into separate sensory or motor cortical areas. Primary sensory cortex processes relatively simple sensory data; secondary cortex generates more complex perceptual constructs of the external world and the body. Associational cortical areas are where higher mental functions are believed to occur (Figs. 9B and 9C). The ancestral dorsal pallium appears as a variably sized island surrounded by the rostrally and caudally interconnected medial and lateral pallia; the reduced sensory/motor and associative representations partly overlap (Fig. 9A). The dorsal pallium is the portion that expands more in mammalian evolution so that the isocortex represents the largest and most variably subdivided cortical domain in mammalian species (Figs. 9B and 9C). Major axonal outputs of the isocortex (apart from the massive layer II/III corticocortical projections, both within the same hemisphere and projecting into the contralateral hemisphere using the corpus callosum) are the corticoclaustral, corticostriatal, corticothalamic, corticopretectal–collicular, corticoreticular, corticopontine, corticonuclear, and corticospinal fiber pathways. They jointly constitute a potent means for

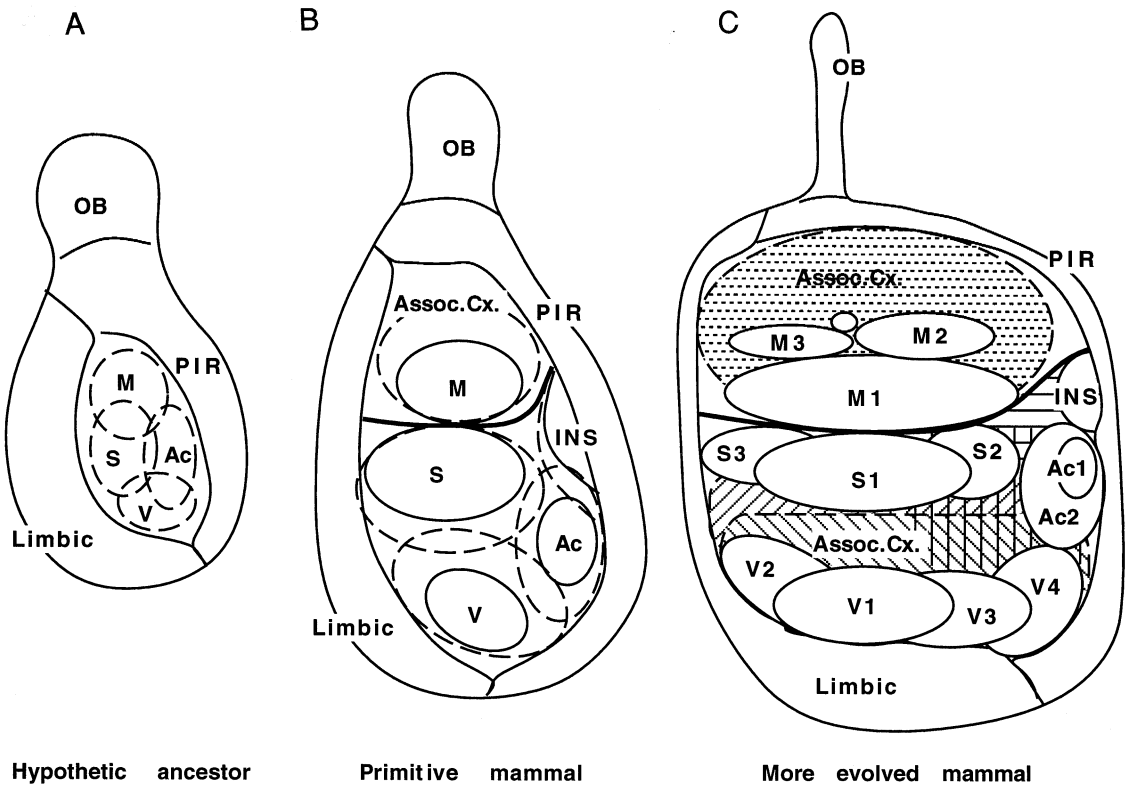

Figure 9 Drawings of flattened cortical surface, with hypothetical three stages of cortical evolution in mammals. The progressive expansion and diversification of specialized and associative fields within the isocortex is put in the context of its invariant topology, both externally [with respect to the surrounding limbic and piriform (PIR) cortexes] and internally (with respect to each area's topological relationship to the other isocortical areas). Dashed lines indicate imprecise boundaries. The thick black lines in B and C indicate the boundary between frontal lobe (action planning and motor functions) and the parietal, occipital, and temporal lobes (sensorial analysis and abstraction). The different patterns of lines in C symbolize associative multimodal intermixing of analysis properties. In man, the number of identified visual areas is approximately 20, and similar numbers may exist for the other specialized regions; this indicates the relative complexity of the functions performed in these domains. See Table I for abbreviations.

descending modulation of subjacent alar and basal centers, and they arise primarily from layer V pyramidal neurons (except those to claustrum and thalamus, which arise from layer VI neurons). The acquisition of direct cortical innervation of motoneurons seems to be a relatively recent evolutionary addition since it is absent in nonmammals.

The lateral and ventral pallial domains both give rise to portions of the olfactory cortex. In addition, each develops underlying pallial nuclei, which have been classified tentatively according to their molecular profiles (Figs. 8A and 8B). The lateral pallial nuclear formation consists rostrally of the dorsolateral claustrum and caudally of the endopiriform nucleus and basolateral parts of the amygdala (plus associated cortical amygdala domains). The ventral pallial nuclear formation is represented rostrally by the ventromedial claustrum and caudally by the lateral and basomedial parts of the amygdala (and associated cortical parts). Little is known of the functions of the claustrum, although the dorsolateral part has a bidirectional topographically ordered projection with the whole isocortex. The ventromedial claustrum may receive multimodal thalamic connections. The pallial nuclei of the amygdala are known to integrate multiple inputs from the isocortex, apparently integrating recognition of contextual Gestalts (characteristic sense data configurations) with entrainment of appropriate instinctive or learned (associated) behavior through motivational (limbic) and direct descending efferents onto extratelencephalic circuitry. It should be noted that the amygdala was long held to be only a part of the basal ganglia, but it has recently emerged as a heterogeneous complex of interactive pallial and subpallial elements (Fig. 8C). The same can be said for the telencephalic septum, found at the interhemispheric or medial wall, which also shows pallial and subpallial portions, although in this case the pallial part (the dorsalmost part of the septum) is much smaller than its subpallial constituents.

B. The Subpallium

The subpallium may be divided for descriptive purposes into a middle sector and two transitional domains at its rostral and caudal ends. The wall of the middle sector bulges into the ventricular cavity early in development, forming two ridges called the medial and lateral ganglionic eminences (MGE and LGE); these transient structures are perforated by the major tract interconnecting the diencephalon with the telencephalon, the internal capsule (ic; arrows in Figs. 7B and 7C; Fig. 8A).

The mantle layer under the MGE matures earliest and gives rise to the globus pallidus (GP) or pallidum (there are dorsal and ventral pallidal formations; the dorsal pallidum divides into internal and external segments in hominids; in other mammals, the internal pallidal segment is called entopeduncular nucleus; Fig. 8A). The internal capsule fibers separate the GP from the periventricular pallidal derivative, which forms a curved complex called the bed nucleus of the stria terminalis (BST in Figs. 7D, 8A and 8B). The stria terminalis is a tract interconnecting the amygdala with the anterior commissure and surrounding areas (Fig. 7D). Together with the LGE, the MGE also produces numerous cohorts of neurons that migrate tangentially to invade the striatum and the whole cortical pallium (they largely become incorporated as cortical inhibitory interneurons).

The mantle developing under the LGE is the striatum [laterally there are dorsal and ventral striatum parts and a rostromedial part, the accumbens nucleus (ACC); Figs. 6E, 7C–7D, and 8A]. In man, the internal capsule partially divides the dorsal striatum into a peripheral portion called putamen and a periventricular portion called caudate nucleus (Fig. 8A). An obsolete anatomical conception artificially joined the putamen to the medially adjacent dorsal pallidum under the concept of ''lenticular nucleus''; this term nevertheless still appears in clinical usage and in some tracts projecting out of the pallidum (lenticular tract and ansa lenticularis).

The respective dorsal and ventral parts of the striatum and pallidum are separated (arbitrarily) by the plane in which rostral and caudal components of the anterior commissure collect and course toward the midline commissural plate. At the subpial (ventral) surface of the subpallium, various superficially migrated cell populations form the laminated olfactory tuberculum. Toward the telencephalic stalk, this ventral area is contiguous with the substantia innominata, which contains both dispersed and dense groups of cholinergic neurons, such as the basal nucleus of Meynert. These constitute the main source of cholinergic input to the overlying cortex.

The striatopallidal complex is integrated into a circuit that modulates the motor output of the motor and premotor cortex. The cortex projects excitatory axons to specific areas of the striatum complex (characteristic afferents: accumbens and ventral striatum, limbic; caudate, associative; and putamen,

sensorimotor). The striatum projects separately to the external and internal parts of the pallidum, where its effect is inhibitory, phasically breaking a tonic inhibitory activity of the pallidum over its targets. The external pallidal part interacts bidirectionally with the subthalamic nucleus, whose fibers counteract striatal inhibition in the pallidum. The internal part of the globus pallidus projects its tonic inhibition on the motor dorsal thalamic nuclei, which connect with the motor and premotor cortex. Phasic striatal inhibition of the pallidal tone thus decreases inhibition on thalamocortical neurons and thereby facilitates movement. Thus, motor plans are filtered through the basal ganglia to modulate the outputs of the motor cortex. It is thought that this circuit is important for regulating the dimensions of movements (e.g., tracing small or larger versions of one's signature) and for improving fluidity in opposite or alternating motions. There is an important ascending activation of striatal activity by nigrostriatal dopaminergic axons, in parallel with an important dopaminergic innervation of the premotor cortex. This input decreases in Parkinson's disease due to degeneration of the dopaminergic neurons in the substantia nigra and ventral tegmental area (partly in midbrain and partly in the basal/floor plate of diencephalon). These patients have hypokinesia (difficulty initiating movements), rigidity, and inexpressive faces. On the other hand, lesion of the subthalamic nucleus (p4 basal plate) diminishes the tonic inhibitory output of the pallidum, which leads to hyperactivity symptoms (involuntary movements are released, e.g., tics, hemibalismus, and choreoathetosis).

The amygdala is caudal to the striatum and pallidum. This massive nuclear formation, formed at the primitive caudal telencephalic pole and brought to the tip of the temporal lobe during morphogenesis (Figs. 6 and 7), can be divided into pallial and subpallial parts according to the expression of genetic markers and other characteristics (Fig. 8B). The numerous amygdaloid subnuclei traditionally have been grouped into central, medial, basal, lateral, and cortical groups (Fig. 8B). The pallial amygdaloid components have considerably increased in size in highly evolved mammals. The subpallial part of the amygdala is represented by the central amygdaloid nucleus, which shares some striatal characteristics, and the medial amygdaloid (plus amygdaloid BST) nuclei, which share some pallidal characteristics.

A recent variant conception of the subpallial amygdala adds the so-called "extended amygdala," which includes all the intratelencephalic supracapsular and subcapsular BST formation (relations to internal capsule) and other specific cell groups related to the anterior commissure. The extended amygdala, however, would belong to the middle and perhaps also the rostral subpallial sectors since it converges on the anterior commissure. According to our embryological formulation, the extended amygdala largely corresponds to pallidal areas surrounding the globus pallidus (Fig. 7D).

Finally, the rostral subpallial sector is constituted largely by the septum, found in front of or partially mixed with the telencephalic commissures in the medial hemispheric wall (See in Figs. 6E, 6F, and 8A). This nuclear complex can again be divided by use of genetic markers and other characteristics into subpallial and pallial portions (the pallial one being very small). The subpallial portion subdivides into an upper, striatum-like part and a ventral, pallidum-like part. Traditionally, the septum has been divided into "medial" and "lateral" septal nuclei, which embryologically correspond to superficial and periventricular strata, respectively. It is unfortunate that the term "lateral" was associated with a periventricular formation since this is somewhat counterintuitive (most other lateral structures in the brain are superficial, i.e., subpial).

Frontal Lobe

LADA A. KEMENOFF, BRUCE L. MILLER, and JOEL H. KRAMER
University of California, San Francisco

GLOSSARY

dysarthria Disturbance of speech articulation or impairment of the speech mechanism, including muscle weakness. It is manifested by slurred pronunciation.

dysprosody Loss of the normal rhythm, melody, and articulation of speech.

gliosis Glial cells migrate to and proliferate in areas of neural tissue where damage has occurred.

hemiplegia Paralysis of one side of the body.

hypophonia An abnormally weak voice resulting from uncoordination of speech muscles, including weakness of muscles of respiration.

paraphasia The production of unintended syllables, words, or phrases during speech.

regional cereberal blood flow (rCBF) Amount of blood flow in a region of the cortex is positively correlated to the metabolic activity of that region. Imaging of the rCBF by scintigraphy with inhaled xenon-133 can be combined with psychological testing during the measurement of blood flow, allowing assessment of the effects of cognitive activation procedures on blood flow in specific regions of the cortex.

Commonly described as the anatomic seat of human self-awareness, the frontal lobes are the most evolutionarily advanced components of the human brain. Scientific advancements during the past decade have considerably improved our understanding of the frontal lobes and their complex role in cognition, personality, and neurological disease. This article presents a contemporary perspective on frontal lobe neuroanatomy; neuropsychological functions; and frontal lobe disorders.

I. NEUROANATOMY OF THE FRONTAL LOBE

The frontal lobes comprise the most anterior portion of the cerebral hemispheres. They are demarcated posteriorly by the central sulcus, laterally by the Sylvian fissure, and medially by the cingulate sulcus. The frontal lobes are anatomically and functionally heterogeneous, and the lateral surface of the frontal lobes can be divided into three major functional sectors: primary motor, premotor, and prefrontal cortex.

A. Primary Motor Cortex

The most posterior region of the frontal lobe, the precentral gyrus, represents the brain's primary motor area. This region forms a narrow strip of tissue along the lateral surface of the frontal lobe and continues down around the medial bank of the cortical apex. Primary motor cortex gives rise to the corticobulbar and corticospinal tracts and is responsible for the mediation of movement.

B. Premotor Cortex

Positioned immediately anterior to the primary motor region, the premotor cortex is composed of several functional areas. The lateral premotor area appears to be involved in the integration of motor skills and

learned action sequences. The supplementary motor area on the medial surface in the superior frontal gyrus appears to mediate the initiation and programming of body movements. Broca's area is situated in the inferior, posterior frontal gyrus and is responsible for controlling voluntary speech.

C. Prefrontal Cortex

The prefrontal cortex is composed of the anterior portion of the frontal lobes. This region has robust connections with limbic and subcortical areas. In 1993, Jefferey Cummings described three frontal–subcortical circuits that mediate cognitive, motivational, and emotional processes: the dorsolateral prefrontal circuit, the orbitofrontal circuit, and the anterior cingulate circuit.

The dorsolateral prefrontal circuit includes the lateral convexity of the frontal lobe, dorsolateral caudate, portions of the globus pallidus and substantia nigra, and ventral anterior and dorsomedial thalamic nuclei. The dorsolateral circuit subserves executive functioning abilities, including response inhibition, fluency, working memory, and retrieval from long-term memory.

Jefferey Cummings also proposed an orbitofrontal circuit composed of two parallel subcircuits: the lateral and medial orbitofrontal circuits. The lateral orbitofrontal circuit projects from orbitofrontal cortex to ventral portions of the caudate; the medial circuit projects to the ventral striatum. Both circuits then project to medial portions of the globus pallidus, midbrain structures, and ventrolateral and dorsomedial thalamus. The orbitofrontal circuit mediates the modulation of social behavior; lesions can produce personality changes, including indifference to others, irritability, tactlessness, and impulsive behavior.

The anterior cingulate circuit projects from the anterior cingulate cortex and incorporates the ventromedial caudate, ventral putamen, and nucleus accumbens. This circuit is thought to mediate motivation; lesions are associated with apathy and disinterest.

II. NEUROPSYCHOLOGICAL FUNCTIONS OF THE FRONTAL LOBE

A. Executive Functioning

Damage to the dorsolateral prefrontal cortex has been associated with compromised performance on neuropsychological measures sensitive to executive functioning. According to Muriel Deutsch Lezak, the term "executive functions" can be defined as the capacities that enable a person to engage in purposive, independent, and self-serving behavior. These functions include the ability to plan, to disengage from the immediate environment, to show flexibility of thinking, to fluently generate concepts, and to inhibit responses to overlearned patterns of behavior. Many researchers contend that executive functioning abilities remain among the most highly developed of human frontal lobe accomplishments.

B. Mental Flexibility

Mental flexibility requires the capacity to shift a course of thought or action according to rapidly changing situational demands. The Wisconsin Card Sorting Test (WCST) is a popular neuropsychological measure used to assess concept formation, abstract reasoning, and the ability to shift cognitive strategies in response to changing environmental contingencies. The subject is presented with four stimulus cards depicting figures of varying forms, colors, and numbers of figures (one red triangle, two green stars, three yellow crosses, and four blue circles). The task is to match each consecutive card from a deck of similar stimulus cards with one of the four key cards. In response to each matching, the subject is told only whether his or her choice was correct or incorrect. After the subject makes a specified number of correct matches, without warning the sorting strategy is changed. The subject is therefore required to use the examiner's feedback to develop a new sorting strategy.

Patients with frontal lobe damage have been found to perform more poorly on the WCST task than patients with nonfrontal damage. The required shifting response is particularly challenging for these patients because it entails the use of mental flexibility and reasoning skills. Frontal lobe patients commonly make perseverative errors by continuing to sort by a certain principle (e.g., by color) long after that sorting principle has been changed (e.g., to form). In some cases, patients appear almost oblivious to feedback and continue to make erroneous perseverations, despite their ability to verbalize the correct sorting strategy. Recent work by Kyle Boone suggests that perseverations on the WCST are more strongly associated with right frontal damage than left frontal damage.

The California Card Sorting Test is another useful measure of concept formation, shifting, and reasoning.

This unique card-sorting task was designed to isolate and measure specific components of problem-solving ability. The subject is asked to sort six cards spontaneously into two groups of three cards each, according to as many different rules as possible, and to report the rule after each sort. In another condition, subjects are required to report the rules for correct sorts performed by the examiner. This test examines several executive components, including the ability to generate and initiate different sorts, the ability to verbalize the principles of accurate sorts, and the ability to inhibit perseverative sorts. In 1992, Dean Dellis and colleagues found that patients with focal frontal lobe lesions and patients with Korsakoff's syndrome were impaired on eight of nine components of the task. Based on these results, the authors suggested that a wide array of deficits in abstract thinking, cognitive flexibility, and use of knowledge to regulate behavior contribute to the problem-solving impairment of patients with frontal lobe dysfunction.

C. Response Inhibition

Another important aspect of executive functioning is the ability to inhibit responses to established patterns of behavior. The Stroop Test is considered a measure of a person's ability to inhibit a habitual response in favor of an unusual one. During the interference condition of the Stroop, subjects are presented with a list of colored words (blue, green, red, etc.) printed in nonmatching colored ink. For example, the word *blue* may be printed in red ink, and the word *green* may be printed in blue ink. The subject's task is to name the ink color in which the words are printed as quickly as possible. This challenge involves suppressing the strong inclination to read the color name. Many patients with frontal lobe damage are unable to inhibit reading the words and thus show impairment on this task.

D. Verbal Fluency

Frontal lobe impairment can also produce deficits in a person's ability to rapidly generate words. The Controlled Oral Word Association Test (COWAT), also known as the "FAS," is a commonly used neuropsychological measure of verbal fluency. The COWAT consists of three word conditions. The subjects' task is to produce as many words as he can that begin with the given letter (F, A, or S) within a 1-min time period. Subjects are also instructed to exclude proper nouns, numbers, and the same word with a different suffix.

The COWAT and other measures of verbal fluency have proven to be sensitive indicators of frontal lobe dysfunction. In 1989, Jerry Janowsky, Arthur Shimamura, and Larry Squire found that patients with circumscribed left or bilateral frontal lobe lesions produced significantly fewer words than did control subjects. Other researchers found that left frontal lesions resulted in lower word production than right frontal ones. Similarly, regional cerebral blood flow findings have shown left-sided frontal activation during the performance of verbal fluency tasks.

Frontal lobe damage can also impair performance on visual or design fluency tasks. Design fluency tests were developed as visual analogs to verbal fluency measures such as the FAS. The subjects' task is to generate as many unique designs as they can within a given time period. Although the left prefrontal region appears to be specialized in using verbal material, Christina Elfgren and Jarl Risberg reported bilateral frontal lobe activation during the performance of visual generation tasks.

E. Planning

Patients with frontal lobe dysfunction have been reported to demonstrate impairments in the ability to plan. A wide spectrum of neuropsychological measures have been designed to assess numerous aspects of planning behavior. The Porteus Maze Test is a maze tracing task commonly used to assess planning and foresight. The subject's task is to trace the maze without entering any blind alleys. Performance level is usually measured on the basis of completion time and the test age level of the most difficult task the subject is able to successfully complete. In 1991, Harvey Levin and colleagues reported that patients with frontal lesions solved the Porteus mazes more slowly than severely injured nonfrontal head trauma patients and control subjects.

A number of tower puzzles have been designed to gauge more abstract forms of planning ability. Some of the most popular are the Tower of London, Tower of Hanoi, Tower of Toronto, and Tower of California. In all these tasks, the subject sees a set of pegs on which a number of beads or disks are placed in an initial starting position. The subject is instructed to move the disks to the appropriate pegs in order to reach a predetermined goal state. Two common test rules

include only moving one disk at a time and never placing a larger disk on top of a smaller disk.

In 1991, Tim Shallice and Paul Burgess found that patients with predominantly left anterior lesions performed more poorly on the Tower of London test than patients with posterior lesions and normal controls. Guila Glosser and Harold Goodglass reported similar results using the Tower of Hanoi: Patients with anterior lesions performed worse than the patients with posterior lesions.

Planning ability can also be measured by an individual's ability to prepare and execute target behaviors required for simulated real-life situations and events. In 1998, Eliane Miotto and Robin Morris developed the Virtual Planning Test with the intention of investigating the planning and organizational abilities of patients with frontal lobe neurosurgical lesions. The simulated planning tasks involved preparations for a fictional "trip" abroad or planning events that related to the subject's immediate environment. The frontal lobe patients were found to be impaired on this task and showed a tendency to select inappropriate activities associated with their immediate environment.

F. Memory

The frontal lobes play an important role in adequate memory functioning. Conventional research suggests that frontal lobe lesions do not produce a primary deficit in memory per se, but that they interfere with critical memory processes. Although encoding deficiencies can be observed in frontal lobe patients, they usually occur secondarily to executive functioning impairments. Thus, relatively speaking, frontal lobe damage does not significantly impair the ability to memorize material but does interfere with the ability to organize, attend to, and spontaneously retrieve information.

G. Retrieval

On measures of recent verbal memory, patients with frontal lobe impairment often demonstrate a pattern of poor recollection or retrieval of information in the context of relatively preserved recognition memory. In 1994, Donald Stuss and colleagues examined the memory abilities of patients with prefrontal, temporal, and diencephalic lesions. Patients with medial temporal and diencephalic lesions performed most poorly and did not improve with cueing. Patients with lateral temporal and prefrontal pathology scored worse in the free recall condition than the controls, but they improved with cueing. In addition, their recognition memory performance was relatively better than their free recall performance.

In 1995, Felicia Gershberg and Arthur Shimamura found similar results in their examination of free recall strategies in a group of patients with unilateral frontal lobe lesions. An example of a typical memory strategy is the rehearsal of associations between words presented in a list learning task. This kind of organizational ability is thought to require considerable executive control. As such, one would expect diminished use of such strategies on the part of patients with frontal lobe impairment. Consistent with their hypothesis, Gershberg and Shimamura found that the frontal lobe patients demonstrated impaired free recall ability and reduced use of subjective organization strategies. The frontal patients also benefited from strategy instruction (e.g., category cues) at either study or test, suggesting that both encoding and retrieval processes may be impaired by frontal lobe damage. Based on these findings, the authors suggested that retrieval impairments by patients with frontal lobe lesions might be partly due to deficits in the use of organizational strategies.

Impaired encoding and retrieval functions in prefrontal syndromes can also be related to deficits in working memory. Allan Baddeley uses the term "working memory" to describe the "scratch pad" of the human memory system—the place where information can be held and manipulated while new information is being processed. Researchers suggest that the prefrontal cortex plays a critical role in these complex working memory abilities. In support of this view, several functional imaging studies have reported activation of the dorsolateral prefrontal cortex during both auditory and visual mental working tasks.

H. Temporal Sequencing

Frontal lobe patients have also demonstrated deficiencies in their ability to integrate temporally separated events. Temporal sequencing can be tested by assessing an individual's ability to recall or recognize the temporal order of recently presented lists of words, abstract designs, or pictures. Patients with prefrontal cortex damage have been shown to demonstrate impairment in recalling the temporal order of such items but have no item recognition problems for the same list of words, designs, or pictures. In 1994,

Raymond Kesner, Ramona Hopkins, and Bonnie Fineman conducted a study in which a group of prefrontal cortex-damaged patients were tested for item and order recognition memory for spatial location, word, abstract picture, and hand position information. Compared to controls, frontal patients showed severe deficits on all order recognition tests. However, relative to controls, the frontal patients showed no deficits in their ability to recognize these same items with the exception of a deficit for hand position. With regard to laterality, order recognition memory deficits for spatial location occurred for right and bilateral but not left prefrontal cortex-damaged patients. Both right and left prefrontal cortex subjects showed order recognition memory deficits for words, abstract pictures, and hand position.

I. Source Memory

In addition to deficits in sequencing temporal information, patients with frontal lobe dysfunction have been reported to show deficits in identifying the source of their knowledge. Thus, an individual with source amnesia may be able to remember a fact but will forget where and when that fact was learned.

In a 1989 study, Jerry Janowsky and colleagues found that patients with frontal lobe lesions exhibited impaired source memory for facts acquired in a recent test session, even though their memory for the facts was normal. During the first phase of the experiment, subjects were asked to learn some general information facts (not known prior to the study session). After a 6 to 8 day retention interval, subjects were asked to answer some additional questions. Some questions were the previously nonrecalled items from the initial study phase, some were new items from the same level of difficulty, and others were easy questions that had not been presented previously. When subjects correctly answered a question, they were asked to recollect where and when the information had been learned. Compared to their age-matched controls, the frontal lobe group made significantly more errors by attributing learned information to an incorrect source. Results of this study suggest that the frontal lobes play an important role in one's ability to associate information in memory to the context in which it was acquired.

J. Autobiographical Memory

The active process of recollecting information from one's earlier life requires the use of executive abilities such as attention, flexible searching, and organization. Given the dysexective syndrome characteristic of frontal lobe patients, it is not surprising that individuals with prefrontal cortex damage occasionally exhibit impaired autobiographical memory. Assessments of autobiographical memory usually involve a lengthy series of questions covering the major periods of a typical life span (childhood, adolescence, and adulthood). Subjects are asked to describe specific events in great detail, including the dates and the importance of the events, and to indicate the names of friends and family members who may have participated in the events. For example, a subject may be asked to remember the date of his or her wedding or to provide the name of the preschool that he or she attended. The subject's family members later corroborate all reported information.

In a 1993 study, Sergio Della Salla and fellow researchers examined autobiographical memory retrieval in a group of patients with frontal lobe lesions. The battery of tests administered included an autobiographical memory enquiry and a series of executive functioning measures. Six of 16 frontal lobe patients were impaired on the autobiographical memory measure. Moreover, poor autobiographical retrieval correlated significantly with impaired performance on the executive functioning measures. Thus, impaired ability to retrieve information from autobiographical memory may have been related to the frontal lobe patient's inefficient organizational and searching ability.

K. Language

Frontal lobe lesions can result in a variety of language disturbances, including loss of grammar (aggramatism) and the production of unintended syllables, words, or phrases during speech (paraphasic errors). The following sections highlight some of the most extensively researched frontal lobe language disorders.

L. Broca's Aphasia

Broca's aphasia is one of the most commonly known syndromes of frontal language disorder. The core features of this syndrome include nonfluent, effortful speech production, semantic and phonemic paraphasias, articulatory errors, agrammatism, and relatively preserved comprehension. Widely accepted definitions of Broca's aphasia also include poor repetition, reading, and writing ability.

The lesion in classical Broca's aphasia involves the left posterior, inferior frontal gyrus. With the advent of sophisticated neuroimaging techniques, researchers have discovered that circumscribed damage to Broca's area does not necessarily result in the complete syndrome of Broca's aphasia. Moreover, some individuals with Broca's aphasia do not have lesions in Broca's area. Therefore, it seems that the underlying pathology in Broca's aphasia can be relatively extensive and varied. Regions including the inferior central Rolandic area, the insula, subcortical regions, and the anterior parietal regions have also been implicated in this language syndrome.

M. Pure Motor Aphasia

Verbal apraxia or pure motor aphasia refers to the articulatory and prosodic disturbance of language output in the absence of the agrammatic component. The underlying lesion is said to involve the left lower motor cortex and posterior operculum. Recently, Nina Dronkers emphasized the relationship between articulatory deficits and damage to the precentral gyrus of the insula.

This clinical syndrome is characterized by impaired articulation, slow and effortful speech, segmentation, phonemic paraphasias, dysprosody, and occasional hypophonia. The outcome for pure motor aphasia ranges from full recovery to a status of normal language with persistent dysarthria and/or dysprosody.

N. Transcortical Motor Aphasia

Transcortical motor aphasia (TCMA) involves lesions of the left frontal lobe–supplementary motor area (SMA), just anterior and superior to Broca's area. During acute phases, patients may initially present as mute but later develop a clinical profile characterized by normal repetition and comprehension, with limited, slow, and perseverative spontaneous speech.

Some researchers hypothesize that the SMA represents the "starting mechanism" or center for initiation of speech. Others suggest that damage to the SMA results in a lack of a plan or program to carry out voluntary speech. In their 1984 study, Morris Freedman and colleagues studied 15 patients with TCMA or near variants of the syndrome. Consistent with TCMA literature, these researchers concluded that small lesions to SMA cause a pure disorder of speech initiation. Furthermore, damage to fibers from SMA to premotor cortex may disconnect the limbic starter mechanism of speech from the cortical regions that control the motoric aspect of speech.

O. Frontal–Subcortical Aphasias

Language deficits can also result from lesions to frontal–subcortical brain regions. Lesions of the putamen and internal capsule will produce a nonfluent language disorder that at times resembles Broca's aphasia. In 1982, Margaret Naeser and her colleagues examined nine cases of subcortical aphasia with capsular/putaminal (C/P) lesions documented by computed tomographic scans. Patients with C/P lesion sites with anterior-superior white matter lesion extension had good comprehension, grammatical but slow dysarthric speech, and lasting right hemiplegia.

III. NEUROPSYCHIATRY OF THE FRONTAL LOBE

A. Personality

One of the most well-known early cases of behavioral change following frontal lobe damage is that of Phineas P. Gage. On September 13, 1848, this young man became a victim of a bizarre accident in which a tamping iron rod caused severe damage to his frontal lobes. Prior to sustaining this injury, Phineas was described as a reserved, intelligent, and responsible individual. Following the mishap, he transformed into an irreverent, irresponsible, and careless human being. This famous case and many modern counterparts that followed sparked considerable interest in the wide spectrum of personality changes seen in frontal lobe pathology.

The diminished capacity to modulate emotional behavior has frequently been associated with damage to the frontal lobes. In the context of traumatic brain injury, the changes customarily involve either an exaggeration or muting of emotions. In some cases, previously outgoing and sociable individuals become apathetic, emotionally flat, disengaged, and withdrawn. On the opposite end of the spectrum, patients can demonstrate uncharacteristically aggressive, impulsive, disinhibited, and socially inappropriate behavior. The apathetic syndrome has been localized to damage to the convexity and medial aspects of the frontal lobes, whereas the aggressive and disinhibited

syndrome has been attributed to the orbitofrontal regions.

A disturbance in self-awareness represents another common feature associated with frontal lobe damage. Deficient awareness may be reflected by the inability to appreciate performance errors on neuropsychological testing or to recognize the impact of one's impairments on others. Patients with compromised frontal lobe functioning have also been reported to demonstrate a failure to appreciate social and interpersonal norms. In an attempt to explain these deficits, some authors have suggested that frontal lobe pathology may actually impair an individual's personal consciousness or sense of self. Endel Tulving and colleagues used the term "autonoetic awareness" (awareness of oneself as a continuous entity across time) to describe this phenomenon. According to Donald T. Stuss, in this context disturbed self-awareness is "not lack of knowledge but impaired judgment of the objective facts in relation to one's own life."

IV. DISEASES OF THE FRONTAL LOBE

A. Frontotemporal Dementia

Frontotemporal lobar degeneration (FTLD) is a common cause of early onset dementia. There are three clinical syndromes that occur in FTLD: frontotemporal dementia (FTD), progressive nonfluent aphasia, and semantic dementia. The following sections are limited to a discussion of the core behavioral, neuropsychological, and pathological features of FTD.

1. Behavioral Features of FTD

The early stage of FTD is characterized by marked changes in personality and behavior. Patients typically become disinhibited, apathetic, and irritable. Gross disinhibition often leads to impulsivity, increased aggressiveness, and antisocial behavior. Antisocial acts can range from inappropriate comments to various forms of criminal behavior. In a 1997 study, Bruce Miller and colleagues compared the presence of antisocial conduct in FTD versus Alzheimer's dementia (AD) patients. Almost 50% of the FTD patients were involved in behaviors such as stealing, physical assault, public urination or masturbation, and unethical job conduct. In contrast, only one of the AD patients manifested these types of behaviors.

According to the FTD consensus criteria proposed by David Neary and colleagues in 1998, declines in social graces and decorum are commonly manifested in tactlessness and a loss of interpersonal etiquette and social awareness. For example, FTD patients often demonstrate increased talking, inappropriate laughter, singing, and invasion of personal space. Improper hygiene, grooming, and other aspects of personal awareness are also observed. These deficits in social and personal awareness are further complicated by the FTD patients' lack of insight into their behavioral disturbance and its impact on others.

FTD patients often lack empathy and are typically described as emotionally indifferent and apathetic. Some patients become self-absorbed and exhibit less concern about the welfare of friends and family members. Other characteristic affective symptoms in FTD include depression, anxiety, and psychotic features. Patients with FTD can also demonstrate hyperorality and dietary changes. Hyperorality may manifest in overeating, bingeing, and excessive consumption of liquids and/or alcohol. Some patients develop a strong preference for sweets and may also place inanimate objects in their mouths.

FTD patients progressively develop changes in speech production and structure. During the early phases of the disease patients may demonstrate excessive talking, frequent use of stereotyped phrases, and echolalia. Later stages may be characterized by mutism.

2. Neuropsychological Features of FTD

According to the 1998 consensus criteria proposed by David Neary and colleagues, the neuropsychological profile for FTD is characterized by significant impairments on frontal lobe measures in the context of relatively preserved memory, language, and visuospatial skills. Frontal lobe measures are tests designed to assess executive functioning abilities, such as planning, mental flexibility, verbal fluency, abstraction, and the ability to inhibit responses to overlearned patterns of behavior. Popular standardized neuropsychological measures of executive functioning include the WCST, Stroop Test, and Trail Making Test.

A number of studies have examined the patterns of executive functioning deficits found in FTD. In a 1996 investigation, Nancy Pachana and colleagues documented the neuropsychological changes that distinguish FTD patients from AD patients. They found that AD patients exhibited relatively greater

impairment on memory than executive tasks, whereas the FTD group showed the opposite pattern.

FTD patients may perform poorly on measures of recent memory, language, and visuospatial tasks. However, these deficits are thought to occur secondarily to executive dysfuntion, such as inattention, inefficient organizational strategies, and poor self-monitoring. For example, on measures of recent verbal memory, FTD patients tend to have difficulty spontaneously recalling information (free recall), whereas their ability to recognize these same items is relatively preserved.

3. Pathological Features of FTD

According to the pathological criteria proposed by Arne Brun and colleagues in 1994, FTD results from bilateral and for the most part symmetrical distribution of pathology in the frontal and anterior temporal lobes. Upon inspection, mild atrophy of these brain regions is commonly observed. At the microscopic level, a degenerative process is noted in the frontal or frontotemproal cortex, characterized by microvaculation (spongiosis), neuronal loss, and gliosis. The presence of argyrophillic, ubiquitin positive inclusion bodies (Pick bodies) and swollen, achromatic neurons (Pick cells) can also be observed. The clinical syndrome of FTD can be seen with and without the presence of Pick bodies and Pick cells.

B. Traumatic Brain Injury

Brain damage following traumatic brain injury, particularly closed head injury (CHI), frequently involves the orbital and polar aspects of the frontal lobes. Commonly observed behavioral features of CHI following frontal lobe damage include posttraumatic amnesia, attentional deficits, and changes in personality. Posttraumatic amnesia (PTA) is thought to result from a disconnection or damage of the basal forebrain and orbitofrontal cortex. PTA usually occurs during the period of acute recovery following a severe head injury. Patients typically experience confusion and disorientation, and tend to confabulate, and have difficulty learning and remembering information. The duration of PTA usually depends on the severity and the outcome of the brain injury.

Attentional deficits are a relatively common behavioral consequence of severe head injury. Distractibility, problems with concentration, inability to focus, and an overall slowing are commonly reported complaints. Attention is considered a complex cognitive process composed of a number of components, including phasic alertness, selective attention, and sustained attention. Several studies of CHI patients suggest that individual attentional components can be selectively impaired following frontal lobe damage. For example, investigators have linked the midfrontal regions to deficits in sustained attention. Others attribute impairments in selective attention to damaged frontal–thalamic and subcortical structures.

Traumatic brain injuries that damage the frontal and temporal lobes can also result in profound changes in personality and social adjustment. Victims of traffic and other common head injury accidents frequently exhibit reduced drive, decreased awareness, blunted affect, and a lack of initiative. This apathetic syndrome is attributed to damage of the medial frontal lobes. Closed head injuries can also produce what is described as a euphoric syndrome, characterized by impulsivity, sexual disinhibition, socially inappropriate behavior, and aggressiveness. The orbitofrontal regions have been implicated in this class of personality deficits.

Functional Magnetic Resonance Imaging (fMRI)

ROBERT L. SAVOY
MGH/MIT/HST Athinoula A. Martinos Center

GLOSSARY

block design Experimental design for functional neuroimaging in which an attempt is made to put the subject's brain in a steady state of activity by using the same type of task for an extended period of time (typically 20–60 sec) and then comparing the brain activation during that block with other blocks that use a different task.

blood oxygen level dependent (BOLD) Refers to a general method of magnetic resonance imaging (MRI) for detecting changes in the nuclear magnetic resonance (NMR) signal that are caused by the varying concentration of deoxyhemoglobin, locally, in the blood near a part of the brain.

event-related design Experimental design for functional neuroimaging in which individual, brief (typically 1–2 sec in duration) stimuli of different types are presented in random order, and where the evoked responses for many such trials of a given type are averaged together to detect a measureable response.

flow via alternating inversion recovery (FAIR) Refers to a specific method of MRI for detecting changes in the NMR signal that are caused by the varying flow, locally, of blood in arteries near a part of the brain.

functional magnetic resonance imaging (fMRI) The use of MRI to detect changes in blood flow and blood oxygenation associated with local changes in neuronal activity in the brain.

gradient magnets Part of the technology of MRI used for supplying strong, operator-controlled linear gradients of magnetic field to enable the generation and detection of the NMR signal associated with a specific point in three-dimensional space.

hemodynamics Changes in the properties (volume, flow rate, and chemical composition) of blood over time.

magnetic resonance imaging (MRI) The use of a variety of operator-controlled electromagnetic fields to generate a NMR signal that can be associated with a particular point in space.

nuclear magnetic resonance (NMR) The physical phenomenon of absorption and reemission of electromagnetic energy associated with the quantum mechanical spin and magnetic field of the nuclei of some atoms.

principle component analysis (PCA) The re-representation of multidimensional data into a collection of components (sometimes called eigenimages and eigenvectors) via an algorithm that accounts for the most variance by the first principal component, the second most by the second component, etc.

retinotopy The regular spatial arrangement of the receptive fields of cortical neurons in many parts of the visual cortex that follows, in a systematic way, the two-dimensional spatial arrangement of the retina.

talairach coordinates The most widely used convention for orienting and scaling human brains to facilitate the averaging and/or comparing of data across multiple subjects.

Functional magnetic resonance imaging (fMRI) refers to the use of the technology of magnetic resonance imaging (MRI) to detect the localized changes in blood flow and blood oxygenation that occur in the brain in response to neural activity. This article presents the basics of fMRI-based research, including the physical and biophysical bases of the signals, the current

developments in experimental design and data analysis, and other practical considerations attendant to the technique, and also provides an overview of the broad range of scientific and clinical questions to which fMRI is being applied.

I. INTRODUCTION

It has long been known that there is some degree of localization of function in the human brain, as indicated by the effects of traumatic head injury. Work in the middle of the 20th century, notably the direct cortical stimulation of patients during neurosurgery, suggested that the degree and specificity of such localization of function was far greater than had earlier been imagined. One problem with the data based on lesions and direct stimulation was that the work depended on the study of what were, by definition, damaged brains. During the second half of the 20th century, a collection of relatively noninvasive tools for assessing and localizing human brain function in healthy volunteers led to an explosion of research in what is often termed "brain mapping." The tool that has been developing the most rapidly, and the tool that currently supplies the best volumetric (three-dimensional) picture of activity in the human brain, is fMRI.

Functional MRI uses the physical phenomenon of nuclear magnetic resonance (NMR) and the associated technology of MRI to detect spatially localized changes in hemodynamics that have been triggered by local neural activity. It has been known for more than 100 years that neural activity causes changes in blood flow and blood oxygenation in the brain, and that these changes are local to the area of neural activation. Techniques using radioactive tracers were developed in the mid-20th century to detect metabolic activity correlated with neural activation and to detect blood volume changes correlated with neural activation. In the early 1990s the technique of MRI was successfully adapted to measuring some of these effects noninvasively in humans. The development of fMRI led to a dramatic increase in neuroscience research in human functional brain mapping across the spectrum of psychological functions—from sensation, perception, and attention to cognition, language, and emotion—in both normal and patient populations.

Functional MRI makes the future of functional brain imaging particularly exciting for at least three reasons. First, fMRI does not involve ionizing radiation, and therefore it can be used repeatedly on a single subject and even on child volunteers. This permits longitudinal studies and it permits improvement in signal-to-noise ratios if the task being used elicits the same general response when repeated multiple times. Second, technical improvements in fMRI (due to more powerful magnets, more sophisticated imaging hardware, and the development of new methods of experimental design and data analysis) promise to yield improvements in spatial and temporal resolution for the technique. Third, there is a growing effort to integrate the findings based on fMRI with those from other techniques for assessing human brain function, such as electroencephalography (EEG) and magnetoencephalography (MEG), which inherently have much greater temporal resolution. It is likely that major advances in functional brain imaging will be made in the near future, but the associated technologies are complicated. In particular, to understand the technique of fMRI, one must consider a collection of interrelated issues, from physics and physiology to the practicalities of experimental design, data analysis, safety, and costs.

II. PHYSICS AND PHYSIOLOGY

MRI operates by creating and detecting a signal generated by the physical phenomenon of NMR. Although an in-depth explanation of the physics of NMR and the technology of MRI is beyond the scope of this article, a basic understanding of how a MR scanner operates is useful in discussing fMRI in its applications to psychology and medicine. The following discussion is based on a description of the "classical electrodynamics" picture of NMR and MRI. A more rigorous and complete treatment of NMR would require quantum mechanics, but MRI is best understood in terms of classical electrodynamics.

A. The NMR Signal

To begin an MRI session, the subject is placed horizontally into the bore of a high-field magnet. In a typical clinical MRI system this magnet has a field strength of 1.5 T. A small fraction of the hydrogen nuclei (single protons) of the water molecules in the body of the subject become aligned with the field of this magnet. (Many other atoms and nuclei with magnetic moments are also aligned, but for the purposes of this article and almost all fMRI applications, it is the hydrogen nuclei of water molecules that are the source

of the signal.) The hydrogen nuclei are oriented in a random collection of directions, relative to the main magnetic field, but there is a small statistical preference to have the longitudinal component of their orientations (i.e., the component in the direction of the main magnet) to be aligned with the main field. To the extent that a proton is not perfectly aligned with the main magnet, it will precess (spin) around the orientation of the main magnet. However, because the orientation of each proton is random (except for the component along the direction of the main field), and because it is only the randomly oriented transverse components (i.e., the components perpendicular to the main field) that generate a signal, the collection of spinning protons do not yield a net, detectable magnetic field.

Application of a radio frequency (RF) pulse of magnetic energy, presented at the frequency of the precession (i.e., the resonant frequency), causes all the hydrogen nuclei to change orientation (nutate). By controlling the power and duration of the RF pulse, the nuclei can be rotated to any desired angle relative to the main magnetic field. Typically, the parameters of the device are set so that the protons are rotated 90°. When the protons continue to precess in this new orientation, the net magnetic field that was originally induced in the body by the main magnet, and that was previously aligned with the main magnet, is now oriented 90° away and thus generates a detectable, changing magnetic field as it spins (precesses). A coil of wire around the subject will have a current generated within because of the changing magnetic field (Faraday's law). This current is the raw signal detected in a MRI scanner (Fig. 1).

B. Relaxation

The signal thus generated decays exponentially over time due to a number of processes. If the raw, exponential decay of the signal is measured (without doing anything else to create images), the process takes about 100 msec and the exponential time constant associated with that decay is conventionally called "T2*" (read "tee-two-star"). This decay in the measured signal is driven by a number of different physical processes.

First, the protons slowly (on the time scale of seconds for most brain tissue) realign with the main magnet. This is called longitudinal relaxation, and the time constant associated with this exponential process is called T1. Second, the signal generated by the collection of precessing protons is weakened by the fact that each individual proton experiences a slightly different *local* magnetic field due to interactions with nearby water molecules and other biological tissues and thus precesses at a slightly different frequency from its neighbors. With time (typically on a scale of tenths of seconds for most brain tissue) these protons get out of phase so that their respective magnetic fields are no longer lined up and therefore do not generate a detectable, macroscopic signal in the surrounding coil of wire. This is sometimes called the spin–spin component of transverse relaxation because it is based on the interaction of the spins (which imply magnetic fields) of nearby nuclei. If the magnetic field were perfectly uniform, then the net decay rate of the signal would be given by the exponential decay rate T2, which is driven by the combination of spin–spin transverse relaxation and the T1 longitudinal component. In the brain tissue of interest, T2 is almost entirely determined by the spin–spin relaxation.

In reality, there are other sources of magnetic field nonuniformity. Imperfections in the main magnet, variable magnetic susceptibility of the differing parts of the human body that has been inserted into the magnet, and changes in blood chemistry caused by externally injected "contrast agents" all contribute to nonuniformities in the magnetic field experienced by the precessing protons. Most important for fMRI, some chemicals that occur naturally in the body also distort the magnetic field. Deoxyhemoglobin is such a molecule, and as its local concentration is varied, the amount of distortion also varies. The rate of exponential decay of the NMR signal is influenced by all of these factors (Fig. 1).

C. Creating an Image

The preceding description yields a single number: T2*, the decay rate of the net NMR signal. This signal is conventionally called the free induction decay (FID) of the NMR signal because it is elicited when nothing else is done to the protons—that is, if the system were left free to decay at its own rate. However, this signal represents the net effect of inducing an NMR signal from the *entire volume of tissue* being subjected to the main magnet and the orientation-flipping RF pulse. To create an *image* in which different NMR signals are measured for different points in the three-dimensional volume, nonuniform magnetic fields are applied intentionally. The basic idea is to use linear magnetic field gradients, applied at various times and in various orientations, to distinguish the NMR signals arising

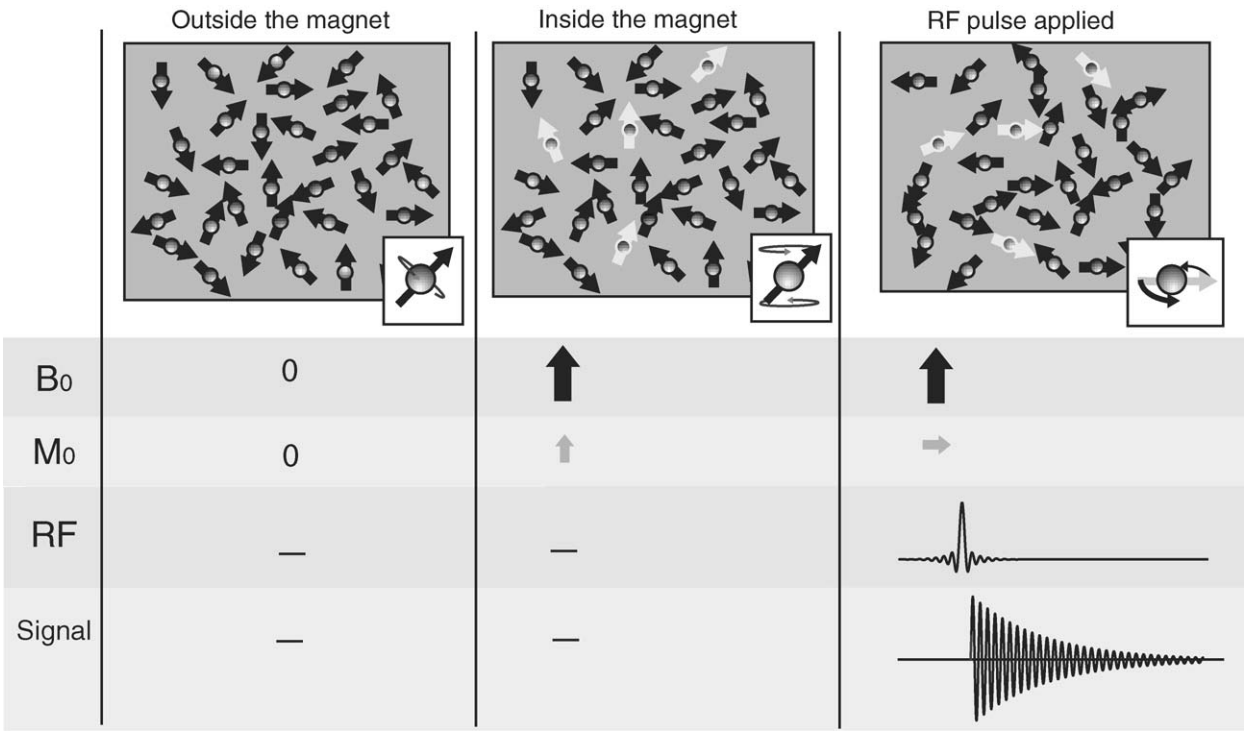

Figure 1 The basics of the NMR signal. The discussion of Section II.A is represented here in a simplified, cartoon form, with the story proceeding from left to right. Protons can be thought of conceptually as positively charged spheres that are always spinning, and this spin about an axis gives the proton an inherent orientation as well as a net magnetic moment along the axis of the spin. Before entering the magnet, the protons (with their magnetic field and spin direction indicated by arrows) are randomly oriented. There is no main field surrounding the body (B_0=0) and there is no induced field within the body (M_0=0). The body is placed in the main magnet ($B_0 \gg 0$). All the protons immediately start processing in a direction around B_0, but because the orientation and phases are random there is no net signal. After a few seconds, a small fraction of the protons change orientation to line up with B_0, which results in the creation of a net magnetic field in the body ($M_0 > 0$) oriented in the same direction as B_0. The individual protons are still precessing, now with a common net orientation, but the components of that rotation perpendicular to B_0 are still random so there is no detectable signal. A radio frequency (RF) pulse is applied for a brief period of time, causing all the protons to change their orientation by 90° so that the net induced magnetic field M_0 is now perpendicular to B_0. Now the individual precessing protons are aligned in such a way that the common component of orientation (M_0) goes around B_0 in a perpendicular direction and generates a macroscopically detectable current—the signal. The strength of that signal decreases exponentially with time for a variety of reasons described in Section II.B.

from different points in the three-dimensional volume. (The application of these nonuniform magnetic fields causes the raw NMR signal to decay even more rapidly than the FID, but the signal can still be measured, and various procedures can be used to create "echos" that enable the recovery of more information.)

The technology of MRI is based on the flexible (but complicated) application of multiple RF pulses and multiple gradients, synchronized precisely (and typically described in a pulse sequence diagram). The pulse sequence diagram indicates how a given slice of the brain is selected for imaging, how individual volume elements (voxels) are detected within each slice, and how the resulting signals are preferentially selected to obtain information about arterial blood flow or about the concentration of deoxyhemoglobin in venous blood flow. Some imaging pulse sequences use multiple RF-pulses in the generation of NMR signals that will yield a single plane of imaging data. Some imaging pulse sequences [such as echo-planar imaging (EPI)] generate data for an entire plane from a single RF pulse. EPI is rapid (with an entire plane collected in less than 50 msec), but it is associated with more expensive hardware and various limitations in spatial resolution or susceptibility to imaging artifacts and distortions.

D. Contrast in an Image

As with any imaging modality, the key variable in producing a meaningful image is contrast. The signal measured at one point in space or time must be higher

or lower than the signal at another point, and the variation in signal intensity across the image should systematically follow some variable of interest. In the endeavor of brain mapping, the ultimate variable of interest is neural activity. In order to measure local brain activity with MRI, one must exploit a chain of indirect linkages from neural activity (a constellation of electrical and chemical events) to changes in brain physiology and metabolism and finally to changes in the magnetic properties of substances within the brain.

Anything that causes a change in the NMR signal from a given voxel relative to other voxels at the same time is a source of *contrast* in the image. The density of protons in a given voxel (due to chemical composition) is one such source of contrast, though not an important one in fMRI. More commonly, it is the variation in rates of relaxation from voxel to voxel that generates contrast in the image.

In the earliest fMRI studies, exogenous contrasts (chemicals injected into the bloodstream of the subject) were used to obtain contrast. These blood-borne chemicals locally distorted the magnetic field, thus allowing increased blood perfusion to be detected. Subsequent studies demonstrated that endogenous contrast agents (i.e., naturally occurring molecules in the body, such as the concentration of deoxyhemoglobin in the blood) could also yield sufficient contrast between different states of neural activity. The use of endogenous contrast agents obviated the need for injecting foreign molecules into the bodies of normal (healthy) subjects, and this is one of the key reasons that fMRI has become so popular as a technique for assessing human brain function. In the short history of fMRI, a wide variety of techniques that produce various contrasts have been developed for detecting changes in brain physiology.

E. Neural Activation MRI

When neurons are active in the brain, there is an increase in blood flow and blood volume local to that region of activity. MRI can be used to detect the change in blood flow directly. The idea is that when fresh blood flows into the slice of the brain that is being imaged, it will have a different "spin history" (i.e., it will not have recently been hit by an orientation-flipping RF-pulse) and will thus have a greater degree of alignment with the main magnet. When another RF pulse is applied, the fresh blood will have a greater concentration of aligned protons to flip and will thus yield a greater NMR signal. The imaging of this signal happens on a timescale that is rapid with respect to the blood flow, so the change is detected. This phenomenon is the basis for one kind of imaging in fMRI. It is largely sensitive to changes in arterial blood flow (where flow is the fastest).

There is a second, and more commonly used, process that yields an fMRI signal. The neural activity that elicited the local increase in blood flow and blood volume surprisingly does not elicit a correspondingly great increase in oxygen utilization. That is, although the neural activity leads to a small increase in oxygen utilization, it is dwarfed by the increase in blood flow. Thus, there is an increase in oxygenated hemoglobin in the venous portion of the circulatory system near the site of neural activity (as well as downstream from that site). The combination of increased oxygenated hemoglobin and increased blood flow results in a *decrease* in the instantaneous concentration of deoxygenated hemoglobin on the venous side of the capillaries. Deoxygenated hemoglobin (unlike oxygenated hemoglobin) is a strongly paramagnetic biological molecule, and it distorts the magnetic field locally. Thus, a *decrease* in the local concentration of deoxyhemoglobin leads to a *more* uniform magnetic field locally and to a longer time period during which the orientations of precessing protons stay in phase. Thus, the NMR signal in a region of decreased deoxyhemoglobin concentration *increases* relative to its normal (neuronally resting) state. This phenomenon is called the blood oxygen level dependent (BOLD) effect. It is the major source of contrast in most fMRI experiments.

F. Other Technical Issues in MRI

Operationally, fMRI differs from conventional MRI in two basic respects. First, it is tailored to be sensitive to contrasts in blood flow and/or oxygenation that reflect neural activity. Second, it is typically conducted with special hardware that permits the very rapid variation of the magnetic field gradients that are needed to create images. This permits much more rapid acquisition of whole-brain volumes than is conventionally done in MRI. This rapid data collection is crucial in most modern fMRI-based experiments.

Functional MRI is made practical and powerful by virtue of special pulse sequences (such as echo planar and spiral scanning) and hardware that permit the encoding of a brain slice while using a single RF pulse, allowing the entire brain to be imaged in a few seconds. A wide variety of different pulse sequences are used in fMRI, and this remains an area of continuous

innovation. Moreover, the versatility of MRI for neuroscience extends beyond fMRI, and MR can also be used to assay various aspects of brain chemistry through a technique known as magnetic resonance spectroscopy (MRS). Because some variants of MRS can measure the presence of brain metabolites at temporal resolutions on the order of minutes and spatial resolutions similar to those of BOLD fMRI, MRS is in many ways conceptually related to fMRI.

G. Summary

A strong, spatially uniform magnetic field aligns a small but significant fraction of the hydrogen nuclei of water molecules in the brain. A carefully controlled sequence of gradient fields and RF pulses is used to generate NMR signals that can be reconstructed to form a three-dimensional image in which contrast is dependent, in part, on the blood flow and/or oxygenation changes caused by neural activity. Thus, MRI can be used noninvasively to detect changes in local neural activity in the human brain.

III. EXPERIMENTAL DESIGN

Designing experiments for fMRI-based studies presents unique opportunities and challenges. First, fMRI [like position emission tomography (PET) using O^{15}] depends on the indirect signals generated by hemodynamic changes (i.e., changes in blood flow and/or blood chemistry) rather than the more direct electrochemical changes associated with neural activity. Second, there are numerous technical challenges that follow from the particular physics of MRI when used for high-speed imaging of the human brain. Third, there are a number of practical considerations associated with both safety and the physical requirement for minimum movement of the subjects in fMRI studies that add to the challenges of fMRI experimental design. All these factors affect (and, in turn, are affected by) the current practical and future potential limits of spatial and temporal resolution associated with fMRI. Finally, as with any experimental approach to important questions concerning human psychology, the most fundamental and difficult problems arise in choosing tasks and stimuli that allow one to be convincing to one's self and to one's audience that the psychological question being asked is truly addressed by the experiment being performed. Can you convince your audience, for example, that when you use fMRI to measure changes in brain activity during the color Stroop task you are actually studying some general attribute of inhibition and higher cognitive function?

A. Experimental Design and Hemodynamics

Functional MRI is dependent on hemodynamic changes rather than the electrical consequences of neural activity. The spatial and temporal characteristics of these hemodynamic effects must be taken into account when designing experiments and analyzing the data from these experiments. The spatial characteristics arise from the underlying vasculature; the temporal characteristics include a delay in the onset of detectable MR signal changes in response to neural activity and a dispersion of the resulting hemodynamic changes over a longer time than that of the initiating neural events.

With regard to the temporal aspects of the hemodynamics, fMRI experiments can be classified into two broad categories: block designs and event-related designs. In block designs, the experimental task is performed continuously in blocks of time, typically 20–60 sec in duration. The idea here is to ignore the details of the temporal characteristics by virtue of setting up a "steady state" of neuronal and hemodynamic change. The fact that there is a brief delay before the MR signal changes are detected is often unimportant when analyzing a long block of steady-state activity. This approach is conceptually simple; it is analogous to older PET experimental designs, and it is of great practical importance for fMRI because it is the optimal technique for *detecting* small changes in brain activity. The major weakness of block design is the requirement that all the stimuli or task characteristics remain unchanged for tens of seconds, precluding the use of many classic psychological paradigms (such as the "oddball" scheme).

The other major approach, event-related design, makes use of the details of the temporal response pattern in the hemodynamics as well as the largely linear response characteristics associated with multiple stimulus presentations. In event-related designs, the different stimuli are presented individually in a random order (rather than in blocks of similar or identical stimuli) and the hemodynamic response to each stimulus is measured. Event-related designs are further subdivided into spaced single-trial designs and rapid single-trial designs. In spaced single-trial designs, stimuli are presented with a long interstimulus interval

(ISI) relative to the hemodynamic response to a single stimulus. Specifically, an ISI of at least 10 sec, and more typically 12–20 sec, is used in an effort to allow the hemodynamic response to each stimulus to return to its resting state before the next stimulus is presented. This approach is conceptually simple but very inefficient in its use of imaging time, much of which is spent collecting data when the MR signal variation due to hemodynamcs is small or not detectable. (This is not only wasteful of expensive imaging time but also boring for the subject, who is only doing something approximately once every 15 sec.)

In contrast to *spaced* single-trial designs, *rapid* single-trial designs take advantage of the linearity and superposition properties of the hemodynamic responses to neural activity. To a first approximation, the hemodynamic changes associated with multiple stimulus presentations are additive and when presented at different times, are simple time shifts of each other. This permits the much more efficient design of experiments in which novel stimuli appear in quasi-random order and with variable ISIs (typically presenting a new stimulus every 1–3 sec). The associated data analysis is more difficult because the hemodynamic responses to the different stimuli overlap in time (and there are consequent weaknesses relative to block designs in terms of the detection of small effects) but the rapid single-trial designs are particularly powerful and useful when it is essential to have random order in the presentation of individual stimuli (i.e., in the situation in which a block design with long periods of the same type of stimulus would not permit the desired comparisons for neural activations). It is also more efficient in the use of imaging time and more engaging (less boring) for the subject.

One final approach to experimental design should be mentioned. All of the previously discussed techniques typically make use of averaging over multiple instances of a given trial type. In block design the trials all occur together, so the averaging is done as much by the hemodynamic and neural systems as by any data analysis software. In event-related designs the averaging over the effects of multiple stimulus presentations is done explicitly in software during data analysis. It is possible, however, to analyze spaced single-trial data on the basis of activation from a *single event* (rather than averaging over multiple instances of the same trial type). This technique has not been widely applied, primarily because the elicited signals to single stimulus events are generally weak. However, high-field MRI systems, and the selection of experimental paradigms that elicit strong, focal neural activity, have been used to demonstrate the feasibility of single-event fMRI.

B. Spatial and Temporal Resolution in High-Speed MRI

The physiology of the circulatory system and the physics of the MRI devices constrain the spatial and temporal resolution of fMRI. Today, it is routine to obtain $1 \times 1 \times 1$-mm structural MR images and $5 \times 5 \times 5$-mm functional MR images. The temporal resolution of fMRI is on the order of 1–3 sec. Neither the spatial nor the temporal resolution numbers are indicative of absolute limits in terms of the physiology or the imaging hardware. Rather, they represent a snapshot in the development of ever-improving resolutions. Moreover, at any give stage of technical development in MRI, the various imaging parameters can be manipulated to emphasize one aspect of resolution in exchange for another.

When investigators approach experimental design in fMRI, they must recognize that the key physical variables—spatial resolution, temporal resolution, brain coverage, and signal-to-noise ratio—are quantities whose values can be manipulated by trading one off against the others. For example, extremely high spatial resolutions are possible, but the techniques needed to achieve them involve reduced temporal resolution, limited brain coverage, and/or decreased signal-to-noise ratio. Alternately, extremely rapid imaging can be performed, but at the cost of spatial resolution and/or brain coverage. Trade-offs will continue to exist even as the overall power of scanning technology improves.

As an indication of the numbers associated with these issues, and the manner in which they are changing, consider the issue of the rate at which individual images can be collected. The first whole-body high-speed (EPI) fMRI system could collect 20 images per second for about 1 min, and then it would overheat. At a slower operating rate of 10 EPI images per second (which was still very fast in 1992), there was no overheating, but the subject (in an fMRI experiment) had to wait a long time between scans for reconstruction of the images from the raw data. At an even slower rate of 5 EPI images per second, the scanner could operate continuously and reconstruct the images in real time, but the memory for buffering those images would fill after about 2000 images. In contrast, modern machines can operate at 20 images per second continuously.

Analogous improvement is ongoing in all of the mentioned domains. Higher field MRI (from 3 to 8 T) will improve spatial resolution and will yield the added signal that may improve the practicality of single-event fMRI designs and the possible use of the "initial dip" in oxygenation to improve temporal resolution. However, these high-field machines are not as widely available as 1.5 T machines, and they are considerably more expensive, difficult, and dangerous to use.

Currently, the message for experimental design is simply that these resolution limits must be taken into account. There is little point to designing a conventional experiment to detect changes in a structure that is much smaller than one's spatial resolution permits, nor in designing a study that requires the detection of temporal changes that are too rapid for one's current technology. At the same time, because these imaging parameters can be traded off, one should not dismiss difficult-sounding experiments too quickly.

C. Practicalities: Psychophysiological Laboratory in the Magnet, Safety, and Costs

The physical properties of MRI, as well as the financial costs, place a number of practical constraints on the design and execution of fMRI-based studies and thereby impact experimental design.

As indicated previously, the experiments take place in the bore of a large, powerful magnet. The presence of this large, static magnetic field precludes the participation of subjects who would be adversely affected by it. For example, subjects with pacemakers or other forms of implanted metalic devices that would be subjected to strong forces by the magnet are clearly ineligible. The fact that subjects must lie in a relatively confined space rules out volunteers who suffer from claustrophobia. The physical position and limitations of the subject's movement also constrain various experimental procedures that would be simple in an ordinary behavioral laboratory (Fig. 2).

In addition to the main, static magnetic field, there are strong varying electromagnetic fields from the gradient magnets (for generating images) and from the RF oscillator (for flipping the protons to obtain the NMR signal). Each of these fields has associated safety considerations. For the most part, this is a minor issue at 1.5 T. It can be more of an issue for some pulse sequences at higher fields. The manufacturers of MRI scanners are required to build in various safety measures to protect subjects (such as calculating the heating effects of the RF pulses for a person of a given size and weight). Nonetheless, each imaging facility normally includes a screening form (and sometimes a metal detector) to prevent the inadvertent harming of subjects from a collection of (sometimes not so obvious) potential dangers.

In addition to these safety considerations, the physics of MRI has other practical consequences. All of the devices used to present stimulation (visual, auditory, etc.) and to obtain behavioral and physiological response measures (button pushes, breathing and heart rate, etc.) must be constructed in an MR-compatible manner. As fMRI has become a more widespread enterprise, various companies have made it a business to supply such equipment. However, custom design of devices for specialized experiments is still common.

The single most vexing problem in the practical application of fMRI is head movement. Although pulse sequences have been developed to collect an entire slice of brain data in less than 50 msec, and multiple slices (for entire brain coverage) can be collected in 2–3 sec, the amount of information in each such image is limited. That is, the amount of *functional contrast* in the images—the differences in the signals between two experimental states—is small. To make up for this, many images are collected over extended periods of time—at least minutes and sometimes hours. During these time periods it is important that the subject's head move as little as possible.

A variety of techniques are used to encourage subjects to keep their heads as motionless as possible, but none is perfect. For well-motivated healthy adult subjects, this is usually not an insurmountable problem. For children and older patient populations, it can be the main reason that data are discarded. Although there are data analytic procedures for transforming images of moving heads back to a fixed position, these procedures are limited. Indeed, because the moving head actually distorts the main magnetic field in different ways, no motion correction algorithms can fix the problem perfectly. There are many extra coils in an MRI scanner that are used to make the main magnetic field as uniform as possible, despite the irregularities introduced by the presence of a human head in the bore of the magnet. These "shimming" coils are supplied with electric current designed to minimize the magnetic field distortions introduced by the head at the beginning of a scanning session. However, they are not modified on the fly, during the session, so any subject head movement results in more than just a displacement of the image; it also causes distortions that are much more difficult to correct.

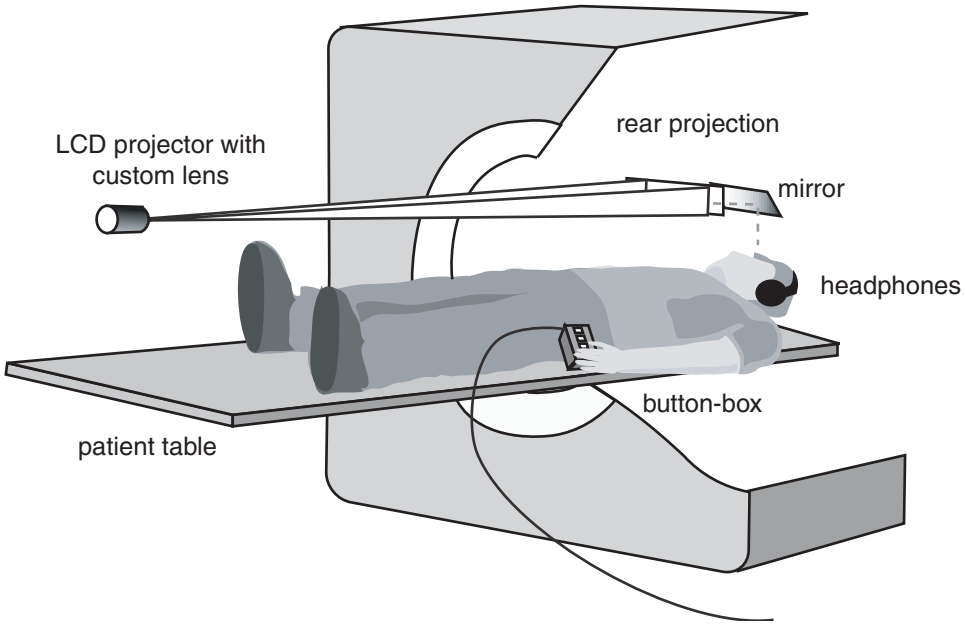

Figure 2 Subject in the magnet. Functional MRI is conducted in the environment of a MRI suite. There are many ways to present stimuli and obtain responses from the subject in such a suite, but all must be compatible with the difficult and hostile electromagnetic environment of MRI. In the example shown, visual stimuli are projected onto a rear-projection screen and are viewed by the subject via a mirror. Auditory stimuli can be presented via MR-compatible headphones or by the speaker systems typically included in MRI scanners. Finally, subject responses can be collected using an MR-compatible button box. A variety of commercial and custom approaches to the problems of presenting stimuli and recording responses in fMRI have been developed.

Finally, it should be noted that MRI time is not cheap. Charges for an hour of clinical imaging are in the hundreds of dollars. Therefore, when designing a study, the total number of imaging minutes is one of the parameters that must also be considered in the trade-offs.

D. Comparing Activation States

Fundamental to the understanding of fMRI as a tool for representing the localization of brain function is the idea that a single image, in isolation, conveys little if any useful information. Rather, it is the comparison of multiple images that are collected during different states of neural activity that supplies interpretable data. Note that this statement is *not* true for structural MR images. A single structural image conveys a great deal of useful information because data about *change* is not sought (except on a much longer timescale, as in developmental and longitudinal studies of brain structure). In contrast, functional imaging data are almost exclusively about *changes* in neuronal activity.

One might ask, Why isn't a single image, collected during rest, a useful definition of the "resting," "neutral," or "idling" state of the brain? In some ways, a single image might be interpretable this way. Indeed, some variants of PET can be used to yield a single snapshot of the metabolic state of the brain. However, the variation in local activity in the brain during "rest" is not very meaningful—the demonstration that one portion of the brain is more active during rest than another has limited value. On the other hand, the demonstration that a particular manipulation (of the stimulus or task requirements for the subject) causes a localized change in neuronal activity is far more useful.

The art of fMRI experimental design lies largely in the creation of tasks that accurately probe the cognitive function of interest. One natural way to design an experiment in functional neuroimaging is to create two tasks that are identical except for one minor difference. This is the basis of the classic subtraction method originally delineated by Donders and widely used in cognitive research. Such experimental designs are sometimes called "tight" task comparisons. The difference between experimental conditions in a tight task comparison is either in the *stimulus alone* (while keeping the response task of the subject fixed) or in the *response task alone* (while keeping the stimulus fixed).

Such an approach is particularly useful for testing specific hypotheses about the activation pattern in a single brain region.

However, there are practical and theoretical reasons for including experimental conditions that are more broadly different from the main conditions of interest. Frequently, this is accomplished via the use of a low-level control task, such as simple visual fixation or rest. This has sometimes been called a "loose" task comparison. It is particularly useful for seeing the simultaneous activation of many areas of the brain. The loose task comparison not only provides an internal check for the integrity of the data collected (because it typically includes robust activations of no direct experimental interest, but the absence of which could indicate a problem with the subject, the machine, or the data analysis) but also serves as an important point of reference for observed differences within the tight task comparison. For instance, a difference between two conditions in a tight task comparison could reflect either an increase in activity in one condition or a decrease in activity in the other. The addition of a loose task comparison provides a means of disambiguating such a situation by providing a baseline against which the two tight task conditions can be compared.

More generally, it is essential to have at least two conditions to be compared, but the power of fMRI-based experiments to test interesting theories is greatly enhanced by the presence of more conditions in the design. Sometimes these multiple conditions are qualitatively different (as indicated previously), but increasingly subtle experiments are being done that make use of quantitative (parametric) variation in the experimental conditions. In general, when attempting to model and understand the networks of the brain, all types of experimental sampling are needed.

Finally, the critical importance (and occasional irrelevance) of behavioral measures must be discussed. It might seem obvious that obtaining observable behavioral responses could only be a good thing in functional neuroimaging research. Certainly most investigators try to have an observable behavioral measure for their tasks when possible. (In "imagination" studies, such as imagining visual images or imagining performance of a motor task, it is sometimes impossible to have an observable *behavioral* response measure, but even in the context of something as "unobservable" as mental rotation, investigators have sometimes found ways to obtain associated reaction times and accuracy measures.) On the other hand, at least one prominent psychologist has argued against the necessity of behavioral response measures, suggesting that the imaging data are sufficient and that adding irrelevant behavioral tasks will only confuse the issue by eliciting neural activity unrelated to the particular cognitive task of interest. Also, several researchers have commented that, independent of anything else, it is good to have a behavioral task associated with the imaging study because it will help keep the subject awake in the scanner.

Each of these observations has merit, but there are more important uses for behavioral response measures in most studies, and for some studies they are critical. Specifically, a number of studies have made the analysis of the imaging data depend crucially on the observed *behavioral* responses. Examples from the study of memory and from the study of the effects of cocaine on brain activity are described in Section I.

E. Summary

Experimental design in fMRI-based experiments is challenging but rewarding. Practical limitations related to the safety and behavior of human subjects, technical limitations in MRI devices, underlying properties of the spatial arrangement of blood vessels, and the temporal characteristics of the coupling between neuronal activity and blood flow are all intertwined. In addition to these technical considerations there is the art of experimental design associated with any question in understanding human psychology. The application of the technology of fMRI to neuroscience entails a collection of trade-offs. Nonetheless, the current strengths of fMRI-based investigations include the best spatial and temporal resolutions for noninvasive, volumetric brain mapping, the most flexible experimental designs, and a constantly improving set of instrument-based limits to the technology's sensitivity and resolution.

IV. DATA ANALYSIS

A typical fMRI scanning session lasts 1–2 hr and results in the collection of hundreds of megabytes of data. The theory and practicalities associated with processing that data are complex and evolving. In contrast to functional neuroimaging associated with PET—in which the total amount of data is much smaller, the understanding and agreement about the sources and nature of noise in the data are well established, and there is a consequent widespread

agreement about the basic issues in data analysis—the situation with fMRI data is much more complex. The sources of machine-related noise in the raw MR images are relatively well understood. However, the general consensus regarding noise in fMRI data is that the most important sources are physiologically based (in the subject) rather than machine based (from the scanner). There is less agreement about the details and the consequences of modeling these noise sources in terms of the practical consequences for data analysis.

Perhaps even more important, the present (and future) spatial and temporal resolution of fMRI data encourages modeling of brain systems at a level that may substantially exceed that of previous volumetric imaging systems. Some of these advances (e.g., the ability to obtain precise delineation of multiple visual areas in occipital cortex by virtue of their retinotopic regularities) require different kinds of data analysis and different kinds of visualization tools than made sense in the context of systems with poorer spatial resolution. Finally, the ability to image the same subject multiple times, and the associated potential for the collection of many kinds of functional data from that same subject, encourages novel approaches to data analysis.

Data analysis is a critical, time consuming, and sometimes controversial part of fMRI-based experimentation. Although the nature of many of the problems is well defined, the appropriate solutions are not. There is general agreement on how to handle some of the issues associated with data analysis (e.g., algorithms to detect head movement and correct for head movement) but there are no universally agreed on approaches to many other issues (e.g., the appropriate statistical tests to define the detection of neural activation, the best way to compare data across different subjects, and the best way to visualize and report the results of data analysis). There are a host of software tools for data analysis, each having its strengths and weaknesses. Because of the rapid development in all aspects of fMRI-based research, no *de facto* standard approach to data analysis has emerged. Figs. 3 and 4 indicate some of the procedures that are discussed in more detail in the following sections.

A. Preprocessing

Before the essential part of data analysis can begin, a number of preliminary steps are typically taken. Some spatial smoothing and temporal smoothing may be applied, but the first and most important step is the assessment of subject head movement during the imaging session.

The problem of subject motion is a pervasive one in fMRI and arises not only in constraining experimental design but also in the analysis of images of a brain that may have moved over the course of an experiment. The high-speed imaging techniques used in fMRI typically minimize the effects of movement in any one image. However, many images are collected in each run, which are typically 2–8 min long, and there are many runs in a typical 2-h session, representing more than 1000 brain volumes per session. Because the fMRI-based signal modulation is intrinsically small (typically 0.5–5%), data from all the images collected in these long runs are normally needed to gain statistical power. Thus, it is important that the images within a run and across runs are properly aligned. Head motion makes this process a challenge. In addition, even if the skull were perfectly immobile, the brain still moves. The pulsatile flow of arterial blood causes movement virtually everywhere in the brain, particularly in subcortical structures.

For all these reasons, the data analytic approach to motion detection and motion correction has been based on the brain images rather than on monitoring head movement externally. Efforts are made to *minimize* subject head movement, and it is not currently possible to correct for severe or rapid movement. All the current algorithms for correcting head movement assume rigid motion of the head. Although a single slice of brain imaging data is collected very rapidly compared to most head movement, the time needed to collect an entire brain volume—consisting of 20 or more slices—is much longer than many head movements. Such motion cannot be corrected with these algorithms. However, if the movement is not too great in amplitude and not too rapid, there are algorithms available in most fMRI data analysis packages that are adequate to detect the motion and to transform the data in an attempt to compensate for the effects of that motion.

A key feature of these algorithms is that they automatically reveal many kinds of movement, including stimulus-correlated movement. If a subject moves every time he or she is supposed to start a task, the movement could create MR signal artifacts that appear as a false activation signal. There is no good way to correct for such data, and these date must be detected and discarded.

Subject movement is generally regarded as the major problem for getting consistent data in fMRI-based experiments. Experienced, well-motivated subjects

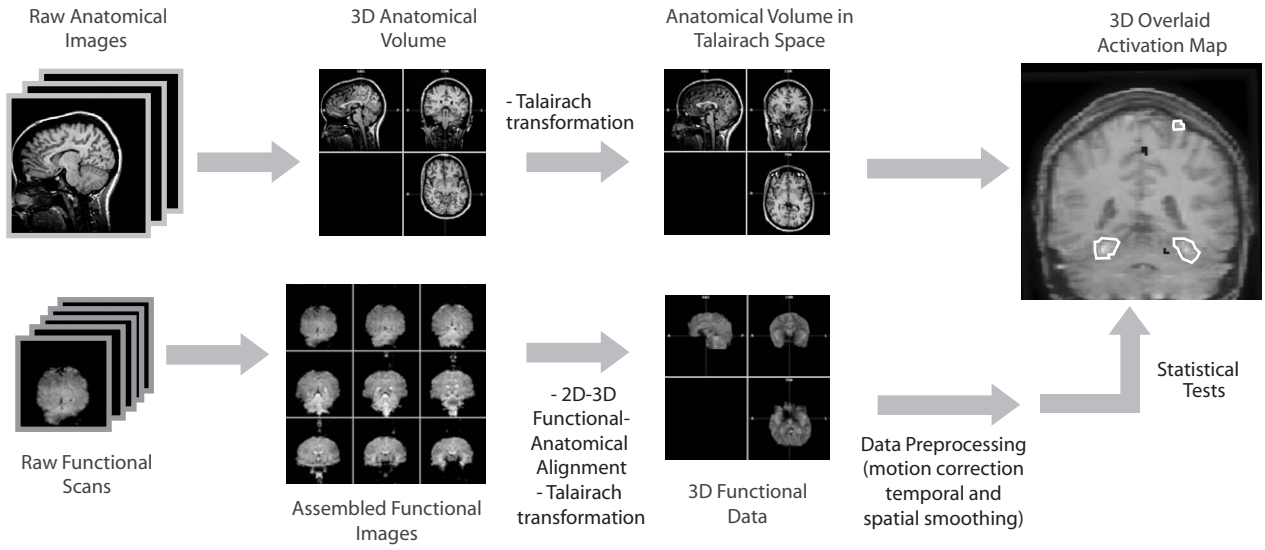

Figure 3 Highlights of an fMRI data processing stream. Data from fMRI-based experiments are analyzed in many steps. The number and order of these steps are still a topic of controversy, with variations across laboratories and software packages. This is a simplified representation of the generic steps. Both high-resolution structural MRI images, and lower resolution functional images pass through a variety of preprocessing steps. Early steps may transform the raw anatomical images from individual (two-dimensional) slices of the brain into volumetric (multislice, three-dimensional) arrays that are more suitable for the detection of head movement. At the same time, data are often transformed to a standard three-dimensional orientation and overallsize scale (Talairach coordinates). In addition to the essential step of *detecting* the presence of head motion in the data, several other (arguably optional) steps may be applied. Motion correction algorithms can help if head movement is not too much (although these algorithms are sometimes unnecessary or counterproductive if motion is little). There are both theoretical and practical reasons for smoothing the data in the spatial and/or temporal domains, although some investigators argue against performing these steps. Finally, statistical tests are performed contrasting the data collected during different experimental conditions. The resulting statistical maps are typically thresholded and overlaid on anatomical images, as indicated in Fig. 4. Further considerations are attendant to the comparisons across the brains of different subjects, as discussed in the text.

who use bite bars in the scanner can routinely be expected to yield data free of serious motion artifact. In contrast, in studies with clinical patients or other difficult subjects, as much as 20–30% of data may need to be discarded because of subject motion. There are methods for helping to minimize physical motion during data acquisition and to detect and possibly compensate for it after data acquistion, but none are fully satisfactory.

B. Basic Detection of Change

The first goal of any analysis of fMRI-based data is to determine whether the experimental manipulation has resulted in a measurable change in the MR signal and to specify where in the brain and when (in time) that change has occurred. In principle, any statistical method that can be applied to a time series can be used with fMRI data. In practice, the demands of the experimental paradigm, limitations of the tool, and the capabilities of distributed software packages constrain the sorts of analyses that are typically performed. A few broad classes of common data analysis options are detailed here, although the presentation is not comprehensive. With the exception of principle component analysis (PCA) and other multivariate techniques, each of these tests is applied at the voxel level. When these statistics are computed for each voxel in the brain, and the resulting collection of statistics is presented in the form of an image in which color or intensity is used to represent the value of that statistic, the result is called a statistical map of brain activation.

High-speed imaging (e.g., EPI) is used to collect many images of the brain during each of the experimental conditions designed. The simplest (and, historically, the first) comparison was obtained by subtracting the average of all the images collected during one condition from the average of all the images collected during another condition. The resulting difference image clearly showed areas that were brighter, indicating greater MR signal during one condition than another.

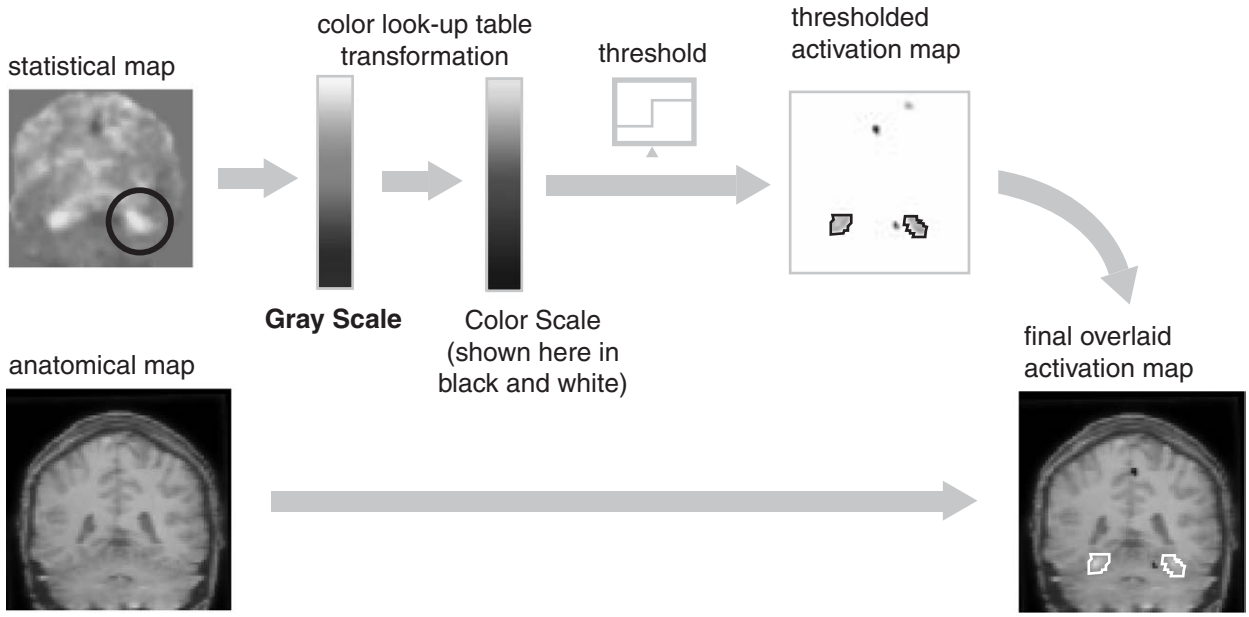

Figure 4 Production of a color–coded activation map. After preprocessing, comparisons of the values of the functional MR images collected during different experimental conditions are used to generate a statistical map. The underlying question is whether the collection of values from one condition is likely to have been generated by statistically different levels of brain activity, when compared with the collection of values obtained during a second condition. These statistics are computed on a voxel-by-voxel basis, resulting in a spatial map (left, top) in which gray-scale intensity indicates magnitude of the statistic. The midgray area represents little difference between the two experimental conditions in question; bright regions occur where the first condition elicited much stronger MR signals than the second condition; and darker regions occur where the first condition elicited much weaker MR signals than the second condition. Because of the need to collect many functional images in a short period of time, functional images typically have substantially less spatial resolution than structural (anatomical) images. (These differences are a consequence of the different pulse sequences that are used to collect functional versus structural MRI data.) In order to combine information from the statistical map with the higher resolution structural images, two transformations are applied to the statistical map. First, the gray-scale intensities used to represent the statistics are mapped into a color scale. Second, a threshold is applied so that statistical values that are within a user-defined range close to zero are mapped to transparency. This permits the combining of the two maps (thresholded pseudocolor map of statistics and high-resolution gray-scale map of anatomy) by overlaying the color map on top of the structural map. In this way, it is possible to get a better sense of the location of the changes in neural activity associated with the different experimental conditions.

This sort of comparison is the only one that, strictly speaking, is "subtraction," although the term is sometimes used informally during discussions of contrasts between conditions, even if those contrasts are based on some other statistic. Instead of subtracting (on a voxel by voxel basis) the averaged data from different conditions, the more general approach is to compute a statistic based on the collection of values at each specific spatial voxel, collected across the times of the many images. Such generic statistical computations on grouped images are more accurately described as "contrasts" or "comparisons" rather than subtractions.

C. Systematic Detection of Change

The most obvious and simple statistical test that can be used in fMRI data analysis is student's *t* test. This test assumes that each number in each group is independent, and that the underlying distribution of numbers is Gaussian (i.e., it is a parametric test). In fact, both of these assumptions are often violated in actual fMRI data. Nonetheless, parametric statistics like the *t* test are the most widely used measures of the difference between the groups of numbers collected in fMRI images across conditions. Other statistical tests are possible and sometimes used.

The most commonly used approach to the detection of systematic effects in fMRI data is the general linear model, which uses correlational analysis. Here, the fMRI data are compared with some kind of reference temporal function to determine where in the brain there are high correlations between the reference function and the MR data. The reference function is obtained from the experimental design. For example, because the brain's hemodynamic response follows a fairly consistent profile, a boxcar function defining the

experimental paradigm is often convolved with an estimated hemodynamic response function to yield the reference function. The resulting reference function is smoother than a boxcar and better takes into account the shape of the hemodynamic response, generally resulting in better correlation between the MR signal time courses and the regressor time course. Several functions have been historically used to model the hemodynamic response, including a Poisson function and, recently, a gamma function. Often, a single canonical hemodynamic response function is used across the entire brain and across subjects, though there is evidence for variation in hemodynamic response shape across subjects and brain regions. Some software packages make provisions for this, allowing for independent modeling of the hemodynamic response function on a voxelwise basis.

There are a number of variations on this general scheme. For multiple experimental conditions, the previously mentioned scheme can be easily extended using multiple regression. In addition, it is also possible, though less common, to perform nonlinear regression on fMRI data, given some nonlinear prior model of expected brain response.

As with any statistical test, one must exercise some caution when using correlational analysis to ensure that incorrect inferences are not made due to violation of the assumptions inherent in the statistical test. In particular, the assumption of independence of consecutive samples is sometimes badly violated in fMRI data, inflating estimates of significance.

All of the preceding approaches make the assumption that the variations of interest in the data are those that occur in temporal synchrony with the experimental variations built in to the design. These tests cannot detect novel temporal variations triggered by the experiment but not part of the design. For instance, if a change was triggered at stimulus onset and stimulus offset, most standard data analytic packages, as they are typically employed, could not detect that response. In contrast, various multivariate approaches (such as PCA) seek regularities in the spatiotemporal structure of the fMRI data that are not specified beforehand. Such techniques typically detect the experimental variation that was designed by the experimenter as well as some physiological variations (such as those due to breathing or heartbeat). The challenge is to refine these tests so that it is easy to interpret the regularities that are detected.

Principal component analysis is not really a statistical test. Rather, it is a re-representation of the data that condenses as much of the variability in that data as possible into a small number of eigenimages, each of which is associated with an eigenfunction that specifies a temporal fluctuation for the entire image. Thus, instead of one temporal variation for each voxel in a brain volume, there are a small number of volumetric images, each of which varies as a single relative image according to some time course. The key virtue of PCA is that it has the power to pick out particular areas in the brain that exhibit a time course similar to that in the experimental design without the experimenter ever having specified that design to the analysis procedure. Similarly, it can detect temporal changes that are different from the ones built into the experiment. On the other hand, there is no obvious way to *know* which eigenimages and eigenfunctions actually correspond to an important or interpretable variation. PCA and related techniques have great theoretical appeal, but they have been rarely used in practical fMRI data analysis. A related multivariate technique, called independent component analysis (ICA), is designed to help with the interpretation of the data. Instead of projecting data into a lower dimensional space that accounts for the most variation (as PCA does), ICA finds a space in which the dimensions are as independent as possible, thus facilitating interpretation of the components.

D. Comparing Brains

Nearly all fMRI studies use multiple subjects and perform statistical analyses across data collected from multiple subjects. This practice introduces a number of practical problems that must be addressed.

A first, relatively simple step toward comparing activity across the brains of multiple subjects is to transform the representations of those brains so that they are similar in overall size and similarly oriented in space. To accomplish this, the brain images are rigidly rotated and linearly scaled into a common "box." The Talairach stereotactic coordinate system is the most widely used standard coordinate system box for comparing brains. In the full Talairach transformation, a rigid rotation and translation to a standardized orientation is followed by a piecewise linear scaling of the anterior, middle, and posterior portions of each hemisphere, independently. The standard orientation in three dimensions is determined by the line between two interhermispheric fiber bundles—the anterior commissure (AC) and the posterior commissure (PC)—and the plane between the two hemispheres. The anterior, middle, and posterior portions of each

hemisphere are defined in terms of the AC–PC line: The portion of each hemisphere in front of the anterior commisure is the anterior, the portion of each hemisphere between the AC and PC points is the middle, and the portion behind the posterior commisure is the posterior.

In some software packages an abbreviated form of the Talairach transformation is performed in which the brain is scaled as a whole, without piecewise linear portions for each hemisphere. This has the advantage of being much faster and simpler to implement. Indeed, some packages compute this transformation automatically by comparing the given brain to a standard "average" brain that was generated by transforming the anatomical MR images of 305 brains to Talairach coordinates and averaging. This process eliminates the tedious and often tricky steps of finding the AC–PC line and other landmarks for each individual brain. Despite the fact that the individual anatomy of the AC–PC line is ignored and the transformation has fewer degrees of freedom than the full Talairach transformation, this automatic process yields data that are adequate for most purposes.

The more serious problems with either the simplified Talairach transformation or the full Talairach transformation are caused by the fact that real brains are not rigid transformations of one another. The simplified Talairach transformation, being strictly linear, cannot account for these differences. Even the full Talairach transformation, which is only piecewise linear with a small number of pieces, is clearly inadequate for dealing with these individual differences in brain anatomy. More powerful nonlinear approaches have therefore been developed.

There are a wide range of approaches to more general transformations of brains to facilitate data display and intersubject comparison. One approach is to permit complicated nonlinear warping procedures based on sulcal and gyral landmarks to guide computer-generated distortions of one brain into another (or to a standard). Another approach, which is also based on nonlinear transformations, is to try to match the perimeters of given brain slices between different brains. Perhaps the most widely used alternative to Talairach and these other nonlinear transformations is to "inflate" the brain as a means of removing all sulci and gyri. This inflation is often followed by cutting the inflated brain in a small number of places to permit "flattening."

The goal of inflating is to obtain a three-dimensional, smooth, nonconvoluted surface representation of cortex. The goal of flattening is to lay that surface representation on a flat plane. Given that a brain hemisphere (when inflated) looks like an ellipsoid, it is necessary to cut it in one or more places to allow it to be flattened. Qualitatively, this is similar to the need to cut a globe to get a flattened representation of the world. Quantitatively, however, for an inflated brain, the analogy is closer to a cylinder. When a globe is cut and flattened, it is necessary to create many cuts or else there will be some very large distortions. On the other hand, when a cylinder is cut, the resulting surface can be flattened with virtually no distortions. In these terms, the inflated cortex is more like a cylinder than a sphere, and the distortions are not terribly large.

Flattened representations are visually and logically very appealing. Unlike Talairach coordinates, however, they are not three dimensional and only apply to the cortical surface. Subcortical structures cannot be represented. (Talairach invented his system for subcortical structures, although it does not include the cerebellum.)

Given the good spatial resolution of fMRI and the ability to detect activations in individual subjects, some researchers eschew averaging across subjects. Their position seems to be that the right way to compare across subjects is to look at *each individual's functional map* (preferably in a flattened brain format to facilitate intersubject comparison). Elaborations on this approach can include warping within the flattened space and could therefore eventually include averaging in that space.

Recent developments in brain comparisons involve the use of more sophisticated algorithms to inflate the brain to a sphere but then warp the surface borders on that sphere (associated with major and almost universal sulcal/gyral landmarks) toward a common standard. This transformation permits a smoother and more effective comparison of activation sites across the brains of different subjects than do the Talairach transformations.

E. Comparing Groups

One of the most obvious and important classes of questions that are addressed with human functional brain imaging is the search for differences between groups. For example, can fMRI be used to detect the early onset of Alzheimer's disease? Does a remedial training program in reading cause changes in brain activity preferentially for one diagnostic classification of dyslexia versus another? Does a given drug

treatment lead to greater area of functional brain activity? All these questions have as an essential component the attempt to make quantitative distinctions between different groups of subjects.

Functional MRI (and functional brain imaging more broadly) can be used to address at least two types of questions. One question might be thought of as the attempt to represent "typical" brain function and associated networks of activity. In that context, collecting increasingly more data about a single brain doing a single task might be useful because the error bars associated with any particular aspect of the brain activity might be expected to decrease with increased measurement. In statistics, this is called a fixed effects model. On the other hand, to determine whether there are differences in brain function and networks of activity between two putatively different *groups* of subjects, it is important to sample many of members of each group, even if the individual measurement of any one member of the group is noisy. In particular, knowing with extreme precision that two members of one group differ from two members of another group is only useful if the within-group variation (i.e., between brains) is as small as the within-brain variation (i.e., between multiple measurements of the same brain). If not, then the exceptional precision of the measurement of the small number of subjects is not useful. In statistics, this is the random effects model.

The practical implication of the fixed versus random effects model of variance for functional neuroimaging is that it is better to have measurements on many brains if the goal is to claim group differences. On the other hand, it may be better to have many measurements on a few brains if the goal is to delineate functional systems as precisely as possible.

V. RESEARCH APPLICATIONS

Human fMRI based on the endogenous contrast agent (deoxyhemoglobin) was first reported in 1991. In the ensuing 10 years the growth of fMRI-based research applications has been explosive. The easiest (and probably the most accurate) way to summarize the range of fMRI-based research applications is "all of psychology and neuroscience". In addition to widespread reports of results of fMRI-based research in general scientific and popular journals, there are two journals devoted exclusively to the technical developments and applications of human brain mapping, for which fMRI is a primary tool. Research applications range from the classical psychophysical questions of sensation, perception, and attention to higher level processes of cognition, language, and emotion, in both normal and patient populations. Even domains ranging from psychotherapy to genetics are beginning to make use of fMRI-based experiments. The impact of fMRI on a few select areas of research is elaborated next.

A. Retinotopy/Multiple Cortical Visual Areas

The first application of fMRI-based research was in the domain of the early stages of visual processing. Indeed, the very first human fMRI study involved the demonstration that a region of the brain associated with early visual processing—occipital cortex in the calcarine fissure—yielded an NMR signal that varied as flashing lights were presented (or not) to a subject.

This demonstration was exciting, but the excitement was limited for several reasons. First, nothing "new" had been demonstrated about human visual cortex. Second, there were a host of technical concerns that, had they been correct, would have meant that the spatial resolution obtainable with fMRI would be seriously compromised. Finally, most of the following simple advances would not go beyond what we already know from (invasive) single cell recordings in nonhuman primates.

However, the development of fMRI in the ensuing years for the study of early visual processing addressed all these concerns and went far beyond them. First, retinopy was demonstrated for area V1 at a level of spatial resolution that exceeded any previously demonstrated with a noninvasive technique. Second, retinotopy was used to delineate multiple visual areas. Differences between the layout of human visual areas compared with those of other primate species were demonstrated, and new visual areas apparently unique to humans were claimed.

At the same time, some classic psychological effects, such as the motion aftereffect, were seen to be associated with detectable brain activity localized to specific parts of the cortex associated with visual motion processing.

The early dependence on the connection to known primate neurophysiology is being lessened. Several laboratories are now developing fMRI suites designed specifically to study nonhuman primates. The idea is to use the invasive technologies such as single cell recording, adapted for the MR environment, to obtain a deeper understanding of both the functional brain structures and the relationship between neural activity

and hemodynamics using methods that would be unethical with human subjects.

B. Modulatory Effects of Attention

One early fMRI-based study demonstrated that the use of voluntary attention (deciding whether to attend to a subset of moving dots or to a subset of stationary dots in a field of moving and stationary dots) caused detectable changes in MR signals associated with a visual motion processing area in cortex (Fig. 5). This study did not have an overt behavioral measure to provide external evidence that subjects were actually performing their assigned tasks. However, the data were sufficiently clean and unambiguous that this study was published and gained considerable attention.

During the ensuing years the study was replicated and extended in a number of ways by different laboratories throughout the world. The initial basic demonstration of attentional modulation became the starting point for much more subtle experiments—experiments that were more tightly tied to behavioral measures. Importantly, both the qualitative and the quantitative measures of attentional modulation were replicated. For instance, the motion processing area was active whenever there was visual movement present, but that activity increased by about 50% when the subject was attending to the movement compared to when the subject was not attending to the movement. The studies that used analogous tasks as part of their design found quantitatively similar changes.

The basic paradigm was adapted to more complex stimulus situations in which subjects could attend to various different aspects of a complex scene. This permitted the testing of specific hypotheses about the allocation and connection of visual attention to different aspects of a stimulus. For example, it was demonstrated that when an object was attended because of one attribute (e.g., motion), there was increased processing of other attributes of that object (e.g., whether it was a familiar face or represented a familiar location) even though the other attributes were irrelevant to the attentional task. Thus, fMRI-based experiments were being applied to theoretical questions of long-standing interest in cognitive psychology.

C. Use of Behavioral Responses

The use of behavioral responses in fMRI-based studies began as a comforting demonstration that subjects were doing what the experimenter had asked them to do. However, behavioral measures can be much more useful. Two studies of memory, for example, made use of behavioral data collected after the MRI scanning session was over and the subject was out of the magnet to retroactively specify the data analytic process. One study of the effects of a drug used the subject's behaviorally reported mental state to obtain a temporal function that could be correlated with the brain imaging data.

The two memory studies each made use of the visual presentation of stimuli during the fMRI scanning session. In one case the stimuli were pictures; in the other case they were words. In both cases the subjects had an irrelevant task to perform related to these stimuli. After the scanning session was over, the subjects were given a memory task (without prior warning) to determine which of the test stimuli they recalled seeing. The key idea here was to group the imaging data according to whether the data were collected during the presentation of stimuli *that were subsequently remembered* versus the presentation of stimuli that were subsequently forgotten. The expectation (which was confirmed) was that various parts of the brain associated with long-term memory and encoding would have been more active on those trials in which the stimulus was subsequently recalled.

The drug study used behavioral measures more directly in analyzing the fMRI data. The study involved the challenging task of measuring fMRI changes during the administration of a psychoactive drug, cocaine. Subjects were regular cocaine users who had declined treatment but who had volunteered for a study. During the course of an imaging session they were given either a placebo or an injection of cocaine. (There were two imaging runs, so each subject received the cocaine on one run and the placebo on the other.) During the runs subjects regularly reported on their subjective state of "high," "low," "rush," and "craving"—terms that were known to be associated with cocaine experiences.

Note that there are unique technical challenges in this study. In addition to being a psychoactive drug, cocaine is also a cardiovascular stimulant. Therefore, before considering the possible effects of cocaine in its psychoactive and addicting role, it was necessary to demonstrate that such effects would not be masked by the circulatory effects of the drug. To accomplish this, the investigators used a standard stimulus (flashing light) to calibrate neuronally triggered hemodynamic responses. Also, they used two imaging pulse sequences: one that was sensitive to BOLD effects and

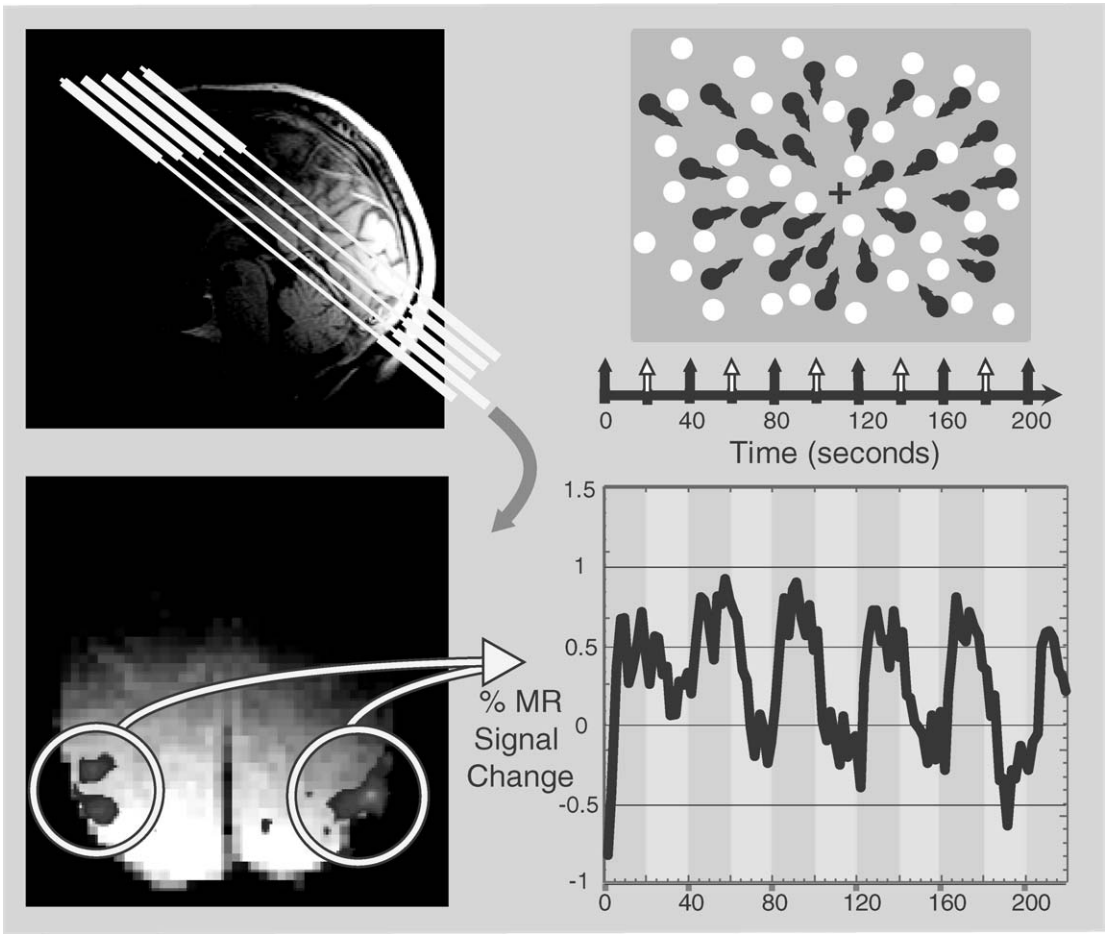

Figure 5 Voluntary attention modulates activity in human visual cortex. This collection of images summarizes an early fMRI-based experiment demonstrating the detection of neural modulation due to the exertion of voluntary attention. Subjects viewed a continuous movie consisting of a cross in the middle of the visual yield (on which they were instructed to fixate) and moving black dots and stationary white dots in the periphery. The cartoon at the upper right represents one frame of this movie, with arrows indicating the direction of motion. In the actual stimuli, of course, there were no arrows present—only moving, stationary dots and the fixation cross. The motion was always radial, toward the fixation point, to make it easy for the subjects to maintain fixation. Additional testing with an MR-compatible eyetracker revealed that subjects could maintain fixation. While looking at this movie for several minutes, subjects received verbal instructions to attend to one collection of colored dots or the other. These instructions alternated every 20 sec, as indicated in the figure by the black (''attend black'') and white (''attend white'') arrows on the timeline, below the visual stimulus. When the subjects heard ''attend black,'' they would continue to fixate the central cross, but they were supposed to pay more attention to the black (moving) dots than the white (stationary) dots during that time. Similarly, when they heard ''attend white,'' they were supposed to attend more to the white (stationary) dots. The imaging data were collected with a small coil of wire (about 13 cm in diameter) placed near the occipital cortex (the back of the head). This yielded a stronger signal in the brain regions of interest for the experiment, but it yielded weak signals from the rest of the brain, as indicated in the structural image shown at the upper left and the functional image shown in the lower left. Data for five slices, oriented parallel to the calcarine fissure (primary visual cortex), were collected (as indicated by the lines in the upper left). Data from one of those slices is shown in the lower left. As described for Fig. 4, a pseudocolor representation of the results of a statistical test comparing the MR data collected during one condition (''attend black'') versus the other condition (''attend white'') is displayed. There was a clear increase in activity on both the left and the right sides of this brain, in a region that corresponds anatomically to a known visual motion processing area of the cortex. Data from the voxels of the brain whose statistic exceeded the threshold used to specify the color map were averaged; the results are plotted as a function of time in the graph in the lower right. Data collected during the time that subjects were attending to moving stimuli (light background portions of the graph) were clearly higher in amplitude than the data collected during the time that subjects were attending to the stationary stimuli (dark background), *even though the visual stimulus was unchanged throughout the entire scanning period.* This experiment represents a simple, dramatic demonstration of the ability of fMRI to detect the neural consequences of changes in cognitive state (data and analysis courtesy of Kathleen O'Craven).

one that was sensitive to flow effects. This combination allowed them to demonstrate that cocaine influenced the flow-dependent MR signal changes but not the BOLD MR signal changes.

Thus, they could use the BOLD changes to study the effects of cocaine in its role as a psychoactive stimulant relatively independent of its role as a cardiovascular stimulant. Using the time course profile obtained from the behavioral ratings (specifically, the temporal modulation of craving and rush) they could find brain areas whose activity followed a similar profile, allowing them to conclude that those areas were implicated in the experience of these sensations.

D. Emotional Affect versus Cognitive Processing Load

A unique strength of functional brain imaging is the ability to test various intuitions and hypotheses about our mental activities by virtue of the quantitative nature of the MR signal changes. Sometimes the most salient aspect of a stimulus (such as its emotional valence) may be less cognitively engaging than the lack of that cue. Specifically, although the localization of function repeatedly found in studies of the low-level aspects of sensory processing appears to have analogs in other cognitive and emotional tasks, the tasks and stimuli that most effectively activate those areas may be counterintuitive. Higher contrast in visual stimuli generally evokes stronger modulation of early visual processing areas in the brain, but high contrast in an emotional domain does not always evoke the strongest variation in the brain areas associated with processing those stimuli. The data and experiment presented in Fig. 6 exemplify this idea.

Subjects were required to classify stimuli along an emotional scale as "neutral," "positive," or "negative." The stimuli were individual words (e.g., "calm," "delighted," and "insecure") intermixed with individual pictures of human faces (Fig. 6, top). There is ample evidence, both from the domain of human functional neuroimaging and from the literature of human brain lesions, that words and faces are exceptionally good stimuli for the activation of specific brain regions. Pictures of faces are good stimuli to activate the fusiform gyrus, especially on the right side. Single words, when associated with a semantic (rather than a purely perceptual) task, are effective stimuli for activating the inferior frontal region, almost always most strongly on the left side. One might reasonably expect that variation along the important dimension of emotional valence would modulate the strength of activation in these two areas. Given the demonstrated power of emotional stimuli to activate areas of the brain associated with general arousal, one might also predict that the most emotionally powerful stimuli (the positive and negative stimuli) would elicit greater neural activity than the neutral stimuli.

The stimuli were presented for 2 sec each, with 8 sec between the onset of each stimulus. This design, as one might deduce from Section II.A, is less than optimal because it does not take advantage of the power of rapid single trials, nor does it completely isolate the hemodynamic responses from the different stimulations. However, it was sufficient to address the preceding question, and it is useful in illustrating the way in which event-related fMRI data are often reported–via overlapping plots of the time course of the hemodynamic responses to the different stimulus types.

The stimuli were effective in eliciting emotional responses. Not surprisingly, the emotional faces (happy, in particular, and, to a lesser extent, sad) evoked stronger amygdala responses than neutral faces, with a weaker finding (but in the same relative order of strength) for words. Also not surprisingly, faces of any type elicited minimal response in left inferior frontal cortex and words of any type elicited minimal response in right fusiform cortex.

However, in the context of this categorization task, neutral stimuli (both faces and words) were far more effective activators of the regions known to be especially responsive to such stimuli (right fusiform and left inferior frontal, respectively) than were the emotionally powerful stimuli. The graphs in Fig. 6 show the time course of activity for each stimulus type in the relevant regions of the brain. The amplitude of the hemodynamic responses to the neutral stimuli was approximately twice as large as that to the positive stimuli, and it exceeded the response to the negative stimuli even more dramatically.

Interpretation of this result is not trivial. Behavioral measures of reaction time and accuracy for the words suggest one possible explanation. In the case of the word stimuli, the reaction times were longest, and percentage correct was lowest, for the neutral words. The fact that it was faster and easier to categorize positive and negative words could mean that the relevant brain area (left inferior frontal) was active for a shorter period of time during the emotional words, resulting in less time for the hemodynamic signal to grow. However, this kind of explanation cannot be the

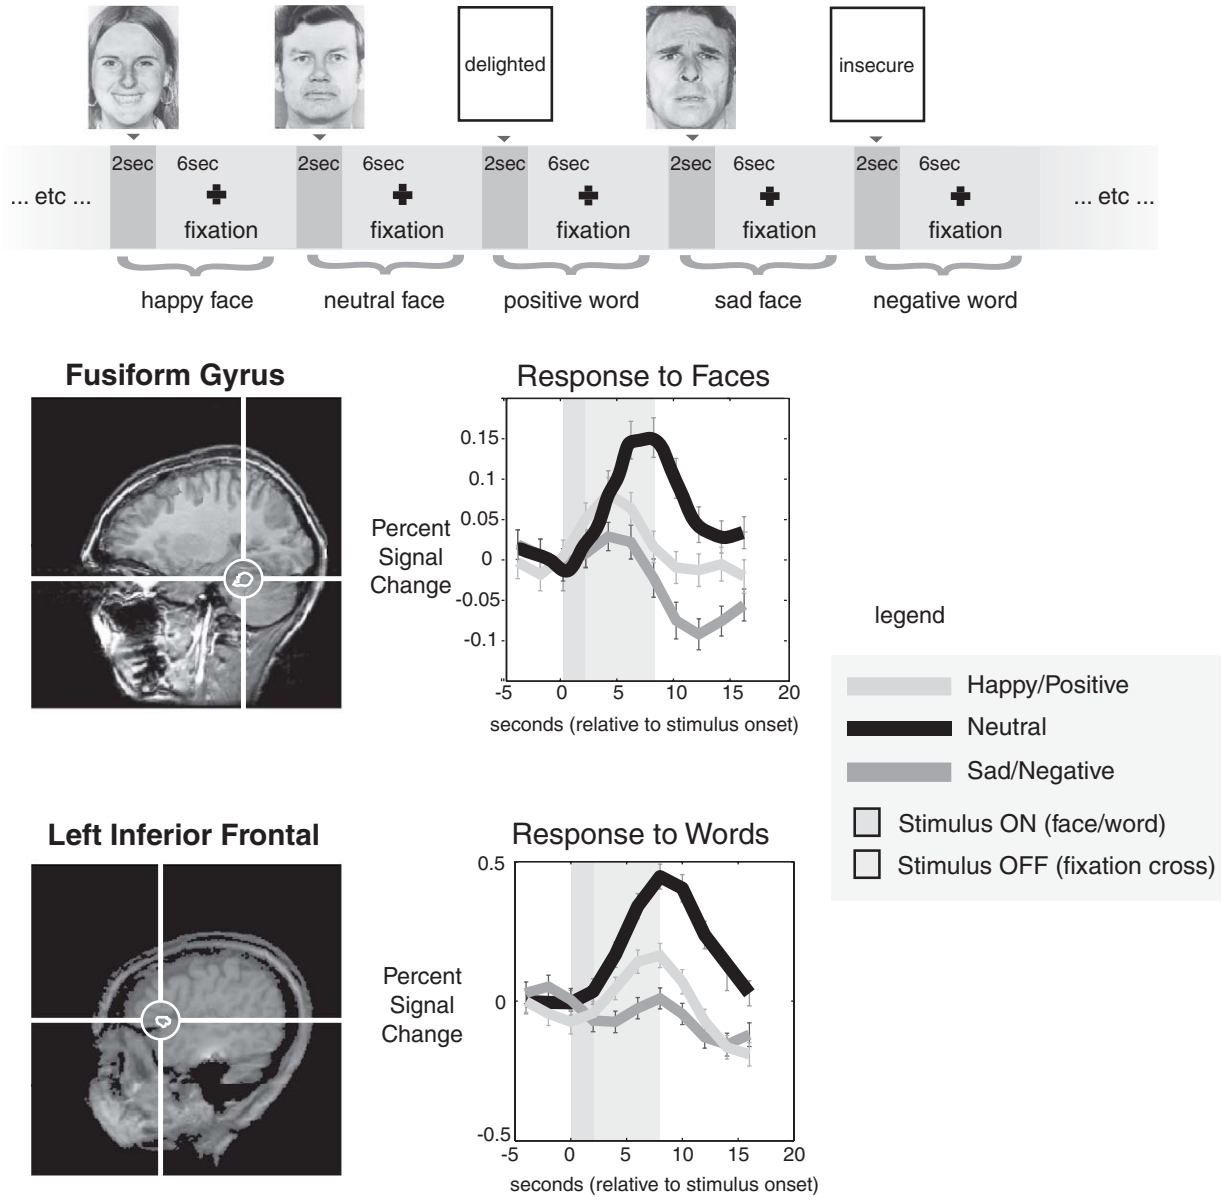

Figure 6 Strength of affect versus difficulty of processing. As described in Section II.A, detection of the hemodynamic responses to different types of events can reveal unintuitive effects. The stimuli and timing for this experiment are indicated in the top row. The stimuli were "positive," "negative," and "neutral" faces and words. One of these was presented for 2 sec every 8 sec in random order. Subjects were required to categorize each stimulus presentation as being positive, negative, or neutral. Two of the resulting activation foci are presented. A region of the brain known to respond strongly to face stimuli (the fusiform gyrus on the right side of the brain) and a region known to respond strongly to words (the inferior frontal region on the left side of the brain) were detected, and their locations are indicated by the crosshairs in the anatomical images shown on the left. The graphs on the right indicate the hemodynamic responses to the three classes of stimuli (positive, negative, and neutral). For words in the frontal region and for pictures of faces in the fusiform region, the most activity was elicited not by the most emotionally salient and affective stimuli but by the neutral stimuli. Apparently, categorizing happy or sad stimuli places a smaller processing load on these areas than categorizing a neutral stimulus (data and analysis courtesy of Patricia Deldin and David Cox).

whole story. In the case of face stimuli, it was the negative (rather than neutral) faces that had the longest reaction times and lowest percentage correct. Face stimuli were generally classified more quickly than words, but neutral faces may still evoke more processing because the observer tries harder to find positive or negative nuances (albeit quickly). However, these are speculations.

The point of recounting this study is to emphasize both the complexity of interpreting fMRI data and their potential nonintuitiveness. To an experimenter, it can naturally seem that positive and negative stimuli will, in one sense, evoke stronger responses than neutral stimuli. For some brain areas, this is no doubt true. However, the constraints of a classification task are different. In that context, the fact that neutral stimuli elicit more activity from their respective processing areas (for words and faces) can be plausibly interpreted as an indicator of greater processing effort.

VI. CLINICAL APPLICATIONS

The ability of fMRI to image brain activity *in vivo* makes it a promising tool for the diagnosis, interpretation, and treatment evaluation of clinical disorders involving brain function. A great deal of effort is currently being exerted to develop concrete clinical applications for fMRI as well as to use fMRI to better understand various psychiatric and neurological disorders. Until we better understand the wealth of data being generated from neurologically intact individuals, however, the use of fMRI-based data in actual clinical applications is likely to be limited.

The development of clinical applications of fMRI is of great importance to the fMRI community for many reasons. Functional MRI-based research has historically been closely tied to the medical community. Indeed, one reason why research using fMRI has been able to expand so rapidly and extensively is the availability of conventional MRI machines. MRI machines are very expensive, and any new, clinically relevant application would help subsidize costs of existing machines and the purchase of new machines (or the upgrading of existing machines) for fMRI use. Additionally, such demand encourages manufacturers to invest in the development of scanners that are more specifically designed with fMRI applications in mind. The widespread acceptance of the development costs for higher field (3 and 4 T) scanners by virtually all MRI manufacturers is almost certainly due to the potential promise of the neural-activation MRI and related imaging techniques, such as diffusion-weighted MRI and diffusion-tensor MRI (which are more relevant to the analysis of stroke and white matter anatomy, respectively).

There is at least one area of clinical importance in which fMRI is already playing an active role: presurgical planning. In situations in which a surgeon is going to be removing portions of a patient's brain, it is critical to know exactly where various motor and sensory functions are mapped in that individual's brain. Some information can be obtained during surgery via direct cortical stimulation or prior to the main surgery via a separate surgical procedure for the implantation of electrode arrays in the brain. Functional MRI, however, is a nonsurgical technique for obtaining similar information well before any surgical intervention starts. Furthermore, it is almost always the case that a structural MRI will be obtained prior to surgery, so it may be a relatively small incremental cost to obtain functional information during the same MRI session.

Many other areas of obvious *potential* clinical importance (in psychopharmacology, neurology, stroke treatment and recovery, drug addiction, and psychiatric disorders) are still largely in the stages of initial research. Although many studies have been performed, there are no specific clinical interventions that are driven by fMRI. A brief summary of some of the ideas in this area is presented in the following sections.

A. Preoperative Planning

One promising clinical application for fMRI is in preoperative planning and risk assessment. Since fMRI allows for the creation of maps of brain activity corresponding to the performance of a specific task, one natural use of fMRI is in identifying areas of the brain that are functionally important and therefore should be carefully avoided during neurosurgery. It should be emphasized that it is the creation of maps specific to the individual patient in question (rather than maps based on averages across many subjects) that is of use to the surgeon. Functional MRI is particularly well suited to the creation of such individualized maps.

Intractable focal epilepsy is sometimes treated by excising the epileptogenic focus surgically. In this context, ''intractable'' means ''not successfully treated with drugs,'' and ''focal'' means that there is a single site that appears to be the source or trigger for the epileptic seizures.) The areas to be removed are often close to brain areas critical to language (so-called ''eloquent'' cortex), so surgeons must exercise extreme caution lest their patients acquire severe language impairments as a result of the operation. For most adults, language function is strongly lateralized,

meaning that damage to one hemisphere (typically the left) has much greater consequences for language comprehension and production than damage to the other (typically the right) hemisphere. Approximately 95% of right-handed individuals are left lateralized for language, whereas left-handed individuals show a much more variable language lateralization (both in left versus right and in the degree of lateralization). Historically, the best procedure for assessing the side and degree of language lateralization in an individual patient has been the Wada test. In this procedure, amobarbitol is injected unilaterally into the left or right carotid artery, resulting in the anesthetization of the corresponding hemisphere of the brain. Both sides are tested in this way. If the subject is relatively unimpaired on language and memory tasks performed during the anesthetization of one hemisphere, then it is deemed safe to operate on that hemisphere. Functional MRI offers several advantages over the Wada test: It is completely noninvasive, and it provides a better estimate of areas important to language within each hemisphere. In the early days of attempting to use fMRI to assess language lateralization, the results were equivocal. Today, fMRI is a robust measure of language lateralization. On the other hand, fMRI has not been demonstrated to be as sensitive a measure of memory function as the Wada test, but progress is being made. At least one hospital in the United States has replace the Wada test with fMRI for presurgical planning, but use of this alternative is not widespread. Notwithstanding this slow start, it can be speculated that the first generally accepted clinical application of fMRI will be as a replacement for Wada test.

More detailed functional maps are being developed for presurgical planning and risk assessment relevant to other brain areas (besides eloquent cortex). For instance, during the surgical removal of tumors and other abnormalities near the central sulcus, one risk is the unnecessary removal of portions of primary motor cortex, resulting in serious impairments of motor control. Functional MRI has been used to map the boundaries of primary motor cortex in order to help weigh the risks and benefits of various treatment options. Obtaining an accurate, *individualized* functional map in this instance is particularly important because brain abnormalities in question often displace structures and make anatomical landmarks ambiguous as well as potentially disturbing the underlying functional maps of normal brain structures. Depending on the type of tumor, if fully resecting a tumor would endanger primary motor cortex, then partial resection might be in the patient's best interest. If, on the other hand, the entire tumor can be safely removed without endangering primary motor areas, then it is in the patient's best interest to remove the entire tumor.

B. Pharmacology

Pharmacology is another area in which fMRI has great potential. Although fMRI is poorly suited to identifying the binding sites of a drug (due to its inherent lack of sensitivity to chemicals in such relatively low concentrations), its good spatial resolution and moderate temporal resolution make it quite well suited to identifying which functional brain systems a drug influences. Studies of the action of clinically and socially significant drugs (such as addictive drugs) have revealed specific patterns and locations of activation via fMRI. Such studies (which include cocaine and nicotine and a growing list of psychoactive pharmaceuticals) are being conducted to learn more about how these drugs affect the brain. A better understanding of the anatomy and physiology of addiction may eventually lead to more effective treatments.

More generally, an important possible use of fMRI could be the determination, on an individual patient level, of whether or not a drug is affecting the appropriate brain systems and the quantification of the strength of that effect and thus potentially guide dosage. Since it is difficult to predict the dose–response effects of a drug on any given individual, fMRI could potentially speed the process of prescribing effective drugs in appropriate doses. Similarly, fMRI has the potential to aid drug development by quickly identifying the brain areas on which a drug acts, increasing knowledge about an existing drug, or helping to identify potential uses of a new drug. Finally, because fMRI has a temporal resolution that is rapid compared to most of the effects of psychoactive drugs, it is possible to use fMRI to follow the pharmacokinetic profile of such drugs.

C. Understanding Neurological and Psychiatric Disorders

In contrast to presurgical planning and some pharmacology, the application of fMRI-based studies to neurological and psychiatric disorders might better be characterized as occurring in the developmental rather than application stages. The primary thrust is in the area of refining diagnosis. The wealth of studies

using neurologically intact subjects supplies a natural baseline for using fMRI to derive more sensitive and/or more specific diagnostic criteria. For every robust finding in the functional localization of tasks involving frontal cortex with healthy subjects, there will eventually be a comparison study involving patients with all manner of neuropsychiatric disorders, from Alzheimer's disease to psychosis, schizophrenia, and autism. Many such studies have been conducted already.

The strength of fMRI is in obtaining spatially localized maps of function, especially in the context of purely cognitive function. These may be of value in diagnosing a variety of disorders. On the other hand, a weakness of fMRI is its extreme lack of sensitivity for directly detecting the presence and concentration of specific drugs in the brain—the discussion so far has referred to the detection of huge numbers of hydrogen atoms in water molecules. In contrast, PET detects virtually every decay of a radioactive atom in a single molecule and is consequently an exquisitely sensitive measure for localizing the sites of activity for suitably labeled psychoactive drugs.

Functional MRI is an *imaging* modality—it generates pictures that have a great deal of spatial specificity. Magnetic resonance spectroscopy (MRS), in contrast, sometimes collects data from the whole head to detect the presence and concentration of some of the body's more plentiful chemicals (such as lactate). There is a trade-off between detecting weak signals (there are far more water molecules than lactate molecules in the body) and being able to make spatial maps. As the MRI devices are made more sensitive (via stronger main magnets, better coils, etc.), the "whole head" MRS data can be refined to yield greater spatial resolution. The clinical relevance of MRS will increase in the future, and some of that improvement will be associated with blood flow changes and hence to fMRI.

D. Dyslexia

A particularly active area of clinically relevant research using fMRI is the study of developmental dyslexia. What makes this effort especially promising is that reading is of such fundamental importance to society and education, but there is limited understanding of the development and actions of the relevant cognitive systems underlying reading, even in normal readers. Psychophysical studies of temporal processing, not only in the auditory domain but also in the context of motor activity and coordination and in the visual perception of motion, have all been implicated, by at least some researchers, in the etiology of dyslexia. Coupling fMRI with behavioral studies in this context has especially rich appeal.

Again, as with some of the preceding potential clinical applications, the likelihood is not for a treatment based on fMRI, but, rather, an improved ability to differentially diagnose different types dyslexia and to monitor the effectiveness and modes of action of any behavioral or drug-based treatments. Dyslexia is a complex disorder, with an etiology that is likely to include low-level physiology, high-level cognitive structures, and other levels as yet undetermined. It is not clear whether fMRI-based research will be able to tap into all aspects of dyslexia, but initial work is encouraging. The discussion of clinical applications of fMRI closes with a simpler disorder than dyslexia, but one that couples directly with the particular strengths of hemodynamically based fMRI.

E. Migraine

A recent tour de force in fMRI-based experimentation brings together some of the most elegant work in a research application context (retinotopic mapping of visual cortex) and a long-standing phenomenon of clinical importance (migraine headaches). Migraines are an intense form of headache, often associated with visual auras (i.e., the perception of various strange visual patterns, typically around a circular arc or perimeter of some portion of the visual field, bilaterally) and an associated temporary blindness (a temporary scotoma) within that perimeter. The fact that these auras and scotomas appear to both eyes at the same portion of the visual field is very strong evidence that the underlying effect is being controlled at the cortical level, where these corresponding portions of the visual field share the same physical location in the brain. Moreover, migraines have long been understood to be associated with changes in dilation and constriction of the cerebral vasculature.

It is very difficult to study this phenomenon using fMRI both because it is relatively short-lived (sometimes 30–60 min and sometimes 2–4 hr) and because it is associated with aversion to loud noises and bright lights (on the part of the sufferer). Therefore, it is difficult to get migraine sufferers to volunteer for an fMRI study; even if they were willing, it would be rare that they got a migraine while they were near the scanner. One research group was fortunate enough to find a volunteer who predictably and regularly triggered his own migraine headache by dint of intense athletic activity

(playing basketball). He was therefore available for repeated (schedulable) scanning immediately before and during the onset of his migraine attacks.

The investigators were experts in visual retinotopy and they designed a protocol that revealed, in exquisite detail, the neurological correlate of the patient's visual symptomotology. As the scotoma grew and as the aura changed in size (both of which phenomena could be reported subjectively by the patient), fMRI data revealed the location on the cortex and the functional variation in amplitude of response to a flickering checkerboard of visual stimulation. Combining this data with previously obtained retinotopic maps of the subjects visual cortex permitted a precise connection between measurable function and subjective loss. Although this study does not immediately suggest a treatment for migraine attacks, it certainly demonstrates a method for objectively assessing the effectiveness of candidate therapies.

VII. CLOSING

Given the strong technical components of fMRI, perhaps it is appropriate to close with a discussion of the ultimate spatial and temporal resolutions that might be obtainable in the near future. The temporal resolution of fMRI is not likely to be limited by the imaging tool but, rather, by the vagaries of the hemodynamic response. We are probably close to that limit already. Although there are aspects of temporal properties of hemodyamics that we can detect on the timescale of 100 msec, for most practical purposes the fMRI temporal resolution limit is likely to remain approximately 1 sec. Significant improvements in temporal resolution *associated* with fMRI are likely to result from integration with modalities such as EEG and MEG, whose intrinsic temporal resolution is the millisecond range.

Technological developments, especially in terms of higher field magnets and more sensitive and versatile imaging coils, will increase the effective spatial resolution of fMRI. Because higher field strength increases the signal-to-noise ratio, less averaging of signals across space is required, allowing for smaller voxels and thus greater spatial resolution. Although there are some safety issues that arise as field strength increases, there is no known reason why MRI cannot be done with humans at much higher field strength than the conventional 1.5 T. An increasing number of 3- and 4-T scanners are in routine use, and a handful of 7- and 8-T scanners for use on humans are either currently in use or are being built. Even without the higher field strengths, it would be possible to increase spatial resolution by using longer imaging times. However, the ultimate spatial resolution limits will not be determined by the MR scanner. Rather, they will be determined by hemodynamic limits, i.e., by the spatial resolution of the smallest vessels that show local changes with neural activity. Based on the available evidence, this limit is approximately the size of a cortical column—between 0.1 mm and 1 mm in linear dimension. If that spatial resolution could be achieved in routine fMRI-based experiments, it should represent a dramatic leap in the ability to develop and test far more interesting and explicit models of functioning neural systems in the human brain.

GABA

SOFIE R. KLEPPNER and ALLAN J. TOBIN
UCLA Brain Research Institute

GLOSSARY

apoenzyme An enzyme without its obligate cofactor, which is therefore inactive.

carrier-mediated release Nonsynaptic release (usually of a neurotransmitter) by a plasma membrane transporter.

GABA γ-Aminobutyric acid; the major inhibitory neurotransmitter of the central nervous system; also found in extraneuronal tissues (e.g., the pancreas and reproductive tracts).

GABA receptor A protein that binds GABA and initiates downstream effects.

GABA-T GABA-transaminase; enzyme that degrades GABA.

GABA transporter A protein that moves GABA across either the plasma membrane or the vesicular membrane.

GAD Glutamic acid decarboxylase; enzyme that converts glutamate to GABA.

holoenzyme An enzyme bound to its obligate cofactor, which is therefore active.

inhibitory neurotransmitter A neurotransmitter that, when it activates its postsynaptic receptor, decreases the probability that the postsynaptic cell will fire.

phasic inhibition Short-term (milliseconds) decrease in excitability of a cell, usually synaptically mediated.

pyridoxal phosphate Vitamin B6; a cofactor required for GAD activity.

receptor agonist A substance that binds to a receptor and mimics or enhances the receptor response.

receptor antagonist A substance that binds to a receptor and blocks or decreases the receptor response.

tonic inhibition Long-lasting decrease in the overall excitability of a cell or cells, usually extrasynaptically mediated.

GABA (γ-aminobutyric acid; 4-aminobutyric acid) is an inhibitory amino acid neurotransmitter. Three separate groups published the first reports of GABA in the brain in 1950, although its function as a neurotransmitter was not recognized until later. Eugene Roberts, the author of one of the first reports, identified GABA in the course of chromatographic studies on the amino acid profiles of murine neuroblastomas. GABA from potatoes was used as a standard and comigrated with an unknown substance isolated from the tumors. Roberts rigorously pursued his studies of GABA synthesis and degradation in the brain and GABA is now recognized as the most prominent inhibitory neurotransmitter in the central nervous system (CNS).

I. INTRODUCTION

Approximately 30% of neurons in the brain produce GABA, and almost every neuron can respond to GABA. Some nonneural cells also make GABA, including the cells of the endocrine pancreas and the reproductive tracts. GABA in the pancreas presumably acts as a signaling molecule, in a similar manner to CNS signaling. GABA function in the reproductive tracts is unknown.

The molecules associated with GABA synthesis, degradation, transport, and signaling include two synthesizing enzymes, one degrading enzyme, two transporting proteins, and two classes of receptors. These molecules, their functions, and their putative locations are listed in Table I and illustrated in Fig. 1.

GABA acts by binding to GABA receptors, which are located on both pre- and postsynaptic cells. Generally, GABA receptor binding hyperpolarizes the cell, producing an inhibitory effect. In some circumstances, however, GABA can exert excitatory effects by depolarizing the membrane. Excitatory GABA effects occur most notably during development but also in the rodent suprachiasmatic nucleus, where it may be related to circadian rhythms.

Table I
GABA-Related Proteins, Their Locations, and Their Functions[a]

Protein	Location	Function
GAD	Intracellular	Synthesizes GABA
GAD_{65}	Axon terminal	
GAD_{67}	Cytosol	
GABA-T	Mitochondria	Degrades GABA
GAT		Transports GABA across plasma membrane
GAT1	Neurons and glia	
GAT2	Glia and periphery	
GAT3	Glia and periphery	
GAT4	Brain and periphery	
vGAT	Synaptic vesicle membrane	Packages GABA into vesicle
$GABA_A$	Postsynaptic membrane	Ionotropic receptor (chloride channel)
α_{1-6}		
β_{1-4}		
γ_{1-3}		
δ		
ρ_{1-3}		
π		
ε		
$GABA_B$	Pre- and postsynaptic membrane	Metabotropic receptor (G protein linked)
R1		
R2		

[a]Abbreviations used: GAD, glutamic acid decarboxylase; GABA-T, GABA-transaminase; GAT, GABA transporter; vGAT, vesicular GABA transporter.

Beyond neurotransmission, GABA also acts as a signaling molecule during development, both in the CNS and elsewhere in the embryo. In the CNS, GABA can influence cell migration, neurite extension, differentiation, and synapse formation. GABA also plays an important role in the actions of steroid hormones in the brain. Outside the CNS, GABA is associated with developmental functions including palate formation.

GABA is found in organisms that lack synapses (e.g., bacteria and plants); therefore, it may have an important role outside of intracellular signaling. GABA can be degraded into succinate, which participates in the tricarboxylic acid cycle. Thus, GABA can provide energy for the cell, and this may be part of its role in nonsynaptic functions.

Alterations in GABA production, degradation, response, and transport have tremendous effects. Within the brain, changes in GABA signaling contribute to epilepsy, movement disorders (e.g., Huntington's disease and Parkinson's disease), anxiety, and panic disorder. Injury can influence the expression of glutamic acid decarboxylase, the enzyme that synthesizes GABA, suggesting that GABA may play a role in recovery. Outside of the brain, a lack of GABA in the embryo is associated with cleft palate, a craniofacial malformation. Autoimmunity to glutamic acid decarboxylase is associated with the death of pancreatic β cells and the development of insulin-dependent diabetes mellitus.

II. GABA PRODUCTION AND DEGRADATION

GABA is unique among neurotransmitters because it can be synthesized by either of two closely related enzymes. Almost all GABA derives from the decarboxylation of glutamate, catalyzed by glutamic acid decarboxylase [glutamate decarboxylase (GAD); L-glutamate 1-carboxylase, E.C. 4.1.1.15]. Pyridoxal phosphate [PLP; derived from pyridoxine (vitamin B_6)] is an obligate cofactor for GAD, as it is for many other decarboxylases. GABA can also be synthesized from ornithine via ornithine decarboxylase, although this is a minor route of synthesis. The GABA-synthesizing pathway is illustrated in Fig. 2.

A. GABA Synthesis

GAD consists almost entirely of homodimers of two distinct polypeptides—GAD_{65} (with M_r of 65,000)

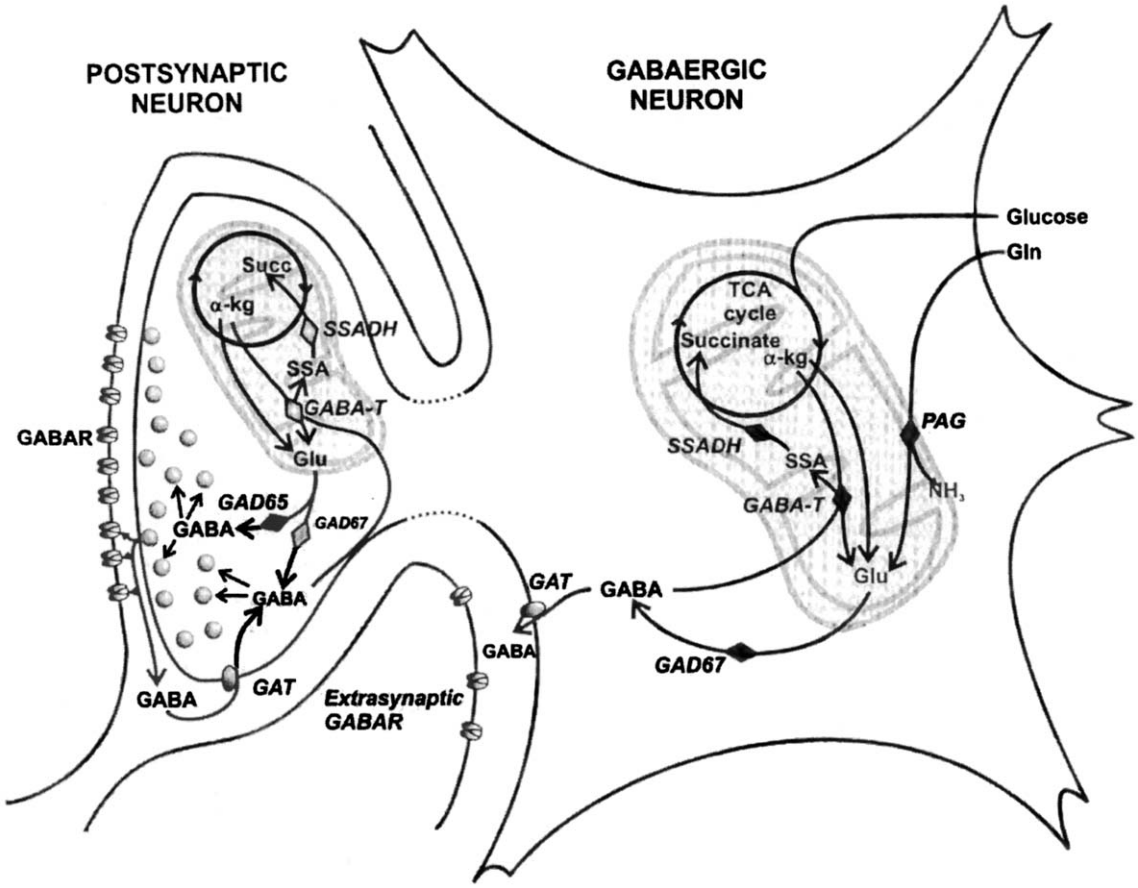

Figure 1 Schematic of GABA-related proteins and their locations within the cell. GAD_{65} or GAD_{67} synthesizes GABA from glutamate. GABA can be packaged into vesicles for release (vesicular GABA transporter not shown) at the synapse, where it binds to GABA receptors. GABA receptors are located on the presynaptic and postsynaptic neuron and can be found outside of the synapse. The plasma membrane GABA transporter (GAT) takes up unbound GABA from the synapse. GABA can also exit the cell via GAT. The GABA shunt is depicted within the mitochondria. Also shown are two sources of glutamate: α-Ketoglutarate can be converted to glutamate by GABA-T, and glutamine, provided by astrocytes, can be converted to glutamate by phosphate-activated glutaminase (PAG). GABAR, GABA receptor; GAD, glutamic acid decarboxylase; GABA-T, GABA-transaminase; α-kg, α-ketoglutarate; Succ, succinate; SSA, succinic semialdehyde; SSADH, succinic semialdehyde dehydrogenase; Gln, glutamine [from D. L. Martin and A. J. Tobin, Mechanisms controlling GABA synthesis and degradation in the brain. In *GABA in the Nervous System: The View at Fifty Years* (D. L. Martin and R. W. Olsen, Eds.). Lippincott, Williams & Wilkins, Philadelphia, 2000].

and GAD_{67} (with M_r of 67,000). The two GADs account for essentially all GAD activity in tissue extracts. Although other purified proteins reportedly have GAD activity, none is known to contribute substantially to GABA synthesis *in vivo*.

The two GAD polypeptides are the products of distinct genes and differ in sequence by about 35%. The two genes have identical exon–intron organizations, suggesting that they share a relatively recent common ancestor. The GAD_{65}s of humans, mice, and rats are 97% identical, as are the GAD_{67}s of humans, rats, and cats. Clearly, the two GADs have been under strong selective pressure during the 150–200 million years since the beginning of mammalian radiation.

Almost every neuron that produces one form of GAD also produces the other, suggesting that the two genes share some transcriptional regulatory mechanisms. During the development of specific brain structures, GAD_{67} usually appears earlier than GAD_{65}. In the hippocampus and the spinal cord, however, GAD_{65} appears earlier in development than GAD_{67}. The ratio of GAD_{65} to GAD_{67} mRNA increases dramatically during synapse formation, both in the striatum and in the cerebellum.

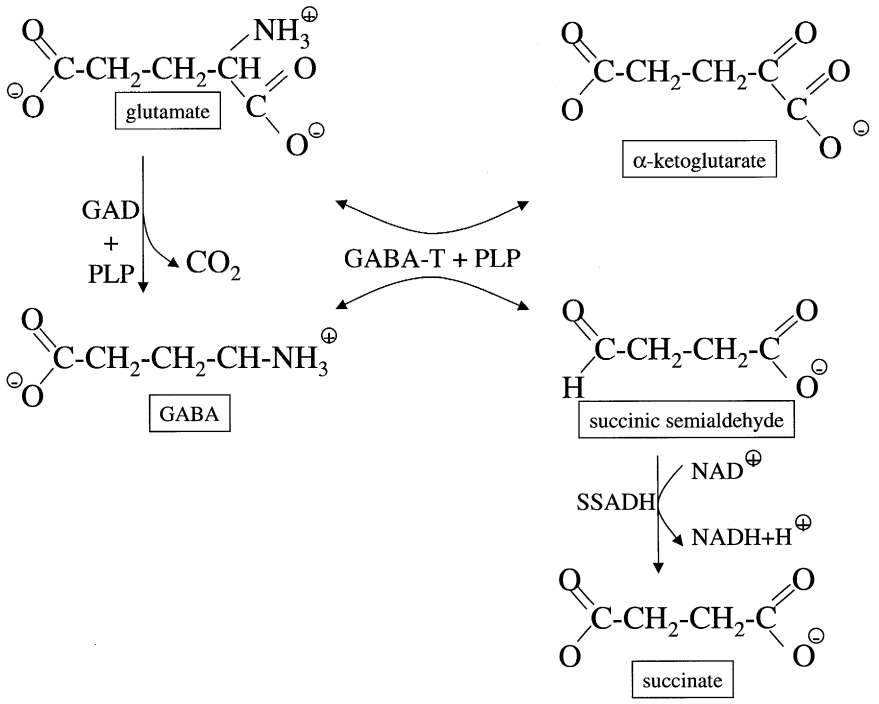

Figure 2 GABA is synthesized from the decarboxylation of glutamate. GABA is degraded to succinic semialdehyde and succinate by GABA-T and succinic semialdehyde dehydrogenase (SSADH). GABA-T can also convert α-ketoglutarate to glutamate, completing the first step of the GABA shunt.

The GAD_{67} gene produces two alternatively spliced transcripts during early development. The two embryonic forms of GAD are GAD_{25} and GAD_{44}, but only GAD_{44} is enzymatically active. GAD_{25} is not enzymatically active because it lacks the PLP binding site. As the embryo develops, the shorter transcripts are replaced by the mature GAD_{67}. GAD_{65} has no identified alternatively spliced transcripts.

GAD_{65} and GAD_{67} differ in their enzymatic characteristics. GAD_{67} exists mainly in the active, holoenzyme form (bound to PLP) and is less sensitive to small changes in neuronal GABA concentration than is GAD_{65}. Most GAD_{65} in the brain is in the apoenzyme form (inactive, not bound to PLP), and the GAD activity of brain extracts increases two- or threefold upon the addition of PLP. The loss of PLP from GAD is not a simple dissociation but a catalytic misstep that results in the formation of succinic semialdehyde and pyridoxamine phosphate (rather than GABA and PLP). This reaction is illustrated in Fig. 3. Pyridoxamine phosphate dissociates from GAD, generating an apoenzyme that lacks enzymatic activity until it again combines with PLP to reform holoGAD_{65}.

The interconversion of apoGAD and holoGAD is sensitive to ATP, phosphate (Pi), and GABA levels. These influences may regulate GABA production in response to altered neuronal activity within GABA neurons. ATP favors the formation of apoGAD and inhibits the formation of holoGAD. Pi enhances the formation of holoGAD. GABA also favors apoGAD formation in the absence of PLP because the GABA-forming steps are readily reversible. Consequently, GAD_{65} is sensitive to small changes in neuronal GABA concentration. GAD has a K_m for glutamate of approximately 0.45 mM and a K_m for GABA of approximately 16 mM. Therefore, given similar concentrations of glutamate and GABA, glutamate is converted to GABA much faster than the reverse reaction.

GAD_{65} and GAD_{67} also differ in their subcellular locations. Both are present in cell bodies and axon terminals, but GAD_{65} is usually more concentrated in axon terminals, whereas GAD_{67} is more concentrated in cell bodies. GAD_{65} associates with vesicle membranes both in neurons and in pancreatic cells, and it is characterized by punctate immunostaining in mature neurons. GAD_{67} generally shows no such association with vesicles, and it is diffuse throughout the cell when examined by immunostaining.

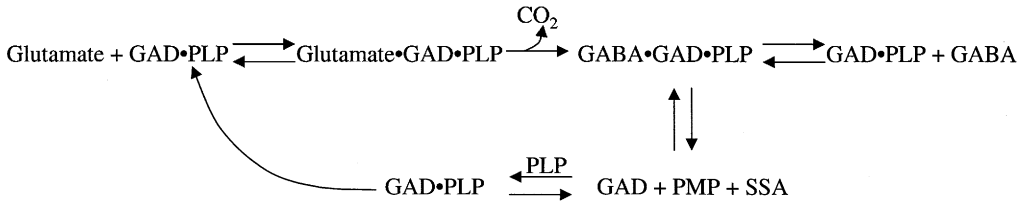

Figure 3 Interconversion of the GAD apoenzyme and holoenzyme. GAD can be converted from its active holoenzyme form, bound to pyridoxal phosphate (PLP), into its inactive apoenzyme form by a catalytic misstep that results in the formation of pyridoxal monophosphate (PMP) and succinic semialdehyde (SSA). GAD must reassociate with PLP to be active [adapted from Brain Glutamate Decarboxylase. In *Neurotransmitter enzymes* (Boulton, Baker, and Yu, Eds.) Humana Press, Clifton, NJ].

GAD_{65} undergoes at least two types of reversible posttranslational modifications—palmitoylation and phosphorylation. These modifications can anchor GAD_{65} to internal membranes, even in cells not specialized for exocytosis, but they are not required for membrane association. Palmitoylation and phosphorylation are limited to a distinct GAD_{65} polypeptide whose electrophoretic mobility is slightly less than that of GAD_{65}, but the structural basis for this difference in mobility is not well understood.

Although most GAD molecules are homodimers, GAD_{65} and GAD_{67} also form heterodimers. The association of some GAD_{67} with synaptic terminals and with the Golgi complex in genetically modified cells appears to depend on its association with membrane-targeted GAD_{65}. The presence of GAD_{67} in a restricted subset of synaptic boutons, observed in the mouse hippocampus, may reflect the distribution of GAD_{65}–GAD_{67} heterodimers.

B. GABA Degradation: The "GABA Shunt"

GABA-transaminase (GABA-T) is the main degradative enzyme for GABA, although steady state GABA levels are normally controlled by GAD. GABA is degraded to succinic semialdehyde (SSA) by GABA-T, a mitochondrial enzyme. Since SSA can be converted to succinate by succinic semialdehyde dehydrogenase (SSADH), GABA can serve as one step in a shunt that bypasses α-ketoglutarate dehydrogenase in the tricarboxylic acid (TCA) cycle. The GABA shunt begins with the conversion of α-ketoglutarate to glutamate by GABA-T, other transaminases, and glutamate dehydrogenase. Glutamate is then decarboxylated by GAD to form GABA, which is degraded to SSA by GABA-T. Finally, SSA is converted to succinate by SSADH. These reactions are summarized in Fig. 4. Normally, the conversion of α-ketoglutarate to succinate produces one NADH and one GTP. The GABA shunt therefore produces approximately 8% less total energy compared to the TCA cycle, although it provides 10–20% of the TCA cycle activity in most brain regions.

III. GABA RESPONSE

Responses to GABA depend on two classes of GABA receptor—$GABA_A$ receptors, which are located on the postsynaptic cell and produce fast (millisecond) responses, and $GABA_B$ receptors, which are found on both pre- and postsynaptic cells and produce slower (second) responses that depend on second messengers. A third class of GABA receptors, the $GABA_C$ receptors, is also ionotropic and is now generally considered to be a subset of $GABA_A$ receptors. The differences in GABA receptor structure, function, and location allow fine-tuning of GABA signaling and response.

A. $GABA_A$ Receptors

Most neurons express $GABA_A$ receptors. $GABA_A$ receptors are GABA-gated chloride channels located on the postsynaptic membrane. Upon binding GABA, the channel opens and chloride flows along its concentration gradient. The extracellular chloride concentration is usually higher than the intracellular concentration, so chloride usually flows into the cell. The inward chloride flux results in hyperpolarization of the postsynaptic membrane and a concomitant decrease in the probability of cell firing. In some cases, however, GABA evokes a depolarizing response, either because of high intracellular chloride concentrations resulting in an outward flow of chloride through the open channel or because of the flow of bicarbonate ions through the channel.

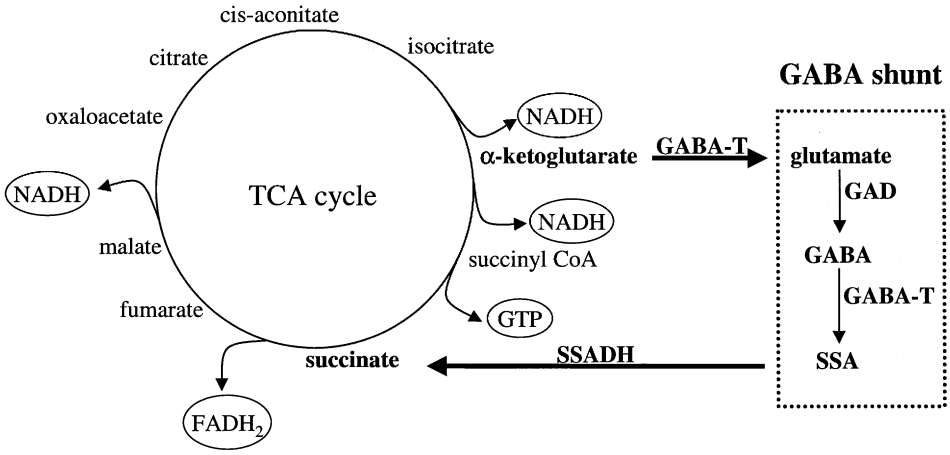

Figure 4 The GABA shunt. GABA can contribute to the TCA cycle via the GABA shunt, which converts α-ketoglutarate to succinate. The GABA shunt provides less energy than the complete TCA cycle because it bypasses the formation of one NADH and one GTP. Nonetheless, approximately 10–20% of TCA cycle activity in most brain regions is provided by the GABA shunt. SSA, succinic semialdehyde; SSADH, succinic semialdehyde dehydrogenase.

1. $GABA_A$ Receptor Topology

$GABA_A$ receptors are highly diverse. Each $GABA_A$ receptor consists of five transmembrane polypeptide subunits. At least 19 subunits exist, named $\alpha(1–6)$, $\beta(1–4)$, $\gamma(1–3)$, δ, ε, $\rho(1–3)$, and π. The recently identified subtype θ may be identical to β_4. Splice variants of several subunits exist as well. Receptor heterogeneity results from at least 20 different combinations of five subunits.

Each subunit consists of a long extracellular amino-terminal region, four transmembrane domains, and a large intracellular loop between the third and fourth transmembrane domains (Fig. 5A). This motif is shared by the channel superfamily that includes nicotinic acetylcholine receptors, glycine receptors, and serotonin 5-HT_3 receptors. Five subunits form a complex with a central pore (Fig. 5B). The amino-terminal domains of the α and β subunits are believed to be exclusively responsible for the GABA binding site. Receptor gating is almost certainly mediated by the M2 regions of all five subunits, which presumably line the pore, as is the case in related receptors.

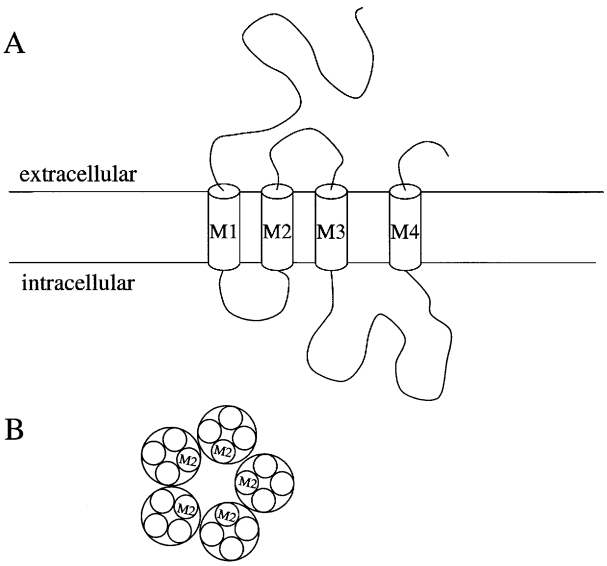

Figure 5 $GABA_A$ receptor subunit and complex topology. (A). Each $GABA_A$ subunit has four transmembrane domains (M1–M4). The amino terminus is extracellular and the carboxy terminus is intracellular. (B). Top view of five subunits that form the receptor complex with a central pore, which is likely lined by the M2 domains of each subunit [reprinted from Cherubini and Conti, *TINS* **24**(3), 155–162, 2001, with permission of Elsevier Science].

2. $GABA_A$ Subunit Composition

The $GABA_A$ subunit genes are located on several chromosomes. For example, human α_1 is located on chromosome 5, α_2 on chromosome 4, and α_5 on chromosome 15. Many of the subunit genes occur in clusters. For instance, $\alpha_1/\alpha_6/\beta_2/\gamma_2$ are clustered on chromosome 5, whereas $\alpha_2/\alpha_4/\beta_1/\gamma_1$ are located on chromosome 4. The chromosomal arrangement of the subunit genes suggests that both gene and cluster duplication occurred during evolution.

Despite the number of potential subunit combinations, there are some common combinations, which are summarized in Table II. Both development and brain region regulate $GABA_A$ subunit composition and presumably each combination has unique properties based not only on each subunit but also on the assembly as a whole. The functional consequences of specific combinations are not well understood but can affect both receptor function and location.

The subunit composition affects receptor binding of GABA and other ligands, but it is also important in receptor targeting, assembly, and clustering. For instance, γ_2 knockout mice show reduced $GABA_A$ receptor clustering as well as reduced ligand binding. α_6 knockout mice also demonstrate decreased δ subunit expression, despite normal mRNA levels, indicating posttranscriptional control by the subunits.

3. Pharmacology of $GABA_A$ Receptors

The $GABA_A$ receptor is affected by a myriad of drugs, including those that both cause and prevent convulsions, those that relieve anxiety, and those that relax, sedate, and anesthetize. Receptor subunit composition is critical in determining drug action. The specific binding sites for many but not all compounds have been identified.

Benzodiazepines (BZs) constitute a class of drugs that act on the $GABA_A$ receptor with sedative, anxiolytic (antianxiety), muscle relaxant, and cognitive effects. BZs bind to the external surface of receptors with specific combinations of subunits: A combination of γ_2 with α_1, α_2, α_3, or α_5 and any β subunit confers BZ binding. Each α subunit may have its own BZ binding affinity. The BZ binding site is thought to be between the γ_2 and α subunits and is highly homologous to the GABA-binding site located between the α and β subunits. Recent work has shown that the α_1 subunit mediates the sedative but not the anxiolytic effect of BZs.

Anticonvulsant and anesthetic drugs can positively or negatively modulate the receptor response to GABA. For example, barbiturates can directly enhance the GABA response either by opening the chloride channel or by increasing the time for which it remains open after binding to GABA. Very high concentrations of barbiturates can block the channel entirely, however. Barbiturates bind within the $GABA_A$ receptor pore and can also act at other receptors, including glutamate and acetylcholine receptors. This may reflect conservation of specific residues within the subunits. The anesthetic binding site is different from the GABA binding site, and it is probably located within the pore.

Table II
Common $GABA_A$ Receptor Subtype Combinations and Their Locations[a]

Subtype	Comments
$\alpha_1\beta_2\gamma_2$	Approx 50% of the total $GABA_A$ receptors; widespread; GABAergic interneurons
$\alpha_2\beta_3\gamma_2$	Approx 15–20% of total $GABA_A$ receptors; cortex, hippocampus, amygdala, septum, hypothalamus
$\alpha_3\beta_3\gamma_2$ ($\alpha_1\alpha_3\beta_3\gamma_2$)	Approx 15–20% of total $GABA_A$ receptors; cortex, amygdala, septum, raphe; monoaminergic, serotonergic neurons
$\alpha_4\beta_x\gamma_2$	$<5\%$ of total $GABA_A$ receptors in whole brain; cortex, hippocampus, thalamus, striatum
$\alpha_4\beta_x\delta$	$<5\%$ of total $GABA_A$ receptors in whole brain; cortex, hippocampus, thalamus, striatum
$\alpha_5\beta_3\gamma_2$	$<5\%$ of total $GABA_A$ receptors in whole brain; hippocampus (approx 20% of total $GABA_A$ receptors), cortex
$\alpha_6\beta_x\gamma_2$ ($\alpha_1\alpha_6\beta_x\gamma_2$)	$<5\%$ of total $GABA_A$ receptors in whole brain; cerebellar granule cells (30–40% of total $GABA_A$ receptors)
$\alpha_6\beta_x\delta$ ($\alpha_1\alpha_6\beta_x\delta$)	$<5\%$ of total $GABA_A$ receptors in whole brain; cerebellar granule cells (20–30% of total $GABA_A$ receptors); extrasynaptic
$\alpha_2\beta_1\gamma_1$ $\alpha_2\beta_1\gamma_1\theta$	$<10\%$ of total $GABA_A$ receptors in whole brain; limbic regions, basal ganglia, tyrosine hydroxylase-positive neurons, Bergmann glia
γ_3-containing receptors	$<5\%$ of total $GABA_A$ receptors in whole brain; widespread, low abundance; little data available
ε-containing receptors	$<5\%$ of total $GABA_A$ receptors in whole brain; hippocampus, hypothalamus; little data available

[a]Adapted from P. J. Whiting, K. A. Wafford, and R. M. McKernan, Pharmacologic subtypes of $GABA_A$ receptors based on subunit composition. In *GABA in the Nervous System: The View at Fifty Years*. (D. L. Martin and R. W. Olsen, Eds.). Lippincott, Williams & Wilkins, Philadelphia (2000).

Alcohol acts on the $GABA_A$ receptor, although its route of action and potential binding site are unclear. In some cases, alcohol potentiates GABA function at the $GABA_A$ receptor, but this effect may depend on receptor subtypes or on an indirect action. Currently, there appear to be alcohol-sensitive and alcohol-insensitive $GABA_A$ receptors, but the basis for that sensitivity is unclear.

B. $GABA_B$ Receptors

$GABA_B$ receptors are located both pre- and postsynaptically and they appear to be largely extrasynaptic. $GABA_B$ receptors are G protein-coupled receptors that interact with a number of proteins on K^+ and Ca^{2+} channels as well as with adenylate cyclase. They belong to the class C metabotropic receptor family, which includes the metabotropic glutamate receptors. The $GABA_B$ receptor has only recently been cloned, and our understanding of this receptor is therefore more limited than that of the $GABA_A$ receptor.

$GABA_B$ activation is inhibitory both pre- and postsynaptically. Presynaptic $GABA_B$ receptor activation causes Ca^{2+} channels to close, which decreases Ca^{2+} conductance. Decreased Ca^{2+} conductance at the nerve terminal reduces exocytotic release of neurotransmitter and also decreases the action potential duration. Postsynaptic $GABA_B$ receptor activation causes inwardly rectifying K^+ channels to open, which increases K^+ conductance. Increased K^+ conductance causes an increase in extracellular K^+ and a concomitant hyperpolarization, rendering Na^+ channels inactive. Thus, the net result of GABA binding to $GABA_B$ receptors is a decrease in the probability of cell firing.

1. Receptor Topology

$GABA_B$ receptors are unique within the metabotropic receptor family because they exist as heterodimers. Functional $GABA_B$ receptors require the GBR1 and GBR2 subunits in order to be expressed at the cell surface, to bind ligand, and to mediate action. Both GBR1 and GBR2 have seven transmembrane domains, with extracellular amino termini and intracellular carboxy termini (Fig. 6). The amino terminus of GBR1 provides a GABA binding site, whereas the intracellular loops and carboxy terminus participate in G protein binding. GBR2 does not appear to interact with GABA. GBR1 and GBR2 interact via the carboxy domain, and this interaction is necessary in order to direct GBR1 expression to the cell surface.

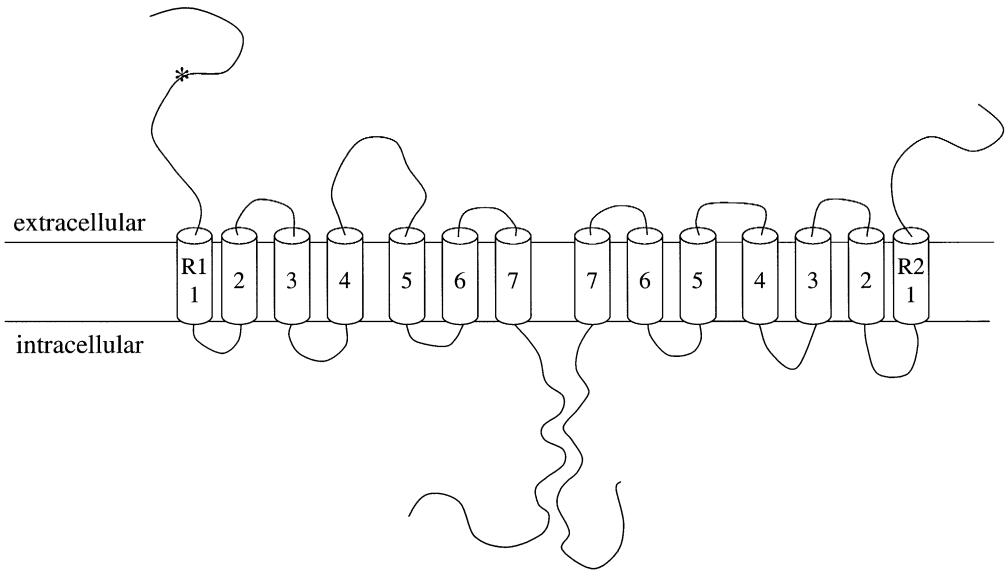

Figure 6 $GABA_B$ receptor subunit and complex topology. The $GABA_B$ receptor is composed of two similar subunits, each with seven transmembrane domains, extracellular amino termini, and intracellular carboxy termini. The putative GABA binding site, denoted by an asterisk, is on the amino terminus of $GABA_B$R1. The subunits interact via their carboxy domains.

2. Subunit Composition

There are at least four isoforms of GBR1, GBR1a–GBR1d, which range in size from approximately 100 to 130 kDa. The GBR1a isoform may be more prevalent at presynaptic sites, whereas the GBR1b isoform is predominantly found postsynaptically. GBR1 and GBR2 share 35% homology with each other but have little homology with other metabotropic receptors.

IV. GABA TRANSPORT

A. Plasma Membrane GABA Transporters

GABA is actively transported across the plasma membrane by GABA transporters (GATs). The four GATs identified so far (GAT1–3 and GAT4 or BGT-1) belong to the superfamily of Na^+- and Cl^--dependent transporters that include transporters for norepinephrine, serotonin, dopamine, and glycine but not for glutamate. The four GATs differ in pharmacology and in cell expression. For instance, GAT1 is inhibited by nipecotic acid and is predominantly found on neurons, although it is also expressed on some glia. GAT2 and GAT3 can transport both GABA and β-alanine. GAT3 is primarily a glial transporter, whereas GAT2 is found on neurons but its cell specificity remains unclear. BGT-1 was first identified in the kidney and transports GABA, betaine, and taurine. GAT2 and GAT3 are also found in peripheral tissues, including the liver and kidney.

Na^+- and Cl^--dependent transporters rely on the ionic gradients across the membrane. GABA transport is an electrogenic process that cotransports approximately two Na^+ ions and one Cl^- ion with each GABA molecule. Since the ionic gradients normally favor inward transport, GABA usually is transported into the cell. Under conditions of high intracellular Na^+ or membrane depolarization, however, GABA can be released through the transporter.

1. Topology

The GATs are glycoproteins with a molecular weight of 70–80 kDa. The presumed topology predicts that both the amino and the carboxy termini are cytoplasmic and that there are 12 transmembrane domains. The GAT1 topology is illustrated in Fig. 7. There are three glycosylation sites between the third and fourth transmembrane domains. The fourth through sixth extracellular loops form a putative GABA-binding site.

2. Carrier-Mediated Release

The GABA transporters reverse to release cytosolic GABA when the Na^+ gradient across the membrane is perturbed and also when the membrane potential increases. Although these changes occur rapidly during an action potential, GAT-mediated GABA release (or carrier-mediated release) is probably not a

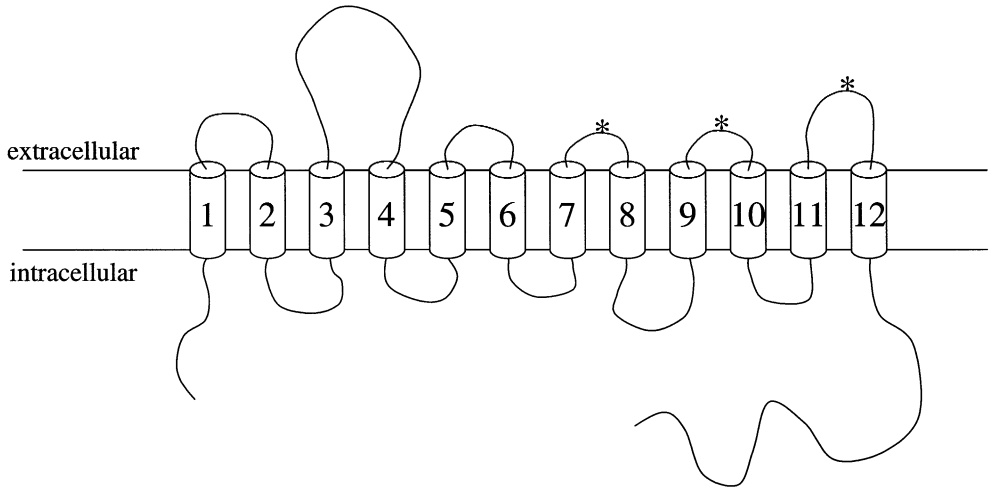

Figure 7 GAT has 12 transmembrane domains, and both the amino and carboxy termini are intracellular. The putative GABA binding site denoted by asterisks, is on the fourth through sixth extracellular domains.

major route of egress during cell firing because the changes in membrane potential are rapid and transient. However, several studies suggest that activation of the glutamate NMDA receptor causes intracellular Na^+ levels to increase sufficiently to produce GAT-mediated GABA release. Small perturbations in the extracellular K^+ concentrations, and concomitant membrane depolarization, can also cause carrier-mediated GABA release at levels sufficient to activate nearby $GABA_A$ receptors. Seizure activity and the accompanying changes in the extracellular ionic environment may therefore stimulate carrier-mediated GABA release.

B. Vesicular GABA Transporters

GABA is packaged into vesicles at the synapse by the vesicular GABA transporter (vGAT), which was recently cloned. Although vGAT transports GABA across a membrane, it bears no resemblance to the GATs. Both the amino and carboxy termini of vGAT are cytoplasmic, and there are 10 predicted transmembrane domains (Fig. 8).

vGAT, with a K_m for GABA in the millimolar range, depends on both pH and electrochemical gradients (ΔpH and $\Delta\Psi$) across the vesicular membrane to concentrate GABA into vesicles. These gradients are maintained by Mg^{2+}-activated ATPase, which belongs to the class of vacuolar ATPases. Vesicular transporters for other neurotransmitters have a different dependence on the same gradients. For instance, the vesicular dopamine transporter depends mostly on ΔpH, whereas the vesicular glutamate transporter depends mostly on $\Delta\Psi$.

Glycine, an inhibitory neurotransmitter, can also be transported by vGAT. vGAT mRNA distribution in neurons coincides with other glycinergic and GABAergic markers. Immunohistochemical studies demonstrate vGAT in terminals and the neurotransmitter phenotype of the particular terminals can be GABA, glycine, or mixed.

V. GABA FUNCTION

The GADs differ in their PLP dependence, encoding gene, membrane association, and subcellular location, which suggests that the GADs may synthesize separate pools of GABA that serve different functions. Although GABA is a neurotransmitter, it also functions as a developmental molecule and can contribute to the tricarboxylic acid cycle to provide energy to the cell. Studies of GABA in transgenic mice deficient in one GAD support the hypothesis that GAD_{65}-synthesized GABA is predominantly packaged for neurotransmission, whereas GAD_{67}-synthesized GABA remains in the cytosol and is available for alternate functions.

A. Effects of GAD Deletions in Knockout Mice

Mice lacking GAD_{67} die shortly after birth, presumably as a result of cleft palate. Their brains contain only 7% of the GABA concentration of control brains and about 20% of the GAD activity. Morphological

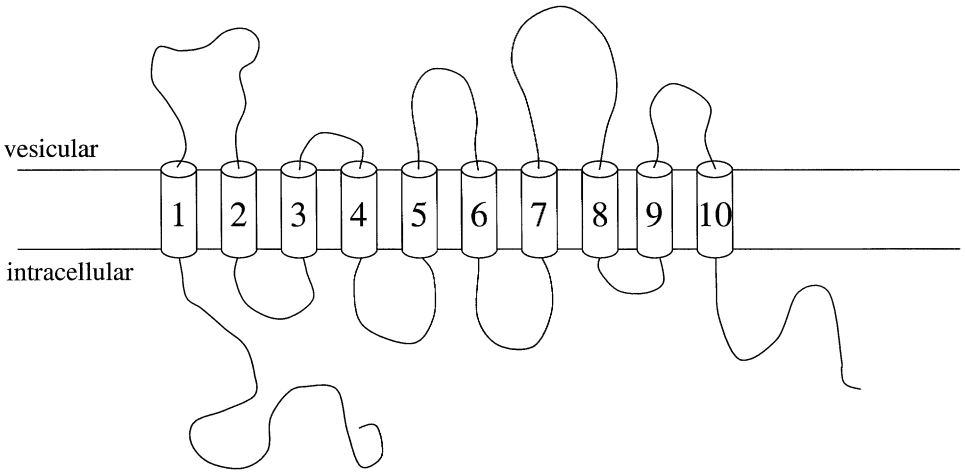

Figure 8 VGAT has 10 transmembrane domains, and both the amino and carboxy termini are intracellular (cytosolic).

analyses of their brains reveal no major abnormalities, but no detailed anatomical or electrophysiological studies of embryonic structures from GAD_{67} knockouts have been reported.

Mice lacking GAD_{65} appear to develop normally but are abnormally sensitive to seizures, particularly in a mouse line that is genetically susceptible to insulin-dependent diabetes mellitus. Perhaps significantly, these mice exhibit both humoral and cellular immune responses to both GAD_{65} and GAD_{67}.

Mice lacking GAD_{65} have a lowered capacity for depolarization-dependent GABA release *in vivo*. The GAD_{65} knockout mice also show impaired experience-dependent plasticity, as determined in monocular deprivation experiments. GAD_{65} may be selectively important in providing GABA to fill secretory vesicles and support exocytotic release of GABA. For example, GAD_{65} knockout mice cannot release normal amounts of GABA during and immediately after sustained stimulation of the retina or hippocampus. Moreover, in contrast to wild-type mice, these GAD_{65} knockout mice show no increase in the probability of GABA release after tetanic stimulation of the hippocampus. Although GAD_{67}-synthesized GABA can evidently be packaged into release vesicles under conditions of low demand, GAD_{67} alone seems to be unable to support the high-efficiency reloading of GABA vesicles required for normal function during conditions of high demand.

Mice lacking both forms of GAD die at birth, presumably from cleft palate. Although these mice have no detectable GABA, there do not appear to be any gross histological abnormalities in their brains. Therefore, GABA's role as a developmental molecule may be redundant, at least in some respects.

B. GABA as a Paracrine "Reset" Signal

GABA-producing cells increase GAD_{67} and GAD_{67} mRNA levels in response to injury, whereas GAD_{65} and its mRNA are usually unchanged. Injuries that produce increased GAD_{67} include chemical lesions of the substantia nigra and hippocampus, neuroleptic drugs, spinal cord transection, and acute stress. The increase in GAD_{67} can be observed as soon as 1 hr after insult, implicating immediate early genes in GAD_{67} regulation.

Most GAD_{67} is not associated with synapses, and GAD_{67} may be responsible for carrier-mediated GABA release. This direct release of cytoplasmic GABA occurs in cultured hippocampal neurons as well as in cells transfected with the GABA transporter and in a pancreatic cell line. Evidence from knockout mice suggests that GAD_{67}-synthesized GABA may not be effectively packaged into vesicles. Therefore, it either remains in the cytosol (where it is available for the GABA shunt) or crosses the plasma membrane via the GABA transporter.

Extrasynaptic GABA (either released via GAT or leaked from the synapse) could interact with extrasynaptic GABA receptors. Such diffuse GABA would cause inhibition diffuse with kinetics different from those at the synapse. Such inhibition would depend on the kinetics of GABA release, diffusion, reuptake, and degradation as well as on receptor composition.

Diffuse GABA could act in a paracrine manner on extrasynaptic $GABA_A$ receptors. Such receptors have been documented electrophysiologically in studies of GABA "spillover" in cerebellar synapses and microscopically by EM immunocytochemistry. The effect of such paracrine action would be to suppress neuronal firing in cells within damaged circuits. Sustained inhibition could allow the plastic remodeling of neural circuits, such as occurs during the retraining of the spinal cord. According to this view, paracrine GABA, synthesized primarily by GAD_{67}, could serve a "reset" function, giving the cells of damaged but plastic circuits the time to recover from challenge or injury. Observed parallel increases in GAD_{67} and extracellular GABA in the hippocampus of kainate-treated rats are consistent with this view. Therefore, GAD_{67} may contribute to a relatively slow mode of paracrine function, whereas GAD_{65} may be mainly responsible for the synthesis of GABA that participates in rapid point-to-point signaling.

C. How Much GABA Is Needed to Evoke a Response?

The cloning of $GABA_A$ and $GABA_B$ receptors has enabled researchers to study the properties of receptors of known covalent structure. In most of these *in vitro* studies, the K_D of the cloned receptors for GABA is in the micromolar range, but *in vivo* GABA often has an EC_{50} in the nanomolar or even subnanomolar range.

Within a synaptic cleft, the concentration of GABA is estimated to be in the millimolar range, enough to saturate postsynaptic $GABA_A$ (and $GABA_B$)

receptors. The occurrence of $GABA_A$ and $GABA_B$ receptors outside of synapses suggests that GABA may also act outside of synapses. The ability of cultured cells and partially purified receptors to bind GABA at nanomolar concentrations is consistent with a role for nonsynaptic GABA, particularly in response to injury, seizures, and other stresses.

D. Neurosteroids and GABA

GABA is involved in the actions of neurosteroids, which are steroid hormones that are synthesized in the brain and are particularly relevant to reproductive behavior and stress responses. Neurosteroids can enhance GABA release. For example, some GABAergic neurons are stimulated by testosterone, via androgen receptors, and may mediate the action or secretion of other hormones. GABA can affect lordosis, the steroid-modulated behavior exhibited by sexually receptive female rats. GABA facilitates or inhibits lordosis depending on the specific region of the brain that is stimulated.

Neurosteroids can directly bind to and activate $GABA_A$ receptors to produce sedative, anticonvulsant, and anxiolytic effects in animals. Neurosteroids can also influence $GABA_A$ subunit expression. Anesthetic effects from neurosteroids are modulated by a different site on the receptor than other types of anesthetics, but the binding site is probably also within the pore. The α, γ, and δ subunits affect neurosteroid response but not necessarily GABA binding.

E. GABA Affects Overall Excitability

GABA is synthesized in both projection neurons (e.g., neurons within the striatum that project to the substantia nigra and globus pallidus) and interneurons (e.g., the basket cells of the dentate gyrus). Projection neurons are thought to play a major role in initiating postsynaptic activity, whereas interneurons are thought to modulate postsynaptic activity. Interneurons within the hippocampus appear to also form large circuits that underlie the theta rhythms in the brain. These slow (4–9 Hz) rhythms are associated with learning and memory and may reflect an overall control of excitation that provides a more amenable environment for synaptic plasticity. Thus, GABA as a neurotransmitter not only provides straightforward neuron-to-neuron signaling but also affects the overall excitability of large regions of the brain.

GABA can initiate two types of responses. Phasic responses occur when GABA binds to postsynaptic receptors. Phasic responses are characterized by fast postsynaptic changes. Tonic responses result from ongoing activation of GABA receptors outside of the synapse. This activation produces continuous inhibition of the postsynaptic cell, thereby controlling its overall excitability.

Tonic and phasic inhibition differ not only because of the receptor location but also in the receptor subunit composition. The extrasynaptic receptors that mediate tonic inhibition have a higher affinity for GABA than do the receptors responsible for phasic inhibition. Different affinities reflect the GABA levels to which the two sets of receptors are exposed. Extrasynaptic GABA levels are lower than those found within the synapse; therefore, extrasynaptic receptors must be sensitive enough to detect low levels, whereas synaptic receptors must not desensitize upon exposure to the high levels of GABA found within the synapse. The role of $GABA_B$ receptors, which are primarily extrasynaptic, has not been elucidated in these two types of inhibition.

VI. GABA AND DEVELOPMENT

GABA functions as more than a neurotransmitter. A growing body of evidence suggests that it also plays an important role in development. GABA appears in most CNS neurons at the beginning of neurogenesis (before synapse formation), as does the $GABA_A$ receptor. During this time, GABA is excitatory because a developmentally regulated chloride transporter maintains high intracellular chloride levels.

The pattern of GAD expression changes during development, again supporting a role for GABA at this time. In the spinal cord, the change from embryonic to mature GAD_{67} transcripts echoes the ventral to dorsal maturation of the cord. GAD immunoreactivity is diffuse early in development, suggesting that there is no vesicle-associated GAD present (which would be characterized by punctate staining) and therefore no synaptic GABA.

GAT-mediated GABA transport decreases from birth through adulthood, whereas vGAT-mediated transport increases from the time of synapse formation through adulthood. The differences in GABA trafficking may account for the developmental properties of

GABA because it does not necessarily act synaptically throughout development. GABA can stimulate both directed and random movement of young neurons, possibly through the $GABA_B$ receptor. However, GABA may not be required during development since GAD knockouts have undetectable GABA but develop anatomically normal brains.

Outside of the CNS, compromised GABA signaling during development produces cleft palate, a craniofacial abnormality in which the roof of the mouth fails to close completely. Animal studies suggest that the barbiturate diazepam, which interacts with $GABA_A$ receptors, can cause palatal defects. In addition, mice lacking GAD_{67} are born with cleft palate and die shortly after birth. The route by which GABA may be associated with cleft palate is not well understood.

VII. GABA AND DISEASE

Defects in GABA synthesis, release, and response have serious consequences. Since GABA is a ubiquitous neurotransmitter, it can be argued that it has a role (direct or indirect) in most neurological diseases. The direct loss of GABAergic neurons in the striatum, for instance, is a hallmark of Huntington's disease. Parkinson's disease, however, results from a loss of dopamine neurons in the substantia nigra. The lost neurons normally project to GABA neurons in the striatum, and those lost projections affect GABA signaling in Parkinson's disease.

A. Changes in GABA Signaling

Epilepsy describes a set of diseases characterized by hyperexcitability and synchronous firing of large groups of neurons. Although there are many different kinds of epilepsy, temporal lobe epilepsy (TLE) is the most common type in adults and is often difficult to resolve. TLE seizures usually begin in the hippocampus and spread to involve large parts of the brain. Genetic mutations, injury, or tumors can all result in TLE. TLE usually causes extensive changes within the hippocampus, including the death of subsets of neurons, neuritic sprouting, and sclerotic lesions. The hyperexcitability characteristic of TLE suggests that this disease compromises GABAergic inhibition.

GAD levels increase in parts of the TLE hippocampus, but GABA levels decrease. Since GAD increases as a result of many types of injury, the changes observed in TLE may not serve to provide more GABA for signaling. Instead, the increase may reflect a general cellular response to injury, and the resultant GABA may be diverted to the GABA shunt to provide energy for the cell.

Hyperexcitability could reflect the loss of GABA neurons, but the neurons that die in TLE are mainly excitatory cells. Only a small subset of GABAergic neurons, which coexpress somatostatin, is lost. Several hypotheses address the compromised inhibitory capability of the TLE hippocampus. One possibility is that the excitatory inputs to some GABAergic neurons are lost, thus decreasing their inhibitory signaling. Another suggestion is that some GABAergic neurons lose their targets and redirect their outputs to many cells. The result is that one inhibitory cell now drives many excitatory cells, causing the synchronized firing that is a hallmark of TLE. A third hypothesis suggests that GABAergic neurons redirect their output to other GABAergic neurons, thus providing a net excitatory output relative to the normal state.

The multitude of changes within the TLE hippocampus may mean that one comprehensive treatment approach is impossible. Although GABA neurons are mainly intact, changes in connections may either increase or decrease net inhibition. GAD levels are increased, GABA receptors are increased in some cells but decreased in others, the GABA transporter is decreased only in some areas of the hippocampus, and overall GABA is decreased. Nonetheless, many of the drugs that are effective for treating TLE increase GABA action through potentiating $GABA_A$ receptors (thus creating a more powerful response to endogenous GABA) or by interfering with GAT1 or GABA-T to increase available GABA.

B. Defects in GABA Receptors

Angelman syndrome is linked to deletions in human chromosome 15, specifically in the area that codes for the cluster of $GABA_A$ receptor subunits $\alpha_5/\beta_3/\gamma_3$. Severe mental retardation, epilepsy, movement disorders, inappropriate laughter, and craniofacial abnormalities characterize this disorder. A similar syndrome, Prader–Willi syndrome, shows mild mental retardation, hypotonia, hyperphasia, and hypogonadism. The two syndromes are linked to the same gene; however, Angelman's is linked to the maternal gene, whereas Prader–Willi is linked to the paternal gene.

Epilepsy and craniofacial abnormalities are characteristic of other GABA-related disorders, highlighting GABA's role in both development and signaling, although the connection between gene deletions and symptoms is unclear.

C. Loss of GABA Neurons

Huntington's disease is an autosomal-dominant disease in which GABAergic projection neurons in the striatum are destroyed. Early symptoms include mood changes progressing to uncontrolled movements (chorea) and eventually to loss of movement and death. Disease progression can be correlated with the loss of three separate populations of GABAergic striatal neurons, although these are not the sole casualties. Cortical neuronal loss occurs later in the disease as well.

The gene for Huntington's disease codes for the huntingtin protein, which contains a long polyglutamine stretch. Normally, the number of glutamines in this protein is less than 40. Huntingtin mutations that include more than 40 glutamines are pathogenic. The number of glutamines is inversely related to the age of onset, and people with longer repeat lengths develop Huntington's disease at earlier ages. The function of the normal huntingtin protein is unknown, as is the reason for the susceptibility of GABAergic projection neurons.

The Huntington's disease gene is expressed throughout life, but disease symptoms normally begin in the fourth decade. This delay in symptom onset may reflect the ability of the brain to compensate for dysfunction for a period of time. Currently, there is no cure for Huntington's disease, and treatments are limited to palliative care.

D. Defects in GAD

Autoimmunity to GAD is a hallmark of two related conditions—insulin-dependent diabetes mellitus (IDDM, juvenile diabetes, or type 1 diabetes) and a rare neurological disorder called stiff-man syndrome (SMS).

1. Diabetes

IDDM is an autoimmune disease in which T cells mistakenly destroy pancreatic β cells, which are the sole producers of insulin. Several β cell proteins are targets of autoantibodies, including GAD_{65}, GAD_{67}, and insulin. These autoantibodies often arise several years before disease onset, possibly providing a window of opportunity for intervention.

The β cells of pancreatic islets contain high levels of GABA and GAD, comparable to those in neurons. GAD_{65} and GAD_{67} are both present in the pancreas of rats and mice, with GAD_{67} and its mRNA at higher levels than GAD_{65} and its mRNA. In humans, however, GAD_{65} greatly predominates and may also be present in pancreatic α cells. Species differences may reflect differences in gene regulation during the development of islet cell precursors. GABA from β cells is thought to act on $GABA_A$ receptors to inhibit glucagon release by α cells.

Autoantibodies to GAD, sometimes in combination with other autoantibodies, provide a highly specific and highly sensitive prediagnostic test for individuals at high risk for developing IDDM, sometimes many years before actual disease onset. GAD autoimmunity also provides a diagnostic marker that distinguishes between adult-onset non-insulin-dependent diabetes mellitus, which does not involve autoimmunity, and late-onset IDDM, which does. Whether it appears in children or adults, IDDM is an autoimmune disease, with GAD_{65} as the most common early target. Autoimmunity to GAD_{65} in IDDM could merely reflect the unmasking of a self-antigen after β cell destruction, but it may well have a causal role in the destruction of β cells.

2. Stiff-Man Syndrome

SMS is a rare neurological disease characterized by muscle rigidity that results from the simultaneous contraction of antagonistic muscle groups. As in the case of spasticity, GABA agonists can ameliorate symptoms.

About 60% of SMS patients have autoantibodies to GAD, but the causal role of GAD remains an open question since there is no apparent difference in the signs and symptoms of SMS patients with and without anti-GAD antibodies. Most SMS patients with GAD autoantibodies also have other autoimmune disorders (such as Hashimoto's thyroiditis and Grave's disease), whereas only a few percent of the GAD antibody-negative patients have any evidence of autoimmune disease. Despite years of attempts, the administration of GAD cannot provoke SMS in experimental ani-

mals, suggesting that GAD autoimmunity in SMS is probably not causal.

VIII. SUMMARY

In the 50 years since its identification as a neurotransmitter, GABA has emerged as a major force in normal CNS function, development, and disease. In addition to neurotransmission, GABA can provide energy through the GABA shunt and can mediate developmental events. Outside of the nervous system, GABA is involved with pancreatic glucagon release and is required for palate formation.

The variety of functions that GABA can perform may be governed in part by the different location and regulation of the two GABA-synthesizing enzymes. GAD_{65} appears to synthesize GABA largely for neurotransmission, whereas GAD_{67} synthesizes GABA that is available for the GABA shunt and also for release directly through GAT. The manner by which GABA leaves the cell may also be important in determining its function. GABA released via exocytosis is largely confined to the synapse, whereas that released through GAT is available to extrasynaptic receptors.

GABA receptors are an additional modulator of GABA function. Different subunit compositions impart different sensitivity, kinetics, and location. The $GABA_A$ receptor can confer inhibition or excitation, depending on the chloride gradient across the membrane. The $GABA_B$ receptor can exert both presynaptic and postsynaptic effects. The diversity of GABA actions is due in no small part to the great variation within the GABA receptor family.

GABA is the major inhibitory neurotransmitter and changes in GABA signaling have widespread effects. A role for GABA dysfunction can be argued even in diseases for which the primary pathology lies elsewhere. The molecules that synthesize, transport, respond to, and degrade GABA are all potential targets for therapy. Drugs that can selectively activate specific receptor subtypes or that can interfere with the kinetics of GABA transport and degradation will certainly be helpful in treating GABA-related diseases. Alternate approaches, including gene therapy, to control local GABA concentrations are also promising. Our understanding of the mechanisms of GABA regulation and signaling will therefore lead to new and effective therapies for a variety of diseases.

Glial Cell Types

CONRAD A. MESSAM, JEAN HOU, NAZILA JANABI, MARIA CHIARA MONACO, MANETH GRAVELL, and EUGENE O. MAJOR

National Institute of Neurological Disorders and Stroke

GLOSSARY

astrocyte The most abundant neuroglial cell type in the brain; named for its characteristic star-like shape due to processes extending radially from the cell body.

ependymoglial cells Glial cells that extend processes to the ventricular lumen in the brain and establish contact with the apical surface of neural tissue.

glial fibrillary acidic protein Type III intermediate filament protein used as a marker to identify mature cerebral astrocytes.

glial limitans Continuous layer at the surface of the cortex and cerebellum formed by the endfeet of radial glial cells.

gliosis Also called reactive astrocytosis; astrocytic response to injury or insult, marked histologically by the accumulation of glial fibers composed of glial fibrillary acidic protein.

microglia Resident macrophage of the brain; primary immune effector cell of the brain.

multipotential stem cells Cells derived from the neuroepithelium of the developing central nervous system that can give rise to different cell types.

myelin Specialized tissue high in lipid content that insulates the axons of neurons; produced in the brain by oligodendrocytes.

neuroglia The cells of the brain, excluding neurons; basic subtypes include astrocytes, oligodendrocytes, microglial, and ependymoglial cells.

oligodendrocyte Neuroglial cell type responsible for the production of myelin.

There are four major types of glial cells in the human brain—astrocytes, oligodendrocytes, microglia, and ependymal cells. This article will review the morphology and normal physiology of the various glial subtypes as well as their involvement in human brain disorders. Although glial cells comprise greater than 50% of the total population in the brain, historically they have been thought of solely as support cells for neurons. However, it has become apparent that the various glial cells perform critical functions during the development and normal functioning of the brain. Additionally, glial cells are central participants in almost all CNS disorders, taking part in both the protection or damage of brain tissue.

I. INTRODUCTION

More than a century and a half ago, Virchow (1846) introduced the word "neuroglia" to describe the tissue that fills the space between the nerve elements in the brain. Although simplistic when compared to our current concepts of neuroglia, the initial definition was correct. Almost four decades passed before the pioneering staining techniques developed by Golgi (1885) paved the way for others in the early 1900s to describe the morphology of the basic cell types that make up the neuroglia: astrocytes, oligodendrocytes, microglia, and ependymal cells.

With regard to establishing functions for neuroglia, His (1889) suggested that embryonic glial cells were responsible for guiding the migration of developing neurons to their final destination within the brain. In 1907, Lugaro proposed that adult astrocytes police the

interstitial milieu and maintain it in a state compatible for neuronal function. He also postulated that astrocytes were the cells responsible for the chemical degradation and uptake of substances released by neurons, which allowed communication and excitation, thus establishing the basis for synaptic transmission of nerve impulses. The concept that glial cells and their processes insulate nerve fibers to enhance neural impulse transmission was proposed in 1909 by Ramón y Cajal. He further postulated that glial cells fill the spatial void created by pathologic neuronal death, setting the precedent for gliosis.

In the 1920s, del Rio Hortega, by use of an innovative and selective silver impregnation technique, was the first to give a detailed morphological description of oligodendrocytes. He also identified oligodendrocytes as the cells that produce the myelin sheath that enwraps the axons of central nervous system neurons. In 1932, by use of the same silver impregnation technique, Rio Hortega also gave the first morphological description of microglia. Unlike astrocytes and oligodendrocytes, microglia have markers normally associated with hematopoietic monocytes. The origin, lineage, and mode of differentiation of microglia are incompletely understood.

Beginning in the 1950s, electron microscopy yielded information about the ultrastructural characterization of the various organelles in glial cells. From these studies came the finding that fibrous and protoplasmic astrocytes contain gliofilaments, which were subsequently determined to be intermediate filaments containing glial fibrillary acidic protein (GFAP) and vimentin. Although not all astrocytes in the normal brain immunochemically stain positive for GFAP, especially those in the gray matter, GFAP immunoreactivity is a major characteristic used to identify astrocytes.

Later in the 20th century, the focus of neuroglial study shifted toward the understanding of various interactive processes that occur between different glial cell types and neurons. These interactions are required to establish, maintain, and regulate normal brain functions and to determine how they may contribute to pathology. In synaptic and nonsynaptic transmission of nerve impulses, neurons and glia were shown to communicate reciprocally. In nonsynaptic regions of the brain, neuron to glia and glia to glia signals were shown to be mediated by neurotransmitters. Prominent among other molecules that are involved in interactive signaling between glia and other cell types of the brain are growth factors, neurotrophic factors, hematopoietic factors, cytokines, and chemokines. In the following sections, the morphology and functions of the subtypes of cells, which make up the "neuroglia," are described along with cellular activities associated with pathology or specific diseases.

II. ASTROCYTES

Astrocytes are generally divided into three subtypes, classified by morphology and anatomic location in the brain: radial, fibrous, and protoplasmic. All astrocytes express varying levels of GFAP, an intermediate filament that bundles together to form gliofilaments. The gliofilaments, 8–12 nm in diameter, are found mainly in the processes and less in the perinuclear region. Astrocytes can be visualized by Golgi impregnation; intracellular dye injection, which allows viewing of the entire cell body and processes; or immunocytochemical staining. Astrocytes are interconnected by gap junctions, which allow intercellular passage of ions and small molecules. The resulting cytoplasmic continuity suggests that astrocytes form a functional syncytium. Gap junctions are also observed between astrocytes and oligodendrocytes but not between astrocytes and neurons. Other characteristic features include the dense granules of glycogen in the cytoplasm and intramembrane "assemblies," observed by freeze fracture electron microscopy. These assemblies consist of 7-nm subunits bundled to form an array in the cell membrane, the function of which is not known. The endfeet of astrocyte processes terminate on the subpial glial limitans, blood vessels, nodes of Ranvier, and axons. Astrocytes are the most abundant cell type in the brain, comprising approximately 55% of the total population, and function in the maintenance of interstitial homeostasis and modulation of synaptic function. Astrocytes respond to almost any central nervous system (CNS) insult by activation and gliosis, which can limit edema, isolate damaged areas, and initiate an immune response.

A. Morphology and Subtypes

1. Radial Astrocytes

Radial astrocytes extend a single or group of long, thick, longitudinal processes that extend from the ventricle toward the surface of the brain. Radial astrocyte processes span the entire white matter and abut on the pia mater, the outermost surface of the brain. Because of their location in the ventricle and

bipolar morphology, some of these cells are sometimes considered ependymal cells. There are three major subtypes of radial astrocytes. First, *Radial glial cells* are primarily observed during development. They extend processes from the ventricle throughout the neural tissue. The main function of these cells is to act as "cables" on which CNS progenitor cells can migrate to their final destination. Radial glial cells are transient since they are scarce in the adult brain. It is thought that some of these cells can later become other astrocyte subtypes. Second, *Bergman glial cells*, also called Golgi epithelial cells, are the radial astrocytes of the cerebellum. The cell bodies are located between the Purkinje neurons and send processes radially through the molecular layer of the cerebellar cortex. Endfeet of Bergman glia processes terminate at the surface of the cerebellum and form a continuous layer known as the glial limitans. Figure 1 demonstrates the immunohistochemical staining for GFAP on human fetal brain. Third, *tanycytes* are radial astrocytes found mainly in adult brain, the nuclei of which are located within or just below the ependymal, or innermost, lining of the ventricle. These cells extend processes radially through the white matter.

2. Fibrous Astrocytes

Fibrous astrocytes are located in the white matter of the brain, characterized by long, unbranched processes that radiate in all directions from the cell body but rarely reach the pia mater. Fibrous astrocytes can be found in the cortex and cerebellum, and they express high levels of GFAP in their processes. The endfeet of these processes terminate on blood vessels and synapses as well as on the cell bodies and processes of neurons.

3. Protoplasmic Astrocytes

Protoplasmic astrocytes are mainly found in the gray matter of the brain. These astrocytes possess numerous short, thin, ramified processes that radiate in all directions from the cell body. These processes express little GFAP and are better observed by Golgi

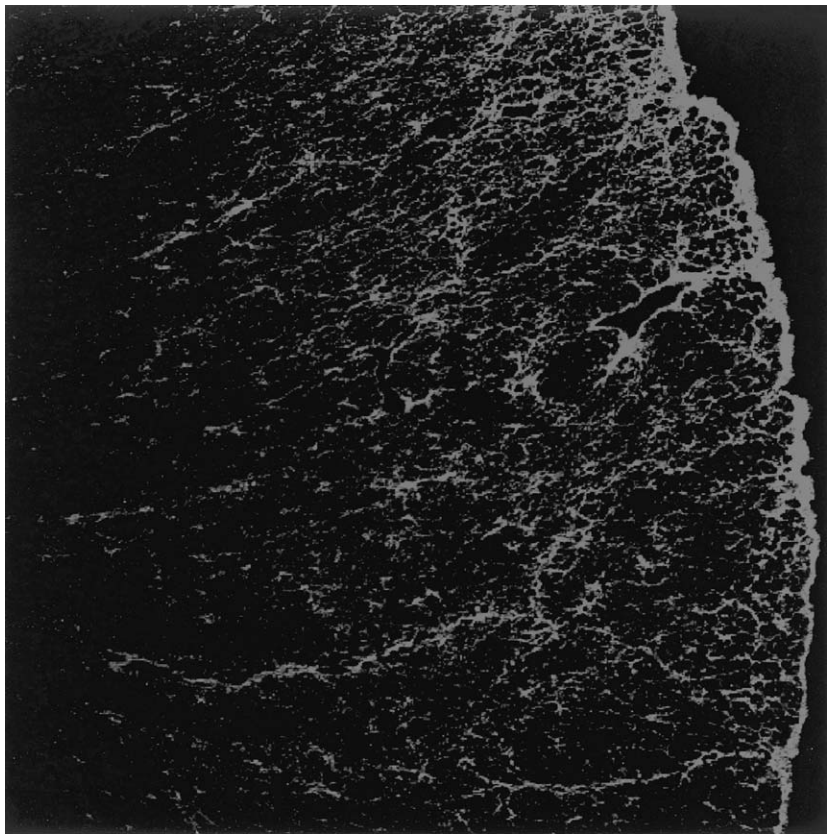

Figure 1 Immunohistochemical staining of adult human brain sections for GFAP. Note the radial morphology of the astrocyte tracts toward the outer surface of the brain. The area of intense GFAP staining at the periphery of the section is the glia limitans.

impregnation or dye injection. The endfeet terminate on blood vessels, synapses, and neuronal cell bodies, and the processes form the subpial glia limitans.

4. Astrocytes *in Vitro*

Astrocytes have varying morphologies in culture that may not fully reflect the range of morphologies found in the brain. *In vitro*, astrocytes can be separated from other neural cell types, thereby generating 95–99% astrocyte-enriched cultures. Figure 2 represents the immunofluorescent staining of cultured human astrocytes. In culture, most astrocytes derived from fetal brain appear fibroblast-like and immunostain with GFAP. These *in vitro* cultures maintain most of the functional properties of astrocytes *in vivo*. Cultured astrocytes are sometimes divided into two subtypes, type 1 and type 2, based on phenotypic characteristics as identified in rodent tissue cultures. Type 1 astrocytes stain with GFAP, whereas type 2 astrocytes costain for GFAP and A2B5, a sialoganglioside. The majority of astrocytes in culture are type 1. The type 2 astrocytes found in culture have not been observed in human brain tissue *in vivo* and may be an artifactual property of culturing.

B. Lineage and Development

Most of the information on development and lineage has been obtained from rodent brain developmental studies, with some confirmation using human fetal brain tissue. Astrocytes are derived from the neuroectodermal tissue of the neural crest. In the brain, the ventricular zone consists of a column of cells lining the ventricle that possesses the highly proliferative multipotential CNS stem cells. These stem cells give rise to progenitor cells of glial and neuronal lineage. Astrocytes are thought to originate from cells in the ventricular zone that migrate to the subventricular zone before traveling to the final destination in the brain. The process by which astrocytic progenitor cells migrate to specific brain regions is poorly understood. Radial glial cells, however, are recognized as the first glial subtype to appear in the brain. They express GFAP and nestin, an intermediate filament characteristic of immature cells. Radial and Bergman glia extend processes from the subventricular zone to the meninges at the outer surface of the brain and serve as the scaffold on which precursor cells migrate to their final location. The production and release of adhesion molecules and chemokines by astrocytes is also

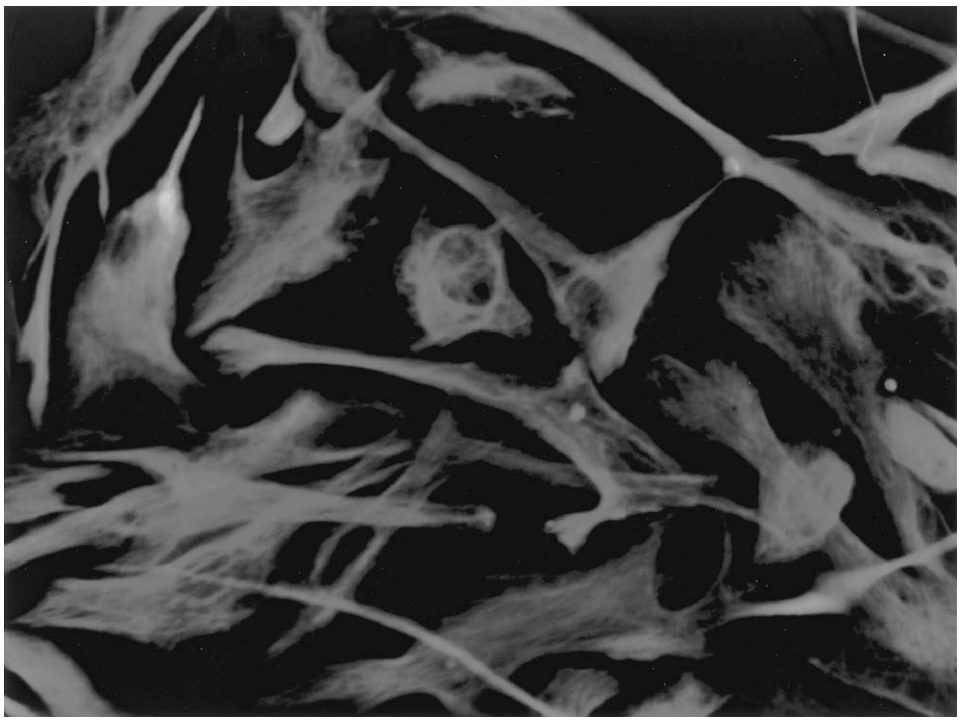

Figure 2 Immunofluorescent staining for GFAP in cultured human astrocytes. Note the filamentous ultrastructure of the cytoplasm. Magnification, × 200.

thought to contribute to the migratory process of progenitor cells during brain development. Additionally, astrocytes are known to produce a variety of trophic factors that assist in the maturation of other neural cells. Studies in rodent brain suggest that radial glia give rise to some astrocytes found in the gray and white matter. Little is known about the lineage progression of astrocyte progenitors and the factors responsible for directing the differentiation of the various astrocyte cell subtypes.

C. Normal Physiology and Function

1. Structural Functions

Astrocytes have several structural functions. They are necessary in conjunction with endothelial cells for the formation of the blood–brain barrier, an anatomic and metabolic barrier at the level of the capillary endothelial cells. The endfeet of astrocytes help to maintain a continuous layer between brain tissue and blood vessels, forming the perivascular glial membrane. The blood–brain barrier is the major obstacle preventing foreign compounds and toxins in the bloodstream from entering and damaging the brain. In effect, this barrier functionally and structurally sequesters the brain from the rest of the body. This protective barrier, however, also hinders the administration of drugs or other therapeutic compounds into the parenchyma of the brain. Another structural function of astrocytes is the formation of the glia limitans, a continuous lining of astrocyte processes, covered by a basal lamina, which is formed between the brain and the meninges. Again, the formation of the glia limitans by astrocytes helps to form the barrier to isolate the brain from other extraneural tissues. With their great abundance, astrocytes and their processes fill the extracellular space of the brain and insulate the various cell types from each other. This also occurs in brain injury, in which astrocytes hypertrophy and increase the size and number of processes at the site of injury to replace degenerated cells. The astrocytic response to CNS injury, termed gliosis, forms a scar that mechanically stabilizes the area of neuronal cell loss.

2. Maintaining Extracellular Homeostasis

Astrocytes contribute to the homeostasis of the extracellular fluid of the brain by helping to regulate pH and the extracellular concentration of K^+. There are several electrical properties characteristic of astrocytes that aid in maintaining K^+ homeostasis: electrical inexcitablity, higher membrane potential than neurons, precision in sensing and maintaining interstitial K^+ levels, and electrical linkage with neighboring astrocytes by gap junctions. The Na^+/K^+ pumps are highly concentrated on the endfeet of astrocyte processes in the vicinity of neurons. The pumps take up excess K^+ after neuronal depolarization, which can then be redistributed to more distal locations via gap junctions. The regulation of interstitial K^+ may limit excitation and be involved in fluid regulation. It is also hypothesized that astrocytes contribute to interstitial pH homeostasis. The Na^+/H^+ exchanger and the Cl^-/HCO_3^- exchangers regulate intracellular pH and may help to regulate extracellular pH as well. Astrocytes may also maintain homeostasis of the extracellular fluid by actively transporting material through the quasisyncytial network from capillary to brain tissue and vice versa.

3. Support and Interaction with Other Neural Cells

Astrocytes serve some essential functions for glutamatergic neurons and the glutamate synapse. The glutamate synapses involve the coordination between the presynaptic terminal of the axons, postsynaptic membrane, and surrounding astrocytes. The processes of astrocytes located around synapses possess high-affinity glutamate and GABA transporters that remove excess released neurotransmitters in order to limit neuronal excitation. Additionally, glutamate synthetase, found only in astrocytes, catalyzes the conversion of glutamate to glutamine, thereby providing neighboring neurons with the substrate for the production of glutamate. Therefore, glutamate synthetase also functions to detoxify neurotoxic levels of glutamate as well as ammonia. Glutamate dehydrogenase, another enzyme found in astrocytes, catalyzes the formation of glutamate from α-ketoglutarate and ammonia. Therefore, astrocytes are able to directly produce glutamate. Astrocytes may also modulate neuronal electrical activity through multiple interactions with neuronal cell bodies and nodes of Ranvier.

Astrocytes perform several functions that can modulate activity, survival, and development of other neural cells. During CNS development, radial glial cells form the highways from the subventricular zone to the parenchyma of the brain, on which the progenitor cells migrate to their final destination. The glycogen stores in radial glia are thought to provide energy for the migrating progenitor cells.

Additionally, astrocytes produce a variety of neurotrophic factors, cytokines, and adhesion molecules that can contribute to neuronal maturation and survival in the normal brain. Table I provides a partial secretory profile of astrocytes during normal function and gliosis. In response to injury, astrocytes can release protective neurotrophic factors to promote neuronal survival or, in other cases, release factors that may exacerbate damage and contribute to neuronal death. Also, the termination of astrocytic endfeet upon the blood vessels facilitates the transport of nutrients from systemic circulation through gap junctions, thereby redistributing the nutrients to neural tissue.

Although there are several studies examining the cellular and biochemical properties of astrocytes, relatively little is known about the molecular factors involved in astrocyte differentiation and normal function. Elucidating the molecular characteristics of astrocytes will be an area of active and intensive research for the future.

Table I
Growth Factors, Cytokines, Chemokines, and Adhesion Molecules Produced by Astrocytes

Factor	Full name	Normal or gliosis[a]
FGF-1 (aFGF)	Acidic fibroblast growth factor	N
FGF-2 (bFGF)	Basic fibroblast growth factor	N
PDGF	Platelet-derived growth factor	N
NGF	Nerve growth factor	N
CNTF	Ciliary neurotrophic factor	N
TGF-α	Transforming growth factor-alpha	N
IGF-1	Insulin-like growth factor	N
GMF	Glia maturation factor	N
TNF-α	Tumor necrosis factor-alpha	R
LIF	Leukemia inhibitory factor	R
TGF-β	Transforming growth factor-beta	N/R
IL-1B	Interleukin-1 beta	N/R
IL-3	Interleukin-3	N/R
IL-6	Interleukin-6	N/R
G-CSF	Granulocyte colony-stimulating factor	N/R
M-CSF	Macrophage colony-stimulating factor	N/R
GM-CSF	Granulocyte and macrophage colony-stimulating factor	N/R
IP-10	Gamma-interferon inducible protein	N/R
MCP-1	Macrophage chemoattractant protein	N/R
IL-8	Interleukin-8	N/R
ICAM-1	Intracellular cell adhesion molecule-1	N/R
VCAM-1	Vascular cell adhesion molecule-1	N/R

[a]Abbreviations used: N, released by normal astrocytes; R, released by reactive astrocytes; N/R, released by both normal and reactive astrocytes.

D. Contribution to Disease

1. Edema

Edema is one of the most common responses to brain injury resulting from astrocytic swelling. There are two types of edemas. The first is cerebral edema, which occurs after a disruption of the tight endothelial junctions of the brain vasculature. This causes fluid influx in the brain parenchyma, resulting in increased intracranial pressure. The second type of edema is cellular edema, which is astrocytic swelling after injury that may not result in a net influx of fluid into the interstitial space. Both types of edema may impair transporter function and the ability of astrocytes to maintain K^+ homeostasis. Acute abnormalities that cause edema include hemorrhage, trauma, and brain infarct. Subacute and chronic conditions such as status epilepticus, malignancy, Reye's syndrome, and encephalitis can also cause edema.

2. Gliosis

Gliosis, also called astrocytic gliosis or astrocytosis, is a common term that refers to the reactive astrocytic response to a brain injury or insult. Almost all brain lesions have a component of gliosis, even with different glial pathologies. Gliosis is a secondary event to CNS damage and may persist for weeks or months after brain injury. This condition occurs after infarct and is associated with infections and neoplasm as well as with demyelinating, toxic, and metabolic diseases. In gliosis, astrocytes hypertrophy, the nuclei become enlarged, and the chromatin becomes less dense while nucleoli become more prominent. There is an increased number of organelles and higher production of the intermediate filaments GFAP, nestin, and vimentin, which results in greater and more highly condensed glial processes and fibers. The increased glial processes replace injured CNS cells and form a gliotic scar. It is thought that the glial scar limits edema and prevents neuronal regeneration in the CNS by blocking regenerating axons from entering the damaged areas. With gliosis there is the release of cytokines, growth factors, and extracellular matrix proteins, which may be

involved in immune response, neuroprotection, or possible further damage. The term ''reactive gliosis'' normally refers to massive hypertrophy of astrocytes; however, it is apparent that gliosis is inherently reactive.

3. Neoplasm

Astrocytomas are neoplastic cells largely derived from astrocytes. They are classified into four categories based on the level of malignancy, with grade I being the least malignant and grade IV being the most malignant. All astrocytomas express some level of GFAP, but less malignant tumors generally express higher levels. The more malignant tumors express higher levels of nestin than GFAP. *Grade I astrocytomas*, called pilocytic astrocytomas, are gray, firm, and often cystic, with tumor cells that have long, hair-like cellular processes. These tumors most often occur in children or young adults. The boundaries are clearly distinguishable from normal brain, and when amenable to surgical removal the prognosis is good with little chance of recurrence. *Grade II astrocytomas* are the low-grade astrocytomas, which occur most often in young adults. They are solid, gray homogeneous tumors, characterized by astrocytes with pleomorphic nuclei and dark, condensed chromatin. These tumors diffusely infiltrate the brain parenchyma, which allows only partial surgical removal. There is variable prognosis with these tumors, with average survival of 3–5 years. *Grade III astrocytomas*, called anaplastic astrocytomas, resemble grade II astrocytomas but have more pleomorphic nuclei and high mitotic activity. Even with surgical removal and radiation therapy, the prognosis is still variable, with average survival of 1–3 years. *Grade IV astrocytomas* are known as glioblastoma multiforme and are the most malignant and frequent brain tumors in adults. These tumors have exaggerated features of grade III tumors with additional coagulation necrosis, vascular proliferation, and occasional hemorrhage. These tumor cells have a very high mitotic rate and the poorest prognosis for survival (less than 1 year after diagnosis).

4. Astrocytes

a. Immune Involvement Astrocytes are immunocompetent cells that participate in local immunological reactions. At the site of CNS damage, these cells can phagocytose dead cells and act as an antigen presenting cell in the initial phase of the immune response. Activated astrocytes express MHC II, which is involved in antigen presentation. Activation after CNS damage or pathogen infection results in the production of a variety of cytokines, interleukins, adhesion molecules, and chemokines. These released factors facilitate recruitment and activation of leukocytes and microglial cells to the area of insult and may contribute to disease development.

b. Involvement in Viral and Other Infectious Agents A variety of neurotropic viruses that cause neuropathogenesis in the human brain also infect astrocytes. Although in many cases infected astrocytes are not a primary target resulting in neuropathy, they contribute to viral latency and amplification of pathology through the release of cytokines. A good example is human immunodeficiency virus (HIV), the virus that causes acquired immunodeficiency syndrome (AIDS). HIV enters the brain and infects microglia and astrocytes, although astrocytic infection is nonproductive. It is hypothesized that astrocytes are a latent reservoir for HIV, complicating the task of complete virus eradication. Astroctyes, in conjunction with microglial cells, contribute to AIDS neuropathy by releasing cytotoxic factors that can amplify the immune response and further contribute to neuronal toxicity.

III. OLIGODENDROCYTES

Oligodendrocytes have a very clear functional definition. They are the cells in the CNS responsible for the production and maintenance of myelin, the insulating layer that surrounds the axons of neighboring neurons. As such, they are considered the most metabolically active cells in the brain. Due to an inherent resistance to early staining techniques, oligodendrocytes were the last cell type of the CNS to be discovered and characterized. Oligodendrocytes develop from the neuroepithelial cells of the neural tube in defined temporal and spatial patterns. In the gray matter of the adult human brain, oligodendrocytes are called satellite cells and function mainly in fluid and respiratory exchange, whereas oligodendrocytes found in the white matter are involved in the synthesis of myelin sheaths. In contrast to the functional diversity among astrocytes, oligodendrocytes appear to be a fairly homogenous population, with a unified purpose of myelinating axons. Structurally, however, oligodendrocytes exhibit a wide polymorphism, and classifying different variants has proven to be a difficult task.

A. Morphology and Subtypes

As a whole, oligodendrocytes are very refractive to stains. *In vivo*, the structure of the oligodendrocyte cell body is shrouded to some extent by the vast networks of myelin it produces as well as by its close association with neighboring axons. In fact, a cell may be identified as an oligodendrocyte based on its continuity with the outermost layer of the myelin sheath. The cells are morphologically diverse and can be classified into four subtypes. Type 1 oligodendrocytes have spherical or slightly polygonal cell bodies. They have several thin processes that emerge from the cell body in the direction of nerve fibers. This subtype can be found in the forebrain, cerebellum, and spinal cord, and these oligodendrocytes are usually arranged around blood vessels, neurons, and fiber tracts. Type 2 oligodendrocytes are polygonal or cuboid in shape, with fewer and thicker processes than those of the Type 1 subgroup. These cells are only found in the white matter and are closely associated with nerve fibers. Type 3 oligodendrocytes have even fewer processes directed toward nerve fibers and are found in the cerebral and cerebellar peduncles, medulla oblongata, and the spinal cord. Finally, type 4 oligodendrocytes are found near the entrance of nerve roots into the CNS and in association with large axons. These categories are arbitrary in nature because oligodendrocytes rarely fit perfectly into any one subgroup. Oligodendroglial cells may also be classified as interfascicular, perivascular, or perineuronal satellite cells, depending on their location.

Although the gross structure of oligodendrocytes varies widely, little difference in the fine structure has been observed in the CNS. The oligodendroglial cell body and the associated myelin membrane are enriched with sphyngoglycolipids such as galactosylceramide and its sulfated form, sulfatide. Immunocytochemical staining of the cell body *in vivo* may prove difficult because the vast network of myelin results in poor antibody penetration. Furthermore, the cell surface marker repertoire changes with different stages of differentiation. However, *in vitro*, isolated oligodendrocytes can be visualized by immunofluorescent staining, as shown in Fig. 3. Similarly, intracellular injection of dyes has revealed much about the ultrastructure of oligodendrocytes. The cytoplasm of the cells has well-developed Golgi apparati and abundant ribosomes, both free and bound to an extensive endoplasmic reticulum. This is to be expected since high-scale myelin protein synthesis and transport are the two main functions of this cell type. The greater density of the cytoplasm and nucleus, as well as the absence of glycogen granules or bundles of specific intermediate filaments, can distinguish oligodendrocytes from astrocytes. Oligodendrocytes do not contain intermediate filaments in the cytoplasm but, rather, actin microfilaments and a high content of microtubules, particularly in the processes. By electron microscopy, oligodendrocytes can be further subdivided into light, medium, and dark, distinguishable by decreasing size and increasing cytoplasmic density. It has been proposed that these structural differences are correlated to functional differences as well. For example, the light oligodendrocytes appear to be highly involved in the production of myelin, whereas the dark oligodendrocytes may be involved with myelin maintenance.

B. Lineage and Development

Most developmental studies of oligodendroglial lineage and development have been conducted in rodent models due to difficulty in culturing human oligodendrocytes. The maturation of oligodendrocyte precursors into mature oligodendrocytes is characterized by a distinct temporal expression of cell surface receptors and response to different growth factors. In mammals, oligodendrocytes originate from multipotential neural stem cells derived from the neuroepithelium of the developing CNS. In the adult brain, mature

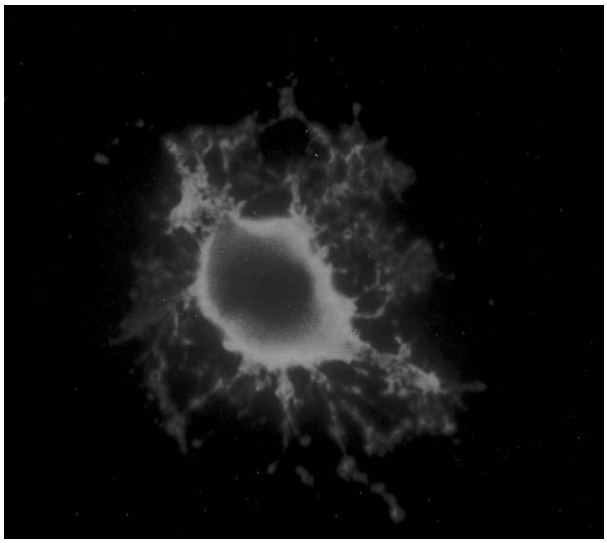

Figure 3 Immunofluorescent staining of a mammalian oligodendrocyte. Stained for Gal-C, a galactocerebroside expressed during the final stages of oligodendroglial development. Note the highly branched processes and intense staining of the cell membrane.

oligodendrocytes are distributed throughout the white and gray matter. In the developing CNS, however, induction of oligodendroglial precursors occurs in spatially restricted areas. Chemical factors released into localized areas of the extracellular environment can initiate changes in morphology and expression of growth factor receptor mRNA. In rodent studies, it is thought that the precursors are initially restricted to the ventral ventricular zone of the developing neural tube. The notochord and surrounding floor plate may release factors such as sonic hedgehog, which results in migration of the precursors dorsally and radially to populate the white matter. Furthermore, oligodendrocyte precursors located in the developing midbrain and forebrain may migrate into the thalamus and hypothalamus later in development, as well as to more dorsal regions of the cerebral cortex.

Induction of the oligodendrocyte progenitors from neuroepithelial stem cells in discrete locations must be followed by an active and large-scale migration throughout the CNS in order to myelinate all the white matter tracts. The cellular terrains or soluble factors utilized during this long-distance migration are unknown. The traveling precursors may interact with radial glial cells or may even utilize axons to guide them to their final destination. The oligodendrocyte precursors do possess a variety of integrin receptors, which may play important roles in migration and differentiation over various extracellular matrix components.

Extensive proliferation occurs in the white matter, and the expansion of the oligodendrocyte population is most likely regulated by a variety of growth factors. Once sufficient progenitor populations have been achieved, proliferation is downregulated and shifted toward differentiation. Again, maturation of the oligodendrocytes is highly influenced by growth factors and hormones. As the precursors mature, they will lose their motility and various cell surface receptors. Table II summarizes the proposed stages of oligodendroglial development and progressive changes in cell surface markers, morphology, and motility. Terminal differentiation of oligodendrocyte precursors and initiation of myelination requires dramatic and highly coordinated changes in the pattern of gene expression. The molecular mechanism by which oligodendrocyte-specific gene expression is regulated is most likely due to the combined action of multiple transcription factors. These include members of the homeodomain proteins in undifferentiated oligodendrocytes and zinc finger proteins in mature oligodendrocytes. Oligodendroglial survival factors secreted at the final destination induce the synthesis of myelin-specific mRNA, such as myelin basic protein (MBP) and proteolipid protein (PLP). MBP is actually a family of seven protein isoforms produced from a single gene by alternative splicing. Little is known about the precise structure of MBP in its native environment, although it is believed that the proteins are self-associating and may exist in an oligomeric form at the cell membrane.

Table II
Oligodendroglial Development[a]

Stage	Specific cell surface marker	Morphology	Motility
Preoligodendroglia, oligodendrocyte precursor (OP)	PDGFRα, O4 immunoreactivity		Highly motile
Immature oligodendrocyte	O1 immunoreactivity		Less motile
Mature oligodendroctye	CNP, PLP, MBP, MOG		None

[a]Abbreviations used: PDGFRα, platelet-derived growth factor receptor alpha; O4, antibody that recognizes cell surface constituents specific for oligodendrocyte precursors; O1, antibody against galactosylcerebroside; CNP, 2′,3′-cyclic nucleotide 3′-phosphotidase; PLP, proteolipid protein; MBP, myelin basic protein; MOG, myelin oligodendrocyte glycoprotein.

PLP is the most abundant protein in CNS myelin and also has alternative splice variants. With several transmembrane domains, functional studies have implicated a role of PLP as an ion channel.

C. Normal Physiology and Function

In the CNS, oligodendrocytes are responsible for the synthesis and maintenance of the myelin that surrounds the axons of neighboring neurons. The purpose of the myelin sheath is to allow saltatory propagation of nerve impulses along the length of the axon, resulting in a faster and more efficient neural impulse than in uninsulated nerve fibers. The exact cellular mechanisms responsible for the process of myelination are unclear. In humans, oligodendrocytes emerge several days or weeks before they actually start to synthesize myelin, and myelination takes place principally within the first year after birth. Recent studies have shown that initiation of myelination may be partially dependent on the activity of protein kinase C (PKC), a family of phospholipid-dependent enzymes ubiquitously present in the CNS. Not only do myelin-associated proteins appear to be excellent substrates for PKC-mediated phosphorylation but PKC activity also increases gradually after birth, coinciding with the temporal pattern of myelination in the human brain. Indeed, in cultures of human adult brain-derived oligodendrocytes, treatment with PKC agonists resulted in the increased synthesis of MBP as well as causing process extension, which are both myelogenic events.

Chemical or structural signals from neighboring axons are most likely the initiators of myelination by oligodendrocytes. An oligodendrocyte process extends from the soma and engulfs a segment of the axon, forming an inner and outer layer. As the cytoplasm is eliminated from the layers, the myelin condenses into compact myelin. The process will continue to encircle the axon, forming layers known as lamellae that abut one another and form a continuous spiral. Cross-linking of MBP oligomers on adjacent layers believed to condense the processes into thin, apposing sheets. Interestingly, the chemical composition of compact myelin is different from the chemical composition of the originating oligodendroglial cell membrane. Myelin has a much higher lipid content than the membrane of the cell body, despite the fact that compact myelin is continuous with the oligodendrocyte cell membrane. This is not surprising, however, since the insulating value of myelin is conferred in large part by its high percentage of lipid constituents. The myelin sheath as a whole is discontinuous because each oligodendrocyte process furnishes the myelin for only one segment of the axon, leaving small areas of exposed axonal membrane called the nodes of Ranvier. The action potentials skip over the myelinated areas and are repropagated only at the nodes, greatly increasing the velocity at which impulses travel. Each oligodendrocyte is capable of myelinating up to 50 internodes at a significant distance. In fact, during periods of active myelogenesis, an oligodendrocyte is capable of producing up to three times its own weight in myelin a day.

Other than the obvious role in the CNS, oligodendrocytes have also been shown to be neurite inhibitors. They prevent abnormal axonal sprouting outside the already established nerve tracts, and they also lend structural integrity to the CNS. However, oligodendrocytes that prohibit axon growth can actually enhance axonal regeneration in instances of neural tissue damage, further contributing to the complexity in function and intercellular relationships of these cells. Satellite oligodendrocytes located in the gray matter may function in regulating ion concentrations and pH levels in the extracellular space by fluid and ion exchange. Further studies must be conducted on mechanisms responsible for the oligodendroglial ability to successfully remyelinate demyelinated regions resulting from traumatic injury or disease. Once elucidated, these cells may be critical for therapeutic purposes in treating demyelinating diseases of the CNS.

D. Contribution to Disease

Damage to oligodendrocytes can occur in a variety of ways, including microbial infections, injury, autoimmunity, genetic defects, inflammation, and exposure to toxins. Although great strides have been made in understanding the core features of many of these demyelinating actions, the molecular events leading to damage of oligodendrocytes and, in many cases, dysmyelation or demyelination are not totally understood.

1. Multiple Sclerosis

Multiple sclerosis (MS) is a major demyelinating disease with pathological features similar to those of the experimental animal model, experimental allergic encephalomyelitis (EAE). Blood vessels in the CNS of MS patients characteristically have inflamed

perivascular cuffs containing T lymphocytes and monocytes recruited from peripheral circulation. Although much studied, the cause of oligodendrocyte death in MS is not clear. Some investigators have presented evidence that oligodendrocytes in acute and chronic demyelinated lesions undergo apoptotic death, whereas many others have found evidence of only necrotic cell death. Plaques of demyelination are present in the white matter, with chronic plaques devoid of both oligodendrocytes and myelin, as shown in Fig. 4. Reactive astrocytosis is also a prominent feature of MS lesions.

Many factors have been linked etiologically with MS. $CD4^+$ and $CD8^+$ lymphocytes have both been reported to lyse oligodendrocytes, with $CD4^+$ cells doing so by a non-MHC-restricted mechanism involving perforin release and $CD8^+$ by a MHC-restricted mechanism. Furthermore, $\gamma\delta$ T lymphocytes found in MS lesions may damage oligodendrocytes by a non-antigen-specific necrotic pathway. Activated macrophage/microglia also have the capacity to necrotically kill oligodendrocytes. Although oligodendrocyte injury and death can be mediated by both antibody-dependent and antibody-independent complement pathways, as well as by exposure to nitric oxide, none of these factors can clearly be shown to be the sole cause of MS.

2. Human T Cell Lymphotropic Virus, Type 1

Human T cell lymphotropic virus type 1 (HTLV-1) is a retrovirus that causes human adult T cell leukemia. Frequently, however, it causes the demyelinating neurological disease tropical spastic paraparesis (TSP), so named because it was thought only to occur in tropical geographic areas of the world. However, it has been found multiracially, in many countries, and in a wide range of climates. Because TSP occurrence has also been documented in individuals residing in countries with temperate climates, the name TSP is considered a misnomer and it has been proposed that it be called HTLV-1-associated myelopathy (HAM).

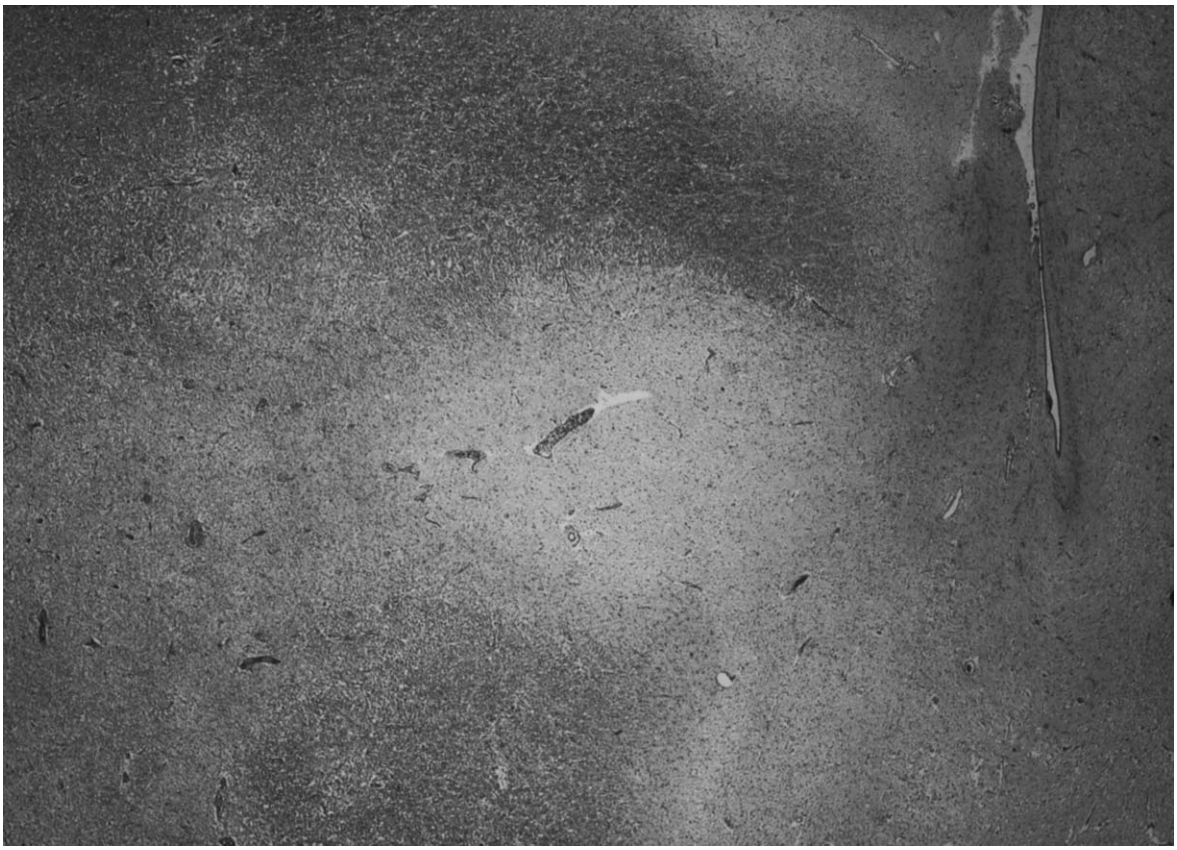

Figure 4 Demyelinated plaque occurring in the brain of a patient with multiple sclerosis. Tissue section staining with Luxol fast blue visualizes myelinated areas (dark) and regions devoid of myelin (light).

Symptoms associated with the chronic form of MS are similar to those of TSP/HAM, particularly in those patients exhibiting cerebellar signs. The occurrence of MS is rare in tropical regions, and the few patients from HLTV-l-endemic regions who were tested for HTLV-1 antibodies were negative. However, some individuals in temperate regions originally diagnosed as having MS in reality had TSP/HAM.

3. Progressive Multifocal Leukoencephalopathy

JC virus (JCV), a human polyomavirus closely related to BK virus and simian virus 40 (SV40), is the cause of the fatal demyelinating disease progressive multifocal leukoencephalopathy (PML), the only human disease known to be caused by infection with JCV. JCV infects 80% or more of the world's population, with initial infection occurring predominantly during childhood. The target of this ubiquitous virus is the myelin-producing oligodendrocyte. The virions can be detected in the nuclei of infected oligodendrocytes in a dense, crystalline arrangement called inclusion bodies. Prior to the AIDS pandemic, PML was a relatively rare disease affecting primarily immunosuppressed cancer patients with lymphoma or leukemia and transplant recipients receiving immunosuppressive therapy. It has been estimated that PML now occurs in about 5% of HIV-1-infected AIDS patients and is a major cause of death. Treatment of PML has been elusive. Some AIDS patients with PML receiving high-intensity antiretroviral therapy, including protease inhibitors, have shown clinical improvement, probably because the drug treatment regimen improved their general immunocompetence. Other AIDS patients with PML receiving high-intensity antiviral drug therapy showed no survival benefit from the treatment.

4. Other

Altered homeostasis of the neurotransmitter glutamate has also been postulated to cause excitotoxic death of oligodendrocytes. This depends on whether glutamate homeostasis is transiently or chronically altered. For example, exposure to short ischemic periods followed by transient increases in extracelluar glutamate may produce only limited damage to oligodendrocytes that can be repaired through the differentiation of oligodendrocyte precursors. Conversely, extended disturbances in glutamate signals may result in progressive oligodendrocyte cell death that exceeds the intrinsic capacity for oligodendrocyte repair, causing permanent damage to the oligodendrocyte population.

Toxic factors and genetic defects such as those seen in the leukodystrophies and Pelizaeus Merzbacher disease can also cause dysmyelination or demyelination. Exposure to free radical donors such as superoxide (O_2^-) or nitric oxide (NO), to free radical generating systems such as catecholamines, heat shock, and irradiation, and to agents that increase intracellular calcium concentrations, such as calcium ionophores, kainite, and myelin basic protein, has also been shown to kill oligodendrocytes.

A small percentage of all gliomas, approximately 5%, are oligodendroglial in lineage. These relatively avascular oligodendrogliomas initially form in the white matter and grow into the gray matter as they progress. The tumors can be grouped into two categories: the low-grade, less aggressive oligodendrogliomas or the more aggressive, anaplastic oligodendrogliomas. As a rule, a tumor in the low-grade category tends to be a pure oligodendroglioma, whereas the anaplastic tumors are a mixture of astrocytomas and oligodendrogliomas, also known as oligoastrocytomas. Although oligodendrogliomas are seen mainly in adults, they can also occur infrequently in children. Treatment strategies for oligodendrogliomas include surgical removal, radiation therapy, and chemotherapy.

IV. MICROGLIAL CELLS

Microglia are the resident macrophages of the brain, comprising 10–20% of all glial cells. They have active functions similar to those of other tissue macrophages, including phagocytosis, antigen presentation, and the production of cytokines, eicosanoids, complement components, excitatory amino acids (glutamate), proteases, and oxidative radicals. The antigenic plasticity of certain microglial populations, the cross-reactivity of the antibodies for microglia and other tissue macrophages, and the lack of a fully microglia-specific antibody argue for a monocytic derivation of these cells. However, a direct lineage relationship between microglia and myelomonocytic will be debated until quantitative and qualitative differences in the expression of some cell surface proteins common to both cell types and in their functions can be evidenced.

A. Morphology and Subtypes

"Brain macrophage" is a general term that comprises several subtypes of cells based on morphology,

localization, surface antigen markers, and function. Perivascular microglia, with an elongate shape, are located around blood vessels in adult tissue. They are thought to be regularly replenished by peripheral monocytes that infiltrate the CNS through the hemoencephalic or blood–brain barrier. The surface antigen profile is similar to that of circulating monocytes. *In vivo*, perivascular microglia are considered the most important antigen presenting cells, given their diversified, anatomical location. Intraparenchymal microglia, or resident microglia, are more numerous in gray matter than in white matter. They are maintained as a pool with a low turnover rate in normal adult brain. Parenchymal microglia can be subdivided into two populations. The first group includes ramified or resting microglial cells, which are highly branched cells with a small amount of perinuclear cytoplasm and a small, dense, and heterochromatic nucleus. The second population consists of ameboid microglial cells, which display migratory capacity and phagocytosis. These cells are particularly present during embryonic development and after CNS injury. In fact, ramified and retracted microglial processes can become ameboid-like, forming reactive microglia during brain injury. The best defined functions of microglial cells are related to microglial activation during pathological processes and include antigen presentation, cytotoxicity, neurovascularization, and phagocytosis. Some of these functions are also important for the normal physiology of the adult brain as well as the developing brain.

B. Lineage and Development

The origin of microglial cells has been debated since the initial silver staining by del Rio-Hortega. Although most macrophages are derived from monocytes, a subset can form locally by division of preexisting macrophages or from other progenitor cells. Here two contrasting theories are discussed in support of a mesenchymal or neuroectodermal origin of microglia.

During the development of the CNS, microglial cells are found after formation of blood vessels. During the vascularization of the CNS, the penetration of the endothelial cells is followed by focal degeneration of subadjacent glial endfeet, which attract monocytes from peripheral circulation. In fact, monocytes can infiltrate the CNS and have the potential to transform into macrophagic cells, giving rise to perivascular macrophages. However, there is not enough evidence that resident mature microglia in the parenchyma are derived from monocytes. They are believed to belong to the mononuclear phagocyte system because they express Fc and CR3 receptors and are capable of phagocytosis. Furthermore, cytoplasmic enzymes expressed by microglial cells, such as lysozyme, nonspecific esterase, and peroxidase, are also found in cells of the mononuclear phagocyte system. Microglia can be identified in human fetuses as early as 13 weeks of gestation. An important accumulation of ameboid cells is observed in the ventricular zone (germinal matrix) of human fetuses at 13–24 weeks of gestation. Human fetuses less than 28 weeks of gestation also have a significant concentration of macrophages in the ventricular zone, perivascular sites, leptomeninges, and subependymal regions. However, there is no correlation between the density of the ramified microglia and areas where there has been a high incidence of cell death. Indisputably, hematopoietic macrophages are present and play an important role in the developing CNS. Nevertheless, as the system develops, the number of dying cells decreases, as does the number of hematopoietic macrophages. The development of ramified microglia seems to be an independent process because they appear later in development, proliferate to occupy the parenchyma, and develop close functional interactions with neurons and other glial cells.

In attempts to demonstrate that microglia can be replaced by hematopoietic monocytes, the use of bone marrow radiated chimeric animals suggests that monocytes–macrophages in leptomeninges, choroid plexus, and perivascular areas are indeed replaced by cells from the bone marrow. In contrast, parenchymal ramified microglia are not replaced by bone marrow-derived marked cells in a significant number. Thus, the majority of microglial cells come from locally present precursor cells, most likely of neuroectodermal origin. The theory of a neuroectodermal origin of microglia assumes that microglia originate from a common glial stem cell, the glioblast, in the ventricular zone and later in the subventricular zone of the developing neural tube. Thus, some of the precursor cells responsible for the turnover of macroglia might be responsible for the turnover of microglia. Another possibility is that the CNS is colonized by hematopoietic stem cells very early during development, and that stem cells become resident cells of the CNS. These cells are then responsible for the regular turnover of the intraparenchymal microglia in normal brain and increased numbers of microglia in pathologic conditions. To date, searches for hematopoietic stem cells in the CNS have been unsuccessful. Attempts to develop cultures

of microglia initiated from the neuroepithelium of mouse embryos prior to vascularization and the appearance of monocytes–macrophages in the yolk sac strongly suggest that at least some microglial cells can originate from the neuroepithelium of the neural tube, as do other glia.

C. Normal Physiology and Function

The morphology and branching patterns of microglial cells display heterogeneity between different brain regions. Microglia in gray matter tend to be ramified, with processes extending in all directions. Cells in the white matter are bipolar and often align their cytoplasmic extensions in parallel, at right angles to nerve fiber bundles. Thus, the morphology of microglia adapts to the architecture of the brain region they populate, whereas their phenotype appears to be influenced by the chemical composition of the microenvironment. For example, MHC class II-positive and CD4-positive microglia are localized mostly in the white matter of normal brain. Regions lacking a blood–brain barrier show microglia and microglia-like cells with a different phenotype, suggesting that serum proteins influence the phenotype.

The microglial plasma membrane contains a large number of receptor and adhesion molecules as well as a wide variety of enzymatic activities (Table III). Therefore, a large number of antibodies can be used to stain microglial cells. Microglia in the human brain can be visualized using analogous antibodies against typical macrophage surface receptors. In addition to the expression of Fc and complement receptors, other cell adhesion molecules are expressed constitutively on resting microglia in normal brain. Belonging to the integrin superfamily of adhesion molecules, these include typical lymphocytic antigens, such as lymphocyte function antigen (LFA), CD4 antigen, and leukocyte common antigen. B lymphocyte antigens are also present on human microglia. Thus, the microglial surface membrane bears molecules associated with white blood cells. It is well documented that the normal brain contains MHC antigens and that the principal MHC-expressing cell type is the microglial cell. The constitutive expression of MHC antigens in the brain is not limited to microglial cells, however; it also includes endothelial cells and certain cell types located in the wall of cerebral blood vessels. MHC antigen expression is considerably increased in pathologic conditions or after systemic administration of cytokines, such as interferon-γ (IFN-γ). The

Table III
Phenotypic Characteristics and Secretory Activity of Microglial Cells[a]

	Antigen expression			Soluble mediator production
	Resting	Activated	Cell specificity	
Fc receptors	±	+	Macrophage	M-CSF
CD68	+	+	Macrophage	G-CSF
Lectin	+	+	Macrophage	TNF-α
CR3 complement receptor	+	+	Leukocytes	IL-1

				Matrix metalloproteinases

[a]Abbreviations used: ICAM, intercellular adhesion molecule; IL, interleukin; G-CSF and M-CSF, macrophage and granulocyte colony-stimulating factors; LCA, leukocyte common antigen; LFA, leukocyte function-associated antigen; MHC, major histocompatibility complex; NGF, nerve growth factor; NT-3, neurotrophin-3; TNF, tumor necrosis factor; TGF, transforming growth factor; VCAM, vascular cell adhesion molecule.

intermediate filament vimentin, which is evident in activated microglia and in brain macrophages, is absent from resting microglia. However, it can be upregulated rapidly in response to neuronal injury. Lectin histochemical staining of nervous tissue revealed that the B4 isolectin derived from *Griffonia simplicifolia* and the lectin from *Ricinus communis* resulted in the selective visualization of microglia. Both lectins have similar sugar-binding characteristics and recognize anomeric forms of galactose in the oligosaccharide side chains of nervous system glycoproteins in the microglial plasma membrane.

Perhaps the most well-known biological function of microglial cells is their role during the development of the CNS. Microglial cells remove dead cell fragments and eliminate transitory or aberrant axons. They can also play a more active role during cell degeneration by inducing the death of certain cells. Microglia support the development and normal function of neurons and glia by producing trophic factors as well as by participating in the growth and guidance of neurites within the developing CNS. They also promote the proliferation of astrocytes, increase myelinogenesis, and stimulate vascularization of the CNS. Many of these microglial effects are apparently mediated by active substances. Microglial cells in culture secrete a number of factors, such as nerve growth factor, neurotrophin-3, chemokines, macrophage and granulocyte colony-stimulating factors (M-CSF and G-CSF), interleukin-1 (IL-1), IL-6 and tumor necrosis factor α (TNF-α). In addition to acting on other populations of the nervous system, tissue culture studies have revealed microglial responsiveness to growth factors such as GM-CSF and CSF-1, which are potent inducers of microglial proliferation and function.

D. Contribution to Disease

Several arguments support a key role for microglia during immunopathologies. They are potentially phagocytic and have a pronounced microbicide and cytotoxic potential. Upon activation, microglia can rapidly upregulate the expression of several immunomolecules, such as MHC I and II, the CD4 antigen, and adhesion molecules. They are the most efficient and the most promptly inducible antigen presenting cells of the brain parenchyma, assuming an active immune surveillance in the CNS. Resting microglial cells stimulated with IFN-γ express MHC II products and display a capacity to present protein antigens in the molecular context of MHC II to CD4-positive T lymphocytes. In the context of MHC I expression, they can also become targets of cytotoxic CD8-positive T lymphocytes. Furthermore, microglia secrete as well as respond to several cytokines.

One of the characteristic features of microglia is the rapid activation in response to injury, inflammation, neurodegeneration, infection, and brain tumors. Microglial activation occurs after injury or changes in microenvironment, even before pathological changes or in the absence of obvious neuropathic changes, as part of an early CNS immune defense system. In terms of structural changes, many intermediate morphologies of activated microglia exist. Microglial hypertrophy begins with the formation of several stout processes, but they do not become phagocytic. If neuronal degeneration occurs in the brain parenchyma, activated microglia proliferate and transform into phagocytic cells. As the primary immune effector cells of the CNS, microglia respond to traumatic insult or the presence of pathogens by migrating to the site of injury, where they may proliferate. Activated microglia at the site of inflammation express increased levels of MHC antigens and become phagocytic. Like other tissue macrophages, microglia release inflammatory cytokines and mediators that amplify the inflammatory response by recruiting effector cells to the site of injury. In addition, microglia can release neurotoxins that may potentiate damage to CNS cells. The intense secretory activity of these cells is associated with diseases such as trauma, stroke, epilepsy, AIDS, and MS, in which the microglial response is prominent and deleterious to the brain tissue. The secretory activity of microglia has also been related to the neuronal destruction seen in Alzheimer's disease (AD).

1. Acquired Immunodeficiency Syndrome

HIV-1 causes an AIDS-associated psychomotor complex in a number of patients, who eventually develop either encephalitis or leukoencephalopathy. The main target cells of HIV-1 infection in the brain are microglia and macrophages, with a very limited infection of astrocytes and endothelial cells. Infected microglial cells can be detected by the presence of HIV antigens. The two pathological hallmarks of the HIV-1 infection of the CNS are multinucleated giant cells as a result of cell-to-cell fusion and microglial nodules (Fig. 5). Although microglial cells and macrophages seem to be the only cell types productively infected by HIV-1 within the brain, the replication rate of the virus remains relatively low in CNS tissue compared to other

tissues. Thus, the neuropathological alterations in AIDS are more likely due to the neurotoxicity of certain viral products, toxic factors, and cytokines released by infected microglia and macrophages. Some of these putative toxic factors, such as viral proteins, are specific to HIV-1 infection of the CNS, whereas other potentially toxic factors are also involved in other diseases in which activation of microglia plays a key role in the pathological process. Among viral proteins, the viral surface glycoprotein gp120 can be released by infected microglia and macrophages. This protein induces excitoxicity in neurons via activation of glutamate receptors, it can inhibit myelin formation in oligodendrocytes, or it can alter Na^+/H^+ ion transport in astrocytes, leading to an increased secretion of glutamate and potassium. The infection of microglial cells and macrophages, and their subsequent activation, also results in the generation of a wide variety of secretory factors that are potentially neurotoxic, such as TNF-α, cytokines, chemokines, arachidonic acid metabolites, and nitric oxide. TNF-α released by infected microglia is particularly toxic to oligodendrocytes and can be an important factor in myelin damage. Arachidonic acid and its metabolites act mainly via potentiation of glutamate receptors on neurons, leading to an increase in intracellular calcium levels and neuronal death. They can also impair the transport of glutamate in astrocytes.

2. Multiple Sclerosis

Pathological studies of MS lesions suggest an important role of macrophages and microglia in MS demyelination. Active or recent plaques have areas of myelin degradation, infiltration by inflammatory cells, and collections of lipid-containing macrophages that may stain for myelin proteins such as myelin basic protein. In chronic plaques, macrophage-like cells remain lipid-laden but no longer express immunoreactive myelin proteins. Some of these macrophages represent phagocytic microglia and some may be of hematogenous origin. MS lesions are frequently localized in perivascular regions and contain not only demyelinated axons and microglia but also lymphocytes and plasma cells. The presence of MHC II molecules in macrophages and microglia in MS lesions indicates that microglia are activated and can exert phagocytosis and antigen presentation functions. They also express Fc receptors and have an increased number of chemotactic receptors, including C5a and IL8.

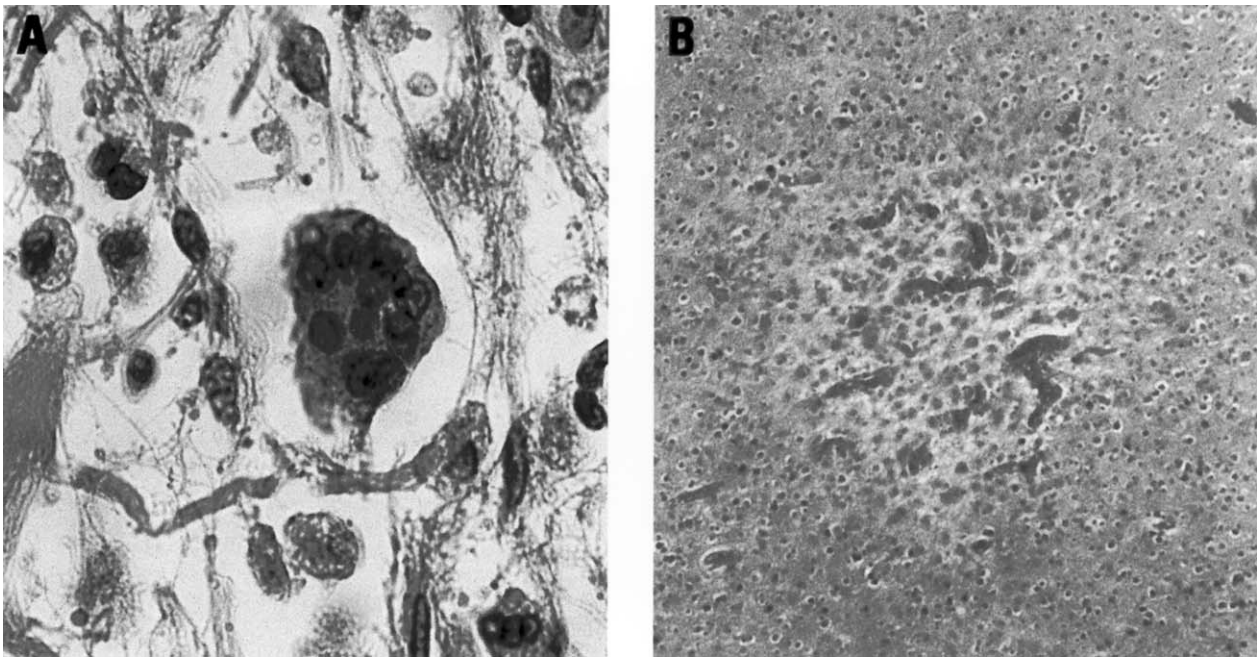

Figure 5 Neuropathological hallmarks of HIV infection. (A) Multinucleated giant cells are considered to be histological lesions directly attributed to HIV infection. (B) Microglial nodules, frequently observed in the brain of HIV-infected patients, are associated with opportunistic cerebral infections.

3. Alzheimer's Disease

Alzheimer's disease is a degenerative disorder characterized by memory loss eventually leading to dementia. Pathologically, AD is characterized by the presence of insoluble structures or depositions in cortical regions of the brain, namely β-amyloid (Aβ)-containing extracellular plaques and intraneuronal neurofibrillary tangles. The presence of large numbers of activated microglia and reactive astrocytes in brain tissue from AD patients has been interpreted as a secondary event. However, evidence suggests a significant role of these cells in the progression of the disease. Microglia cluster around Aβ-containing senile plaques with markedly enhanced MHC II protein expression on microglial cells associated with areas of degenerative pathology. Cytokines such as IL-1, IL-6, and TNF-α also have increased expression in microglia in the vicinity of senile plaques. These cytokines can potentially coordinate the majority of inflammatory changes found in AD brain tissue; however, a classic immune response as defined by the involvement of T cells or immunoglobulins does not appear to occur. The presence of microglia in the vicinity of amyloid plaques suggests a function in phagocytosis and plaque removal. Microglia can also uptake and degrade Aβ with a limited rate. In culture studies, synthetic Aβ not only recruits and activates microglia but also induces the secretion of cytotoxic products by these cells. Thus, rather than being protective, the activation of microglial cells may result in further neurotoxicity. Moreover, microglia can synthesize and secrete Aβ. Therefore, the stimulus of Aβ production may be Aβ.

V. EPENDYMOGLIA CELLS

The introduction of the term "ependyma" was meant to describe the cell layer lining the ventricles of the brain. However, a recent definition or classification of ependymoglial cells has been under debate. Some argue that certain members should be classified as astrocytes, whereas others argue that ependymoglial cells are distinct since they have many characteristics not shared by typical astrocytes. An ependymoglial cell is usually defined as a glial cell extending at least one of its processes to the ventricular space and having physical contact with the outer surface of neural tissue. Ependymoglia are made up of different members, including fetal radial glia, tanycytes, and Müller cells. Other cell types, such as Bergmann glia, have radial processes that extend to the ventricles of the brain. However, since they do not actually establish contact with the apical surface of neural tissue, they are considered to be astrocytes and not ependymoglia.

A. Morphology and Subtypes

Structurally, ependymoglial cells are characterized by different types of processes that are determined by contact with various microenvironmental compartments. The type I process is a feature of every ependymoglia cell. The endfoot comes into contact with a fluid or space into which extend many microvilli. The apical pole contains abundant mitochondria, which indicates a high level of metabolic activity. Another characteristic of apical processes in some but not all ependymoglia is the presence of kinocilia, a simple cilia consisting of a ring of nine pairs of tubules. Type 1 processes are interconnected by various types of apicolateral junctions. In regions where no endothelial blood–barrier exists, ependymoglia cells form a cerebrospinal fluid (CSF) barrier by the expression of tight junctions. Ependymoglial type 2 processes are characterized by basal mesenchymal contact and a cytoskeleton with abundant intermediate filaments. These filaments consist primarily of vimentin when the endfoot is in contact with CSF, but they consist primarily of GFAP when in contact with a blood vessel. The basal processes extend to the basal lamina of the mesenchymal layer underlying the nervous epithelium, forming processes of type IIa. Processes extending to the basal lamina of blood vessels are termed type IIb. Type III processes are defined by contact with neurons. These processes are characterized by the formation of flat or lamellar sheaths that enclose the neuronal somata (type IIIa), synapses (IIIb), or axonal internodes (IIIc1) or by finger-like extensions that contact the nodal specializations of axons (IIIc2). These processes may act as stores of sodium or calcium ions and cannot be elaborated until neurons have completed their differentiation.

B. Lineage and Development

In the human brain, ependymoglial cells are thought to be derived from the developing neuroepithelium along a caudal-to-rostral gradient. Radial glial cells are the first subtype of neuroglia to appear during human fetal brain development. They stain intensely with GFAP and nestin early in development but lose

immunoreactivity with time. It is thought that ependymoglia arise from a radial progenitor in a pathway that can also give rise to astrocytes. The radial progenitors differentiate into radial glial cells, which can then morphologically transform into the subtypes of ependymoglial cells mentioned earlier as well as into astrocytes.

C. Normal Physiology and Function

The function of ependymoglia cells is unclear. Physiological stimulation of brain compartments evokes specific reactions among ependymoglia. It has been reported that fetal ependymal cells play an important role during development of the nervous system by forming the cellular highway for the migration of progenitor cells. Furthermore, they arrest neurogenesis, facilitate motor neuron differentiation, and aid in transport of nutrients before development of capillary networks. Evidence of ependymal involvement in neuroendocrine function has also been reported as changes in ependymal cell morphology, coincident with changes in pituitary hormone secretion. In the adult brain, these cells provide only limited transport of ions, small molecules, and fluids between the brain and the CSF. The ependymal cells lining the ventricles act as a barrier for filtration of brain molecules and for the protection of the brain from potentially harmful substances in the CSF. From these examples, it is apparent that ependymoglia cells are continuously adapting to the changing needs of the neuronal tissue.

D. Contribution to Disease

Ependymomas and ependymoblastomas develop from the ependymal cells surrounding the ventricles and the central canal of the spinal cord. Intracranial ependymomas occur predominantly in children and tend to fill the ventricular lumen. The mean age at diagnosis of ependymoma and ependymoblastoma is 5 years. The incidence of these ependymal tumors in males and females is approximately equal. Clinical symptoms, although related to the location of the tumor, are usually due to blockage of CSF fluid flow, which may lead to a sudden increase in intracranial pressure. Ependymal tumors are sensitive to radiation.

Subependymomas are slow-growing, benign neoplasms originating from the subependymal glial matrix, consisting of a mixture of astrocytic, ependymal, and transitional cell clusters surrounded by their fibers. They generally project into the ventricular lumen. About one-fourth of the symptomatic intracranial tumors have mixed tumor cell populations and consist of a mixture of ependymomas and subependymomas. The prognosis in these cases is worse than that of a pure ependymoma. Another factor that affects the prognosis is the size of the neoplasm; symptomatic tumors tend to be large. Subependymoma is more common in men and has been reported in all decades of life, although no cases of subependymomas have been reported in children less than 2 years of age. The mean age for symptomatic tumors is 39 years, whereas that for asymptomatic lesions is 59 years. Microscopically, subependymomas consist of a nest of glial cells separated by glial fibers. Histologic studies have shown that some of the cells within these glomerate nests have attributes of ependymal cells and others of astrocytes; still others are transitional between the two.

VI. CONCLUSIONS

Neuroglial cells were described initially as specialized cells surrounding the neurons to provide structural support and insulation. In fact, neuroglial cells comprise a wide variety of phenotypes and functions. It is now known that complex intercellular communication exists not only between glial cells and neurons but also among the neuroglial members. This relationship becomes evident during pathological conditions of the brain. Selective damage of any one cell type can have severe ramifications on the functions of others as well as on the neuronal population. In the normal human brain, glial cells and neurons exist in a very delicate and highly coordinated balance. The diversity of neuroglial cells serves to contribute to the complexity of the human CNS.

Hallucinations

JANE EPSTEIN, EMILY STERN, and DAVID SILBERSWEIG
Weill Medical College of Cornell University

GLOSSARY

delirium A state of altered attention, arousal, and thought, often caused by an acute medical condition.

delusion A false belief, not generally endorsed by the individual's culture, held despite contradictory evidence.

epilepsy A chronic disorder consisting of intermittent episodes of excessive neuronal electrical discharge (seizures).

ictal Relating to a seizure.

partial seizure An episode of excessive electrical discharge originating from a discrete region of cerebral cortex and remaining confined to one part of the cortex.

psychosis A condition in which unreal beliefs or experiences are believed to represent reality.

Hallucinations are involuntary sensory experiences perceived as emanating from the external environment, in the absence of stimulation of relevant sensory receptors. They were first defined in this manner in 1837 by Esquirol, who differentiated them from illusions, which are perceptual misinterpretations of existing external stimuli. Hallucinations can occur in a variety of contexts but are perhaps most striking and debilitating in the setting of schizophrenia, in which they are combined with a failure to realize that they do not represent reality. In this instance, they are generally experienced as real, emotionally significant, and related to concurrent delusions, and they represent a form of psychosis. Hallucinations can occur in any sensory modality or can involve multiple modalities, with auditory hallucinations most common in schizophrenia and other illnesses traditionally termed psychiatric and visual hallucinations most common in illnesses termed neurologic. This article presents a functional neuroanatomic approach to hallucinations, describing and analyzing them in terms of disorders of sensory input, midbrain/thalamus, and higher brain regions, including cortical sensory, limbic, and frontal regions. It also discusses other investigational approaches to hallucinations as well as treatment considerations. The focus is on visual and auditory hallucinations because they occur most frequently and have been most thoroughly investigated.

I. FUNCTIONAL NEUROANATOMIC APPROACH TO HALLUCINATIONS

The variety of forms, contents, and settings of hallucinations can be described and analyzed in a number of ways, each with its own strengths and weaknesses. Of these, a functional neuroanatomic approach, based on evolving data, is perhaps most heuristically satisfying. In order to present such an approach, we first review the functional neuroanatomy of normal sensory perception as set forth by Mesulam.

A. Functional Neuroanatomy of Normal Perception

External auditory, visual, tactile, gustatory, and olfactory stimuli are first detected by modality-specific

receptors in the periphery. Information from most of these sensory receptors converges on modality-specific nuclei in the thalamus, where extraneous information is filtered out or "gated" and relevant information relayed to various parts of the cortex. At the cortex, the first regions to receive these inputs are the primary sensory areas: visual at the occipital pole and banks of the calcarine fissure, auditory at Heschl's gyrus on the posterior supratemporal plane, and somatosensory at the postcentral gyrus. These highly differentiated, or distinctly structured, regions carry out the most specialized processing within each modality, extracting basic features of sensory information. Output from these regions flows to adjacent unimodal association cortices, where modality-specific sensory elaboration occurs. Output from multiple unimodal association areas converges on heteromodal association cortices in temporoparietal and prefrontal regions, where unimodal percepts are linked with associated information to form multimodal constructs.

The path of information flow can be illustrated by considering the well-studied visual system. In this sensory modality, unimodal processing is mediated by regions stretching from the occiput anteriorly, with information flowing along two major pathways. The first, known as the ventral pathway, begins in association areas adjacent to primary visual cortex, where individual features of visual information, such as color and shape, are processed in separate subregions. As the information moves along the lower surface of the brain toward anterior temporal regions, these features are integrated and complex patterns are extracted, permitting discrimination of individual objects such as faces. Information from anterior temporal regions flows to heteromodal cortex, where highly processed visual percepts are integrated with input from other sensory modalities and with stored information about their characteristics, history, and emotional/motivational relevance, leading to object recognition. Integration is achieved via interconnections with limbic and paralimbic regions involved in mnemonic and emotional processing. The second, dorsal pathway leads from occipital unimodal association areas on the upper side of the brain to adjacent heteromodal regions in the posterior parietal cortex that mediate object localization. As information flows from more differentiated primary sensory areas to less differentiated heteromodal regions, specialized perception merges into complex cognition. Higher level cognitive processes are mediated by prefrontal heteromodal cortices involved in monitoring, categorizing, modifying, and integrating multiple streams of information processing to form an overview of the current situation and generate a relevant plan of action. This serial, hierarchical flow of information occurs within a context of bidirectional feedback projections and concurrent parallel processing.

Although much remains to be learned about the nature and precise localization of the neural phenomena that give rise to hallucinations, the existing data, along with our knowledge of the pathways involved in normal perception, allow for the categorization and analysis of hallucinations based on their probable neuroanatomic substrates.

B. Disorders of Sensory Input Associated with Hallucinations

Hallucinations produced by disorders of the peripheral sensory system appear to result from ongoing cortical sensory processing in the setting of degraded or absent sensory input. Sometimes referred to as "release" phenomena, the use of the term in this context can be misleading because it has traditionally been used to connote neural activity released by the failure of higher level inhibitory centers rather than by disordered lower level input. The probable mechanism by which these hallucinations are generated is best understood by considering the interplay between peripheral and central processing in normal perception. Although the previous description of sensory processing emphasizes the flow of information from periphery to thalamus to cortex ("bottom-up" processing), the connections between thalamus and cortex are in fact bidirectional, as noted. This pattern of connectivity enables the cortex to play a role in selecting from among the massive array of inputs to the thalamus those most likely to be relevant in light of past and current experience. Thus, perceptions arise from an interplay between cortically generated expectations ("top-down" processing) and data (confirmatory or otherwise) from peripheral sensory receptors. In this setting, a dearth of peripheral input might give rise to perceptions dominated by expectations rather than current environmental conditions.

Hallucinations caused by disordered peripheral input are most frequently seen in the visual system. The term Charles Bonnet syndrome has been applied to such phenomena, but without a consistent definition. The hallucinations are most often vivid, colorful, and complex representations of people, animals, scenery, trees, buildings, or flowers that fill the entire

visual field. They frequently appear smaller than normal, or Lilliputian, and may move. Hallucinations tend to have an abrupt onset, can last seconds to hours, and may disappear with movement or closure of the eyes. They can occur in the setting of acute blindness following altered blood flow or trauma to the eye, a phenomenon sometimes referred to as phantom vision, or during a gradual visual decline. In either case, they may fade as the visual disturbance continues. Notably, the individuals experiencing the hallucinations are aware that they do not represent reality and generally have no strong emotional association or reaction to them. Although primary abnormalities within the central nervous system may increase the risk of developing Charles Bonnet syndrome (a hypothesis supported by its greater prevalence in the elderly, who are at increased risk of subtle brain dysfunction), it can occur on the sole basis of peripheral visual system dysfunction. Indeed, its prevalence rate of 20% in people who develop blindness is similar to the 19% of normal individuals who experience visual hallucinations during sensory deprivation experiments—a clear example of hallucinations caused solely by disordered peripheral input.

Conditions such as stroke, that involve destruction of primary visual cortex or the cerebral pathways leading to it can also lead to complex visual hallucinations. Although the lesion in this instance is central, the phenomenology and mechanism are similar to those seen with peripheral lesions because primary visual cortex provides input to the unimodal association areas involved in the generation of complex hallucinations. The major phenomenologic difference derives from the organization of visual processing in primary cortex, where the right visual field is mediated by left occipital cortex and vice versa. When central lesions are limited to one hemisphere, hallucinations occur only in the affected contralateral visual field.

In the somatosensory system, a striking example of hallucinations caused by disordered sensory input occurs in the phantom limb syndrome, as described by Melzack. After amputation of a limb, approximately 95% of adults experience the limb as still present, able to move in space, and to feel pain or tingling. Over time, the perception weakens such that the proximal part of the limb no longer seems to exist, leaving the hand or foot hanging in midair, or the entire limb seems to "telescope" into the body, leaving the hand or foot directly connected to the stump. Phantom experiences have also been reported after the loss of eyes, teeth, external genitalia, and breasts. They are not dependent on sensory input from the residual scar and can occur even in those with congenitally absent limbs, suggesting a central representation of the body that is at least partly innate.

In the auditory system, individuals with peripheral dysfunction can develop complex hallucinations, such as music (either instrumental or vocal) or voices, or simple hallucinations, such as ringing, buzzing, or isolated tones of various pitches. Although more common with bilateral dysfunction, hallucinations can accompany unilateral peripheral auditory disease, in which case they are experienced as emanating from the affected side.

C. Midbrain/Thalamic Disorders Associated with Hallucinations

Hallucinations similar to those produced by peripheral lesions can occur with lesions of the upper midbrain and adjacent thalamus. First described in 1922 by Lhermitte, who attributed them to a lesion in the midbrain peduncular region, they remain known as "peduncular" hallucinations. Like Charles Bonnet hallucinations, they are often vivid, complex visual hallucinations (although other sensory modalities may be involved), frequently of people or animals (sometimes Lilliputian) often engaged in animated activities. Unlike those produced by peripheral lesions, peduncular hallucinations are generally associated with disturbances in sleep and arousal and may at times be interpreted as real.

These disturbances in sleep and arousal provide clues to the mechanism by which hallucinations are generated by midbrain and thalamic lesions. Frequency-specific oscillations in thalamocortical circuits have been associated with the temporal binding of perception and with dreaming. As pointed out by Manford and Andermann, brain stem connections to the thalamus are important in switching thalamic relay nuclei out of waking relay mode, in which they faithfully transmit sensory inputs to the cortex, into sleeping mode, in which they do not. This is accomplished via neurotransmitters, notably acetylcholine and serotonin, whose cell bodies lie within the basal and brain stem reticular regions involved in modulation of arousal, selective attention, and cortical processing. Abnormalities of acetylcholine and serotonin transmission brought on by disease, medication, or drug use (including such hallucinogens as LSD) are frequently accompanied by hallucinations. Similarly, transitions between states of sleep and wakefulness are

associated with hallucinations, usually in the setting of sleep disorders such as narcolepsy or insomnia. Hypnagogic hallucinations occur prior to falling asleep, whereas hypnopompic hallucinations occur upon awakening. Both are generally multimodal, vivid, and emotionally charged. Common examples are the feeling or experience of being about to fall into an abyss or attacked, of being caught in a fire, or of sensing a presence in the room. Hallucinations in the settings of delirium and sedative drug withdrawal are also associated with disturbances in sleep and arousal.

Abnormal thalamic activity was also present in a functional neuroimaging study, performed by our group with colleagues (as described below), of hallucinations in the setting of schizophrenia. This may relate to the modulatory and integrative roles of thalamocortical circuits in the generation of perceptual experience. A possible role for the thalamus in this setting is supported by a number of electrophysiologic, neuropathologic, structural, and functional imaging studies revealing sensory gating deficits and thalamic abnormalities in individuals with schizophrenia.

D. Disorders of Higher Brain Regions Associated with Hallucinations

Hallucinations are also associated with primary pathology at higher levels of the brain. Most prominent in this category are those that occur in migraine, epilepsy, and schizophrenia. Investigation of cerebral activity associated with hallucinations in these settings has been aided in recent years by the development of techniques such as electroencephalography (EEG), evoked potentials, single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). Combined with data from other avenues of investigation, studies employing these tools have implicated a number of higher brain regions in the generation of hallucinations, corresponding to their form, content, and setting.

1. Cortical Sensory Activity Associated with Hallucinations

Regardless of the mechanism by which they are generated (primary peripheral, midbrain/thalamic, or higher brain disturbances), hallucinations appear to be associated with activity in cortical sensory regions corresponding to their modality and complexity. The hallucinations described previously may be described as complex or formed. Noncomplex hallucinations are referred to interchangeably as simple, unformed, or crude. In the visual system, these are known as photopsias, and they occur frequently with migraines. In this setting, the most common forms are colorless glittering spots and black-and-white zigzag patterns known as fortification lines. They often occur unilaterally but may fill the entire visual field. Photopsias can also occur, briefly, at the onset of partial seizures and for the first few days following an infarction of the central visual system. In both settings they tend to be brightly colored and unilateral. In addition, disorders of visual input may give rise to photopsias. Simple hallucinations are believed to reflect activity in primary sensory or adjacent early unimodal association areas and to correspond in form to the area's functional specialization. For example, colored photopsias would be associated with activity in occipital subregions involved in color processing, as described previously.

Complex hallucinations are associated with activity in sensory association areas, with or without involvement of primary sensory cortex. As with simple hallucinations, their form and content correspond to the location of activity. We investigated neural activity associated with auditory/visual hallucinations in a 23-year-old man with schizophrenia. The subject underwent PET scanning while experiencing frequent hallucinations of colored, moving scenes containing disembodied, rolling heads that spoke to him in a derogatory fashion. Using techniques that allow for identification of activity simultaneous with hallucinatory events, we detected activations in occipital and temporal visual association cortex (higher order visual perception), temporal auditory–linguistic association cortex (speech perception), and temporoparietal and prefrontal heteromodal association cortex (intermodal processing) (Fig. 1). Activations were bilateral but more extensive on the left, perhaps reflecting the dominance of that hemisphere for language.

2. Limbic/Paralimbic Activity Associated with Hallucinations

The previously mentioned study included five other subjects, all of whom experienced frequent auditory/verbal hallucinations in the setting of schizophrenia. Although each had a somewhat different pattern of sensory cortical activation, perhaps reflecting differences in the form and content of their hallucinations, group analysis revealed a highly significant pattern of common activations in thalamic, limbic, and

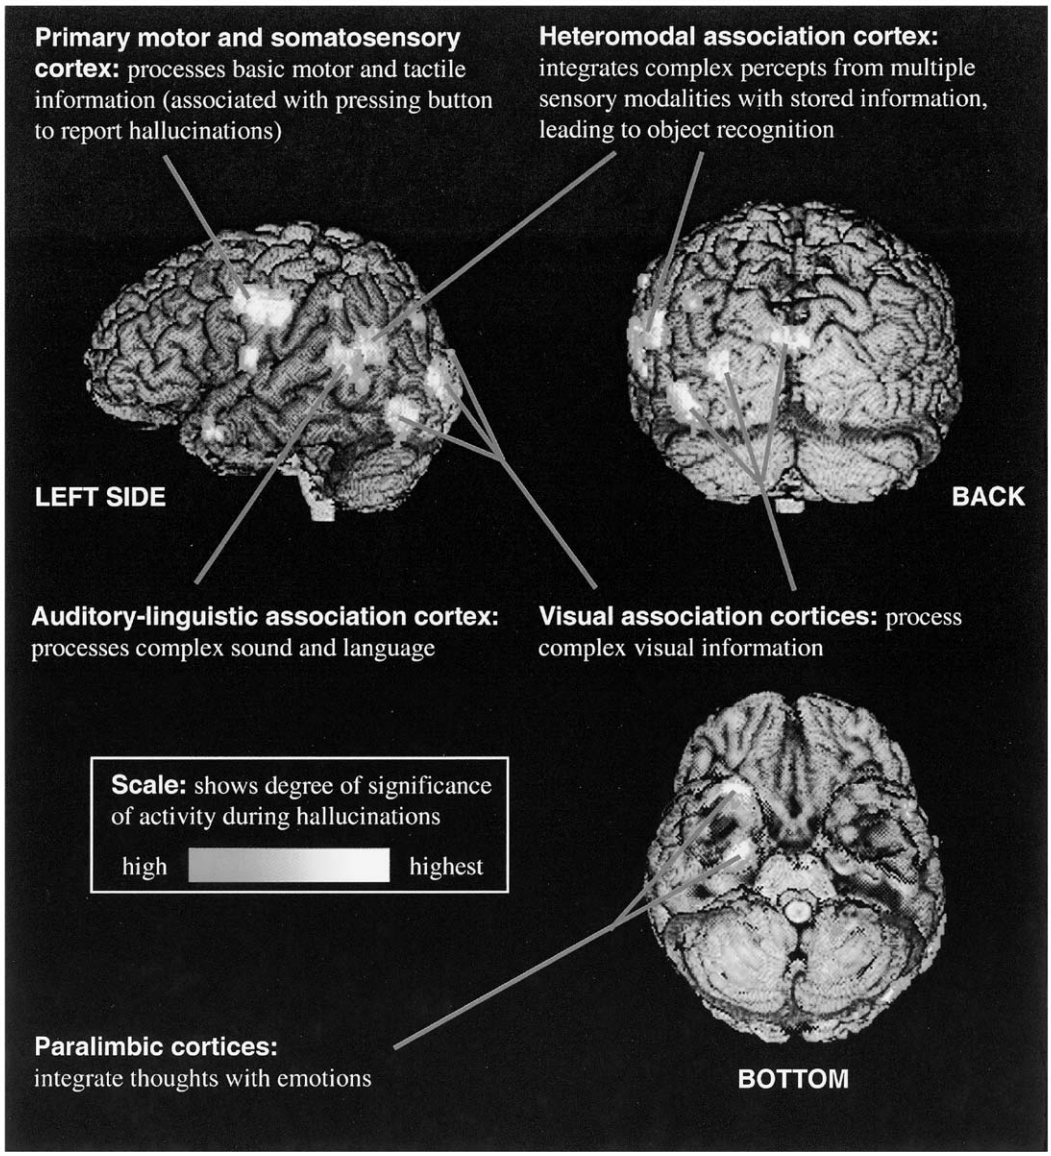

Figure 1 Brain regions active in a schizophrenic patient experiencing auditory–visual hallucinations of disembodied, rolling heads speaking to him. The functional PET results are superimposed on the subject's own structural brain MRI scan. The bright areas pinpoint regions of heightened cortical activity associated with hallucinatory events [reproduced with permission from D. A. Silbersweig *et al.* (1995), A functional neuroanatomy of hallucinations in schizophrenia. *Nature* **378,** 176–179].

paralimbic regions that may be involved in the generation or modulation of hallucinations (Fig. 2). Limbic structures, the least differentiated, or least distinctly structured, older regions of the cortex, are involved in the linking of drives with experience and the processing of emotion. Paralimbic regions are intermediate in structure between, and interconnected with, limbic and heteromodal association areas and serve to integrate emotion and drive with highly processed sensory information. Because limbic and paralimbic structures are closely interconnected and functionally integrated, they are often referred to collectively as the limbic system.

In our study, activation in limbic regions involved hippocampi (extending to the adjacent amygdalae) and ventral striatum. The hippocampal formation, a convoluted structure within the medial temporal lobe, is involved in memory and the processing of contextual

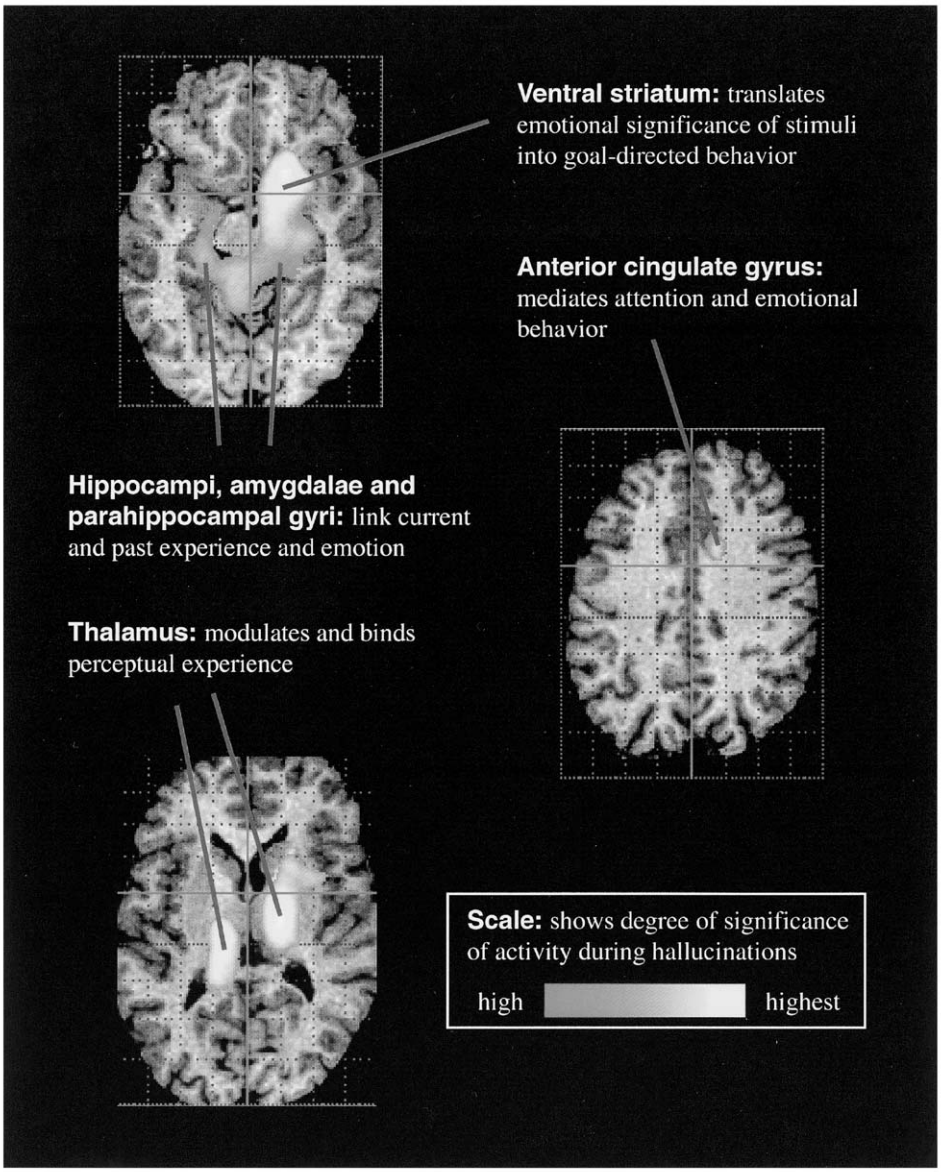

Figure 2 Common areas of brain activity in a group of schizophrenic patients experiencing auditory/verbal hallucinations. The functional PET results are superimposed on an anatomical MRI template. The bright areas pinpoint regions of heightened thalamic, limbic, and paralimbic activity associated with hallucinatory events [reproduced with permission from D. A. Silbersweig *et al.* (1995), A functional neuroanatomy of hallucinations in schizophrenia. *Nature* **378,** 176–179].

aspects of emotional evaluation. The amygdaloid complex, a collection of nuclei adjacent to and interconnected with the hippocampus, plays a central role in evaluating the emotional significance of internally and externally generated stimuli. Both of these structures send output to the ventral striatum, the limbic portion of the subcortical basal ganglia, where emotional significance is translated into goal-directed behavior. Activation in paralimbic regions involved parahippocampal gyri, anterior cingulate, and orbitofrontal cortex. The parahippocampal gyrus, which lies on the medial surface of the temporal lobe, integrates sensory output from heteromodal and more complex unimodal association areas with limbically processed information. The anterior cingulate, the frontmost portion of a band running from medial frontal to parahippocampal regions, is involved in attention and social/emotional behaviors. The orbital frontal cortex

is located in the medial ventral frontal lobes. Like the amygdala, it participates in the evaluation of emotional significance and sends output to the ventral striatum. In contrast to the amygdala, the orbital frontal region is able to modulate emotional responsivity and readjust behavioral responses to stimuli when their reinforcement value is changed or when a more complex assessment of the current context suggests the need for modification.

Just as abnormal activity in cortical sensory regions is correlated with the form and content of hallucinations, it is likely that aberrant activity in limbic/paralimbic regions gives rise to the marked emotional significance of hallucinations in the setting of schizophrenia. Further evidence of a role for limbic system dysfunction in the generation of schizophrenic symptoms is provided by postmortem, neuropsychological, and neuroimaging studies that reveal structural and functional abnormalities of limbic regions in individuals with schizophrenia, including hyperactivity of temporal regions (left greater than right) associated with psychosis. Activity of the limbic system is closely interconnected with that of dopamine, a neurotransmitter implicated in the generation of hallucinations and delusions in the settings of schizophrenia, medication toxicity, and drug abuse. Dopaminergic activity is regulated, in part, by input from limbic system structures and in turn appears to modulate the responsiveness of ventral striatal neurons to limbic inputs. Recent work suggests that glutamate, an excitatory neurotransmitter, may also play a role in both limbic dysregulation and schizophrenia. Hallucinations that occur in the context of severe emotional stress may also involve abnormal limbic activity.

Temporolimbic structures also play a role in the generation of hallucinations associated with epilepsy. In addition to photopsias, the onset of partial seizures can be accompanied by simple hallucinations in any modality, reflecting ictal discharges in primary sensory areas, or by complex hallucinations, reflecting discharges in limbic and sensory association areas. These often involve temporal regions including hippocampus and amygdala, which have the lowest seizure thresholds of all brain structures, as well as sensory association areas. Like the complex hallucinations seen in schizophrenia, these are often emotionally charged. Unlike those seen in schizophrenia, they are more often visual than auditory and are not usually believed by the person experiencing them to represent reality. Relatedly, electrical stimulation of temporal lobe regions, including the amygdala, can give rise to hallucinatory experiences. In addition to hallucinations experienced during seizures, there is evidence that individuals who have suffered from epilepsy for more than 10 years may develop hallucinations between seizure episodes. These are more likely to resemble fully those seen in schizophrenia as they are often emotionally charged, are as likely to be auditory as visual, are accompanied by delusions, and are believed to represent reality. As in schizophrenia, they appear to be associated with temporal lobe abnormalities (left more often than right).

3. Frontal/Executive Activity Associated with Hallucinations

The lack of awareness that hallucinatory experience does not correspond to reality is a striking feature of schizophrenia. In addition to temporal lobe abnormalities, numerous studies have revealed frontal dysfunction and abnormal frontotemporal connectivity associated with schizophrenia. The frontal lobes, in concert with interconnected regions, mediate the higher, more complex aspects of cognition, such as judgment, insight, and self-monitoring. These are termed executive functions. Although relevant studies have produced mixed results, there is evidence that frontal dysfunction may contribute to the inability of individuals with schizophrenia to identify the internal origin of their hallucinatory experience and its relation to their illness. Temporal lobe epilepsy may also be accompanied by executive as well as other forms of cognitive dysfunction and by abnormalities of frontal activity.

II. OTHER INVESTIGATIONAL APPROACHES TO HALLUCINATIONS

The descriptive and analytic framework employed in this article represents one approach to hallucinations. Others tend to be complementary, rather than exclusive, with their boundaries increasingly blurred as convergence and integration occur. The resulting interdisciplinary synthesis has enhanced our understanding of hallucinations. At the cognitive level of analysis, numerous mechanisms have been posited to play a role in the generation of hallucinations, with support derived from psychologic, electrophysiologic, and animal studies. Several theories focus on abnormalities in the processing of input or its comparison with past experience. These can be seen to dovetail with the sensory input, midbrain/thalamic, sensory cortical,

and limbic/paralimbic disturbances described previously. Others focus on cognitive abnormalities that may give rise to deficits in the ability to discriminate between external and self-generated events. These theories, in turn, are related to frontal/executive disturbances. At the neurochemical level, much work has been done on the relation between disturbances in neurotransmitter systems, such as dopamine, serotonin, and glutamate, and hallucinations. This is clearly relevant to the limbic and midbrain/thalamic disturbances noted previously. At the computational level, neural networks models have been used to investigate links between posited cognitive or physiologic abnormalities and hallucinations, with intriguing results. At the social/psychological level, investigations and clinical observations suggest that personal, social, and cultural factors play a role in the development and content of hallucinations—a role likely to be mediated by limbic and cortical brain regions involved in learning and complex cognition.

III. TREATMENT OF HALLUCINATIONS

For hallucinations in the setting of schizophrenia, medications that alter transmission of dopamine and related neurotransmitters, termed neuroleptics, are the mainstay of treatment. In other settings, the first step in the treatment of hallucinations is to address the condition that underlies their existence. When this is impossible or ineffective, neuroleptic medications may be tried. However, these tend to be less effective in settings that do not involve limbic, striatal, or dopaminergic pathology. Fortunately, hallucinations in the setting of sensory input disorders, where neuroleptics are least effective, are often less disturbing to those experiencing them, as described previously. Such hallucinations sometimes respond to carbamazepine, a medication often used for seizure prevention, mood stabilization, or control of pain originating in the nervous system. This is consistent with models of aberrant neural activity described previously.

When hallucinations are distressing and unresponsive to medication, psychological treatments may be helpful. Cognitive–behavioral approaches involve distracting activities or sensory input as well as behavioral and cognitive tasks. Supportive approaches involve helping patients understand their condition, solve problems, and adapt to reality. Psychological approaches tend to decrease distress associated with hallucinations and improve overall functioning rather than ameliorate hallucinations per se.

Future developments in the treatment of hallucinations are likely to be guided by the functional neuroanatomic approach. Recent investigations into the mechanism of action of antipsychotic medications have increasingly focused on the specific cerebral regions modulated by relevant neurotransmitters. In addition, a recent study examined the efficacy of transcranial magnetic stimulation (TMS), a novel technique for altering focal cortical activity through application of a magnetic pulse, in the treatment of persistent auditory hallucinations in schizophrenic patients. The results suggest that administration of TMS to the left temporoparietal regions noted (in the PET study discussed previously) to be active during auditory hallucinations can markedly decrease the severity of such events.

IV. FUTURE DIRECTIONS

The approach to hallucinations presented in this article represents an attempt to organize and synthesize current knowledge from a functional neuroanatomic perspective. It should be regarded as a framework on which further data from disciplines relevant to neuroscience can be laid. As new data emerge and interdisciplinary integration proceeds, our understanding of hallucinations will undoubtedly gain increased specificity and complexity and grow in new directions.

GLOSSARY

grasp stability control The control of grip forces such that they are adequate to prevent accidental slips but not so large as to cause unnecessary fatigue or damage to the object or hand.

haptic perception Perception through the hand based on tactile and somatosensory information.

internal models Neural circuits that mimic the behavior of the motor system and environment and capture the mapping between motor outputs and sensory inputs.

precision grip The grip formed when grasping an object with the distal tips of digits. Usually refers to grasping with the tips of the thumb and index finger on either side of an object.

sensorimotor control The use of both predicted and unexpected sensory information in the control of action.

The human hand and the brain are close partners in two important and closely interconnected functions: exploration of the physical world and reshaping of parts of this world through manipulation. The highly versatile functions of the human hand depend on both its anatomical structure and the neural machinery that supports the hand. This article focuses on the sensorimotor control of hand movements in object manipulation–a hallmark of skilled manual action. The article also examines relationships between the two main functions of the hand–object perception and object manipulation.

I. THE ACTING AND PERCEIVING HAND

Many of our cultural and technological achievements that mark us as human depend on skilled use of the hand. We use of our hands to gesture and communicate, make and use tools, write, paint, play music, and make love. Thus, the human hand is a powerful tool through which the human brain interacts with the world. We use our hands both to perceive the world within our reach (haptic perception) and to act on this world. These two functions of the hand, which are largely accomplished by touching and manipulating objects in our environment, are intimately related in terms of sensorimotor control. Haptic perception requires specific hand movements that are tailored to the kinds of information the perceiver wishes to extract. For example, to obtain information about the texture of an object, people rub their fingertips across the object's surface, and to obtain information about shape they trace the contour of the object with their fingertips. Conversely, in object manipulation sensory and perceptual information is critical for precise motor control of the hands. The fact that individuals with numbed digits have great difficulty handling small objects even with full vision illustrates the importance of somatosensory information from the fingertips.

To control both the exploratory and manipulatory functions of the hand, the brain must obtain accurate descriptions of various mechanical events that take place when objects are brought into contact with the

hand. Mechanoreceptive (tactile) sensors in the glabrous skin of the volar aspect of the hand play an essential role in providing such information. The density of mechanoreceptors increases in the distal direction of the hand and is exquisitely high in the fingertips. As a perceptual organ, the hand has several advantages over the eyes. The hand can effectively "see around corners," allowing us to explore all sides of an object, and it can directly appreciate object properties such as weight, compliance, and slipperiness.

The numerous skeletal and muscular degrees of freedom of the hand, orchestrated by highly developed neural control systems, provide for tremendous dexterity that allows for both delicate exploration and versatile manipulation of objects. With approximately 30 dedicated muscles and approximately the same number of kinematic degrees of freedom, the hand can take on all variety of shapes and functions, serving as a hammer one moment and a powerful vice or a delicate pair of tweezers the next. The utility of hand movements is further enhanced by our ability to amplify the functions of the hand by using tools.

Different primates have very different hand movement capacities, with humans demonstrating the greatest dexterity. For example, true opposition between the thumb and index finger is only observed in humans, the great apes, and Old World monkeys. New World monkeys can manage pseudo-opposition, but prosimians are only capable of crude grasping. It seems improbable that the tremendous dexterity of the human hand can be explained solely by differences in anatomical factors given that the structural anatomy of the hands of different primates seems similar. This is not to say, however, that anatomical differences do not contribute. For example, the human thumb is much longer, relative to the index finger, than the chimpanzee thumb. This allows humans to grasp small objects precisely between the distal pads of the thumb. Similarly, the greater independence of finger movements in humans compared to monkeys arises, in part, from differences in the passive biomechanical connections among tendons. Humans have more individuated muscles and tendons with which to control the digits.

In addition to structural factors, a major contributor to differences in hand movement capacity among primates, and between primates and lower mammals, is the neural machinery underlying hand movement. Compared to lower mammals, primates have evolved extensive cerebral cortical systems for controlling the hand and the corticospinal pathways have taken on an increasingly dominant role in controlling movement. Moreover, in primates the corticospinal tracts include direct connections between neurons in cortical motor areas and spinal motorneurons. Through these corticomotoneuronal connections, the cerebral cortex possesses monosynaptic control over motorneurons whose axons connect, in particular, with the hand muscles. In effect, these direct connections have moved the hand "closer" to the cerebral cortex. Furthermore, through cortical motor areas the corticospinal tracts provide rapid access to the hand from most other cortical areas and from subcortical structures, including the cerebellum and the basal ganglia, tightly involved in motor control.

The development of cortical systems for controlling the hand in primates parallels the evolution of the arm from a prop for balance and locomotion (in four-legged mammals) to a free and dexterous tool for sensing and acting on objects in the environment. The denser neuronal substrate for hand control provides more flexibility in the patterning of muscle activation and supports the ability to perform independent finger movements. Interestingly, across primates, there is a linkage between the number of corticomotoneuronal connections and manual dexterity in terms of performing tasks that require independent finger movements. Although there are many advantages in terms of control, the reliance on cortical control comes at a cost. Lesions to the motor cortex or corticospinal pathways due, for example, to cerebral vascular accident can be particularly devastating in humans.

The importance of the cortical involvement in fine fingertip control can be further appreciated by considering parallels between the ontogenetic development of central neural pathways and that of hand function. The efficacy of the corticomotoneuronal system can be probed using transcranial magnetic stimulation (TMS) of the brain. TMS applied over the hand area of the motor cortex activates muscles of the contralateral hand. During development the latency of this activation, and the stimulation strength required to elicit a response, decreases as the corticomotoneuronal connections are established. The conduction delays in these motor pathways, as well as in the somatosensory pathways conveying signals from the sensors of the hand, rapidly decrease during the first 2 years after birth and thereafter remain constant at adult values. Responses within the adult latency range appear during the age range in which young children demonstrate important improvements in their ability to grasp objects using the tips of the index finger and thumb. Similar parallels between hand function and corticomoto neurone (CM) system development have

been demonstrated in monkeys using various electrophysiological and anatomical techniques.

II. SENSORIMOTOR CONTROL OF HAND MOVEMENTS IN OBJECT MANIPULATION

To understand and appreciate how the brain controls movements of the hand, it is best to study the natural behavior of the hand in everyday manipulatory tasks. During the past 20 years, the sensorimotor control of the hand in precision manipulation task has been investigated in great detail. In this section, we review what has been learned about the sensorimotor control of natural hand movements when grasping and manipulating objects with the fingertips.

The remarkable manipulative skills of the human hand are the result of neither rapid sensorimotor processes nor fast or powerful effector mechanisms. Rather, the secret lies in the way manual tasks are organized and controlled by the nervous system. Successful manipulation requires the selection of motor commands tailored to the manipulative intent, the task at hand, and the relevant physical properties of the manipulated object. For instance, most tasks require that we stabilize the object within our grasp as we move the object or use it as a tool. To prevent slips and accidental loss of the object we must apply adequately large forces normal to the grip surfaces (*grip forces*) in relation to destabilizing forces tangential to the grip surfaces (*load forces*) (Fig. 1). At the same time, excessive grip forces must be avoided because they cause unnecessary fatigue and may crush fragile objects or injure the hand. Hence, the term grasp stability entails prevention of accidental slips as well as excessive fingertip forces.

When grasping and manipulating objects, the forces needed to ensure grasp stability depend on the physical properties of the object. Object properties such as weight, slipperiness, shape, and weight distribution all impose constraints on the fingertip forces (including their magnitudes, directions, and points of application) required for stability. Thus, a basic question for understanding the control in manipulation is how do people adapt their fingertip forces to the constraints imposed by various object properties. Although visual information about object properties may be helpful in terms of force selection, ultimately people adapt to such constraints by using sensory information provided by digital mechanoreceptors. Individuals with impaired digital sensibility have great difficulty performing manipulation tasks even under visual guidance. For instance, they often drop objects, may easily crush fragile objects, and have difficulties in dressing themselves because they cannot complete such apparently simple tasks as buttoning a shirt. Thus, it is clear that critical sensorimotor control processes required for manipulation are lost with impaired digital tactile sensibility.

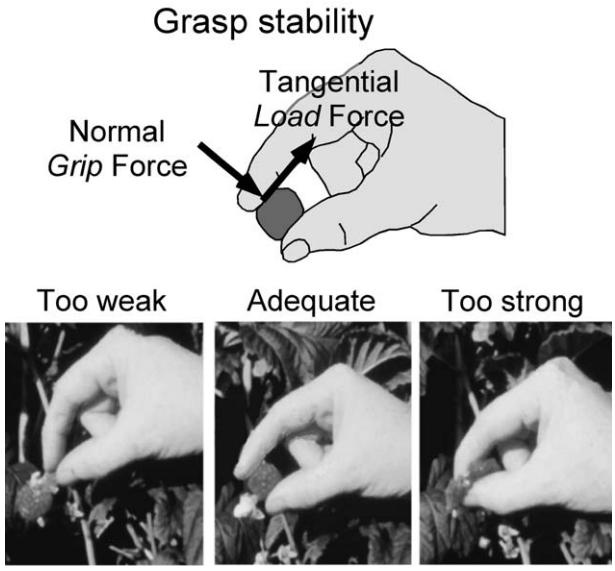

Figure 1 When manipulating objects grasped with a precision grip, we must carefully control the balance between grip force, normal to the contact surfaces, and load force tangential to the grasp surfaces. If grip force is too weak for a given load force, we risk having the object slip from our grasp. If grip force is too strong, we may crush the object or damage our hand and we waste energy.

The control of grip and load forces in object manipulation involves subtle interplay between two types of control: reactive control based on sensory feedback and predictive or feedforward control. These two control mechanisms are closely linked. On the one hand, reactive control mechanisms are invoked when errors arise between actual sensory feedback and the expected sensory feedback predicted from feedforward mechanisms. On the other hand, errors in sensory prediction are not only used for feedback control but also used to update feedforward mechanisms to reduce future prediction errors. In the following sections, we consider these two control processes in detail.

A. Feedback Control Based on Digital Sensors

One way to use digital sensors to adjust the force output would be to engage these sensors in feedback

loops. However, such loops imply large time delays. These time delays arise from impulse conduction time in peripheral nerves, conduction and processing time in the central nervous system, and the inherent sluggishness of muscles. In humans, these factors sum to at least 100 msec for the generation of a significant force response. Consequently, closed-loop feedback is not effective for rapid movement involving frequencies above 1 Hz. In natural manipulation tasks, movement frequency components up to 5 Hz can be observed. Thus, feedback control alone cannot support control of grip force for grasp stability in these movements.

Despite these control limitations, feedback control is essential in certain types of manipulative tasks. For example, feedback control is required in reactive tasks in which we restrain "active" objects that generate unpredictable load forces tangential to the grip surfaces. Examples of tasks in which we must deal with active objects are holding a dog's leash, restraining a child by holding his or her arm, or operating power tools. Consider the situation depicted in Fig. 2A

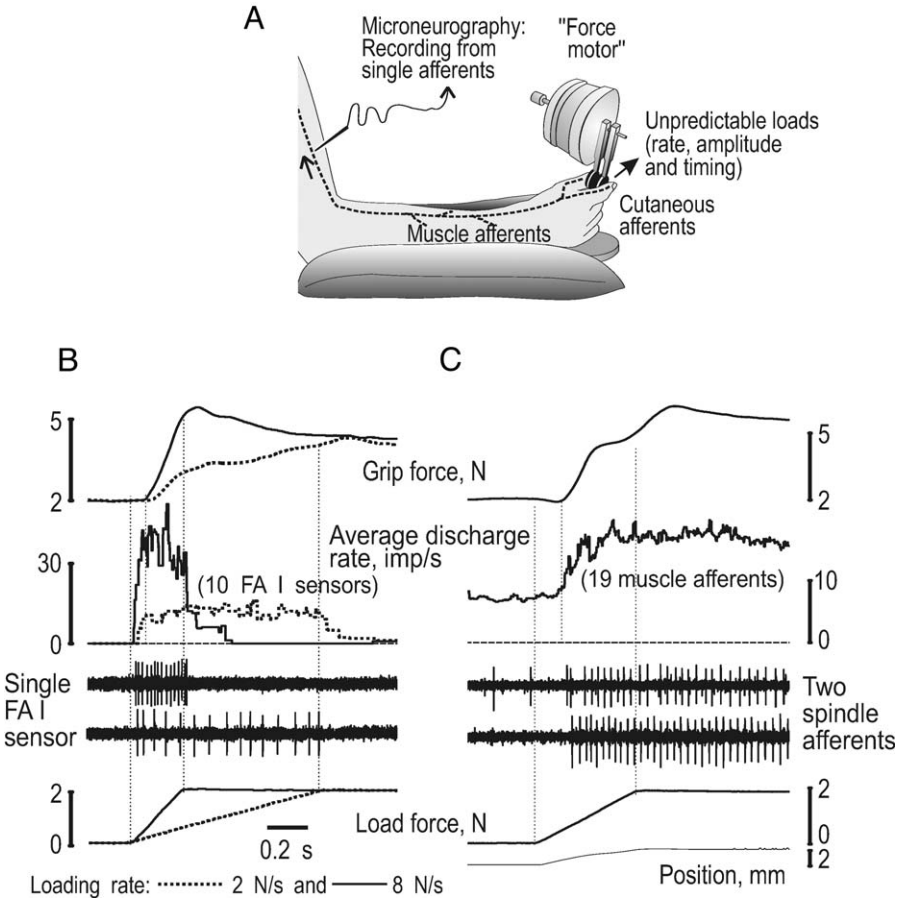

Figure 2 Peripheral afferent and reactive grip force responses to unpredictable loading of the precision grip by a pulling force. (A) The subject grasped the manipulandum with the tips of the thumb and index finger contacting parallel grip surfaces 25 mm apart. The force motor could deliver load forces pulled away from or pushed toward the hand. The grip and load forces, normal and tangential to the grip surfaces, respectively, and the position of the manipulandum were recorded. Afferent activity was recorded from the median nerve, with percutaneously inserted tungsten needle electrodes impaling the nerve about 10 cm proximal to the elbow. (B) Grip responses and average discharge rate of 10 FA I sensors to 2 N pulling loads delivered to the receptor-bearing digit at 2 N/sec (dashed lines) and 8 N/sec (solid lines). The two traces of single unit recordings are examples of responses in a single FA I sensor during load trials at 8 N/sec (upper trace) and 2 N/sec (lower trace). (C) Grip response and average discharge rate of 19 muscle afferents located in the long flexor muscles of the index, middle, or ring finger to 2.0 N pulling loads delivered at 4 N/sec. The single unit recordings are examples of responses in two different muscle spindle afferents. (B and C) The averages of forces and discharge rates are synchronized to the onset of the loading ramp; discharge rate represents average instantaneous frequency (adapted with permission from Macefield, V. G., Häger-Ross, C., and Johansson, R. S., *Exp. Brain Res.* **108,** 155–171, 1996; and Macefield, V. G., and Johansson, R. S., *Exp. Brain Res.* **108,** 172–184, 1996. Copyright © 1996 by Springer-Verlag).

in which an individual grasps an object attached to a force motor using a precision grip with the tips of the thumb and index finger on opposing vertical surfaces. The motor is used to generate increasing load forces (tangential to the grip surfaces) that are unpredictable in terms of onset time, amplitude, and direction (loading and unloading). To prevent the object from slipping, people automatically respond to increases in tangential load by increasing grip force normal to the grip surfaces in parallel with the load force changes (see load and grip force signals in Figs. 2B and 2C). When the load stops increasing, the grip force also stops increasing and may decrease slightly. Importantly, the changes in grip force lag behind the load force changes because they are reactively generated. A reactive grip response is initiated after a delay of approximately 100 msec but this varies with the load force rate. Because of this time lag, the object will slip from grasp unless the background grip force prior to a load increase is strong enough to meet the initial load increase. Indeed, following slips and trials with a high rate of load force increases, people learn to increase the initial background grip force as an adaptation to the expected range of loadings.

Figure 2A also shows signals, recorded using the technique of microneurography, from single nerve fibers of the median nerve that supply cutaneous, muscle, and joint sensors. Experiments with cutaneous anesthesia have demonstrated that reactive fingertip force responses are driven primarily by digital cutaneous inputs. Signals from fast adapting (FA I) cutaneous afferents seem most important, but slowly adapting cutaneous afferents may also contribute. As illustrated in Fig. 2B, the intensity of the cutaneous afferent responses is scaled by the rate of load force increase, and the afferent responses commence before the onset of the grip response. Furthermore, the size and duration of the grip force increase is scaled with the intensity and duration of the afferent response. This scaling is an attractive feature for feedback-based control.

Whereas cutaneous afferents contribute to the initiation and initial scaling of grip force responses, afferents from intrinsic and extrinsic hand muscles and interphalangeal joints do not respond to load increases early enough to allow them to contribute to the initiation of these grip responses. The muscle afferents respond reliably after the onset of the reactive grip force response and their discharge rates are related to changes in force output and, hence, to muscle activity (Fig. 2C). Thus, these muscle afferents are primarily concerned with events in the muscle itself rather than functioning as exteroceptors sensing mechanical events at the fingertips.

B. Feedforward Control Processes

Almost everyone will recall having fallen victim to an older sibling, cousin, or friend who passed us an empty box while pretending it was very heavy. When we took the box, our arms flailed upwards. This trick demonstrates that when we interact with objects, we anticipate the forces required to complete the task. Although it may occasionally result in large movement errors, anticipatory or feedforward control is essential for skilled object manipulation. Feedback control is important when our predictions are erroneous or, as in reactive tasks, when predictions are unavailable. However, because of the long time delays, feedback control cannot support the swift and skilled coordination of fingertip forces observed in most manipulation tasks that involve ordinary "passive" objects. Instead, the brain relies on feedforward control mechanisms that take advantage of the stable and predictable physical properties of these objects. These mechanisms parametrically adapt force motor commands to the relevant physical properties of the target object.

Figure 3 illustrates parametric anticipatory adjustments of motor output to object weight, friction between the object and skin, and shape of the contact surface. The task is to lift a test object from a support surface, hold it in air for a couple of seconds, and then replace it. To accomplish this task, the vertical load force increases until liftoff occurs, stays constant during the hold phase, and then starts to decrease when the object contacts the support surface during replacement. When lifting objects of different weight (Fig. 3A), people scale the rate of increase of both grip force and load force to object weight such that lighter and heavier objects tend to be lifted in about the same amount of time. The scaling occurs prior to liftoff–before sensory information about object weight becomes available–and is therefore predictive. To deal with changes in friction, the motor system adjusts the balance between grip force and load force. As shown in Fig. 3B, when lifting equally weighted objects of varying slipperiness, people scale the rate of increase of grip force while keeping the rate of change of load force constant. Thus, the ratio of these force rates is a controlled parameter that is set to the current frictional conditions. A similar scaling of the grip-to-load force ratio is observed when object shape is varied. A larger

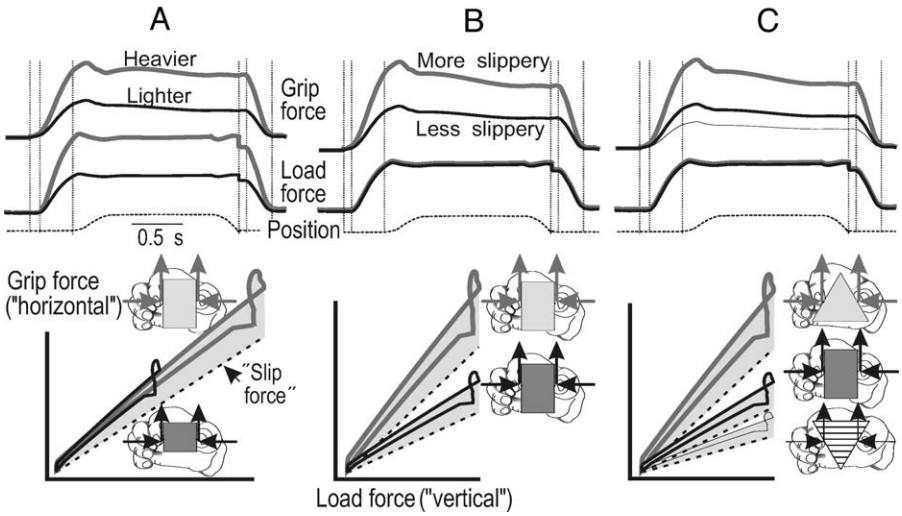

Figure 3 Feedforward adjustments of motor output to object weight (A), frictional conditions (B), and object shape (C) in a task in which a test object is lifted with a precision grip, held in air, and then replaced. The top graphs show horizontal grip force, vertical load force, and the vertical position of the object as a function of time for two superimposed trials. The bottom graphs show the relation between load force and grip force for the same trials. The dashed line indicates the minimum grip-to-load force ratio required to prevent slip. The gray area represents the safety margin against slip. After contact with the object (left most vertical line, top), grip force increases by a short period while the grip is established. A command is then released for simultaneous increases in grip and load force (second vertical line). This increase continues until the load force overcomes the force of gravity and the object lifts off (third vertical line). After replacement of the object and table contact occurs (fourth line), there is a short delay before the two forces decline in parallel (fifth line) until the object is released (sixth line) (adapted with permission from Johansson, R. S., and Westling, G., *Exp. Brain Res.* **56,** 550–564, 1984 by Springer-Verlag; Johansson, R. S., and Westling, G., *Exp. Brain Res.* **71,** 59–71, 1988. Copyright © 1988 by Springer-Verlag; and Jenmalm, P., and Johansson, R. S., *J. Neurosci.* **17,** 4486–4499, 1997 Copyright © 1997 by the Society for Neuroscience).

ratio is used when the grip surfaces are tapered upward compared to downward (Fig. 3C).

In each example shown in Fig. 3, grip force increases and decreases in phase with (and thus predicts) changes in vertical load force. This parallel coordination of grip force and load force ensures grasp stability. The grip force at any given load force is controlled such that it exceeds the corresponding minimum grip force, required to prevent slip, by a small safety margin (gray areas in the bottom of Fig. 3). This minimum grip force depends on the weight of the object, the friction between the object and skin, and the shape (e.g., angle) of the contact surfaces.

This parallel coordination of grip force and load force is a general feedforward control strategy and is not specific to any particular task or grip configuration. Parallel force coordination is observed when grasping with two or more digits of the same hand or both hands, when grasping with the palms of both hands, and even when gripping objects with the teeth. Moreover, it does not matter whether the object is moved by the arm or, for example, by the legs as when jumping with the object in hand. Importantly, the parallel coordination of grip and anticipatory load force is not restricted to common inertial loads. People also adjust grip force in parallel with load force when pushing or pulling against immovable objects and when moving objects subjected to elastic and viscous loads. Figure 4 illustrates parallel coordination of grip and load forces under varying load conditions. People alternately pushed and pulled an object instrumented for force sensors and attached to a simple robot that could simulate various types of opposing loads acting tangential to the grasp surfaces (Fig. 4A). Figures 4B and 4C show kinematic and force records obtained under three different load conditions: an acceleration-dependent inertial load, a velocity-dependent viscous load, and an elastic load that largely depended on position but also contained viscous and inertial components. In all three cases, the grip force normal to the grasp surfaces changes in parallel with the magnitude of the load force tangential to the grasp surface. Importantly, the relationship between arm movement motor commands and the load experienced at the fingertips depends on the type of load being moved. Thus, to adjust grip force in parallel with load

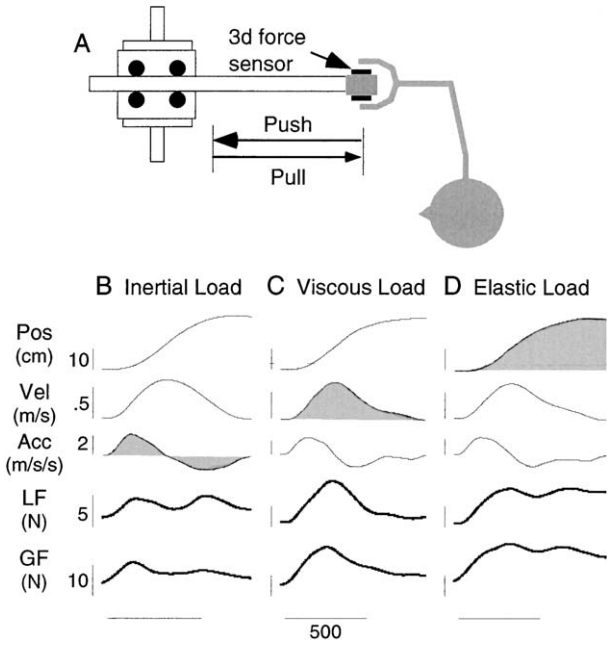

Figure 4 Kinematic and force records from one subject under the three load conditions. Shaded regions indicate the primary kinematic variable on which load depended. Under all three load conditions, grip force (GF) is adjusted in parallel with fluctuations in load force (LF), with the resultant load tangential to the grasp surface. The dashed vertical lines indicate movement onset (modified with permission from Flanagan, J. R., and Wing, A. M., *J. Neurosci.* **17,** 1519–1528, 1997. Copyright © 1997 by the Society for Neuroscience).

force under the different load conditions, people had to alter the mapping between the motor command driving arm movement and that driving the grip force.

In most everyday tasks, destabilizing loads acting on the grasp include not only linear load forces but also torques tangential to the grasped surfaces. Such torsional loads occur whenever we tilt an object around a grip axis that does not intersect the vertical line through the object's center of mass. In addition, torque loads arise in many natural manipulatory tasks due to changes in the orientation of the grip axis with respect to gravity. For example, this occurs when we hold a book flat by gripping it between the fingers beneath and the thumb above (vertical grip axis) and then rotate it by a pronation movement to put it in a bookshelf (horizontal grip axis). Because we rarely take a book such that the grip axis passes through its center of mass, a torque will develop in relation to the grasp. Importantly, the sensorimotor programs for object manipulation account for torsional loads by predicting the consequences of object rotation both when we rotate objects around the grip axis and when we rotate the grip axis in the field of gravity. Rotational slips are prevented by automatic increases in grip force that parallel increases in tangential torque. The sensorimotor programs thus model the effect of the total load in terms of linear forces, tangential torques, and their combination.

C. Internal Models Underlying Predictive Force Control

As illustrated in Fig. 3A, with objects of different weight, people use different rates of force increase prior to liftoff. Since there is no sensory information available about object weight until liftoff, this behavior indicates that people predict the final force requirements. Likewise, with objects of different friction (Fig. 3B) and shape (Fig. 3C), the force output is tailored to the properties of the object from the start of the initial force attack, well before sensory information from the digits obtained after contact with the object could have exerted any influence. Thus, in all three cases, the motor controller operates in a feedforward fashion and uses motor command parameters determined by internal models that capture the physical properties of the object. Figure 4 further illustrates that such internal models also capture dynamic properties of objects. The question arises as to how such models are selected and updated for different objects and after changes in object properties.

1. Prediction Based on Object Shape

Figures 5A and 5B show three consecutive trials taken from a series of lifts in which the angle of the grasped surfaces was changed between trials in a pseudorandom order. The sequence is 30°, −30°, and −30° and thus includes a transition from an upward tapered object (30°) to a downward tapered object (−30°). In the trials preceding this sequence, a 30° object was lifted. First consider the trials in which vision of the objects is available (Fig. 5A). When the shape of the object is changed, the grip force is adjusted from the very start of the lift in anticipation of the lower grip force required to lift the object. In particular, grip force is now increased more slowly before sensory feedback from the digits could have influenced the motor output. The predictive adjustment in grip force observed in the first trial after the switch in object shape is very accurate. Indeed, no further adjustment is

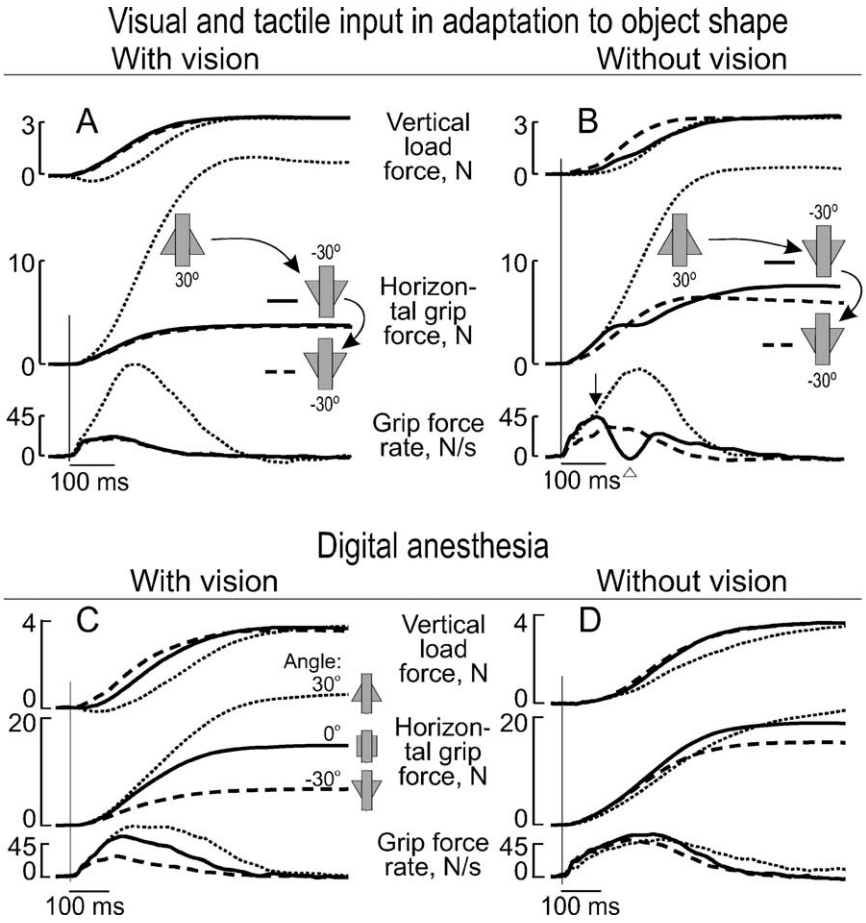

Figure 5 (A and B) Force adjustments to changes in surface angle during lift series in which surface angle was unpredictably varied between lift trials. Vertical load force, horizontal grip force, and grip force rate shown as a function of time for trials with (A) and without (B) vision and with normal digital sensibility. The dotted curves are from the last trial before the switch with the 30° object. The solid curves show the next trial with the −30° object. These curves illustrate adjustments to the smaller angle. The dashed lines show the following trial again with the −30° object. The downward arrow in B indicates the point in time when the new surface angle was expressed in terms of motor output. (C and D) Adaptation to surface shape during digital anesthesia with (C) and without (D) vision. Vertical load force, horizontal grip force, and grip force rate as a function of time for trials with 30° (dotted lines) 0° (solid lines and −30°, (dashed lines) surface angle (modified with permission from Jenmalm, P., and Johansson, R. S., *J. Neurosci.* **17,** 4486–4499, 1997. Copyright © 1997 by the Society of Neuroscience).

observed on the second trial after the change when information about shape has been obtained through tactile sensory signals. These results demonstrate that visual geometric cues can be used to efficiently specify the force coordination for object shape in a feedforward manner. These cues are used to parametrically adapt the finger force coordination to object shape in anticipation of the upcoming force requirements.

When vision of the object is not available, a very different pattern of force output is obtained. On the first trial after the switch to the −30° object, grip force develops initially according to the force requirements in the previous trial. This indicates that memory of the previous surface angle determines the default force coordination in a feedforward manner. However, about 100 msec after the digits contacted the object, the grip force was modified and tuned appropriately for the actual surface angle (see first trial with the −30° in Fig. 5B). This amount of time is required to translate tactile information into motor commands, a process that likely involves supraspinal processing. By the second trial after the switch, the force output is appropriately adapted to the −30° surface angle from the onset of force application. Thus, an internal model related to object shape determines the force coordination in a feedforward fashion and tactile sensory information obtained at initial contact with the object mediates an updating of this model to changes in

object shape. Furthermore, a single trial is enough to update the relevant internal model.

Sensors in the digits are thus used to update the force coordination for object shape when visual cues are unavailable or misleading. When digital sensibility is removed by local anesthesia, leaving neither visual nor somatosensory cues about shape, the adaptation in force output is severely impaired (Fig. 5D). Although grip force and load force still change in parallel, force output is no longer updated following contact. People adapt to the loss of both visual and tactile sensory cues about shape by applying strong grip forces regardless of surface angle. When vision is available during digital anesthesia, people are able to adapt their forces to object shape with only minor impairments (Fig. 5C). Thus, visual geometric cues can be used effectively for feedforward control even in the absence of somatosensory cues about shape.

The curvature of the grasp surfaces is another aspect of object shape. Surprisingly, the curvature of spherically curved symmetrical grasp surfaces has little effect on grip force requirements for grasp stability under linear force loads. However, it becomes acute in tasks involving torsional loads. The relationship between the grip force and tangential torque is parametrically scaled by surface curvature: For a given torque load, people increase grip force when curvature increases. As with linear force loads, this scaling of grip force is directly related to the minimum grip force required to prevent slip. Under torsional loads, people maintain a small but adequate safety margin against rotational slip. As with surface angle, visual information about surface curvature can be used for feedforward control of force. Likewise, people use cues provided by tactile afferents to adapt force once finger contact is established.

2. Prediction Based on Object Weight

When we manipulate familiar or common objects that we can identify either visually or haptically, we are extremely adept at selecting fingertip forces that are appropriately scaled to the weight of the object. That is, during the very first lift of a common object, before sensory information related to weight becomes available at liftoff, the force development is tailored to the weight of the object. This indicates that we can use visual and haptic cues to select internal models that we have acquired for familiar objects and can use these models to parametrically adjust our force output to object weight. For ''families'' of familiar objects that vary in size (e.g., screwdrivers, cups, soda cans, and loafs of bread), we can exploit size–weight associations, in addition to object identity, to scale our force output in a feedforward fashion. However, as we have all experienced, our force output may sometimes be erroneous. Such situations can be created experimentally by unexpectedly changing the weight of a repeatedly lifted object without changing its visual appearance. In such cases, the lifting movement may be either jerky or slow. For example, if the object is lighter than expected from previous lifting trials, the load force and grip force drives will be too strong when the load force overcomes the force of gravity and liftoff takes place. Although somatosensory afferent events, evoked by the unexpectedly early liftoff, trigger an abrupt termination of the force drive, this occurs too late (due to control loop delays) to avoid an excessively high lift. Burst responses in FA II (Pacinian) afferents, which show an exquisite sensitivity to mechanical transients, most quickly and reliably signal the moment of liftoff. Conversely, if the object is heavier than expected, people will initially increase load force to a level that is not sufficient to produce liftoff and no sensory event will be evoked to confirm liftoff (Fig. 6A, solid curves). Importantly, this *absence* of a sensory event at the expected liftoff causes the release of a new set of motor commands. These generate a slow, discontinuous force increase until terminated by a neural event at the true liftoff (Fig. 6A, afferent response during the 800-g lift following the 400-g lift). Taken together, these observations indicate that control actions are taken as soon there is a mismatch between an expected sensory event and the actual sensory input. Thus, the absence of an expected sensory event may be as efficient as the occurrence of an unexpected sensory event in triggering compensatory motor commands. Moreover, this mismatch theory implies that somatosensory signals that represent the moment of liftoff are mandatory for the control of the force output whether or not the weight of the object is correctly anticipated. Finally, once an error occurs, the internal model of the object is updated to capture the new weight. In natural situations, this generally occurs in a single trial. As shown in Fig. 6A, in the trial after the switch trials when the weight of the object was unexpectedly increased from 400 to 800 g, the forces were correctly scaled for the greater weight (dashed curves).

3. Prediction Based on Friction

Whereas people use visual information about object size and shape to scale fingertip forces, there is no

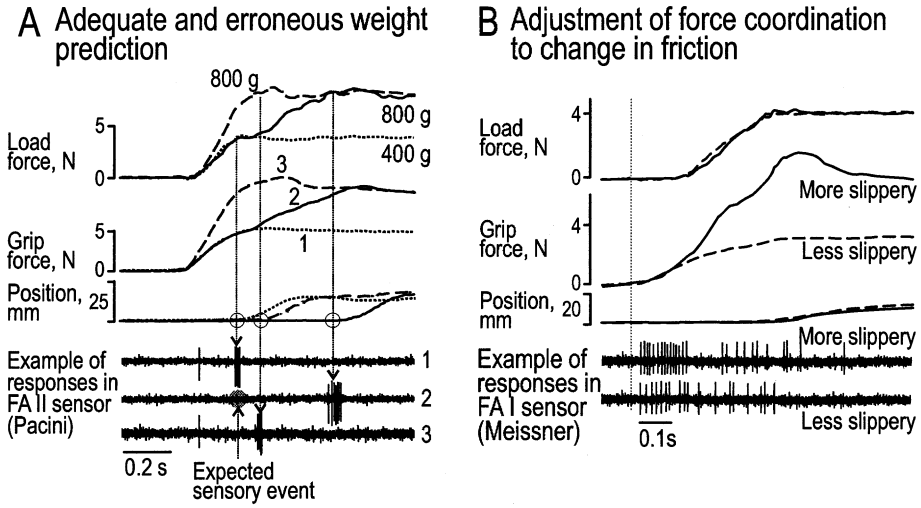

Figure 6 Single unit tactile afferent responses and adjustments in force to changes to object weight (A) and to the frictional condition between the object and the digits (B). Data are from single lift trials. (A) Three successive trials in which the subject lifted a 400-g object (dotted curves), an 800-g object (solid curves), and then the 800-g object again (dashed curves). The forces exerted in the first lift are adequately programmed because the subject had previously lifted the 400-g object. The forces are erroneously programmed in first lift of the 800-g object because they are tailored for the lighter 400-g object lifted in the previous trial. The vertical lines with arrowheads pointing downward indicate the moment of liftoff for each trial and they indicate the evoked sensory events exemplified by signals in a single FA II afferent. The absence of burst responses in FA II afferents at the expected point in time for the erroneously programmed 800-g trial is used to initiate a new control mode. This involves slow, discontinuous, and parallel increases in grip force and load force until terminated by sensory input signaling liftoff. (B) The influence of friction on force output and initial contact responses in a FA I unit. Two trials are superimposed, one with less slippery sandpaper (dashed lines) and a subsequent trial with more slippery silk (solid lines). The sandpaper trial was preceded by a trial with sandpaper and therefore the force coordination is initially set for the higher friction. The vertical line indicates initial touch (modified with permission from Johansson, R. S., and Westling, G., *Exp. Brain Res.* **66,** 141–154, 1987. Copyright © 1987 by Springer-Verlag; and from *Curr. Opin. Neurobiol.* Johansson, R. S., and Cole, K. J., **2,** 815–823, Copyright © 1992, with permission from Elsevier Science).

evidence that they use visual cues to control the balance of grip and load force for friction. However, tactile receptors in the fingertips are of crucial importance. The most important adjustment after a change in friction takes place shortly after the initial contact with the object and can be observed about 100 msec after contact (Fig. 6B). Prior to this force adjustment, there are burst responses in tactile afferents of different types but most reliably in the population of FA I (Meissner) afferents. The initial contact responses in subpopulations of excited FA I afferents are markedly influenced by the surface material as exemplified in Fig. 6B with a single afferent. The adjustment of force coordination to a change in frictional condition is based on the detection of a mismatch between the actual and an expected sensory event. This adjustment involves either an increase in the grip-to-load force ratio if the surface is more slippery than expected (as shown in Fig. 6B) or a decrease in the ratio of the surface if less slippery than expected. The adjustment also includes an updating of the internal model so as to capture the new frictional conditions between the object and the skin for predictive control of the grip-to-load force ratio in further interactions with the object. However, sometimes these initial adjustments to frictional changes are inadequate and an accidental slip occurs at a later point, often at one digit only. Burst responses in dynamically sensitive tactile afferents to such slip events promptly trigger an automatic upgrading of the grip-to-load force ratio to a higher maintained level. This restores the grip force safety margin during subsequent manipulation by updating the internal model controlling the balance between grip and load force.

In summary, skilled manipulation involves two major types of control processes: *anticipatory parameter control* and *discrete event, sensory-driven control.* Anticipatory parameter control refers to the use of visual and somatosensory inputs, in conjunction with internal models, to tailor finger tip forces for the properties of the object to be manipulated prior to the execution of the motor commands. For familiar objects, visual and haptic information can be used to

identify and select the appropriate internal model that is used to parametrically adapt motor commands, prior to their execution, in anticipation of the upcoming force requirements. People may also use geometric information (e.g., size and shape) for anticipatory control, relying on internal forward models capturing relationships between geometry and force requirements. There is ample evidence that the motor system makes use of internal models of limb mechanics, environmental objects, and task properties to adapt motor commands.

Discrete event, sensory-driven control refers to the use of somatosensory information to acquire, maintain, and update internal models related to object properties. This type of control is based on the comparison of actual somatosensory inflow and the predicted somatosensory inflow—an internal sensory signal referred to as corollary discharge. (The somatosensory input provided by tactile signals in the digital nerves is obviously critical in the control of skillful manipulation.) Thus, when we lift an object, we generate both efferent motor commands to accomplish the task and this internal sensory signal. Together, these are referred to as the sensorimotor program. Predicted sensory outcomes are produced by an internal forward model in conjunction with a copy of the motor command (referred to as an efference copy). Disturbances in task execution due to erroneous parameter specification of the sensorimotor program give rise to a mismatch between predicted and actual sensory input. For example, discrete somatosensory events may occur when not expected or may not occur when they are expected (Fig. 6A). Detection of such a mismatch triggers preprogrammed patterns of corrective responses along with an updating of the relevant internal models used to predict sensory events and estimate the motor commands required. This updating typically takes place within a single trial. With respect to friction and aspects of object shape, the updating primarily occurs during the initial contact with the object. In trials erroneously programmed for object weight and mass distribution, the updating takes place when the object starts to move (e.g., at liftoff in a lifting task).

III. ONTOGENETIC DEVELOPMENT OF SENSORIMOTOR CONTROL IN MANIPULATION

The ability to grasp using a precision grip involving the tips of the thumb and index finger first emerges in humans at approximately 8–10 months of age. However, fully mature patterns of grasping, lifting, and holding objects are not observed until about 8 years of age. During this period, there is gradual improvement in grasping behavior as well as qualitative improvements in the capacity to produce independent finger movements. These changes parallel the gradual maturation of the ascending and descending neural pathways that link the hand with the cerebral cortex. These observations strongly suggest that the control of the skilled precision lifting and manipulation relies to a large extent on cerebral processes.

As noted previously, when adults lift objects, they increase grip force and load force in phase such that the two forces increase and decrease together. As a consequence, a linear relationship between these forces is observed (Figs. 3B, 3C, and 7B). The motor system adapts the slope of this relationship to factors such as the frictional conditions and the shape of the contact surfaces but robustly maintains this force synergy (Figs. 3B and 3C). However, before 18 months of age, children do not exhibit such parallel control of grip and load forces (Fig. 7). Instead, they tend to increase grip force in advance of the load force in a sequential fashion. The transition from sequential force coordination to the mature parallel coordination is not completed until several years later. Young children also produce comparably slow increases in fingertip force before liftoff and these increases are discontinuous, featuring multiple peaks in force rate (Fig. 7A). In contrast, adults smoothly increase grip force and load force with a single peak in force rate. The discontinuous or start-and-stop force increases observed in young children suggest that they employ a feedback control strategy rather than feedforward control. That is, they continue to increase force in small increments until liftoff occurs. It is not until they receive somatosensory information that liftoff has occurred that they stop these increases. This feedback strategy is similar to that observed when adults underestimate the weight of an object and then have to increase force again until liftoff occurs (Fig. 6B, solid lines). These observations suggest that young children may not have the cognitive resources for accurate feedforward control.

In addition, very young children appear to be relatively inefficient at integrating sensory information into sensorimotor programs. In precision lifting, people start to increase grip force and load force soon after the digits contact the object. Signals from tactile afferents related to object contact trigger the next phase of the lift. In very young children, there is a

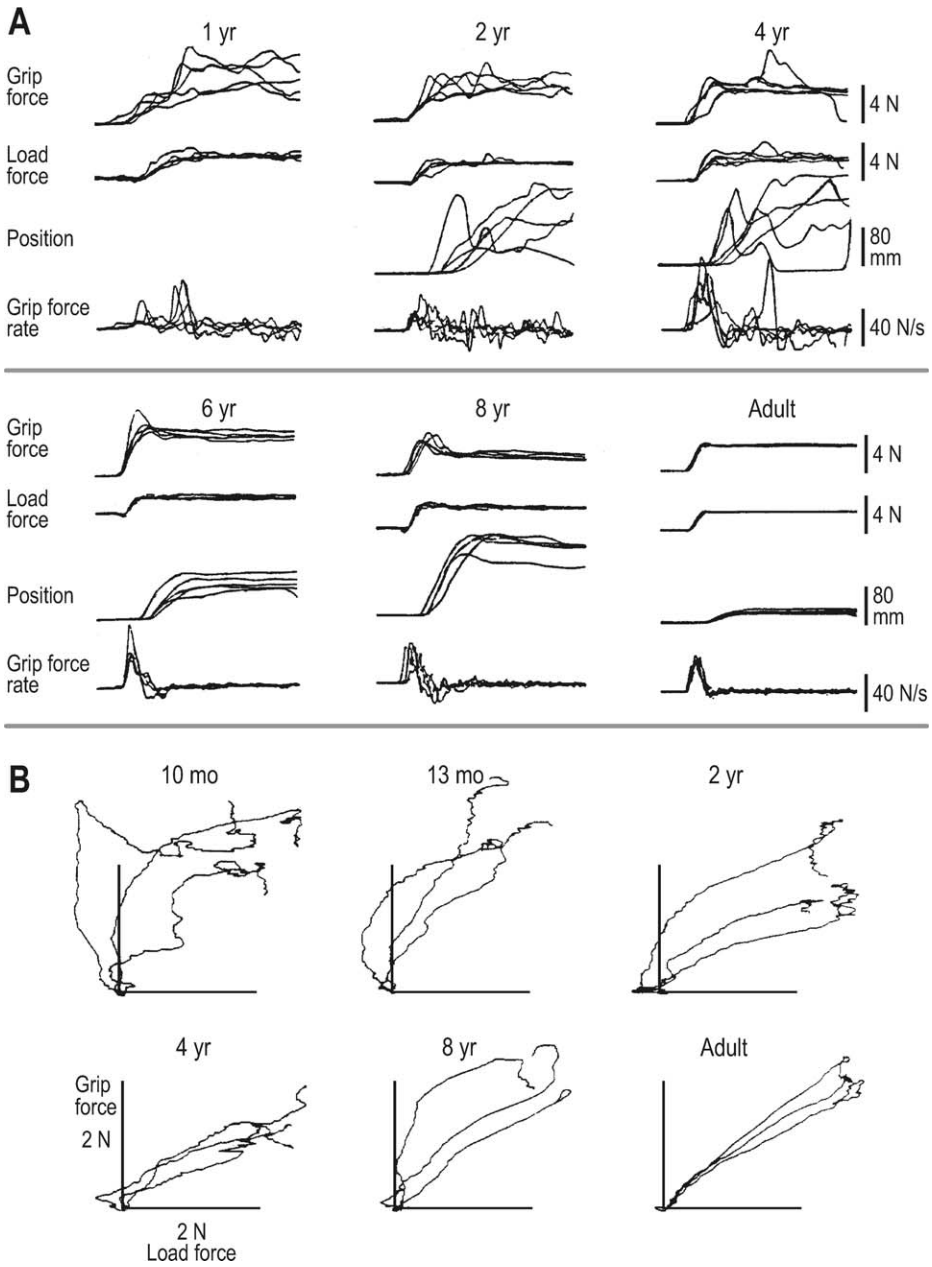

Figure 7 Ontogenetic development of the coordination of grip and load forces during precision lifting. (A) Grip force, load force, and grip force rate as a function of time during several consecutive trials (superimposed) for individual children of various ages and an adult. Note the large variability and excessive grip forces used by young children compared to the adults. (B) Relationship between grip force and load force during the initial parts of lifting trials by children of various ages and an adult. Note the nonparallel increase in grip and load forces for young children compared to adults. (A and B) Surface material and object's weight are constant (adapted with permission from Forssberg, H., Eliasson, A. C., Kinoshita, H., Johansson, R. S., and Westling, G., *Exp. Brain Res.* **85,** 451–457, 1991. Copyright © 1991 by Springer-Verlag).

relatively long delay between initial contact and the onset of increases in grip and load force. This long delay indicates immature control of hand closure and inefficient triggering of the motor commands by cutaneous afferents. The decrease in this delay during subsequent years parallels a maturation of cutaneous reflexes of the hand as assessed by electrophysiological methods.

During the latter part of the second year, children begin to use sensorimotor memory, obtained from

previous lifts, for scaling forces in anticipation of object weight. However, adult-like lifting performance with precise control of the load force for smooth object acceleration does not appear until 6–8 years of age. At about 3 years of age, children start to use vision for weight estimation through size–weight associations for classes of related objects. Thus, additional cognitive development is apparently required before the necessary associative size–weight mapping can take place. Unlike adults, once children begin to use visual size cues, they are unable to suppress adequately their influence when the cues are misleading (i.e., in situations in which weight and size do not reliably covary). This observation is consistent with the view that vision has a particularly strong influence on motor coordination in children. Thus, the context-related selective suppression of visual cues appears to require even further cognitive development.

Young children display a limited capacity to adapt the ratio of grip force and load force to frictional conditions. These children use unnecessarily high grip forces in trials with high friction (or low slipperiness) and their behavior is reminiscent of that of adults with impaired digital sensibility. This increased grip force may be a strategy to compensate for immature tactile control of precision grip because overgripping will prevent slips when handling slippery objects. Nevertheless, even the youngest children (1–2 years) show some capacity to adjust grip force to friction if the frictional conditions are kept constant over several consecutive precision grip lifts. The need for repetitive lifts suggests a poor capacity to form sensorimotor memory related to friction and/or to use this memory to control force output. Older children require fewer lifts to update effectively their force coordination to new frictional conditions, and adults require only one lift.

IV. DISSOCIATIONS AND INTERACTIONS BETWEEN PERCEPTION AND ACTION

An important concept in neuroscience is the idea that sensory information is processed in multiple pathways for different uses. For example, in the visual system, there is strong evidence that neural systems that process visual information for use in guiding action are at least partly distinct from neural systems involved in processing visual information for perception and cognitive reasoning. Similarly, there is evidence that sensory information obtained from the hand can have differential effects on action and perception. Here, we discuss evidence for a dissociation between perception and action related to hand movement. However, first we discuss how manipulatory actions can influence perception.

A. Influences of Action on Weight Perception

Because haptic perception of objects generally involves manipulation, the question arises as to whether the perception of particular object properties is influenced by other object properties or by the way in which the object is handled. For example, does the perceived weight of an object depend on the angle of its contact surfaces or the friction between the object and the digits, both of which influence the grip force required to lift the object? Here, one question is whether the grip forces in lifting influence weight perception even though the grip forces are not directly involved in overcoming the force of gravity. For example, does the greater effort required to lift a slippery object give rise to the perception of it being heavier than a less slippery object of the same weight?

More than 150 years ago, Ernst Heinrich Weber observed that the ability to discriminate weight is better when the weights are actively lifted by the hand than when they are supported by a passive hand. This observation suggests that a sense of effort, associated with voluntary muscular exertion, contributes to the perception of weight. Although afferent signals contribute to weight perception, at least under some conditions there is ample evidence that effort, defined as the level of central or efferent drive, contributes to weight perception. The idea is that when we generate motor commands to lift an object, a copy of the commands (efference copy) generates an internal sensation (corollary discharge) that influences perceived weight. The centrally generated sensation is referred to as the sense of effort.

Figure 8A shows the results of an experiment in which people were asked to compare the weights of a reference object and a series of randomly presented test objects of varying weight both heavier and lighter than the weight of the reference. The test objects had the same size and shape as the reference object, and the objects were lifted using a precision grip with the tips of the index fingers on either side. In one condition, the reference object was covered in less slippery sandpaper and the test objects were covered in more slippery satin (Fig. 8, solid circles and solid curve), whereas in a second condition the reference object was covered in satin and the test objects were cover in sandpaper

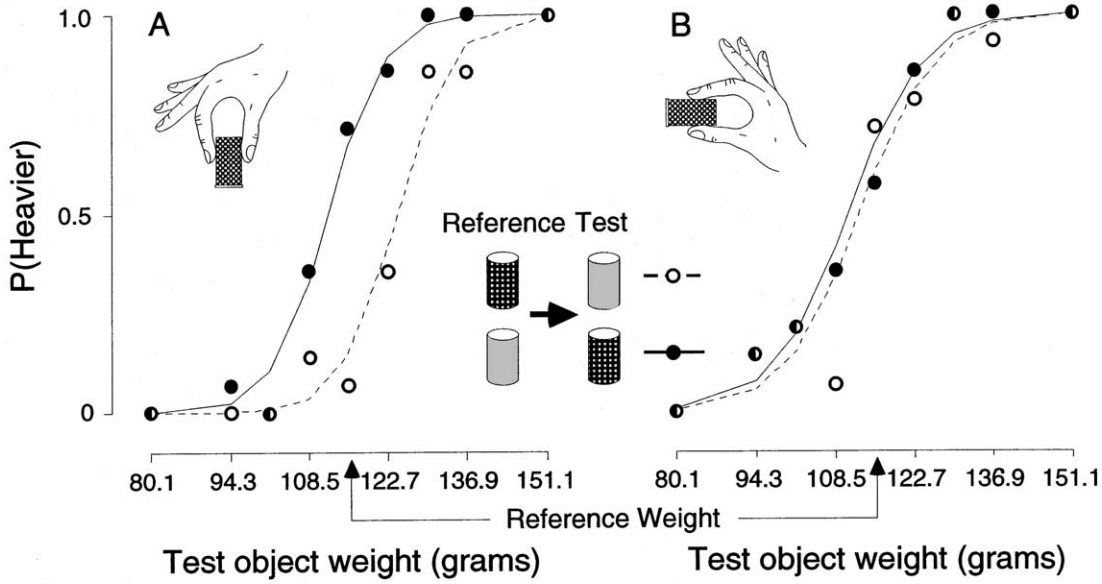

Figure 8 Probability (n=14) of responding that the test canister is lighter than the previously lifted reference canister as a function of the test canister weight. In different experiments, the canisters were lifted with either a vertical (A) or horizontal (B) precision grip. Open circles and dashed lines code the condition in which the test canister was covered in less slippery satin, and the closed circles and solid lines code the condition in which the test canister was covered in less slippery sandpaper. The triangles indicate the reference weight (modified with permission from Flanagan, J. R., Wing, A. M., Allison, S., and Spencely, A., *Perception Psychophys.* **57,** 282–290, 1995).

(Fig. 8, open circles and dashed curve). Figure 8A shows the probability of judging the test object to be heavier than the reference as a function of the weight of the test object. In both conditions, when the test object is much heavier (151.1 g) than the reference (115.6 g) the test object is always judged to be heavier. Conversely, when the test object is much lighter (80.1 g), it is never judged to be heavier. However, in between these extremes, the probability of judging the test object to be heavier is greater when the test object is covered in slippery satin. (Note that there is a general tendency to judge the second of two successively lifted weights, in this case the test object, to be heavier.) This indicates that when lifting with the fingertips on the sides of the object, a more slippery object is judged heavier than an equally weighted object that is less slippery. One interpretation of the results shown in Fig. 8A is that humans judge the more slippery object to be heavier because the grip force used in lifting is greater. When people hold the reference and test objects with a horizontal grip (Fig. 8B), in which surface slipperiness has little influence on the required grip force, there is no effect of surface slipperiness on weight perception.

The results shown in Fig. 8A suggest that people fail to fully distinguish between the effort related to grip force and that related to load force when judging weights lifted with a precision grip. However, this overflow effect may only pertain to muscle actions that are functionally related. Support for this view comes from the observation that the perceived heaviness of a given weight, lifted by one digit, increases if a concurrent weight is lifted by any other digit of the same hand. When the foot or other hand lifts the concurrent weight, the perceived heaviness is not affected.

Although differences in grip force influence weight perception when these differences are determined by frictional conditions, grip force does not appear to influence perceived heaviness when it is manipulated by changing surface shape. When people compare the weights of triangular blocks lifted either on the angled or flat side, there is no effect of angle of perceived weight. It may be that when the grip force requirements strongly match those prescribed by visual cues, people suppress the effort related to grip force differences in evaluating weight. Recall that visual cues related to surface angle can be used effectively for feedforward force control but that there is no evidence that visual information related to frictional condition can be exploited for anticipatory force control.

B. Independent Sensorimotor and Perceptual Predictions of Weight

As discussed previously, people use visual information about object size and shape to estimate parametrically the impending force requirements in manipulation. Thus, people will increase grip and load force more rapidly when lifting a large object than a similar looking small object. This feedforward strategy takes advantage of the link between size and weight that normally pertains to a class or family of similar objects; for example, big cups should weigh more than small ones. However, it fails when this link is altered. In such a case, people must rely on reactive control mechanisms to correct for their erroneous prediction and on feedback mechanisms to tune the internal models used for predictive control. Such a situation arises in the classic size–weight illusion in which people are asked to compare the weights of two equally weighted objects of similar form but unequal size. This illusion, first documented more than 100 years ago, refers to the fact that people reliably judge the smaller of the two objects to be heavier when lifted, even after many lifting trials.

A leading theory of the size–weight illusion is that the illusion arises from a mismatch between predicted and actual sensory feedback. The idea is that when we lift the smaller object, the actual sensory feedback about liftoff will not occur when predicted and the object will thus be judged heavier. Conversely, the larger object, which is lighter than expected, will be judged heavier.

The sensory mismatch seems entirely plausible when one considers lifting the two equally weighting objects the very first time. Here, visual size cues will be misleading and we would expect people to use too much force for the larger object and too little force for the smaller object. However, we also know that people acquire sensorimotor memory related to object weight over repeated lifts. The question arises whether people will continue to misjudge the force required when repeatedly lifting large and small objects of equal weight. Figure 9 reveals the answer. People were asked to repeatedly lift a small and a large cube (Fig. 9A) in alternation. Predictably, when the two objects are lifted for the first time, the forces required for the large object are overestimated and the forces required for the small object are underestimated (Fig. 9B, left). Compensatory, reflex-mediated adjustments in force are triggered in either case. When lifting the small object, the initial increase in grip force and load force is too small and liftoff does not occur when expected. As a result, the forces increase again until liftoff is achieved. When lifting the large object, overshoots occur in the grip and load forces and liftoff occurs earlier than expected. The unexpected early liftoff

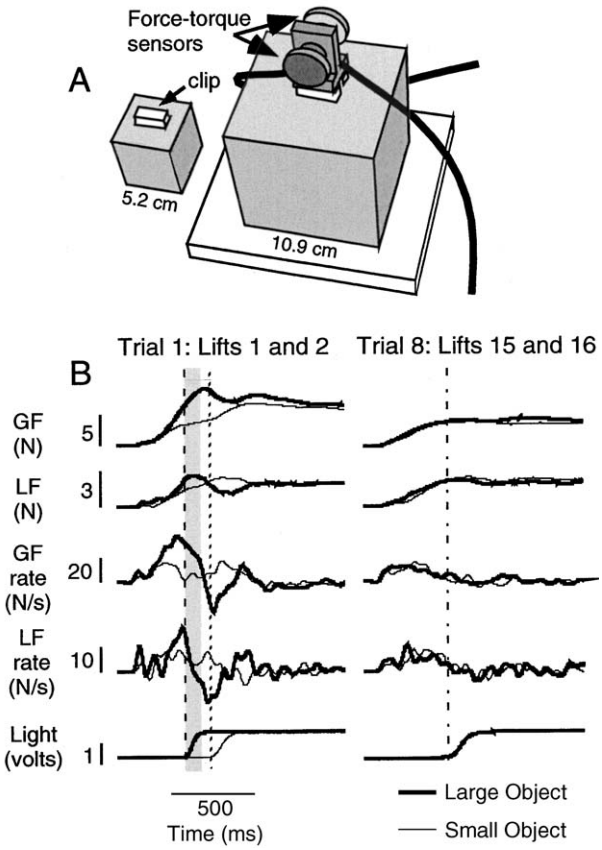

Figure 9 Independent sensorimotor and perceptual predictions of weight. (A) Drawing showing the relative sizes of two equally weighted cubes. Subjects lifted the cubes using a precision grip with the tips of the index finger and thumb on either side of a handle. The handle was attached by clips located on top and in the center of each object. The handle was instrumented with two sensors that measure the forces and torques applied by each digit. Plastic contact disks (3 cm in diameter) were mounted on each sensor and covered in medium-grain sandpaper. A light-sensitive diode embedded into the center of the lifting platform recorded liftoff. (B) Grip force (GF), load force (LF), grip and load force rates, and light-sensitive diode recorded in the first trial (lifts 1 and 2) and the eighth trial (lifts 15 and 16). The subjects lifted the large object (thick traces) and then the small object (thin traces) in each trial. In all trials, subjects grasped the object and increased grip and load force together until liftoff, signaled by the light diode, occurred. In the first trial, peak grip and load force rates were scaled to object size, whereas by the eighth trial the peak force rates were similar for the two objects and appropriately scaled to object weight. Although the subjects adapted their motor output to the true object weights, they still reported verbally that the small object was heavier (adapted with permission from Flanagan, J. R., and Beltzner, M. A., *Nature Neurosci.* **3,** 737–741, 2000).

triggers a decrease in force approximately 100 msec later. However, a very different pattern of force output is observed by the time the cubes are lifted for the eighth time (Fig. 9B, right). Now the force and force rate functions for the small and large cubes are very similar and liftoff occurs at about the same time for both cubes. In contrast to the initial lift trials, grip and load force neither overshoot nor undershoot their final levels, and no corrective adjustments in force are observed. These results illustrate that people adapted their force output, and thus their sensory predictions used for force control, to the actual object weights. Thus, sensorimotor memory about object weight, obtained from previous lifts and based on somatosensory information, comes to dominate visual size cues in terms of feedforward force control.

Although the motor system gradually adapts force output to the true, equal weights of the size–weight stimuli, the perceptual system that mediates awareness of object weight does not adapt. After lifting the two cubes 20 times each, people still reported that the small object was heavier. Moreover, the strength of the size–weight illusion—measured using magnitude estimation techniques—is equally strong. That people experience the size–weight illusion while accurately predicting the fingertip forces required for lifting clearly debunks the theory that the perceptual illusion is accounted for by a sensory mismatch. Instead, the results indicate that the illusion can be caused by high-level cognitive factors. Although the size–weight illusion occurs while there is no evidence of mismatch at the sensorimotor level, the mismatch theory may still operate at a purely perceptual level. For example, people may continue to make erroneous *perceptual* predictions about weight based specifically on visual size cues. A mismatch between these perceptual predictions and actual sensory feedback may give rise to the size-weight illusion. This implies separate comparison processes for perceptual and sensorimotor predictions.

The finding that people continue to experience the size–weight illusion even though they learn to make accurate sensorimotor predictions about object weight indicates that sensorimotor systems can operate independently of perceptual systems. This idea is supported by a growing body of research on visuomotor control showing that partly distinct neural pathways are used depending on whether the sensory information is used to control actions or make perceptual judgments.

Headaches

SEYMOUR DIAMOND and GEORGE J. URBAN
Diamond Headache Clinic and Finch University of Health Sciences, Chicago, Illinois

GLOSSARY

aura A complex of focal neurological symptoms mostly in a visual form preceding some migraine attacks.

basilar Originating from the basilar artery at the base of the skull, supplying the brain stem.

biofeedback A behavioral treatment, relaxation technique that involves displaying, on monitors, some physiologic functions with the goal of attaining voluntary control over them.

hemiparesis Weakness of one side of the body.

hemiplegic Related to total paralysis of one side of the body.

ophthalmoplegia Weakness of one or more ocular nerves leading to double vision.

osmophobia Sensitivity to odors.

phonophobia An increased sensitivity to sound.

photophobia An increased sensitivity to light.

postdrome A set of symptoms occurring following remission of the headache.

prodrome A set of symptoms starting as early as 48 hr before the onset of a headache.

rebound headache A headache caused by or worsened by the withdrawal of analgesics, ergotamine, or caffeine.

status migrainosus Migraine attack lasting more than 72 hr.

Headache is defined by *Webster's* as "a pain in the head" and "a vexation or baffling situation or problem." Attempting to understand the source of headaches, and efforts at selecting appropriate treatment, is indeed a vexing problem. Headache is one of the oldest and the most common medical complaints, with references to it as early as 4000 BC. In the United States, the prevalence of headaches is about 70%. Headache has an enormous socioeconomic impact on society and personal lives. Headache can be a primary disorder or a symptom of another disease of benign or malignant origin, and it can occur at any age. The most simple classification divides headache types into three major categories; vascular (migraine and cluster), tension type, and traction and inflammatory (organic). Every major type of headache is defined, and the clinical picture, pathophysiology, and therapy are described.

I. VASCULAR HEADACHES

A. Migraine

By definition, migraine is an idiopathic, recurring headache disorder manifesting in attacks lasting 4–72 hr (untreated or unsuccessfully treated), usually unilateral location, of pulsating quality, and of moderate to severe intensity that may inhibit or prohibit daily activities. Pain is aggravated by routine physical activity and is associated with nausea and/or vomiting, photophobia, and phonophobia. History, physical, and neurological examinations do not suggest a secondary headache due to other disorders.

Migraine is an inherited neurological condition. A parental history can be obtained in 50–60% of patients with migraine. The form of inheritance has not been identified, although some genetic studies suggest an autosomal-dominant type in familial hemiplegic migraine. For the more frequent types of migraine, genetic influence is less clear.

Migraine has a marked impact on the economy and society. Surveys show that 8% of men and 14% of women miss all or part of a day of work or school in any given month. In the United States, the annual cost of lost productivity due to migraine has been estimated between $5.6 and $17.2 billion.

1. Clinical Features

Typically, there are five stages of a migraine attack: the prodrome, the aura, the headache, resolution, and the postdrome. The two major types of migraine are distinguished by the occurrence of an aura, a set of warning symptoms, that can precede the headache by 10–60 min. Migraine with aura was previously known as classical migraine, and migraine without aura was common migraine.

The aura is a complex set of focal neurological symptoms that precedes or accompanies an attack and may occur in almost 40% of patients, although not necessarily before each acute migraine headache. The frequency of aura may vary. The most common and most recognizable aura is visual occurring in more than 90% of patients with aura. There are three groups of visual aura: positive—fortification spectra or zigzag lines, flashing of lights and colors, stars, circles, and angles mostly appearing in both visual fields and migrating across the visual field at the rate of 3 mm per minute; negative—scotoma or blind spots, transient loss of vision, grayout, whiteout, heat waves, or the opaque glass-like experience; and metamorphopsia —illusion of distorted size, shape, and location of fixed object and Alice in Wonderland syndrome consisting of complex visual hallucinations. Other auras may consist of sensory phenomena (occurring in 30% of patients), such as numbness in the extremities and/or face, which may be fixed or may migrate. Motor disturbances (6%) and difficulty speaking or understanding language (18%) can also occur. The headache following the aura has rapid onset and graduation, is more lateralized, and has the same quality as the migraine without aura.

During the prodrome phase, patients with migraine with aura or migraine without aura may experience vague symptoms. These forerunners may precede the attack by up to 48 hr and gradually increase in intensity up to the headache onset. These signs are usually ambiguous and consist of mental, neurological, or generalized constitutional symptoms. Mental symptoms include euphoria, depression, restlessness, irritability, mental slowness, fatigue, drowsiness, and hyperactivity. Neurological symptoms may include hypersensitivity to light, sound, and smells. Constitutional symptoms may present with a feeling of cold, sluggishness, thirst, increased urination, fluid retention, decreased appetite or food craving, diarrhea or constipation, or equivocal symptoms of non-well-being.

The onset of headache is usually gradual. The pain is unilateral in 60% and on both sides in 40% of cases. The pain is localized most commonly in the temple, but it may radiate to the upper or posterior part of the head, including the neck and shoulders. Pain may travel from one part to the other or from one side to the other, or it may become generalized. Scalp tenderness may also develop in about two-thirds of patients. The headache usually last from 4 to 72 hr; in children, the headache may be briefer. The pain peaks and then subsides, but in some patients it may plateau for longer intervals. The pain varies in intensity, from annoying to debilitating, and is described as throbbing, pulsating, deep-seated pressure or aching and can be aggravated by routine physical activity such as walking or moving the head. During an attack, patients prefer to remain still in a dark and quiet room.

Accompanying symptoms are very common and are one of the criteria for migraine. The most common associated symptoms are gastrointestinal disturbances, including anorexia, nausea in more than 80%, vomiting in more than 50%, and diarrhea in 16%. Stomach motility is reduced as well as the absorption from the stomach including medications. Neurophysiological accompaniments include photophobia in 82%, phonophobia, blurred vision, osmophobia, lightheadedness in more than 70%, vertigo in one-third of patients; short-lasting numbness and weakness, and mood and mental changes. Visible distension of veins and arteries on the forehead and temples is not unusual. Fluid retention with edema and weight gain may occur in a weight-dependent part of the body, such as the feet, ankles, legs, face, and around the eyes. Increased urination may occurs during and after the headache.

Vomiting and sleeping may be the culmination of the migraine attack leading to the recovery phase. Following the headache, during the postdrome, patients may feel tired, irritable, exhausted, and washed out, may describe hangover-like symptoms, and may experience impaired concentration, muscle aching, and anorexia.

About one-third of migraineurs report severe disability with their attacks. It is estimated that in the United States approximately 30 million individuals experience severe migraine headache. Twenty-five

percent of migraine sufferers experience four or more severe attacks per month, 35% experience one to three severe attacks per month, and the remaining migraine sufferers complain of one or less severe attacks per month.

2. Diagnostic Features

Initial onset of migraine usually occurs during adolescence or the early twenties, but it can start in childhood. In a classic study from Sweden, headaches of all types increase in a stepwise manner between ages 7 and 15. By age 15, 5% of all children have experienced a migraine, and another 15% complain of daily or almost daily tension-type headaches. In a follow-up completed 40 years later, in girls from age 11 years, there was a gradual increase in migraine headache. The original subgroup of 73 children with migraine reported being headache-free by age 25, with a more significant number of males reporting complete migraine remission. The data from an epidemiological study in Washington County, Maryland, revealed that 56% of boys and 74% of girls between the ages of 12 and 17 complained of a headache during the past month. Migraine prevalence (i.e., the proportion of the population with the disease) increases from 12 to 38 years of age in both females and males and is highest between ages 25 and 55 years. The lifetime prevalence of migraine ranges between 14 and 18%. However, many migraine sufferers remain undiagnosed. The highest incidence of new cases of migraine peaks between ages 12 and 17. In older patients, the prodromal aura symptoms may continue after the headaches disappear. Initial onset of migraine is rarely reported after age 50 years.

In children under the age of 14 years, no significant difference in migraine prevalence has been demonstrated. The female-to-male ratio is suggested to be between 2:1 and 3:1. This proportion peaks at about age 42, but thereafter it declines.

Migraine can start at any time of the day, and in many cases the headache will be present upon awakening. In some patients, the acute migraine attack will occur after a stressful episode or on weekends or vacations—the so-called ''let down'' headaches. Migraine patients may be hyperresponsive to various internal and external stimuli that, under certain conditions, can provoke a migraine attack. Environmental precipitants include weather changes (in 50% of migraineurs), high humidity, glare, bright light, fluorescent lighting, high altitude, cigarette smoke, and pungent odors. Nitrites, monosodium glutamate, tyramine, aspartame, histamine, and other chemicals contained in certain foods or beverages are recognized migraine precipitants. Alcohol, chocolate, aged cheeses, pickled, cured and fermented products, caffeinated drinks, and nuts are frequently named offenders for susceptible migraine sufferers. Too much or lack of sleep as well as jet-lag, alternating shift work, and physical exertion can provoke migraine.

Emotional stress of positive or negative character, anxiety, anticipation, anger, fear, and worry are common precipitants. Menstruation or other hormonal changes, including hormonal treatment (oral contraceptives or hormone replacement therapy), play a major role in migraine in 60% of female migraineurs. Some medications, including nitroglycerine, blood pressure agents, antidepressants, and arthritis agents, as well as vitamins and herbal remedies in excess, can provoke an acute migraine attack.

3. Pathophysiology

The mechanism of the attack is still poorly understood. Three basic pathophysiological changes take place during the process of migraine: vascular, neurogenic, and neuropeptides abnormalities or dysfunction. It is unclear which process is primary and which is secondary. In the brain stem of migraine patients, there is evidence of a dysfunctional area of neurons, a so-called ''central migraine generator,'' with abnormal reactivity to varying internal or external stimuli. This dysfunction is a result of genetic abnormalities and leads to a cascade of pathophysiological alterations producing the migraine attack. Initially, vasoconstriction occurs in the blood vessels of the brain, during the prodromal or aura stage. When a stimulus crosses a pain threshold, which differs in every individual and is determined by a complexity of physiological and emotional conditions, the migraine generator sends signals that lead to dilation of certain blood vessels in the brain. Migraine pain is thought to arise when intracranial blood vessels become dilated and as a consequence activate the terminals of trigeminal sensory nerves that surround them. Activation of those terminals leads to release of vasoactive neuropeptides, such as calcitonin gene-related peptide, substance P, bradykinin, prostaglandin, and other neurokinins. Vasoactive neuropeptides exacerbate blood vessel swelling and increase pain transmission back to the brain stem. From there, the signals are relayed to higher cortical centers, where the migraine pain is registered and other symptoms are produced, including nausea, vomiting, and photo- and

phonophobia. Serotonin and serotonin receptors play a major role in this cascade and mediate many of these processes.

4. Therapy

Migraine therapy can be classified into four types: general measures, abortive therapy, pain relief measures, and prophylactic (preventive) therapy. Overall, the treatment consists of behavioral and pharmacological interventions and is individualized for each patient. General measures includes behavioral therapy, such as recognition and avoidance of migraine triggers, regulation of sleep and meal schedules, dietary modification, stress management, exercise, and biofeedback and other relaxation techniques.

The other three types of migraine treatment include pharmacological agents. Abortive medications used to stop the process of migraine in its development include the triptans, ergotamine preparations, and isometheptene. These drugs act on serotonin receptor sites, reducing activation of neuropeptides as well as constricting dilated intracranial blood vessels.

If abortive therapy is unsuccessful, the pain relief measures are indicated to reduce the symptoms of migraine, such as pain, nausea, vomiting, irritability, and anxiety. The agents used for symptomatic treatment include single or combined analgesics, antinauseants, nonsteroidal antiinflammatory agents (NSAIDs), sedatives, and tranquilizers.

Prophylactic treatment is instituted to reduce the frequency, duration, and intensity of migraine attacks. It may be considered if the patient is experiencing more than two migraine attacks per month or if the severity of the headache and its associated symptoms impact on the individual's ability to function. Beta blockers, methysergide, and divalproex sodium have been approved for the indication of migraine prophylactic therapy. Other medications that have been beneficial in migraine treatment include the calcium channel blockers, anticonvulsants, NSAIDs, and antidepressants.

5. Other Forms of Migraine

Migraine with prolonged aura, perviously termed complicated or hemiplegic migraine, is characterized by one or more aura symptoms lasting more than 60 min and less than 1 week. Any of the various forms of aura may occur. This type of migraine is relatively rare.

The headache usually starts within 1 hr of aura onset, becomes progressively more intense, and may linger for a prolonged period. Different forms of aura can be experienced at the same time. The intensity of the pain is usually less than that in the more common types of migraines. The aura persists into the headache stage and may continue after the pain subsides. The typical clinical features of the headache are the same with this complicated form of migraine.

The etiology or mechanism of migraine with prolonged aura and related symptoms is unclear. It has been assumed that a neurological deficit of longer duration is caused by prolonged vasoconstriction or limited spasm of a cerebral artery occurring as a part of the migraine syndrome. It appears that the constriction is probably secondary as the part of a complex cascade of migraine process. Computed tomography (CT) scan and magnetic resonance imaging performed during the attack of a migraine with prolonged aura show no abnormalities.

In patients with this form of migraine, risk factors such as smoking and estrogen use should be avoided. Hypertension and diabetes should be treated vigorously. Vasodilatory medications, such as calcium channel blockers mainly of a rapid onset of action (e.g., sublingual nifedipine) and sublingual nitroglycerine, have been shown to be effective in prompt alleviation of prolonged aura or neurological symptoms. Similar effects have been demonstrated with isoproterenol, administration of CO_2, and papaverine. These vasodilators are known to cause headache. However, interestingly, if they are used at the onset of an attack, the headache does not occur or is lessened. The use of ergotamine and triptans is controversial and generally not recommended due to the increased risk of complications such as stroke.

a. Hemiplegic Migraine Hemiplegic attacks usually start during childhood. The headache may occasionally precede the hemiparesis or be absent. The onset of hemiparesis may be abrupt, lasting for days, and may imitate a stroke. The headache is on same side as the weakness in about 20% of patients, on the other side in almost 50%, and can be generalized in 30%. Nausea and vomiting are unusual. Speech difficulty occurs in about 44% of patients in association with hemiparesis, and confusion can occur in one-third. The diminished sensitivity of the half of the body or extremities on one side accompanies the weakness. Visual aura and hemiparesis occur together in 88%. In most patients, the weakness continued for up to 1 hr, in 14% it lasted for up to 3 hr, in 12% from 3 to 24 hr, and in 16% of patients between 1 day and 1 week. The longer lasting episodes are associated with more

profound weakness. A higher incidence of neurological symptoms accompanying the migraine attacks has been noticed in middle-aged patients. Hemiplegic migrainous attacks occur infrequently and irregularly. Typically, the patients experience complete recovery.

b. Ophthalmoplegic Migraine In this form of complicated migraine, repeated attacks of headache are associated with paresis of one or more of the ocular cranial nerves in the absence of demonstrable intracranial lesions. It is relatively rare, and its victims are usually children, affecting males six times more often than females. Adults may experience their first attack during the fourth and fifth decade. The most commonly affected nerve is the third cranial nerve (oculomotor), occasionally the fourth and sixth nerves are affected, and the ophthalmic division of the fifth cranial nerve may also be involved. The headache that precedes the ocular symptoms is of migrainous quality, usually localized behind or around the affected orbit with radiation to the same side of the head. The pain may last 1–4 days, and as it subsides other symptoms appear—the ptosis (droopy eyelid) on the same side, diplopia (double vision), and blurred vision. The ophthalmoplegia may persist for several weeks but usually completely resolves. After repeated attacks, some weakness of the ocular muscles may persist with permanently dilated pupil and deviated eye.

The isolated involvement of the cranial ocular nerves suggests that the anatomic localization of the lesion is the cavernous sinus. Research demonstrated narrowing in the internal carotid artery, probably due to edema of the wall. The swelling of the carotid wall is probably responsible for compression of the involved nerve or reduced blood flow to the nerve through the nourishing arteries.

These attacks are treated symptomatically with analgesics and antinauseants. Corticosteroids in large doses, instituted at the beginning of the attack of ophthalmoplegia, may reduce inflammation and edema and hasten the recovery. Ergotamine agents and triptans should not be used during the acute attacks as abortive drugs because it is unknown if the vasoconstricting effect of these medications would not further reduce the blood flow to the affected nerve. Prophylactic drugs are indicated if the attacks occur frequently. Neuroimaging is imperative to exclude an aneurysm or tumor.

c. Familial Hemiplegic Migraine This form of migraine with aura, which may be prolonged, includes some degree of hemiparesis and is characterized by the patient having at least one first-degree relative with identical attacks. The pattern of occurrence in family members suggests that familial hemiplegic migraine is an autosomal-dominant genetic disease. Researchers have found a locus on chromosome 19 in the majority of the investigated families.

d. Basilar Migraine This type of complicated migraine is also known as basilar artery migraine, Bickerstaff's migraine, and syncopal migraine. Its symptoms clearly originate from the brain stem or from both occipital lobes. To fulfill the criteria, two or more aura symptoms must be of the following types: visual symptoms in both the temporal and nasal fields of both eyes, difficulty articulating, vertigo, tinnitus, decreased hearing, double vision, ataxia (difficulty controlling bodily movements), numbness on both sides of body, weakness and numbness on both sides of the body, and decreased level of consciousness.

Originally considered to be mainly a migraine disorder of adolescent girls, it affects all age groups and both sexes. These attacks often occur with relationship to menstruation. The aura commonly lasts less than 1 hr. The neurological symptoms, of various duration, are consistent with dysfunction of the posterior part of brain supplied by the vertebrobasilar artery system. These symptoms usually precede the headache but may also begin during the actual headache. Typically, the numbness is bilateral, starting in the periphery of all four extremities, with slow and gradual radiating up the limbs. Confusion and disorientation are not uncommon. Syncopal episode occurs in 7% of the patients with this form of migraine. Various levels of decreased consciousness, including stupor and coma, can last for hours or days. The headache of basilar migraine is often bilateral and localized in the posterior part of the head, but it may radiate to the temporal and frontal areas. The pain is of a pulsatile quality and moderate in intensity. Associated nausea may become severe and progress to prolonged and intractable vomiting. Commonly, the attack ends with sleep. Typical attacks of basilar migraine infrequently occur in these patients, and more common forms of migraine occur in between the attacks. Basilar migraine is very rare after the fourth decade, and any episode in this circumstance should be considered nonmigraine in origin. Symptoms of basilar migraine are consistent with a disturbance in the vertebrobasilar artery supplying the territory of the brain stem and brain and are probably the result of ischemic changes.

6. Migraine Aura without Headaches

Another term for migraine equivalent is acephalic migraine, which is a migrainous aura unaccompanied by headache. It is quite common in individuals with migraine with aura to experience the aura with the headache absent. As patients age, the headache may lessen in frequency and eventually disappear, even if the aura continues. Recurring symptoms of aura for which no underlying organic cause has been found should be considered a possible manifestation of migraine aura without headache or a migraine equivalent. These symptoms may occur in a person with a strong family history of migraine or who has previously experienced attacks of migraine. Symptoms of aura without headache may occur in 20% of all migraineurs and in more than 40% of patients who have migraine with aura. Symptoms usually last about 20–30 min and only occasionally for longer periods. The most common symptoms are visual. They have a similar presentation as the typical aura. Patients with monocular visual defects should be evaluated to exclude the presence of ocular or other diseases. The recurrent abdominal pain and cyclic vomiting may also represent a migrainous phenomenon but only after organic disease has been excluded. The neurological episodic symptoms may represent this form of migraine and include numbness, weakness, vertigo, confusion, and amnesia lasting 1 hr or less. The sensory symptoms continue as long as a typical aura. These symptoms may slowly spread up one arm from the fingers to the body and descend the opposite arm. This march is slower than the abrupt onset of similar symptoms occurring with a typical transient ischemic attack. A neurogenic and vasoconstricting origin has been implicated.

Treatment is not necessary if symptoms of migraine aura without headache do not occur often and do not cause significant discomfort. With frequent attacks, the usual prophylactic agent such as the beta blockers, calcium channel blockers, and GABA-receptor agonist anticonvulsants (divalproex sodium, gabapentin, and topiramate) may be utilized. Sublingual nifedipine and sublingual nitroglycerine have been shown to be effective in prompt alleviation of prolonged aura. Isoproterenol, administration of CO_2, and papaverine have demonstrated similar efficacy.

a. Migraine with Acute Onset Aura In migraine with acute onset aura, the warning symptoms fully develop in less than 5 min. The subsequent headache has all the features of migraine. Transient ischemic attack and other intracranial lesions should be ruled out by appropriate investigation. The neurological symptoms develop within 5 min and last as a typical aura for 20–60 min. The presence of a typical headache phase is required to establish the diagnosis, and previous migraine attacks of another type or a strong family history of migraine support diagnosis. Extensive investigations are necessary to rule out a transient ischemic attack.

b. Childhood Periodic Syndromes These syndromes may be precursors to, or associated with, migraine. The syndromes are characterized by multiple, repeated brief attacks of neurological symptoms without headaches, or the headaches cannot be detected because of the young age. Abdominal migraine and cyclic vomiting are included in this group.

c. Benign Paroxysmal Vertigo of Childhood This disease is characterized by brief attacks of vertigo in otherwise healthy children. Neurological examination and electroencephalogram are normal. It has been found that in 13% of reported cases of benign paroxysmal vertigo of childhood, the individual subsequently developed migraine. Multiple, short-lasting, sporadic spells of disequilibrium are often associated with nystagmus, nausea, vomiting, and anxiety. In 14%, vertigo is accompanied by headache. The pathophysiology is unknown.

Treatment of an acute attack is symptomatic. Beta-blocking agents, as well as cyproheptadine, may reduce the frequency of attacks.

7. Complications of Migraine

a. Status Migrainosus Previously, this condition was called intractable migraine or persistent (pernicious) migraine. It is distinguished as a migraine attack with the headache phase lasting more than 72 hr despite treatment. A headache-free interval of less than 4 hr may occur. Any episode of migraine, in any form of migraine, may evolve into an intractable, daily, continuous headache attack, unresponsive to standard treatments. The headache may be unilateral or global, pulsatile or pressure-like, or may have characteristics of both migraine and tension-type headaches. The headache progressively intensifies to a debilitating pain, accompanied by the usual characteristics of migraine. Typically, the associated nausea and vomiting are severe, leading to osmophobia, dehydration,

refusal to eat, and prostration. The photophobia, phonophobia, and headache exacerbated by any movement forces the patient to remain in a dark and quiet room, unable to function at even a basic level. Some patients will even wear dark sunglasses indoors because of excessive sensitivity to light. Dehydration and anorexia may cause electrolyte disturbances, further complicating their condition. Emotional despair and depression with suicidal ideation are generally present. Status migrainosus is considered "headache urgency" requiring immediate care, preferably in an inpatient setting for rehydration, pain control, and reversal of continuous headache.

Status migrainosus, is often iatrogenically induced due to overuse or inappropriate use of analgesics, ergotamine preparations, narcotics, caffeine, or triptans or due to inadequate treatment of migraine. In susceptible patients, high stress, anxiety, and poor sleeping and eating habits may lead to this condition. Rebound headaches, transformed migraine, mixed headache, and chronic daily headaches may ultimately cause intractable debilitating headache. Status migrainosus is thought to be due to a sterile inflammation of the intracranial blood vessels involved in migraine process. The vasodilatation and inappropriate release of vasoactive neuropeptides, some of which are very potent vasodilators, as well as other active peptides that mediate neurogenic inflammation are self-perpetuating processes leading to endless activation of the trigeminal neurovascular system and fueling the central migraine generator. The plausible mechanism responsible for the refractoriness of status migrainosus is that the constant activation and release of neuropeptides downregulates serotonergic receptors and depletes endorphins.

Patients with acute status migrainosus may require hospitalization, particularly if the condition was induced by dependency on medication, is accompanied by dehydration, or if the patient is depressed or has a prior experience of adverse reactions to medications (Table I). The offending medication causing rebound headache phenomenon must be withdrawn. The withdrawal is usually done in an abrupt manner, but all precautions to prevent seizures and/or other withdrawal reactions should be instituted. Treatment for patients with status migrainosus should be aggressive and includes rest; rehydration and electrolyte replacement; detoxification; round-the-clock parenteral analgesic therapy; symptomatic treatment of nausea, anxiety, insomnia, and withdrawal symptoms; concurrent initiation of prophylactic therapy; and behavioral treatment. Corticosteroids and NSAIDs are used to reduce the neurogenic inflammation. Phenothiazine-based neuroleptics are utilized to control nausea and vomiting, reduce pain perception, and induce sedation. A series of intravenous dihydroergotamine (DHE) administered every 8 hr for 3 days is very effective in interrupting the painful cycle. It cannot be used when the patient is rebounding from ergotamine preparation or when DHE is contraindicated. Pain control is achieved by scheduled administration of parenteral narcotics, neuroleptics, benzodiazepines, and ketorolac. "As needed" pain control is not recommended because of reinforcement of dependency on analgesics. Appropriate prophylactic therapy, education, psychotherapy, and biofeedback should be concomitantly instituted.

Table I
Criteria for Admission to Inpatient Headache Unit

Prolonged, unrelenting headache with associated symptoms, such as vomiting, that if continued would pose a further threat to the patient welfare
Status migraine
Dependence on analgesics, caffeine, narcotics, barbiturate, and tranquilizers
Habituation to ergots, with rebound headache
Pain accompanied by serious adverse reactions from therapy
Pain occurring in the presence of significant medical disease
Chronic cluster unresponsive to therapy
Treatment requiring copharmacy with drugs that may cause a drug interaction and necessitating careful observation within a hospital environment
Patients with probable organic cause to their headache requiring appropriate consultations, diagnostic testing, and perhaps neurosurgical intervention

b. Migrainous Infarction Occasionally, a migraine attack with one or more migraine aura symptoms is not fully reversible within 7 days and/or is associated with an abnormal neuroimaging test, confirming ischemic brain infarction. To fulfill the criteria, cerebral infarction must occur during the course of a typical migraine attack and other causes of infarction must be ruled out. The prevalence of migrainous infarction is about 3.36 cases in 100,000 adult migraineurs. Some studies indicate that women are more in risk, particularly those who are smokers, on oral contraceptives, and experiencing migraine with regular and prolonged aura. Neurological symptoms may occur abruptly or more slowly, may present as aura preceding the headache, or may start during the

headache phase. Various symptoms and the intensity are dependent on anatomical location of infarction. The stroke must be confirmed by neuroimaging, and other causes of stroke must be ruled out. Prolonged, decreased blood flow during the migraine attack may cause ischemia in a susceptible migraineur. Abnormal blood coagulation, platelet changes, and other unrecognized factors also have a causative role.

Treatment consists of reducing the known risk factors, such as smoking, high cholesterol, and oral contraceptives. Supportive and analgesic treatment is indicated, and ergotamine and triptan preparations are contraindicated. Corticosteroids may reduce concomitant neurogenic inflammation and swelling. Calcium channel blockers facilitate vasodilatation and increase of blood flow in affected areas. Aspirin has been found to reduce risk of further stroke. Rehabilitation should be initiated in early stages.

B. Cluster Headache

This form of vascular headache has been known as histaminic cephalalgia, Horton's headache, migrainous neuralgia, sphenopalatine neuralgia, petrosal neuralgia, red migraine, Raeder's syndrome, Sluder's syndrome, erythromelalgia, and Bing's erythroprosopalgia. The defining characteristic of cluster headaches is their occurrence in cycles (clusters) that occur and disappear spontaneously. There are two forms of cluster headache—episodic and chronic. The majority of patients with cluster headaches experience the episodic form, in which the headache cycles or series last for several weeks or months and then may disappear for years. For those unfortunate few with the chronic form, headache remission is briefer than 14 days, or the cycle of headaches is continuous, without any headache-free intervals.

1. Clinical Features

The head pain and the associated symptoms characterize the acute cluster attack. During a cluster series, the acute headaches usually occur several times per day. The acute episodes are characterized by their brief duration (compared to migraine), usually lasting 15–180 min.

The headache is very severe, localizing at the orbital or supraorbital regions, and the patient may have temporal pain. The pain is strictly unilateral without alternating sides during a series, with a slight predominance of right-sided headaches. The side shift may occur between cycles. The most common localization of pain is around and behind the eye, temporal and frontal lobes, and upper and lower jaw. The pain begins abruptly without any warning or just with a slight "awareness" or mild pain. It peaks in intensity within a few minutes and may last from 5–10 min up to more than 3 hr, but in most cases the average duration is 30–60 min.

The intensity of pain is excruciating, almost unbearable; it is said to be probably the most severe type of head pain known. The pain is described as boring, burning, pulsating, squeezing, deep knife-like pain, stabbing, piercing, or as a combination. In most cases, the frequency of attacks ranges from less than one to three per 24 hours up to six to eight per 24 hours. Attacks may occur at any time but usually happen in clockwork regularity at the same time each day or night. There is a high preponderance of nocturnal attacks, with frequent headaches occurring 2 or 3 hr after retiring to sleep. During an attack, patients tend to be restless, unable to remain still; many pace the floor, constantly moving, rocking, and engaging in bizarre activities and behavior that sometime lead to self-mutilation and even suicide.

Typically, the pain is accompanied by various autonomic phenomena. The most common, in descending order, are lacrimation, redness of the conjunctiva, nasal congestion, nasal discharge, forehead and facial sweating, small pupil, droopy eyelid, and eyelid swelling on the same side of the pain. Nausea and photophobia may present in some patients.

The most common triggers during a series are alcohol, nitroglycerine, and hypoxia. During the cluster cycle, patients will voluntarily avoid alcohol consumption and will not note any headache provocation by alcohol during the remission intervals.

2. Diagnostic Features

Cluster headache is the least prevalent of the primary headache syndromes, with an occurrence of about 1:1000 persons. The migraine-to-cluster ratio ranges from 7:1 to more than 20:1. Cluster headache is predominantly a male headache disorder, with the male-to-female ratio ranging from 4.5:1 to 6.7:1. The mean age of onset is approximately 27–30 years, with the youngest 6–8 years old. The incidence of the disease as well as the episodes of cluster headaches decrease after the age of 60.

The mean duration of a cluster cycle is approximately 6–8 weeks, with only about 3% of patients having bouts of 1-week duration and 4% having cycles

lasting more than 26 weeks. The frequency of periods is less than one per year in 13%, one per year in 40%, two per year in 30%, and three per year in 8%. Cycles of one or two per year occur in 60% of patients. There appears to be a cyclic periodicity to the "clusters," with two seasonal peaks in early spring and early autumn. Rhythmicity in daily occurrence has also been noted, with attacks usually occurring 24 hr apart and frequently presenting at the same time of the day or night. During remission periods attacks spontaneously cease. The most frequently reported remissions last 7–12 months in 48%, 1–6 months in 20%, and 2 or more years in the remaining 32%. During the remission period the cluster attack cannot be provoked.

In the chronic form, there are no cycles, and by definition remission does not occur, nor does it last longer than 14 days. Patients with chronic cluster headaches have a tendency to habituation problems because of the continuous nature of the headache. The chronic form has similar clinical features as the episodic type. Attacks of cluster headache recur for a period of time at least 50 weeks in 1 year. The age of onset seems to be higher, with a mean onset of 39 years. Male preponderance of the chronic forms is at least as significant as that in episodic cluster. The mean frequency of attacks and duration are slightly higher. Pain localization, quality, and associated symptoms are the same as those in the episodic form.

3. Pathophysiology

The mechanism of cluster headache is unclear and involves vascular changes and impaired autonomic neuronal activity as well as biochemical, hormonal, and chronobiological changes. The abnormal autonomic neuronal activity is most likely due to a primary disorder of the central regulation of autonomic functions controlled by the hypothalamus. Several vasoactive substances, including histamine, serotonin, and substance P, have been observed to be activated during the cluster attack. Hormonal level changes, including those of testosterone and melatonin, have also been noted. Circadian and circannual rhythmicity suggest the pathological involvement of the "biological clock" in hypothalamus. Furthermore, hypoxia and the role of the carotid body (the most sensitive chemoreceptor for hypoxia) have been discussed in regard to the pathomechanism of cluster attacks. It appears that the origin of cluster headache is in the hypothalamus, with abnormal activation of the autonomic nervous system causing vascular and biochemical changes.

4. Therapy

Treatment for both the episodic and the chronic forms is similar and consists of abortive and prophylactic therapy. Because of the brief nature of acute cluster attacks, medication used to stop the pain requires rapid onset of action (within 30 min). The most effective and safest method is self-administration of 100% oxygen, via facial mask, at high flow of 8–10 liters per minute for 10–15 min. Dramatic termination of an acute attack has been achieved within 10–15 min in 80% of patients. Other effective abortive therapies include parenteral and intranasal administration of sumatriptan or dihydroergotamine; sublingual ergotamine; and intranasal instillation of viscous lidocaine, a local anesthetic, to the affected nostril. Parenteral ketorolac, chlorpromazine, and narcotic analgesics may help control the pain.

The prophylactic treatment should be initiated at the very onset of a cluster cycle and continued at least 2–4 weeks after the last acute cluster episode. Corticosteroids may hasten the interruption of the cycle. Verapamil (a calcium channel blocker), lithium, methysergide, ergotamine, and divalproex sodium have been found to be effective in reducing and preventing acute cluster attacks during the episodic cycle or the chronic form. In some inpatient headache centers, intractable cluster headaches have been successfully treated with intravenous histamine desensitization treatment.

5. Chronic Paroxysmal Hemicrania

Chronic paroxysmal hemicrania (CPH) is a rare disorder. It has the same characteristics as cluster headache, including similar associated symptoms. These episodes are briefer, more frequent, occur mostly in females, and responsive to indomethacin.

The patient with CPH will characteristically complain of 10–20 brief, intense focal episodes of head pain, localized mostly in the temporal, ocular, frontal, and upper jaw area. The pain has the same quality as cluster headache pain, but of even shorter duration (an average of 10–20 min). CPH attacks are associated with autonomic symptoms and signs that are characteristic for cluster headache. In some patients, head movement or pressure on certain points in the neck can trigger attacks. About 70% of diagnosed patients are female and the mean age of onset is 34 years. The pathogenesis is unknown, but it is considered to be a cluster variant. One of the diagnostic criteria for CPH is absolute responsiveness to indomethacin, an

NSAID. Indomethacin selectively stops the attacks, usually within 2 days of treatment.

6. Cluster Headache Variant

These headache attacks are believed to be a form of cluster headache or CPH but do not meet their criteria. Cluster headache variant, originally described by Diamond and Medina, is a syndrome consisting of a triad of symptoms: atypical cluster headaches, multiple jabs, and background continuous headache. The atypical cluster headache is irregular in location, duration, and frequency, occurring several times a day. Multiple jabs are sharp, variable, painful episodes, lasting only a few seconds and occurring several times a day. Background headaches are chronic, continuous, often unilateral, sharply localized and of variable severity, and have vascular features—throbbing and exacerbated by physical exertion. The pathophysiology is unknown. The therapy consists of indomethacin or lithium.

II. TENSION-TYPE HEADACHE

Tension-type headache was previously known by several terms: muscle contraction headache, stress headache, ordinary headache, essential headache, psychogenic headache, or psychomyogenic headache. It is defined as recurrent episodes of headache lasting minutes to days. There are two primary forms—episodic and chronic. The pain is bilateral, with pressing or tightening (nonpulsating) quality of mild-to-moderate severity. The headache is not aggravated by routine physical activity. Photophobia or phonophobia may be present, and nausea may occur in the chronic form. The episodic type has been experienced by almost everyone, is usually relieved by over-the-counter analgesics, and does not require a physician's intervention. The chronic type is daily or almost daily, and the victim is prone to dependency problems with analgesics, tranquilizers, or sedatives.

A. Diagnostic Features

The prevalence in the general population ranges from 30 to 80%. The 1-year prevalence of episodic tension-type headaches is about 55% in men and 70% in women; in the chronic form the prevalence is only about 2–5%. The prevalence decreases with increasing age.

The pain is usually described as steady, nonpulsatile, band-like, vise-like, tightness, ache, soreness, and pressure in a hat-like distribution. Feelings of increased tension may be also felt in the occipital and cervical areas. Muscles of the scalp and neck may be tender to the touch, with palpable, sharply localized nodules. Combing or brushing the hair or wearing a hat may elicit soreness. Electromyographic recording from the scalp and cervical muscles may or may not register increased activity. In many individuals, the headache starts during the afternoon or evening but rarely impacts on the sufferer's daily activity.

The various psychological factors associated with chronic tension-type headaches include anxiety, fear, hostility, and, very frequently, depression. Typically, in the chronic form, the victim may complain of a sleep disturbance. In chronic tension-type headache due to anxiety, the patient may complain of insomnia (difficulty falling asleep). However, in patients with chronic tension-type headaches due to depression, early or frequent awakening may be prominent complaints. Physical exercise may alleviate the headache. Chronic tension-type headache is often associated with concomitant cervicogenic disease. Trigger and aggravating factors are usually identifiable and may include stress in marital, social, occupational, sexual, and interpersonal relationship; fatigue; overwork; insomnia; personality traits; and methods of handling stressful situations.

B. Pathophysiology

The mechanism of tension-type headache is poorly understood. In the episodic form, more peripheral mechanisms seem to be involved, including slightly increased electromyographic activity during resting conditions that are due to insufficient relaxation or reflex contraction. Slightly decreased electromyographic activity during maximal voluntary contraction may be due to impaired recruitment of muscle fibers at maximal activity. In the chronic form, it appears that sensory information is abnormally processed. Plausible mechanisms have been proposed, including sensitization of peripheral myofascial nociceptors and spinal and trigeminal neurons; decreased antinociceptive activation from supraspinal structures; and increased sensitivity of supraspinal pain perception. Furthermore, neurochemical processes involved in depression are also thought to be part of the pathophysiology of chronic tension-type headache. There is strong evidence that depression lowers tolerance to pain.

C. Therapy

The patient should avoid identifiable trigger factors. The episodic form responds well to simple analgesics, muscle relaxants, relaxation techniques, biofeedback, and exercise. Mild headaches of shorter duration are self-limited and in order to prevent analgesic dependency do not need to be treated. Patients with the chronic form need to be evaluated for depression and other psychological and psychiatric comorbid conditions. The daily use of analgesics is inappropriate because of the potential for dependency problems or a rebound phenomenon.

The antidepressant drugs provide the most effective treatment for this condition. Antidepressant prophylaxis should be used even if depression is not detected. Only a few antidepressants in the tricyclic category have been tested in placebo-controlled studies for chronic tension-type headaches. However, clinical experience suggests that other tricyclic and nontricyclic antidepressants, including the newer serotonergic types, are similarly effective. There is a minimal difference in their efficacy, but the adverse reactions can be significant. The choice of antidepressants is therefore made on the avoidance or use of certain side effects. For instance, tricyclic antidepressants such as amitriptyline or doxepin, which have sedative effects, can be used in the patient who has a sleep disturbance. The average dose of antidepressant for treatment of chronic tension-type headache is lower than that used for depression. Pain control is achieved with muscle relaxants, simple analgesics, and NSAIDs. Narcotic-type analgesics and tranquilizers, particularly the benzodiazepine types, are not recommended because of their high propensity of dependency, abuse, and addiction, particularly in a patient with coexisting chronic tension-type headache and depression. Psychotherapy, stress management, and cognitive therapy are essential parts of successful treatment.

III. TRACTION AND INFLAMMATORY HEADACHES (ORGANIC)

Headaches due to organic disease are rare, occurring in about 2% of headache patients. The term traction and inflammatory headaches refers to any headache resulting from inflammation, traction and displacement, and distortion of the pain sources of the head, such as the cranial vessels. Headaches associated with traction include hematomas, abscesses, aneurysms, brain tumor, and nonspecific brain edema from lumbar puncture. Examples of inflammatory headaches include eye infection, iritis, and glaucoma; ear diseases; and acute sinus infections.

A patient presenting with recent onset or change in character of headaches should alert the physicians to a possible organic cause. It is essential to rule out possible morbid causes of the headache. The danger signals for headaches that may suggest the presence of serious illness include

- Headaches that do not fit a recognizable pattern or a pattern that is easily identified
- Headaches occurring for the first time in childhood or after age 50
- Headaches occurring for the first time that rapidly increase in frequency and intensity
- The presence of neurological symptoms, such as dizziness, blurred vision, or memory loss
- A patient who feels sick or "not right" with his or her headaches
- Abnormal physical symptoms, for example, heart murmurs or kidney problems
- Any rigidity (stiffness) of the neck accompanying a headache may indicate an infection or inflammation of the spinal fluid

These signals are important for all headache sufferers—even those with a prolonged history of migraine headaches.

A. Mass Lesions

This category includes brain tumors, hematomas, brain abscesses, and expanding aneurysms. Headache is one of the cardinal signs of a mass lesion but may not present until the size is sufficiently large or the lesion expands to press on structures that will trigger a headache and associated neurological symptoms. Headache will occur if the lesion is expanding rapidly and is producing traction on one of the pain-sensitive structures of the head, especially if the ventricular system is compromised, with obstruction of absorption or flow of cerebrospinal fluid (CSF) and a resulting hydrocephalus.

The headache resulting from a brain mass is usually associated with neurological signs, including seizures (focal or general), progressive loss of neurological function, and mental symptoms. Headache onset is usually intermittent, with dull and aching pain. The frequency and duration will progressively increase, and the headache will sometimes be altered by changes

in posture and tone. A rapid increase in intracranial pressure will usually manifest as a headache.

The headache associated with a brain tumor may facilitate locating the tumor. If the tumor is above the tentorium, the pain is frequently at the vertex or in the frontal regions. If the tumor is below the tentorium, the pain is occipital, and cervical muscle spasm may be present. Headache is almost always present continually with posterior fossa tumor. If the tumor is midline, the pain may be increased with cough or straining or sudden head movement. However, this exacerbation also occurs with migraine. If the tumor is hemispheric, the pain is usually felt on the same side of the head. If the tumor is chiasmal, at the sella, the pain may be referred to the vertex. Colloid cysts of the third ventricle can cause an acute increase in intracranial pressure when the patient assumes certain positions and the tumor blocks the flow of CSF. The pain is relieved when the patient moves the head back to a position in which the flow of CSF is unobstructed. The management of mass lesions requires neurosurgical intervention.

B. Post-Lumbar Puncture Headache

If a patient complains of headache following a lumbar puncture, it is probably related to a loss of CSF secondary to leakage through a dural defect. The headache is often exacerbated in the upright position and relieved with recumbency. The pain has been described as a dull ache that may become throbbing. The headache onset starts within hours to days after the procedure and may persist for 2 to 3 weeks. The symptoms usually subside spontaneously.

Prevention is the key and the use of smaller needles has been recommended to decrease the incidence of these headaches. Treatment of the post-lumbar puncture headache consists of bed rest in the horizontal position. A blood patch to stop the leak may be beneficial.

C. Headaches of Ocular Origin

Headache is rarely due to the eye, with the exception of obvious ocular pathology. Photophobia, associated with migraine, is rarely caused by diseases of the eye, eye muscles, or the optic nerves. Reading, eye strain, eye muscle imbalance, or refractive errors are rare causes of headache.

The pain of glaucoma is due to an increased intraocular pressure within the globe. The severity is more directly related to the rate of increase of the intraocular pressure rather than the absolute pressure. Glaucoma can be easily classified as: (i) open if the anterior angle filtration is patent, (ii) closed if the chamber is blocked, or (iii) combined if the chamber is patent and blocked. The type of glaucoma with the most severe pain is caused by acute closure of the angle in the anterior chamber. On exam, the orbit is ''rock hard'' and immediate ophthalmologic referral is necessary.

D. Sinus Headache

Sinus headache is an often cited complaint of many patients, although the acute headache due to actual sinusitis occurs less frequently than the rate quoted by the advertising media. Acute sinusitis presents with fever, pain triggered by pressure or direct percussion, and headache. Fever is the cardinal sign of this infective process. The pain associated with sinus diseases is a constant, dull ache. If the patient is suffering from acute sinusitis, the headache will typically increase in intensity as the day progresses. To confirm the diagnosis, sinus X-rays or sinus CT should be performed. Treatment consists of antimicrobial therapy and decongestants.

E. Facial Pain

The facial pain syndromes are a group of disorders that usually occur in paroxysms and are characterized by pain of severe intensity. The most common types are trigeminal and glossopharyngeal neuralgia. Trigeminal neuralgia, also known as tic douloureux, is usually seen in the elderly. The nature of the pain and its intensity may cause the patient to wince or twitch. The patient can identify trigger points, and avoidance of these trigger points is a diagnostic feature. The patient avoids these points by circumventing them during shaving, washing the face, or applying makeup. Glossopharyngeal neuralgia is similar to trigeminal neuralgia in its presentation. However, the site of pain is located in the ear, tonsils, or pharynx and is triggered by swallowing, yawning, or eating.

The prophylactic treatment for facial neuralgias consists of the anticonvulsants, and carbamazepine has produced a dramatic response. Its initial dose is 100–200 mg, two or three times daily. Most physicians would use gabapentin or baclofen after carbamazepine. Neurosurgical intervention is indicated for

approximately 25–50% of patients who are refractory to therapy. Due to the chronic nature of the pain, habituating analgesics should be avoided.

F. Temporal Arteritis

Temporal arteritis is caused by an inflammatory process to the cranial arteries, and headache is the most common presenting complaint. It is also associated with night sweats, weight loss, aching of joints, low-grade fever, and jaw claudication. The headache pain is usually localized to the affected scalp vessels. Many patients will complain of pain on chewing. Temporal arteritis should be ruled out in any patient over the age of 50 who presents with an initial onset of headache and who was previously asymptomatic. The female-to-male ratio is 2:1. The area around the temporary artery is tender and the skin may appear red, depending on which artery is involved. Diagnosis is suggested by an elevated sedimentation rate by the Westergren method and confirmed by temporal artery biopsy.

It is essential that a diagnosis be established early and treatment started immediately because 50% or more of untreated cases result in irreversible blindness. Therapy with corticosteroids can be initiated while awaiting the results of the biopsy to avoid delays in treatment.

G. Headache with Vascular Disorders

Fortunately, headaches due to disorders of the cerebral vessels are rare. Because of the gravity of these disorders, these potentially life-threatening disorders should be quickly diagnosed and appropriate treatment started immediately.

1. Epidural Hematoma

Bleeding into the cranium may occur into the epidural, subdural, or subarachnoid space or directly into the parenchyma of the brain. Severe headaches are commonly manifested by these hemorrhages. However, the headache may not be a dominant feature or may be absent in some cases. An epidural hematoma is usually caused by a tear in the middle meningeal artery as it passes under the surface of the temporal bone. Because the dura is sensitive to stretching as it is being torn away from the bone, headache often occurs. Restlessness and combativeness also occur and progress to an altered consciousness. Neuroimaging will confirm the diagnosis. Prompt neurosurgical referral is essential.

2. Acute Subdural Hematoma

Subdural hematoma can be due to either an acute or a chronic event. In acute subdural hematoma, a brief lucid interval occurs between the head trauma and the patient becoming comatose, although the patient is usually comatose from the time of trauma. The bleed may be unilateral or bilateral and is often accompanied by lacerations of the scalp and contusions to the brain and parenchyma. A CT scan will confirm the diagnosis in up to 90% of cases, although angiography may be necessary. Neurosurgical intervention is required.

Chronic subdural hematoma is usually precipitated by minor head injury, which is often forgotten by the patient, and the trauma may have occurred several months previously. This form of hematoma occurs more commonly in the elderly and in patients receiving anticoagulant therapy. In addition to the headache, the patient may have decreased mentation, confusion, and drowsiness. The headache is considered secondary to the stretching of the tributary veins that drain the vessels of the cerebral hemispheres into the sagittal sinuses. Neuroimaging will establish the diagnosis, although angiography may be required. Treatment consists of surgical burr holes and evacuation of the clot.

3. Subarachnoid Hemorrhage

Most subarachnoid hemorrhages (SAHs) are caused by a ruptured berry aneurysm. The patient with SAH will describe the ''worst headache of my life.'' Other causes of SAH include arteriovascular malformations, bleeding disorders, and miscellaneous or cryptogenic causes. A berry aneurysm results from a congenital weakness in the arterial wall, usually occurring in the vessels of the circle of Willis and at these vessels' bifurcations. Frequently, patients are drowsy, may vomit, and have meningeal signs on physical exam. If SAH is being considered, an unenhanced CT scan should be performed and immediate neurosurgical consultation should be provided. A four-vessel cerebral angiogram is usually the next stage of the workup and serves as a road map for surgical intervention.

4. Arteriovenous Malformations

Unless there is active bleeding, arteriovenuous malformations (AVMs) do not usually cause headaches. If

there is bleeding, the AVM can mimic the symptoms of SAH. A slow leak from an AVM could possibly occur and irritate the meninges, thus causing headache.

5. Hypertensive Headache

Hypertensive headache is typically bilateral and often presents in the occipital region. Characteristically, the headache is worse upon awakening and gradually improves throughout the day. The diagnosis can only be confirmed with a diastolic blood pressure of 110 mmHg or higher.

GLOSSARY

characteristic frequency The frequency of a tone (kilohertz) that excites an auditory neuron at the lowest threshold (decibel sound pressure level). Sometimes called the "best" frequency.

cytoarchitecture The structural organization of neuronal cell bodies in the brain as revealed by specific histological staining methods. The cerebral cortex in particular may be subdivided based on cytoarchitectural differences.

decibel (dB) The unit of sound intensity usually expressed as sound pressure level (SPL). Each 10-fold change in sound pressure is a 20-dB change in SPL.

Hertz (Hz) The unit of the frequency of a sound, defined as the number of cycles that a periodic signal undergoes each second. 1 kilohertz (kHz) = 1000 Hz.

Heschl's gyrus A gyrus (or in some cases multiple gyri) on the superior temporal plane that is the location of primary auditory cortex in the human.

response area The area within the threshold tuning curve.

superior temporal plane The dorsal surface of the superior temporal gyrus, buried in the Sylvian fissure, that contains much of auditory cortex in humans and in nonhuman primates.

threshold tuning curve A plot of an auditory neuron's sensitivity to sound frequency. Acoustic threshold (dB) is plotted as a function of stimulus frequency (kHz). The tip of the tuning curve is at the neuron's characteristic frequency.

tonotopy The orderly representation of stimulus frequency in the auditory system; often studied by mapping with a microelectrode the distribution of neurons' characteristic frequencies within an auditory structure.

transduction As related to hearing, it is the process by which sound energy is changed (transduced) into electrical energy (nerve impulses) within the inner ear.

Hearing engages a set of complex processes by which humans and other animals detect and discriminate sounds in the environment and determine the directions in space from which they arise. It also involves perceptual and cognitive processes that allow for sound source identification, for species-specific communication, and, in the apparently unique case of humans, for speech and language. Normal hearing is made possible through efficient sound transmission by the external and middle ears, transduction of sound energy into nerve impulses in the inner ear, transmission to the brain by the auditory nerve of information-bearing impulse trains, transformations of the transmitted information along the central auditory pathways, and integration of this information by widely distributed neuronal assemblies within and outside of the classical auditory pathways of the brain. Knowledge of the mechanisms underlying these processes in the human auditory pathways has been obtained from comparative anatomical, physiological, and behavioral studies in laboratory animals, from psychophysical experiments and noninvasive measurements of central

auditory function in normal human subjects, and from intraoperative and chronic electrophysiological studies of auditory function in neurosurgical patients.

I. HUMAN HEARING

Human hearing operates over a wide range of frequency and intensity (Fig. 1), and within this range humans have a remarkable capacity to detect, discriminate, and locate sounds. A young listener hears sounds ranging in frequency from about 20 to 20,000 Hz, and over a considerable portion of this range a change in frequency as little as 0.15% is detectable. This same listener detects sounds that move the eardrum over a distance no greater than the diameter of a hydrogen atom, and yet hearing remains quite clear as sound pressure level is then raised by a factor of 106 or more. Within this dynamic range of 120 decibels (dB), a change in sound intensity of 1 or 2 dB is easily detected. Listeners also detect with uncanny accuracy the location of a sound in space and discriminate between two speakers located within a few degrees of each other on the horizontal plane. Periodic envelope fluctuations, some highly complex, are common and important information-bearing features of natural sounds including speech. The even more complex process of speech communication, which in order to develop properly requires hearing ability, is normally acquired very early in life and shortly thereafter is carried out effortlessly even in environments filled with competing sounds.

II. TRANSMISSION OF SOUND BY THE EXTERNAL AND MIDDLE EARS

The functions of the external and middle ears are to capture sound energy and transmit it efficiently to the receptor organ of the inner ear. Figure 2A illustrates the structural relationships that underlie these functions.

The external ear consists of a highly convoluted protrusion, called the pinna (or auricle), and an ear canal (or external acoustic meatus). Together the pinna and ear canal amplify sound waves and guide them to the tympanic membrane (or eardrum).

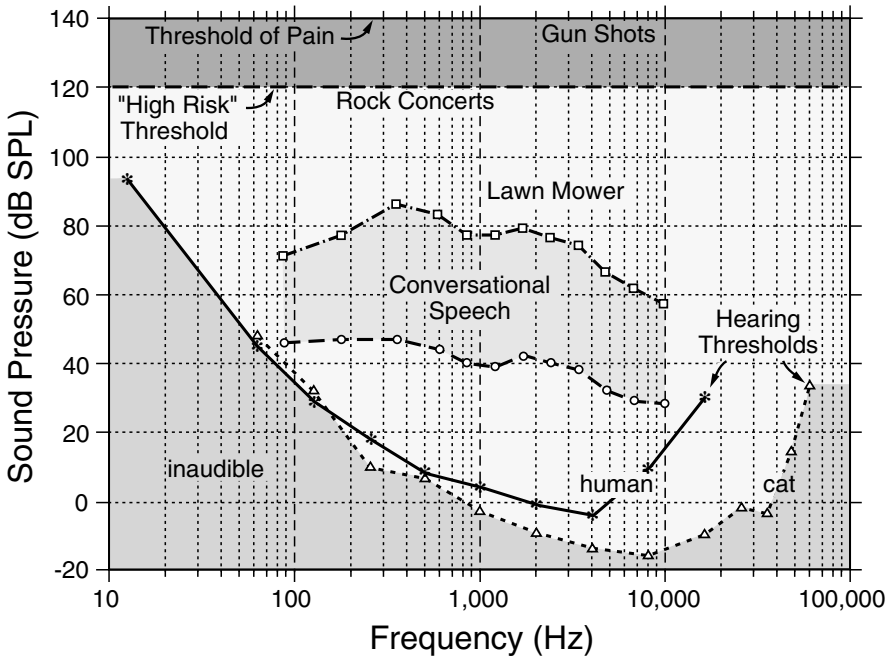

Figure 1 Hearing threshold and range of hearing for human listeners. Shown also are the ranges of frequency and sound pressure level of common environmental sounds, including human speech. The most intense sounds are capable of damaging the inner ear receptor organ. The hearing sensitivity of the cat, a laboratory animal commonly used in studies of the peripheral and central auditory systems, is illustrated as well (adapted with permission from Geisler, C. D, *From Sound to Synapse*. Oxford Univ. Press, New York, 1998).

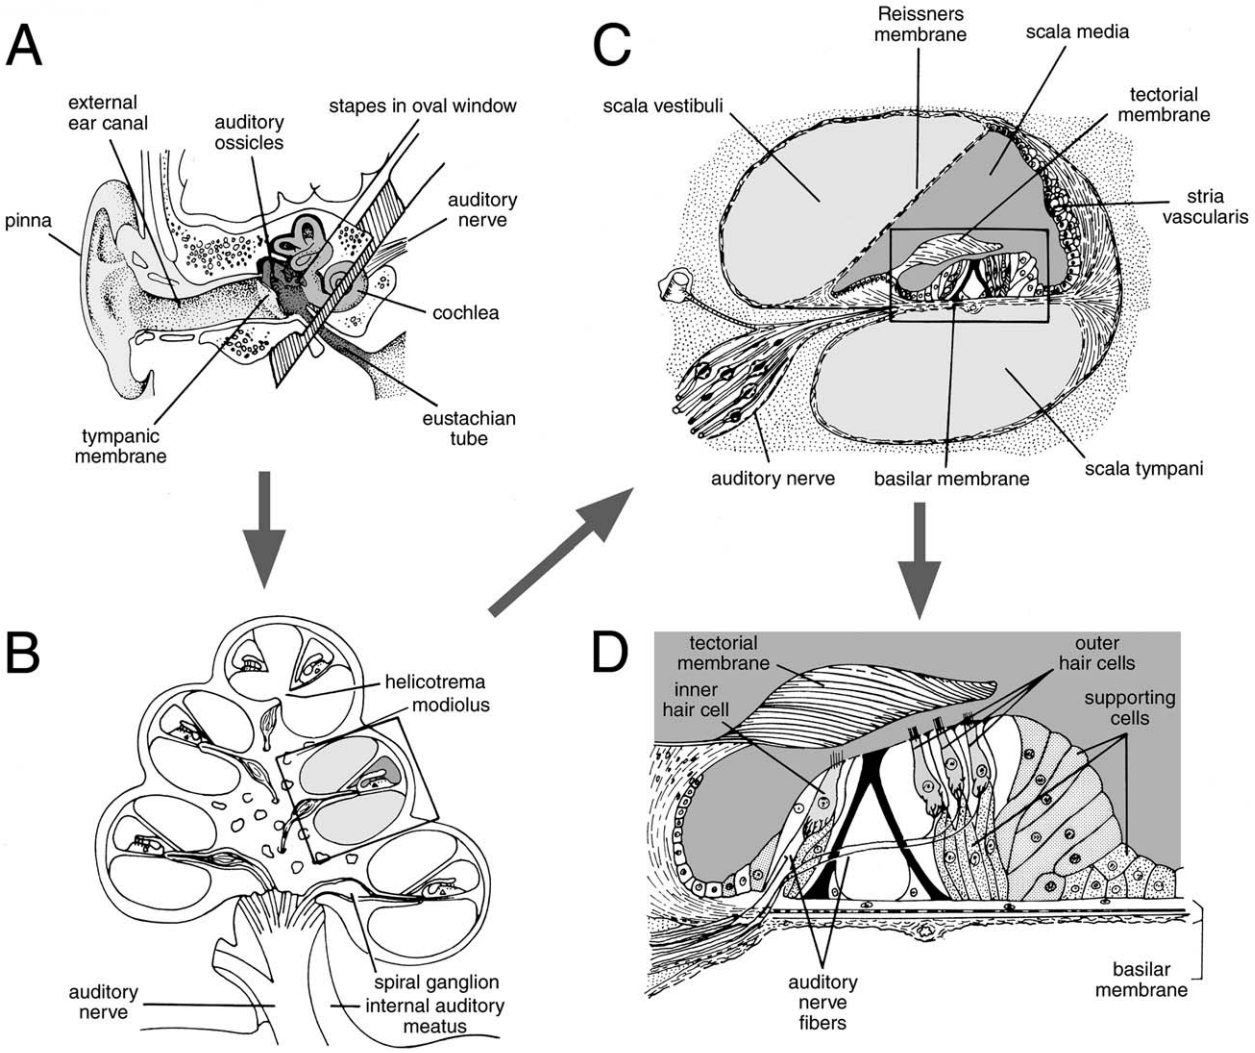

Figure 2 Structures of the external, middle, and inner ears [adapted with permission from Brugge, J. F., Auditory system. In *Encyclopedia of Neuroscience* (G. Adelman, Ed.). Birkhauser, Boston, 1987].

Amplification of sound ranges from 5 to 20 dB for frequencies within the speech range (about 1.5–7 kHz). This improvement in signal-to-noise ratio, which is due mainly to the resonant properties of the external ear canal, provides a way of enhancing speech intelligibility in the presence of many unwanted competing sounds. The pinna, on the other hand, acts as a directional amplifier for high frequencies. Spectrally transformed sound reaching the tympanic membrane provides cues for localizing the source of a sound in space, especially when the sound is on the midsagittal plane, where interaural time and intensity differences are small or nonexistent. Sounds originating from sources on either side of the midline reach the near ear before reaching the far ear, thereby creating an interaural time difference (ITD). The head also acts as an acoustic barrier at high frequencies, creating an interaural intensity difference (IID). The magnitudes of the ITD and IID depend on the location of the sound on the horizontal plane, and neural circuits in the auditory central nervous system have evolved to detect them.

The middle ear cavity is located just behind the tympanic membrane. It is normally air-filled and in equilibrium with atmospheric pressure due to the periodic opening and closing of the Eustachian tube connecting the middle ear cavity with the nasopharynx. Three auditory ossicles (malleus, incus, and

stapes) connect the tympanic membrane with the oval window of the inner ear. Reflex contraction of muscles attached to the stapes and malleus stiffens the ossicular chain and thereby reduces transmission of potentially damaging low-frequency sounds. The real need for a middle ear arises because the auditory receptor organ is an "underwater receiver" operating in the fluid environment of the inner ear. If sound waves in air were to strike this fluid boundary, 99.9% of the energy would be reflected. This interruption in the flow of sound to the inner ear would result in a conductive hearing loss, possibly as much as 30 dB. Thus, the role of the middle ear is to overcome this impedance mismatch between air and fluid and to transfer to the inner ear as efficiently as possible sound energy that impinges on the tympanic membrane.

The first, and most important, mechanism used to overcome impedance mismatch relies on the relatively large area of the tympanic membrane compared to the oval window into which the stapes footplate exerts pressure on the fluid of the inner ear. The force acting on the tympanic membrane is concentrated through the ossicles onto a small area of the oval window resulting in a pressure increase proportional to the ratio of the areas of the two membranes (approximately 20:1). Second, the lever arm of the malleus is longer than that of the incus with which it articulates, giving an additional mechanical advantage of about 1.3. Third, the conical shape of the tympanic membrane imposes additional force on the malleus. Sound energy transmitted to the inner ear is then transduced, through a cascade of mechanical and electrical events, to electrical nerve impulses in axons of the auditory nerve.

III. TRANSDUCTION OF SOUND BY THE INNER EAR

A. Structure of the Inner Ear

The inner ear, located in the temporal bone of the skull, is a complex structure serving both hearing and balance. Figures 2B–2D illustrate in detail the structures that make up that portion involved in hearing known as the cochlea (Fig. 2A). The cochlea is a coiled, tapered, and fluid-filled chamber divided along almost its entire length by a membranous partition. The two spaces thus formed, the scala vestibuli and scala tympani, are filled with a fluid called perilymph. The two scalae communicate with each other through an opening at the top (apex) of the cochlea called the helicotrema. At the base of the cochlea each scala terminates at a membrane that faces the middle ear cavity. The scala vestibuli ends at the oval window into which the footplate of the stapes rocks when the ear drum moves; the scala tympani ends at the round window, a structure that provides a pressure relief for movement of the cochlear fluid. The partition that divides the cochlea lengthwise is a fluid-filled tube called the scala media or cochlear duct. Its fluid, endolymph, is chemically different from perilymph. The cochlear duct is bounded on three sides by a bed of capillaries and secretory cells (the stria vascularis), a layer of simple squamous epithelial cells (Reissner's membrane), and the basilar membrane, on which rests the receptor organ for hearing—the organ of Corti.

The organ of Corti contains the auditory receptor cells (hair cells) and a system of supporting cells that hold them in place. Hair cells are modified epithelial cells with hairs (stereocilia) protruding from their apical ends (Fig. 2D). Figure 3 is a drawing of a stereotypic ear hair cell. A kinocilium, which seems to play no active role in the transduction process, is seen throughout life in the vestibular epithelium but is no longer present in the adult cochlea. Within the organ of Corti two kinds of hair cell—inner (IHC) and outer (OHC)—are distinguishable by location, morphology, and connections with the auditory nerve. Approximately 3500 IHCs form a single linear array, from base to apex (Fig. 2D). About 12,000 OHCs are arranged in three or four rows, parallel to the IHCs (Fig. 2D). Approximately 100–150 stereocilia form a V or W pattern on each OHC, whereas approximately 40–50 stereocilia, arranged in a U shape, adorn each IHC. Displacement of stereocilia is the adequate stimulus for generating receptor currents in hair cells that eventually lead to action potentials in auditory nerve axons.

Spiral ganglion cells, located in the bony core of the cochlea, are the bipolar first-order neurons of the auditory pathway. Their distal processes make synaptic contact with the base of hair cells. The central axons, which in the human number approximately 35,000, form each auditory nerve bundle. The majority ($\sim$95%) of the central processes of spiral ganglion neurons originate at the base of IHCs. Thus, axons connected to IHCs transmit to the brain trains of nerve impulses that encode essentially all the acoustic information eventually perceived by a listener. The innervation is highly focused: Each auditory nerve is connected to one IHC, whereas each IHC is innervated

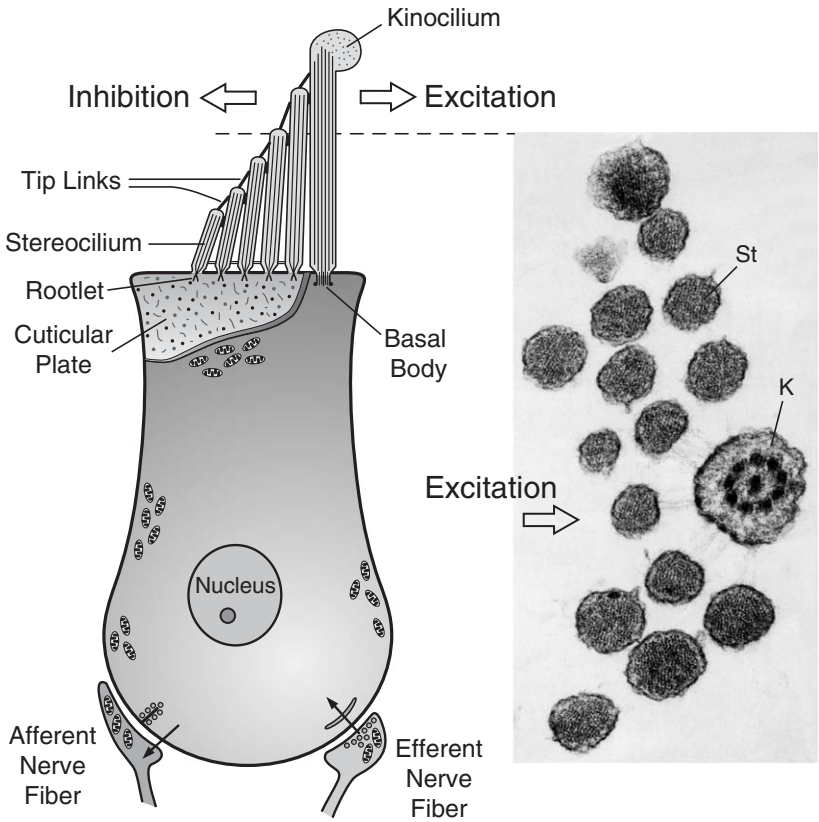

Figure 3 Stylized hair cell of the vertebrate inner ear (left). Deflection of stereocilia toward the kinocilium and basal body results in hair cell depolarization and excitation of auditory nerve fibers, whereas movement in the opposite direction leads to hyperpolarization and inhibition. Cross section of hair bundle is shown at the right (adapted with permission from Geisler, C.D, *From Sound to Synapse*. Oxford Univ. Press, New York, 1998).

by no more than approximately 10–20 spiral ganglion cells. The remaining 5% of axons of the auditory nerve are efferent fibers arising from cells in and around the superior olivary complex of the brain stem. Upon entering the organ of Corti they branch profusely, with each axon reaching many OHCs over considerable distance.

B. Mechanical Motion in the Inner Ear in Response to Sound

The basilar membrane is a resonant structure varying systematically in width and stiffness. It is wider (0.42–0.65 mm) and more flaccid at the cochlear apex than at the base (0.08–0.16 mm). When a sound wave is transmitted to the fluid of the inner ear, the basilar membrane is set in motion. Basilar membrane motion is best described as a traveling wave of deformation, which begins at the cochlear base and moves apically toward a frequency-dependent place of maximal amplitude (Fig. 4). When very high-frequency sound waves reach the ear, only the region nearest the cochlear base vibrates. As the frequency of the sound is lowered, the place of maximal amplitude of vibration shifts toward the cochlear apex. Because of this resonance gradient, the basilar membrane is said to be "tonotopically" organized. Consequently, complex sound (e.g., speech) entering the inner ear is resolved into its component frequencies. This physical separation of sound energy into its spectral components, coupled with the focused innervation of the auditory nerve array, provides an orderly and spectrally segregated projection of the nerve into the auditory brain stem, thereby setting the stage for tonotopic organization along the entire central auditory pathway.

Normal cochlear vibration is not simply the result of passive mechanical resonance as once thought, but rather it involves active processes. Under certain conditions, OHCs are capable of changing shape,

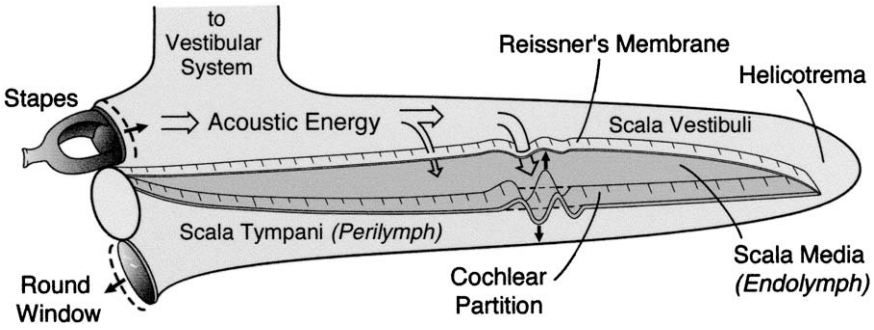

Figure 4 Stylized mammalian cochlea, shown uncoiled to illustrate the flow of energy and pattern of vibration of the cochlear partition in response to a midfrequency tone of modest intensity. The scalae vestibuli and tympani are assigned the same shading as in cochlear cross sections shown in Fig. 2. [Adapted with permission from Geisler, C.D. (1998). *From Sound to Synapse.* Oxford Univ. Press, New York].

which feeds energy back into the organ of Corti and alters the mechanical properties of the cochlear partition and possibly the transduction process. This active process may be controlled, in part, by feedback via olivocochlear axons originating in the auditory brain stem and profusely terminating at the base of OHCs. Apparently as the result of an active process, the organ of Corti acts not only to receive sound but also to generate it, as an otoacoustic emission (OAC) recorded by a microphone in the ear canal. There are several categories of OACs, reflecting perhaps more than one nonlinear active process in the cochlea. OACs are proving useful as an objective tool for diagnosing sensorineural hearing loss.

C. Transduction Process in Cochlear Hair Cells

Stereocilia of IHCs are in functional contact with an overlying auxiliary structure called the tectorial membrane. The base of the hair cell is in synaptic contact with the distal ends of auditory nerve axons. Sound waves that reach the inner ear set the basilar membrane, and hence the organ of Corti, into motion. This causes a shearing motion between the tectorial membrane and the tops of the hair cells that, in turn, displaces the stereocilia and triggers the flow of transducer currents. These changes in the receptor potential are mediated by the opening and closing of mechanically gated ion channels (transduction channels) at the tips of the stereocilia. This action leads to opening and closing of voltage-gated ion channels distributed over the basolateral surface of the cell body and then to the release of neurotransmitter at the afferent synapses at the base of the hair cell. The hair bundle is ''polarized,'' which means that displacement of the stereocilia in the direction of the kinocilium (or basal body) results in hair cell depolarization and an increase in firing of auditory nerve fibers, whereas displacement in the opposite direction leads to hyperpolarization and a decrease in firing (Fig. 3). Thus, the modulation of neurotransmitter release, and, as a consequence the pattern of action potentials in the auditory nerve, is linked tightly to the intensity, frequency, and temporal structure of sound waves entering the ear.

Inner ear structures are easily damaged by intense sound, drugs, viruses, and bacteria, and there are genetic causes of inner ear malformation. The resulting hearing loss is called sensorineural, and in such cases no treatment has been found to fully restore normal inner ear function. Some functional hearing may be restored, however, by electrically stimulating surviving spiral ganglion neurons through a cochlear prosthesis.

IV. TRANSMISSION OF SOUND INFORMATION BY THE AUDITORY NERVE

The term ''code'' as applied to the auditory system is simply a way in which information about a sound is represented in impulse activity of neurons. As in other regions of the central and peripheral nervous systems, the auditory system exhibits a variety of neural activities and, hence, a variety of candidate coding mechanisms. These include labeled lines (place), firing frequency (rate), temporal patterning, and ensemble firing. Each auditory nerve encodes the frequency, intensity, and temporal pattern of the sound reaching the ear. Coding for the direction of sound in space involves more complex processing in the central auditory pathway, where inputs from the two ears converge and where sound direction is computed from ITD and IID cues.

Auditory nerve fibers exhibit a frequency specificity that reflects the mechanical tuning properties of the basilar membrane and the highly focused innervation of IHCs. The discharge threshold of an auditory nerve fiber occurs around a particular frequency, referred to as the fiber's characteristic frequency (CF). Thus, a fiber's CF is directly related to the location along the basilar membrane innervated by that fiber. The fact that auditory nerve fibers and many central auditory neurons are frequency selective has been taken as evidence to support a place theory of hearing. The place theory is a labeled-line theory stating that the pitch of a tone (i.e., the psychological attribute associated with frequency) is determined by those fibers in the auditory nerve array (and, by extension, central auditory neurons) excited by that sound.

Not all sounds having pitch quality exhibit spectral energy at the pitch frequency; pitch is also perceived when a sound waveform is modulated in amplitude. Hence, frequency (or pitch) information may be transmitted from the ear to the brain in the temporal pattern of nerve impulses in auditory nerve fibers. Action potentials evoked by low-frequency tones (below about 4 kHz) or by temporally modulated sounds (below about 1000 Hz) occur at preferred times on a stimulus cycle, a phenomenon known as phase locking. Phase locking is the direct result of to-and-fro displacement of IHC stereocilia in response to low-frequency modulation of the basilar membrane. As a consequence of phase locking, nerve impulses tend to occur at integral multiples of the period of the stimulus time waveform, a behavior that is predicted by the volley theory of hearing. The volley theory states that the pitch of a sound is determined by the temporal rhythm of the discharges of an ensemble of auditory nerve fibers. High-fidelity transmission of temporal information from the cochlea to the brain serves at least two purposes. First, because much of human speech (especially vowel sounds) has its acoustic energy concentrated below about 4 kHz and contains amplitude-modulated components, phase locking serves to preserve temporal information found in human speech sound. Second, it serves to transmit temporal information to neural circuits of the brain stem capable of detecting ITD cues used by listeners for localizing the source of a sound in space. Neither the place theory nor the volley theory alone, however, fully account for a listener's ability to distinguish one tone from another, to encode the entire spectrum of speech, or to localize equally well both low- and high-frequency sounds. Hence, a duplex theory of hearing was postulated that states that temporal coding operates at low spectral frequency and that rate and place coding operate at high spectral frequency.

Sound intensity is likely encoded, in part, by the firing rate of auditory nerve fibers. As stimulus intensity is raised, the number of discharges steadily increases up to a plateau approximately 30–40 dB above threshold. Because a typical single auditory nerve fiber responds more or less linearly only over a 30- to 50-dB range of intensity, a second mechanism is needed to achieve the nearly 100 dB of dynamic range experienced by human listeners. This mechanism involves recruiting additional fibers with different discharge threshold into the active population.

Through the coding mechanisms outlined previously, the cochlear output faithfully reflects the time structure and intensity of speech and other naturally occurring sounds, with the spectrotemporal components of these coded messages distributed across the tonotopic array of primary afferent fibers. The representation of speech in the auditory periphery thus involves the full complement of temporal, rate, place, and ensemble encoding mechanisms operating in concert. Which mechanism dominates depends on the CF and spontaneous rate of the auditory nerve fiber and, in each instant in time, on the acoustic properties of the utterance and of the ambient environment.

Information transmitted in the auditory nerve array is received and transformed by neurons and neuronal circuits of the cochlear nuclei, and the resulting outputs are distributed over various pathways of central auditory system for further processing.

V. STRUCTURE AND FUNCTION OF THE CENTRAL AUDITORY PATHWAYS

The central auditory pathways have been studied extensively in many primate and nonprimate species using a wide range of anatomical and physiological methods. There are far fewer comparable studies in humans, but from them we may conclude that much of the neural circuitry and many of the neural mechanisms underlying mammalian hearing are, to the first approximation, shared by humans and nonhumans alike. Functional studies of the human central auditory system are discussed later. The top of Fig. 5 is a dorsal view of the human brain stem, midbrain, and thalamus showing the relative positions of the major nuclei in the ascending and descending mammalian auditory system. Auditory cortex on the temporal lobe is shown in cross section. The major connecting pathways are illustrated schematically below.

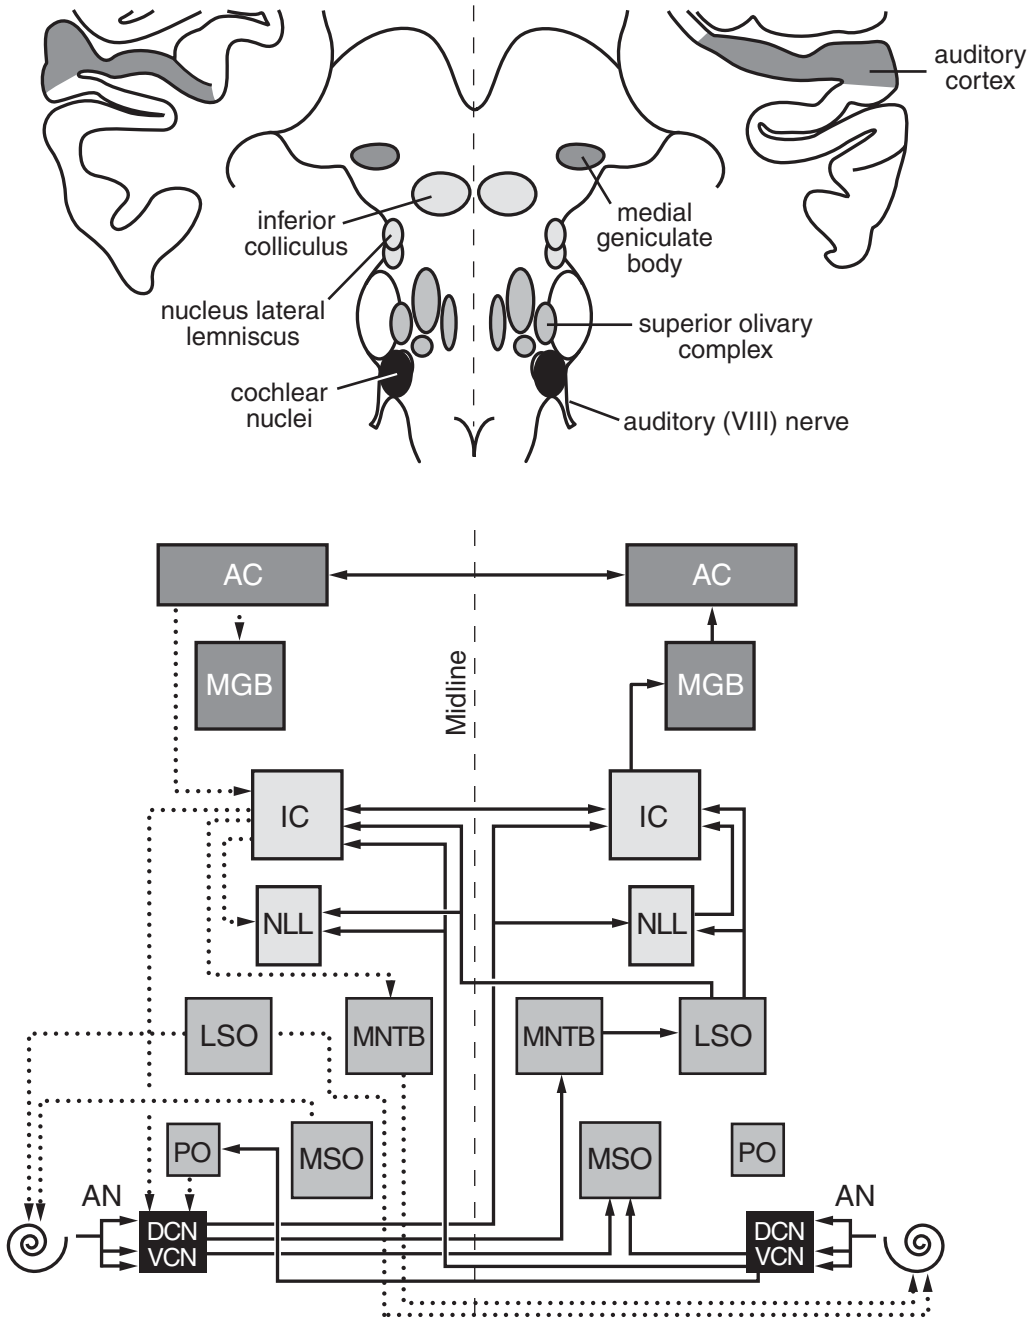

Figure 5 (Top) Dorsal view of the human brain stem, midbrain, thalamus, and cross section of the cortex showing the relative locations of the major nuclei in central auditory pathways. (Bottom) The major ascending (black lines and arrows) and descending (dotted lines and arrows) pathways connecting the major nuclei.

A. Cochlear Nuclear Complex: Initial Transformation of Sound Information Reaching the Brain

The cochlear nuclei, located bilaterally at the pontomedullary junction, are the first synaptic stations in the central auditory pathway. The cochlear nuclei are obligatory relays, meaning that all information flowing from the cochlea must here encounter at least one synapse before being transmitted to higher auditory centers. In humans, as in all other mammals studied, two major cochlear nuclei are recognized: a dorsal

cochlear nucleus (DCN) and a ventral cochlear nucleus (VCN). The latter is often subdivided into anterior and posterior divisions. Auditory nerve fibers penetrate this nuclear complex, bifurcate in an orderly (tonotopic) way, and terminate on neurons in both the DCN and the VCN. In addition to its major afferent supply from the inner ear, the cochlear nuclei receive input from a variety of other sources both intrinsic and extrinsic to the complex. Extrinsic sources include the other major brain stem nuclei. The role of these inputs in modulating the activity produced by primary afferent input from the ears is essentially unknown.

Cochlear nuclear neurons have been categorized based on their synaptic structure, cell morphology, pharmacology, connectivity, and acoustic response properties. Incoming spike trains that reach CN neurons are transformed by combinations of synaptic convergence and physiology, intrinsic membrane properties of target neurons, and feedback of excitation and inhibition via intrinsic or extrinsic circuitry. Cells of each category tend to extract particular features of sound that are transmitted by auditory nerve fibers, such as intensity, spectral composition, modulation amplitude and frequency, low-frequency time structure, and the timing of acoustic transients. Information received about human speech, for example, is thus distributed in such a way that one cell type preserves the temporal representation of vowels, whereas another cell type represents vowel information best in its rate of discharge. Similarly, other cell types extract formant transitions and still others transients (e.g., voice onset). Temporal information needed to detect ITD is preserved by still other cell types in the VCN having a highly specialized synaptic relationship (end bulb of Held) with auditory nerve fibers. Transformed information is sent to higher auditory centers for further processing over three pathways (stria).

Most axons leaving the VCN form a broad pathway that crosses the brain stem ventrally as the ventral stria or trapezoid body. A much smaller pathway, the intermediate acoustic stria, also leaves the VCN and joins the trapezoid body as it approaches the superior olivary complex, where many of its axons terminate. Axons of projecting neurons of the DCN form the dorsal acoustic stria, which reaches primarily the contralateral dorsal nucleus of the lateral lemniscus and the central nucleus of the inferior colliculus. At the level of the cochlear nuclei the input from the two ears has, for the most part, remained separated. One of the next levels of processing takes place in the superior olivary complex, where the inputs from the two ears converge and interact to encode sound direction.

B. Superior Olivary Complex: A Major Site for Integrating Input from the Two Ears

The superior olivary complex (SOC) comprises several interrelated nuclear groups located symmetrically on either side of the brain stem. There are three major SOC nuclei in most mammals studied: the lateral superior olivary nucleus (LSO), the medial superior olivary nucleus (MSO), and the medial nucleus of the trapezoid body (MNTB). In higher primates, including the human, the MNTB tends to be represented more by a collection of scattered neurons than by a coalesced structure. A number of periolivary nuclei (PO) are recognized as well. The major nuclei are the first stations in the auditory pathway that receive substantial bilateral input, and thus the SOC plays crucial roles in extracting and integrating information it receives from the two ears. Localizing the source of a sound in space is crucial to the survival of most animals, and to do so they rely on the fact that the positions of the ears on opposite sides of the head provide frequency-dependent ITD or IID. For human listeners, sound localization also plays an important role in identifying a talker in the presence of competing talkers (the so-called cocktail party effect). Sound localization in the horizontal plane is accomplished by engaging neural circuits in the SOC that compare these interaural time and intensity differences.

Principal neurons of the MSO have been shown in animal studies to receive direct input from particular cell types in the bilaterally placed ventral cochlear nuclei that preserve and transmit precise time information about a sound source in space. To a first approximation, these MSO neurons perform a cross-correlation on the spike trains arriving from the left and right ears. The projections from each ear form what may be considered a neural "delay line." As a result, phase-locked spikes transmitted over the two monaural channels arrive simultaneously at different MSO neurons depending on the interaural time delay and, hence, on the azimuthal (horizontal) location of a sound source. Next, the azimuthal location of a sound source is computed and is now represented at a "place" in the MSO.

In contrast, LSO neurons receive bilateral input from a different population of cochlear nuclear neurons. The ipsilateral input to the LSO is direct and excitatory, but the contralateral input involves an

inhibitory interneuron in the MNTB. This arrangement renders LSO neurons particularly sensitive to IIDs. Hence, at this point in the central auditory system information concerning two of the major cues used by listeners in localizing the source of a sound in space has been extracted and to some extent segregated along two ascending pathways.

Periolivary nuclei in the human tend to encircle the MSO and LSO and are not easily distinguishable into subnuclei as they are in several other mammalian species. PO neurons in experimental animals have been shown to project profusely back to the cochlear nuclei as well as forward to midbrain auditory structures.

A bundle of axons arising in the SOC as well as passing axons form the CN is referred to as the lateral lemniscus. Two major cell groups embedded in this band of axons form the dorsal (DNLL) and lateral (VNLL) nuclei, respectively, of the lateral lemniscus. A third, intermediate (INLL) nuclear group has been identified in several animal species but not in humans. The VNLL receives its major input from the contralateral VCN via the trapezoid body and from the ipsilateral SOC. In contrast, the DNLL receives convergent input from a wide variety of sources, including the contralateral DCN and DNLL and ipsilateral SOC and VNLL. Ascending axons originating in the DNLL and VNLL contribute to the lateral lemniscus, which is now destined for the inferior colliculus.

Although the functions of the SOC and LL nuclei have not been studied directly in humans, synchronous firing of neurons in and around these auditory brain stem areas is believed to be the source of the wave IV–V complex in the sound-evoked averaged brain stem potential recorded from the scalp (Fig. 7).

C. Olivocochlear Efferent System: Central Modulation of Inner Ear Transduction

The cochlea, in addition to supplying afferent input to the brain stem, receives efferent projections that originate in the SOC. In animal studies it has been shown that two basic groups of brain stem neurons provide efferent innervation to the organ of Corti. Based on the general locations of their cell bodies in the SOC, they form the lateral (LOC) or medial (MOC) olivocochlear system. The LOC originates from AChE-positive neurons in and around the LSO and terminates primarily in the ipsilateral cochlea, at the base of inner hair cells. Small AChE-positive cells, believed to be LOC neurons, are found in this location in the human brain stem. The MOC arises for the most part from neurons medial to the MSO and reaches the base of outer hair cells mainly in the contralateral inner ear. Collaterals of olivocochlear axons terminate in the cochlear nuclei. Both LOC and MOC neurons receive input from the ventral cochlear nucleus, with the MOC also receiving input from the inferior colliculus. Cochlear efferents are activated by sound and thereby provide reflex feedback to the cochlea. The consequence of this feedback is increased acoustic threshold due to reduced OHC amplification, which helps protect the cochlea from potentially damaging loud sounds and improves detectability of wanted sound in the presence of unwanted background masking noise. Sound induced reflex contraction of the middle ear muscles serves to complement the action of the olivocochlear system.

D. The Auditory Midbrain: Major Integrating Centers

The inferior and superior colliculi collectively form the roof of the midbrain. Both are major integrating centers, receiving converging input from a wide variety of sources representing the auditory, visual, and somatosensory systems.

Anatomically, the IC is subdivided into a central nucleus (ICC) and a surrounding cortex (divided into external and pericentral nuclei). The ICC forms an essential link in the mainline lemniscal auditory system and thus is critically involved in the transmission of auditory sensory information to the forebrain from lower auditory centers. The ICC also receives a rich supply of afferents from many other sources and directs its outputs to a variety of targets. This results in numerous feedback loops (Fig. 5) that involve essentially all major auditory areas of the forebrain, midbrain, and brain stem of the same side of the brain. In addition, several major axonal bundles (commissures) connect auditory areas of one side of the brain with their counterparts on the other. Hence, it is not surprising that essentially all information transmitted to the auditory forebrain is first transformed within the ICC. Transformations involve changes in the balance of excitation and inhibition exerted by converging afferent inputs—changes that are reflected in such fundamental attributes of coding as frequency tuning curves, timing of spike discharges, spontaneous background activity, sensitivity to modulations in frequency and intensity, binaural interactions, and spatial tuning. Remarkably, the diverse

parallel input and output, and the transformations associated with them, are highly organized within the ICC tonotopic map, which is best described as being made up of frequency-specific layers or bands. Within each band are overlapping functional maps related to a wide array of response features and stimulus attributes such as amplitude modulation, pitch, intensity, threshold, onset latency, sharpness of frequency tuning, and binaural sensitivity. It is thought that these functional maps may provide the early substrates from which sound percepts are eventually derived. Information transformed by the ICC is carried to the auditory forebrain via the brachium of the IC.

The superior colliculus (SC) is a layered structure involved primarily in the control of movements of the eyes to an auditory or visual target. Thus, in the classical sense it is not a "sensory" structure. Auditory input carries information on the direction of a sound source to deep SC layers. Sound-source direction is represented by SC neurons having spatial receptive fields arrayed to form a map of auditory space. Visual input is received in the upper layers, and information on target direction is provided by its position on the SC visuotopic map. The auditory and visual maps are normally in alignment, presumably to coordinate visual and auditory directional information so that the eyes can move quickly and accurately to an object that appears in the visual and sound fields.

VI. FUNCTIONAL ORGANIZATION OF THE AUDITORY FOREBRAIN

The auditory forebrain consists of auditory thalamic relay nuclei and those cortical areas with which they have intimate reciprocal relationships. Together these forebrain areas carry out the highest levels of information processing in the auditory pathway.

A. Thalamus

The medial geniculate body (MGB) is a complex of nuclei that receive massive input from the IC and thus serve as major synaptic stations in the pathways for information reaching auditory areas of cerebral cortex. The MGB nuclei can be differentiated from one another on the basis of cytoarchitecture, chemoarchitecture, tonotopy, connectivity patterns, and acoustic response properties. Neighboring nuclei of the posterior complex and pulvinar also receive auditory input and project upon auditory cortex. The auditory thalamus receives its input over pathways that originate in brain stem nuclei contributing to the lateral lemniscus as well as pathways that are nonlemniscal in origin. The cellular architecture of the human MGB is remarkably similar to that of OldWorld and NewWorld monkeys. Although the relative size and strength of each auditory cortical projection differ from one MGB subdivison to the next, each auditory cortical field receives highly convergent input from a subset of auditory thalamic nuclei and each auditory thalamic subdivision projects in a topographic way to a subset of auditory cortical fields. Thus, the auditory thalamocortical system, like auditory brain stem circuitry, exhibits widespread convergence and divergence. Tones evoke a characteristic pattern of cortical activation that reflects the thalamic projection to that active site. The earliest electrical response is thought to represent monosynaptic activation of neurons in cortical laminae 3 and 4, whereas later activity is considered polysynaptic activation through supragranular cortical layers. In addition to receiving massive ascending input from brain stem and midbrain auditory structures, the MGB also receives a substantial projection from those areas of cerebral cortex to which it projects. This reciprocal relationship provides opportunity for feedback control of ascending auditory input.

The ventral divison (MGBv) displays a high degree of tonotopy imposed by input from the similarly organized ICC. Nonauditory input to the ventral division is derived from the thalamic reticular and ventrolateral medullary nuclei. The MGBv projects heavily on the core areas of auditory cortex, including the primary field. Neurons in the MGBv preserve and convey to cortex with high fidelity the temporal and frequency-specific properties exhibited in the auditory brain stem. In the human, the dorsal division (MGBd) is larger and structurally more heterogeneous than the ventral division. It receives its auditory input from neurons primarily in the pericentral nucleus of the IC. Other afferents arise from the thalamic reticular nucleus, ventrolateral medullary nucleus, nucleus sagulum, superior colliculus, and brachium of the inferior colliculus. Neurons of the MGBd, in contrast to those of the MGBv, are poorly responsive to most sounds and are broadly tuned for frequency; hence, tonotopy is not a remarkable feature. The main targets of MGBd neurons are the belt areas of cortex. The medial, or magnocellular, division (MGBm) also exhibits diverse cellular architecture, and it receives input mainly from the external nucleus of the IC. Tonotopy is not a remarkable feature of this nucleus,

again reflecting the organization of its main afferent source. Neighboring thalamic nuclei, including the posterior group and the pulvinar, receive auditory input and send projections to auditory cortical fields.

MGB neurons in all divisions appear to preserve ITD or IID information extracted at brain stem levels and widely disperse this information to auditory areas of cerebral cortex. Neurons within the MGB and auditory cortical fields respond best when the sound source is in the contralateral acoustic hemifield. There is no obvious anatomical specialization in MGB in humans for speech, nor is there evidence for bilateral asymmetry in the size of the MGB.

B. Auditory Cortex

1. Auditory Cortex Is Made up of Multiple Fields to Carry out Parallel and Serial Processing

In all mammals studied, auditory cortex is made up of multiple fields, which are distinguished from one another on both anatomical and functional grounds. The number of such fields varies among species studied from as few as 2 in rodents to as many as 15 in the rhesus monkey. The number, location, and organization of such fields in the human are not fully known. It would be highly desirable, however, to know the functional and structural counterparts of human and monkey auditory cortex. Although much less is known about the functional organization of temporal auditory cortex in the human than in the monkey, from available data there are some striking anatomical similarities between the two species. These data, together with modern imaging [functional magnetic resonance imaging (fMRI) and positron emission tomography (PET)] and direct [electrocorticography (ECoG)] and indirect [electroencephalography (EEG) and magnetoencephalography (MEG)] electrophysiological recording data in humans, enable us to tentatively apply to the human a model of functional organization of auditory cortex developed for the monkey. Figure 6C shows a schematic representation of monkey auditory cortex based on modern anatomical and physiological studies. Primary auditory cortex is combined with adjacent cortex to form a core area. Surrounding the core auditory cortex is an auditory belt area, and around that is a parabelt region. The belt and parabelt areas are often referred to as secondary or associational areas. Figures 6A and 6B show two views of the human brain showing the general locations and extent of what may be equivalent core, belt, and parabelt areas in the human. There is general agreement about the location, extent, and tonotopic organization of the human primary auditory field (AI), on the mesial aspect of Heschl's gyrus (HG). There is less agreement about the organization of surrounding auditory. Whether this monkey model is adequate to describe the human auditory cortex is yet to be determined. Currently, however, it provides a tool for further exploration using modern recording and imaging technology.

We know from animal studies that auditory fields receive ascending input from the auditory thalamus, that they are richly interconnected on the same and opposite cerebral hemispheres, and that they provide afferent input to the MGB and IC as part of a massive parallel descending system of pathways that eventually reaches the lower auditory brain stem and the cochlea (Fig. 5). These auditory cortical areas are confined to temporal cortex and serve primarily a sensory function. This means that their neurons and neuronal circuits are sensitive mainly to changes in physical parameters of a suprathreshold acoustic signal reaching the ears, and thus they are designed to detect, discriminate, identify, and localize sound sources. Multiple auditory areas are thought to represent hierarchical processing levels. Some areas involved in higher order processing of acoustic stimuli, such as speech, lie outside of these "classic" auditory fields, on the frontal and parietal lobes.

2. Functional Organization of Primary Auditory Cortex: Maps of Stimulus Features

The primary auditory field (AI) has been identified anatomically and studied physiologically in a wide range of mammalian species, including humans. It is reciprocally and topographically tied to MGBv. Within AI, neurons are typically sharply tuned for frequency. Like other sensory cortices, AI exhibits a columnar representation of the peripheral sensory epithelium: Neurons occupying a vertical column tend to have the same or very similar CF. A tone just above threshold would activate a relatively small population of neurons in a cortical band having length, depth, and width (a cortical "sheet"). AI is thus said to be organized into isofrequency bands or sheets. The organization of the AI tonotopic map varies from one subject to the next, possibly suggesting that environmental factors may be involved in the formation and shaping of functional maps. It is now known that the AI tonotopic map exhibits plasticity because it undergoes dramatic change following a cochlear lesion. One can only

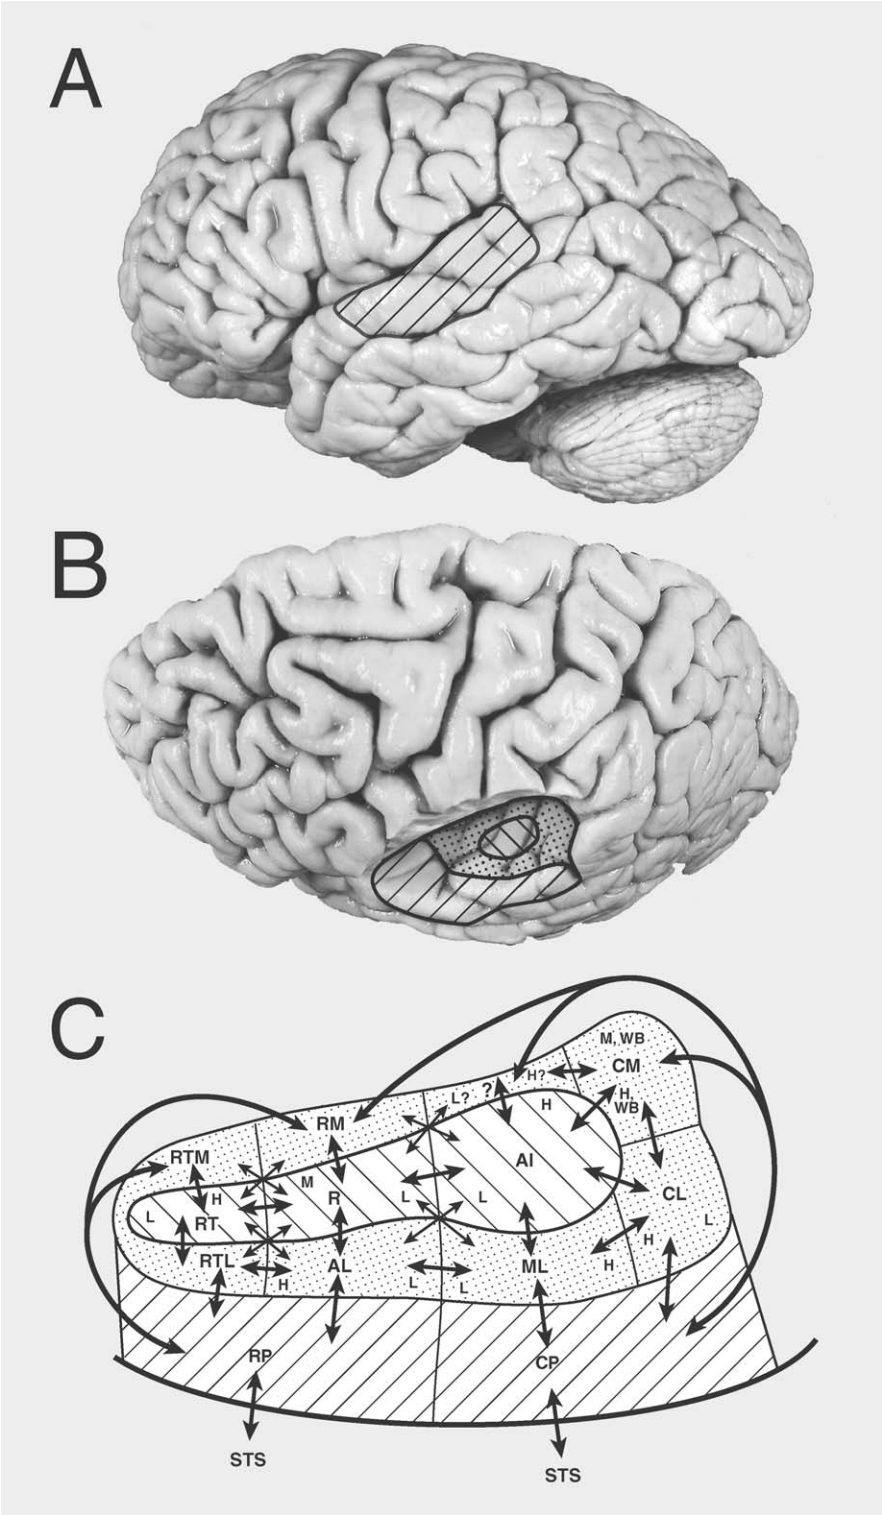

Figure 6 (A and B) Lateral and dorsal views, respectively, of the human brain showing the approximate extent and locations of known auditory fields on the lateral and superior surfaces of the superior temporal gyrus. (C) Diagram of the organization of auditory cortical fields on the same temporal lobe areas of the rhesus monkey (adapted with permission from Hackett, T. A., Stepniewski, I. and Kaas, J. H., *J. Comp. Neurol.* **394,** 475–495, 1998).

wonder if, for example, the improvement in hearing performance over time exhibited by subjects with a cochlear prosthesis may, to some degree, be attributed to auditory cortical plasticity.

In addition to a tonotopic representation within AI, studies of experimental animals have revealed spatial maps related to other functional properties associated with pure tones, ripple spectra noise, broadband transients, frequency sweeps, and binaural stimuli. The picture that emerges from this work is one of primary auditory cortex being made up of overlaid topographic representations of numerous independent stimulus features. To complicate matters even further, these representations, which are based on neuronal firing rate and spike timing, depend on stimulus intensity. Thus, individual stimulus features *per se* are probably not coded at the cortex simply by some fixed place within the primary auditory field. Instead, they may be coded by spatiotemporal activation patterns created by neuronal assemblies within cortex that change in dynamic ways to reflect the many and changing acoustic features that make up complex natural sounds, including speech.

Several auditory cortical maps represent fundamental acoustic features of a stimulus (e.g., spectrum and noise bandwidth), whereas others represent derived properties (e.g., binaural interactions) or perceptual qualities (e.g., pitch). The binaural organizational patterns distributed across AI are examples of computational maps representing the direction of a sound source in acoustic space. Because there is no extraction of spatial direction by the cochlea, such maps can only result from neural interactions taking place in the lower auditory brain stem, where spike trains arriving over the two monaural channels converge. Similarly, a cortical map of pitch may be laid out orthogonal to the tonotopic map. Pitch is the psychological attribute associate with fundamental frequency even in the absence of spectral energy at the pitch frequency. Hence, its representation on cortex would provide evidence for a higher order cortical representation of a percept rather than simply a sensation tied directly to the physical attributes of a complex stimulus.

AI cortical neurons may encode the frequency of temporal modulation of the sound envelope in the phase-locked activity of cortical neuronal assemblies. Indeed, the phase-locked thalamocortical input may provide the upper frequency limit of pitch encoding (approximatley 400–600 Hz) based on temporal mechanisms. Studies of cortical coding of species-specific vocalization and human speech in monkey have revealed no simple correlation between a single cortical neuron's response properties and a particular utterance. Thus, auditory cortical neurons may be specialized to respond more on the basis of the presence or absence of certain acoustic components embedded in a vocalization rather than on a unique vocalization per se. fMRI studies in humans have also revealed that activation of the core auditory area differed little from the surrounding cortex when speech and nonspeech sounds were presented to normal-listening subjects, again indicating that these fields are more involved in detecting the acoustic rather than linguistic parameters of speech. Indeed, the tonotopic constraints imposed on AI and the highly individualistic responses of its neurons to complex sounds suggest that specific mechanisms for identification of individual phonemes, for example, would not reside in this field and, moreover, that such specificity to speech or other species-specific communication sounds is more likely accomplished by ensembles of cortical neurons rather than by single cells. On the other hand, fields on the ventral aspect of the temporal lobe and on the temporal–parietal boundaries of the left cerebral hemisphere show greater activation to speech than to nonspeech sound.

3. Temporal Lobe Lesions Impair Acoustic Processing

Lesion behavioral studies, mainly in rat, cat, and monkey, have provided limited information on the function and organization of auditory cortex. Differences in species and in experimental paradigms have led to conflicting results across studies. One major impairment associated with auditory cortical lesions in cat and monkey, however, is localization of brief sounds in space. Lesioned animals exhibit an inability to localize sound in the acoustic hemifield opposite the side of the lesion. Additional consequences of auditory cortical lesions are impaired discrimination and retention of certain temporal patterns, including species-specific vocalizations.

Lesion studies in experimental animals usually aim to produce damage confined to a particular cortical field or portion of that field, often guided by electrophysiological mapping. This may be done repeatedly in a series of animals in which well-controlled behavior studies are carried out before and for varying period of time after the lesion is made. Far fewer systematic studies of human patients with auditory cortical lesions have been reported. Under ideal conditions a human subject communicates and cooperates well with the examiner in performing complex psychophy-

sical tests. Specific deficits in auditory processing can then be quantified and correlated with anatomical data now obtainable from brain MRIs. Rarely, however, is this ideal achieved. For the most part, patients present with clinical symptoms resulting from large, spontaneously occurring lesions; hence, no two patients experience lesions of the same size and location. The damage is rarely, if ever, confined to a single cortical field. Patient–subjects are scattered geographically and thus examined by different investigators having different specific scientific interests using different experimental methods. Possible exceptions to this are studies of epilepsy patients undergoing temporal lobectomy. Even here, however, a unilateral temporal lobe resection varies in size from one patient to the next and usually does not extend into the core auditory cortex on the mesial aspect of HG. When a cortical lesion is made for clinical purposes, only rarely are preoperative baseline psychophysical data obtained. Even when this is done, however, attention is not always paid to the fact that following an acute brain lesion considerable recovery in function occurs over time. Futhermore, many cases may be overlooked because marked, clinically significant deficits in basic auditory functions are observed only in patients who have sustained bilateral temporal lobe damage. Hence, results of psychophysical testing in the chronic state may not provide a comprehensive picture of the functional significance of regions of auditory cortex affected by a lesion.

With these caveats, it is clear that apart from speech function, which strongly lateralizes to one (usually the left) hemisphere, basic auditory functions are subserved by both hemispheres. However, there does appear to be a degree of lateralization of musical processing to the right hemisphere. Bilateral lesions approximately confined to the core auditory areas are reported to result in transient auditory agnosia, which is a lack of awareness of auditory stimuli combined with abnormal pure tone thresholds in the absence of peripheral or brain stem damage (sometimes referred to as cortical deafness). With time, this condition may evolve into auditory agnosia for speech (pure word deafness), whereby patients regain near normal auditory acuity but remain impaired in their ability to interpret speech sounds. It is hypothesized that speech decoding requires more precise temporal analysis than is necessary for the detection and identification of most nonverbal sounds. This capacity to represent auditory stimuli with a high degree of temporal resolution is dependent on having intact core auditory cortex in at least one hemisphere. Conversely, the core regions can be destroyed, but recognition of nonspeech sounds can remain intact, presumably mediated by surrounding auditory cortical fields that are functionally activated via parallel thalamic afferent inputs that do not synapse, or course through, the auditory core region. Anecdotal observations of localization ability in patients with temporal lobe lesions have suggested repeatedly that humans and nonhuman species suffer impairment in sound-localization ability. Recent and carefully controlled experiments indicate that such impairment is less marked than previously believed.

A small number of patients who have bilateral temporal lobe lesions that spare at least one core region while destroying portions of the middle and anterior regions of the superior temporal gyri (but not Wernicke's speech area) display a strikingly different pattern of auditory impairment than those with bilateral core lesions. Receptive speech function is preserved but there is a marked dysfunction of musical processing and of recognition of nonverbal auditory stimuli. It seems clear that lesions of auditory association cortex that spare core auditory regions are sufficient to impair melody discrimination and the perception of speech prosody. The existence of cases in which each one of these categories of nonverbal auditory processing is selectively impaired suggests that different subregions of auditory association cortex may serve a specialized role in representing different attributes of nonverbal auditory stimuli. It is not clear how these subregions, whose existence is implied by lesion study results, might correlate with cytoarchitectural or electrophysiologic findings in humans.

4. Functional Studies of the Human Central Auditory System

Studies of the neural mechanisms underlying hearing in humans have, with few exceptions, necessarily involved noninvasive and hence indirect methods of measurement of functional brain activity, including EEG, MEG, PET, and fMRI. These methods have proved to be most effective when used in complementary ways.

a. Electrophysiological Measures: EEG and MEG An electrode placed on the scalp records the summated electrical potentials generated by large groups of neurons in the brain. These neuronal assemblies at each station along the auditory pathway fire sychronously and in sequential order in response to a brief and abrupt acoustic stimulus. This orderly

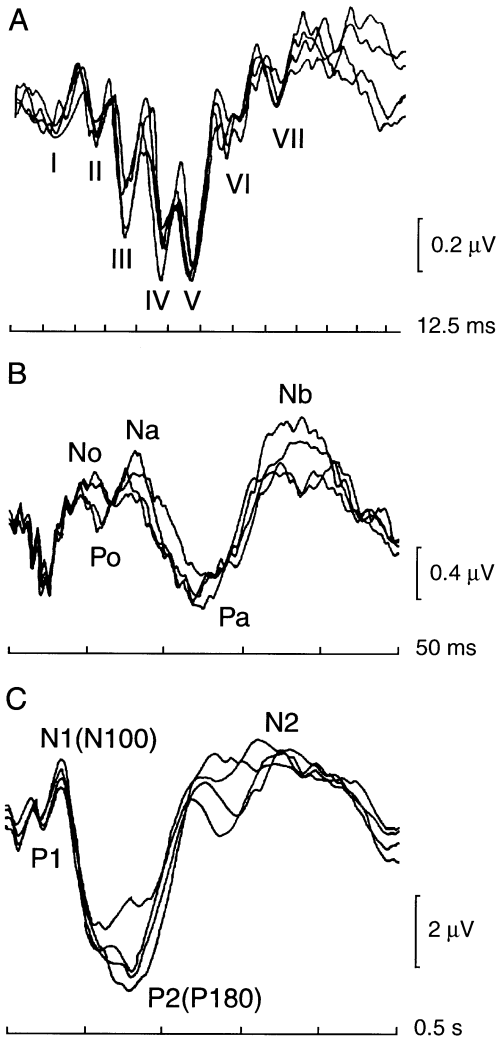

Figure 7 Auditory event-related potentials (ERPs) recorded from the scalp of a human subject in response to the presentation of brief sounds. The ERP is divided into three epochs: a short latency auditory brain stem response (ABR) (A), a middle latency response (MLR) (B), and a late, long-latency response (C) (adapted with permission from Picton, T.W., *et al.*, *EEG Clin Neurophysiol.* **36,** 179–190, 1974).

firing pattern is reflected in the sequence of peaks and valleys that make up the resulting evoked potential waveform, referred to as the event-related potential (ERP). The ERP typically is of very low amplitude and usually indistinguishable from the ongoing EEG. Thus, in practice, averaging the responses to hundreds or thousands of stimulus presentations is needed to reveal the ERP temporal waveform. The ERP is traditionally divided into three time epochs (Fig. 7). The seven waves arising during the first 10–15 msec (Fig. 7A) after stimulus onset constitute the averaged brain stem response (ABR). Intraoperative recording from the human auditory nerve, cochlear nuclei, and inferior colliculi has provided the most compelling evidence that waves I and II are generated by the auditory nerve, wave III by the cochlear nuclei, and wave IV by the SOC. Wave V probably originates in or below the inferior colliculus, whereas waves VI and VII originate in the ICC or thalamocortical projection system. Thus, the temporal waveform of the ERP, its spatial distribution on the scalp, and its sensitivity to various acoustic parameters can provide information about the transmission and encoding properties of large neuronal assemblies at all levels of the central auditory pathway. The ABR is highly stable under a wide range of conditions, including various stages of consciousness, attention, sleep, wakefulness, and sedation. It is present at birth and mature by approximately 18 months. Today, it is used routinely to screen for hearing impairment in newborn babies. Overall, the ABR has proven to be a very useful noninvasive and objective way to test for hearing impairment and other disorders of the peripheral and central auditory pathways, especially in those subjects who are unwilling or unable to participate.

A cluster of three major wave peaks with onset latency beyond the ABR components (out to about 50–60 msec) are widely recorded over the frontal and temporal cortex and referred to as the middle latency response (MLR; Fig. 7B). The generation of the MLR may involve the interaction of many brain structures within and outside of the classic lemniscal auditory pathways. Lesions of auditory cortex in humans and animals disrupt MLR waveforms. MLR is influenced by the state of arousal of a subject, suggesting involvement of the reticular formation. The MLR is used clinically to assess hearing thresholds in the low-frequency range and to evaluate auditory pathway function in hearing individuals and in subjects who have cochlear implants.

When trains of brief stimuli are presented the MLR components become time locked to the individual stimuli at frequencies of approximately 40 Hz. This 40-Hz response to the appropriate stimulus is exhibited by other sensory systems as well, indicating that it represents a general mechanism for recognizing a sensory event. Spontaneous electrical oscillation in the human brain at frequencies of approximately 40 Hz and its resetting by a sensory stimulus have been postulated to reflect cortical mechanisms involved in temporal binding of sensory stimuli and perceptual scene segregation.

Finally, a series of peaks and valleys is recorded with latencies exceeding 50 msec (Fig. 7C). The amplitudes of the waves are higher but more variable than earlier ones, depending on the conscious state of the subject and the stimulus paradigm employed to evoke the waveform. This has led to the suggestion that the late components represent the convergence of input from a number of forebrain systems whose interactions are related to the attentive or cognitive state of the subject.

The currents that give rise to the electrical voltage recorded on the scalp also give rise to weak magnetic fields. These weak fields can be measured by an array of sensitive magnetometers (superconducting quantum interference devices) surrounding the head. The method is known as MEG, and the response to a sound is referred to as the auditory-evoked magnetic field (AEF) (Fig. 8). AEF data reveal many of the same cortical processes as the ERP. Both methods yield similar waveforms with excellent response times capable of tracking with high fidelity neural events in time. In addition, the MEG offers relatively high spatial resolution, on the order of millimeters. Because of its differential sensitivity to currents flowing tangentially to the scalp, the MEG is particularly suited for noninvasive study of the cortex buried within fissures, including auditory cortex within the Sylvian fissure on the superior temporal plane. Because any electrical potential or magnetic signal may have more than one source in the brain (the so-called inverse problem), a source model is applied in which the orientation, strength, and location of the equivalent current dipoles are best accounted for on statistical grounds.

The ERP and AEF methods have been used effectively to study the neural activity associated with

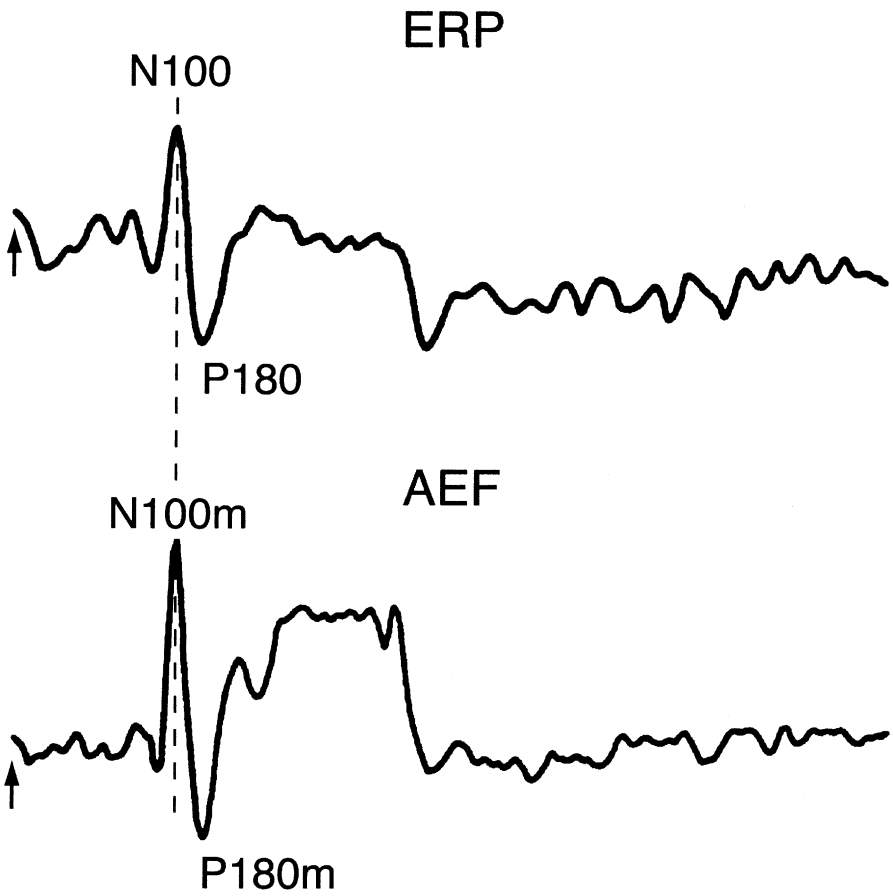

Figure 8 Electromagnetic waves generated by the cortex and recorded on or near the head in response to an acoustic stimulus. Event-related potential (ERP) represents electrical potentials recorded with an electrode in contact with the scalp. The auditory-evoked magnetic field (AEF) is the magnetic field recorded from a detector very near the head. The major component is a middle latency response because it occurs approximately 100 msec after stimulus onset (adapted with permission from Hari, R., *Adv. Audiol.* **6,** 222–282, 1990).

attentional and cognitive processes. Figure 9 (top) shows an example of the ERP obtained when a subject heard the same sound repeatedly and then when a rare, or odd-ball, stimulus was introduced at random times. The major changes associated with the waveform occurred relatively late, after about 200 msec. Similarly, the AES waveforms (Fig. 9, bottom) were obtained under conditions in which the subject was awake but reading and when the subject was attending to the stimulus. Like the ERP, the late components are the ones most affected by this difference in state of attention. These late components are thought to reflect the processing of auditory stimuli.

b. Functional Imaging: PET and fMRI In recent years, the use of noninvasive functional imaging techniques—fMRI and PET—has provided a wealth of new information concerning the location and extent of regions of the human brain that are metabolically activated by acoustic stimulation. Both methods provide indirect evidence of neuronal activation based on the facts that when neurons become more active they require more oxygen and glucose and that this increased demand is met by a compensatory increase in regional cerebral blood flow. Using these indirect imaging methods, investigators have noted that broad regions of the supratemporal plane and lateral superior temporal gyrus are bilaterally activated by a wide

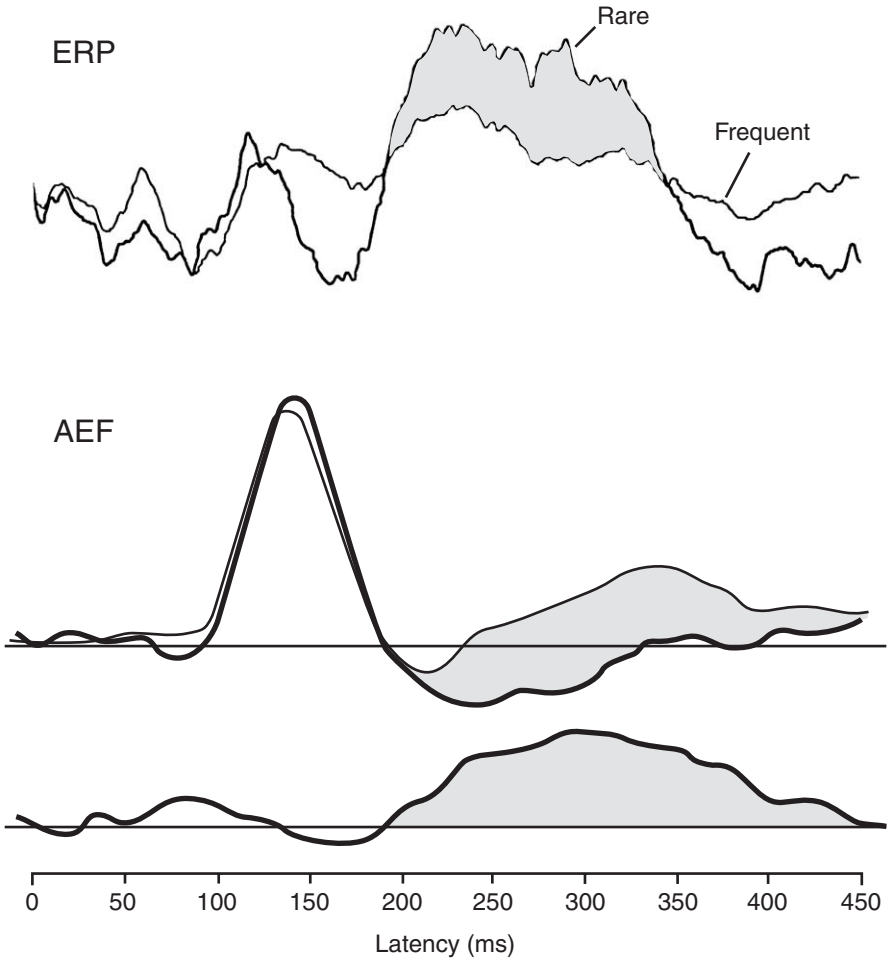

Figure 9 Sound-evoked event-related potential (ERP) and AEF are sensitive to unexpected changes in the sound and to shifts of the listener's attention. (Top) ERPs obtained when the same sound was repeated many times (frequent) and when that stream of repeated sound was interrupted occasionally by a different (rare) sound [adapted with permission from Kraus, N., and McGee, T., *The Mammalian Auditory Pathway*: Neuroanatomy (A. N. Popper and R. R. Fay Eds.). Springer-Verlag, New York, 1992]. (Bottom) The auditory-evoked magnetic field (AEF) obtained when listener attended (counting stimuli) or did not attend (reading) to the stimulus (adapted with permission from Hari, R., *Adv. Audiol*. **6,** 222–282, 1990). The main effect of both activities was seen in the late waves, beyond the 100-msec component.

range of acoustic stimuli, including speech sounds. Tones of different frequency induce localized changes in blood flow within subregions of HG, indicating a tonotopic organization, with higher frequency tones activating the more posterior–medial portion of HG. More complex tasks have been used in conjunction with fMRI to search for evidence of regional functional specialization within auditory cortex. Results from these investigations indicate that the right temporal lobe may play a more important role in the processing of musical stimuli (e.g., pitch and rhythmic temporal patterns) than the left. There have also been reports suggesting functional specialization of right-sided temporal (and parietal) lobe regions in processing information concerning the movement of sound sources. Both fMRI and PET methods have been used extensively to map patterns of cortical activation during speech sound processing.

Inherent limitations of these methods have prevented direct extrapolation of data obtained with these methods to results obtained in nonhuman primates using microelectrode recording techniques. In the future, however, the spatial resolution of fMRI may improve to the extent that the functional organization of human auditory cortex can be studied in far greater detail. Because activity-induced changes in blood flow patterns occur over a period of seconds, it is unlikely that fMRI techniques alone will be capable of delineating the fine temporal patterns of activity that characterize coding and processing of information at the level of auditory cortex.

c. Direct Recording (ECoG) and Stimulation of Auditory Structures in Human Direct electrical-stimulation mapping of the cortex during surgery to relieve medically intractable epilepsy or to remove a tumor is commonly carried out as a way of guiding the surgeon's decision on the location and extent of brain tissue to excise. When the primary auditory field on HG is stimulated, patients report hearing sounds, which are often referred to the ear contralateral to the stimulated cortex. Stimulation of the belt of cortex surrounding the primary field may result in the perception of more complex sounds, although it is now thought that some of this—especially the so-called experiential hallucinations—may be the result of spread of stimulus current to underlying limbic structures. In the caudal region of the superior temporal gyrus (Wernicke's area), and on the angular and supramarginal gyri electrical stimulation may result in the arrest of speech, which is similar to the results of stimulation of the classic Broca's area on the inferior frontal gyrus.

Direct recording from the human auditory cortex has also been carried out in neurosurgical patients both acutely in the operating room and chronically under more controlled experimental conditions. This recording is referred to as the ECoG to differentiate it from the scalp recorded EEG. Results from these experiments show acoustically evoked activity on the superior temporal plane and the lateral surface of the superior temporal gyrus. A field on HG is distinguished from a field on superior temporal cortex based on the HG tonotopic map and the properties of acoustically evoked potentials. Thus, cytoarchitectonic, electrophysiologic, and functional imaging data leave little doubt that the cortex on mesial HG is the primary auditory field of the human and the homolog of AI in nonhuman primates and other mammals. The cortex of the lateral surface of the superior temporal gyrus represents one or more separate auditory fields. Intraoperative electrophysiological studies show that single neurons in this cortex respond vigorously to complex sound, including speech—a finding similar to that in the rhesus monkey.

GLOSSARY

algorithm A strategy for solving a problem that guarantees solution in a finite number of steps if the problem has at least one solution. An example of a very simple algorithm is that for obtaining temperature on the Fahrenheit scale when the value for the centigrade scale is known: Multiply the known value by 1.8 and add 32.

bounded rationality Principles underlying nonoptimizing adaptive behavior of real information processing systems working under conditions of limited time, information, and computational capacities. Among those principles specified by Herbert Simon is satisficing.

cognitive illusions or biases Systematic deviations of human judgments from rules of probability theory and logic. The occurrence of cognitive illusions is attributed to some judgment heuristics that are often useful but sometimes lead to predictable errors.

heuristic An approximate strategy or "rule of thumb" for problem solving and decision making that does not guarantee a correct solution but that typically yields a reasonable solution quickly or brings one closer to hand.

noncompensatory heuristic A heuristic is noncompensatory if, once it has used a piece of information to make a decision, no further information in any combination can undo or compensate for the effect of the original information. In contrast, a heuristic is compensatory if there is at least one piece of information that can be outweighed by other pieces of information. A compensatory strategy integrates at least some of the available information and makes trade-offs between the relevant pieces of information to form an overall evaluation of each of the available alternatives or options.

satisficing According to Herbert Simon, satisficing is using experience to construct an expectation (or aspiration level) of a reasonable solution to some problem and stopping the search for solutions as soon as one is found that meets the expectation.

unbounded rationality Decision-making strategies that have no regard for constraints of time, knowledge, or computational capacities. Modern mainstream economic theory is largely based on unbounded rationality models that portray economic agents as fully rational Bayesian maximizers of subjective utility.

Many decisions faced by people cannot be made in an optimal way because optimal solutions may take too much computation to find or may not even exist. Instead, real decision makers must often take shortcuts and use heuristics that yield reasonable solutions in a reasonable amount of time, even if they do not guarantee always reaching a good decision. These heuristics are thus an essential aspect of human intelligence, leading to adaptive behavior despite the challenging conditions of limited time, knowledge, and computational capacity under which people have to solve problems. Heuristics are most commonly studied in psychology, particularly within the domains of judgment and decision making, and in computer-based applications in artificial intelligence and operations research. This article focuses on research in psychology that has proposed heuristic models of how people search for information and make decisions and choices.

I. A SHORT HISTORY OF THE CONCEPT "HEURISTIC"

Recent research on decision heuristics descends from earlier schools of thought. For this reason, understanding current thought can be aided by first considering the history of the concept. In 1905, the 26-year-old Albert Einstein published his first fundamental paper in quantum physics, titled "On a Heuristic Point of View Concerning the Production and Transformation of Light." In that Nobel prize-winning paper, Einstein used the term heuristic to indicate that he considered the view he presented therein as incomplete, even false, but still useful. Einstein could not wholeheartedly accept the quantum view of light that he started to develop in this paper, but he believed that it was of great transitory use on the way to building a more correct theory. As used by Einstein, a heuristic (a term of Greek origin meaning "serving to find out or discover") is an approach to a problem that is necessarily incomplete given the knowledge available, and hence unavoidably false, but that is useful nonetheless for guiding thinking in appropriate directions.

A few decades later, Max Wertheimer (a close friend of Einstein's), Karl Duncker, and other Gestalt psychologists spoke of heuristic reasoning, but with a slightly different meaning from that of Einstein. Gestalt psychologists conceptualized thinking as an interaction between inner mental processes and external problem structure. In this view, heuristic methods such as "looking around" and "inspecting the problem" are first used to guide the search for appropriate information in the environment, which is then restructured or reformulated by inner processes.

Heuristic methods also play a prominent role in George Pólya's approach to mathematical problem solving. According to the Hungarian mathematician, effective problem solving consists of four main phases—understanding the problem, devising a plan, carrying out the plan, and looking back—all of which can incorporate heuristics. Devising a plan, for instance, can include heuristic methods such as "examine a simpler or special case of the problem to gain insight into the solution of the original problem," "work backward," or "identify a subgoal."

In the 1950s and 1960s, Herbert Simon and Allen Newell started to develop heuristics for searching for solutions to problems. They replaced the somewhat vague notion of heuristic reasoning of the Gestalt school and of Pólya's with much more precise computer-based models (e.g., in the General Problem Solver system) of human problem solving and reasoning largely based on the means–ends analysis heuristic. This heuristic found some way to reduce the distance between the current state and the goal state. With the advent of information processing theory in cognitive psychology, a heuristic came to mean a useful shortcut, an approximation, or a rule of thumb for guiding search through a space of possible solutions, such as a strategy that a chess master uses to explore the enormous number of possible moves at each point in a game.

Such general-purpose or "weak" methods as the means–ends analysis heuristic, however, proved insufficient to deal with problems other than artificial and well-defined mathematical problems or the games of chess and cryptoarithmetic that Newell and Simon investigated. As a consequence, research in artificial intelligence (AI) in the 1970s turned to collecting domain-specific rules of thumb from specialists in a particular field and incorporating these into expert systems. At approximately the same time, mathematicians working in operations research began dealing with new results from computational complexity theory indicating that efficient algorithmic solutions to many classes of challenging combinatorial problems (such at the traveling salesman problem) might not be found; as a consequence, they too turned to the search for problem-specific heuristics, although through invention rather than behavioral observation.

In psychology after 1970, researchers became increasingly interested in how people reason about unknown or uncertain aspects of real-world environments. The research program that spurred this interest was the heuristics-and-biases program initiated by Amos Tversky and Daniel Kahneman. This program's research strategy has been to measure human decision making against various normative standards taken from probability theory and statistics. Based on this strategy two major results about people's reasoning under uncertainty emerged: a collection of violations of the normative standards (that in analogy to perceptual illusions are often called "cognitive illusions" or "biases") and explanations of these illusions in terms of a small number of cognitive heuristics. According to Kahneman and Tversky, people rely on a limited number of heuristics—most prominently representativeness, availability, and anchoring and adjustment—that often yield reasonable judgments but sometimes lead to severe and systematic biases. Diverging from earlier usage, the term heuristics now gained a different connotation: fallible cognitive shortcuts that people often use when faced with

uncertainty and that can lead to systematic biases and lapses of reasoning indicating human irrationality. This more negative view of heuristics—and of the people who use them as "cognitive misers" using little information or cognition to reach biased conclusions—has spread to many other fields, including law, economics, medical decision making, sociology, and political science.

Recently, however, a new appreciation is emerging that heuristics may be the only available approach to decision making in the many problems for which optimal logical solutions do not exist (as researchers in operations research realized). Moreover, even when exact solutions do exist, domain-specific decision heuristics may be more effective than domain-general logical approaches, which are often computationally infeasible (as AI found). This has led to research programs such as the study of ecological rationality by Gigerenzer, Todd, and colleagues. Their program focuses on precisely specified computational models of heuristics and how they are matched to the ecological structure of particular decision environments. It also explores the ways that learning and evolution can achieve this match in human behavior, something that has already been widely accepted for other animals in research on rules of thumb in behavioral ecology.

In the following sections, the focus is on research in psychology exploring heuristics proposed to model how people search for information and make decisions and choices. Researchers such as Payne, Bettman, and Johnson and Svenson have been concerned with psychological heuristics for preferences, but here we are mostly concerned with inference heuristics. Heuristics and shortcuts are also important in human perception and higher order reasoning processes (e.g., hypothesis testing), planning and problem solving, as well as in computer applications in these domains.

II. UNBOUNDED RATIONALITY VERSUS THE BOUNDED REALITY OF HUMAN DECISION MAKING

Both the heuristics-and-biases program and the recently emerging work on ecologically rational heuristics have been linked to Herbert Simon's notion of bounded rationality. This concept can be understood by contrasting it to the traditional decision-making approach embodied in unbounded rationality, illustrated by the following example. Imagine being faced with the decision of whether or not to marry. How can this decision be made in a rational way? Assume that you attempted to resolve this question by maximizing your subjective expected utility. To compute your personal expected utility for marrying, you would have to determine all the possible consequences that marriage could bring (e.g., children, companionship, and countless further consequences), attach quantitative probabilities to each of these consequences, estimate the subjective utility of each, multiply each utility by its associated probability, and finally add all these numbers. The same procedure would have to be repeated for the alternative "not marry." Finally, you would have to choose the alternative with the higher total expected utility.

Maximization of expected utility in this way is probably the best known realization of the prominent vision of unbounded rationality. Models of unbounded rationality have been criticized for having little or no regard for the constraints of time, knowledge, and computational capacities that real humans face. For instance, while you are deliberating about whether marrying is the right choice, considering each of the myriad conceivable consequences and assigning probabilities to each, any potential partner will probably have married someone else. To this criticism proponents of unbounded rationality generally concede that their models assume unrealistic mental abilities, but they nevertheless defend them by arguing that humans act as if they were unboundedly rational. In this interpretation, the models of unbounded rationality do not describe the process but merely the outcome of reasoning.

If the lofty ideals of human reasoning do not capture the processes of how real people make decisions in the real world, what then are those processes? In other words, what models take into account the challenging conditions under which people have to solve problems, including limited time, knowledge, and computational capacity? Herbert Simon proposed that these constraints force humans to use "approximate methods" (heuristics) to handle most tasks. These approximate methods form the basis of bounded rationality.

Simon's vision of bounded rationality has two interlocking components that act like a pair of scissors to shape human rational behavior. The two blades in this metaphor are the computational capabilities of the actor and the structure of task environments. First, the computational capability blade implies that models of human judgment and decision making should be built on what we actually know about the mind's limitations

rather than on fictitious competencies assumed in models of unbounded rationality. There are two key limitations central to bounded rationality. First, contrary to models of unbounded rationality, humans cannot search for information for all of eternity. In computationally realistic models, search must be limited because real decision makers have only a finite amount of time, knowledge, attention, or money to apply to a particular decision. Limited search requires rules to specify what information to seek and in what order (i.e., an information search rule) and a way to decide when to stop looking for information (i.e., a stopping rule).

Another key limitation of the human mind is that the pieces of information uncovered by the search process are not likely to be processed in an overly complex way. In contrast, most traditional models of inference, from linear multiple regression models to Bayesian models to neural networks, try to find some optimal integration of all information available: Every bit of information is taken into account, weighted, and combined in some more or less computationally expensive way. Models of bounded rationality instead rely on processing steps that are computationally bounded. For instance, a bounded decision or inference can be based on only one or a few pieces of information, whatever the total amount of information found during search. The simple decision rule used to process this limited knowledge need not weigh or combine pieces of information, thus eliminating the need to convert different types of information into a single common currency (e.g., utilities). Note that decision rules and information search and stopping rules are connected. For instance, when a heuristic searches for only one (discriminating) cue, this largely constrains the possible decision rules to those that do not integrate information. On the other hand, if search extends to many cues, the decision rule will be less constrained. The cues may then be weighted and integrated, or only the best of them may determine the decision.

These two key limitations, limited information search and limited processing of information, can be instantiated into models of heuristics. The limitations help explain how heuristics achieve one of their most important advantages, namely, speed. In fact, for much decision making in the real world—the stock broker who decides within seconds to keep or sell a stock, or the captain of the firefighter squad who within a few moments must predict how a fire will progress and whether or not to pull out the squad—speed is often the crucial objective.

The second blade in Simon's scissors metaphor, operating in tandem with computational capability, is environmental structure. This blade is of crucial importance in shaping bounded rationality because it can explain when and why heuristics perform well, namely, if the structure of the heuristic is adapted to the structure of the environment (i.e., if the heuristic is ecologically, rather than logically, rational). Simon's classic example concerns foraging organisms that have a single need—food. An organism living in an environment in which little heaps of food are randomly distributed can survive with a simple heuristic: Run around randomly until a heap of food is found. For this, the organism needs some capacity for movement, but it does not need a capacity for inference or learning. For an organism in an environment in which food is distributed not randomly but in patches whose locations can be inferred from cues, more sophisticated strategies are possible. For instance, it could learn the association between cues and food and store this information in memory. The general point is that in order to understand which heuristic an organism employs, and when and why the heuristic works well, one needs to examing the structure of the information in the environment.

III. HEURISTICS FOR HUMAN JUDGMENT, CHOICE, AND SEARCH BEHAVIOR

The models of heuristics for human judgment, choice, and decision making that have been proposed in psychology since 1970 can be linked to two traditions of heuristics with earlier beginnings as described previously. These two traditions have employed different levels of description. First, following the line of the heuristic methods studied by the Gestalt psychologists, one class of heuristics consists of psychological principles that are verbally described. These models are only relatively loosely specified and usually do not explicate all the processes they involve (e.g., in terms of information search, stopping, and decision rules). Second, following from Simon and Newell's computer-based models of human decision making, another class of heuristics has been formulated as process models, with explicit specification of the processes involved. Because of this explication, the latter heuristics can be both mathematically analyzed and tested with the help of computer simulations. We consider each class of heuristics in turn.

A. Heuristics for the Judgment of Probability and Frequencies: Availability, Representativeness, and Anchoring and Adjustment

The heuristics most widely studied within psychology are those that people use to make judgments or estimates of probabilities and frequencies in situations of uncertainty (i.e., in situations in which people lack exact knowledge). Most prominent among these are the availability, representativeness, and anchoring and adjustment heuristics.

The availability heuristic leads one to assess the frequency of a class or the probability of an event by the number of instances or occurrences that can be brought to mind or by how easy it seems to call up those instances. For instance, which class of words is more common: seven-letter English words of the form "_ _ _ _ _ n _" or the form "_ _ _ _ i n g"? According to the availability heuristic, to estimate the frequency of occurrences people draw a sample of the events in question from memory. Specifically, for this case they retrieve words ending in –ing (e.g., "jumping") and retrieve words with "n" in the sixth position (e.g., "raisins") and then count the number of words retrieved in some period or assess the ease with which such words could be retrieved. They then answer that the more numerous or easier class of words is more common. Because people find it easier to think of words ending with –ing than to think of words with the letter "n" in the next-to-last position, they usually estimate the class "_ _ _ _ i n g" to be more common. This judgment, however, is wrong because all words ending with –ing also have "n" in the sixth position; in addition, there are seven-letter words with "n" the sixth position that do not end in –ing.

The availability heuristic has been suggested to underlie diverse judgment errors, ranging from the tendency to overestimate how many people die from some specific causes of death (e.g., tornado) and underestimate the death toll of others causes (e.g., diabetes) to why people's answers to life satisfaction questions ("How happy are you?") may be overly influenced by events that are especially memorable.

The representativeness heuristic has been proposed as a means to assess the probability that an object A belongs to a class B (e.g., that a person described as meek is a pilot) or that an event A is generated by a process B (e.g., that the sequence HTHTHT was generated by randomly throwing a fair coin). This heuristic produces probability judgments according to the extent that object A is representative of or similar to the class or process B (e.g., meekness is not representative of pilots, so a meek person is judged as having a low probability of being a pilot). This heuristic can lead to errors because similarity or representativeness judgments are not always influenced by factors that should affect judgments of probability, such as base rates. The representativeness heuristic has also been evoked to explain numerous judgment phenomena, including "hot hand" observations in basketball (the belief that a player is more likely to score again after he or she already scored successfully than after missing a shot) and the gambler's fallacy (the belief that a successful outcome is due after a run of bad luck).

Another heuristic, anchoring and adjustment, produces estimates of quantities by starting with a particular value (the anchor) and adjusting upward or downward from it. For instance, people asked to quickly estimate the product of either $8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1$ or $1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8$ give a higher value in the former case. According to the anchoring and adjustment heuristic, this happens because the first few numbers presented are multiplied together to create a higher or lower anchor, which is then adjusted upwards in both cases, yielding a higher final estimate for the first product.

Although it has been pointed out that availability, representativeness, and anchoring and adjustment are quite useful heuristics (because they often lead to good judgments without much time or mental effort), most of the large body of evidence amassed that is consistent with the use of these heuristics comes from studies showing where they break down and lead to cognitive illusions or biases (i.e., deviations from some normative standards). This heuristics-and-biases research program has caught the attention of numerous social scientists, including economists and legal scholars. There are good reasons for this attention, since systematic biases question the empirical validity of classic rational choice models (i.e., models of unbounded rationality) and may have important economic, legal, and other implications.

However, the exclusive focus on cognitive illusions has evoked the criticism that research in the heuristics-and-biases tradition equates the notion of bounded rationality with human irrationality and portrays the human mind in an overly negative light, with some researchers even arguing that cognitive illusions are the rule rather than the exception. It has also been criticized that, to date, the cognitive heuristics posited have not been precisely formalized such that one could either simulate or mathematically analyze their

behavior, leaving them free to account for all kinds of experimental performance in a post hoc fashion. For instance, it is still an open question of how people assess similarity to make probability judgments with the representativeness heuristic or how many items (e.g., words ending with –ing) the availability heuristic retrieves before it affords a frequency estimate of a class of object (albeit theoretical progress has been made, for instance, by testing whether availability works in terms of ease of recall or number of items recalled). Moreover, the heuristics-and-biases program focuses on human computational capabilities (the first blade of Simon's scissors), largely ignoring the role of the environment by not specifying how such heuristics capitalize on information structure to make inferences. Finally, this program appears to consider heuristics as dispensable mechanisms (that would not be needed if people had the right tools of probability and logic to call on), in contrast to Simon's view of indispensable heuristics as the only available tools for solving many real-world problems.

Kahneman and Tversky have countered some of this critique by drawing a parallel between their heuristic principles and the qualitative principles of Gestalt psychology—the latter being still valuable despite not being precisely specified. Irrespective of the various criticisms, the heuristic and biases program has undoubtedly led to a tremendous amount of research into the idea that people rely on cognitive heuristics made up of simple psychological processes rather than on complex procedures to make inferences about an uncertain world. As a result, this insight has been firmly established as a central topic of psychology.

B. Fast and Frugal Choice Heuristics

More precisely specified models of heuristics have been studied by a another research program that emerged in psychology in the 1990s. This new program considers fast and frugal heuristics for making decisions as the way the human mind can take advantage of the structure of information in the environment to arrive at reasonable decisions. Thus, it focuses on how mental capabilities and structured environments together can lead to accurate and useful inferences rather than focusing on the cases in which heuristics may account for poor reasoning. Most of the fast and frugal heuristics that Gigerenzer, Todd, and colleagues have proposed model the way humans make choices rather than probability judgments (a few others deal with additional tasks, such as estimation and classification).

Many of the choices humans make involve an inference or prediction about which of two objects will score higher on a criterion: Which soccer team will win? Which of two cities has a higher crime rate or higher cost of living? Which of two applicants will do a better job? When making such choices, we may have different amounts of information available. In the most limited case, if the only information available is whether or not each option has been encountered before, the decision maker can do little better than rely on his or her own partial ignorance, for instance, choosing recognized options over unrecognized ones. This may not sound like much for a decision maker to go on, but there is often information implicit in the failure to recognize something, and this failure can be exploited.

This kind of "ignorance-based" decision making is embodied in the recognition heuristic. This heuristic states that, when choosing between two objects (according to some criterion), if one is recognized and the other is not, then select the former. For instance, if predicting whether Manchester United or Bayer Leverkusen will win the European Soccer Champions League, this heuristic would lead most of us to bet on Manchester United. Why? European soccer teams are often named after European cities (e.g., Arsenal London or AC Milano), and people who are ignorant of the quality of European soccer teams can still use city recognition as a cue for soccer team performance. Cities with successful soccer teams are likely to be large, and large cities are likely to be recognized; hence, Manchester, which is more than two times as large as Leverkusen, is also more likely to be recognized and thus chosen as the winner.

The recognition heuristic will yield good choices more often than would random choice in those decision environments in which exposure to different possibilities is positively correlated with their ranking along the decision criterion being used. Animals also behave as if they apply similar rules: Norway rats, for instance, prefer to eat things they recognize through past experience with other rats (e.g., items they have smelled on the breath of others) over novel items.

Employing the recognition heuristic can lead to a surprising phenomenon called the less-is-more effect. This is the analytical and empirical observation that an intermediate amount of (recognition) knowledge about a set of objects can yield the highest proportion of correct answers—knowing (i.e., recognizing) more than this will actually decrease the decision-making performance. A context in which this effect appears in the reasoning of people is judgments about

demographics. When American students were asked to pick the larger of two cities, they scored a median 71% correct inferences when city pairs were randomly constructed from the 22 largest U.S. cities and 73% when city pairs were from the 22 largest cities in Germany. The result is counterintuitive when viewed from the premise that more knowledge is always better: The students knew a lifetime of facts about U.S. cities that could be useful for inferring population, but they knew little or nothing beyond mere recognition about the German cities—and they did not even recognize about half of them. The latter fact, however, allowed them to employ the recognition heuristic and to pick German cities that they recognized as larger than those they did not. This heuristic could not be applied for choosing between U.S. cities, however, because the students recognized all of them and thus had to rely on additional retrievable information.

In choosing one of two options, most of the time we have more information than just a vague memory of recognition to go on. The situation of American students comparing American cities is just one example. When multiple pieces of information (or "cues") are available for guiding decisions, how can a heuristic that limits search and processing of information proceed? A decision maker following the dictums of unbounded rationality would collect all the available information, weight it appropriately, and combine it optimally before making a choice. A more frugal approach is to use a stopping rule that terminates the search for information as soon as enough has been gathered to make a decision. One such approach is to rely on "one-reason decision making": Stop looking for cues as soon as one is found that differentiates between the two options being considered. This allows the decision maker to follow a simple loop, depicted in Fig. 1: (i) Select a cue dimension; (ii) search for the corresponding cue values of each alternative; (iii) if they differ, then stop and choose the alternative for which the cue indicates a greater value on the choice criterion; (iv) if they do not differ, then return to the beginning of this loop to search for another cue dimension.

This four-step loop specifies a stopping rule (stopping after a single cue is found that enables a choice between the two options) and a decision rule (deciding on the option to which the one cue points). Depending on how cue dimensions are searched for in the first step, (i.e., depending on what kind of specific information search rule the heuristic uses), different one-reason decision-making heuristics can be formed. The Take The Best heuristic searches for cues in the order of their ecological validity (i.e., their correlation with the decision criterion). Take The Last searches for cues in the order determined by their past success so that the cue that was used for the most recent previous decision is checked first during the next decision. Finally, the Minimalist heuristic selects cues in a random order.

For example, consider the task of inferring which of two cities in the United States has a higher homelessness rate. Assume that possible cues are "rent control," "temperature," "unemployment," and "public housing," each turned into a binary value (0 or 1) according to whether the actual value is below or above the median for U.S. cities. Rent control has the highest ecological validity, temperature has the second highest, and so on. The Minimalist heuristic only needs to know in which direction a cue "points." For instance, the heuristic needs to know only whether warmer or cooler weather indicates a city with a higher rate of homelessness (in the United States, warmer weather is indeed associated more often with higher homelessness rates than with lower rates). The strategy of Minimalist is to search for cues in random order,

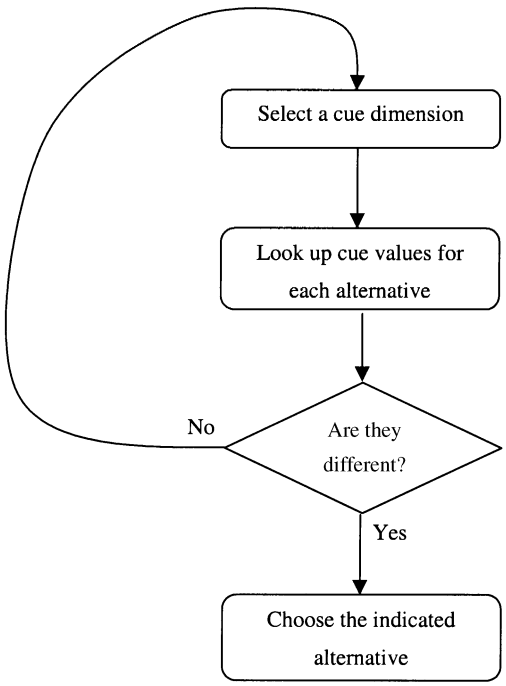

Figure 1 A flowchart of one-reason decision making. First, select a cue dimension and ascertain the corresponding cue values for each alternative; next, check whether the values for that cue discriminate between the alternatives. If so, then choose the indicated alternative; if not, select another cue dimension and repeat this process. Random choice can be used if no more cues are available.

stop cue search when a cue is found that discriminates between the two cities, and then choose the city that has the cue value 1 when the other city has cue value 0. For instance, when inferring whether New York or Los Angeles has a higher homelessness rate, the unemployment cue might be the first cue randomly selected, and the cue values are found to be 1 for both cities. Because this cue does not discriminate between the cities, search is continued, the public housing cue is randomly selected, and the cues values are 0 for New York and 1 for Los Angeles. Search is stopped at this discriminating cue and the inference is made that Los Angeles has a higher homelessness rate, as it indeed does.

The Take The Best heuristic is exactly like Minimalist except that it considers cues in order of their validity from highest to lowest. If the highest validity cue does not discriminate, the next best cue is tried, and so forth. Thus, Take The Best differs from Minimalist only in the information search rule, but it has the same stopping and decision rule. Take The Best (unlike the Minimalist, Take The Last, and recognition heuristics) is an instance of the class of lexicographic decision strategies. This term signifies that the cues are looked up in a fixed order of validity, and the first cue where choices differ is used alone to make the decision, like the alphabetic order used to arrange words in a dictionary. The Arabic number system is also lexicographic. To determine which of two numbers with equal digit length is larger, one has to start by examining the first (leftmost) digit: If this digit is larger in one of the numbers, the whole number is larger. If they are equal, one has to examine the second digit, and so on (a simple method that is not possible for Roman numbers). There is growing empirical evidence that people actually use lexicographic heuristics such as Take The Best, particularly when time is limited.

How well do these one-reason decision heuristics perform? Table I compares the performance of three fast and frugal heuristics (Minimalist, Take The Best, and Take The Last) to that of multiple regression and Dawes's and Franklin's rule. Unlike the heuristics, multiple regression is a computationally expensive linear strategy that calculates weights that reflect the covariances between predictors or cues. When the task is merely fitting the given data set, multiple regression is the most accurate strategy, by two percentage points, followed by Take The Best. However, when the task is to generalize from a training set to a test set, a simple heuristic such as Take The Best can outperform multiple regression (note that multiple regression has all the information Take The Best uses and more). The reason is that by being simple, the heuristics can avoid being too matched to any particular environment—that is, they can escape the curse of overfitting.

Table I

Performance of Three Fast and Frugal Heuristics (Take The Best, Minimalist, and Take The Last) and Three Linear Strategies (Dawes's rule, Franklin's rule, and multiple regression) Averaged across 20 Empirical Data Sets[a]

Heuristic/strategy	Frugality	Accuracy	
		Fitting (% correct)	Generalization (% correct)
Take The Best	2.4	75	71
Minimalist	2.2	69	65
Take The Last	2.1	70	65
Franklin's rule	7.7	75	71
Dawes's rule	7.7	73	69
Multiple regression	7.7	77	68

[a]The average number of predictiors available in the 20 data sets was 7.7. Frugality indicates the mean number of cues actually used by each strategy. Accuracy indicates the percentage of correct answers achieved by the heuristics and strategies when fitting data (i.e., fit a strategy to a given set of data) and when generalizing to new data (i.e., use a strategy to predict new data).

Overfitting refers to the problem of a model that is closely matched to one situation (set of data) failing to predict accurately in another similar situation (another set of data). This phenomenon can arise from assuming that every detail in a given environment is of great relevance. Consider forecasting of the U.S. presidential elections as an example. Beyond traditional variables such as incumbency and the state of the election-year economy, a plethora of additional variables have been suggested as predictors of recent U.S. presidential elections, including the voting behavior in Okanogan County (a rural stretch of north-central Washington), the rise or fall of women's hemlines, and the height of the candidates. General strategies such as multiple regression can in fact incorporate each of these and many more variables into the unlimited collection of free variables in their forecast models. As accurate as such parameter-laden forecast models may be for describing particular recent presidential elections, their accuracy in predicting other situations (e.g., earlier U.S. presidential elections or elections in other locations) may well be minimal. That is, these models can easily overfit the particular (training) data set and thereby fail to generalize to the new (testing) data set. In contrast, if a forecast model uses many

fewer parameters, for instance, just incumbency and height of the candidates (which predicted the winner of every election since World War II, except in 1976 and 2000), it is likely to avoid overfitting and thereby generalize better to new situations.

Fast and frugal heuristics (like lexicographic strategies) are noncompensatory, meaning that once they have used a single cue to make a decision no further cues in any combination can undo or compensate for that one cue's effect. When the information in the decision environment is structured in a matching noncompensatory fashion (i.e., the importance or validity of cues decreases rapidly such that each weight of a cue is larger than the sum of all weights to come, e.g., one-half, one-fourth, one-eighth, and so on), the Take The Best heuristic can exploit that structure to make correct decisions as often as compensatory rules. Take The Best also performs comparatively well when information is scarce; that is, when there are many more objects than cues to distinguish them. Further research is needed to explore what environment structures can be exploited by different fast and frugal heuristics.

C. Heuristics for Multiple Alternative Choices

Not all choices in life are presented to us as convenient pairs of alternatives, of course. Often, we must choose between several alternatives, such as which restaurant to go to, which apartment to rent, or which stocks to buy. Table II lists various decision heuristics that have been proposed in the psychological literature for choosing one out of several alternatives, where each alternative is characterized by cue (or attribute) values and where the importance of a cue is specified by its weight (or validity). This collection is not exhaustive, and it only focuses on heuristics for inference rather than preference (albeit some could be applied to preferences as well). However, the heuristics represent a wide range of different information search, stopping, and decision rules. Among the heuristics for multiple alternative choice, lexicographic (LEX), lexicographic semiorder (LEX-Semi), and elimination by aspects (EBA) are noncompensatory, whereas the rest are compensatory heuristics, integrating (at least some of) the available information and making trade-offs

Table II
Description of Various Multiple Alternative Choice Heuristics[a]

Heuristic	Description
Franklin's rule or weighted additive rule	Calculates for each alternative the sum of the cue values multiplied by the corresponding cue weights (validities) and selects the alternative with the highest score.
Dawes's rule or additive rule	Calculates for each alternative the sum of the cue values (discretized to either 1 or -1) and selects the alternative with the highest score.
Good features	Selects the alternative with the highest number of good features: a good feature is a cue value that exceeds a specified cut-off.
Weighted pros	Selects the alternative with the highest sum of weighted "pros." A cue that has a higher value for one alternative than for the others is considered a pro for this alternative. The weight of each pro is defined by the validity of the particular cue.
LEX or lexicographic	Selects the alternative with the highest cue value on the cue with the highest validity. If more than one alternative has the same highest cue value, then for these alternatives the cue with the second highest validity is considered, and so on.
LEX-Semi or lexicographic semiorder	Works like LEX, with the additional assumption of a just-noticeable difference. Pairs of alternatives with less than a just-noticeable difference between the cue values are not discriminated.
EBA or elimination by aspects	Eliminates all alternatives that do not exceed a specified value on the first cue examined. If more than one alternative remains, another cue is selected. This procedure is repeated until only one alternative is left. Each cue is selected with a probability that is proportional to its weight.
LEX-Add or lexicographic additive combination	Represents a combination of two strategies. It first uses LEX-Semi to choose two alternatives as favorites and then evaluates them by Dawes's rule and selects the one with the highest sum.

[a]Defined in terms of alternatives (options), cues (information), and weights (importance of information).

between the relevant cues to form an overall evaluation of each alternative.

Weighing and summing of all available information has been used to define rational judgment at least since the Enlightenment: The concepts of expected value and utility, Benjamin Franklin's moral algebra, and Homo economicus all rely on these two fundamental processes. The heuristics for multiple alternative choices in Table II can be seen as various shortcuts of these two processes. Dawes's rule, for instance, questions the importance of precise weighting. In the 1970s and 1980s, Robyn Dawes and colleagues showed that tallying information (cues) in terms of simple unit weights, such as $+1$ and -1, typically led to the same predictive accuracy as the "optimal weights" in multiple regression (particularly when generalizing to new data). Thus, in situations in which the task is to predict what is not yet known (rather than to fit what is already known), weighting information does not seem to matter much, as long as one gets the sign right.

On the other hand, LEX (a generalization of Take The Best), LEX-Semi, and EBA do not require summing procedures. All three heuristics use a simple form of weighting by ordering the cues, but they do not sum the cues. Gigerenzer and colleagues collected counterintuitive evidence that this simple weighting without summing (as in the Take The Best heuristic) can be as accurate and in some circumstances (e.g., generalization) even more accurate than complex decision strategies such as multiple regression.

Among the choice heuristics listed in Table II, EBA, proposed by Amos Tversky, is the most widely known elimination model in psychology. In sequential elimination choice models, one alternative is chosen from a set of possibilities by repeatedly eliminating subsets of alternatives from further consideration until only a single choice remains. One of the motivating factors in developing EBA in particular as a descriptive model of choice was that there are often many relevant cues that may be used in choosing among complex alternatives. EBA deals with this challenge by probabilistically considering successive cues (which are chosen with a probability proportional to their importance), selecting one at a time, and eliminating all the alternatives that do not possess this current cue, until a single alternative remains as the final choice. Other elimination heuristics select cues in a different manner (e.g., deterministically or based on validity) or use them to process the alternatives in other ways (e.g., in terms of thresholds rather than presence or absence).

D. Heuristics for Sequential Search

The heuristics discussed so far for choosing one option from many operate with the assumption that all the possible options (e.g., cities to choose between) are presently available to the decision maker. In many real-world choice problems, though, an agent encounters options in a sequence spread out over time. The options typically appear in random order and are drawn from a distribution with parameters that are only partially known in advance. In this case, the search for possible options, rather than just for information about those already present, becomes central.

The traditional normative approach to such problems is to search until one finds an option below a precalculated reservation price that balances the expected benefit of further search against its cost; this requires full knowledge of the search costs and the distribution of available alternatives. Heuristics that simplify the reservation price calculation (by replacing an integral with a weighted sum) can come very close to normative performance (e.g., at selecting good prices during a shopping trip to several stores). Other heuristics require less knowledge, such as "Keep searching until the total search cost exceeds 7.5% of the best price found." Herbert Simon's bounded rationality principle of satisficing suggests setting an aspiration level equal to an alternative that is good enough for the decision maker's needs (rather than optimal) and searching until that aspiration is met. Exactly how the aspiration level can be set varies with the search setting (e.g., whether it is a one-sided search such as shopping or a two-sided mutual search such as finding a mate). Finally, another type of search heuristic that people use stops search after a particular pattern of alternatives is encountered rather than after some threshold is exceeded (despite the fact that pattern should not matter from a normative perspective). For instance, the "one-bounce" and "two-bounce" rules state that one should keep searching for a low price until prices go up for the last or two last alternatives, respectively.

E. Social Decision Heuristics

Decision-making mechanisms can exploit the structure of information in the environment to arrive at better outcomes. The most important aspects of an agent's environment are often created by the other agents with which it interacts. Two of the key problems social agents face are the questions of how to (fairly)

divide up resources among one another and how to make cooperative decisions in situations in which the pursuit of self-interest by each agent would lead to a poor outcome for all. We consider each of these problems in turn.

The task of fairly dividing up resources is ubiquitous, ranging from distributing a cake among siblings to dividing an estate among heirs and splitting a fixed budget among a group of faculty members at an academic institution. Although there are a plethora of fair-division procedures, Brams and Taylor classified them according to a few dimensions, such as the number of players to which they are applicable (n=2, 3, 4, or more), the properties they satisfy (e.g., proportionality, envy-freeness, and efficiency), and whether or not the division has to be exact or only approximate. A simple but well-known decision heuristic that may be familiar to many parents is "one divides, the other chooses." Although this heuristic stipulates division of labor, it does not specify how the person who divides the resource (i.e., a cake) actually does it. If, however, the person who divides the cake understands the strategic interest of the other, the implied division rule is to divide up the resource such that one is indifferent between the two parts; the other person will then choose whatever he or she considers to be the larger piece. This way each person is assured of getting what he or she perceives to be at least half the resource, and neither party thinks that the other received a larger piece of cake. A fair-division procedure with these properties is said to be proportional and envy-free.

An example of a situation in which the pursuit of self-interest by each party leads to a poor outcome for all is that in which two industrialized regions of the world (e.g., the United States and the European Union) have established trade barriers to each other's exports. Because of the mutual advantages of free trade, both regions would be better off if these barriers were eliminated. However, if either region were to unilaterally give up the barriers, it would be faced with terms of trade that hurt its own economy. In fact, no matter what America does, the European Union (EU) is better off retaining its own trade barriers and vice versa. This strategic situation, in which the incentive to retain trade barriers for both regions produces a worse outcome than would have been possible had both decided to cooperate, is known as a prisoner's dilemma game. This game is just one among many situations that game theorists examine in order to analyze and model the strategic interactions of social agents.

If there is some likelihood that the players will encounter each other in the future, as in trade between the United States and the EU, the interaction become an iterated prisoner's dilemma game. There are a number of possible decision heuristics for this situation. A particularly simple but surprisingly successful decision heuristic is the tit-for-tat heuristic that Anatol Rapoport submitted to Axelrod's famous computer tournament. Given the possibility of cooperating with or defecting against the other player at each time step, tit-for-tat starts with a cooperative choice and thereafter does what the other player did on the previous move. In other words, tit-for-tat searches for a minimal amount of information (the counterpart's behavior in the last round) and cooperates if the last move was cooperative but defects if the last move was defective. Thus, akin to some of the heuristics described previously, tit-for-tat does not have to weigh and combine pieces of information in some more or less computationally expensive way. Many other successful heuristics, such as generous tit-for-tat and win–stay–lose–shift, have also been proposed for iterated prisoner's dilemma and other games.

IV. HOW TO MEASURE A HEURISTIC'S SUCCESS

The study of heuristics is a key approach to understanding how real minds make decisions for two main reasons. First, many of life's important problems, from choosing a mate to finding a job, cannot be solved in an optimal way because the space of possibilities that must be taken into account is often unlimited; hence, heuristic shortcuts are called for. Second, even when this space of possible solutions is limited and knowledge is complete, optimization may require unfeasible amounts of computation (as in trying to determine the best next move in chess) so that, again, heuristics will be an appropriate approach for the mind to take.

The fact that there are no optimal strategies for many real-world tasks, however, does not mean that there are no performance criteria. One set of criteria that is often used to evaluate judgments and decisions is their internal coherence, defined as accordance with the laws of probability theory and logic. For instance, if judgments are consistent (e.g., "I always think that event A is more likely than B") and transitive ("I think that A is more likely than B, B is more likely than C, and therefore that A is more likely than C"), this is taken as an indication that the underlying decision strategies are rational. If such criteria are violated, this is typically held to be a sign of irrationality on the part of the decision maker. The heuristics-and-biases

research program has focused on such relatively abstract coherence criteria to indicate when a heuristic produces reasonable or unreasonable decisions.

Alternatively, the success of a heuristic can be measured by comparing its performance with the requirements of its environment, such as accuracy, frugality, and speed. Lexicographic strategies (e.g., Take The Best) are often evaluated via correspondence criteria relating to real-world decision performance (such as how often they correctly choose the larger object in a pair). Comparing heuristics' performance to the requirements of the external world rather than to internal consistency stems from the view that the primary function of heuristics is not to be coherent. Rather, their function is to make reasonable adaptive inferences about the real social and physical world given limited time and knowledge.

The two kinds of criteria, coherence and correspondence, can sometimes be at odds with each other. For instance, in social situations, including some competitive games and predator–prey interactions, it can be advantageous to exhibit inconsistent (and hence noncoherent) behavior in order to maximize adaptive unpredictability (and hence correspondence with real-world goals) and avoid capture or loss. As another example, the Minimalist heuristic violates the coherence criterion of transitivity but nevertheless makes fairly robust and accurate inferences in particular environments. Thus, intransitivity does not necessarily imply high levels of inaccuracy, nor does transitivity guarantee high levels of accuracy: Logic and adaptive behavior are logically distinct.

Finally, it is important to measure the performance of decision mechanisms in terms of how well they make decisions when applied to new data; that is, how they generalize to new situations rather than merely how closely they can be adjusted or fit to a static set of data. In this regard, simple heuristics will often do very well, being about as accurate as complex general strategies that work with many free parameters. The reason is that simple heuristics can avoid being too matched to any particular environment; that is, they can escape the curse of overfitting mentioned earlier. As a consequence, a computationally simple heuristic that uses only some of the available information can be more robust, making more accurate predictions for new data.

V. CONCLUSION

Simplicity in models has aesthetic appeal. The mechanisms are readily understood and communicated, and they are amenable to step-by-step scrutiny. Furthermore, Popper has argued that simpler models are more falsifiable. However, the idea that humans make many decisions using simple heuristic mechanisms is important not just because the resulting simple models are transparent and easily falsifiable. More important, simple heuristics may be the only approach available for real minds making decisions in the real, uncertain, time-pressured world.

Hindbrain

JOEL C. GLOVER
University of Oslo

GLOSSARY

Hox genes Encode transcription factors bearing a DNA-binding portion called the homeodomain. Originally identified in *Drosophila* through the homoeotic effects of their mutation. In vertebrates their expression is strongly associated with the rhombomeric domains of the hindbrain.

Pax genes Encode transcription factors with a DNA-binding domain encoded by a sequence called the "paired box." Certain Pax genes are expressed in longitudinal domains within the hindbrain.

raphe Ventral seam of the brain stem, derived from the embryonic floor plate. Contains commissural axons and neuron populations termed the raphe nuclei.

reticular formation Central region of the brain stem extending from mesencephalon to medulla oblongata and containing relatively diffuse populations of neurons. Has a reticular appearance in histological sections stained to reveal nerve fibers. Regulates a wide variety of neural functions.

rhombencephalon Most caudal of the three primary brain vesicles; synonymous with the term "hindbrain." Assumes a form roughly approximating a rhombus during later development and eventually gives rise to the medulla oblongata, pons, and the greater portion of the cerebellar primordium.

rhombic lip Region of the hindbrain rimming the dorsolateral recess of the fourth ventricle.

rhombomeres Rhombencephalic segments, transiently visible as swellings or partitions during early stages of hindbrain development.

The hindbrain, or rhombencephalon, is an embryological term denoting the caudalmost of the three primary embryonic brain vesicles that form in the rostral neural tube. It gives rise to the pons and medulla oblongata as well as the greater portion of the cerebellum. Here, we restrict our view of the hindbrain to that region encompassing the pontine and medullary divisions since the cerebellum is discussed in a separate article. The pons and medulla oblongata are complex anatomical structures that subserve a wide range of vital functions. This article provides a general description of the anatomical and functional organization of the pons and medulla and then discusses the embryonic development of the hindbrain, including mechanisms involved in patterning its anatomy and function. It concludes with some brief considerations of pathology.

I. ANATOMICAL AND FUNCTIONAL ORGANIZATION

A. General Features

The pons (metencephalon or "behind-brain") and medulla oblongata (myelencephalon or "medulla-brain") are the two most caudal divisions of the brain, lying between the mesencephalon and the spinal cord. Seen from the ventral surface (Fig. 1A), the boundaries between mesencephalon and pons (pontomesencephalic sulcus) and between pons and medulla oblongata (pontomedullary sulcus) are clearly demarcated by the massive population of transversely oriented pontocerebellar fibers. In contrast, there is a smooth transition from medulla oblongata to spinal cord the only indication being the pyramidal decussation. Most of the dorsal surface of the pons and medulla oblongata

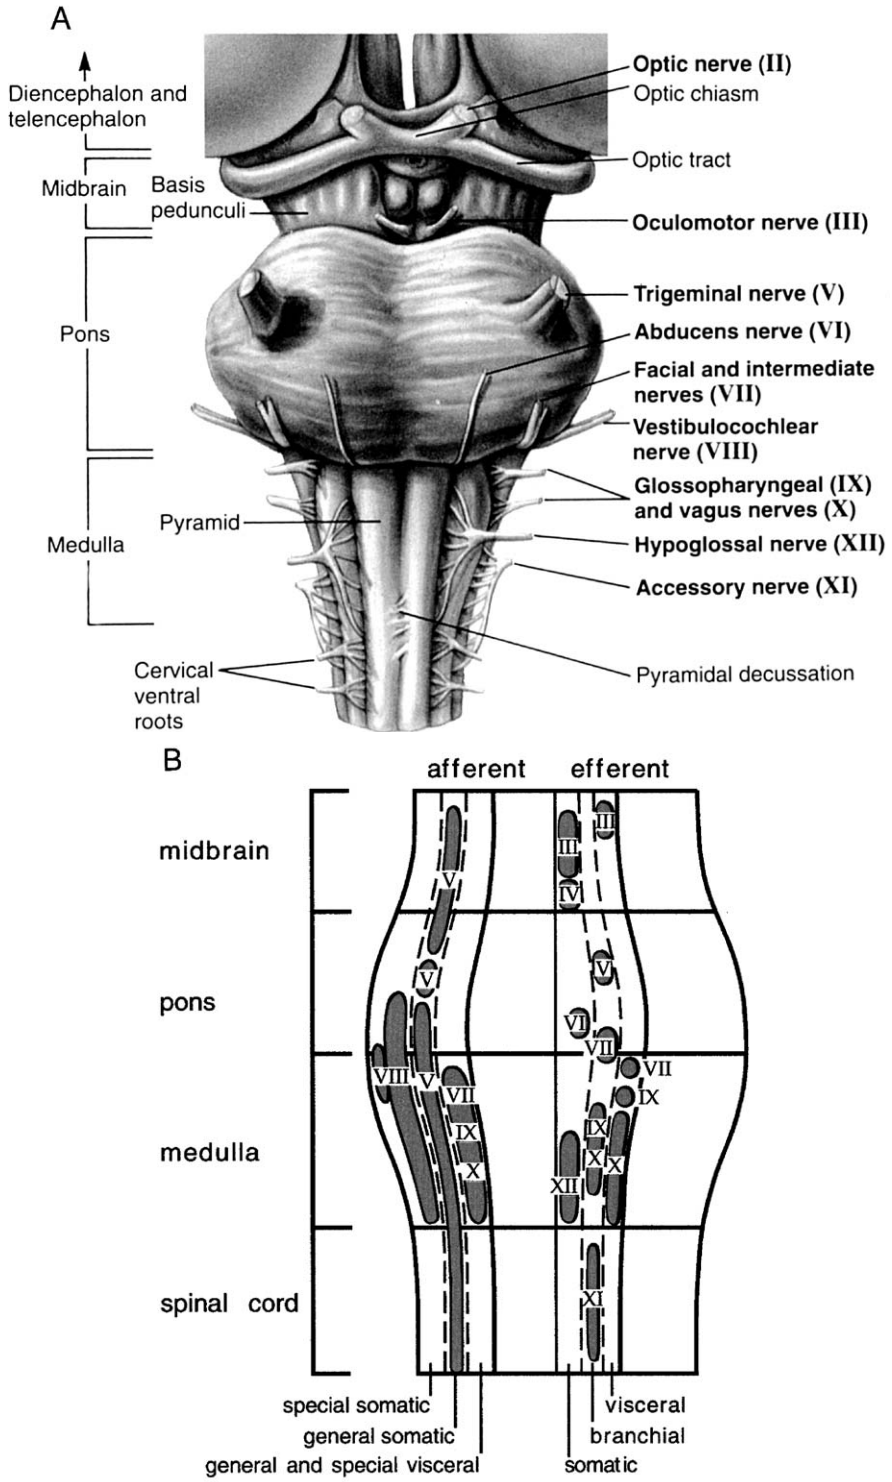

Figure 1 (A) Ventral view of the human brain stem showing the major structural features of the pons and medulla oblongata, including the cranial nerves (modified from Kandel *et al*., 1992, *Principles of Neural Science*, 3rd ed., with permission of the McGraw-Hill Companies). (B) Organization of cranial nerve-associated nuclei into afferent (sensory) and efferent (motor) columns. The locations of nuclei relative to mesencephalic (midbrain), pontine, and medullary divisions are approximate. Phylogenetic variants on this theme exist. Because of longitudinal migrations of certain nuclear groups, embryonic origins may not correspond to final locations. For example, the trochlear nucleus (IV) has been shown to derive from the pontine division in lower mammals [redrawn and modified from Martin (1989), *Neuroanatomy*, with permission of the McGraw-Hill Companies].

underlies the fourth ventricle as its floor. The floor of the fourth ventricle and the ventral surface of the medulla oblongata show a relief of underlying longitudinal fiber tracts and nuclei. The lateral recesses of the fourth ventricle are bounded by a rim of neural tissue called the rhombic lip, which is continuous with a thin velum overlying the fourth ventricle. The caudal portion of the velum differentiates into choroid plexus. In the intact brain, the fourth ventricle is hidden by the cerebellum.

Eight of the 12 cranial nerves originate from the pons or medulla oblongata, issuing from specific sites on the ventral and lateral aspects (Fig. 1A). The trigeminal nerve issues from among the pontocerebellar fibers on the lateral aspect of the pons. The abducens, facial, and vestibulocochlear nerves issue from respectively medial to lateral positions at the pontomedullary border. The glossopharyngeal, vagus, and spinal accessory nerves issue from respectively rostral to caudal sites along the ventrolateral aspect of the medulla oblongata, dorsal to the inferior olive. The hypoglossal nerve issues from the ventral aspect of the medulla oblongata between the inferior olive and the pyramid.

The nuclei associated with the cranial nerves are organized into longitudinal motor and sensory columns that are subdivided according to which peripheral structures are innervated (Fig. 1B). The organization is similar to that in the spinal cord except for the presence of special columns that innervate structures specific to the head. The motor columns lie more medially and innervate either striated muscle (somatic and branchial columns) or parasympathetic ganglia (visceral column). The sensory columns lie more laterally and transmit tactile, proprioceptive, pain, or temperature signals (general somatic and visceral columns) or other specific sensory modalities such as audition and balance (special somatic column) and taste and olfaction (special visceral column). The sulcus limitans, a shallow longitudinal groove visible in the floor of the fourth ventricle, separates the motor from the sensory columns (Fig. 2).

The pons and medulla oblongata contain many fiber tracts that relay information between the cerebrum, cerebellum, and the spinal cord. The transversely oriented pontocerebellar projection is one of the largest of these and is the dominant external feature of the pons (Fig. 1A). Within the pons, longitudinal fiber tracts course internally to or intermingled with the pontocerebellar fibers. Within the medulla oblongata, most longitudinal tracts course at or near the outer (pial) surface. Some longitudinal tracts,

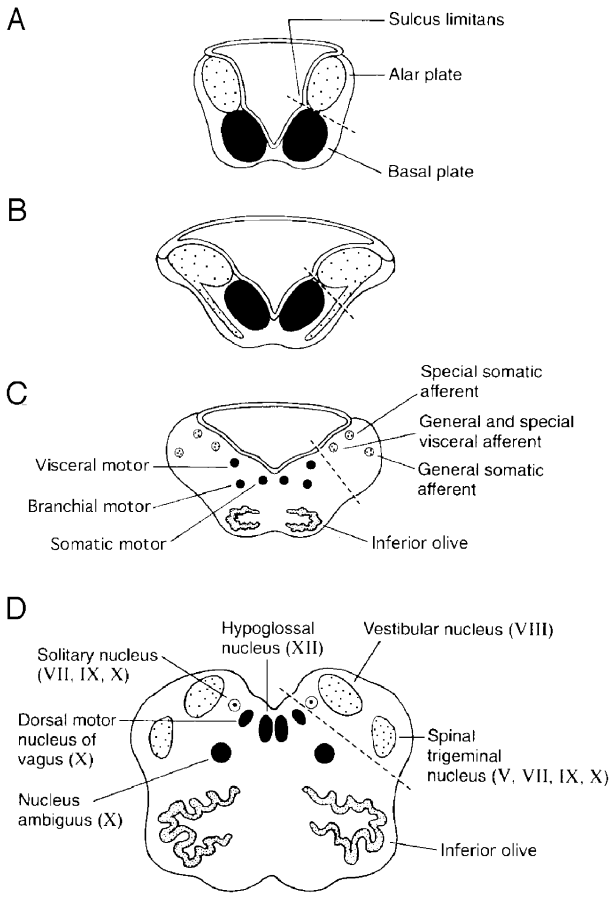

Figure 2 Series of transverse sections through the medulla oblongata at different stages of development. Different nuclei originate from basal and alar plates in a specific pattern. Motor and sensory cranial nerve-associated columns, for example, derive from the basal and alar plates, respectively. Note that inferior olive neurons derive from the alar plate but emigrate to the basal plate where they coalesce to form the nucleus [modified from Kandel *et al.*, (1992), *Principles of Neural Science*, 3rd ed., with permission from the McGraw-Hill Companies].

however, course at deeper locations near the ventral midline of the medulla oblongata. These include several important descending tracts to the spinal cord. The largest longitudinal tract, the corticospinal tract, is visible along the ventral medullary surface as the bilaterally paired pyramids, one of the dominant external features of the ventral medulla oblongata (Fig. 1A).

Like the cranial nerve nuclei, the longitudinal fiber tracts are differentially situated according to functional modality. Ascending tracts conveying sensory information from spinal and medullary centers to higher centers generally course at more dorsal and

dorsolateral locations, whereas descending tracts generally course at more ventral and ventromedial locations. Exceptions to this general rule are the rubrospinal tract, which attains a lateral position within the medulla oblongata as it descends to the spinal cord; the medial lemniscus and ventral trigeminal tract, two sensory tracts that initially have a ventromedial course; and the spinal trigeminal tract, a sensory tract that descends along the dorsolaterally located spinal trigeminal nucleus.

Several well-defined nuclei exist within the pons and medulla oblongata in addition to those associated with the cranial nerve nuclei. The largest of these is the inferior olive, which produces a prominant bulge along the ventrolateral surface of the rostral medulla (Fig. 1A), and whose characteristically convoluted appearance in transverse sections makes it an unmistakable landmark (Fig. 2). The inferior olive is the source of climbing fiber afferents to the contralateral cerebellum.

The bulk of the pontine and medullary core is filled by a more diffusely organized population of neurons that make up the reticular formation, so named because it appears highly reticulated when stained nonspecifically for nerve fibers. This appearance, along with early physiological findings that demonstrated a lack of modality-specific activity in reticular efferents, led to the early notion that much of the reticular formation functioned as a distributed network involved in general activation and arousal. Recent anatomical and physiological studies, on the other hand, have demonstrated a higher degree of anatomical and functional mosaicism within the reticular formation than was previously appreciated. Anatomical subdivisions with characteristic patterns of connections and neurotransmitter profiles exist, and a number of well-defined premotor networks have been identified that organize and integrate specific goal-directed movements.

Certain reticular neuron populations are distinct enough anatomically to be defined as nuclei, even though most of these are not sharply delimited from the rest of the reticular formation. Two of the most distinct reticular nuclei are of special interest because of their neurotransmitter phenotypes. The raphe nuclei are clusters of neurons located within the ventral raphe, the majority of which are serotonergic. The locus coeruleus is a collection of noradrenergic neurons in the pons. The raphe nuclei and the locus coeruleus have exceptionally widespread projections and terminations and exert modulatory effects on a variety of neural systems.

B. Overview of Constituent Neuron Populations

1. Efferent Neurons

These include (i) motoneurons of cranial nerves V–VII and IX–XII that innervate striated muscle in the head and neck region (trigeminal motor, abducens, facial, ambiguus, and accessory nuclei), (ii) preganglionic neurons that innervate cranial parasympathetic ganglia (superior salivatory nucleus of cranial nerve VII and inferior salivatory nucleus of cranial nerve IX) and autonomic ganglia in the trunk (dorsal motor nucleus of nerve X), and (iii) cochlear and vestibular efferents from respectively the superior olive and reticular formation that innervate hair cells in the inner ear. All of these efferent populations are cholinergic.

2. Nuclei That Receive Cranial Nerve Sensory Afferents, and Some of Their Secondary Nuclear Targets

These include (i) sensory columns of the trigeminal system which receive inputs from nerves V, VII, and X; (ii) the vestibular and cochlear nuclei, which receive inputs from nerve VIII; and (iii) the solitary nucleus, which has subdivisions that receive afferents conveying taste via nerves VII, IX, and X, afferents from receptors in cranial skin and mucous membranes, and afferents from receptors in the gut, cardiovascular system, and lungs.

3. Other Relay and Integration Centers

These include the pontine nuclei, which relay primarily cortical inputs to the contralateral cerebellum; the inferior olive, which supplies climbing fiber inputs to the contralateral cerebellum, the nucleus prepositus, which is involved in regulating eye movements; the dorsal column nuclei, which integrate afferent information from the spinal cord and relay it to the thalamus; the deep cerebellar nuclei, which relay efferent information from the cerebellum; and various subdivisions of the reticular formation.

4. Sources of Descending Inputs to the Spinal Cord

These include the vestibulospinal, reticulospinal, and raphespinal populations and the locus coeruleus.

C. Functional Centers and Networks

In addition to being clustered into discrete nuclei with specific modalities, the neuron populations of the pons

and medulla oblongata constitute interconnected networks that integrate somatic and autonomic sensory and motor functions. Many of these networks subserve reflex pathways that link the afferent inputs from certain cranial nerves with the motor output of others via interposed populations of interneurons within the reticular formation and specific relay nuclei. The complex coordination of the mouth, tongue, pharynx, and upper alimentary canal during the eating of a meal exemplifies the substantial degree of integration of different cranial nerve nuclei. The control of eye movements, the regulation of cardiovascular function, and a variety of autonomic reflexes, such as hiccuping, sneezing, and vomiting, are all examples of the interplay of different cranial nerve nuclei. The networks of interneurons that mediate these reflexes are not fully characterized, but some of them have been localized to specific sites within the reticular formation. Thus, in addition to functioning to some extent as a distributed integrative network, the reticular formation exhibits a substantial degree of functional compartmentalization.

Indeed, many of the regulatory functions exerted by the pons and medulla oblongata on other regions of the brain arise from specific, localized centers within the reticular formation. These include the regulation of pain impulses, the initiation of locomotion, and the control of cardiovascular function and respiration.

II. EMBRYONIC DEVELOPMENT

The development of the hindbrain has been the focus of intensive research during the past 10 years. Although the human hindbrain has been the subject of a few studies, most of our knowledge of the developmental programs and mechanisms that pattern the hindbrain is derived from animal studies. Since the hindbrain is an evolutionarily ancient brain structure, many of the key developmental features gleaned from other species are likely to be conserved throughout the vertebrate radiation, including primates. Nevertheless, species differences do exist, and the reader should note that some of the description that follows may differ in certain details from the developmental events occuring in the human embryo.

A. General Features

1. Morphogenesis

The brain and spinal cord originate from the embryonic ectoderm through the action of inductive signals from underlying mesoderm and within the ectoderm. During this process, a region of dorsal ectoderm called the neural plate is delineated, folds together at the midline to form the neural tube, and invaginates into the dorsal aspect of the embryo. Even before closure and invagination of the neural tube are complete, three initial subdivisions of the brain can be discerned, first by the appearance of indentations within the neural plate and subsequently by the expansion of the intervening regions into vesicles of the neural tube. These are the primary brain vesicles, the prosencephalon, mesencephalon, and rhombencephalon (Fig. 3). Within a short time (by about 4 weeks of development), further subdivisions of the neural tube, called neuromeres, can be seen. The neuromeres of the rhombencephalon are called rhombomeres (Fig. 3A).

During flexure of the developing neural tube, the rhombencephalon assumes a shape approximating a rhombus, hence the name (Fig. 4). This occurs at least in part because the mesencephalic and cervical flexures create constrictions in the neural tube, whereas the pontine flexure creates a lateral expansion. Initially, the wall of the rhombencephalic neural tube has approximately the same thickness around its entire circumference. As the flexures appear, however, morphometric changes occur that presage the mature structure (Fig. 2). The ventral portion starts proliferating extensively and eventually gives rise to the bulk of the pons and medulla oblongata. A specialized structure at the ventral midline known as the floor plate eventually gives rise to the raphe. The dorsal portion, also called the roof plate, becomes relatively much thinner and eventually gives rise to the velum of the fourth ventricle with its associated choroid plexus. No neurons differentiate within the roof plate and its derivatives. At pontine levels, the dorsal portion of the neural tube, on either side of the roof plate, develops into progressively thicker flaps of neural tissue that establish the major portion of the cerebellar primordium. A longitudinal indentation, called the sulcus limitans, appears in the floor of the fourth ventricle about midway between the floor plate and roof plate. This sulcus divides the wall of the neural tube into two longitudinal plates or columns, the basal plate and the alar plate.

Shortly after the hindbrain neural tube forms, and during the period when rhombomere and flexure formation is shaping the hindbrain, a population of progenitor cells at the dorsal aspect of the tube emigrates into the periphery. This population, a part of the cranial neural crest, contributes much of the mesenchyme of the cranium and branchial arches and

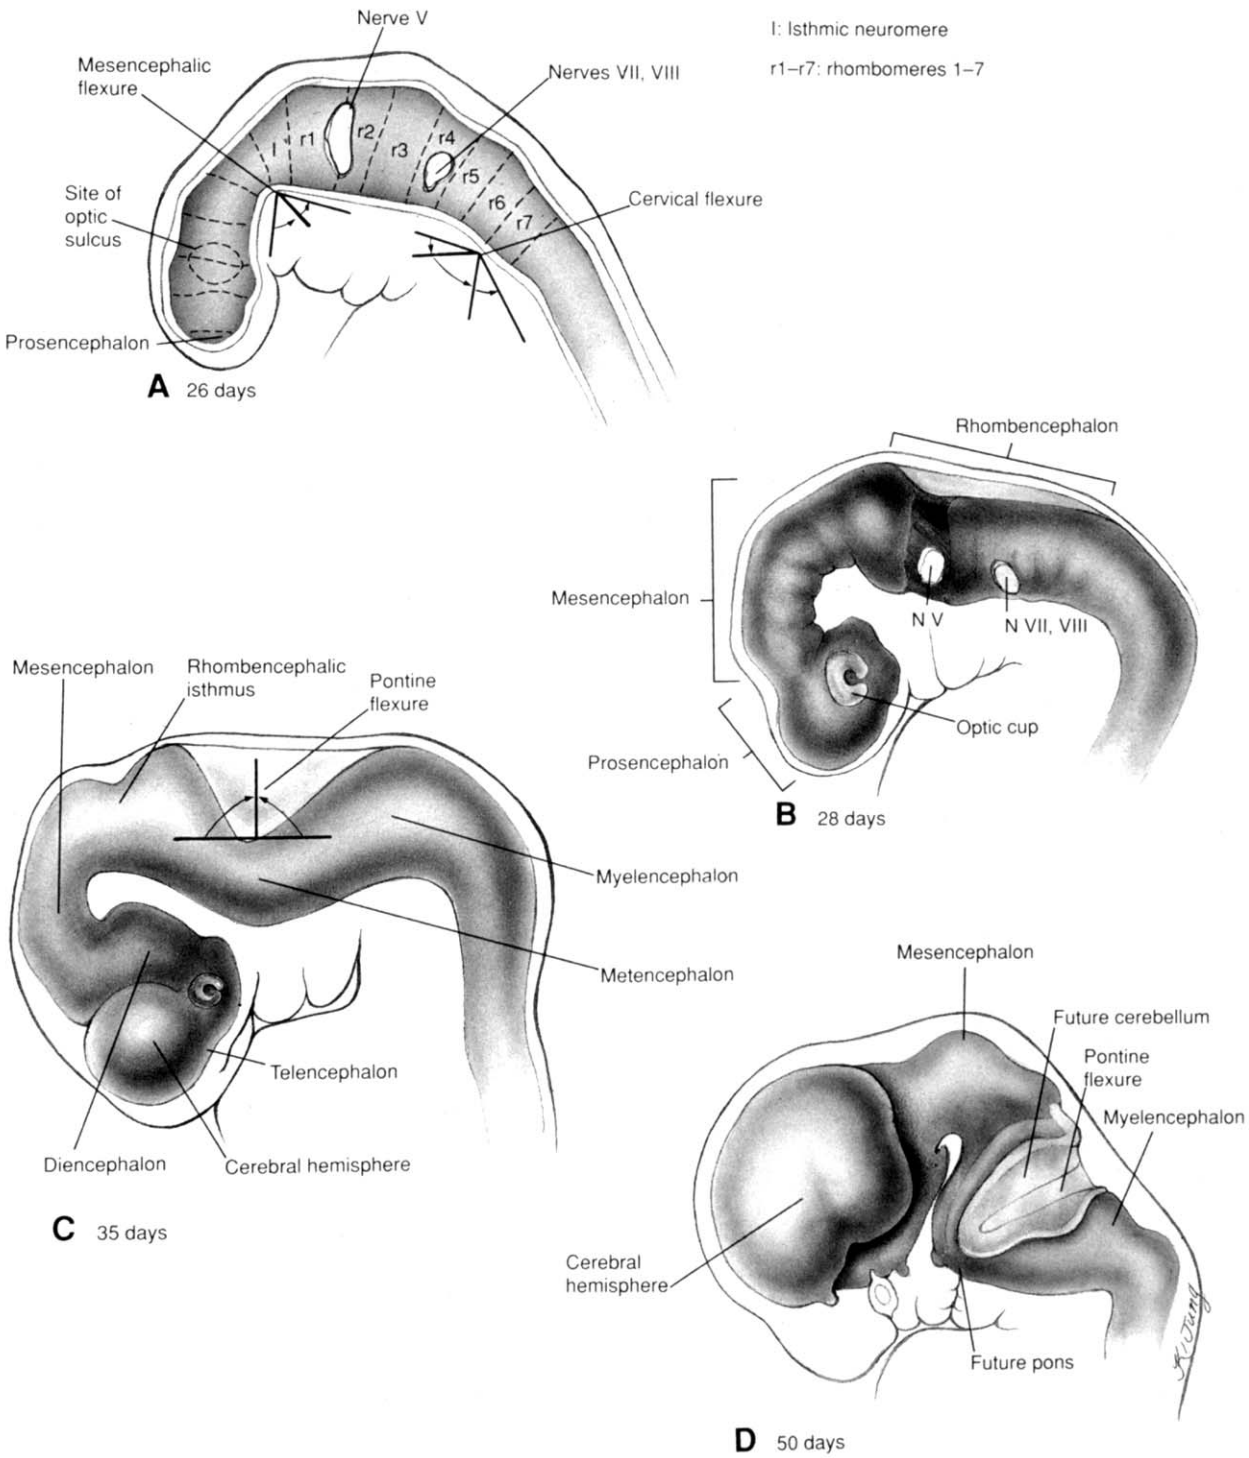

Figure 3 Important morphogenetic changes in the neural tube that shape the hindbrain [reproduced with permission from Larsen (1997), *Human Embryology*. Churchill Livingstone, New York].

of certain regions of the thorax including the developing thymus and heart. The neural crest cells proliferate and differentiate into a large number of cell types, including cartilage and other connective tissue structures, smooth muscle, melanocytes, peripheral neurons, and Schwann cells.

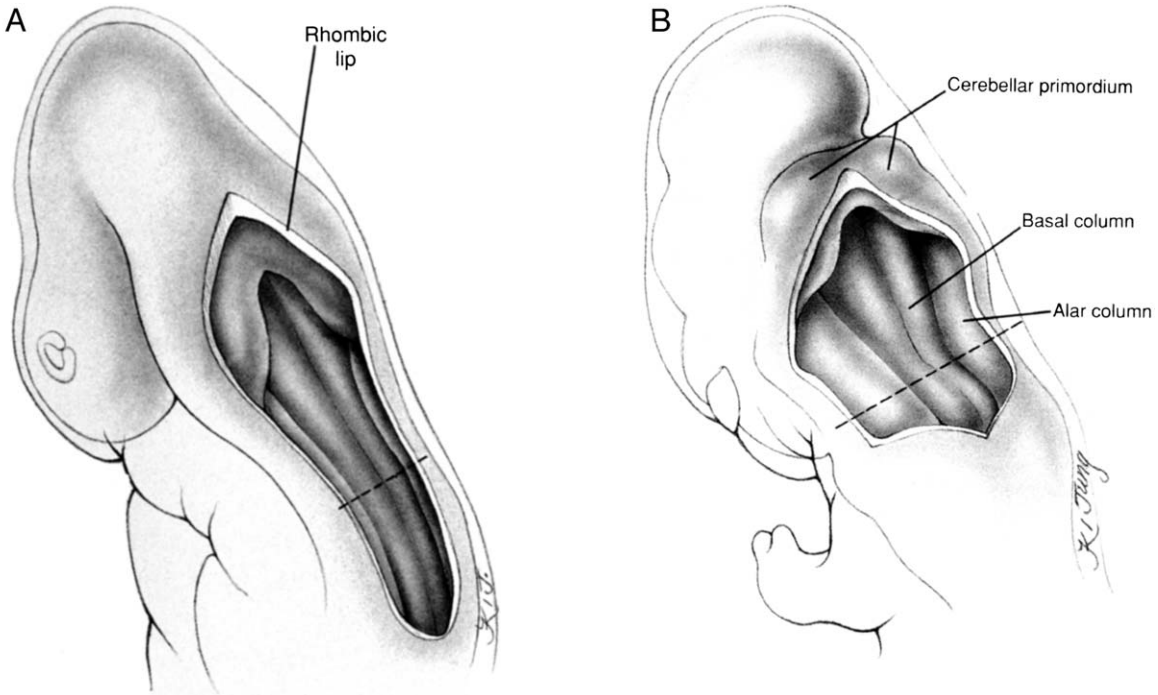

Figure 4 Dorsal views of the human embryo at approximately 4 weeks (A) and 5 weeks (B), showing the development of structural features in the floor of the fourth ventricle and the dorsolateral aspect of the hindbrain. The dotted line indicates the level of section shown in Fig. 2 [modified from Larsen (1997), *Human Embryology*. Churchill Livingstone, New York].

2. Neurogenesis and Migration

Neural progenitor cells of the neural tube proper are located and undergo mitosis near the inner (luminal) surface of the tube in a layer called the ventricular zone. As postmitotic neurons are generated, they migrate radially toward the outer (pial) surface, establishing a mantle zone where they begin to differentiate and aggregate into nuclei. Most neurons take up residence somewhere along this radial trajectory, but some turn to migrate circumferentially, either toward the floor plate or toward the roof plate, or longitudinally. Neurons generated in the alar plate, particularly the rhombic lip region, have a particular predilection for circumferential migration. Indeed, several nuclei, including the raphe nuclei and the inferior olive, are established within the basal plate through immigration from the alar plate (Fig. 2B).

By and large, the alar and basal plate domains maintain a coherent relationship to the sensory and motor divisions of the cranial nerve nuclei, respectively (Fig. 2), with the sulcus limitans persisting in the mature hindbrain as a landmark of this division. In general, motoneurons are generated within the basal plate, whereas the neurons of the sensory nuclei are generated within the alar plate. Some hindbrain cranial nerve nuclei, however, undergo circumferential migration, such as the trigeminal motoneurons, which migrate away from the floor plate, and the cochlear efferent neurons, which migrate toward the floor plate and cross the midline. The disposition of neuron groups in the mature hindbrain therefore does not necessarily accurately indicate their embryonic origins.

3. Axon Outgrowth and Tract Formation

Axon outgrowth is an early feature of neuronal differentiation and may be quite advanced even as neurons are migrating. Many axons are commissural, crossing the midline to course in axon tracts and innervate synaptic targets on the opposite side of the neuraxis. Once axons begin to project longitudinally, they tend to fasciculate into bundles that are located predominantly either near the pial surface or adjacent to the raphe. Two major axon bundles are present at early stages of hindbrain development: a medial longitudinal fascicle (mlf) and a lateral longitudinal

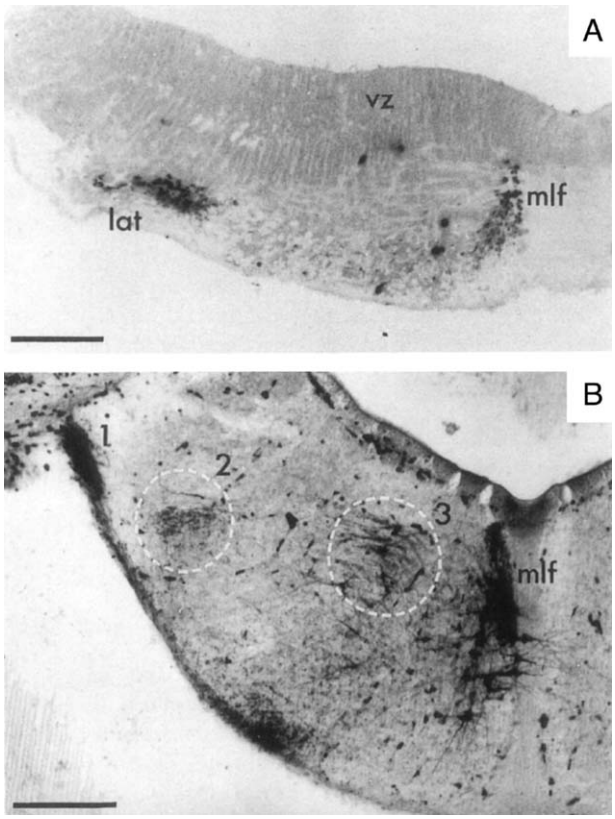

Figure 5 Transverse sections through the developing medulla oblongata of a chicken embryo illustrating the initial two longitudinal fiber bundles [A; medial longitudinal fascicle (mlf) and lateral longitudinal fascicle (lat)] and the splitting of the lateral longitudinal fascicle into separate tracts (B; 1, spinocerebellar tract; 2, spinal trigeminal tract; 3, lateral vestibulospinal tract) (modified from Glover and Petursdottir, 1991).

fascicle (llf) (Fig. 5). Each contains ascending and descending axons, which tend to be segregated into subfascicles containing axons of a given type. As the transversal area of the hindbrain expands, the mlf maintains its coherence alongside the raphe and remains as the tract of the same name in the mature brain. The llf, on the other hand, splits into several tracts, including various ascending sensory tracts, the spinal trigeminal tract, and the lateral vestibulospinal tract. This splitting is accompanied by intercalation of increasing numbers of neurons and other axons. Thus, the early formation of longitudinal axon tracts occurs on a simple scaffold that increases in complexity by a process of fission. Later formed tracts, such as the corticospinal tract and the pontocerebellar projection, are layered externally to the early formed tracts.

B. Gene Expression and Regionalization

1. Rhombomeres and Longitudinal Patterning

The rhombomeres are transient subdivisions that were described in the embryos of a number of species including the human starting in the late 1800s. Their analysis underwent a dramatic renaissance nearly 100 years later with the application of modern cellular and molecular techniques, spearheaded by the efforts of Andrew Lumsden and colleagues.

As many as eight rhombomeres have been described, and these are denoted r1, r2, r3, and so on from rostral to caudal (Fig. 3). The second through sixth rhombomeres (r2–r6) are similar in length and readily visible in most species. The first and last two rhombomeres may represent transitional neuromeres at the junctions between hindbrain and mesencephalon and hindbrain and spinal cord.

Rhombomere boundaries have several features that contribute to a physical segmentation of the hindbrain neural tube. The proliferation rate is lower at the boundaries, creating the indentations that mark their positions visibly. The pattern of intercellular communication via gap junctions is modulated at the boundaries, several extracellular proteins are preferentially expressed there, and cells in alternating rhombomeres have different cell adhesion properties such that they tend to segregate if mixed. All of this contributes to the formation of a physical barrier to cell movement over rhombomere boundaries. Indeed, in contrast to the extensive circumferential migration that occurs among certain hindbrain neuron populations, rostrocaudal migration is much more limited. This has led to the idea that the rhombomeres compartmentalize the hindbrain, confining progenitor cells and their offspring to specific rostrocaudal domains. Of course, longitudinal fibers penetrate the rhombomere boundaries, and some neuron populations breach the barriers as well, especially at sites of intersection by fiber tracts.

The rhombomeres appear during a period when many hindbrain neurons are being generated, and they fade away by the time most of the major nuclei of the hindbrain have appeared. The temporal concurrence with neurogenesis and differentiation suggests that the rhombomeres play a role in patterning that differentiation. Molecular correlates of rhombomeric compartmentalization strongly support this notion. In particular, the rhombomeric domains are correlated with the expression of a number of developmental regulatory genes that are involved in controlling the

differentiation of neurons into specific phenotypes along the rostrocaudal axis.

One class of regulatory genes that figures prominently is the Hox gene family, which encodes transcription factors whose differential expression establishes regional patterns of differentiation in a variety of organisms and organ systems. Hox genes are ordered in a specific sequence within the genome, a relationship that is reiterated in their tissue expression pattern. Within the hindbrain, Hox genes have a sequentially overlapping pattern of expression that is strongly correlated with the rhombomeres and provides each of them with a unique combinatorial address (Fig. 6). Evidence that the Hox genes are important determinants of neuronal differentiation comes from a variety of manipulations that alter the pattern of Hox gene expression. These include transgenic knockouts of specific Hox genes, ectopic expression of Hox genes by retroviral gene transfer, heterotopic transplantation of rhombomeres, treatment with retinoids, perturbations of Hox gene promoter sequences that alter the region-specific expression pattern, and manipulation of other genes that regulate Hox gene expression. In parallel with alterations in Hox gene expression, these manipulations lead to changes in the regional pattern of neuronal differentiation, such that neuronal phenotypes characteristic of a given rhombomere appear in a different rhombomere.

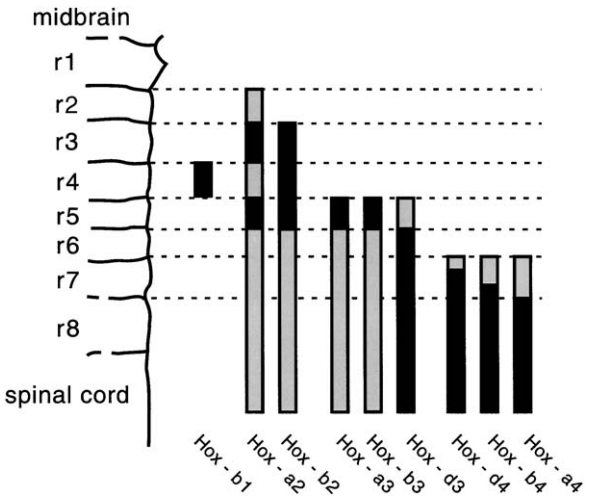

Figure 6 The relationship of rhombomeric domains to the longitudinal expression patterns of Hox genes in the mouse hindbrain. Black indicates strong expression, and gray indicates weaker expression (reproduced with permission from Keynes and Krumlauf, *Annual Review of Neuroscience*, Vol. 17, © 1994 by Annual Reviews, www.AnnualReviews.org).

Hox genes are also expressed by the emigrating cranial neural crest cells and are involved in patterning the various mesenchymal derivatives of the cranium, branchial arches, and neural crest-derived thoracic structures.

How is the normal, longitudinally sequential pattern of Hox gene expression established? This appears to be a complicated issue that involves a number of factors. Hox gene expression is known to be regulated by retinoids, acting through nuclear retinoid receptors, which are ligand-dependent transcription factors that interact directly with Hox gene promoter sequences. This regulation is concentration dependent. Since retinoid synthesis has been shown to be high in the spinal cord but very low in the hindbrain, a diffusion gradient of retinoids from the spinal cord rostrally into the hindbrain could contribute to setting up the pattern. Hox gene expression is also regulated by the action of other transcription factors via specific promoter sequences that direct expression differentially according to tissue type and region. The pattern of expression of such transcription factors is therefore pivotal in setting up the pattern. Lastly, Hox gene expression is cross-regulated and autoregulated by Hox proteins, in cooperation with other transcription factors. An important feature that underscores the complexity of Hox gene regulation is the dynamic pattern of expression in the hindbrain. Hox genes do not merely pop up in specific longitudinal domains but may be expressed in broader domains that eventually become restricted and that are modulated over time also in the transverse plane.

The Hox genes are not the only genes that exhibit rhombomere-related patterns of expression, but they are the most extensively studied so far with respect to a role in regulating neuronal differentiation. Some of the other rhombomere-related genes are likely to be downstream targets of the Hox genes because they code for membrane receptors and signaling molecules that are involved in features of differentiation, such as directed cell migration and axonal outgrowth. Others, such as the *kreisler* and *Krox-20* genes, are also transcription factor genes that participate with the Hox genes in the network of gene activity that sets up the regional patterning of the hindbrain.

2. Patterning in the Transverse Plane

In addition to the longitudinal patterning of the hindbrain exemplified by the rhombomeres, there is a

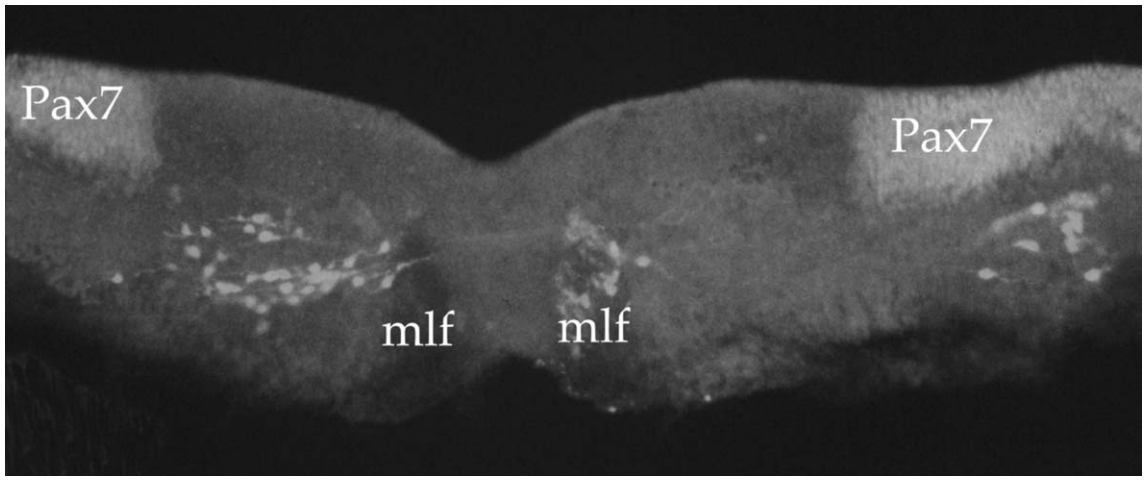

Figure 7 An example of hindbrain patterning in the transverse plane. Expression of the transcription factor *Pax7* by progenitor cells within the proliferative zone (immediately subjacent to the fourth ventricle) defines two zones with a sharp boundary at a specific site along the floor plate–roof plate axis. The hindbrain has been opened dorsally and laid flat prior to sectioning, such that the floor plate–roof plate axis runs medial to lateral on each side. Two different hindbrain neuron groups are retrogradely labeled from their axons in the right-side medial longitudinal fascicle (mlf). The group on the left side derives from the *Pax7*-negative progenitors, whereas the group on the right side derives from the *Pax7*-expressing progenitors.

systematic patterning along the floor plate–roof plate axis. This is not as obvious from the morphological standpoint because there are few related structural landmarks aside from the sulcus limitans. The organization of the cranial nerve nuclei into longitudinal columns, however, gives an immediate reflection of this transverse element of patterning. Transcription factors also figure prominently in setting up longitudinal domains within the hindbrain. Expression of Pax and Nkx genes within the progenitor cell population provides a good example. These genes, like the Hox genes, encode transcription factors known to regulate the regional differentiation of cells in a variety of tissues and species. They are expressed in overlapping longitudinal bands along much of the neuraxis, including the hindbrain, with very sharp boundaries of expression at specific levels along the floor plate–roof plate axis (Fig. 7). They can exhibit dynamic changes prior to boundary formation, and they can also exhibit modulations in expression intensity within the expression domain that becomes established. Thus, these genes provide a sequentially ordered combinatorial scheme of gene expression along the floor plate–roof plate axis in much the same way that the Hox genes pattern the longitudinal axis.

How is the normal pattern of gene expression in the transverse plane generated? This has been studied primarily in the developing spinal cord, but the emerging picture appears to be generally applicable to the hindbrain as well. Diffusible signals are released at or near the ventral and dorsal poles of the neural tube. Ventral signals derive from the notochord, a mesodermal structure that lies immediately ventral to the neural tube, as well as from the floor plate. Dorsal signals derive from the roof plate and overlying surface ectoderm. These signals establish opposing gradients that dictate which genes are expressed at different positions along the floor plate–roof plate axis. The way these signals work and the way the genes whose expression they regulate interact are complex issues that remain the subject of active research. The end result, however, is the establishment of overlapping, longitudinal bands of differential gene expression that, like the zones of differential Hox gene expression, can be correlated with the differentiation of specific neuron groups (Fig. 7).

3. From Gene Expression to Neural Networks

In combination, transcription factors encoded by these and other gene families are expressed in a kind of checkerboard pattern of intersecting rhombomeres and longitudinal bands. How does this relate to the regional pattern of neuronal differentiation? The spatial and temporal correlation of hindbrain neuron types to gene expression patterns is far from complete, but several conclusions can be made.

First, certain neuron groups are neatly delimited longitudinally by rhombomeric domains, and certain groups are neatly delimited along the floor plate–roof

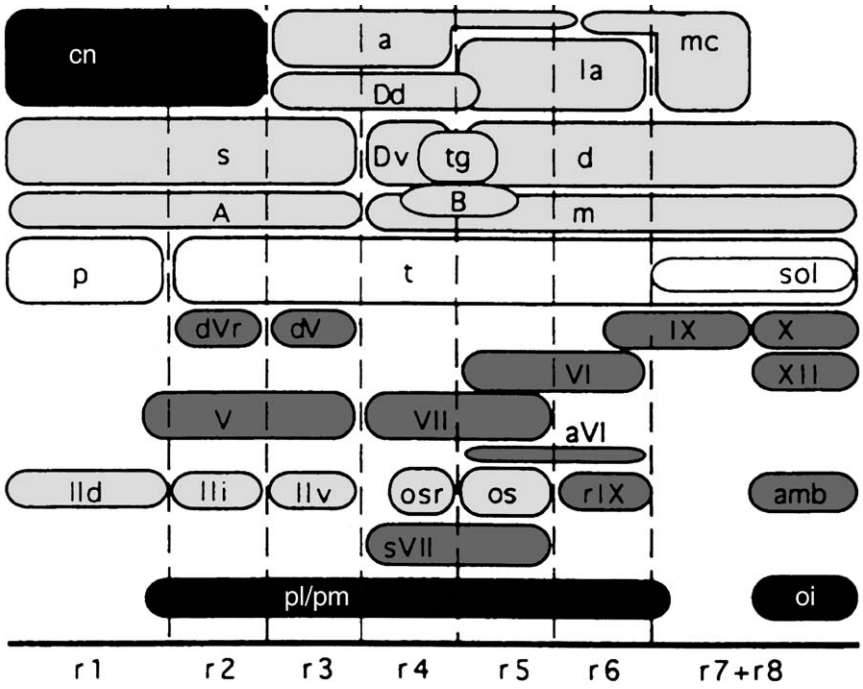

Figure 8 The relationship of hindbrain nuclei to rhombomeric domains in the chicken embryo. Nuclei are ordered roughly along the floor plate–roof plate axis from bottom to top. Different shades of grey indicate classes of related nuclei. Note that the rhombomeric pattern exhibits phylogenetic variants. cn, cerebellar nuclei; a, angularis; la, laminaris; mc, magnocellularis; Dd, Deiters dorsalis; s, superior vestibular; Dv, Deiters ventralis; tg, tangentialis; d, descending vestibular; A, vestibular cell group A; B, vestibular cell group B; m, medial vestibular; p, principal trigeminal; t, descending trigeminal; sol, nucleus of solitary tract; dV, dorsal trigeminal (r, rostral part); V, trigeminal motor; VI, abducens; aVI, accessory abducens; VII, facial; IX, glossopharyngeal; X, vagus; XII, hypoglossal; lld, nucleus of lateral lemniscus, (d, dorsal; i, intermediate; v, ventralis); os, superior olive (r, rostral part); rIX, retrofacial glossopharyngeal; amb, ambiguus; sVII, superficial facial; pl/pm, lateral and medial pontine nuclei; oi, inferior olive (modified from Marin and Puelles, 1995).

plate axis by longitudinal gene expression domains, whereas others are not (Fig. 8). There are several potential explanations for examples of noncongruity between neuron groups and these domains. For example, the pattern as described to date may be incomplete. Additional genes could subdivide the currently known expression pattern into additional domains; similarly, additional information about the phenotypic diversity of neuron groups may introduce novel group subdivisions. Alternatively, the noncongruity might result from the dynamic features of both gene expression and neuron group formation. As noted previously, gene expression patterns can change over time, and neurons can migrate, so correspondences may be evident only within very particular time windows and then disappear.

Second, the relationship between gene expression patterns and neuron groups is not necessarily applicable only to the classically defined cytoarchitectonic nuclei of the hindbrain. Rather, correlations may be stronger to neuron groupings defined by specific phenotypic characters, such as neurotransmitter profile or axon projection pattern. For example, within such populations as the reticulospinal neurons and the vestibular nuclear complex, subdivisions on the basis of axon projection pathway are more readily correlated to gene expression domains than are the classical nuclear divisions.

Third, it appears that the relationship between gene expression patterns and neuron groups can be extended to the connectivity patterns of hindbrain neurons. This feature has only been examined in a few instances, but there are compelling examples of neuron groups whose subdivision according to termination patterns onto synaptic targets can be correlated to gene expression domains. The vestibular nuclear complex provides an example. Here, the different subgroups connect in stereotyped patterns to target motoneurons, creating highly specific reflex pathways for eye and body movements. Although the action of particular genes in establishing this pattern of connectivity has not been experimentally tested, the striking

correlation of the vestibular subgroups to gene expression domains suggests a direct link. Other functional systems within the hindbrain similarly appear to be constructed through the action of regional patterns of gene expression. For example, primordial respiratory activity is generated by a neural network with definable components localized to specific rhombomeres. Genetic manipulations that perturb the rhombomeric pattern lead to specific functional deficits in the network.

To summarize, hindbrain neurons are organized into distinct cranial nerve and other nuclei, with the reticular formation as a central core. The pattern of specific functional subdivisions within these nuclei and within the reticular formation is likely to be directly linked to the highly mosaic pattern of gene expression seen at early stages of hindbrain development. Moreover, this relationship likely contributes to establishing the basic pattern of synaptic connectivity within hindbrain networks. Identifying the gene combinations responsible for specifying the various neuron types and their synaptic connections is one of the major challenges of future research on the hindbrain.

III. BRIEF CONSIDERATIONS OF PATHOLOGY

Given the many critical functions of the pons and medulla oblongata, pathology in these hindbrain derivatives can have a wide variety of effects. Specific or diverse symptoms may result, depending on whether the pathology is focal, involving a particular nucleus or pathway, or more widespread. In either case, the pathological manifestations can be devastating and potentially life-threatening since so many areas of the pons and medulla participate in vital processes. Thus, contusions, tumors, and vascular lesions are often fatal. Several well-known pathological syndromes can be distinguished on the basis of particular combinations of symptoms, as these relate directly to the location of the lesion and the level at which fiber tracts decussate. For example, medial lesions typically present symptoms such as contralateral hemiparesis (corticospinal tract) and loss of proprioception (medial lemniscus). In contrast, lateral lesions typically present symptoms such as ipsilateral loss of facial cutaneous sensation (trigeminal sensory nucleus and tract), contralateral loss of pain and temperature sensation (spinothalamic tract), and Horner syndrome (ipsilateral descending autonomic fibers). In addition, each type of lesion will potentially affect the function of specific cranial nerves.

The different medial and lateral pontine and medullary syndromes lie within the basic diagnostic repertoire of the practicing neurologist. Hindbrain pathology reulting from genetic disorders is a less common class of diagnosis but almost certainly occurs more frequently than is currently recognized. Mutations in transcription factor genes have been established as the cause of a few pathological syndromes, such as Waardenberg's syndrome, that involve developmental defects in the cranial neural crest (cristopathies). Similar mutations in genes patterning the hindbrain neural tube could lead to catastrophic consequences if they disrupt major elements of the pattern, but they could also lead to more focal defects compromising the function of specific networks, with more subtle symptoms as a result. For example, nonlethal mutation of the *Krox-20* gene in the mouse, which disrupts rhombomeric patterning, perturbs the development of respiratory networks and leads to varying degrees of apnea. There are probably a large number of idiopathic conditions affecting the hindbrain that have a genetic basis, and it is not unreasonable to expect that as genetic analysis of hindbrain patterning progresses new syndromes will be classified for which mutation of identified patterning genes is the underlying cause.

HIV Infection, Neurocognitive Complications of

IGOR GRANT
University of California, San Diego, and VA San Diego Healthcare System

GLOSSARY

acquired immune deficiency syndrome A disease resulting from collapse of cell-mediated immunity, resulting in infections, cancers, and other complications that lead to death. Human immunodeficiency virus is the causal agent.

antiretroviral drugs Drugs that interfere with various stages of the reproduction of human immunodeficiency virus.

CCR5 A type of chemokine receptor found on macrophages, dendritic cells, and certain other cells.

CD4 cells A type of lymphocyte that is important in coordinating numerous immune events. Infection and depletion of CD4 lymphocytes by HIV results in the evolution of acquired immunodeficiency.

cerebrospinal fluid Fluid surrounding the brain and spinal cord and also contained within the cavities of the brain. Analysis of cerebrospinal fluid may provide clues about pathological processes in the brain.

chemokines, chemokine receptors Chemokines are a family of molecules that are produced in the course of inflammation. Docking sites for such molecules (receptor sites) may be important for HIV entry into a host cell and also in HIV-mediated neural injury.

CXCR4 A type of chemokine receptor found predominantly on CD4 lymphocytes.

dementia, cortical A pattern of neurocognitive change similar to that seen in Alzheimer's disease.

dementia, subcortical Pattern of neurocognitive changes resembling those seen in Huntington's disease, Parkinson's disease, and certain "white matter" diseases of the brain.

gp120 A molecule in the envelope coating of HIV that may be neurotoxic.

human immunodeficiency virus The virus that causes HIV disease and AIDS.

integrase An enzyme of HIV necessary for the process whereby proviral DNA is integrated into the genome of the host cell.

neurocognitive Mental processes whose disruption strongly suggests reversible or irreversible brain injury. The neurocognitive functions (abilities) include attention, perceptual motor abilities, abstracting (including problem solving, planning, and executive functions), learning, remembering, and speeded information processing.

neurocognitive complications A spectrum of disturbances of neurocognitive functions ranging from asymptomatic impairment to frank dementia.

protease An enzyme contained in HIV that is involved in the late stages of HIV maturation.

protease inhibitors Drugs whose antiviral activity derives from their ability to interfere with the HIV enzyme protease.

reverse transcriptase An enzyme carried by HIV that allows it to form viral DNA from its RNA template.

reverse transcriptase inhibitors Drugs whose antiviral properties derive from their ability to interfere with the HIV enzyme reverse transcriptase.

virion A particle of HIV.

Acquired immune deficiency syndrome (AIDS) results from infection with human immunodeficiency virus (HIV). HIV infection is associated with destruction of certain immune cells, most notably the CD4 or "helper" T lymphocytes, leading ultimately to collapse of cell-mediated immunity and consequent susceptibility to various types of "opportunistic" infections and cancers. In the course of HIV disease, virus enters the central nervous system and this can result in disturbances in neurocognitive function—that is, deficits in mental processes such as attention, learning, remembering, problem solving, speed of information processing, and various sensory and motor abnormalities. In addition to the direct effects of HIV on brain function and structure, late complications that involve infection of the brain by other pathogens or development of neoplasia or vascular disturbances can also contribute to neurocognitive complications in late-stage HIV disease.

I. HUMAN IMMUNODEFICIENCY VIRUS

HIV is a member of the lentivirus subfamily of retroviruses. Retroviruses carry their genetic information on RNA (rather than DNA) but require the formation of viral DNA as a step in reproduction. This is accomplished by harnessing the machinery of the cell that the virus infects, wherein the viral enzyme reverse transcriptase facilitates forming DNA from the two strands of viral RNA within the infected host cell. The viral DNA so formed is integrated into the cell's genetic material and directs the host cell to manufacture new viral constituents. Essentially, these consist of a viral core surrounded by a glycoprotein envelope. Steps involved in viral replication are illustrated schematically in Fig. 1.

From a genetic standpoint, there are two types of HIV: HIV-1 and HIV-2. The predominant cause of AIDS worldwide is HIV-1, whereas HIV-2 remains limited to portions of western Africa. HIV-1, in turn, is classified on the basis of genetic analysis into a major group (group M) and an outlier group (group O). Again, the vast majority of infections worldwide are with group M viruses, with subtype B of group M predominating in the industrial world. The greatest diversity of subtypes is found in Africa.

A. Transmission of HIV

In the industrialized world, transmission occurs most commonly through men having sex with men and through sharing of infected "works" by injection drug users. Heterosexual transmission is on the rise in industrialized countries, and it is the most prevalent form of transmission in Africa and India. Transmission also occurs from infected mother to fetus and through the administration of contaminated blood products. The latter is no longer an important risk in industrialized nations but poses a continuing hazard elsewhere. From the standpoint of sexual transmission, both unprotected anal and vaginal intercourse constitute the most risky circumstances, with orogenital sex representing a fairly small risk and other activities such as kissing regarded as essentially risk free.

B. Course of HIV Infection

Not all exposure to HIV, be it through unprotected sex or sharing of needles, results in infection. Whether infection occurs seems to depend on factors such as amount of inoculum, pathogenicity of virus, and host resistance. In terms of sexual transmission, the presence of sores, other venereal disease, and mucosal tears may all facilitate transmission.

Once HIV gains access to a tissue, its replication depends on its ability to enter host cells. Such entry appears to require at least two types of receptors (docking mechanisms on cell surfaces). Sections of viral envelope protein (gp120) are capable of attaching to CD4 receptor sites on host cells. However, full attachment leading to fusion of virus with cell requires a coreceptor of the chemokine type. Dozens of types of chemokine receptors are known, but the most important in terms of HIV infection appear to be CXCR4 [found predominantly on CD4 (T4) lymphocytes] and CCR5 (found on macrophages, dendritic cells, and other cells).

Once virus successfully enters host cells, replication begins. The presence of viral RNA can be found in the blood of infected individuals within 1 week of infection. Initially, there is a rapid proliferation of virus, with as many as 10 billion virions being formed every day, accompanied by massive destruction of CD4

lymphocytes of which millions must be replaced on a daily basis. Within several weeks to months, however, a "steady state" is reached wherein the host's defenses succeed in suppressing viral replication. At this point, viral load in the blood is significantly reduced or may even become undetectable. Antibody to HIV is present, however, and it is the basis for the commonly used HIV test (the enzyme-linked immunosorbent assay).

For reasons that are still incompletely understood, host responses are not ultimately effective in eradicating HIV. Chronically infected host cells (e.g., in lymph nodes) continuously seed HIV, which may gradually undergo further genetic variation (termed quasispecies formation) that may create genotypes that are increasingly more successful in eluding host defenses. Over the years, the host's capacity to mount an effective immune response diminishes, leading to a critical drop in CD4 lymphocyte concentration (normal CD4 counts are on the order of 1000 cells per cubic millimeter; persons with CD4 counts below 200 per cubic millimeter are diagnosed as having AIDS).

The collapse of cell-mediated immunity sets the stage for infection by organisms that are normally held in check by these mechanisms. These include various mycobacteria, fungi, yeasts, protozoa, as well as cancers stimulated by proliferation by other viruses (e.g., Kaposi sarcoma, which is linked to herpesvirus infection).

C. Classification of HIV Disease

AIDS represents the final stage of HIV disease. It is defined as the experience of certain major complications of HIV infection and/or the presence of CD4 cell counts below 200 (Table I). Although the course of HIV infection varies widely, it is typical for a person to experience HIV infection for 10 years before AIDS-defining events occur. Prior to that time, the individual may spend many years as an asymptomatic carrier (CDC stage A; Table I).

D. Scope of the Problem of HIV Infection

The World Health Organization estimates that approximately 33 million people are currently HIV infected worldwide. There are probably about 750,000 HIV-infected persons in the United States, and approximately 600,000 persons have died of the disease in the United States since it was first described in 1981. In some countries of southern Africa, 25% or more of the population is HIV infected.

E. Treatment and Prevention of HIV Disease

In terms of prevention, some efforts have shown singular success (e.g., the virtual elimination of medical transmission in industrialized countries by ensuring the safety of blood supplies and use of universal precautions during medical treatments). On the other hand, the modification of sexual and drug use practices has been more difficult. Some successes have been achieved in selected high-risk groups (e.g., homosexual/bisexual men and some injection drug users participating in needle exchange programs). On a worldwide level, anti-AIDS campaigns have often been limited by political, cultural, socioeconomic, and education factors.

Progress toward developing a vaccine that might prevent the establishment of infection in the first place has been slow because of the great genetic diversity of HIV and its tendency toward rapid mutation. Several vaccines are in the process of being tested, but it remains to be seen whether such vaccines, usually based on the subtype B2 of HIV-1, will be useful in areas of the world where other subtypes predominate.

Considerable progress has been made in the development of antiretroviral medications that interfere at various stages of HIV replication. The earliest example was zidovudine [azidothymidine (AZT)], which interferes with HIV's ability to utilize reverse transcriptase (RT) to form viral DNA. There are now multiple examples of RT drugs of the nucleoside type, of which AZT is an example. Other types of RT inhibitors, termed nonnucleoside RT, have also been developed. Recently, drugs that interfere with another critical step in viral assembly, the protease inhibitors, have become available. The use of combination therapies that interfere at different stages of viral replication has proved effective in lowering plasma viral load to undetectable levels in many individuals that are treated. However, these drug combinations often have very significant undesirable and toxic side effects that may limit their tolerability; additionally, HIV's ability to rapidly mutate can eventually produce quasispecies that are resistant to various drug combinations. It is uncertain whether combination therapies can be effective in controlling viral replication on an indefinite basis. For a list of currently available drugs, see Table II. The U.S. federal guidelines for use of these drugs are shown in Table III.

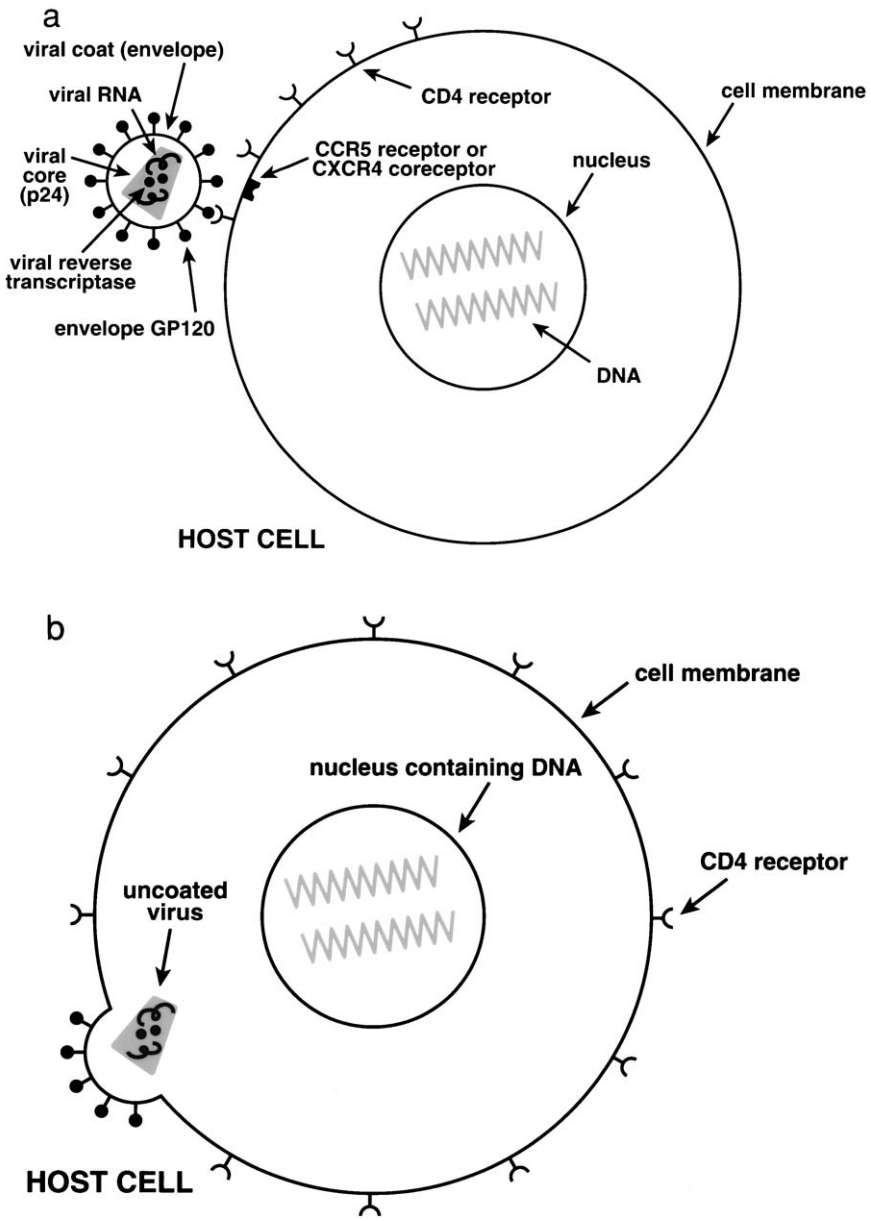

Figure 1 Stages of HIV replication. (a) HIV virion attaching to host cell. A segment of HIV envelope protein gp120 attaches to host cell CD4 receptor. Further process of attachment will involve linkage to a second host cell site, a chemokine coreceptor either of the CXCR4 (lymphocyte) or CCR5 (macrophage, dendritic cell) type. (b) After fusing with host cell wall, the uncoated HIV enters host cell cytoplasm. (c) Using its RNA template, HIV utilizes the viral enzyme reverse transcriptase to manufacture viral DNA within the host cell. This viral DNA ultimately enters the host cell nucleus and becomes integrated into host cell's DNA. (d) The viral DNA that is integrated into host cell's DNA directs formation of a viral RNA transcript, which leads to formation of viral RNA and genomic RNA. Through a translation process viral proteins are formed. (e) Viral constituents are assembled, virus particle buds off from host cell, and viral proteins are clipped into functional units by the viral protease enzyme.

II. HIV INFECTION OF THE BRAIN

There were reports of neuropsychiatric complications in AIDS even before HIV was determined to be the cause of the disease. Brain autopsies of persons dying with AIDS revealed a number of changes beyond those attributable to opportunistic infections or neoplasms. These HIV-related brain changes include

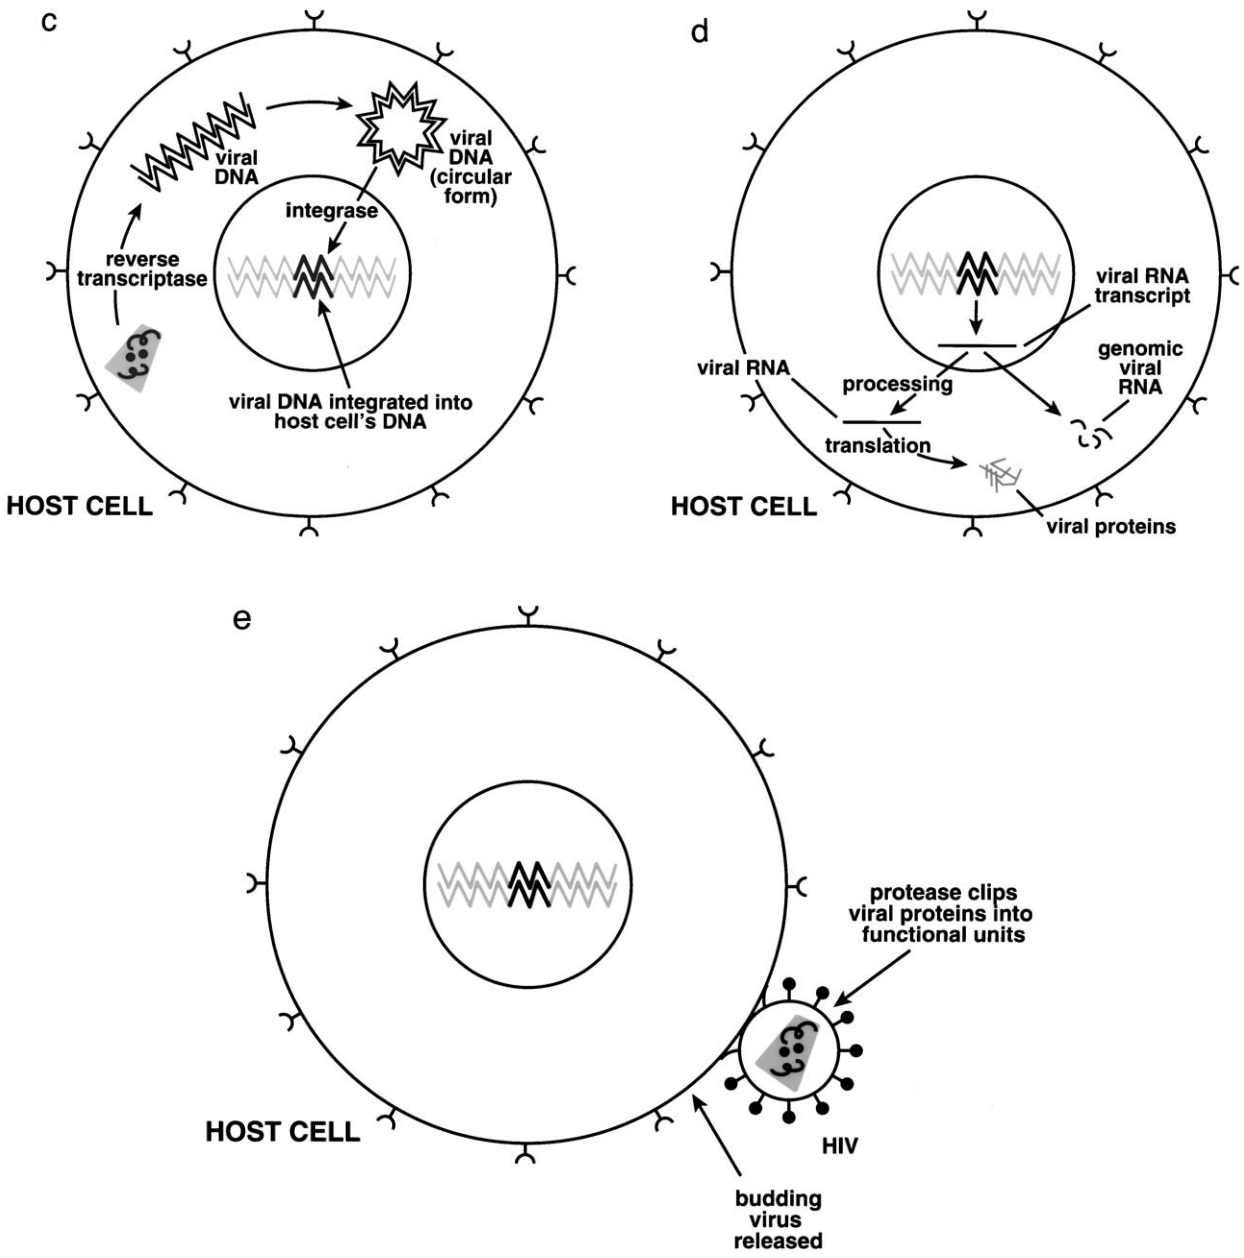

Figure 1 *(continued)*

inflammation, white matter abnormalities (vacuolar myelopathy), and nerve cell loss (poliodystrophy). The inflammatory process can be evidenced by perivascular lymphocytic infiltrates, accumulations of microglia into nodules, formation of multinucleated giant cells, as well as astrogliosis (Fig. 2).

Most persons dying with HIV infection have some detectable HIV in the brain. Although HIV can be found in any brain region, the greatest concentration of virus tends to be in subcortical gray structures (e.g., caudate nucleus) and surrounding white matter. HIV is localized within microglia and multinucleated giant cells but is not found in neurons. Despite this, the neurons of persons dying with HIV often display injury consisting of dendritic simplification and loss of synapses (Fig. 3). This has led to speculation that neural damage, and ultimately neuronal loss, may represent some combination of toxic factors and

Table I
1993 CDC Classification System for HIV Infection[a]

	Clinical categories		
	A[b]	B[c]	C[d]
CD4+ cell count categories	Asymptomatic or lymphadenopathy	Symptomatic but not A or C conditions	AIDS indicator conditions
$>500/mm^3$	A-1	B-1	C-1[e]
$200–499/mm^3$	A-2	B-2	C-2[e]
$<200/mm^3$	A-3[e]	B-3[e]	C-3[e]

[a]From CDC (1992).
[b]Category A includes acute HIV infection, asymptomatic infection, and progressive generalized lymphadenopathy.
[c]Category B includes conditions associated with HIV infection but that were not included in the CDC's 1987 case surveillance definition of conditions associated with severe immunodeficiency. Examples of "less severe" conditions include oropharyngeal candidiasis (thrush), persistent vulvovaginal candidiasis, severe cervical dysplasia or carcinoma, oral hairy leukoplakia, and recurrent herpes zoster involving more than one dermatome.
[d]Category C conditions are those associated with severe immunodeficiency identified in the CDC's 1987 surveillance definition for AIDS.
[e]CDC (1993) AIDS indicator conditions.

inflammatory mechanisms, balanced by protective mechanisms (Fig. 4).

III. MECHANISMS OF HIV NEUROPATHOGENESIS

A. Toxic Factors

It has been suggested that viral products, such as envelope protein gp120, may be neurotoxic. For example, gp120 causes cell death in neuronal cultures, and transgenic mice that constitutively overproduce gp120 show neuronal injury, with loss of dendritic spines and synapses. Lipton and colleagues suggested that gp120 may exert its effect by activating *N*–methyl-D-aspartate (NMDA) receptors, causing influx of calcium. Further evidence of this has been suggested by the fact that memantine, an NMDA antagonist, can block gp120-induced neurotoxicity. Recently, it has also been suggested that gp120 may bind to chemokine receptor sites on neurons, and this process may lead to activation of NMDA receptors and excitotoxicity.

Nonviral toxic products have also been implicated. For example, activated macrophages and astrocytes within the central nervous system are capable of producing increased quantities of quinolinic acid, an excitotoxic molecule. Previous research has found that the amount of quinolinic acid in the cerebrospinal fluid increases with stage of disease and is highest in those with HIV dementia (Fig. 5).

B. Inflammatory Factors

HIV probably enters the central nervous system within macrophages from the periphery, thereby establishing an intracerebral focus of infection in closely related microglia. Microglia (immune cells within the brain closely related to macrophages) may become infected, and these two cell populations feature prominently in two of the hallmark changes found in the brain of persons dying with HIV encephalitis—microglial nodules and multinucleated giant cells (Fig. 2). Astrocytes may also become activated; in addition to producing abnormal quantities of various molecules

Table II
Currently Available Antiretroviral Medications

Medication	Generic name	Brand name	Usual abbreviation
Nucleoside analog reverse transcriptase inhibitors	Abacavir	Ziagen	ABC
	Didanosine	Videx	ddI
	Lamivudine	Epivir	3TC
	Stavudine	Zerit	d4T
	Zalcitabine	Hivid	ddC
	AZT + 3TC	Combivir	
	AZT + 3TC + ABC	Trizivir	
Nonnucleoside analog reverse transcriptase inhibitors	Delavirdine	Rescriptor	DLV
	Efavirenz	Sustiva	EFV
	Nevirapine	Viramune	NVP
Nucleotide analog reverse transcriptase inhibitors	Tenofovir	Viread	TFV
Protease inhibitors	Amprenavir	Agenerase	APV
	Indinavir	Crixivan	IDV
	Lopinavir + RTV	Kaletra	LPV
	Nelfinavir	Viracept	NFV
	Ritonavir	Norvir	RTV
	Saquinavir	Fortovase Invirase	SQV

Table III
U.S. Federal Guidelines for Initial Treatment of HIV Infection

One from group A (highly active protease inhibitors) and one combination from group B (NARTIs):	
Group A	Group B
Indinavir	AZT + ddI
Ritonavir	d4T + ddI
Nelfinavir	AZT + ddC
Saquinavir SGC	AZT + 3TC
	d4T + 3TC
or	
A combination of ritonavir + saquinavir	

that may be neurotoxic (e.g., lymphokines and quinolinic acid), they may also alter their production of trophic factors that are necessary to sustain neurons. Examples of immune signaling molecules that can be damaging to neurons include tumor necrosis factor-alpha (TNF-α) and interleukin-6.

Masliah and colleagues suggested that different neuronal populations may be sensitive to differing types of injury. For example, pyramidal neurons may be particularly sensitive to NMDA-linked excitotoxic injury. However, interneurons, that are also damaged in HIV disease, contain proteins such as calbindin and parvalbumin that tend to protect against disruptions of calcium homeostasis. Masliah and colleagues argue that these neurons may be more vulnerable to damage by inflammatory mechanisms.

C. Protective Factors

Whether or not a neuron is injured may depend not only on the presence of inflammatory and toxic factors but also on protective mechanisms. For example, Sanders and colleagues recently reported that regions of the brain in which fibroblast growth factor (FGF) is expressed show less evidence of neural injury in the context of HIV infection. They suggested that FGF may be involved in altering intracellular signaling so that cascades leading to apoptosis (programmed cell death) are downregulated.

IV. DIAGNOSIS AND CLASSIFICATION OF NEUROCOGNITIVE COMPLICATIONS

The diagnosis of neurocognitive complications associated with HIV-1 infection requires the demonstration that there has been an acquired change in cognitive performance that has occurred since the person became HIV infected and that cannot be explained by other causes. Three levels of impairment have been described.

A. Asymptomatic Neuropsychological Impairment

This mildest form of neurocognitive complication is characterized by subtle changes in cognitive functioning that appear not to interfere in any obvious way in day-to-day functioning. Typically, a person will report feeling that he or she is not as "sharp" as he or she used to be and may complain of mild memory difficulties, difficulties in concentration, or some slight slowing down in mental functions. However, self-report alone is not sufficient to establish a diagnosis because this may be biased by mood disturbance (depression may lead to complaints that are unrelated to actual cognitive functioning) or lack of insight. The diagnosis requires demonstrating at least mild impairments in two different cognitive areas on comprehensive neuropsychological testing (Table IV).

B. Mild Neurocognitive Disorder

As described by the American Academy of Neurology, mild neurocognitive disorder, also known as minor cognitive motor disorder (MCMD), represents another mild form of cognitive abnormality that, however, is of sufficient magnitude that there is some impairment in at least one area of life functioning, such as inefficiency at work or management of domestic or financial affairs (Table V). As with asymptomatic neuropsychological impairment, comprehensive neuropsychological testing is necessary to establish that there are at least two areas of cognitive function in which performance is at least one standard deviation below that expected for persons of similar age, education, and sociodemographic background.

C. HIV-Associated Dementia

Dementia is diagnosed when there is impairment in at least two (and usually multiple) cognitive areas of sufficient severity to interfere markedly with day-to-day life (Table VI). Persons with HIV dementia are

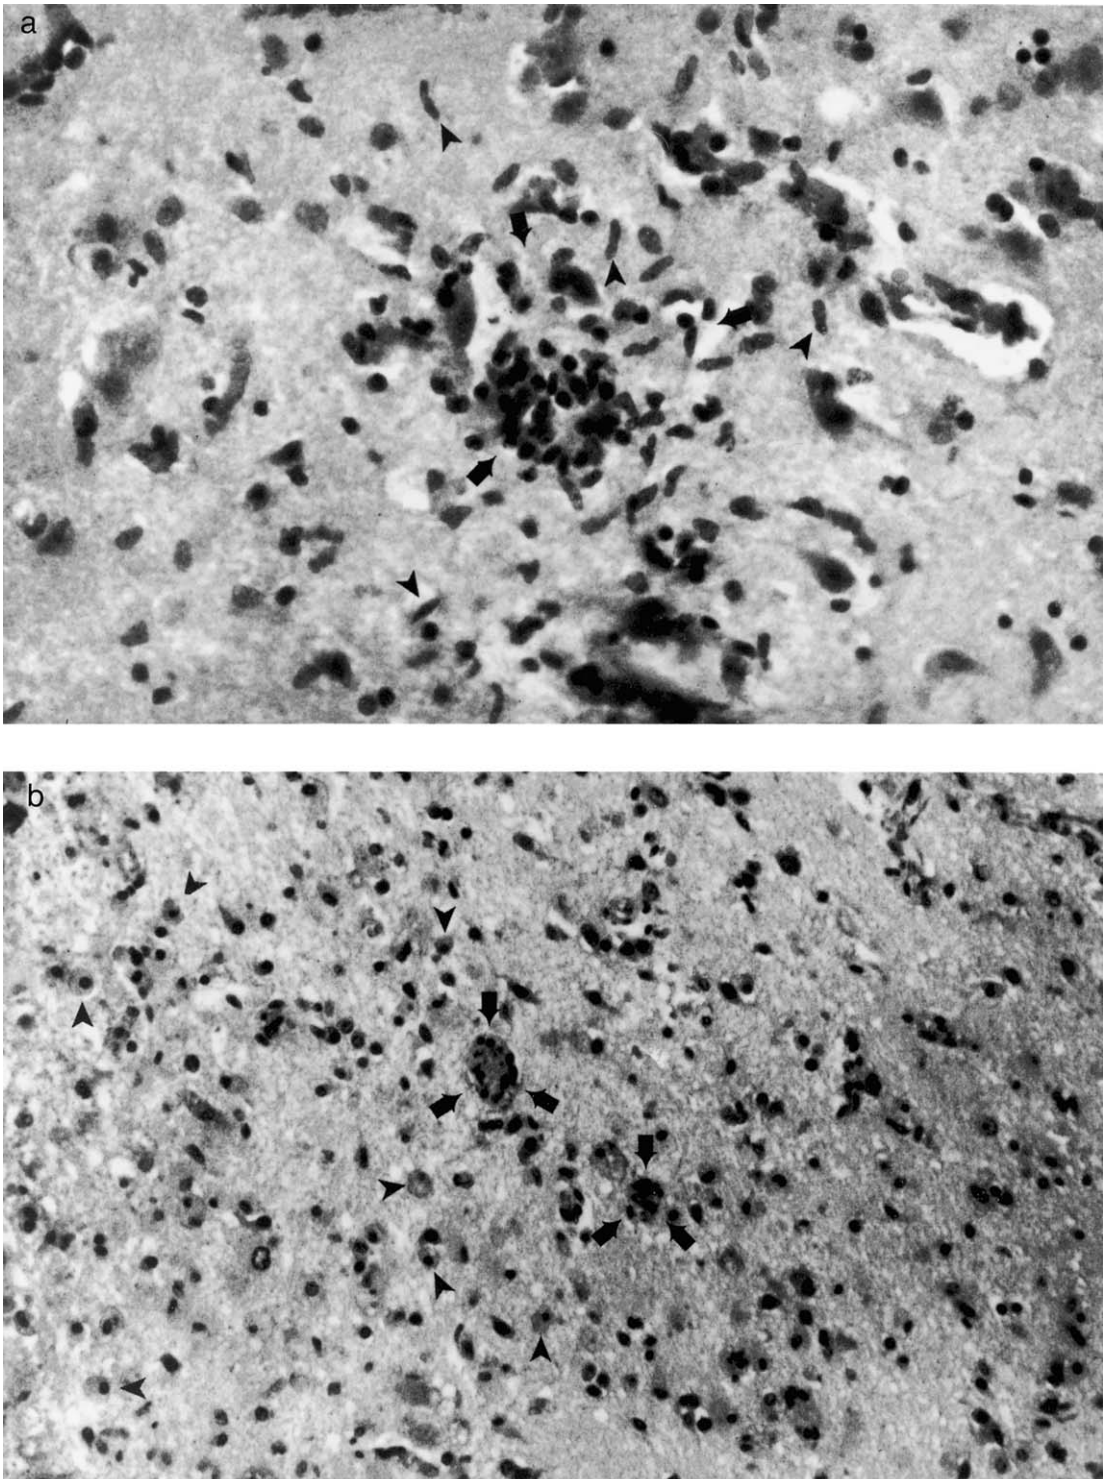

Figure 2 Microscopic anatomy of HIV brain disease. (a) Hematoxylin and eosin-stained, paraffin embedded section of AIDS brain tissue. A large microglial nodule is present in the center of the section (surrounded by three arrows). Numerous elongated microglial nuclei are present both within the nodule and in the surrounding tissue (arrowheads). Original magnification, × 600. (b) HIV p24 immunoperoxidase-stained, paraffin embedded section of AIDS brain tissue. Several large multinucleated giant cells (surrounded by arrows) contain black, amorphous immunoprecipitate of density similar to that of the oval nuclei. Numerous mononuclear macrophages (arrowheads) are distributed throughout the tissue. Original magnification, × 300 (courtesy of Clayton A. Wiley, University of Pittsburgh).

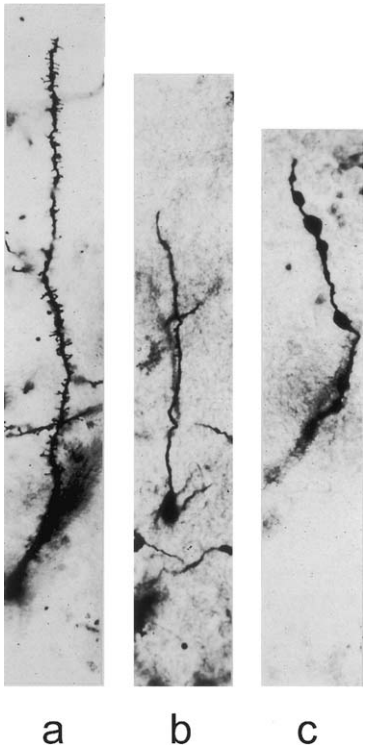

Figure 3 Dendritic pathology in HIV. Golgi-impregnated dendritic segments from control (a) and two cases with HIV dementia. There is loss of dendritic spines (b and c) and distortion and abnormal vacuolation of dendritic segment (c) (courtesy of Drs. Eliezer Masliah, University of California, San Diego, and Clayton A. Wiley, University of Pittsburgh).

typically unemployable and may have difficulty with independent living. The symptoms include significant psychomotor slowing and incoordination, marked inattention, slowness in information processing, difficulty in learning new information, and impairment in fluency. In some cases, the dementia may be accompanied by psychosis, including manic and paranoid phenomena. Some patients become markedly agitated, and others become apathetic and sometimes mute. The onset of frank dementia is a poor prognostic sign in HIV disease and is predictive of near future death in many instances.

V. EPIDEMIOLOGY OF NEUROCOGNITIVE COMPLICATIONS

Neurocognitive complications become more prevalent with progression of HIV disease. Thus, HIV dementia almost never occurs in stages A and B of HIV disease, but it may be found in 4–7% of those with frank AIDS. In earlier stage disease, neurocognitive impairment, if it is seen, is typically mild and may have a relapsing–remitting course. Observers continue to disagree on the prevalence of these complications in earlier stage disease. Data from the San Diego HIV Neurobehavioral Research Center are presented in Fig. 6. It can be seen that the rate of impairment increases with stage of disease. In the medically asymptomatic form of disease, only the mildest form of neurocognitive impairment tends to be observed (i.e., asymptomatic neuropsychological impairment). Minor cognitive motor disorder becomes more prevalent in stage B and stage C disease.

VI. ASSOCIATED FACTORS AND CORRELATES OF HIV NEUROCOGNITIVE COMPLICATIONS

It is difficult to predict who will and who will not develop neurocognitive complications. Clearly, progression of disease is one factor, as the data in Fig. 6 illustrate. However, general markers of disease progression, such as a decrease in CD4 count and an increase in beta-2 microglobulin (a marker of immune activation), are not powerful predictors of future cognitive complications. Plasma viral load is associated with neuropsychological impairment, but measuring the concentration of HIV in the cerebrospinal fluid (CSF) may provide a more specific indicator. For example, Ellis and colleagues reported that in patients with AIDS there was an association between CSF viral load, but not plasma viral load, and likelihood of neurocognitive impairment.

Markers of immune activation in the CSF have also been associated with neurocognitive impairment (e.g., an increase in CSF neopterin and CSF beta-2 microglobulin). As noted previously, concentration of the

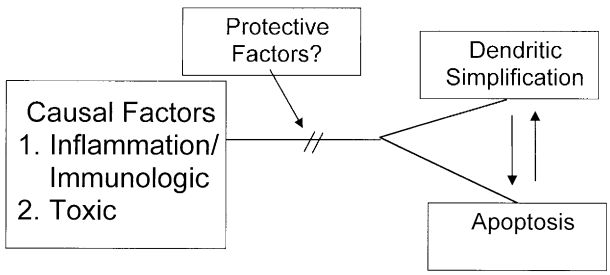

Figure 4 General model for HIV neural injury.

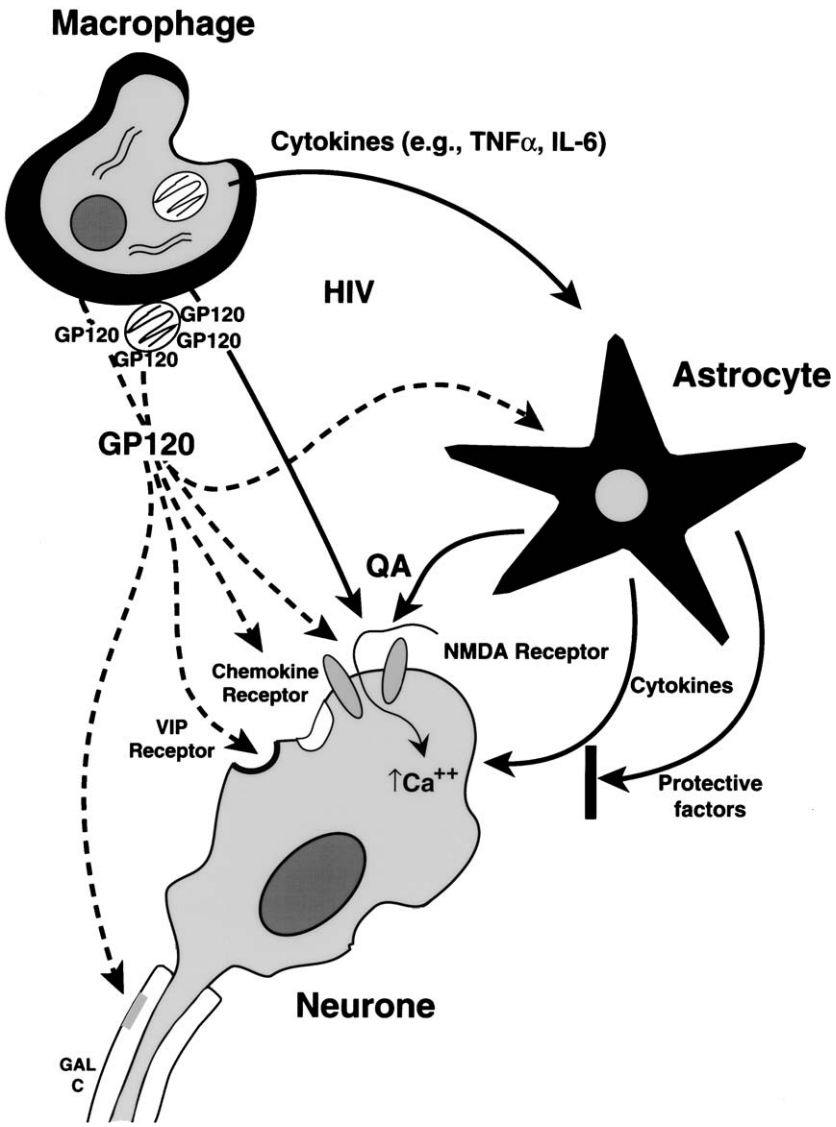

Figure 5 Some putative pathways in HIV neuropathogenesis.

excitotoxic compound quinolinic acid is also elevated in the CSF of those with HIV dementia; however, it is not clear whether quinolinic acid is another marker of immune activation or is somehow causally related to the neurocognitive impairment.

In terms of risk factors, contrary to expectation, there is no clear-cut association between injection drug use and heightened risk of neurocognitive complications. Although the rates of neuropsychological impairment tend to be higher among injection drug users generally, there does not seem to be an interaction between drug abuse and HIV status. An exception to this rule may be dependence on central stimulant drugs, especially methamphetamine. Preliminary observations suggest that history of methamphetamine dependence may enhance the likelihood of HIV-associated neurocognitive impairment perhaps because of some commonalities in mechanisms of neural injury that involve excitotoxicity.

There has been speculation that some of the subtle neuropsychological impairment found in HIV-infected persons might be due to depression, fatigue, or other nonspecific factors. This matter has received considerable exploration and the overall conclusion is that depression and medical symptoms generally do not explain the neuropsychological impairment. For

Table IV
Research Definition for HIV Neuropsychological Impairment

Performance at least 1.0 standard deviation below age–education norms in at least two different cognitive areas[a]
The impairment cannot be explained by comorbid conditions (e.g., substance abuse and medications)
The impairment does not occur solely as part of a delirium (e.g., due to CNS toxoplasmosis, lymphoma, or CMV)

[a]At least five of the following ability areas must be assessed: attention/information processing, language, abstraction/executive, complex perceptual motor, learning, recall/forgetting, motor skills, and sensory.

example, although depressive symptoms increase with frequency with disease progression, there is not a strong association between such symptoms and the likelihood of finding neurocognitive impairment. Similarly, Heaton and colleagues found that neuropsychological impairment could not be explained simply on the basis of fatigue and constitutional symptoms.

VII. COURSE OF NEUROCOGNITIVE COMPLICATIONS

HIV-related neurocognitive complications differ from those seen in degenerative disorders, such as Alzheimer's disease or Parkinson's disease. Most persons with mild impairments do not progress to develop dementia; indeed, many recover and some have a relapsing–remitting course. This is illustrated by the data in Figs. 7 and 8, derived from research at the San Diego HIV Neurobehavioral Research Center (HNRC). In Fig. 7, it can be seen that after a period of 1 year only about half of the cases judged to have MCMD or asymptomatic neuropsychological impairment remain in the same category. About one-fifth improve, and a small proportion worsen. When data over a period of 5 years were considered, it was found that about one-fourth of HIV-infected persons had a "wobbly" or relapsing–remitting course. This pattern of waxing and waning symptomatology is consistent with the presumed underlying etiology, which is thought to be linked to periodic flare-ups of viral activity or immune activation within the central nervous system.

VIII. QUALITATIVE FEATURES OF NEUROCOGNITIVE COMPLICATIONS

HIV neurocognitive complications are often described as having "subcortical" features. This means that the pattern of impairment is somewhat reminiscent of that seen in neurological diseases that affect primarily the subcortical structures or white matter and possibly pathology involving frontostriatal circuits (e.g., Huntington's disease, Parkinson's disease, and multiple sclerosis). Persons with this pattern of neuropathology tend to have difficulties in psychomotor abilities, speed of information processing, initiation, divided

Table V
Criteria for Mild Neurocognitive Disorder[a]

Acquired impairment in cognitive functioning, involving at least two ability domains, documented by performance of at least 1.0 standard deviation below the mean for age–education-appropriate norms on standardized neuropsychological tests. The neuropsychological assessment must survey at least the following abilities: verbal/language, attention/speeded processing, abstraction/executive, memory (learning and recall), complex perceptual–motor performance, and motor skills.
The cognitive impairment produces at least mild interference in daily functioning (at least one of the following):
Self-report of reduced mental acuity or inefficiency in work, homemaking, or social functioning.
Observation by knowledgeable others that the individual has undergone at least mild decline in mental acuity with resultant inefficiency in work, homemaking, or social functioning.
The cognitive impairment has been present at least 1 month.
The cognitive impairment does not meet criteria for delirium or dementia.
There is no evidence of another preexisting cause for the MND.[b]

[a]As defined by Grant and Atkinson (1995).
[b]If the individual with suspected mild neurocognitive disorder (MND) also satisfies criteria for a major depressive episode or substance dependence, the diagnosis of MND should be deferred to a subsequent examination conducted at a time when the major depression has remitted or at least 1 month has elapsed following termination of dependent-substance use.

Table VI
Criteria for HIV Dementia[a]

Marked acquired impairment in cognitive functioning, involving at least two ability domains (e.g., memory and attention): typically, the impairment is in multiple domains, especially in learning of new information, slowed information processing, and defective attention/concentration. The cognitive impairment can be ascertained by history, mental status examination, or neuropsychological testing.
The cognitive impairment produces marked interference with day-to-day functioning (work, home life, and social activities).
The marked cognitive impairment has been present for at least 1 month.
The pattern of cognitive impairment does not meet criteria for delirium (e.g., clouding of consciousness is not a prominent feature) or, if delirium is present, criteria for dementia need to have been met on a prior examination when delirium was not present.
There is no evidence of another, preexisting etiology that could explain the dementia (e.g., other CNS infection, CNS neoplasm, cerebrovascular disease, preexisting neurological disease, or severe substance abuse compatible with CNS disorder).

[a]As defined by Grant and Atkinson (1995).

attention, learning difficulties, difficulties in retrieval of information but not accelerated forgetting, and some executive dysfunction. To the extent that there are language problems, these are more in the area of fluency rather than naming. In contrast, the so-called "cortical" dementias (Alzheimer's disease and multi infarct dementia) are characterized by severe memory impairment that includes difficulty in learning new information as well as rapid forgetting, problems in naming and comprehension, and disturbances of praxis.

Thus, HIV-infected persons with asymptomatic neuropsychological impairment or MCMD tend to have mild learning difficulties, some problems with attention, difficulties with speed of information processing, some psychomotor slowing, and occasionally, difficulties with fluency. Although this may be the most typical pattern, it should be noted that since HIV-associated neurological injury can be widespread in the brain, there are some cases that have symptoms that are more cortical in nature, and others that have mixed features.

IX. SIGNIFICANCE OF NEUROCOGNITIVE COMPLICATIONS

Despite typically being mild and fluctuating in nature, HIV-associated complications can affect multiple aspects of life. For example, Heaton and colleagues demonstrated that those with impairment were twice as likely to be unemployed as persons without impairment. Also, even among the employed, those with mild impairment were performing at a level less

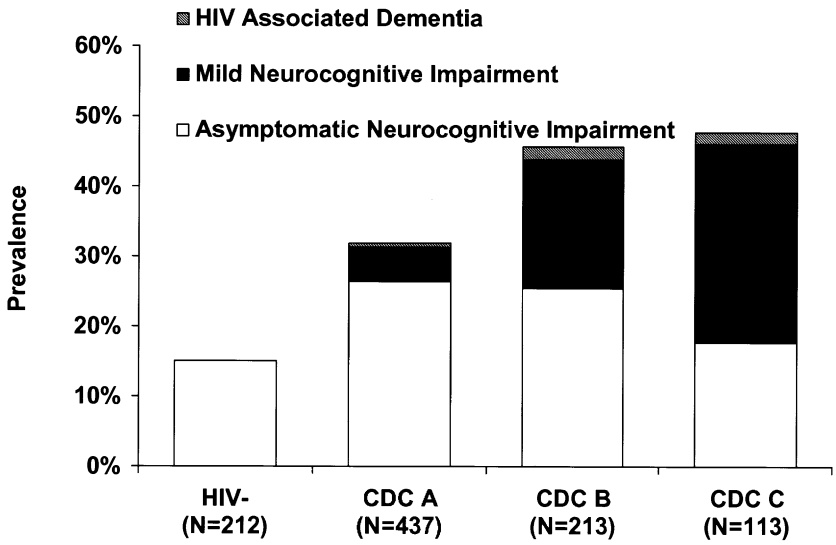

Figure 6 Prevalence of HIV neurocognitive complications at different stages of disease.

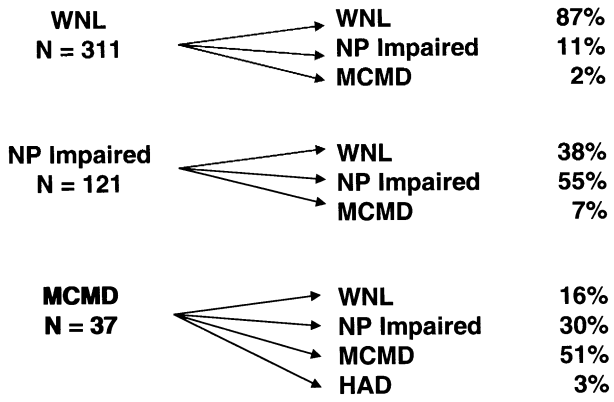

Figure 7 One-year progression of neurocognitive complications. HAD, HIV-1-associated dementia; NP, neuropschological; MCMD, minor cognitive motor disorder; WNL, within normal limits.

than expected based on uninfected comparison groups and also on infected but not impaired controls. Neuropsychological impairment associated with HIV may also affect important life activities, such as driving and medication management. For example, Marcotte and colleagues, utilizing the driving simulator, noted that those with impairment had more simulated accidents than the unimpaired. Recent data suggest that such individuals also had more actual on-road accidents and incidents. Recent observation at the HNRC also indicates that those with neuropsychological impairment may have more difficulties with managing their antiretroviral medication regimens. For example, Fig. 9 shows that more of the mildly impaired patients fail to take their medications as scheduled or as directed.

The presence of neurocognitive complications also predicts earlier death. For example, Ellis and colleagues noted that patients with MCMD had a median survival of 2.2 years, and those with asymptomatic neuropsychological impairment 3.8 years, versus 5.1 years for those who were neurocognitively normal. Adjustment of the survival analysis for CD4 count and other disease indicators revealed an independent effect for neurocognitive impairment. The mechanism for this remains unclear, but similar data were also reported from the Columbia University cohort.

X. TREATMENT AND PREVENTION OF NEUROCOGNITIVE COMPLICATIONS

The extent to which antiretroviral therapy protects against neurocognitive complications remains uncertain. Historical data indicate that the advent of the first antiretroviral (AZT) was associated with reduction in diagnosis of AIDS-associated dementia. However, not all investigators have reached the same conclusion.

The advent of potent antiretroviral combination therapies holds with it the promise of reducing viral load to unmeasurable or very low levels. Studies are under way to determine whether such viral load reductions are associated with neurocognitive improvement. Preliminary observations indicate that reduction of viral load in the CSF may be more specifically associated with neurocognitive improvement than reduction in plasma load. If correct, this would raise questions about the differential efficacy of new antiretrovirals. In other words, the possibility arises that agents may be extremely potent in lowering peripheral viral load but, because of their poor

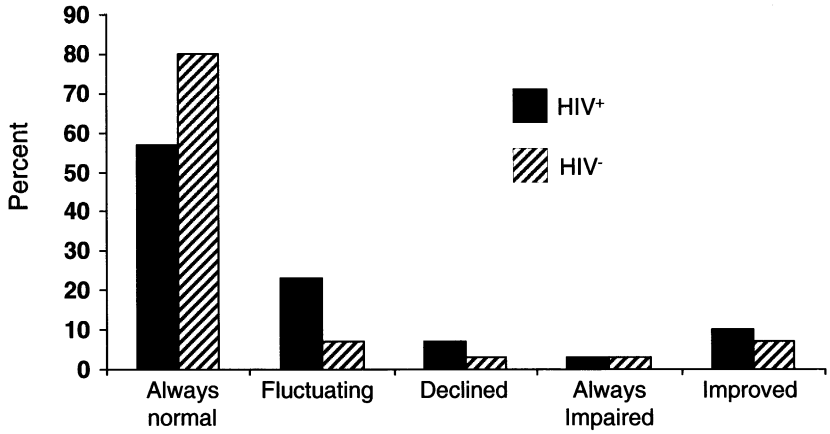

Figure 8 Neuropsychological course in participants with 5 years of annual assessments.

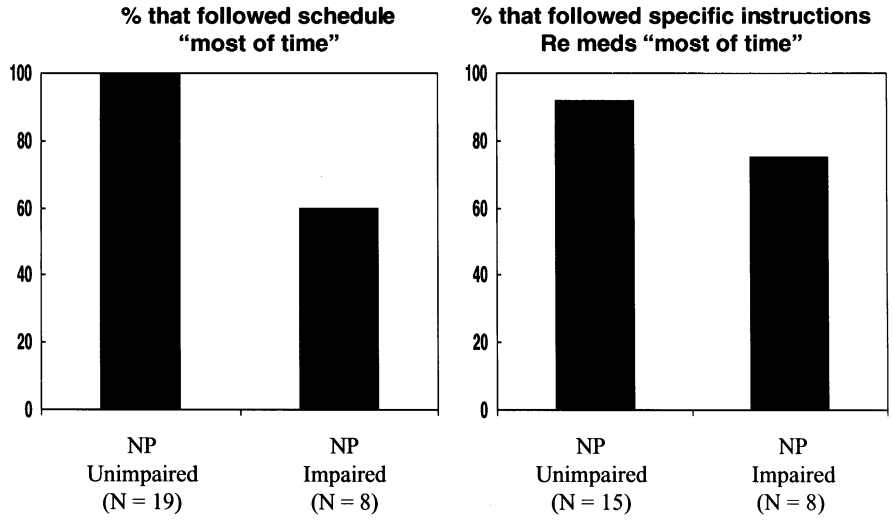

Figure 9 HIV neurocognitive impairment associated with worsened adherence to antiretroviral treatment.

penetration into the central nervous system, they may not be equally effective with regard to CNS complications.

Research is also ongoing to test drugs that may impact the putative mechanisms of neural injury. For example, a treatment trial is currently under way with the NMDA blocker memantine to determine whether reducing activity at glutamatergic receptor sites may be associated with neurocognitive improvement. A trial of peptide T, which putatively competes with viral envelope protein gp120 at neural receptor sites (e.g., receptor sites for VIP and possibly chemokine receptor sites), produced mixed results. Overall, it appeared that peptide T did not yield neurocognitive improvement; however, an analysis based on a subset of definitely impaired HIV-infected individuals did suggest some benefit. Thus, the question of peptide T's effectiveness remains unresolved. Pentoxyfylline, which blocks the action of TNF-α, was not promising in improving neurocognitive functioning in a preliminary trial.

XI. SUMMARY

Neurocognitive complications commonly occur in HIV disease, and their prevalence increases with disease progression. The impairments are typically mild in nature, often wax and wane, and affect primarily the capacity to learn new information, cognitive and psychomotor speed, and attention—a profile reminiscent of "subcortical" dementias such as those associated with Huntington's disease, Parkinson's disease, and white matter dementias. One of the fundamental substrates of the cognitive impairment is neural injury, including loss of dendritic spines and synaptic simplification. The mechanism of injury may involve the toxic effects of viral products such as gp120 as well as inflammatory mechanisms involving perhaps abnormal expression of various lymphokines. Protective factors may also be important, although the role of FGF and other trophic factors has yet to be established. Alhough they are usually mild in nature, HIV-associated neurocognitive disturbances can have substantial effects on day-to-day life, including employment, and day-to-day tasks such as medication management and driving skills. The presence of impairment is also associated with earlier mortality. Currently available antiretroviral drug combinations have increased survival of patients with HIV, but their potential to avert or improve neurocognitive complications is not conclusively established.

Acknowledgments

The work summarized in this article was performed in the context of the HIV Neurobehavioral Research Center (HNRC) (principal support by National Institute of Mental Health Grant MH45294). The San Diego HIV Neurobehavioral Research Center (HNRC) group is affiliated with the University of California, San Diego, the Naval Hospital, San Diego, and the San Diego Veterans Affairs Healthcare System and includes the following: director, Igor Grant,

codirectors, J. Hampton Atkinson, J. Allen McCutchan; center manager, Thomas D. Marcotte; Naval Hospital, San Diego, Mark R. Wallace; neuromedical component, J. Allen McCutchan, Ronald J. Ellis, Scott Letendre, and Rachel Schrier; neurobehavioral component, Robert K. Homeostatic Mechanisms

PIERRE-MARIE LLEDO
Pasteur Institute

GLOSSARY

cybernetics A term introduced by the mathematician N. Wiener (1894–1964) from the Greek *kubernetes* (''steersman''). This term, which defines a theory of feedback systems (namely, self-regulating systems), could be applicable not only to living systems but also to machines.

emotion From the earliest philosophical speculations onwards, emotion has often been seen as interfering with rationality, as a remainder of our presapiens inheritance: Emotions seem to represent unbridled human nature ''in the raw.'' Emotions are the product of an individual's own processing of occurrences on the basis of his or her own prior history and biology, and emotional response activates neural and neuroendocrine effector systems and leads to a variety of short- and long-term consequences that may or may not result in disease.

homeostasis The physiologist C. Bernard (1813–1878) introduced the concept of the constancy of the *milieu intérieur*. This internal milieu ensures the biological unity of the organism and confers a certain autonomy relative to the external milieu. The term homeostasis was coined some years later by W. B. Cannon (1871–1945). He developed the concept of homeostasis, which in modern terminology is the feedback control of servo-systems. This concept was not mathematically expressed until the 1940s, when it became the basis of cybernetics. Today, the term homeostasis refers to the adaptative response of an organism and tends to be substituted by a newer term, allostasis, which means ''stability through anticipatory change''; the long-term consequences of continued demand on the physiologic response are referred to as allostatic load.

hypothalamus A brain area that encompasses the most ventral part of the diencephalon where it forms the floor and, in part, the walls of the third ventricle. The hypothalamus consists of several nuclei that form a neuronal continuum. It plays a central role in homeostasis by controling the autonomic nervous system, the neuroendocrine system through its control of both the anterior and posterior parts of the pituitary gland, and the motivational states.

limbic system In 1878, P. Broca was the first to describe an annular ring of tissue on the medial face of the cerebral hemisphere that represents the free edge of the cerebral cortex. He named this part of the brain *le grand lobe limbique* (''the great limbic lobe''), which led to the concept of the limbic system. This system includes the hippocampal formation, entorhinal area, olfactory regions, hypothalamus, and amygdala. Functionally, the limbic system is generally thought to be concerned with visceral processes, particularly those associated with the emotional status of the organism. In fact, the interaction of all the structures in the complex, from the entorhinal area to the hypothalamus, plays a major role in the elaboration of the final actions of an organism in a particular environment and in the formation of adaptive behavior patterns.

How does the body adapt to environmental conditions? How does it organize its reactions to the world and other people? What are desire, pleasure, and pain? Going beyond the traditional dichotomies of body and soul, or reasonable brain and passionate body, we shall deal with what is called the constancy of the internal milieu for a human being brought by homeostatic mechanisms. Are we reductionist when we decide to approach the molecular mechanisms of our emotions? It must be recognized that while we announce that being is not just the sum total of the parts of the machine, this very machine shows itself to be increasingly complex as it gradually yields the secrets of its inner workings. It is indeed astonishing that we can analyze networks of billions of interconnected elements of an extraordinary

complexity and at the same time develop a single molecule capable of causing or correcting the most inextricable disorders of the mind. Therefore, the scientist is not the only one accused of reductionism: Nature provides an example of radical simplification.

Even a unicellular being has a certain degree of freedom between the information receptors on the cell surface and the effectors on the inside. The evolution of a species consists of a gradual increase in the number of intermediaries between information from the outside world and effectors responsible for actions. An animal's freedom increases in proportion to the number of these intermediaries. However, it is only because the liquid element and the substances it transports bring a solution of continuity to cell organization that this freedom is possible.

We shall therefore deal with the constancy of the internal milieu. The external milieu was a Greek invention, but the concept of internal milieu was introduced by C. Bernard (1813–1878). For Greek doctors and their disciples, man lived in harmony with nature. Temperament fixed the conditions of this harmony. However, the living being had no real identity or biological unity: The humors were nothing but a kind of reproduction, inside the animal, of the surrounding natural elements; there was no substantial difference between nutrients and living matter. The internal milieu ensures the biological unity of the animal and confers a certain autonomy relative to the external milieu. It is supposed to reconstitute around the cells the characteristics of the original marine environment.

In homeostasis, any departure from the norm draws mechanisms into play that tend to bring the trouble spot back to its initial state. Passions could thus be interpreted as a kind of neurosis of the normal, itself a fictitious immobile system of reference. In fact, behind the impassivity of the internal milieu a confused mesh of false constants is hidden, all of which are more or less dependent and variable from one species to the next, from one individual to the next, and, within each individual, from one situation to the next.

We can see the kind of safeguard that the constant agitation of the humors of the internal milieu offers the nervous system and its operational flexibility: Perhaps the brain runs the risk of falling victim (losing its soul?) to such a commotion. For its own protection, it can organize its own disorder: The brain–gland reveals itself as grand master of the humors by its multiple secretions of neurohormones. Like the brain–machine, the humoral brain simultaneously acts as the passionate victim and the orchestrator of its own passion.

I. THE INTERNAL MILIEU

Homeostasis is a widely and somewhat loosely used term for describing all kinds of responses following the principle of negative feedback control. The main concept of homeostasis is founded in the production of stability in dynamic systems by negative feedback. This concept is the basis of cybernetics, whose founding fathers were N. R. Ashby and G. Walter in the 1950s. However, the term homeostasis was coined years before cybernetics by the founders of modern physiology—C. Bernard, W. B. Cannon, and W. R. Hess. In Cannon's germinal book, *Wisdom of the Body*, the basic idea of feedback as a fundamental physiological principle is stated. In this context, constancy in the internal environment of the body is the result of a system of control mechanisms that limit the variability of body states. The internal milieu takes the form of a certain number of volumes called regulated variables. Without regulation, the changes in the external milieu and the functioning of the cells would make these volumes vary, when the very survival of the organism depends on their stability. Hence, stability is obtained as a result of a regulating system comprising several subsystems, each of which is subjected to control mechanisms and responsible for controlled variables. A regulated variable thus remains fixed within strict limits because of the intervention of controlled variables that have a much wider scope for variation. It is clear that this is an extremely important principle for almost all physiological processes as well as for the guiding of skilled behavior. Indeed, such a concept serves as a theoretical basis for the physiology of regulation. However, homeostasis, in the sense of constancy, does not adequately describe normal physiology, in which blood pressure, heart rate, endocrine output, and neural activity are continually changing—from sleeping to waking—in response to external factors and in anticipation of future events. At all times in the daily cycle, these parameters are maintained within an operating range in response to environmental challenges. The operating range, and the ability of the body to increase or decrease vital functions to a new level within that range upon challenge, particularly in anticipation of a challenge, has been defined as *allostasis* (or "stability through change"). The operating range for most physiological systems is larger in health than in disease, and it is larger in younger compared to older individuals. Exceeding this range can lead to disaster, as is the case when exertion leads to a myocardial infarction.

It is worth mentioning that the cell theory is inseparable from the concept of the internal milieu. The organism is composed of a host of cells that are scattered or grouped together in tissues. Each cell, individualized by its plasmatic membrane, plays out its fate under the genetic control of the nucleus. These cells are bathed with water-like fluid that forms the extracellular space, providing a medium for diffusion and homogenization around the cells. Bernard, comparing the weight of a mummy with that of a living human being of the same size, estimated the water content of the latter to be 90%—to be more precise, two-thirds water for one-third dry matter. This extracellular space, including the blood and lymph, is indeed a unifier of the organism. Unlike the external environment, which is subjected to uncontrollable change, the internal milieu oscillates slightly around normal values. Thus, the autonomy acquired by the organism relative to its external environment gives it an independent and free life since the constancy of the internal milieu does not mean fixity but rather a possibility to evolve.

The regulated variables define the constancy of the internal milieu. The most important are the gas content of the blood, acidity or pH, temperature, sugar content, blood pressure, and osmotic pressure. For example, we know that the more salty a solution, the higher its osmotic pressure. If for any reason an animals loses water, the salt concentration in the internal milieu (i.e., the osmotic pressure) increases. Because it is a regulated variable, osmotic pressure will be kept constant by regulating mechanisms: diminishing the outflow of water and/or increasing the intake. The outflow is reduced by slowing down the elimination process through the kidneys. Vasopressin, an antidiuretic hormone secreted by the brain, performs this function. The amount of this antidiuretic hormone circulating in the blood is a controlled variable that increases in responses to any increase in osmotic pressure. This is an example of hormonal regulation. The best way to increase intake is to drink. Beyond a certain level, the increase in osmotic pressure causes thirst and an urgent need to drink. Therefore, the regulating mechanisms can be of two kind: hormonal or behavioral. Despite the dry heat of the desert, a camel does not suffer from a much higher osmotic pressure than that of a bartender; it merely possesses more powerful regulating mechanisms that are adapted to the external milieu and that give the controlled variables, diuresis and water intake, a wider scope for action.

Nevertheless, there is a hierarchy to be respected. The most important constants must be maintained at all costs, even if this means sacrificing one of the lower orders. In case of need, a regulated variable can become a controlled variable. For example, blood pressure is constant, but if the oxygen content of the blood is endangered, because it is a hierarchical superior it will rise in order to provide a higher flow of gas and will thus temporarily become a controlled variable instead of remaining a regulated variable.

The internal milieu defined by Bernard—the blood and the fluids in which the cells are bathed—is thus the unifier of the organism. The cell draws from the extracellular fluid the nutrients its need, the fuel and oxygen that provide its energy, and the chemical factors that keep it in working order. It discharges into this milieu its waste and the produce of its activity. Here, we have Bernard's second idea, internal secretion, which is inseparable from the concept of the internal milieu. He discovered internal secretion while describing the glycogenic function of the liver. The hepatic cell draws from its reserves of glycogen the sugar that the organism needs and reintroduces it into the bloodstream. Internal secretion, which differs from excretion, demands a fluid medium that can receive the cell's outpourings. The term endocrinology, introduced by N. Pende (1909) to refer to the study of internal secretions, is now used only for the secretions of the so-called vascular glands, which are now called the endocrine glands. The function of these glands, which is much narrower than that of internal secretion, refers to a cellular secretion with no strictly metabolic function but that has a communicative role.

Although virtually all of the brain is involved in homeostasis, neurons controlling the internal environment are mainly concentrated in the hypothalamus, a neuronal structure located at the interface of the brain and peripheral functions. Here, I first focus on the anatomy of the limbic system and then on the anatomy of the hypothalamus, a small area that belongs to the diencephalon and that comprises less than 1% of the total brain volume. I then consider how the hypothalamus and other closely linked structures in the limbic system receive information from the internal environment and how they act directly to keep it constant by regulating endocrine secretion and the autonomic nervous system. Finally, other parts of the brain that may indirectly affect the internal environment by acting on the external environment through emotions and drives are described.

II. ANATOMY OF THE LIMBIC SYSTEM AND THE HYPOTHALAMUS

In 1953, J. Olds and P. Milner reported that the weak electrical stimulation of specific sites, most located in the hypothalamus or in its rostral continuation, the septum, could elicit in experimental animals an internal state of pleasure or in any case what psychologists describe as a state of reward. For the first time, this work provided a basis to the claim that the hypothalamus, and more generally a continuum of brain tissue in which the hypothalamus is central, is implicated not only in endocrine and visceral functions but also in affect and motivation. I first consider the structures and connections of the brain tissue related to the hypothalamus that belong to this neuronal continuum before examining the anatomy and numerous functions of the hypothalamus.

A. The Limbic System and Its Connections with the Hypothalamus

The neural continuum in which the hypothalamus is central is composed of a part of the brain stem and the limbic system. Part of the brain stem, the mesencephalic reticular formation, which receives inputs from spinoreticular fibers, possesses axons that ascend to the hypothalamus. There are also connections formed by axons directed upward to the hypothalamus from the nucleus of the solitary tract, a cell group in the medulla oblongata. These connections are quite revealing. The nucleus of the solitary tract is the only known case of a circumscribed secondary sensory cell group whose primary sensory input is from the visceral domain.

A second part of the continuum in which the hypothalamus is central lies rostral to it. It is largely interconnected with the phylogenetically primitive cortical tissue that surrounds the upper brain stem. A little more than a century ago, P. Broca observed an almost annular ring of tissue on the medial face of the cerebral hemisphere that represents the free edge of the cerebral cortex. This part of the brain, called *le grand lobe limbique* (the great limbic lobe) by Broca, has led to the concept of the limbic system. This "lobe" surrounds the diencephalon and the cerebral peduncles. He called it *limbique* from the Latin *limbus* because he conceived it as a threshold to the newer pallium. It is sometimes called the rhinencephalon to indicate that these regions of the brain derived during the course of evolution from structures previously associated with the sense of smell. However, the fact that the rhinencephalon is highly developed in animals such as the dolphin and man, in whom the sense of smell is nonexistent or limited, shows that it participates in other activities.

We shall retain only its key-ring structure opening upwards toward the neocortex and downwards toward the brain stem. Like the limbo of Christian mythology, the limbic system is the intermediary between the neomammalian brain heaven (represented by the neocortex) and the reptilian brain hell (including the reticular formation and the striate cortex). The limbic lobe includes the parahippocampal, the cingulate, and the subcallosal gyri. It also includes the underlying cortex of the hippocampal formation, which is composed of the hippocampus, the dentate gyrus, and the subiculum.

In the 1930s, it became evident to J. W. Papez that the limbic lobe formed a neural circuit that provides the anatomical substratum for emotions. He proposed that the hypothalamus is connected with higher cortical centers since it plays a crucial role in the expression of emotion. According to this idea, the neuronal circuit originally proposed by Papez consists of the cortex, which influences the hypothalamus through connections of the cingulate gyrus to the hippocampal formation. Information is then processed by the hippocampal formation and projected to the mammillary bodies of the hypothalamus by way of the fornix. The hypothalamus in turn provides information to the cingulate gyrus through a pathway from the mammillary bodies to the anterior thalamic nuclei and from the anterior thalamic nuclei to the cingulate gyrus (Fig. 1). P. MacLean's resynthesis of Papez's theory of emotions resurrected Broca's concepts and breathed new life into the concept of the all-pervasive limbic system. He included in the limbic system other structures anatomically and functionally related to those described by Papez, including parts of the hypothalamus, the septal area, the nucleus accumbens, neocortical areas such as the orbitofrontal cortex, and the amygdala (Fig. 1).

It is also noteworthy that all of the senses represented in the neocortex—vision, hearing, and the somatic sense—direct part of their information toward either one or both of two cortical districts: the frontal association cortex and the inferior temporal association cortex. The two are interconnected by a massive fiber bundle called the uncinate fasciculus. In turn, the inferior temporal cortex projects to the entorhinal area. The entorhinal area could be

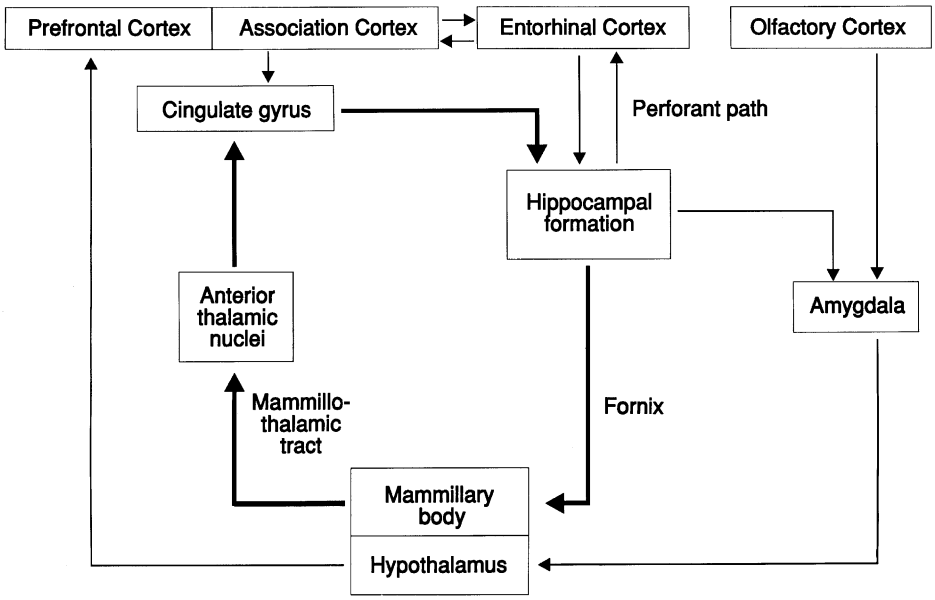

Figure 1 The neural pathways for emotion. The first circuit proposed by Papez is indicated by thick lines, whereas thin lines illustrate recently described connections.

considered as a cortical gateway for projections to the amygdala. In fact, in primates it gives the amygdala its single most important input. The projection is reciprocated; indeed, the amygdala directs its cortical projections to the inferior temporal cortex and to the frontal cortex (specifically the orbital surface of the frontal cortex). Therefore, the amygdala projects to the parts of the neocortex in which the final stages of the cascade of sensory information occur. Evidently, the amygdala also screens its neocortical input. Therefore, it has been tempting for many scientists to speculate that such a brain region could intervene in ideation and cognition. Ordinarily, one thinks of brain function as working inwards, i.e., sensory information being directed from sensory receptor organs over a sequence of synapses to the sensory cortex and from there (in what Papez called "the stream of thought") toward the limbic system. Here, we encounter the opposite: a set of connections directed outward. It is indeed as if the amygdala were participating in the brain's appreciation of the world.

The interoceptive and exteroceptive data reaching the neural continuum in which the hypothalamus is central are clearly distinguishable. The former consist of visceral sensory signals from the spinal cord and the brain stem. These data are unconditional stimuli pertinent to the maintenance of life. On the other hand, what enters the limbic system from the neocortex is fundamentally different. One might call it a repeatedly preprocessed, multisensory representation of the organism's environment. In this situation, the perception of the world is only biased by physiological needs.

It is also remarkable that among all the senses, olfaction possesses a particular link with the limbic system that was taken to be the "nose–brain". Today, it is clearly established that the primary olfactory cortex projects to the entorhinal area, which in turn contact the hippocampus. Thus, after years of fervent affirmation followed by years of fervent denial, the idea that the hippocampus receives olfactory signals was reintroduced. Indeed, the pathway that links olfaction with the limbic system is privileged. Hence, the path from the olfactory epithelium is more direct than the path from sensory surfaces such as the skin. Moreover, the primary olfactory cortex projects to the amygdala, in large part onto a particular cell group (the lateral nucleus of the amygdala), by bypassing the neocortex (Fig. 1). However, although it is clear that the main olfactory bulb (the first central relay for olfaction) projects to the amygdala in rodents, one wonders whether this connection is still present in humans. Indeed, the existence of a specialized area of the nasal mucosa called the vomeronasal organ, which sends information to a compartment of the accessory olfactory bulb, has been demonstrated in animals such as rats. The vomeronasal organ and the corresponding region of the accessory olfactory bulb are thought to

form an apparatus dedicated to the processing of sexually significant odors, but in the fully formed human body none of these structures have been identified. Finally, to emphasize the privileged link between olfaction and the limbic system, it has to be mentioned that the primary olfactory cortex also projects to the hypothalamus.

B. Structure of the Hypothalamus

The hypothalamus in the mammalian brain encompasses the most ventral part of the diencephalon, where it forms the floor and, in parts, the walls of the third ventricle. Its upper boundary is marked by a sulcus in the ventricular wall, the ventral diencephalic or hypothalamic sulcus, which separates the hypothalamus from the dorsally located thalamus (Fig. 2). Caudally, the hypothalamus merges without any clear limits with the periventricular gray and the tegmentum of the mesencephalon. However, it is customary to define the caudal boundary of the hypothalamus as represented by a plane extending from the caudal limit of the mammilary nuclei ventrally and from the posterior commissure dorsally. Rostrally, the hypothalamus is continuous with the preoptic area, which lies partly forward to and above the optic chiasm.

By means of the previously mentioned external landmarks at the ventral surface of the brain, the hypothalamus can be subdivided in the anterior–posterior direction into an anterior part that includes the preoptic area, a middle part, and a posterior part. Another subdivision in the lateral–medial direction consists of three longitudinal zones recognized as the periventricular, the medial, and the lateral zones. The

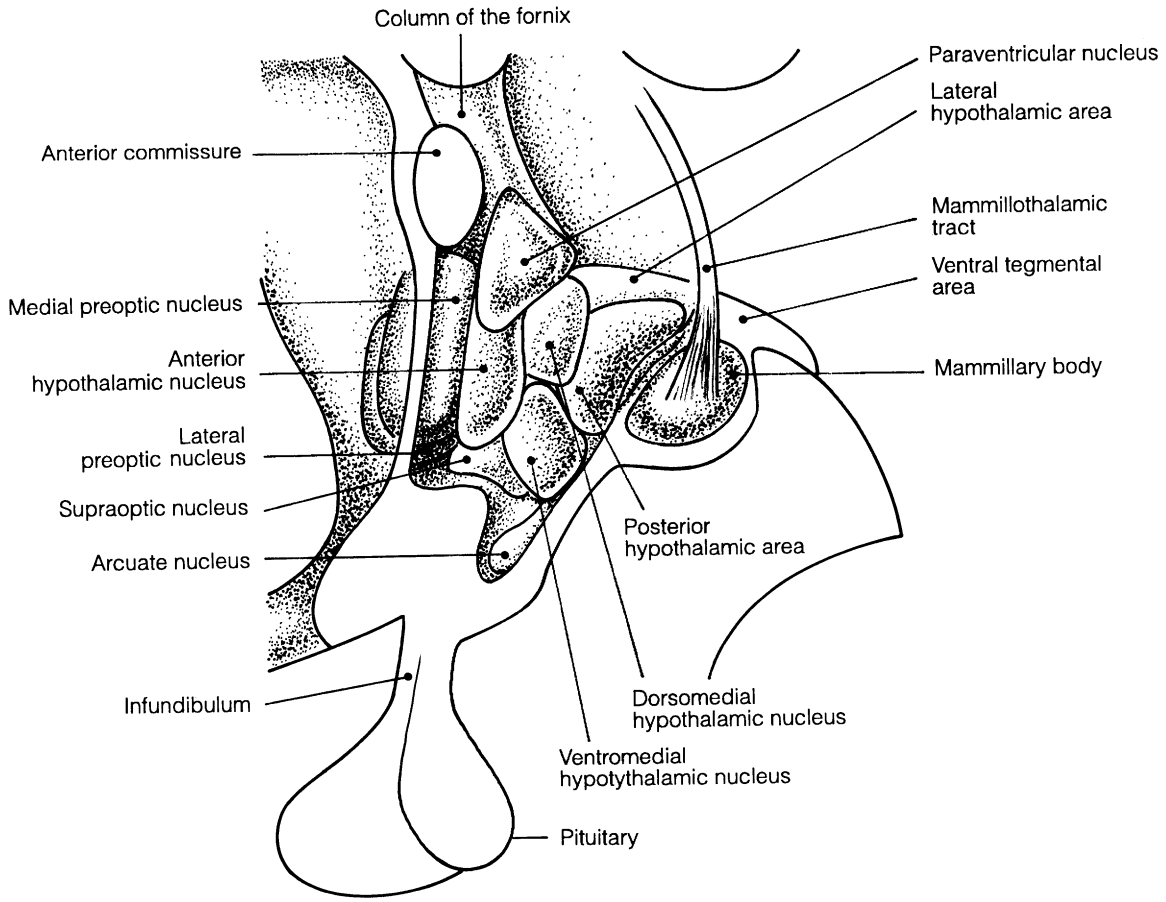

Figure 2 The location of the main hypothalamic nuclei shown in a medial view. The hypothalamus contains a large number of neuronal circuits that regulate vital functions, such as body temperature, heart rate, blood pressure, blood osmolarity, water and food intake, emotional behavior, and reproduction.

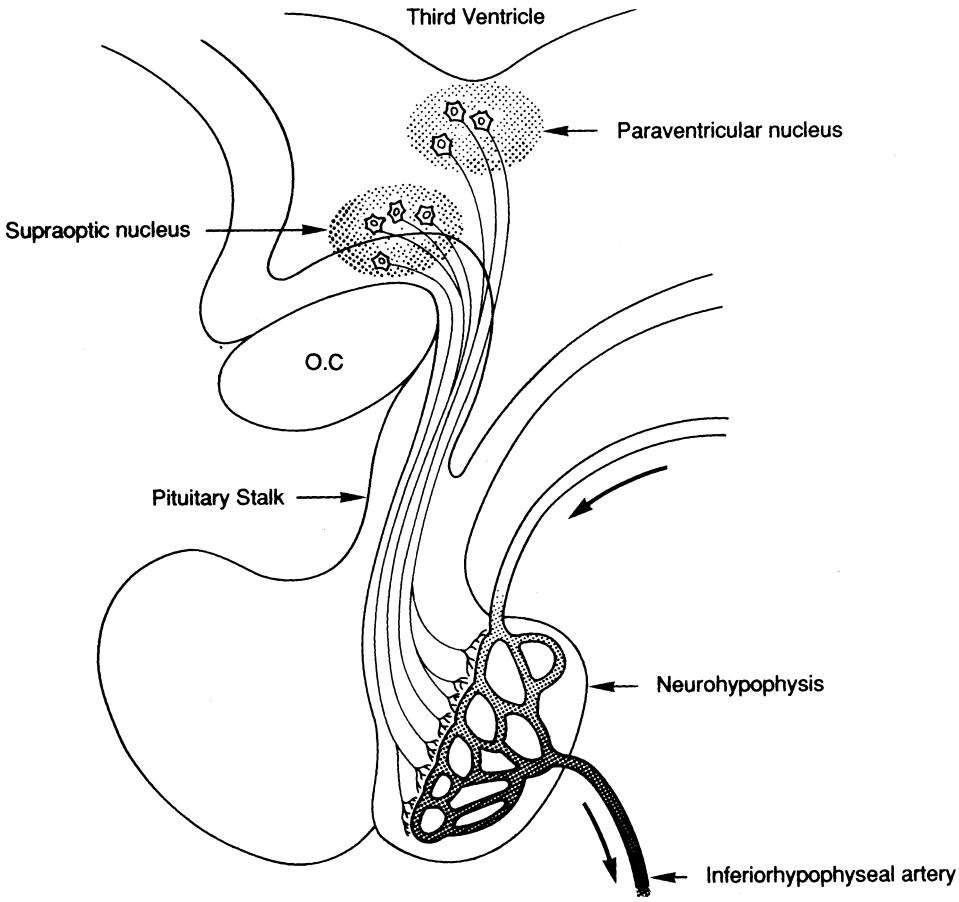

Figure 3 The posterior lobe of the pituitary gland. In the posterior lobe, axons from hypothalamic cell groups called supraoptic and paraventricular nucleus release vasopressin and oxytocin into the systemic circulation (inferior hypophyseal artery). OC, optic chiasm.

periventricular zone consists mostly of small cells that, in general, are oriented along fibers parallel with the wall of the third ventricle. The medial zone is cell rich, containing most of the well-delineated nuclei of the hypothalamus that include the preoptic and suprachiasmatic nuclei in the anterior region; the dorsomedial, ventromedial, and paraventricular nuclei in the middle region; and the posterior nucleus and mammillary bodies in the posterior region (Fig. 2). The lateral zone contains only a small number of cells interposed between the longitudinal fiber system of the medial forebrain bundle. This region possesses long fibers that project to the spinal cord and cortex as well as extensive short-fiber, multisynaptic ascending and descending pathways. The basal portion of the medial region and the periventricular region contain many of the small hypothalamic neurons that secrete the substances that control the release of anterior pituitary hormones. Most fiber systems of the hypothalamus are bidirectional. Projections to and from areas caudal to the hypothalamus are carried in the medial forebrain bundle, the mammillo-tegmental tract, and the dorsal longitudinal fasciculus. Rostral structures are interconnected with the hypothalamus by means of the mammillo-thalamic tracts, fornix, and stria terminalis. However, there are two important exceptions to the rule that fibers are bidirectional in the hypothalamus. First, the hypothalamo-hypophyseal tract contains only descending axons of paraventricular and supraoptic neurons, which terminate primarily in the posterior pituitary (Fig. 3). Second, the hypothalamus receives one-way afferent connections directly from the retina. These fibers terminate in the suprachiasmatic nucleus, which is involved in generating light–dark cycles. The role of these rhythms in the control of motivated behaviors is discussed later.

The following section describes the interrelated functions of the hypothalamus and the pituitary gland as well as some of the major functions of the limbic system.

III. PARTICIPATION OF THE HYPOTHALAMUS AND THE LIMBIC SYSTEM IN HOMEOSTASIS

The internal environment of the body, a term embracing tissue fluids and organ functions such as blood pressure, heart rate, and respiration rate, is under the control of three independent processes. The autonomic nervous system plays an important role in homeostasis. Hence, in the brain, neurons that affect the activity of the preganglionic motor neurons of the sympathetic and the parasympathetic nervous systems are concentrated in the hypothalamus. The evidence is clear: When the hypothalamus of almost any animal, including man, is suddenly destroyed, the animal dies as a consequence of severe disruption of what Bernard called the internal milieu of the body. However, controling the autonomic nervous system is not the only means by which the hypothalamus maintains homeostasis. In addition, the hypothalamus governs the neuroendocrine system through its control of both the anterior and posterior parts of the pituitary gland, which in turn play a major role in the constancy of the internal milieu. Finally, the internal environment of the body is also regulated by motivational states; therefore, we shall also consider some of the hypothalamic funtions involved in a repertoire of voluntary behavioral responses.

In analyzing the nerve mechanisms involved in homeostasis, two centers, one an inhibitor and the other an excitator, are always involved in controlling the same function. This dualistic conception is in the traditon of C. Bernard and W. Sherrington. The former taught us that the centers come into play each time the internal milieu records an abnormal value, and the latter noted that these centers are linked by the principle of reciprocal innervation. The nervous control of eating behavior illustrates this mechanism perfectly when the hunger center is inhibited by the satiety center. An entire theory of paired centers could be built on the hypothalamus. Besides the centers of hunger and satiety, these are centers of pleasure and aversion, approach and retreat, a parasympathetic region opposed to the orthosympathetic region. This anatomical and functional Manicheism goes beyond the hypothalamus to other structures, especially the limbic system and the amygdala, in which facilitating and inhibiting areas confront each other for each of the passions.

A. The Autonomic Nervous System

The autonomic nervous system is primarily an effector system that innervates smooth musculature, heart muscle, and exocrine glands. It is a visceral and largely involuntary motor system. Anatomical principles underlying the organization of both somatic motor and autonomic nervous systems are similar (Fig. 4) and the two systems function in parallel to adjust the body to environmental changes. Nevertheless, the two systems differ in several ways. Within the autonomic nervous system, two subsystems, the sympathetic and the parasympathetic, have long been distinguished by means of anatomical, chemical, and functional criteria. The sympathetic is the most extensive of the two systems. Its preganglionic motor neurons are located in the spinal cord, where they occupy a region called the latteral horn of the spinal gray matter. The preganglionic fibers employ the neurotransmitter acetylcholine, whereas the postganglionic fibers often must travel a substantial distance and employ the neurotransmitter norepinephrine. The sympathetic division of the autonomic nervous system promotes the organism's ability to expend energy (Hess called it ergotropic) and governs an endocrine gland, the adrenal medulla, considered to be a modified autonomic ganglion. It is indeed a universal mobilizing mechanism, valuable in emergencies, with postganglionic ramifications throughout the visceral realm.

In contrast, Hess described the parasympathetic nervous system as trophotropic to signify that it promotes the restitution of the organism. The parasympathetic nervous system in fact antagonizes the sympathetic's effects. The preganglionic motor neurons of the parasympathetic nervous system are in the brain stem and in a short stretch of the spinal cord near its caudal tip. Like the preganglionic motor neurons of the sympathetic nervous system, they employ acetylcholine as their transmitter, but the postganglionic transmitter of the parasympathetic is also acetylcholine. Their axons are long because the ganglia to which they project lie near the tissues of the viscera and sometimes even inside them (Fig. 4). The resilence of autonomic control is in good accordance with what is known about the conduction lines descending from the hypothalamus. Indeed, the hypothalamus emits axons

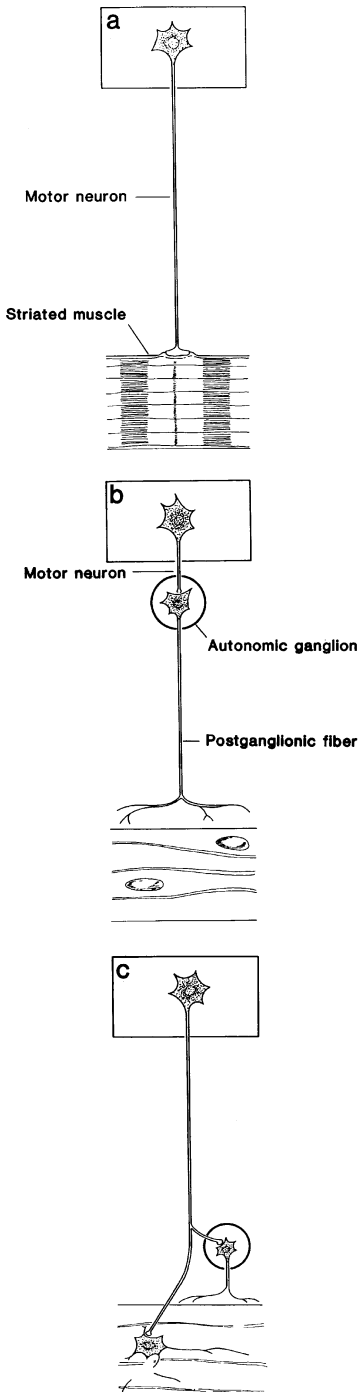

Figure 4 Three different motor innervations. (a) In the somatic motor pattern, a motor neuron from the spinal cord or in the brain stem animates striated muscles directly. In the visceral motor pattern, a two-neuron chain is required. (b) The sympathetic nervous system stations a "preganglionic" visceral motor neuron in the spinal cord. (c) The parasympathetic nervous system employs a two-neuron pathway. The first neuron is situated in the brain stem or toward the bottom of the spinal cord, and the ganglion is close or even inside the viscera.

that descend toward both sympathetic and parasympathetic preganglionic visceral motor neurons, thus regulating the viscera. Hence, the hypothalamus may function as the so-called head ganglion of the autonomic nervous system that mediates conventional reflexes involving neural inputs and outputs. Fibers passing directly from the hypothalamus to the lateral horn of the spinal cord's gray matter, where the preganglionic motor neurons of the sympathetic nervous system are situated, have recently been found. However, these fibers seem to constitute a small minority of hypothalamic efferents; the hypothalamus has nothing similar to a pyramidal tract to carry its descending outputs. Instead, it appears in large measure to project no further than the midbrain, where neurons of the reticular formation take over. It is noteworthy that pathways descending to autonomic motor neurons are interrupted at numerous levels, at which further instructions can enter the descending lines.

Most of the regions of the brain that influence the autonomic nervous system's output (e.g., the cerebral cortex, the hippocampus, the entorhinal cortex, parts of the thalamus, basal ganglia, cerebellum, and the reticular formation) produce their actions by way of the hypothalamus, which integrates the information it receives from these structures into a coherent pattern of autonomic responses. The hypothalamus controls the output of the autonomic nervous system in two ways. The first one is direct and consists of projections to nuclei in the brain stem and the spinal cord that act on preganglionic autonomic neurons to control respiration, heart rate, temperature and blood pressure. Thus, stimulation of the lateral hypothalamus leads to general sympathetic activation (increase in blood presure, piloerection, etc.). Second, the hypothalamus that governs the autonomic nervous system by controlling the endocrine system, which releases hormones that influence autonomic functions is discussed in the following section.

B. The Neuroendocrine System

The Scharrers (1940) first hypothesized that the peptides of the neurohypophysis were in fact synthetized by specialized hypothalamic neurons and transported within their axons to the neural lobe to be released into peripheral blood. In the late 1940s, Harris and collaborators proposed the hypophysial portal chemotransmitter hypothesis of anterior pituitary

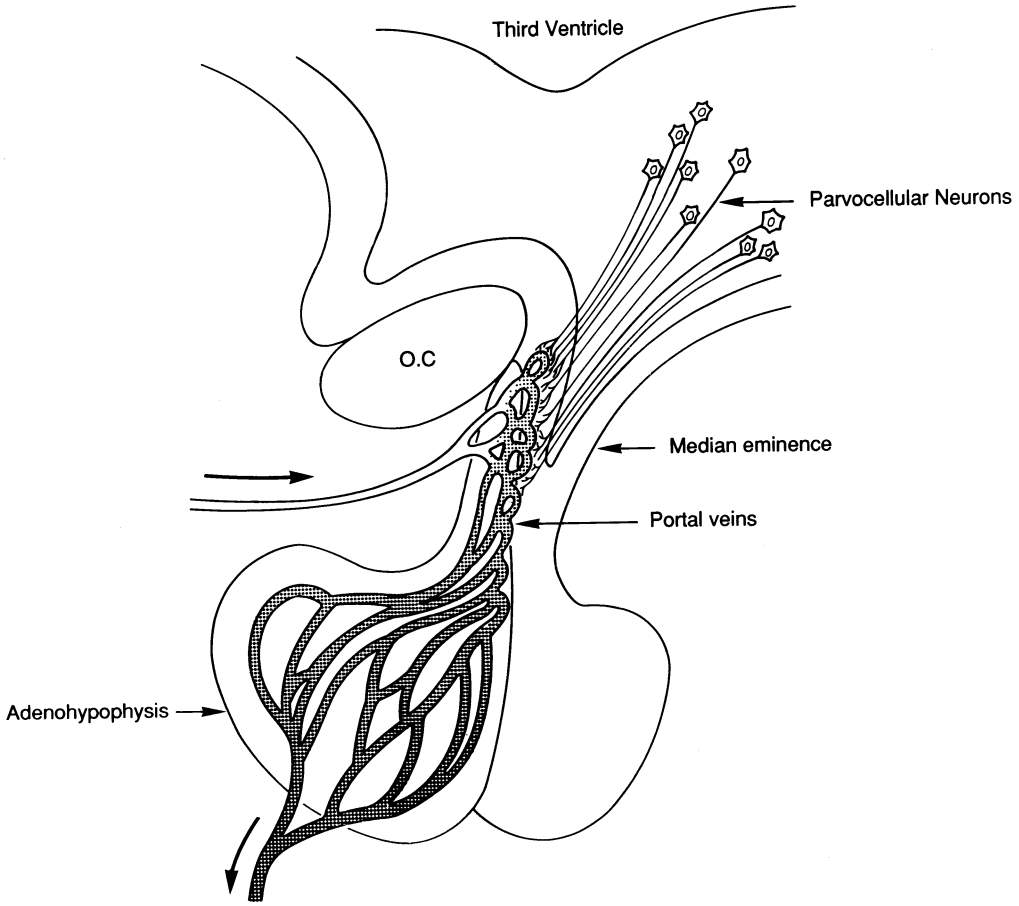

Figure 5 The anterior lobe of the pituitary gland. The anterior lobe synthetizes several hormones. Their release is induced by chemical signals, called releasing factors, that are secreted by hypothalamic neurons. These factors enter the hypothalamo-pituitary portal system, comprising first a capillary bed in the hypothalamus and then a venous drainage channel and, in the anterior lobe, a second capillary bed. OC, optic chiasm.

control, which stated that the factors regulating the anterior lobe are formed by hypothalamic neurons (later termed hypophysiotropic neurons) and transported to be released into the hypophysial portal circulation and carried to the anterior pituitary (Fig. 5), where they control the synthesis and release of anterior pituitary hormones into the general circulation. Both of these hypotheses have been confirmed and rationalized into a unified theory of neurosecretion in which the nervous system controls endocrine function. Neurosecretion is the phenomenon of synthesis and release of specific substances by neurons. Some neurosecretions are exported into the peripheral or hypophysial blood and act as true hormones; others, released in close apposition to other neurons, act as neurotransmitters or neuromodulators. Translation of neuronal signals into chemical ones has been termed neuroendocrine transduction and the cells have been called neuroendocrine transductors by R. J. Wurtman and F. Anton-Tay (1969). Two types of neurotransducer cells regulate visceral function: (i) neurosecretomotor cells, in which the neurosecretion acts directly through synapses on gland cells, and (ii) neuroendocrine cells, in which the neurosecretion passes into the blood and acts on distant targets.

Neurosecretory cells possess in common with other neurons the usual aspects of neuron functions. Most of the insight into the physiology of neurosecretory systems has been gained from studies of the hypothalamo-hypophyseal system. This system brings nervous and endocrine cells together in one anatomical entity in which the nervous system and the glandular cells of the

anterior hypophysis communicate. These two structures share common properties. They both secrete peptidergic hormones (releasing and inhibiting hypothalamic factors and the hypophyseal stimulins), and both exhibit electrical properties such as excitability, with production of action potentials. Thus, electrophysiological techniques, which were previously reserved for studies of nerve and muscle cells, can be applied to the hypothalamo-hypophyseal system in both its nervous and endocrine structures. The electrophysiological properties of these cells reveal the existence of (i) stimulus-secretion coupling, particularly at the level of neurosecretory terminals in the posterior hypophysis, the median eminance, and the endocrine cells of the anterior hypophysis, and (ii) modifications in membrane electrical properties exerted by the binding of different regulatory factors to their receptors. These observations are used to explain the modulatory mechanism of membrane properties brought into play by each factor in order to enhance or inhibit hormonal release. Thus, the electrical properties play a central role in the regulation of endocrine secretion in the anterior hypophysis. These electrical properties, common to nervous and endocrine cells, are linked to changes in membrane permeability to different ions (i.e., Ca^{2+}, Na^{+}, K^{+}, and Cl^{-}).

The pituitary gland is divided into two main functional units—the neural (or posterior) lobe and the adenohypophysis (or anterior) lobe (Figs. 3 and 5). In many mammalian species an intermediate lobe (derived embryologically from the same tissue as the anterior lobe) is present, but in humans these lobe cells are dispersed throughout the entire pituitary gland.

In the neurohypophyseal system, hypothalamic neurons transmit action potentials along their axons in a similar manner to that used by unmyelinated neurons, and each action potential triggers the release of secretory granules from nerve endings by calcium-dependent exocytosis into the general circulation. The neural lobe is an anatomical part of the neurohypophysis that is commonly viewed as consisting of three portions—the neural lobe (infundibular process or posterior pituitary), the stalk, and the infundibulum. This latter portion forms the base of the third ventricle (Figs. 3 and 5). In fact, there is a fourth intrahypothalamic component of the neurohypophysial system that consists of the cells of origin of the two principal nerve tracts that terminate in the neural lobe—supraopticohypophysial and paraventriculohypophysial.

The neurohypophysial hormones secreted by the magnocellular neurons are vasopressin (antidiuretic hormone) and oxytocin, which are synthesized within the cell bodies in association with specific proteins, the neurophysins. Like most peptidergic hormones, vasopressin and oxytocin are cleaved from a larger prohormone. These prohormones are synthesized in the cell bodies of the magnocellular neurons and are cleaved within vesicles during their transport down the axons. Vasopressin, oxytocin, and at least two forms of neurophysins are secreted into the blood circulation; they are responsive to appropriate physiological stimuli and can be altered by stressful conditions.

Although the anterior lobe does not receive any direct nerve supply, its secretions are under control exerted by the hypothalamus. This control is mediated by chemical factors (hypophysiotropic hormones) secreted by the parvocellular neuroendocrine neurons located in several hypothalamic regions: the medial basal and periventricular regions and the arcuate, tuberal, preoptic, and paraventricular nuclei. Parvocellular neurons secrete peptides in the interstitial space of the base of the third ventricle and then diffuse into the capillary plexus of the median eminence that is interposed between the peripheral arterial system and the pituitary sinusoidal circulation (Fig. 3). By this anatomical arrangement, neurohormonal mediators synthesized and released by the hypothalamus are brought into direct contact with the adenohypophysis. The hormones released by the anterior lobe of the pituitary gland are called tropic (literally "switch-on") hormones. Each is the second and final messenger in a sequence of chemical signals leading from the brain to a particular endocrine gland. All the tropic hormones of the anterior lobe are simultaneously trophic hormones, in whose absence their target glands atrophy.

A different functional link leads from the neurons of the hypothalamus to the posterior lobe of the pituitary complex. This link is more direct since it does not include part of the circulatory system. It begins in two circumscribed magnocellular nucleus. They are the first hypothalamic nuclei whose function has been identified with some precision. All, or nearly all, of the axons originating in the supraoptic nucleus, along with approximately 30% of the axons originating in the paraventricular nucleus, pass through the pituitary stalk and reach the posterior lobe of the pituitary. The remaining 70% have several destinations, of which one is especially notable: The paraventricular nucleus is a substantial contributor to the pathway descending from the hypothalamus direct to the lateral horn of the spinal cord, which contains the spinal cord's preganglionic sympathetic motor neurons.

Unlike the anterior one, the posterior lobe is a part of the brain. Nevertheless, it contains no neurons; the

terminations of the supraoptic and paraventricular axons make no synaptic contacts. Instead, they lie embedded in a tissue composed of modifed glial cells called the pituicytes and a dense plexus of capillaries. The glandular products of the supraoptic and paraventricular nuclei are synthesized in the cell body and packaged in neurosecretory vesicles in which some hormonal maturation may occur. These neurosecretory vesicles are transported down the axon to the neural terminal, where hormones are stored and released by secretion when the neuron is stimulated.

Recently, it has been demonstrated that a type of ependymal glial cell called tanycyte, which ensheaths the terminals of hypothalamic neurons, regulates the release of luteinizing hormone-releasing hormone (LHRH) from the hypothalamus and may therefore play a key role in the onset of puberty. LHRH axons that travel with the processes of tanycytes can be covered by slips of glioplasm. At the perivascular space level, the nerve terminals may be partially covered or exposed, potentially impeding or enhancing the secretion of LHRH into capillaries. Such observation, realized at a cellular level, illustrates the tremendous plasticity of the hypothalamus. Interestingly, it was found that these glial cells in the median eminence possess estrogen and epidermal growth factor receptors, whereas LHRH neurons apparently do not. Taken together, these observations provide strong evidence that, at puberty, glia is a crucial target for estrogenic action that may induce morphological changes accompanied by release of chemical signals that modulate hypothalamic neurons.

C. Behavioral Responses

When Hess succeeded in implanting electrodes in the brain and permanently fixing them to the skull of animals, he found that stimulation of different parts of the hypothalamus produced a array of behavioral responses. For example, electrical stimulation of the lateral hypothalamus in cats elicited autonomic and somatic responses characteristic of anger: increased blood pressure, raising of body hair, pupillary constriction, raising of the tail, and other characteristic emotional behaviors. Thus, the hypothalamus is not only a motor nucleus for the autonomic nervous system, as well as a neural part controlling the neuroendocrine system, but also a coordinating center that integrates various inputs to ensure a well-organized, coherent, and appropriate set of autonomic and somatic responses. In line with this view, vasopressin, oxytocin, and other regulating hormones are not the only peptides of neurobiological interest that can be found in the hypothalamus. The opioid peptides, β-endorphin, and the enkephalins can also be detected in this structure, as can angiotensin II, substance P, neurotensin, cholecystokinin, and a host of other peptides known to be involved in multiple behavioral responses. Interestingly, almost every type of peptidergic neuron previously studied, including both parvocellular and magnocellular hypothalamic neurons, has been found to contain more than one type of peptide that could act synergistically. Furthermore, peptides released by the hypothalamic magnocellular and parvocellular neurons are not unique to these cells; they have also been found in other regions of the nervous system. Such peptidergic projections are well suited for coordinating neuroendocrine and autonomic responses. For example, regulatory peptides released at brain sites other than the median eminence may modulate behavior by actions independent of the release of pituitary hormones. The behavioral effects of regulatory peptides are thematically related to the type of endocrine effects produced by the same peptide acting on the pituitary. Corticotropin-releasing hormone (CRH) is an example of such a regulatory peptide. On the one hand, it acts on the pituitary to stimulate the release of adrenocorticotropic hormone in response to stress. On the other hand, when injected intracerebroventricularly, CRH evokes many of the behavioral and autonomic reactions normally seen in response to stress.

D. Limbic Functions

In 1937, Papez suggested that the limbic lobe formed a neuronal circuit that provided the anatomical substratum for emotions. Based on experimental results suggesting that the hypothalamus plays a critical role in the expression of emotions, Papez argued that since emotions reach consciousness and thought and, conversely, higher cognitive functions affect emotions, the hypothalamus must communicate reciprocally with higher cortical centers.

The representation of the outside world and the internal milieu are superimposed in the limbic system. All the sensory information about the perceiver's environment is inscribed in the neuronal network of the limbic cortex, the hippocampus, and the amygdala. The vegetative, nervous, and humoral functions that

contribute to homeostasis are represented simultaneously in the limbic system. Moreover, the hippocampus has been described as a gatekeeper embodying the brain's ability to commit things to lasting memory. Evidence for such a role of the hippocampus is clear. For instance, the neurosurgical removal of the hippocampus on both sides of the human brain, as a treatment of otherwise intractable forms of epilepsy, leads to a central disorder called hippocampal amnesia. The patient retains the memories he or she collected well before the surgery but cannot collect new ones.

Other evidence suggests that the amygdala is not only essential for olfactory discrimination but also commands a number of adaptative responses. Lesions and electrical stimulations of the amygdala produce a variety of effects on autonomic responses, emotional behavior, and feeding. Consequently, the amygdala has been implicated in the process of learning, particularly learning those tasks that require coordination of information from different sensory modalities or the association of a stimulus and an affective response.

Finally, it has been extensively described that the interplay between the neural activity of the hypothalamus and the neural activity of higher centers results in emotional experiences that we describe as fear, anger, pleasure, or satisfaction. For example, the behavior of patients from whom a part of the limbic system (frequently the prefrontal cortex) has been removed supports this idea. Indeed, these patients are no longer bothered by chronic pain or, alternatively, when they do perceive pain and exhibit appropriate autonomic reactions the perception is no longer associated with a powerful emotional experience.

In summary, neurons from the limbic system form complex circuits that collectively play an important role in numerous behavioral responses, such as learning, memory, and emotions. Such a role played by motivational states in homeostasis is discussed in the next section.

IV. ROLE OF MOTIVATIONAL STATES IN HOMEOSTASIS

The role of the hypothalamus and the limbic system in the neuroendocrine and autonomic regulation of homeostasis was previously described. Here, I discuss the control of homeostasis by motivational states, the internal conditions that arouse and direct elementary behavior. Motivational states (also called drives) are inferred mechanisms to explain the intensity and direction of a variety of voluntary behaviors, such as temperature regulation, feeding, consumption of water, and sexual behaviors. It is the internal state that creates drives by deviations from the norm that defines the conditions of equilibrium for the milieu. A drive is not the stimulus that triggers the behavioral response but rather the internal force that underlies it. However, a stimulus may cause a drive when it has been associated in the past with a particular internal state. Because of the flexibility of internal parameters that define a pseudoequilibrium for the internal milieu of a living organism, it would be more appropriate to refer to the internal state as a fluctuating central state.

Specific motivational states possess two components: *needs* and *rewards* participating in homeostatic drives. Drives represent urges or impulses based bodily needs that lead animals into action. This concept is central to Freudian psychology, which is related to needs and experiences of satisfaction. Needs are experienced as an intolerable internal situation that must be stopped. This internal state, called motivation by psychologists, induces a drive to accomplish the act that will relieve it. For example, a temperature-regulating drive is said to control behaviors that directly affect body temperature, such as rubbing one's hands together. Therefore, physiological deprivation may lead to the satisfaction of a need and this, in turn, will lead to response reinforcement. This means that this action will become more likely in similar future situations. Such a psychological process is considered by some behaviorists to be the basis of learning.

So far, I have dealt with the role of tissue needs in generating appropriate behaviors and physiological responses to fight against a bodily deficit. However, another component linked with motivated behaviors is reward, which may lead to a profit. For example, sexual responses do not appear to be controlled by the lack of specific subtances in the body but are rather oriented toward hedonic factors. In this case, drives, by producing goal-oriented behaviors, are defined by the goal to be reached and justified by the reward obtained. One form of reward is pleasure; therefore, the duality of profit and pleasure is the major component of drive. On the other hand, drive–reward constitutes one of the rules of learning.

Finally, in describing the factors that regulate motivated behaviors, I must also be noted out the role of ecological constraints and anticipatory mechanisms. The characteristics of most behavioral responses are determined by evolutionary selection,

which retains only appropriate responses in a defined ecological surounding. In this context, one of the most determinant parameters that participate in keeping a specific behavioral response is the cost-benefit ratio. The other component that also controls motivated behaviors, namely anticipator mechanisms, gives to the homeostasis concept its temporal dimension. Sometimes, lack rather than need is able to activate drives. In the case of sexual arousal, a feeling of lack becomes a simulation of need. Accordingly, homeostatic regulation is often anticipatory and can be initiated before any physiological deficit occurs. Such a role is played by clock-like mechanisms that turn physiological behavioral responses on and off before the occurrence of any tissue deficits. The master clock mechanism that drives and coordinates many rhythms is located in the suprachiasmatic nucleus of the hypothalamus. One such common cycle is a daily rhythm called the circadian rhythm, which controls feeding, drinking, locomotor activity, and several other responses. After experiencing jet-lag due to long distances, travelers can confirm the important role played by circadian rhythms.

V. CONCLUSIONS

Homeostatic processes can be analyzed in terms of control systems or servomechanisms, comprising a set point, an error signal, controlling elements, a controlled system, and feedback detectors. This approach has provided a convenient and precise language to describe both concepts and experimental results. Moreover, it has been successfully applied to temperature regulation, feeding, and drinking. For example, in the temperature regulation system, the integrator and many controlling elements appear to be located in the hypothalamus. The normal body temperature is the set point and the feedback detector collects information about body temperature from two main sources—peripheral and central temperatures. The analysis of feeding and thirst behaviors can also be approached in terms of a control system, as for temperature regulation, although at every level of analysis the understanding is less complete than for the control of temperature.

The hypothalamus is concerned with the regulation of various behaviors directed toward homeostatic goals, such as consumption of food and water or sexual gratifications. Through its control of emotions and motivated behavior, the hypothalamus acts indirectly in maintaining homeostasis by motivating animals and human beings to act on their environment.

In regulating emotional expression, the hypothalamus functions in conjunction with higher control systems in the limbic system and neocortex. In addition to regulating specific motivated behaviors, the hypothalamus and the cerebral cortex are involved in arousal, namely the maintenance of a general state of awareness (the level of arousal varies from different degrees of excitement to coma, sleep, and drowsiness). However, because of its intimate relationship with both the autonomic and the endocrine systems, the hypothalamus appears to play a central role in regulating homeostatic behaviors. The hypothalamus contributes to these adaptative behaviors by integrating information from both external and internal stimuli that report on the homeostatic state of the animal.

Humor and Laughter

JYOTSNA VAID
Texas A & M University

GLOSSARY

Duchenne display A characteristic facial display accompanying laughter in humans involving the joint contraction of lip and eye muscles.

gelastic seizure Typically unprovoked, stereotyped, and inappropriate laughter accompanying an epileptic seizure.

The ability to perceive and produce humor, highly valued across human societies, has been the subject of much philosophical interest but little sustained, empirical study. This article summarizes the variety of theoretical perspectives and available research relevant to the study of humor, including its nature, its origins in ontogeny and phylogeny, its behavioral manifestation in laughter, its psychological and evolutionary significance, and its hypothesized neural mediation. Although responding with humor may appear to be a way of evading a serious problem, it might also turn out to be a rather effective way of counteracting the seriousness, or even danger, in a situation by deflecting its adverse effects and by offering an alternative to despair. Humor can provide a way for individuals to conceal or to reveal their vulnerabilities; it can also enable them to transcend a predicament. A person with a good sense of humor is viewed more favorably than one who is humorless. Humor is said to confer mental flexibility, openness to experience, playfulness, and maturity and, as such, is highly valued whether in a coworker, a leader, a friend, or a prospective mate. Indeed, the ability to be playful and humorous appears to be universally valued.

Although scholarly interest in the nature and functions of humor has a long history, empirical inquiry into the forms, uses, and biological bases of humor and laughter is fairly recent. This article addresses both well-researched and relatively unexplored questions pertaining to humor and laughter. The following are some of the questions that are considered here: What is humor? What is the role of laughter in humor? What are the ontogenetic and phylogenetic origins of laughter? How does humor work, cognitively? What is the functional significance of humor? What are the varieties of laughter and how are they perceived? What kinds of disorders of laughter have been documented and what do they suggest about the neural circuitry underlying laughter and humor?

I. DEFINING HUMOR

Humor normally requires at least two individuals (the humor initiator and the receiver) who cooperate in setting up what Gregory Bateson termed a play frame,

in which the parties involved tacitly agree that what is inside the frame is not to be taken seriously. A play frame may also be set up by a single individual in response to a perceived incongruity in an event or situation. Verbal humor is a particular form of skilled language use in which at least two disparate meanings are interwoven into a text by making use of ambiguity, polysemy, intertextuality, or inconsistency in such a way that the listener is led to expect one meaning but actually experiences the other. The pleasure of humor is thought to arise upon the sudden recognition of the mismatch between the expected and the experienced meaning.

II. HUMOR AND LAUGHTER

In his 1872 monograph, *The Expression of the Emotions in Man and Animals*, Charles Darwin noted that "Joy, when intense, leads to various purposeless movements—dancing about, clapping the hands, stamping, etc., and to loud laughter." Laughter is indeed commonly seen as an expression of joy, happiness, or amusement. It typically occurs in informal social situations, usually in the presence of a close friend, sibling, caregiver, or intimate.

Although laughter is normally taken to be an indicator that the laugher is in a happy emotional state, it does not exclusively or necessarily signal such a state. One can clearly find something amusing without it actually making one laugh out loud. Similarly, one can feign laughter even when one is not actually amused. Other emotional states that give rise to laughter include scorn, embarassment, and nervousness. It remains to be determined whether the laughter in these different states is morphologically different. Under certain clinical conditions, laughter can be triggered in adults without their ability to control it. In such cases it occurs for no apparent reason and usually without accompanying positive affect. The occurrence of such dissociations between the motoric act of laughter and associated affective or cognitive states raises the possibility that laughter is under the control of a variety of different neural structures and systems at different levels and that these may be selectively disrupted in pathology.

III. ONTOGENY OF LAUGHTER

Laughter and crying both appear to be innate mechanisms in humans, although laughter's onset occurs later: whereas crying emerges at birth and smiling at approximately 2 or 3 weeks of age, the characteristic expiratory movement of laughter does not appear until approximately 4–6 months. However, cases of so-called gelastic (or laughing) seizures in neonates indicate that neural and physiological structures subserving laughter are in place at birth. Laughter's innateness is further suggested by the fact that it is observed in deaf–blind children, even those who could not have learned about it by touching people's faces. Although laughter initially occurs involuntarily, whether in response to tickling or peek-a-boo games or as a reaction to a sudden change in the sensory environment, such as an unexpected noise, over the course of development laughter becomes more regulated, under voluntary control, and elicited in response to cognitive and social stimuli rather than physical stimuli per se.

IV. PHYLOGENY OF LAUGHTER

Laughter is estimated to be 7 million years old. Like other vocalizations, such as moaning, sighing, and crying, laughing is thought to have preceded speech and, like these vocalizations, it may also have a communicative function.

Although laughter is often claimed to be unique to humans, behaviors similar to human laughter have been observed in other primates and something akin to laughter has even been argued to be present in rodents. In 1997, Signe Preuschoft and Jan van Hooff examined variations in the contexts and social functions of bonding displays in various primate species, including Old World primates, macaques, baboons, great apes, and humans. They noted a silent bared-teeth display (also called a grin, grimace, or smile) associated with inhibited locomotion, evasive and protective body movements and postures, and grooming and embraces. This display was observed in all macaque and baboon species and humans. A relaxed, open-mouth display ("play face"), marked by a widely opened mouth but without pronounced baring of the teeth, was observed in all macaque and baboon species, in each of the great apes, including the chimpanzee, bonobo, orangutan, and gorilla, in humans, and in more distant species such as vervets and squirrel monkeys.

One variant of the play face noted in some species was an open mouth, bared-teeth display with associated staccato breathing and bursts of vocalization. This latter display, which Preuschoft and van Hoof

termed the "laugh face," appeared strikingly similar to human laughter. It was accompanied by boisterous body postures, brusque movements, mock biting, playful chasing, and evasive, repetitive glancing movements rather than a tense gaze. The laugh face was found only in certain macaques, mandrills, geladas, the orangutan, the bonobo, and, of course, humans, and it occurred primarily in social play contexts, although in some cases it was observed to accompany solitary play, but in these cases it occurred only when conspecifics were near. The presence of an audience thus appears to be at least facilitative, if not necessary, for releasing the laugh face display.

In 1987, Preuschoft and van Hooff proposed a functional significance of play that is relevant to the current analysis. They noted that in bonding behaviors (i.e., those involving care, sex, and affiliation), it is important to deemphasize competition and focus on shared interests. Play is one form of bonding behavior. An important element of play is the partner's unexpected performance of an expected behavioral act. Preuschoft and van Hooff suggested that the "essence of play seems to be to actively bring about incongruous and unexpected behaviors and to interpret them as nonthreatening." This, they argued, allows for affective and cognitive mastery of incongruous situations.

Whereas laughter in nonhuman primate species is found principally in play contexts and primarily occurs in the young of the species, laughter in humans occurs in a variety of social contexts throughout the life span. Moreover, there is no evidence that nonhuman primates have anything comparable to the human ability to produce, comprehend, and enjoy humor.

V. PRECONDITIONS FOR THE EMERGENCE OF HUMOR

Various factors have been proposed as preconditions for the emergence of humor perception in a species, including sociality, an exploratory drive, a system of communication (to allow for the members of the species to express and communicate beliefs and feelings), an ability to mentally represent and order the physical world, and an ability to construct possible imaginary worlds. Additional criteria proposed include a capacity to use logic and reasoning independently of affective or real-world constraints, a capacity to deceive or misrepresent the truth, a capacity for collaboration, reciprocity, compassion, and a theory of mind.

VI. WHAT MAKES SOMETHING HUMOROUS?

Speculating about the causes of mirthful laughter in human adults, Darwin noted that "[s]omething incongruous or unaccountable, exciting surprise and some sense of superiority in the laugher, who must be in a happy frame of mind, seems to be the commonest cause." In comparing laughter arising from actual tickling and that arising from the tickling of the imagination, he noted:

> *From the fact that a child can hardly tickle itself, or in a much less degree than when tickled by another person, it seems that the precise point to be touched must not be known; so with the mind, something unexpected—a novel or incongruous idea which breaks through an habitual train of thought—appears to be a strong element in the ludicrous.*

Darwin's insights anticipate many subsequent theoretical accounts of humor. With respect to its cognitive basis, an early formulation of the mechanisms underlying humor may be found in the work of a Gestalt psychologist, Norman Maier. Maier noted that a key element of humor is a sudden and unexpected restructuring of the elements of a configuration, not unlike that experienced during a flash of insight. A humorous narrative manipulates our expectations by leading us down a garden path only to present us with an altogether different conclusion than the one we were led to expect. Inasmuch as the conclusion disrupts the way in which we have been thinking about the events in the narrative, we are totally unprepared for it. After a momentary confusion of thought, we experience the newly restructured configuration with clarity; the amusement arises when we realize how we were misled. In 1992, Wyer and Collins proposed that diminishment is a key element in humor elicitation: For humor to be elicited, the new perception of the situation must in some sense be diminished in importance in comparison to the apparent reality that was first assumed.

Subsequent theorists have elaborated on these accounts. For example, cognitive approaches characterize humor perception in information processing terms as involving at least two and possibly three stages: a setup stage, a stage in which the incongruity is recognized, and a stage of incongruity resolution. Although there is debate regarding whether humor appreciation requires that the incongruity be satisfactorily resolved (with some arguing that incongruity recognition per se is sufficient to experience humor),

theorists generally agree on the importance of the juxtaposition of two or more mental representations for humor to be perceived, following Arthur Koestler, who, in *The Act of Creation*, described humor as an example of bisociative thinking, which juxtaposes and brings together two disparate matrices of thought. Recent theoretical formulations in cognitive science have used concepts such as frame shifting and conceptual integration of mental spaces to formalize the processes underlying humor perception. To date, there has been little cognitively oriented experimental research on humor comprehension and even less on the processes underlying humor generation.

It has also been acknowledged that it is not enough to postulate incongruity as a prerequisite of humor because, in certain situations, incongruity may give rise to other emotional reactions, such as fear or apprehension, rather than humor. A humorous rather than apprehensive reaction is more likely when the receiver does not have too much invested in the content of the humor—that is, when the humor does not threaten the receiver's beliefs or feelings in any profound or disturbing way. Second, a humorous reaction is more likely when the receiver was led to expect something dangerous that turns out not to be. Indeed, Ramachandran suggests that laughter may have evolved as a false alarm signal—that is, as an immediate signal to conspecifics that some potentially threatening event has trivial rather than terrifying implications. This notion is similar to the diminishment view of humor developed by Wyer and Collins.

VII. FUNCTIONAL THEORIES OF LAUGHTER AND HUMOR

Theories about the uses of laughter and humor range from psychological and social/anthropological approaches to metaphysical and evolutionary ones.

A. Psychological

Among psychological theories, that of Sigmund Freud, as described in *Jokes and Their Relation to the Unconscious* (1963), is one of the earliest. For Freud, jokes allow a temporary expression of socially undesirable impulses from the subconscious. Freud notes that tendentious humor makes possible "the satisfaction of an instinct (whether lustful or hostile) in the face of an obstacle that stands in its way." The association of humor with aggressive or sexual impulses has characterized subsequent accounts as well, although there is no current consensus as to whether hostility is inherent in humor.

Proponents of the so-called superiority theory (e.g., Aristotle, Plato, Hobbes, and Bergson) view laughter as reflecting a moral stance on the part of the laugher. For Bergson, laughter asserts the human values of spontaneity and freedom and therefore erupts whenever a person behaves rigidly, like an automaton: "Humor consists in perceiving something mechanical encrusted on something living." Hobbes described the passion of laughter as "nothing else but sudden glory arising from a sudden conception of some eminency in ourselves by comparison with the infirmity of others, or with our own formerly." Superiority is asserted not just by laughing at others' defects but also by showing that one can laugh at (and rise above) one's own imperfections.

In contrast to negative uses of humor, as in put-down or derisive humor, recent clinically based research has directed considerable attention to positive aspects of humor. Humor is increasingly viewed as a useful mechanism for coping with stress and regulating affect. In 1999, Galloway and Cropley proposed that laughter may reduce some existing mental health problems and a sense of humor may moderate the perceived intensity of negative life events.

B. Social/Anthropological

Social and ethological theorists (e.g., Martineau) have viewed laughter as a marker of group membership and solidarity (for those who share a joke) or exclusion (for those who are the "butt" of the joke) and as a means of maintaining social control and group cohesiveness.

Anthropologists have described "joking relationships" in various traditional societies; these refer to ritualized teasing between specific kin in which the receiver is required to take no offense. In an incisive analysis, anthropologist Mary Douglas suggested that joking is a subversive act in that it levels hierarchy and represents a triumph of intimacy over formality and of unofficial values over official ones. Not surprisingly, this subversive aspect of humor is particularly evident among members of minority groups who may use humor to portray reality in a way that exposes social inequities. Much feminist humor and political humor, particularly that found in Central and Eastern European countries while under authoritarian rule, is of

this type. So-called "gallows" humor also has elements of this subversive aspect of humor.

C. Metaphysical

Although laughter appears to be associated with happiness and joy, some have taken the position that laughter arises precisely from the experience of suffering. The philosopher Nietzsche, for example, argued that humor was invented precisely because of the extent to which humans suffer. This view is echoed in existentialist philosophy. For the most part, though, humor has not been taken seriously in classical philosophical thought in the Western tradition, which has tended to regard it as irrational, irresponsible, and frivolous. In contrast, Eastern traditions, such as Hindu, Buddhist, and Sufi worldviews, regard humor as an appropriate reaction in the face of the vicissitudes of death, disease, and aging; humor here is seen as an insight that all human aspirations are ultimately comical and that wisdom ensues from that insight.

D. Evolutionary

Laughter is clearly an important aspect of human nature. All societies appear to value it. It has distinct facial and vocal manifestations. It emerges spontaneously in early childhood and persists through the life span and it is an intensely pleasurable social activity. All these aspects suggest that laughter may be a reasonable candidate for a psychologically adaptive characteristic. Indeed, it has been accorded a special place in several recent theoretical accounts of human evolution. Aside from the false alarm theory mentioned earlier, at least five different evolutionary accounts of laughter and humor may be distinguished.

1. Humor as a Temporary Disabling Mechanism

When we are truly amused by something, more often than not it takes us by surprise and distracts us from whatever it was that we were in the middle of doing or thinking. If we are heartily laughing, we quite literally cannot think of, let alone do, anything else. Wallace Chafe suggests that this disruptive effect of humor may be evolutionarily significant (i.e., that humor's basic adaptive function is a disabling one). Chafe proposes that the humor state may have arisen precisely in order to keep us from doing things that might be counterproductive; that is, things that our usual form of reasoning might lead us into but that, in a larger sense, would be undesirable. This view fits with a related notion of humor as a device for pointing out and sharing counterexamples, or providing disconfirmatory evidence, which in turn is useful in reasoning and problem solving. Chafe further suggests that the fact that laughter provides an audible signal to others may be significant because laughter signals to the receiver that the laugher is in a humor state and thus cannot be taken seriously; moreover, the laughter may in turn infect others present, rendering them temporarily disabled as well.

The notion that humor is a disabling device that is ultimately adaptive is an intriguing hypothesis and one that readily lends itself to empirical test. For example, one could ask whether the effect attributed to humor depends on the type of humor, the type of problem from which the laugher has been disrupted, the relevance of the humor content to the problem content, the presence of others, etc.

2. Humor as Social Learning

According to G. Weisfeld, humor provides exposure to fitness-relevant scenarios in a nonserious, playful context, motivating the practice of social skills that will be useful in serious contexts. In this view, humor is basically a form of social–intellectual stimulation that allows for the seeking and practicing of social skills that are fitness enhancing at some later point. Laughter, according to Weisfeld, conveys appreciation and gratitude to the humorist for having provided such stimulation.

3. Humor as Status Manipulation

The notion that mirthful laughter serves to create and solidify group boundaries forms the centerpiece of an evolutionary account of humor proposed by Richard Alexander in which humor is seen as a way of favorably manipulating one's status in a group to improve one's access to resources for reproductive success. Specifically, it is proposed that humor developed as a type of ostracism, a means of manipulating one's social status in a group (and thereby one's access to critical resources) by facilitating bonds with certain members and ostracizing others, through explicit or implicit exclusion.

Alexander's theory views humor primarily as a device for establishing dominance and thereby for being more competitive for critical resources. He

suggests that humor, as a form of social scenario building, gives one an edge in learning how to negotiate in fitness-relevant domains. Humorous put-downs may be more successful than direct criticism or insults as a way of establishing dominance since they are indirect and therefore more face-saving ways of manipulating status than direct displays of hostility or strength. In Alexander's model, all humor, whether or not it has an ostensible butt or target, essentially developed in the service of status manipulation.

4. Humor as Vocal Grooming

An emphasis on vocal grooming characterizes an evolutionary view of language proposed by Robin Dunbar that has implications for humor. Dunbar speculates that human language evolved as a vocal extension of physical grooming, allowing, as it were, the simultaneous grooming across space of more than one partner and thereby the facilitating of social bonds with larger groups of animals. Language fosters social bonding by permitting the exchange of gossip, i.e., socially relevant information (specifically, who is doing what with whom), as well as the sharing of one's own experiences, actual or desired. The fact that laughter typically accompanies speech suggests that it facilitates and cements the social bonding process.

In this view, the pleasure in shared laughter is analogous to the pleasure of actual physical touch. Humor has in fact been characterized as a form of vicarious touch. The importance of touch for primate emotional development is well documented. Laughter may have served to attract like-minded others in the bonding process; as Konrad Lorenz noted, finding the same thing funny is not only a prerequisite to a real friendship but also very often the first step to its formation. Thus, just as language facilitates social bonding, laughter accompanying speech, and humorous discourse with or without laughter, could have evolved as a way of solidifying affectional bonds.

5. "The Wit to Woo": Humor as Mate Attraction

The most recent evolutionary proposal regarding humor emphasizes its importance in courtship and suggests that the creativity and unpredictability that is inherent in humor is seen as attractive to a prospective mate. In this account, proposed by Geoffrey Miller in *The Mating Mind*, creativity is seen as not just a random by-product of chaotic neural activity but also as something that evolved as an indicator of intelligence and youthfulness and as a way of playing into our attraction to novelty. Creativity not only allows one to find unpredictable solutions to problems but also provides inherent pleasure because of its protean, unpredictable nature. Humor encapsulates these elements of creativity and it is therefore not surprising that a sense of humor is highly desired in a prospective mate. In this view, humor evolved because of its importance in courtship and mate choice.

The five evolutionary hypotheses emphasize different elements of humor. Humor is hypothesized to disrupt our routine for the better, to teach and reward us in our social interactions in fitness-relevant domains, to unify a group but also create group divisions, to create and strengthen affective bonds, and to attract and sustain a partner. Although there is evidence consistent with each of these views, research designed to examine the assumptions and claims of the different accounts is clearly warranted.

In the remaining sections we review theory and research on the expression and neural mediation of normal and abnormal manifestations of laughter and humor.

VIII. NORMAL LAUGHTER

A. Visuomotoric and Physiological Aspects

Laughter is a motoric and vocal activity requiring the coordinated action of 15 different facial muscles and associated clonic contractions of the thoracic cage and the abdominal wall. Laughter produces spasmodic skeletal muscle contractions, tachycardia, changes in breathing pattern, and increases in catecholamine production. Hearty laughter increases heart rate, blood pressure and respiratory rate, and muscular activity.

Physiologically, laughter is the opposite of crying. Although the upper half of the laughing face appears indistinguishable from the crying face, the lower half and the respiratory pattern in laughter are the reverse of those of crying. In laughter a characteristic facial display known as the Duchenne display is invoked. This display involves the joint contraction of the zygomatic major muscles (i.e., pulling the lip corners back and upwards) and the orbicularis oculi muscles (i.e., raising the cheeks and causing the eyes to wrinkle). Indeed, the movement of the eye muscles may serve as a marker for distinguishing emotional from voluntary (forced) laughter since the orbicularis oculi muscles do not contract during voluntary laughter. Laughter is also accompanied by the flaring of

nostrils, mandible retraction, and brightening and sparkling of the eyes.

In terms of respiration, laughter typically begins with an abrupt exhalation followed by rhythmic expiration/inspiration cycles, which may or may not be phonated as "ha ha ha." No inspiration preceding the laugh is needed since laughter is produced at a low lung volume. The rhythmic pattern of laughter respiration is produced by contractions of muscles that are typically passive during normal expiration, i.e., the diaphragm, the abdominal (rectus abdominus), and the rib cage muscles (triangularis sterni). These muscles work together with the larynx. In crying, the saccadic contractions occur mainly with inspiration, whereas in laughing they occur with expiration; in both cases the contractions are accompanied by short, broken sounds. Autonomic correlates of laughter include arousal and muscle tension followed by relaxation of muscle tone, dilatation of cutaneous vessels of the face, neck, and hands, lacrimation, and fatigue.

In 2000, Niemitz, Loi, and Landerer examined specific visuomotoric aspects of the human laughing face and their affective interpretation by human raters. The expressive facial movements of 45 videotaped laughing adults and 13 children were shown to more than 100 adult raters. The results suggested that visual aspects of laughing faces that are judged as cheerful, winning, or generally positive were those in which (i) the laughs were fairly long, ranging from 3 to 6 sec; (ii) there were rapid eye and mouth movements during the first second of the expression of laughter; (iii) there was repetition of the mouth and eye movements; and (iv) there was almost complete closing of the eyelids, sometimes repeatedly, for 0.1–1.5 sec. There is a need for more such research quantifying how the various laughing expressions are decoded and interpreted, not just in the visual channel but also acoustically.

B. Acoustic Aspects

Willibald Ruch and Paul Ekman proposed a useful framework for describing the structure of laughter. They define a laughter bout as all the respiratory, vocal, facial, and skeletomuscular elements involved in a particular laughter event. A bout of laughter, in turn, consists of an onset (the prevocal facial component), an apex (involving vocalization or forced exhalation), and an offset (the postvocalization part, typically a smile that fades out). The apex contains laugh cycles, (i.e., repetitive laugh pulses); there are typically 4 pulses in a laugh cycle, although the number can range from 9 to 12 depending on lung volume. There are usually about 5 pulses per second. At the level of laryngeal movements, a laugh pulse can be further subdivided into the number and duration of vibratory cycles of the vocal cords. In one analysis, the duration of laughter pulses varied from 30 to 100 msec. Phonation in laughter pulses involves a series of stereotypic laryngeal adjustments that include four stages: an interpulse pause (a moment of quiet aspiration in the periods between voicing), adduction (closing) of the arytenoid cartilages, vibration of vocal chords, and abduction (opening) of the arytenoid cartilages.

Several features in the acoustic signal may serve to cue the degree of positive affect experienced by the laugher. Widening versus narrowing of the pharynx is known to affect voice quality and may signal friendly versus scornful laughter, respectively. Other cues may be provided by harmonics, melodic contour, and duration. The melodic contour, including the intonation and pitch contour, may be particularly informative of emotional state and meaning. The vocal ligaments are more likely to be tensed under conditions of arousal or anticipation, giving rise to laughter that has a rising melodic contour. The lips and the cheeks are typically elevated in joyful smiling or laughter; contraction of the muscles involved in the Duchenne display changes the form of the mouth opening, constraining the vowel sounds that can thus be produced. Indeed, one study showed that listeners can reliably infer a smiling from an unsmiling version of the same spoken message purely on the basis of the voice.

Fewer than a dozen studies have been conducted on the acoustic characteristics of laughter. Almost all have used adult participants. One study examined the acoustic characteristics of a group of 30 male and female adults from whom one laugh was elicited under each of four conditions: social, humor, tension release, and tickle. Significant differences in duration, intensity, and mean frequencies of three vowel formants above the fundamental frequency were found between the humor and social laughs and the tension release and tickle laughs. Moreover, listeners could reliably classify the laughs into the different types, suggesting a communicative aspect to the laughs. The mean fundamental frequency of laughter for males (175 Hz) was higher than that for females (160 Hz) and highest for the tickling condition. In another study, a group of 11 male college students were recorded while they viewed a videotape of comedic storyteller Bill Cosby. Analyses

of 55 bouts of laughter showed that the mean peak fundamental frequency while laughing was more than twice as high as that when the subjects were counting. Moreover, an extended range of frequencies was exhibited during laughter, with a difference of 344 Hz between the lowest and the highest range observed. In general, there was considerable variability both within and between subjects on all the measures studied.

A limitation of existing studies with adults is the lack of naturalistic social interaction contexts. Studies with children fare better in this regard. One study recorded laughter among four 3-year-olds during three sessions of spontaneous free play between mother and child. An acoustic analysis revealed that the duration of laughter syllables in children was about the same as that found in adult laughter (i.e., about 200–220 msec). The total duration of the average laugh was also similar to that of adults. The main difference between adult and child laughter was in fundamental frequency, with most children's laughter having a frequency in the upper range of adult female laughter (400–500 Hz) or, in the case of one type of laughter (squeals), even higher (nearly 2000 Hz). Four distinct laughter types were noted in the child sample: (i) comment laughter (i.e., laughter occurring in conversational contexts that lasted about one-fifth of a second), which was subdivided into dull comment and exclamatory comment laughter; (ii) chuckle laughter, which lasted half a second and tended to occur in situations provoking more excitement than comment laughter; (iii) rhythmical laughter, which lasted 1–15 sec; and (iv) squeal laughter, which lasted half a second, had a very high fundamental frequency, and usually occurred without a break. The latter two kinds were more prevalent in the context of physical stimulation, anticipation, and fear.

It appears, therefore, that different types of spontaneous laughter have different acoustic characteristics. Moreover, laughter differs in different social contexts. Additional studies are needed with different kinds of communication dyads and with different age groups to examine in more detail the relationship between acoustic distinctions in laughter production and their affective interpretation by listeners. The specific ways in which spontaneous versus contrived laughter may differ, both structurally and neurobehaviorally, also warrant study.

C. Health Aspects

An implicit belief underlying most accounts of humor is that it confers psychological benefits. As reviewed by Martin, the benefits of humor may also extend to the physiological level. For example, laughter is known to increase respiratory rate and clear mucus. It is entirely conceivable that laughter may thus be beneficial to patients with chronic respiratory conditions such as emphysema. The increased heart rate and blood pressure accompanying laughter can exercise the myocardium and improve arterial and venous circulation, allowing a greater flow of oxygen and nutrients to tissues. This in turn may facilitate the movement of immune elements useful in fighting infections. Muscle relaxation following hearty laughter may break the spasm–pain cycle in patients with neuralgias or rheumatism. A reduction in laryngeal muscle tension accompanying laughter may help patients with vocal fold pathology to produce a more relaxed voice, and it may facilitate the recovery of phonation in patients with psychogenic dysphonia, an inability to phonate during speech despite intact articulation and the absence of any identifiable pathology of the larynx. Finally, the increased catecholamine levels associated with laughter may be responsible for the beneficial effects humor is thought to exert on mental functions, such as alertness and creativity. Many of these claims of the healthful benefits of laughter and humor have yet to be subjected to systematic study.

D. Neuroanatomical Hypotheses

There has been very little direct empirical investigation of neuroanatomical correlates of normal laughter. A hypothetical neural circuit was first theorized in 1924 by Kinnier Wilson. According to Wilson's model, laughter is produced by a medullary effector center that links the seventh nerve nucleus in the pons with the 10th motor nucleus in the medulla and with phrenic nuclei in the upper cervical cord. This center is modulated by the cerebral cortex and limbic structures by means of an integrative center in the mesial thalamus, hypothalamus, and subthalamus.

Activity of the laughter center is thought to be determined by a voluntary pathway (corticobulbar fibers) and fibers extending from the orbital surface of the frontal lobes through the bulbar nuclei. Input to these fibers comes from an involuntary pathway (the basal ganglia), which appears to be inhibited by the voluntary one. No single cortical area supplies the origins for the voluntary and involuntary fibers; the input derives from diffuse cortical regions including the frontal, premotor, motor, parietal, temporal, and hippocampal regions.

The notion of hypothalamic integration of cortical and limbic control on the brain stem laughter center remains to be substantiated, although it is consistent with clinical observations.

IX. DISORDERS OF LAUGHTER

Disorders of laughter and crying are very rare. Although strong emotional reactions are not uncommon following brain injury, the most common reaction described is fear. Medical research on laughing and crying disorders consists largely of case reports, with few systematic, large-scale investigations. Abnormal laughter, defined as laughter that is involuntary and inappropriate to the situational context, is most often seen in generalized affective or cognitive disturbances such as psychoses (e.g., schizophrenia). Individual cases of hysterical laughter spells, marked by silly, unrestrained, unmotivated, and unprovoked laughter, have been reported, as has epidemic hysterical laughter.

In many cases of abnormal laughter, the motor act of laughing may be dissociated from its emotional aspect. Such a condition has been termed pathological laughter. Kinnier Wilson defined pathological laughter and crying (PLC) as "a sequel to and consequence of a recognizable cerebral lesion or lesions in which attacks of involuntary, irresistible laughing or crying, or both, have come into the foreground of the clinical picture." This definition draws attention to the impaired control and the episodic aspect of the abnormal emotional expression.

In 1994, Shaibani, Sabbagh, and Doody proposed four criteria to distinguish pathological laughter and crying from normal laughter and crying. First, PLC is inappropriate to the situation since it occurs spontaneously or in response to nonspecific stimuli or inappropriate, arbitrary stimuli (e.g., one patient with a left cerellar hematoma showed pathological laughter following left hand tremor). Second, PLC is unmotivated; that is, there is no relation between the affect and observed expression, nor is there relief or mood change afterwards. Third, PLC is involuntary; that is, it has its own pattern and occurs against the patient's will. Neither the duration nor the content of PLC can be controlled, and patients do not gradually change from smiling to laughing but have a sudden, brief outburst without any warning. Fourth, PLC differs from emotional lability, which refers to an exaggerated emotional response to a normal stimulus. The latter characterizes patients with multiple sclerosis and Alzheimer's disease. These patients are overcome by uncontrollable laughter and crying that is usually appropriate to the situation and accompanied by mood alteration.

Very few patients actually meet the criteria for PLC. However, researchers do not concur on the ideal classification system and whether PLC must involve a dissociation between the expressed affect and the mood. It is acknowledged that the degree of volitional control of PLC varies from complete absence to some control.

The most common conditions associated with PLC are summarized in the following sections, subdivided into disregulatory and excitatory conditions.

A. Disregulatory Conditions

One disregulatory condition giving rise to abnormal laughter is amyotrophic lateral sclerosis (ALS). In 25% of ALS patients there is bulbar involvement; of these, 30–50% develop PLC. Patients without bulbar involvement do not develop PLC.

Multiple sclerosis is another condition that in 7–10% of patients leads to PLC, sometimes with euphoria. Characteristics of so-called pseudobulbar palsy associated with multiple sclerosis (as with bilateral strokes) include dysarthria, dysphagia, bifacial weakness, and weak tongue movements but preserved coughing, yawning, laughing, and crying.

In one large-scale study, PLC was observed in 15% of stroke patients 1 month after the stroke, in 21% at 6 months after the stroke, and in 11% a year following the stroke. Abnormal emotional reactions were particularly associated with lesions in the left frontal and temporal regions.

A rare syndrome of PLC is associated with acute infarction—the so-called "fou rire prodromique," first described in 1903 and in only a few cases since. In these cases, laughter lasts from between 15 minutes to 24 hours and is almost always followed by death. Lesions in this syndrome typically involve the left internal capsule-thalamus, left basal ganglia, or ventral pons. This syndrome contrasts with pseudobulbar palsy since it is not recurrent and, unlike epileptic laughter, it is not associated with electroencephalograph (EEG) changes or confusion.

A host of extrapyramidal disorders, including Parkinson's and Wilson's disease, are also associated with PLC. The syndrome of Angelman, a genetic disorder characterized by mental retardation and stiff puppet-like movements in children between the ages of

2 and 6 years, is also associated with frequent bursts of laughter. A variety of toxins, such as nitrous oxide and insecticides, have also been related to pathological laughter. Finally, various malignant brain stem tumors, such as clival chordoma and pontine glioma, have been implicated in pathological laughter.

B. Excitatory Conditions

The most common excitatory condition that is associated with pathological laughter occurs in epileptics. Laughter as part of an epileptic seizure was documented by the neurologist Trousseau in 1873 and was described in Dostoevsky's novel *The Idiot*. In 1957, the term "gelastic epilepsy" was coined to refer to epileptic fits in which laughter is the only or the most common symptom. More than 160 cases of gelastic epilepsy have been reported in the literature. Gelastic epilepsy often occurs in patients with hypothalamic hamartomas and precocious puberty, in patients with complex partial seizures and temporal lobe origin seizures, and in children with infantile spasms. The seizures usually begin in infancy or childhood and are associated with cognitive decline in later years. In patients with these seizures, involuntary, mechanical giggling typically occurs as the initial ictal behavior before an alteration in consciousness. The duration of the laughter in patients with hamartomas is usually less than 30 seconds and the seizures occur several times a day.

In a recent review of published reports of seizures involving laughter, Biraben and colleagues proposed the following neural hypotheses for the genesis of laughter:

1. Laughter arising as a reactional behavior (i.e., in response to a pleasant feeling or mirth: Only a few such cases have been observed, all involving seizures with a temporal focus. In one such case, involving stimulation of the left temporobasal region (fusiform and parahippocampal gyri), the individual experienced a change in the semantic connotation of stimuli (things became funny); in another case with stimulation in the same region, the modification experienced was perceptual (things changed in a funny way). Biraben *et al.* suggest that the laughter in these cases might be a physiological response to a modified cognitive process.
2. Laughter arising as a forced action or an automatism: Seizures with a frontal focus have characteristically produced laughter described as forced and unmotivated. Arroyo and colleagues describe one patient with a cavernoma of the anterior cingulate gyrus whose laughter appeared to be an irrepressible motor behavior; resection of the lesion eliminated the laughing behavior. They suggest that the premotor mesial system acts as an interface between the limbic loop, which includes the anterior cingulate gyrus, and the motor loop, which includes the supplementary motor area. Biraben *et al.* propose that cases of gelastic seizure originating in the anterior cingulum involve a critical functional disconnection between the motor loop and the limbic loop within the mesial premotor system. The laughter arising in these cases reflects a behavioral output from a motor program separated from all motivation.

Laughter in one other epileptic patient reviewed, a nongelastic case, occurred after cortical electrical stimulation of the lateral border of the rostral part of the supplementary motor area. The laughter was natural, rather than forced, and was accompanied by a general feeling of amusement toward the environment at large. Biraben *et al.* suggest that such laughter may reflect an imbalance between the mesial and lateral premotor systems.

C. Neuroanatomical Hypotheses

Evidence for the neuroanatomy of pathological laughter and crying comes from the following sources: a limited number of autopsy reports; studies of congenitally malformed infants; case reports of patients with pathological laughter following neurological disease; EEG activity and electrical stimulation of the cortex; injection of a barbiturate to the right or left cortex, typically done in patients with epilepsy to determine the language-dominant hemisphere; and studies of humor comprehension in patients with left versus right hemisphere damage.

The autopsy data are of limited value in localizing laughter since the patients had suffered diffuse brain pathology. A review of such cases revealed no single cortical lesion as causing PLC. Together with clinical case reports, the autopsy data indicate that both unilateral and bilateral lesions that affect the descending tracts to the bulbar nuclei can cause PLC, as can lesions on either side in the anterior limb and genu of the internal capsule adjacent to the basal ganglia, thalamus, hypothalamus, and pons. Even localized brain stem lesions can cause pathological laughter. Case studies do not explain why some patients develop pathological laughter while others develop pathological crying or both. Studies of congenitally malformed

newborns with severe anencephaly but with preserved pons and medulla indicate that newborns do not smile but can cry; those with intact midbrains can both cry and smile.

The predominant neuroanatomical account of pathological laughter and crying, first proposed by Wilson, regards it as arising from a loss of direct motor cortical inhibition of a laughter and crying center located in the upper brain stem. However, this explanation does not fully account for the range of phenomena observed in PLC. A recent alternative account, developed by Parvizi and colleagues, in light of new neuropathological findings, suggests that PLC is caused by dysfunction in circuits that involve the cerebellum (as well as the cortex) and influence brain stem nuclei.

There is evidence that the cerebral hemispheres may play different roles in the control of emotional states. In normal subjects the right hemisphere appears to be specialized for the perception and expression of emotion, particularly negative emotion. Lesions in the right hemisphere have been found to impair prosodic and lexical expression of emotion. Moreover, in epileptic subjects, injection of the right hemisphere with intracarotid sodium amytal has elicited unprovoked laughter, whereas left-sided injection has tended to produce bouts of crying. Patients with crying seizures tend to show right-sided foci, whereas those with gelastic seizures show mainly left-sided foci.

Patients with right hemisphere damage show a preserved sensitivity to the surprise element of humor but a diminished ability to establish narrative coherence. Disorders of humor, such as foolish or silly euphoria (so-called *moria*), and a tendency toward making inappropriate jokes (so-called *witzelsucht*), have been reported in patients with frontal lobe disorders including neurosyphilis. In 1999, a functional neuroimaging study by Shammi and Stuss determined that deficits in humor appreciation are restricted to patients with right frontal damage, supporting the view that the right frontal lobe serves an important role in integrating cognitive and affective information.

X. CONCLUSION

As may be evident from this overview, laughter and humor offer fertile ground for future investigation undertaken from a variety of theoretical and methodological perspectives, including ethological, cognitive, linguistic, clinical, and neuroscience. In a recent review, Jaak Panksepp observed that incisive research in this area has only just begun and that substantive research remains meagre. Many basic questions remain, such as the occurrence and significance of laughter in play and other social contexts; the role of laughter and humor in courtship, mate choice, and relationship maintenance; what different kinds of laughter communicate and to whom; and the neural circuitry responsible for normal laughter and feelings of mirth and joy.

Hydrocephalus

CHIMA OHAEGBULAM and PETER BLACK
Children's Hospital/Brigham & Women's Hospital, Boston

GLOSSARY

basal cisterns The cerebrospinal fluid containing spaces on the undersurface of the brain, the largest of which is the cisterna magna in the angle between the cerebellum and the back of the brain stem.

cerebrospinal fluid (CSF) The fluid contained within the ventricles and surrounding the brain and spinal cord.

choroid plexus The structures within the ventricles that produce most of the CSF.

fontanelle The soft membranous gap between growing skull bones in the infant skull, the largest of which is the anterior fontanelle.

lumbar puncture The insertion of a needle between lumbar vertebrae in the midline of the back into the space around the spinal cord containing CSF.

shunts Systems, typically involving tubing and a valve, diverting CSF from the ventricles to another body site.

ventricles The system of interconnecting fluid-filled cavities within the brain.

Hydrocephalus is the abnormal accumulation of cerebrospinal fluid (CSF) within the ventricles of the brain. This always involves enlargement of ventricles, and there may or may not be increased intracranial pressure. Hydrocephalus is almost always a result of impaired CSF absorption or circulation.

I. INCIDENCE/PREVALENCE

The true incidence or prevalence of hydrocephalus is unknown. As an isolated congenital disorder, it probably occurs in about 1 in 1000 live births. There are no good data on the incidence of adult hydrocephalus.

II. HISTORY

A. Early Concepts/Myths

Early references suggest that Hippocrates was aware of the condition now described as hydrocephalus. In 1768, Whytt published "Observations on the Dropsy in the Brain," in which he cited other writers as far back as the 13th century. Numerous herbal remedies were recommended in those times, though success rates were described as very low. Other treatments included head binding, leeching or bloodletting, injection of strong iodine solution into the ventricles, and exposure to the sun.

B. First Therapies Based on Anatomy

CSF was given its name by Magendie in 1825, and he and others, including Key and Retzius, elucidated its circulatory pathways later in the 19th century. Better understanding of the location of CSF within the ventricles led to more direct surgical approaches such as ventricular puncture. In 1891, Quincke described lumbar puncture as a treatment for hydrocephalus,

and this has evolved into the important diagnostic and therapeutic tool that it is today.

C. Early Shunts

As a better understanding of CSF circulation emerged, there were attempts to circumvent "obstructions" in the ventricular system in order to relieve hydrocephalus. Initial attempts to "shunt" CSF included external drainage in the late 19th century, invariably complicated by fatal infections. Other attempts were made using glass wool, gold tubes, catgut strands, and other materials to create conduits from the ventricles to the space beneath the scalp, the dura, and other areas. In 1908, Payr attempted the use of autologous vein to drain the ventricles into the sagittal sinus initially and later the jugular veins with some success. Others could not duplicate his results.

Cushing attempted bypass from the spinal subarachnoid space into the peritoneal cavity or retroperitoneal space by passing silver cannulae through the fourth lumbar vertebra. This had some success. The introduction of vulcanized rubber led to the availability of suitable conduit for the creation of shunts from the ventricular system to other body cavities. The first major innovation with the use of rubber catheters was by Torkildsen in 1939 to divert CSF from the lateral ventricles to the cisterna magna, but operative mortality remained high. It was eventually replaced by the more modern shunting procedures.

Numerous shunting procedures were created to other body cavities, notably the ureters. The ventriculoureteral shunt, reported by Matson in the 1950s, required a nephrectomy and had several infectious and metabolic complications. It also had a number of long-term survivors, however, and was the first effective shunt system used. Later shunts were developed to the atrial system, the pleura, and the peritoneum.

D. Other Operations

Walter Dandy, with Blackfan, identified the choroid plexus as the primary source of CSF production. On physiologic principles, in 1919, Dandy introduced choroid plexectomy as a treatment for hydrocephalus, in which the choroid plexus was ablated by cautery. This was initially performed as an open operation with a very high mortality rate but later was performed endoscopically by himself, Scarff, and others with a success rate of 70–80% and a mortality rate of approximately 15%. This procedure eventually fell out of favor with the subsequent discovery of significant extrachoroidal sources of CSF as well as the introduction of simpler shunting procedures.

Dandy also introduced open procedures for creating openings in the third ventricle into the basal cisterns on the undersurface of the brain. These were again developed into endoscopic procedures with success and mortality rates similar to those for choroid plexectomy. Patient selection for these was problematic before the modern imaging era because the optimal patient was one who had an obstruction in the aqueduct of Sylvius, which was the outflow tract for the third ventricle. There is a resurgence of interest in this procedure because of more sophisticated endoscopic techniques and equipment as well as the availability of appropriate imaging to select the right candidates.

E. Modern Era Shunts/Valves

The modern era of shunts owes its origin to the development of one-way valves by Spitz and Holter as well as by Pudenz. Polyvinyl chloride was initially used, but it was soon evident that silastic was better tolerated by the body.

The most popular shunting operation of this era was the ventriculoatrial shunt, in which the distal end of the catheter was introduced into the jugular vein and then to the right atrium. Numerous other sites for drainage have been reported, including the subdural space, mastoid air cells, thoracic lymphatic duct, fallopian tube, gall bladder, salivary ducts, stomach, and small intestine. Most of these sites are rarely, if ever, used today.

Ventriculoatrial shunting remained the most popular shunting procedure until ventriculoperitoneal procedures began to gain popularity at the end of the 1960s. The ventriculoperitoneal shunt was attractive for its simplicity, the absence of a permanent foreign body in the vascular system, and the reduced need for revision with inevitable growth of the patient.

III. CSF PRODUCTION AND ABSORPTION

A. Anatomy

1. Ventricular System

The foramen of Munro allows CSF to travel from the lateral ventricles to the third ventricle and the

aqueduct of Sylvins connects the third and fourth ventricles. Much of CSF is produced by the choroid plexus of the ventricular system and leaves through the openings in the fourth ventricle (foramina of Luschka and Magendie) into the subarachnoid space that surrounds the brain and spinal cord. It then travels around the convexities up to the sagittal sinus.

2. Choroid Plexus

The choroid plexus is the source of 60% of CSF production: It is composed of villi, which secrete CSF. Hypersecretion of CSF is virtually never a source of hydrocephalus. It should be noted that 40% of CSF is probably derived from fluid from brain parenchyma.

3. Arachnoid Villi

Arachnoid villi are specialized clusters of arachnoid cells that appear to allow CSF absorption into the sinuses and perhaps along nerve roots. In dogs and some other animals, there are no villi: CSF is absorbed along nerve root sheaths. In humans, arachnoid villi seem to absorb about 60% of CSF; the rest may be absorbed by nerve root sheaths as well.

B. CSF

CSF is continuously produced at the rate of approximately 500 cc/day. The total volume of CSF is approximately 150 ml at any time. CSF is formed as an ultrafiltrate from the villi of the choroid plexus and production is partially regulated by the enzymes sodium potassium ATPase and carbonic anhydrase. One function of the CSF appears to be mechanical, serving as a kind of water jacket for the spinal cord and brain, protecting them from potentially injurious blows to the spinal column and skull and acute changes in venous pressure. CSF hydraulically balances the brain within the skull.

The CSF is also believed to serve to remove waste metabolites of cerebral metabolism and may act as a pathway for distribution of peptides and hormones within the nervous system. This possible function has never been adequately explored.

IV. CLASSIFICATION

Hydrocephalus may be classified as acute or chronic (in acute, there are symptoms for weeks; in chronic, there are symptoms for months); communicating versus noncommunicating (in communicating hydrocephalus, there is flow between the ventricular system and subarachnoid space; in noncommunicating hydrocephalus, there is a block to flow within the ventricular cistern); congenital (acquired at birth) versus acquired; and normal pressure versus high pressure, a distinction that depends on the symptom complex.

A. Congenital

Several congenital structural abnormalities can lead to obstruction of CSF flow and result in hydrocephalus.

1. Aqueductal Stenosis

Different conditions may obstruct the aqueduct, leading to CSF accumulation above the level of the aqueduct that may be congenitally stenosed, occluded by a septum, compressed by gliosis in the surrounding periaqueductal tissue, or "forked." It can also be compressed or kinked by structural abnormalities or masses.

In aqueductal stenosis, the fourth ventricle, which lies beyond the point of obstruction, is typically normal in size. The term triventricular hydrocephalus has been used for this condition, referring to the enlargement of the third and both lateral ventricles.

2. Dandy–Walker Malformation

In this abnormality, there is atresia of the foramina of Luschka and Magendie along with agenesis of the cerebellar vermis. A large posterior fossa cyst results that communicates with an enlarged fourth ventricle. Hydrocephalus results in most of these cases.

3. Neonatal Intraventricular Hemorrhage

This condition is acquired particularly in premature infants and is characterized by progressive ventricular enlargement.

B. Acquired

1. Mass Lesions/Tumors

Masses may compress CSF pathways. This is a potential cause of hydrocephalus in those portions of

the ventricular system proximal to the obstruction. Any tumor along the CSF path may be involved. Colloid cysts of the third ventricle, pineal region tumors, and fourth ventricular tumors are examples. A tumor in the midbrain, for example, can cause critical aqueductal compression, resulting in hydrocephalus similar to congenital aqueductal stenosis. A cyst around the foramen of Monro can cause trapping of the lateral ventricle on that side. A posterior fossa tumor blocks aqueductal flow as well.

Tumors associated with abnormally high CSF protein concentrations impede reabsorption; ependymomas and other tumors of the spinal canal can do this. Diffuse spreading of tumor in the subarachnoid space can lead to hydrocephalus presumably due to both a higher CSF protein concentration and blockade of the arachnoid granulations.

2. Infection

Meningitis can result in fibrosis of the basal cisterns and arachnoid granulations that can lead to an obstruction of CSF around the brain stem. This includes tuberculosis meningitis, which is notorious for producing hydrocephalus.

3. Posthemorrhagic

Subarachnoid hemorrhage (most commonly from aneurysmal bleeding) and intraventricular hemorrhage can result in hydrocephalus because of the protein obstruction of arachnoid villi as well as inflammation of the aqueduct.

4. Idiopathic Normal Pressure Hydrocephalus

This entity was described by Hakim in 1965. It comprises communicating hydrocephalus with normal intraventricular pressures. Although a cause is not identified in most cases, it is usually believed to result from one of the obstructive causes described previously. An initial increase in pressure may lead to ventricular dilatation that reaches equilibrium, with pressures then returning to the normal range.

It is an important diagnosis because it is a treatable cause of dementia and gait disorder in the elderly. It is classically characterized by the triad of progressive gait disorder, dementia, and urinary incontinence. The gait disorder is usually shuffling with a broad base. Dementia is a recent memory disorder.

C. Pseudotumor Cerebri/Idiopathic Intracranial Hypertension

This diagnosis of exclusion is characterized by elevated intracranial pressure and papilledema in the absence of intracranial tumor or other recognized cause for increased pressure or hydrocephalus. Unlike hydrocephalus, most adults with this condition have normal or even "slit" ventricles on imaging studies. Headache is the cardinal syndrome. The mechanism of increased pressure is unclear in this condition but it appears to be a result of blockage at CSF outflow.

D. "Arrested" Hydrocephalus

This term refers to a condition of ventriculomegaly with no symptoms: The ventricles may sometimes be very large. It is not clear whether it is truly asymptomatic, as there may be very subtle problems associated with it.

V. DIAGNOSIS

A. Clinical

Infants may present with such symptoms as a large head, irritability, delayed development, and vomiting. Older children and adults may describe headaches, nausea/vomiting, or visual changes (diplopia, decreased acuity, or field cuts) as high-pressure symptoms. In normal pressure hydrocephalus the symptoms are gait difficulty, slowing of action, memory loss, and incontinence.

1. Exam

a. Infants Before the cranial sutures are "closed," the size of the head will enlarge in hydrocephalus. The fontanelles may be noted to be bulging and/or firm, with palpable separation of the suture lines between cranial vault bones. The scalp veins may be engorged and the eyes may not elevate above the meridian. The head circumference is increased when compared with standard growth charts.

b. Ophthalmologic Findings Infants may present with the "setting sun sign." This results from upward gaze palsy from pressure in the suprapineal recess.

There may also be an abducens nerve palsy that manifests as a weakness of sideways gaze. The long intracranial course of the abducens nerve makes it vulnerable to stretch injury in hydrocephalus.

These symptoms may also present in adults, but they are typically later or more unusual findings. More common is the presence of papilledema that results from transmission of CSF pressure along the sheath of the optic nerve to the optic disc.

2. Other Findings

Severe cases or those of rapid onset may be associated with reflex bradycardia or, in infants, apneic spells. Sudden death may occur from rapid decompression. A variety of endocrine abnormalities have also been associated with hydrocephalus, including infantilism and precocious puberty. These have been ascribed, at least in part, to the compression of the pituitary gland by ballooning and thinning of the floor of the third ventricle.

Memory loss, spastic paraparesis with mild spastic weakness of the upper extremities, and less often a mild dysmetria of the extremities may be signs and symptoms. Agitated state is sometimes a factor.

In adults and children older than 1 year, hydrocephalus may present with either a high-pressure or normal pressure syndrome. The high-pressure syndrome includes headache, nausea, and vomiting. The normal pressure syndrome includes gait disturbance with a broad base and small steps, memory loss, urinary incontinence, and slowing of action.

B. Imaging

1. Computed Tomography

Computed tomography (CT) scanning will show ventricular enlargement and may also help determine the cause of hydrocephalus (e.g., tumors/cysts, congenital anomalies, or the presence of blood). Asymmetry of the ventricular system or the pattern of ventricular enlargement may also suggest the cause, as in aqueductal stenosis. Periventricular hypodensity may be present in some cases, suggesting **extravasation** of fluid into the periventricular space. Besides their role in diagnosis, CT scans are also essential for assessing response to treatment as well as follow-up.

2. Magnetic Resonance Imaging

Conventional magnetic resonance imaging (MRI) provides similar information as that of CT scanning about ventricular size, but MRI has a higher yield in identifying or characterizing associated or causative abnormalities. Special sequences are useful for identifying or quantifying flow through the aqueduct, for example, and making the diagnosis of aqueductal stenosis as well as determining the efficacy of certain forms of treatment, such as endoscopic ventriculostomy.

3. Ultrasound

This imaging modality is practical only in infants who have a patent fontanelle. Its usefulness lies in its relative low cost (compared to CT and MRI) as well as its ease of application at the bedside or in restless infants. It is excellent at establishing ventricular size, symmetry, and even the cause of hydrocephalus (most commonly, intraventricular blood in this age group). It is also extremely useful for follow-up after treatment until the age of approximately 6 months, when the anterior fontanelle becomes too small.

C. CSF Pressure Monitoring

Monitoring of ventricular pressure is used occasionally in the context of normal pressure hydrocephalus. Lumbar puncture is an important tool in assessing CSF pressure but should be avoided in noncommunicating hydrocephalus. Measurement over several hours may result in the diagnosis of normal pressure hydrocephalus.

VI. TREATMENT

The treatment of hydrocephalus is largely surgical. Medical therapies are either obsolete or temporizing.

A. Medical Therapy

Abandoned therapies include glycerol, isosorbide, radioactive gold, and head wrapping. Diuretics are occasionally used for neonatal hydrocephalus secondary to intraventricular hemorrhage to temporize ICP control until enough blood is reabsorbed. Acetazolamide and furosemide are the drugs typically used, but both can cause significant electrolyte imbalance.

In neonatal IVH, spinal taps also serve as a temporizing measure to keep ICP in the ''safe'' range

until CSF reabsorption resumes. In cases in which ventricular enlargement persists after the disappearance of blood and return of CSF protein to near normal levels, the patients must proceed to surgical therapy.

B. Surgical Therapy

The bulk of therapy for hydrocephalus is surgical. In an acute situation, CSF may be drained via a ventricular catheter to a sterile bag. Normally this is not done for longer than 2 weeks. Most hydrocephalus is treated by shunt placement. Shunts are permanently implantable devices for the diversion of CSF to one of several extracranial sites. They consist of a ventricular catheter, a valve, and tubing draining to a body cavity.

1. Temporary Diversion

Temporary diversion is sometimes sought when there is known infection in the CSF space precluding the implantation of permanent devices. This temporary diversion typically employs a catheter inserted into the ventricle that is tunneled underneath the scalp and connected to an external drainage bag. These systems are utilized for a few days until a permanent shunt can be placed if possible.

2. Routes of Diversion

The ventriculoperitoneal shunt is the most frequently employed route of diversion. Advantages include its relative simplicity and its complications are typically easier to manage than with other routes of diversion.

The ventricular catheter is inserted into the frontal horn of one of the lateral ventricles via frontal or occipital approaches. It is attached underneath the scalp to a valve, from which tubing passes subcutaneously down to the peritoneal cavity. This operation is often performed employing only two small incisions—the first for passing the catheter into the ventricle and the second for entry into the peritoneal cavity. The tubing is passed from one incision to the other using specially designed tunneling devices.

Ventriculoatrial shunting was the preferred route for shunting before ventriculoperitoneal shunting became popular. It is still widely employed primarily in some centers or where peritoneal shunting cannot be used.

The ventricular catheter is placed in the standard way, and the distal tubing is passed into the internal jugular vein and down to the right atrium, usually through the common facial vein, which is a small tributary of the jugular vein in the neck.

Other distal sites include the pleural cavity (a common option for diversion after the peritoneal cavity), the gallbladder, and ureter. These are rarely employed because of technical difficulty, much higher complication rates, and diversion to the ureters has typically required a nephrectomy.

Torkildsen preceded extracranial CSF shunting in its development. It involves the placement of a catheter from the lateral ventricle into the cisterna magna—the large subarachnoid space adjacent to the cerebellum and brain stem. It is useful only for aqueductal stenosis, a fourth ventricular pathology. It has been replaced by endoscopic ventricular fenestration.

There are two main valve types: differential pressure valves and variable resistance constant flow vavles. Different pressure valves provide a constant resistance and permit the flow of CSF when a certain hydrostatic pressure has been exceeded. This is the common basic valve design and includes slit valves, ball-in-cone valves, and diaphragm valves. Recently, a variable pressure valve has been created that controls the pressure of CSF release.

Variable resistance constant flow valves attempt to maintain more natural constant flow rates by varying the amount of resistance to flow in response to pressure changes and, indirectly, to posture. These valves are believed to lead to overdrainage less often than do differential pressure designs.

The use of lumboperitoneal shunts fell out of favor largely because of distal obstruction and the high incidence of kyphoscoliosis. Use of these shunts involved a laminectomy, and the tubing initially used had a propensity to cause a chemical arachnoiditis.

This technique has been repopularized with the introduction of less irritating Silastic tubing and due to the ability to place the tubing percutaneously, with specially designed needles, into the subarachnoid space without a laminectomy.

3. Endoscopic Therapy

The most common endoscopic technique in use today is the third ventriculostomy method. This is used when CSF absorption is believed to be normal but there is an obstruction to its egress from the third ventricle. In this procedure, an endoscope is introduced into the third ventricle (typically via a frontal approach) and a small hole is made in the floor of the third ventricle to permit the flow of CSF from this cavity into the subarachnoid

space, thereby bypassing any mechanical obstruction in the ventricular system. The major indication for this procedure is aqueductal stenosis. Most surgeons, however, are not specifically trained in performing this procedure, and its widespread application is further limited by patient selection.

Newer endoscopic techniques include aqueductoplasty, which involves the endoscopic repair of short-segment strictures in the aqueduct, but experience is still limited with this procedure.

4. Lesion Removal

Occasionally, there are clinical situations in which a single lesion can be removed to cure, or at least improve, hydrocephalus. Certain tumors are amenable to removal. A choroid plexus papilloma, which overproduces CSF, can be resected, thereby obviating the need for a shunt. Another typical example is a colloid cyst, which commonly occurs around the foramen of Monro, obstructing CSF flow. Resection can lead to complete resolution of the obstructive hydrocephalus.

5. Choroid Plexectomy (Obsolete)

This procedure was performed as an open operation and involved the cauterization of choroid plexus. This carried a very high mortality early on, and it fell into disfavor. Later attempts were made to perform this endoscopically, and mortality rates decreased significantly, but it has not regained widespread use because of the relative safety and ease of other operations.

VII. COMPLICATIONS

Hydrocephalus, treated or untreated, results in a number of problems, some of which are described here. Untreated, hydrocephalus can result ultimately in death. Where its onset is relatively acute, the resulting increase in intracranial pressure will compress brain stem structures to the point at which neurovegetative functions are compromised. In more chronic courses, progressive neurological decline occurs, which will affect motor function, gait, and behavior.

Blindness may result from cortical lesions or damage to the visual pathways. Cortical blindness is caused by occlusion of the posterior cerebral arteries by downward pressure on them against the tentorial notch. Papilledema caused by increased CSF pressure may lead to optic atrophy and blindness.

Neurodevelopmental impairment can be attributed to both hydrocephalus and the initial condition that resulted in it. Hydrocephalus, where untreated, appears to cause sustained stretching of neurons and associated fibers, and this probably results in many of the clinical manifestations seen in the condition.

A. Shunt Malfunction

Shunt malfunction is typically the result of an obstruction in the shunt system. This may be proximal (in or around the ventricular catheter) or distal (in or around the peritoneal or other distal end). Occasionally, the valve may be obstructed by debris. These situations will often require surgery for replacement of the obstructed portion.

Proximal obstruction of the ventricular catheter is typically caused by adherent choroid plexus, debris, blood, or adherent brain tissue. Rarely, growing tumor or the inflammation resulting from infection can also result in proximal obstruction.

In the peritoneal cavity, obstruction is typically the result of low-grade infection that eventually causes formation of a pseudocyst around the tip of the catheter. Obstruction may also be caused by debris or malposition of the catheter from the initial surgery. Progressive growth of a patient who had a catheter placed early in childhood can lead to its withdrawal from the peritoneal cavity because it becomes too short for the patient's gradual increase in length. This previously common occurrence is relatively rare today because long redundant lengths of tubing are left in the abdomen at initial placement to account for expected growth. Disconnections, breaks, kinks, and other mechanical disruptions in the distal tubing may also occur.

B. Overdrainage

It is possible to "overdrain" CSF with a shunt. In the short term, this can result in symptoms similar to those of a "spinal headache," specifically headaches, nausea, and vomiting that tend to be postural and are relieved by recumbency. These symptoms will sometimes improve with time, but they may require shunt revision with a valve of higher pressure/lower flow rate or the addition of a so-called "antisiphon" device to the system to prevent overdrainage with upright posture. With variable pressure valves the pressure can simply be raised.

Overshunting of ventricles in the presence of thinned or atrophic brain can lead to collapsing away from the skull. This creates a subdural hygroma. This can result in tearing to bridging veins in the subdural space, causing bleeding, and the accumulation of a subdural hematoma.

Slit ventricle syndrome is a poorly understood complication of ventricular shunting characterized by collapsed or slit ventricles. It appears to occur when chronic overshunting of the ventricles results in a very low compliance state. The ventricles become slits and their walls may occlude the catheter impeding CSF drainage. The low compliance of the ventricular system then causes an abnormal increase in intraventricular pressure with small accumulations of CSF and symptoms of increased ICP result.

This problem is very difficult to treat. Options include replacing the ventricular catheter, changing to a higher pressure valve, or inserting an antisiphon device. Skull decompression is sometimes employed as a last resort on the principle that the miniscule increase in intracranial volume is enough to compensate for the changed compliance of the brain in this condition.

C. Shunt Infections

Shunt infections occur in about 10% of shunt procedures in children but are much less common in adults. They may occur at any time in relation to shunt placement and have been reported more than 10 years after shunt placement. The bacteria causing such infections are typically skin flora such as *Staphylococcus epidermidis* and *Propionibacterium* spp.

Most authorities recommend removing the entire shunt system in these circumstances, using an external diversion system during treatment with appropriate intravenous antibiotics, and placement of a new shunt after an interval from several days to a couple of weeks depending on a number of factors, including the virulence of the identified organism and the sterilization of CSF on serial cultures.

Other complications with shunts include the following:

- Occasional seizures (1%) that can result from the cortical irritation from catheter placement.
- Ascites (with peritoneal shunts) or pleural effusions (with pleural shunts) from poor local absorption of CSF.
- Bowel perforation, which can occur at the time of shunt insertion or even years later from gradual erosion of the shunt tubing into the bowel lumen.
- Specific problems with atrial shunting, including bacteremia and endocarditis as well as shunt nephritis, which for poorly understood reasons appears to result from the deposition of antigen–antibody complexes in the renal glomeruli following shunt infection. Pulmonary emboli (which can be septic) can also occur, leading to pulmonary infarction.

Outcome in hydrocephalus is related to the increased ICP as well as the primary cause of the condition. Deaths from hydrocephalus in countries in which neurosurgeons and shunt are available are uncommon. One study cited an 80–90% 5-year survival rate in children with hydrocephalus. Most data on mortality are set in the context of treatment complications. Death from shunt failure is rare, with reported rates of approximately 1%.

Cognitive deficits are difficult to interpret in the context of underlying brain abnormalities. One study examining children with arrested (untreated) hydrocephalus found 25% with IQs below 50 and 45% with IQs higher than 85%. Another study examining children with treated hydrocephalus found 72% with IQs between 70 and 100 and 32% with IQs higher than 100. Only 4% had IQs below 70.

VIII. OUTCOME

Some patients have a higher likelihood of benefiting from CSF diversion than others, in terms of motor function. Up to three-fourths of patients with normal pressure hydrocephalus in which gait dysfunction is the primary symptom will improve after shunting. On the other hand, patients with dementia and no gait disorder will rarely benefit from surgery.

In children, shunt placement for high pressure hydrocephalus is likely to lead to complete reversal of high pressure symptoms.

GLOSSARY

circumventricular organs Areas of the brain that lack a blood–brain barrier and are found on the midline surrounding the third and fourth ventricles. These regions are essential "windows" through which the brain exerts humoral control of peripheral systems and are also responsive to feedback humoral influences from the systems that they modulate.

fornix A well-defined myelinated fiber bundle that serves as an important histological landmark in the hypothalamus and is also the principle conduit through which neurons in the subiculum project to the mammillary bodies.

infundibular stalk The ventral evagination of the floor of the third ventricle that connects the hypothalamus to the pituitary gland. It contains the long portal vessels that transport release and inhibiting factors from hypothalamus to the anterior lobe of the pituitary gland and is also the conduit for axons of magnocellular neurons that terminate in the posterior (neural) lobe of the pituitary.

median eminence The highly vascularized portion of the tuber cinereum that is essential for hypothalamic regulation of the anterior lobe of the pituitary. The blood vessels in this region lack a blood–brain barrier and are therefore capable of transporting peptides and neurotransmitters from the hypothalamus to the anterior lobe.

stria terminalis A major fiber pathway through which the amygdala communicates with the hypothalamus.

tuber cinereum The protuberance on the ventral surface of the diencephalon that contains the median eminence and gives rise to the infundibular stalk.

The hypothalamus is a remarkable region of the central nervous system. This small subdivision of the ventral diencephalon communicates extensively with other regions of the neuraxis via classical synaptic interactions and also has profound influences on the hormonal regulation of peripheral organ systems. In essence, it is directly responsible for the regulatory control of homeostatic systems essential for survival of the parent organism. The ability of this region to exert such profound influence over behavioral state and physiology is reflected in both the properties of hypothalamic neurons and the mechanisms through which they communicate. Thus, the dynamic regulatory capabilities of the hypothalamus are defined by the unique properties (e.g., timekeeping capabilities) of its constituent neurons, the ability to influence peripheral systems by virtue of hormonal or "humoral" communication, and the responsiveness of hypothalamic neurons to feedback control by the peripheral systems that they regulate. This article reviews the basic organizational principles fundamental to hypothalamic function, focusing on well-studied hypothalamic systems that illustrate the functional parcellation of this small but influential region of the brain.

I. HYPOTHALAMIC ORGANIZATION

As its name implies, the hypothalamus is found below the thalamus in the diencephalon (Fig. 1). It is

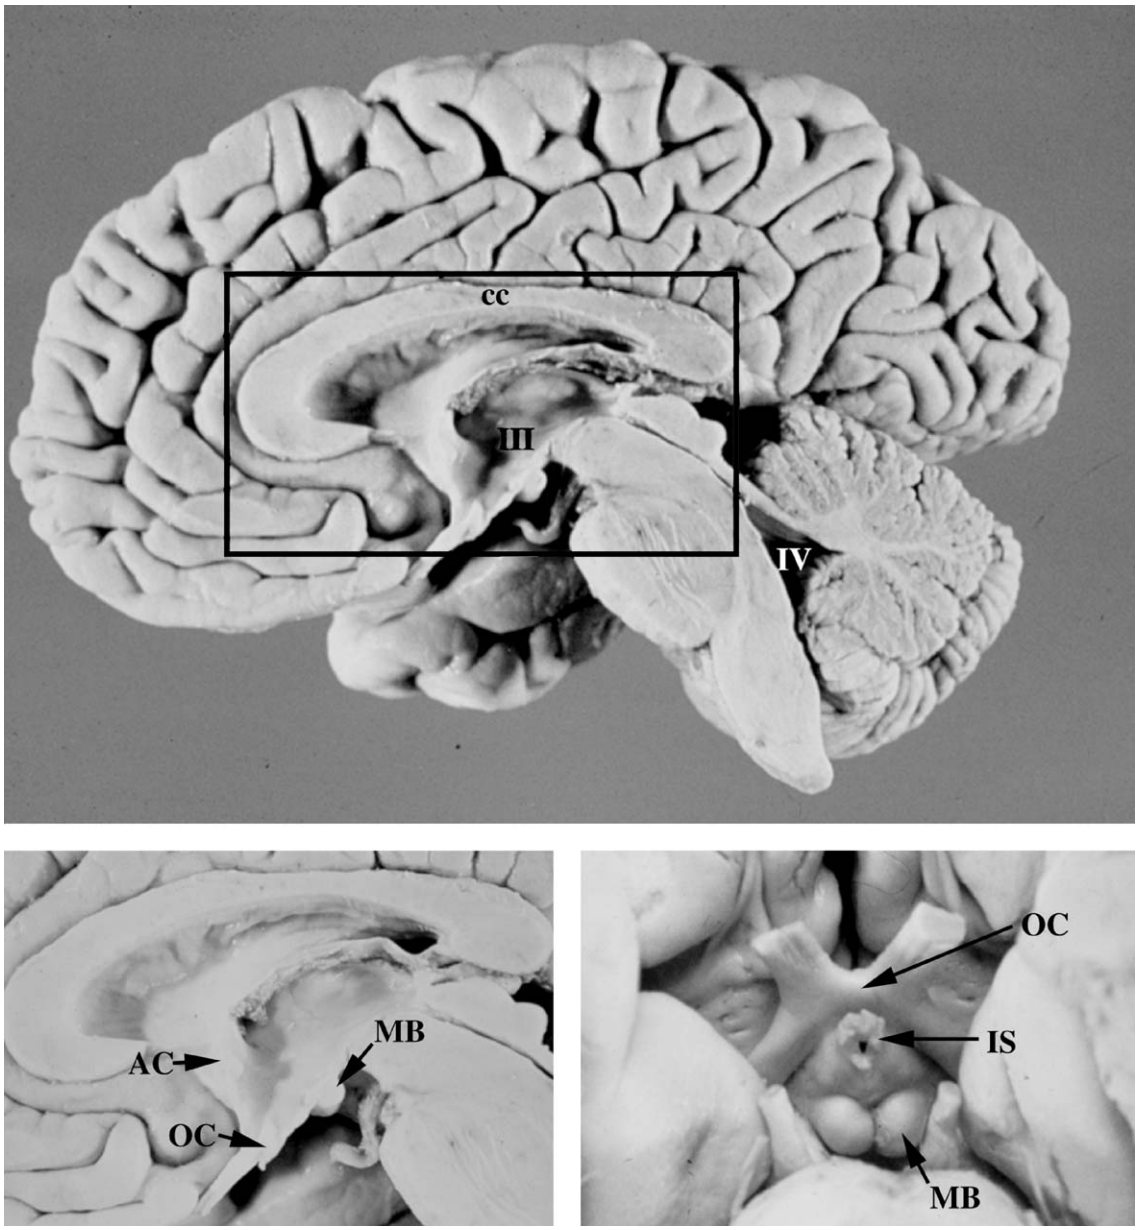

Figure 1 The disposition of the hypothalamus in relation to other regions of the central nervous system is illustrated in sagittal and ventral exposures of the human brain. In sagittal exposures of the brain the hypothalamus occupies a small region bounded by the anterior commissure (AC), optic chiasm (OC), and mammillary body. Ventral exposure of the brain reveals the three prominent landmarks that define the floor of the hypothalamus: the OC rostrally, the infundibular stalk (IS) arising from the tuber cinereum, and the paired spherical protuberances that constitute the MBs. III, third ventricle; IV, fourth ventricle.

distinguished by distinct external landmarks on the ventral surface of the brain that define its full rostrocaudal extent. These include the optic chiasm rostrally, the intermediate tuber cinereum marked by the prominent infundibular stalk, and the caudally placed mammillary bodies. Classic literature used these external landmarks to define internal subdivisions of the hypothalamus. Thus, it is still common to find references to the chiasmatic, tuberal, and mammillary subdivisions of hypothalamus. However, as our knowledge of the organization, connectivity, and function of hypothalamic cell groups has improved,

the rationale for dividing the hypothalamus into three regions defined by external landmarks has become less compelling. Nevertheless, these landmarks remain useful designations for defining the general location of hypothalamic cell groups and are commonly found in the literature.

Coronal sections through the hypothalamus reveal prominent internal landmarks that have proven useful in defining the basic organization of hypothalamic cell and fiber systems. Among the most prominent is the third ventricle that separates much of the hypothalamus into identical halves. The fluid-filled reservoir is particularly prominent in the intermediate portion of the hypothalamus demarcated by the tuber cinereum. In coronal sections through this level, the lumen of the ventricle defines the dorsoventral extent of the hypothalamus. The floor of the third ventricle is formed by a thin bridge of tissue, commonly known as the median eminence, that is continuous with a stalk connecting the ventral hypothalamus to the pituitary gland. The median eminence is among the most important interfaces through which the hypothalamus exerts regulatory control over peripheral systems in that it is essential for regulation of hormone secretion from the pituitary gland. It is similar to another midline strip of tissue that contains the organum vasculosum of the lamina terminalis (OVLT) and that forms the rostral wall of the third ventricle in that it lacks a blood–brain barrier (BBB). The absence of the BBB at these sites provides the essential means for neurohumoral communication and will be considered in greater detail later.

The internal organization of the hypothalamus is characterized best in histological preparations of coronal sections. Classic Nissl preparations reveal three longitudinal zones that extend throughout the rostrocaudal extent of the hypothalamus. The location of each zone can be defined in relation to its proximity to the third ventricle and a prominent myelinated fiber bundle, the fornix, that enters the hypothalamus rostrally and then courses caudally to terminate in the mammillary bodies. The *periventricular* zone is a densely packed group of neurons immediately adjacent to the third ventricle. Occasionally, it contains well-demarcated cell groups, such as the suprachiasmatic, arcuate, or paraventricular nuclei. However, in the majority of its extent it is composed of a thin, densely packed group of neurons immediately adjacent to the ependymal lining of the ventricle. The *medial* zone is found between the periventricular zone and a vertical plane passing through the fornix. Nuclear groups in this region (e.g., the ventromedial and dorsomedial nuclei) are among the most prominent and well-delineated cell groups in the hypothalamus. The *lateral* zone is found between the medial zone and the optic tract and internal capsule at the lateral extent of the diencephalon. Neurons in this region are more dispersed and do not form the distinct nuclear groups characteristic of the periventricular and medial zones. Nevertheless, immunohistochemical studies that have revealed distinct phenotypic parcellation of neurons in the lateral zone have contributed greatly to improving our understanding of the functional organization of this region.

II. MAJOR HYPOTHALAMIC CONNECTIONS

Connectional analyses have contributed greatly to our understanding of hypothalamic function and organization. Two well-known fiber tracts, the fornix and stria terminalis, provide major conduits through which the hypothalamus interacts with subdivisions of the limbic system. Each of these fiber tracts originates in the temporal lobe and pursues a looping trajectory over the thalamus to enter the hypothalamus dorsally and rostrally. An interesting new literature, particularly with respect to the fornix, has provided novel insights into the way in which axons traversing these pathways influence hypothalamic function. These advances have not only improved our understanding of how the hypothalamus functions within a larger ensemble of neurons but also provided a functional rationale supporting the aforementioned zonal organization of the hypothalamus.

As noted previously, early descriptions of hypothalamic organization established the intrahypothalamic course of the fornix as an important landmark separating the medial and lateral hypothalamic zones. Fibers traversing this tract divide into pre- and postcommissural bundles that pass either rostral or caudal to the anterior commissure. Individual axons of the postcommissural bundle leave the fornix along its course to terminate in hypothalamic nuclei while others continue caudally to terminate in the mammillary bodies. Axons in the precommissural fornix pass rostrally to terminate topographically within subdivisions of the lateral septum. The lateral septal neurons, in turn, project densely on the periventricular, medial, and lateral zones of the hypothalamus. Thus, the hippocampus provides a prominent topographically organized influence upon hypothalamic zones through parallel organized disynaptic projections involving the lateral septal nuclei. From the standpoint of sheer

magnitude and number of hypothalamic neurons targeted by these disynaptic projections, it would appear that the precommissural fornix has a much more substantial influence upon hypothalamic function than the axons that course through the postcommissural branch.

Prominent limbic influences on hypothalamic function also arise from the amygdaloid complex and course into the hypothalamus through either the stria terminalis or the ventral amygdalofugal pathway. In contrast to the fornix, these afferents do not segregate within hypothalamic zones. Rather, evidence indicates that they provide more directed input to hypothalamic areas and cell groups. For example, axons that course through the stria terminalis terminate more densely in the rostral rather than the caudal hypothalamus and also provide dense input to subsets of nuclei within a zone.

The medial forebrain bundle (MFB) is another prominent fiber tract associated with the hypothalamus. The trajectory of this projection system brings it through the full rostrocaudal extent of the lateral hypothalamus. This pathway is more diffusely organized than the postcommissural fornix and carries both ascending and descending fibers. Many of the axons that pass through the MFB are simply traversing the hypothalamus in transit to other forebrain targets. The prominent dopaminergic projections from the substantia nigra and ventral tegmental area fall into this category. Brain stem noradrenergic and cholinergic neurons also project through the MFB to both diencephalic and telencephalic targets. Thus, whereas the MFB is an important conduit for axons innervating the hypothalamus, it is also a major projection pathway for axons projecting to and from forebrain nuclei. Loss of function in response to lesions that interrupted these fibers of passage confounded the interpretation of results from early studies that incorrectly ascribed functions to hypothalamic nuclei that were, in fact, subserved by axons passing through the hypothalamus in the MFB. Improvements in tract tracing and lesioning methods, as well as the development of other functional probes, have clarified many of these false interpretations.

III. THE HYPOTHALAMUS AND THE TEMPORAL ORGANIZATION OF BEHAVIOR

The hypothalamus has long been recognized as an important integrative area for the regulatory control of behavioral state and the temporal organization of behavior. Early evidence from lesion and stimulation paradigms implicated regions of the hypothalamus in the control of sleep and other rhythmic aspects of behavior and physiology. However, identification of the specific circuitry through which the hypothalamus coordinates internal homeostatic function with sensory stimuli of the environment only occurred with the advent of technical advances that permitted the identification and functional dissection of populations of hypothalamic neurons. Today, our knowledge of the neural systems that exert regulatory influence over these functions is far more precise, and in some instances the molecular mechanisms that contribute to this control are beginning to be unraveled. The following sections review the functional organization of hypothalamic systems that participate in the control of rhythmic functions, sleep, and arousal.

A. A Biological Clock in Hypothalamus

It has long been clear that mammals and other organisms exhibit daily cycles in physiology and behavior that persist in the absence of sensory input from the environment. These cycles are approximately 1 day in length (hence the term circadian) and in normal circumstances are synchronized with the environment. In essence, they are rhythms of behavior and physiology that are tightly coupled to the most pervasive signal in our environment, the daily rhythm of light and dark. The adaptive significance of such an endogenous timekeeping mechanism is obvious when one considers the practical benefits of synchronizing behavior to the light-dark cycle. Certainly, the restriction of the activity of nocturnal animals to nighttime has the practical advantage of reducing the possibility of predation, and the ability to precisely measure day length permits seasonal breeders to deliver their progeny during the portion of the year when nutrients are most prevalent. Thus, it is not surprising that this endogenous timekeeping system is among the oldest and most highly conserved systems of regulatory control in the animal kingdom.

Although circadian rhythms in both plants and animals have been long been recognized, determination that a "biological clock" resides in the hypothalamus of mammals is a relatively recent event that can be traced to anatomical studies conducted in the early 1970s. Recognizing that the entraining influences of light are essential to any timekeeping system, two research groups independently utilized new methods

of defining neuronal connectivity to demonstrate that a circumscribed group of neurons overlying the optic chiasm receives dense retinal inputs. These neurons, comprising the suprachiasmatic nuclei (SCN), became the experimental focus of circadian biologists and there is now considerable evidence supporting the conclusion that a biological clock resides in the SCN of mammals. Specifically, animal studies have shown that the cells of the SCN exhibit a circadian rhythm of activity that is entrained by light, and that rhythmic aspects of physiology and behavior are abolished in animals in which the SCN have been destroyed. Importantly, it is also known that the rhythmicity of SCN neurons is genetically determined rather than the emergent property of a network, and "clock" genes that impart rhythmicity to SCN neurons have been identified. Thus, the hypothalamus contains a clock, the SCN, whose activity is synchronized to the external environment by virtue of sensory input transduced by the retina.

Elucidating the connections of the SCN has been an important component of understanding how this group of hypothalamic neurons imposes its temporal message on the physiology and behavior of the parent organism. One of the most well-characterized systems in this regard is the circuitry through which the SCN exerts regulatory control over the secretion of the hormone melatonin. Melatonin is secreted by the pineal gland in a circadian manner but is also responsive to light such that light stimulation during the dark phase of the photoperiod inhibits the normally high levels of melatonin secretion. This dynamic regulatory capacity renders the temporal profile of melatonin secretion a precise measure of day length. A large literature has established that the SCN controls both the circadian and photoperiodic aspects of melatonin secretion through multisynaptic pathways that sequentially involve the paraventricular hypothalamic nucleus, the intermediolateral cell column of the spinal cord, and neurons of the superior cervical ganglion that project to the pineal. Additionally, binding studies and localization of melatonin receptors have revealed that melatonin exerts feedback influence on the brain by binding to neurons in the SCN, paraventricular thalamic nucleus, and pars tuberalis of the infundibular stalk. Thus, the SCN not only regulates the secretion of melatonin but also is subject to feedback regulation by the hormone that it modulates. This is a common feature of the neurohumoral regulation exerted by the hypothalamus.

The SCN also imparts temporal organization to other systems and appears to do so through efferent projections that are largely confined to the hypothalamus. SCN neurons project to a relatively restricted group of nuclei in the hypothalamus that includes, but is not limited to, the region subjacent to the paraventricular nucleus (the subparaventricular zone), the preoptic area, and medial hypothalamic nuclei (e.g., arcuate and dorsomedial) involved in neuroendocrine regulation of pituitary function. These projections provide a substrate through which the SCN imparts temporal influences on a variety of systems.

B. The Hypothalamus and Sleep

Evidence that the hypothalamus is involved in the control of sleep emerged from a large literature dating to the early 1900s. Lesion studies correlating anterior hypothalamic damage with insomnia and caudal hypothalamic damage with somnolence were particularly informative. These and subsequent studies resulted in the concept of hypothalamic "sleep centers." A fascinating recent literature has demonstrated a cellular basis for hypothalamic influences on sleep and also provided insights into the means through which temporal organization is imparted on this behavior. It is now apparent that at least two distinct populations of neurons in the rostral and caudal hypothalamus are responsible for the hypothalamic effects on sleep. Using a creative experimental approach, it was demonstrated that neurons in a circumscribed region of the preoptic area [the ventrolateral preoptic nucleus (VLPO)] in rats express Fos, the protein product of the protooncogene *c-fos*, shortly following the onset of sleep. Since Fos expression reflects neuronal activation, this observation raised the possibility that VLPO neurons are involved in the initiation of sleep. A number of subsequent observations have validated this hypothesis and also revealed the larger network of hypothalamic neurons that participate in this function. Specifically, evidence now supports the conclusion that VLPO neurons inhibit arousal through projections to histaminergic neurons in the tuberomammillary (TM) nuclei of the caudal hypothalamus. In support of this conclusion, it was shown that GABAergic neurons in VLPO synapse on TM neurons and that pharmacological inhibition of TM neurons or blockade of histaminergic receptors promotes sleep. Those who recall the drowsiness that typically follows the use of early antihistamines (which act on central as well as peripheral histamine receptors) prescribed for the treatment of colds and allergies can

appreciate the major influence of the diffusely projecting neurons of the TM nuclei upon arousal.

Importantly, neurochemical lesions of VLPO and surrounding neurons have revealed greater functional parcellation of the anterior hypothalamic circuitry involved in sleep regulation. Cell-selective lesions that do not interrupt fibers of passage were shown to compromise different aspects of sleep based on the localization of the lesion. Lesions confined to the compact portion of VLPO dramatically reduce non-REM sleep and, in circumstances in which lesions are incomplete, the amount of non-REM sleep is linearly correlated with the number of Fos-expressing neurons in the portion of the VLPO that survived the lesion. Interestingly, lesions dorsal to VLPO that eliminate galanin-containing neurons that project to TM produce sleep deficits more closely associated with REM than with non-REM sleep. Collectively, these observations provide compelling evidence in support of a prominent role for the hypothalamus in sleep regulation and further indicate that there is functional parcellation in the neurons of the VLPO that participate in this control.

It is also clear that the hypothalamus plays an important role in the temporal organization of the sleep–wake cycle. Sleep is a circadian function, and although the SCN is not essential for the generation of sleep, it is responsible for consolidation of sleep within cycles that occur within a circadian framework. Thus, if the SCN are destroyed, rats will sleep approximately the same amount of time but this sleeping time will be distributed in many short bouts throughout the light–dark cycle rather than in a consolidated period. The circuitry through which the SCN imposes this circadian influence on sleep remains to be established, but it is likely that it occurs via polysynaptic connections that link the clock to nuclei involved in sleep regulation.

C. Hypothalamic Influences upon Arousal

Certainly, the aforementioned studies that have demonstrated a role for hypothalamic nuclei in sleep indicate that the hypothalamus influences arousal states. However, recent studies have demonstrated that the influence of the hypothalamus on arousal is not restricted to the TM neurons in caudal hypothalamus. In particular, a prominent group of neurons confined to the lateral hypothalamus has recently been implicated in the sleep disorder known as narcolepsy. These neurons express novel neuropeptides known as hypocretins or orexins and are differentially concentrated within the perifornical nucleus that surrounds the fornix in the tuberal hypothalamus. Mapping studies have shown that hypocretin/orexin neurons are similar to TM neurons in that they are confined to hypothalamus and give rise to extensive projections throughout the neuraxis. However, it is also clear that these neurons densely innervate areas (e.g., locus coeruleus) involved in the control of arousal, and there is good evidence that pathology of signaling pathways involving hypocretin neurons may be causal in narcolepsy. In this disorder, individuals exhibit daytime sleepiness and lapse unexpectedly into bouts of REM sleep. A dog model of the disease has identified a deletion in the gene encoding the hypocretin 2 receptor, and knockout mice lacking the hypocretin gene exhibit sleep disturbances similar to narcolepsy. Further, examination of postmortem human brains of narcoleptics has revealed substantial reductions in the number of hypocretin neurons, raising the possibility that the disease may be due to an autoimmune attack on the neurons. Thus, there is strong evidence that caudal hypothalamic neurons play an integral role in the regulation of arousal states.

IV. THE HYPOTHALAMUS AND NEUROENDOCRINE REGULATION

Neural regulation of pituitary secretion is one of the most important, well-characterized, and diverse functions of the hypothalamus. In fact, the demonstration that the hypothalamus exerts regulatory control over the pituitary is one of the landmark discoveries that tied the fields of neurobiology and endocrinology together. Recognition that hypothalamic control over the pituitary was humoral in nature resulted from structural studies that demonstrated a vascular link, or portal plexus, connecting these structures. Thus, the organizational features of the hypothalamic–pituitary axis are introduced below as a prelude to examining specific examples of hypothalamic control over pituitary secretion.

As noted earlier, the ventral diencephalon is connected to the subjacent pituitary via the infundibular stalk. Large-caliber magnocellular axons whose parent neurons reside in rostral hypothalamus traverse this stalk to terminate directly in the posterior lobe of the pituitary gland. This is the only direct neural

connection between the hypothalamus and pituitary and represents only a small portion of the regulatory capacity of the hypothalamus over pituitary function. Control of the secretory activity of the anterior pituitary is achieved through a portal vascular plexus that arises in the median eminence and then pursues a directed course along the stalk to end in the anterior lobe of this gland. An important feature of this portal system is the absence of the BBB in the capillaries of the median eminence. Fenestrations in the median eminence vessels allow peptides and neurotransmitters released from axons in their vicinity to gain access to the portal plexus, whereupon they are transported to the anterior pituitary to influence the secretory activity of cells in that portion of the gland. This architecture forms the basis for the neurohumoral regulation of pituitary function that is the foundation of neuroendocrinology (Fig. 2).

The absence of the BBB is a defining feature of a group of structures known as circumventricular organs (CVOs). These regions, which include the median eminence, are found on the midline of the brain

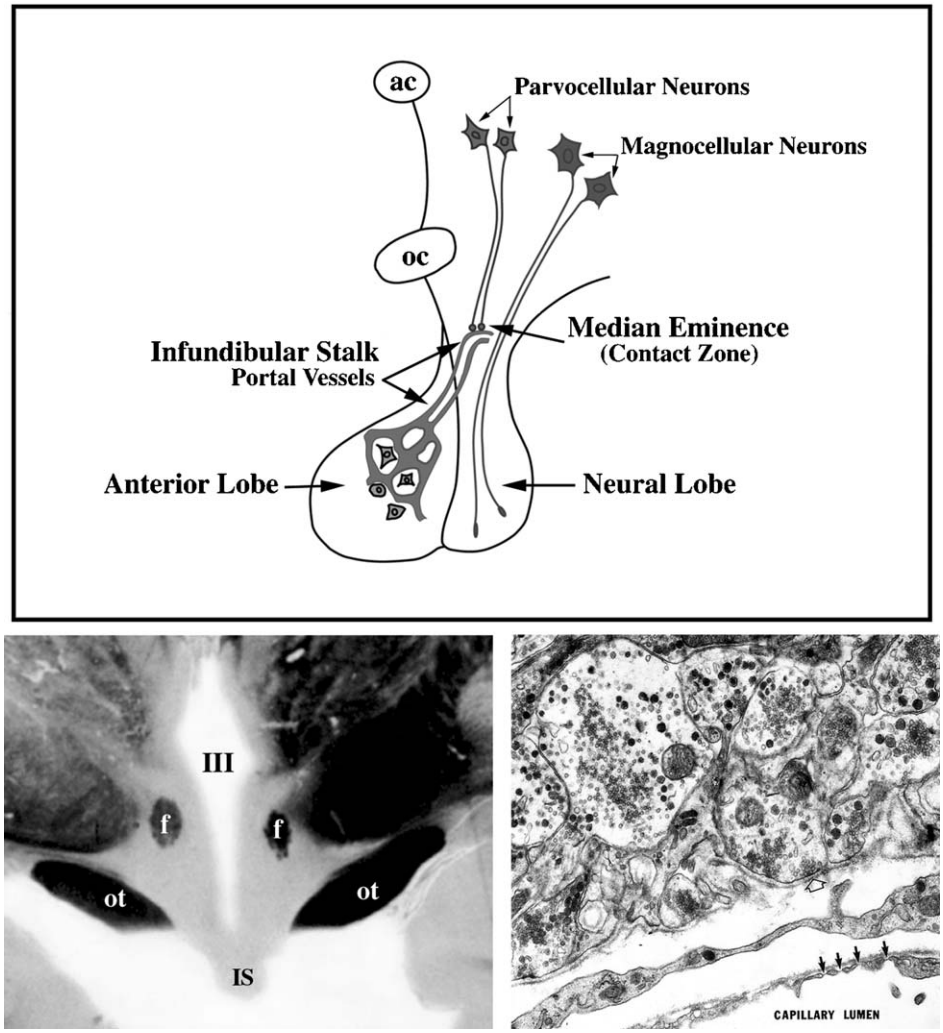

Figure 2 The basic organization of the hypothalamic–pituitary axis is illustrated in the schematic diagram. The anterior lobe of the pituitary is regulated by hypothalamic peptides and neurotransmitters that are released from parvocellular hypothalamic neurons into a vascular (portal) plexus and then travel to the anterior lobe to either stimulate or inhibit the release of hormones from cells in this portion of the gland. This is possible because the vessels at the neurohemal contact zone in the median eminence are fenestrated and large numbers of axon terminals terminate on the perivascular space adjacent to these vessels (bottom, right). Large magnocellular neurons project through the infundibular stalk (IS) to terminate in the posterior, or neural, lobe of the pituitary. ac, anterior commissure; f, fornix; OC, optic chiasm; ot, optic tract; III, third ventricle.

surrounding the third and fourth ventricles. Only two of the CVOs (the median eminence and OVLT) are found within the hypothalamus, but all are intimately associated with hypothalamic function by virtue of the connections that they maintain with various hypothalamic nuclei. For example, the absence of the BBB in the subfornical organ and area postrema allows neurons in these regions to respond to circulating cues and then modulate the activity of the hypothalamic–pituitary axis through classical synaptic connections with hypothalamic neurons. Thus, the absence of the BBB is essential not only for the ability of the hypothalamus to control the secretory activity of the pituitary but also for the feedback regulation of the hypothalamic–pituitary axis that imparts precision on endocrine regulation of peripheral systems.

The neurons that contribute to regulation of anterior pituitary secretion exhibit common features that are reflective of their function. First, they are confined to the hypothalamus and give rise to axons that terminate in the median eminence. Two hypothalamic nuclei, the paraventricular and arcuate, are particularly devoted to anterior pituitary regulation. Substantial numbers of parvocellular neurons in these nuclei give rise to dedicated projections to the external zone of the median eminence where their terminals abut on the perivascular space (contact zone) surrounding the fenestrated capillaries of the portal plexus. Neurons exhibiting the same organization are also dispersed in other areas of hypothalamus. For example, neurons involved in the regulation of growth hormone secretion are concentrated in the rostra1 periventricular and arcuate nuclei, whereas those that are important for regulation of ovulation in females are dispersed throughout the preoptic area. All these neurons project exclusively to the portal plexus in the median eminence and thereby exert their function in a neuroendocrine fashion.

A second feature of these neurons is their neurochemical diversity. Although they all have common structural features, the differing functions of these neurons are defined by their neurochemical phenotype. Many of the neurons manufacture and release small peptides that either stimulate or inhibit the secretory activity of cells in the anterior pituitary. Others utilize small molecule neurotransmitters such as dopamine toward the same end. These ''releasing'' or ''inhibiting'' factors impart another level of regulatory control over the hypothalamic–pituitary axis that is best illustrated by considering a specific example, such as growth hormone (GH) secretion. Peripheral metabolism is heavily influenced by release of GH from the anterior pituitary gland and this release, in turn, is regulated by two populations of hypothalamic neurons that produce opposite effects in the pituitary. Stimulation of GH release is under the control of neurons in the arcuate nucleus that produce growth hormone-releasing hormone, whereas inhibition of GH release results from the activity of somatostatinergic neurons in the rostral periventricular nucleus. Differential activation of these opposing systems permits precise regulation of GH secretion and emphasizes the importance of feedback regulation in activating the appropriate regulatory circuitry.

A role for hypothalamic timing mechanisms in neuroendocrine regulation is predicted by the rhythmic profiles of hormone release by the anterior pituitary and its target organs. This is clearly exemplified by the temporal profile of cortisol secretion by the adrenal gland. Release of plasma corticosteroids is under control of the hypothalamic–pituitary–adrenal (HPA) axis and exhibits a circadian profile, with peak levels occurring at the end of the dark phase in humans and the end of the light phase in rat. Although the temporal relations of these peaks differ between the two species, the temporal association of the peaks to activity is the same. Release of corticosteroids from the adrenal is under the control of corticotropin-releasing factor (CRF) neurons in the paraventricular hypothalamic nucleus. Release of CRF into the portal plexus at the median eminence elicits the synthesis and release of adrenocorticotropin hormone from the anterior pituitary, which subsequently stimulates corticosteroid release from the adrenal. Evidence suggests that the SCN modulates the activity of the HPA axis through a disynaptic pathway in which SCN neurons synapse on neurons in the dorsomedial hypothalamic nucleus that are presynaptic to CRF neurons in the paraventricular nucleus. Control of the HPA axis is also exquisitely sensitive to other sensory cues, such as feeding and stress. Thus, control of the HPA axis is a dynamic process in which the hypothalamus plays an important integrative role that defines the magnitude and temporal profile of corticosteriod release. It is probable that similar organizational principles account for the rhythmic release of other hormones.

V. HYPOTHALAMIC CONTROL OF AUTONOMIC OUTFLOW

As noted earlier, the hypothalamus plays an essential role in the maintenance of homeostasis. Neuroendocrine regulation of pituitary function constitutes one of

the primary ways through which this is achieved. However, the autonomic nervous system (ANS) is also intimately involved in homeostatic regulation. A substantial body of work clearly indicates that the hypothalamus plays a major role in controlling the activity of the ANS. Extensive descending connections to brain stem and spinal preganglionic neurons of the ANS arise from hypothalamic nuclei, and these hypothalamic nuclei are the target of feedback regulation that is both synaptic and humoral in nature. However, it is important to emphasize that these hypothalamic nuclei function within a larger set of forebrain areas that influence autonomic outflow either indirectly by virtue of their connections with hypothalamus or directly via descending projections to autonomic nuclei in the brain stem and spinal cord. These areas include the visceral cortices (prefrontal and insular cortex) and components of the limbic system such as the amygdala.

The major hypothalamic efferents to autonomic nuclei arise in the paraventricular nucleus and the lateral hypothalamic area. Neurons in both of these regions give rise to descending projections to preganglionic neurons in both the sympathetic and parasympathetic subdivisions of the spinal cord and brain stem. The paraventricular nucleus (PVN) is a particularly important integrative center for both neuroendocrine and autonomic regulation of homeostatic function. As noted earlier, parvicellular neurons in the PVN are major contributors to the neuroendocrine regulation of anterior pituitary secretion by virtue of their projections to the portal plexus in the median eminence. Additionally, magnocellular vasopressinergic and oxytocinergic neurons in the PVN and supraoptic nuclei project through the median eminence to terminate in the posterior lobe of the pituitary gland. These peptidergic systems are important for the regulation of fluid homeostasis and lactation and are distinct from the large numbers of PVN parvicellular neurons that give rise to descending projections to autonomic nuclei. The latter projections arise from phenotypically distinct PVN neurons sequestered within subfields of the nucleus that are devoted to autonomic function (dorsal parvicellular subdivision) or to both neuroendocrine and autonomic regulation (medial parvicellular subdivision). This juxtaposition of neurons in the PVN that contribute to homeostatic regulation via neuroendocrine or autonomic pathways makes efficient use of the sensory feedback signals that are relevant to both modes of regulation. Defining the means through which this sensory information is integrated in the PVN to influence endocrine and autonomic function remains an active and important area of research. The complexity of the integrative capacities of the PVN is illustrated in the following section on the neural control of feeding.

VI. HYPOTHALAMIC CONTROL OF FEEDING

Our understanding of how the hypothalamus contributes to the regulation of feeding behavior has advanced substantially during the past decade. Identification and functional dissection of phenotypically distinct populations of hypothalamic neurons that are now known to influence ingestive behavior and energy metabolism have contributed greatly to these advances. Recent identification of peripheral signaling molecules that act centrally to modulate these hypothalamic circuits has also provided tremendous insights into how the hypothalamus participates in energy homeostasis.

Results from classic lesion studies carried out in the 1940s and 1950s led to a ''dual-center'' model for the hypothalamic control of hunger and satiety that drove scientific research in this area for more than 30 years. The model was based on profound and consistent changes in ingestive behavior observed in rats after bilateral mechanical or electrolytic lesions centered in the ventromedial nucleus of the hypothalamus (VMH) or lateral hypothalamic area (LHA). Rats with VMH lesions displayed an apparently insatiable hunger and would become quite obese when food was made freely available. Conversely, rats with LHA lesions displayed adipsia and anorexia, and they required careful nursing during the postlesion period to prevent fatal dehydration and starvation. The dual-center model of hunger and satiety enjoyed strong appeal as an organizing framework for understanding how the hypothalamus contributes to the central control of ingestive behavior. However, the model ultimately was undermined by demonstrations that the method commonly used to create the VMH and LHA lesions produced effects that were not specific to hypothalamic regulation of ingestive behavior but extended to other sensorimotor and metabolic control systems.

Although the original dual-center model of hunger and satiety eventually fell out of favor, it remains generally accepted that certain subregions of the hypothalamus play a key role in energy homeostasis, at least in part by influencing ingestive behavior. Recent findings have served to renew scientific interest in the role of the LHA in controlling ingestive behavior

and energy balance. We now know that LHA neurons receive synaptic inputs from multiple sensory modalities relevant to ingestive control, and that their responses to these inputs vary as a function of nutritional status. Two distinct but partially overlapping populations of LHA neurons have been identified based on their content of unique neuropeptides (melanin-concentrating hormone and hypocretin/orexin) that appear to play important roles in the control of food intake and energy metabolism through distinct central neural pathways. LHA neurons that express these neuropeptides project to key areas of the brain stem and forebrain that mediate ingestive behavioral responses. Improved chemical methods for lesioning the diffusely scattered LHA neurons without damaging intermingled fibers of passage (including, most notably, the medial forebrain bundle) have demonstrated that the LHA is indeed necessary for normal feedback regulation of ingestive behavior.

Synaptic inputs to orexin/hypocretin- and MSH-containing neurons in the LHA arise from many regions of the central neuraxis. Perhaps most relevant to the control of ingestive behavior and energy balance is a recently discovered circuit that originates in the arcuate nucleus of the hypothalamus. Early studies indicated that neurotoxic damage to the arcuate nucleus (e.g., as produced by systemic administration of monosodium glutamate during early development) could produce syndromes of overeating and obesity in laboratory animals. New and exciting research findings have provided a possible explanation for this phenomenon. In 1994, a hormone called leptin was discovered that appears to exert tremendously potent inhibitory effects on feeding behavior. Leptin also produces significant physiological effects on thermoregulation and on the reproductive, thyroid, and adrenal axes. Leptin is released continuously from adipocytes and is present at a relatively high concentration in plasma (approximately 4 ng/ml). Leptin binds to receptors expressed in peripheral tissues and in a circumscribed set of brain regions, most notably the arcuate nucleus of the hypothalamus. Animals seem to adapt to their own unique circulating leptin levels (which are directly proportional to body adiposity), such that experimental perturbation of those levels will shift the animal's behavior and physiology toward either gaining or losing body weight in an apparent effort to restore normal leptin levels. For example, mice with genetic mutations that render them incapable of producing either leptin or leptin receptors become obese, whereas experimental elevation of circulating leptin levels causes animals to lose body weight. A wealth of recent data indicate that circulating leptin provides a physiologically important negative feedback signal to constrain body weight by affecting both ingestive behavior and metabolic activity.

There is general consensus that the arcuate nucleus plays a major role in transducing the effects of leptin on both the behavioral and physiological components of energy balance. Arcuate neurons that express functional leptin receptors project to the LHA and to other hypothalamic areas implicated in energy homeostasis, including the dorsomedial and PVN nuclei. Arcuate projections to the PVN provide a basis for documented leptin effects on parvicellular neurosecretory neurons comprising the central limbs of the HPA and hypothalamo–pituitary–thyroid axes, the activities of which are regulated by leptin. The arcuate nuclei and PVN also provide important descending projections to autonomic neurons in the brain stem and spinal cord, and may play a role in leptin-mediated increases in energy expenditure through the stimulation of brown fat thermogenesis. Leptin-sensitive arcuate neurons that project to the LHA and PVN contain neuropeptides (including neuropeptide Y, proopiomelanocortin, and agouti-related protein) that exert potent effects on food intake and other relevant neuroendocrine and autonomic aspects of energy homeostasis. Thus, the arcuate nucleus can be viewed as a nodal point in the hypothalamic regulation of energy balance.

VII. CONCLUSIONS

There can be little doubt that our understanding of hypothalamic organization and function has improved dramatically during the past 25 years. Many of these advances can be traced directly to technical advances that have allowed the dissection of hypothalamic circuits from both organizational and functional perspectives. Thus, the ability to define the connectivity and phenotype of hypothalamic neurons and to assess the activity of anatomically defined circuits with functional probes such as Fos has proven to be enormously informative in defining the function of hypothalamic cell groups. Continued application of these experimental approaches promises to further illuminate our understanding of this small subdivision of the diencephalon that has long been recognized as a central integrative center for the control of homeostasis and behavioral state.

RICHARD S. J. FRACKOWIAK
University College, London

Disorders of the human nervous system are among the most debilitating and devastating of all human illnesses. Such disorders not only affect the physical abilities of patients but often severely compromise the quality of life, the ability to function in society, family relations, and the ability to maintain gainful employment. As such, neurological, neurosurgical, and psychiatric disorders affect not only the patients but also their families and society at large because of the tremendous economic burden that results from their prevalence. Undoubtedly, this is one of the reasons brain mapping methods have advanced so rapidly and hold such promise for improved diagnostics, monitoring of therapeutics, and providing insights into the basic mechanisms of brain disease. Never before have so many methods been available to tackle these vexing problems. This article provides an overview of the methods and their applications in human diseases.

Throughout this article, it is important for the reader to keep in mind a number of important physical and physiological factors when trying to understand the approaches of different brain mapping applications to the study of human cerebral disorders (Table I).

First, it is important to keep in mind that specific methods address only one or a few aspects of underlying cerebral physiology and pathophysiology. For example, electromagnetophysiological techniques, such as electroencephalography (EEG), event-related potentials (ERPs), and magnetoencephalography (MEG), provide information about large constellations of neurons and the net electromagnetophysiological vector that their firing produces. The electrical techniques are weighted toward surface structures, whereas the magnetic ones convey information about deeper brain structures with less distortion. This indicates another important aspect in assessing methods for the evaluation of disease states. That is, certain techniques are better suited to examination of particular sites in the brain than others.

Second, a number of techniques are devoted specifically to describing brain structure. These include X-ray computed tomography (CT), conventional magnetic resonance imaging (MRI), and blood vessel imaging using conventional angiography, magnetic resonance angiography (MRA), or helical CT. A number of techniques assess hemodynamic responses as a measure of function. These techniques include xenon-enhanced CT, functional MRI (fMRI), perfusion MRI, and cerebral blood flow or blood volume measurements using positron emission tomography (PET) or single photon emission computed tomography (SPECT). All the techniques that evaluate cerebral

Table I

Advantages and Limitations of Current Brain Mapping Techniques of Use in the Study of Patients with Neurological, Neurosurgical, and Psychiatric Disorders

Method	Advantages	Limitations
X-ray computed tomography	Excellent bone imaging	Ionizing radiation
	~100% detection of hemorrhages	Poor contrast resolution
	Short study time	
	Can scan patients with ancillary equipment	
	Can scan patients with metal devices/ electronic devices	
Magnetic resonance imaging	High spatial resolution	Long study duration
	No ionizing radiation	Patients may be claustrophobic
	High resolution	Electronic devices contraindicated
	High gray–white contrast	Acute hemorrhages problematic
	No bone-generated artifact in posterior fossa	Relative measurements only
	Can also perform chemical, functional, and angiographic imaging	
Positron emission tomography	Can perform hemodynamic, chemical, and functional imaging	Ionizing radiation High initial costs
	Quantifiable results	Long development time for new tracers
	Absolute physiologic variables can be determined	Limited access
	Uniform spatial resolution	Low temporal resolution
Single photon emission computed tomography	Can perform hemodynamic, chemical, and functional imaging	Ionizing radiation Relative measurements only
	Widely available	Nonuniform spatial resolution
		Low temporal resolution
Xenon-enhanced computed tomography	Uses existing equipment	Ionizing radiation
		High xenon concentrations have pharmacologic effects
Helical computed tomography (CT angiography)	Provides high-resolution vascular images	Ionizing radiation
		Vascular and bony anatomy only
Electroencephalography	No ionizing radiation	Low spatial resolution
	High temporal resolution	Weighted toward surface measurements
	Widely available	
	Can identify epileptic foci	
Magnetoencephalography	No ionizing radiation	Low spatial resolution
	High temporal resolution	
	Can identify epileptic foci	
Transcranial magnetic stimulation	No ionizing radiation	Low spatial resolution
	Potential for therapy	Has produced seizures in certain patient groups
	Can be linked to other imaging methods (PET, MRI)	
Optical intrinsic signal imaging	No ionizing radiation	Complex signal source
	High temporal resolution	Invasive only (intraoperative)
	High spatial resolution	

function based on hemodynamic measurements are, by their very nature, at a physiological "distance" from the actual neuronal event. These methods assume that neuronal firing and blood flow increments or decrements are tightly coupled. In most cases, this holds true in the normal brain, but it may not always be true in pathologic states.

Third, the determination of chemical processes in the brain falls mainly in the domain of PET and magnetic resonance spectroscopy (MRS). The former can measure cerebral glucose metabolism, protein synthesis, amino acid uptake, pH, and other variables and does so in a quantitative manner reported in physiological units when appropriate rate constants and other factors are incorporated into mathematical models for their estimation. MRS provides relative measurements of chemical compounds relying primarily on hydrogen spectra but, at higher magnetic field strengths, can also estimate relative quantities of sodium fluorine-carbon, and phosphorus-containing molecules as well.

Fourth, the evaluation of receptor systems in the brain, both transmitter molecules and receptor complexes, has been an active area of research in both health and disease using PET and SPECT. Most information has been derived for the dopaminergic system but data also exist for the cholinergic, serotonergic, opioid, and benzodiazepine systems.

Last, there are interactive approaches. The most time honored, of course, is the direct observation of signs and symptoms in patients with cerebral disorders. Such information can be obtained in the traditional clinical setting or in the highly unusual circumstance of awake surgical procedures where recording from or stimulation of cerebral tissue can be correlated with behavioral states in a conscious patient. These latter methods, while in use for more than 50 years, still provide unique information about structure–function relationships in the human brain. Recently, such measurements have been augmented through the use of optical intrinsic signal imaging, in which changes in optical reflectance from the cortex are measured during surgery. Measurements can be made either in awake patients during behavior or with anesthetized patients receiving sensory stimulation or direct peripheral nerve stimulation. They provide measures of functional specificity for different brain regions in the operative field. The technique of transcranial magnetic stimulation allows the investigator to stimulate the cortex of the brain magnetically, resulting in an induced electrical discharge in the cortex and an observed or reported behavior from the subject. This technique has been used experimentally to map normal brain systems and in patients for experimental, diagnostic, and therapeutic purposes.

Each technique is capable of making measurements with a characteristic resolution in both the spatial and temporal domains. Tomographic imaging techniques produce the highest spatial resolution currently available, whereas the electromagnetophysiological methods provide the highest temporal resolution. Although knowledge of resolution is important, it must be matched to the question of interest in a particular patient population—a decision that also requires knowledge of the sampling characteristics of the technique. This latter term refers to the volume of brain tissue that can be assessed with a particular measurement. Thus, whereas fMRI may survey functional responses through out the entire brain, electrophysiological measurements from a depth electrode, despite producing data with exquisite spatial and temporal resolution, sample only a very small volume of brain tissue. As such, investigations aimed at trying to identify a functional disorder in a disease of unknown etiology (e.g., autism) would be better done with a global technique that surveys the entire cerebral landscape rather than with measurement at multiple sites with an electrophysiological method such as depth electrodes. The latter are better used to understand the local electrophysiology of a site that has a high probability of being abnormal and possibly also causative of a given disorder.

With these principles in mind, we now consider a more specific examination of the different strategies that can be employed with modern brain mapping methods to assess patients, either as individuals or as groups, with neurological, neurosurgical, or psychiatric disorders (Table II).

I. DIAGNOSTIC METHODS

A. Individual Processes

1. Structural Anatomy

a. Computed Tomography X-ray CT was the first noninvasive imaging technique that allowed for direct visulization of the brain parenchyma. It revolutionized the evaluation of patients with neurological and neurosurgical disorders because it could image bone and provided the first opportunity to see the brain directly. It has a small dynamic contrast range so that

Table II

Brain Mapping Methods of Use in the Study of Human Disease along with the Types of Measurements They Provide and Some of the Clinical Situations in which They May Be of Use

Method	Measurements provided	Disorders
X-ray computed tomography (CT)	Brain structure	Acute/chronic hemorrhages
	Blood–brain barrier integrity	Acute trauma
		General screening of anatomy
		Focal or generalized atrophy
		Hydrocephalus
Magnetic resonance imaging	Brain structure	Acute ischemia
	Brain and cervical vasculature	Neoplasms
	Relative cerebral perfusion	Demyelinating disease
	Chemical concentrations	Epileptic foci
	Fiber tracts	Degenerative disorders
	Blood–brain barrier integrity	Infections
		Preoperative mapping
Positron emission tomography	Perfusion	Ischemic states
	Metabolism	Degenerative disorders
	Substrate extraction	Epilepsy
	Protein synthesis	Movement disorders
	Neurotransmitter integrity	Affective disorders
	Receptor binding	Neoplasms
	Blood–brain barrier integrity	Addictive states
		Preoperative mapping
Single photon emission computed tomography	Perfusion	Ischemic states
	Neurotransmitter integrity	Degenerative disorders
	Receptor binding	Epilepsy
	Blood–brain barrier integrity	Movement disorders
Xenon-enhanced computed tomography	Perfusion	Ischemic states
Helical computed tomography (CT angiography)	Vascular anatomy	Vascular occulsive disease
	Bony anatomy	Aneurysms
		Arteriovenous malformations
Electroencephalography	Electrophysiology	Epilepsy
		Encephalopathics
		Degenerative disorders
		Preoperative mapping
Magnetoencephalography	Electrophysiology	Epilepsy
Transcranial magnetic stimulation	Focal brain activation	Preoperative mapping
Optical intrinsic signal imaging	Integrated measure of blood volume, metabolism, and cell swelling	Intraoperative mapping

differentiation of gray and white matter is difficult (Fig. 1A). However, it is very sensitive for identifying cerebral hemorrhage and also lesions associated with an alteration in the blood–brain barrier, by virtue of leakage of iodinated contrast material in them. These abilities make X-ray CT ideal for direct and immediate assessment of patients with cerebral hemorrhage, multiple sclerosis, brain tumors, and traumatic

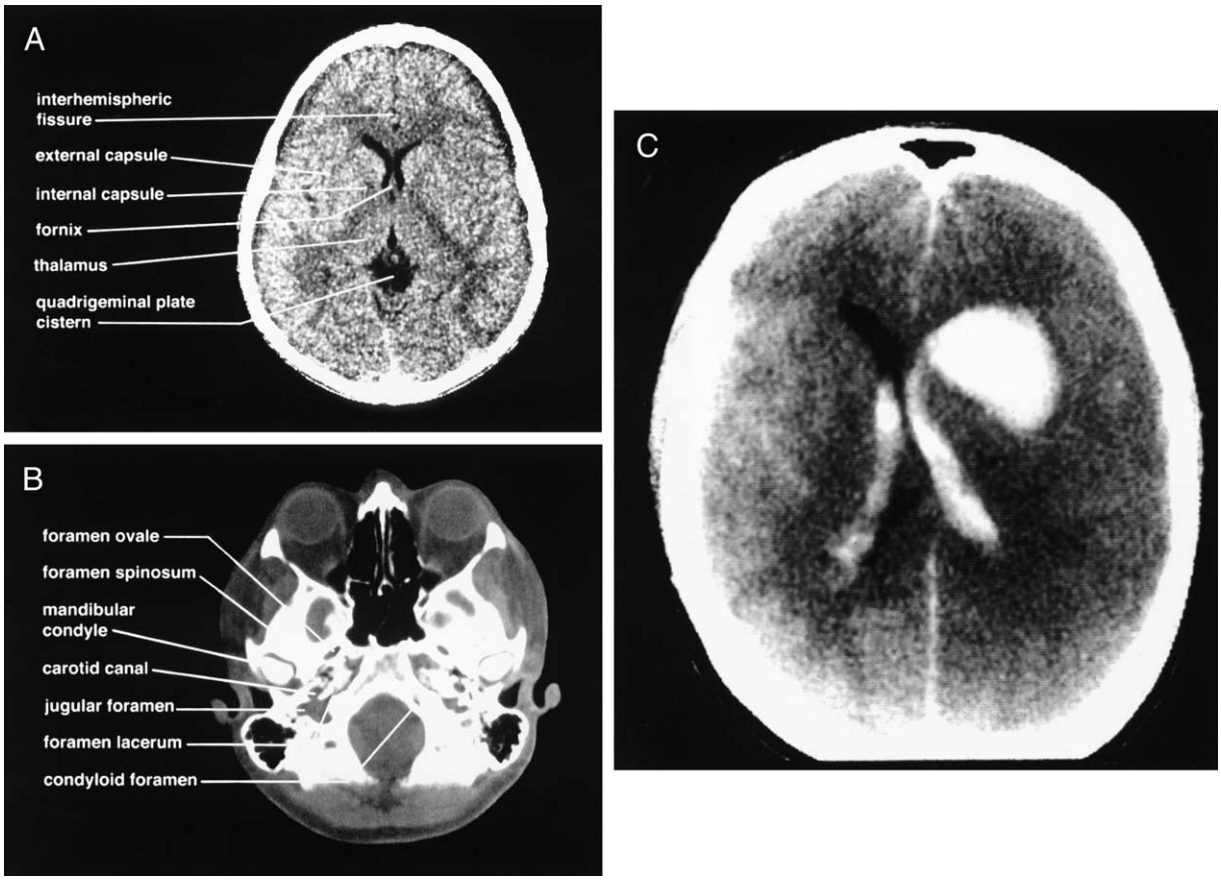

Figure 1 X-ray CT. (A) Images of the human brain from an X-ray CT device, demonstrating good anatomical detail, particularly of the skull and ventricular system as well as the subarachnoid CSF spaces. Note that there is less gray–white contrast than in MRI images (Fig. 2A). (B) X-ray CT provided very detailed images of bony structures that surround the central nervous system. This is particularly useful in evaluating pathologic states at the base of the skull, where conventional radiography is often difficult because of patient positioning and the overlap of bony structures in a two-dimensional radiograph. Furthermore, in situations in which trauma is a factor, often patients cannot be manipulated easily because of the possibility of fractures at the base of the skull or in the cervical spine. (C) Intracerebral hemorrhage demonstrated by X-ray CT. Sensitivity for detection of intracranial bleeds is effectively 100% with X-ray CT and it remains the imaging modality of choice in acute patients when identification of cerebral hemorrhage is urgent and important. This is typically the case in patients with an acute cerebral deficit when cerebral hemorrhage must be identified if thrombolytic or anticoagulant therapy is being contemplated.

injuries. Contrast sensitivity and the time needed for scanning have improved since X-ray CT was introduced, but with the advent of MRI technology many diagnostic studies that were formerly in the province of X-ray CT are now done with MRI. Nevertheless, X-ray CT continues to have an important role in resolving certain diagnostic questions and in particular patient circumstances.

X-ray CT has remained the imaging modality of choice for patients requiring urgent evaluation of suspected intracranial hemorrhage (Fig. 1C) and in patients with acute head trauma. In both these circumstances, the speed of the study and ease of patient access as well as availability of equipment are well matched to the ability of CT to evaluate such patients. X-ray CT is also the procedure of choice when evaluating abnormalities of bony structures of the head particularly the skull base (Fig. 1B). Lastly, patients who cannot tolerate MRI because of claustrophobia or implanted ferromagnetic or electronic devices or that need to be attached to ancillary equipment such as is frequently encountered in critical care situations are also best scanned by X-ray CT if structural information is needed for clinical evaluation.

b. MRI Magnetic resonance imaging is the structural imaging modality of choice in all other situations. Its superior spatial resolution and contrast range, particularly useful in differentiating gray and white matter, are but two features of MRI that make it

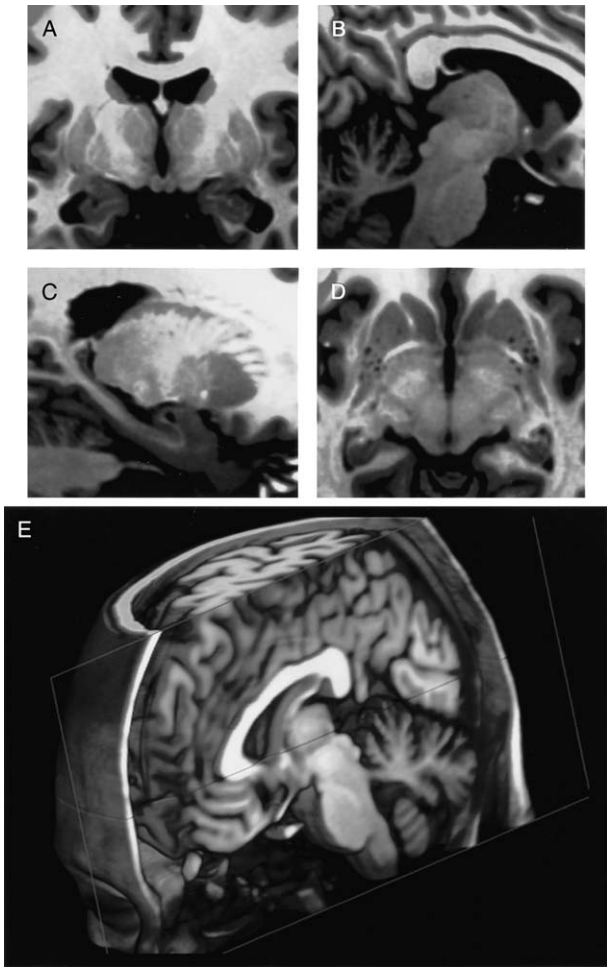

Figure 2 Magnetic resonance imaging. (A–D) Typical two-dimensional MRI images of the brain. Notice that the detailed anatomy of the brain parenchyma has better gray–white contrast than X-ray CT images (Fig. 1A). Notice also that there are none of the typical CT artifacts caused by the juxtaposition of dense bone and brain parenchymay. (A) Coronal view through the thalamus demonstrating the subnuclei of the thalamus, the mamillary bodies, and the internal, external, and extreme capsules as well as the two segments of the globus pallidus. Also note the detailed anatomy of the hippocampi. (B) Sagittal view demonstrating the colliculi of the midbrain, the midline of the thalamus, and the detailed anatomy of the midsagittal region of the cerebellum. (C) Sagittal view through the hippocampus and striatum. Note the fine bridges of gray matter between the caudate and the putamen. (D) Transverse section through the basal ganglia and upper midbrain. Note the periaqueductal gray matter, the detailed anatomy of the hippocampi, and the bilateral flow voids produced by the presence of the lenticulostriate arteries in the posterior portion of the putamen. (E) Three-dimensional reconstruction with cutaway of an MRI data set demonstrating the kind of anatomical detail that can be provided with three-dimensional MR images (courtesy of Colin Holmes and colleagues, UCLA School of Medicine, Los Angeles). [A–D from Holmes *et al.* (1998). Enhancement of magnetic resonance images using registration for signal averaging. *J. Computer Assisted Tomogr.* **22**(1), 139–152].

superior to CT for structural imaging (Fig. 2). The ability to image brain structures from any angle and avoidance of CT artifacts that result from soft tissue-dense bone boundaries in the field of view provide further arguments for the use of MRI in patients with cerebral disorders. This advantage is most notable in the posterior fossa, where artifacts from the dense petrous bones often obscure or obliterate relevant clinical information about the brain stem and cerebellum. Gadolinium and other paramagnetic contrast agents can be used with MRI to provide the ability to detect blood–brain barrier defects in a manner analogous to that used in X-ray CT with iodinated contrast agents.

2. Vascular Anatomy

a. MR Angiography The observation that protons leaving the field of view reduce the local signal in MRI studies has led to an entire field of MR angiography and associated flow-based MRI techniques. The so-called flow void occurs in the vascular system when blood that encounters a radiofrequency pulse leaves the field of view of the scanner and the resultant energy is therefore emitted outside the field of view. The result is a loss of signal within the lumina of blood vessels. When partitular pulse sequences are utilized to optimize this effect, an image of vascular anatomy results. Like most angiographic procedures, the image depicts the contents of the blood vessel (within the lumen) as opposed to the blood vessel wall and associated structures. However, unlike conventional angiography, in which arterial, capillary, and venous phases are distributed in time and images of each phase can be produced independently, MRA provides a composite image of all medium-to large-diameter vessels, including arteries and viens.

Such studies have provided important opportunities for the evaluation of intracranial and cervical, medium and large vessels for abnormalities, including arteriovenous malformations, aneurysms, and occlusive disease. Smaller caliber vessels still require conventional angiographic or helical CT evaluation for the assessment of disorders such as vasculitis.

b. Helical CT In this technique, also called spiral CT or CT angiography, conventional CT technology is modified to produce very rapid sequential images of the head by having the relationship between the patient and the X-ray tube/detector system traverse a helical course through the tissue. This process is rapid and so

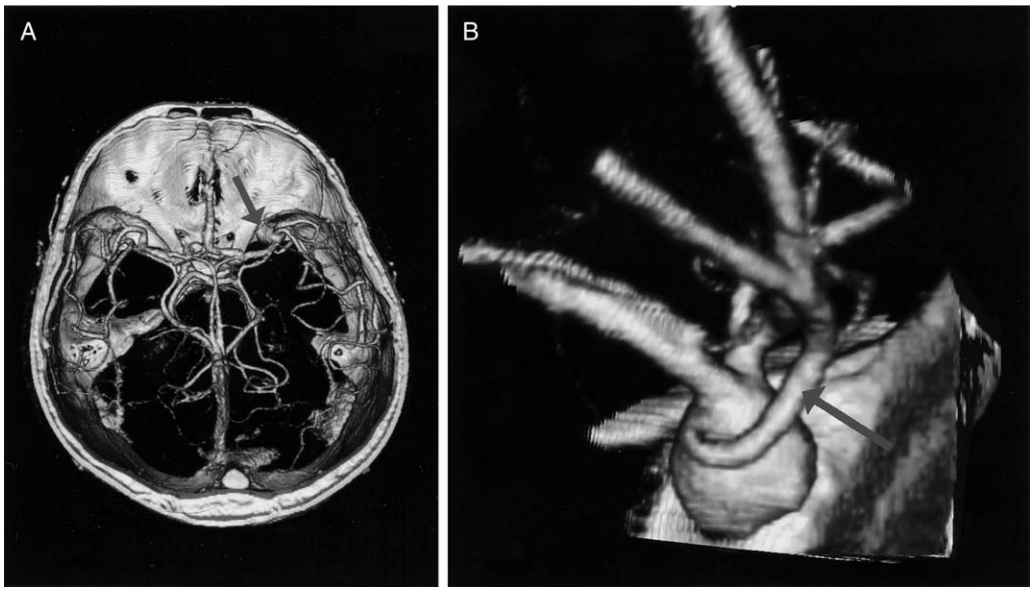

Figure 3 Helical CT angiography. (A) The cerebral vasculature is superimposed on this cutaway view of the skull seen from above. Note the line detail provided for the vascular structures, including the circle of Willis, the anterior, middle, and posterior cerebral arteries, and many of their branches. The arrow indicates an aneurysm arising from the middle cerebral artery at the anterior edge of the middle cerebral fossa. (B) Close-up view of the aneurysm demonstrated in A. Note that in this three-dimensional reconstruction, it is possible to see all of the blood vessels that contribute to or arise from the aneurysmal sack (left). Unlike conventional angiography, where the overlap of the aneurysm and the parent or daughter vessels can be obscured because of the two-dimensional projection required in this technique, full three-dimensional images are possible with helical CT angiography. By digital reconstruction and rotation of the data set from helical CT, these complex and important relationships can be evaluated prior to surgery, whereas with conventional angiograms multiple view would be required and still may not provide a sufficiently detailed view of these relationships. In addition, multiple views obtained with conventional angiography expose the patient to additional radiation and contrast risks. In this case, the angular artery (arrow) arises from the aneurysm sack. Endovascular coil placement might lead to obstruction of this important vessel, thereby making such a patient a candidate for surgical rather than endovascular treatment of this lesion (courtesy of Pablo Villablanca, UCLA School of Medicine).

arranged that it is coincident with the delivery of a bolus of iodinated contrast material into the cranial and cervical vessels from a peripheral vein. The resultant images are high-resolution depictions of the intracranial anatomy that can be reconstructed in three dimensions (Fig. 3A). Currently, limited information is available about the technique in terms of its clinical applications, but it is likely that there are circumstances in which it may be superior to conventional angiography. One of those is in the assessment of the local vascular anatomy of patients with aneurysms and arteriovenous malformations. In this case, conventional angiography, while high in spatial resolution, collapses the three-dimensional structure of such lesions into a two-dimensional projection. As such, the important relationship between aneurysm neck and a parent or daughter vessel may be difficult to ascertain or may require multiple intraarterial contrast injections and radiation exposure for the patient. Helical CT allows for a true three-dimensional reconstruction of local anatomy that can be manipulated to assess such relationships in greater detail, while subjecting the patient to only a single radiation exposure and dose of iodinated contrast material (Fig. 3B). A similar situation exists when defining feeder vessels to arteriovenous malformations.

3. Blood Flow and Perfusion

a. PET The assessment of cerebral perfusion (i.e., cerebral blood flow per volume of tissue) can be determined quantitatively with PET using ^{15}O-labeled water, ^{11}C-labeled butanol, and potentially other agents. These agents are freely diffusible and knowledge of the time–activity relationship of the tracer compound in arterial blood and the tissue concentration over time in the brain permits a calculation of cerebral perfusion with approximately $5 \times 5 \times 5$-mm spatial resolution. These methods have been used extensively to evaluate increments in perfusion associated with underlying neuronal activity such as that

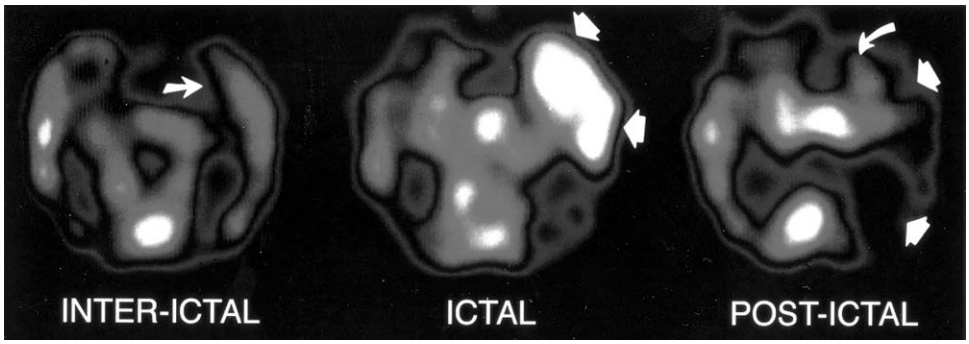

Figure 4 SPECT studies of a seizure focus in a patient with epilepsy, obtained using technetium-^{99}m-labeled HMPAO. By comparing the ictal study (hyperperfusion), obtained by injecting the tracer on a telemetry ward, with the postictal and interictal scans (hypoperfusion), it is possible, with a high degree of accuracy, to identify seizure foci responsible for focal epilepsies. Although such SPECT studies of relative perfusion may be confusing or misleading when evaluated in only one of these states, the composite information obtained from ictal, postictal, and interictal studies, particularly when the studies are aligned, registered, and subtracted, is useful in the presurgical evaluation of patients with focal or complex partial epilepsy [courtesy of Sam Berkovic, Austin Hospital, Melbourne, Victoria, Australia. From Berkovic, S. F., Newton, M. R., and Rowe, C. C. (1991). Localization of epileptic foci using SPECT. In *Epilepsy Surgery* (H. Luden, Ed.), pp. 251–256. Raven Press, New York].

associated with the performance of behavioral tasks, and as such can be used in patients to evaluate critical cortical and subcortical areas as part of the process of mapping brain regions adjacent to abnormalities that are under consideration for surgical resection.

Perfusion measurements are also of value in assessing patients with ischemic cerebrovascular disease not only to determine baseline conditions but also in the assessment of "cerebral perfusion reserve" by challenging such patients with cerebral vasodilation drugs such as acetazolamide.

b. SPECT Perfusion measurements with SPECT can be obtained in a semiquantitative way using xenon-133 or in a relative fashion using a host of technetium-99 m labeled agents (e.g., HMPAO). Studies have been used to evaluate patients with cerebrovascular disease in the assessment of patients with epilepsy. In the latter circumstance, ictal, postictal, and interictal studies are made using these agents and subtracted to identify foci of epileptic discharges that increase cerebral perfusion during seizures and reduce perfusion postictally and interictally (Fig. 4).

c. Xenon-Enhanced CT Nonradioactive xenon-133 alters the X-ray attenuation characteristics of the tissues that absorb it. Xenon-133 can be readily inhaled. Using strategies similar to those discussed previously, one can calculate changes in X-ray attenuation associated with the concentration of xenon in tissue to calculate an index of cerebral perfusion. This approach has been used to evaluate patients with cerebrovascular disease and head trauma. One confounding factor with this approach is that relatively high concentrations of xenon are needed in brain tissue to produce accurate perfusion estimates. At these concentrations, patients experience pharmacological effects, including sedation and, ultimately, anesthesia. These direct neuronal effects of xenon can, in turn, affect cerebral perfusion and contaminate physiological measurements. Nevertheless, such studies have been used to assess patients in specific diagnostic categories when alternate techniques are not available.

d. MRI Relative and semiquantitative measurements of cerebral perfusion can be obtained with MRI using a variety of techniques. The basic difference among these techniques is whether exogenous agents are infused into the patient or whether changes in endogenous signals from the vascular system are monitored. With the former, bolus contrast agents such as gadolinium are delivered to a subject intravenously. Their local concentration in the cerebral vasculature estimates local cerebral perfusion, which in turn is proportional to neuronal firing rates. The change in MR signal, induced by a local change in concentration of a contrast agent, reflects a relative change in local perfusion that can be estimated. A refinement of this approach requires information about the concentration of the contrast agent in the blood over a period of time. This can be measured directly from an arterial source, although such a method is rarely employed, or from a large-diameter

blood vessel in the scanner's field of view (e.g., arteries in the circle of Willis).

Alternatively, one can record endogenous local signal changes associated with alterations in cerebral perfusion induced by changing neuronal activity. When local neuronal firing increases, there is an increment in cerebral blood flow to an area. However, there is a proportionally smaller change in local tissue oxygen metabolism. As a result, more oxygen is delivered per unit volume of tissue (because of decreased fractional extraction) but there is little change in the amount of oxygen used. Thus, the oxygen content (i.e., the concentration of oxyhemoglobin) in venous blood increases. When compared to images in a state of ''baseline'' neuronal firing, this local change in venous oxyhemoglobin results in an alteration of the MR signal since deoxygenated blood is more paramagnetic than oxygenated blood (the difference is about 0.2 ppm). The change in signal provides an estimate of relative local cerebral perfusion changes associated with the change in underlying neuronal activity. This observation has resulted in the widespread use of the so-called blood oxygen level dependent technique in the evaluation of normal subjects performing behavioral tasks and in patients who are candidates for surgical resection of brain lesions such as tumors, vascular malformations, or epileptic foci. Such methods may ultimately supplant more invasive approaches to determining language dominance and memory function such as those employing the intraarterial injection of barbiturate compounds (e.g., Wada testing).

Diffusion imaging is also possible using MR scanning. Water, and hence protons, is freely diffusible. In the brain, however, the microscopic anatomy of the tissue compartmentalizes (with cells, along axons, etc.) this process. It is possible to obtain MRI images that are diffusion weighted (DW) and in which the signal is dependent on the ease with which protons diffuse in their local environment. Initially tested in cats, DW images were shown to demonstrate the boundaries of acute infarcts within minutes. Infarcted or ischemic areas are visible as regions of hyperintensity corresponding to local decreases in the apparent diffusion coefficient of water. The use of DWI in screening patients with early ischemia who are candidates for thrombolytic therapy is especially relevant (Fig. 5). When combined with MRI perfusion imaging, an assessment of the proportion of jeopardized and infarcted tissue can be made.

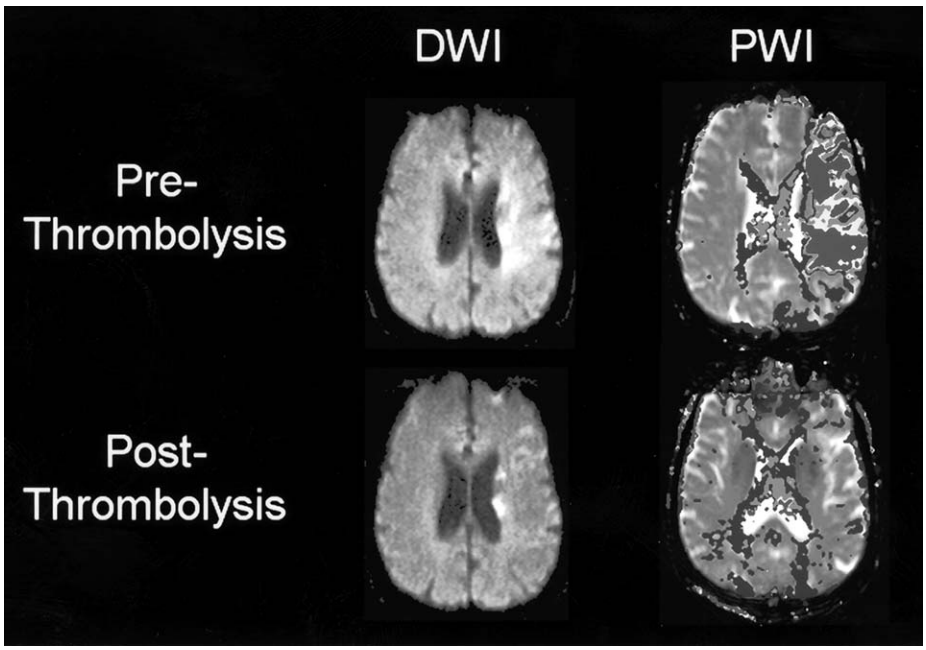

Figure 5 Diffusion-weighted (DWI) and perfusion-weighted (PWI) images from MRI are useful in selecting patients for cerebrovascular intervention therapies and monitoring their outcome. Here, a patient with a large region of hypoperfusion in the distribution of the middle cerebral artery already has some evidence of tissue ischemia as demonstrated by the white areas that border the ventricle in the prethrombolysis DW image (top left). Following thrombolysis (bottom row), note that perfusion has been reestablished to the area of the middle cerebral artery and the patient is left with only a small ischemia injury on the posterior border of the lateral ventricle (courtesy of Chelsea Kidwell, Jeffrey Saver, and Jeffrey Alger, UCLA School of Medicine).

4. Metabolism

a. PET Glucose and oxygen metabolism can be assessed using PET and ^{18}F-labeled fluorodeoxyglucose (FDG), ^{11}C-labeled glucose, and ^{15}O-labeled oxygen. A common approach has been to use FDG to evaluate glucose metabolism. Thought to be primarily an assessment of synaptic activity (i.e., deoxyglucose uptake is maximal in the neuropil rather than in regions dominated by cell bodies), scanning of patients using FDG has provided useful observations in a wide range of disorders. Hypometabolic regions are found interictally at epileptic foci and in specific cortical and subcortical regions in a wide range of degenerative and dementing processes and also appear to reflect the malignancy grade of cerebral neoplasms, particularly gliomas (Figs. 6–8). Oxygen metabolism and extraction measurements are of greatest utility in assessing patients with cerebrovascular disease, particularly that unique subset of patients for which extracranial–intracranial bypass or other surgical reperfusion approaches are contemplated.

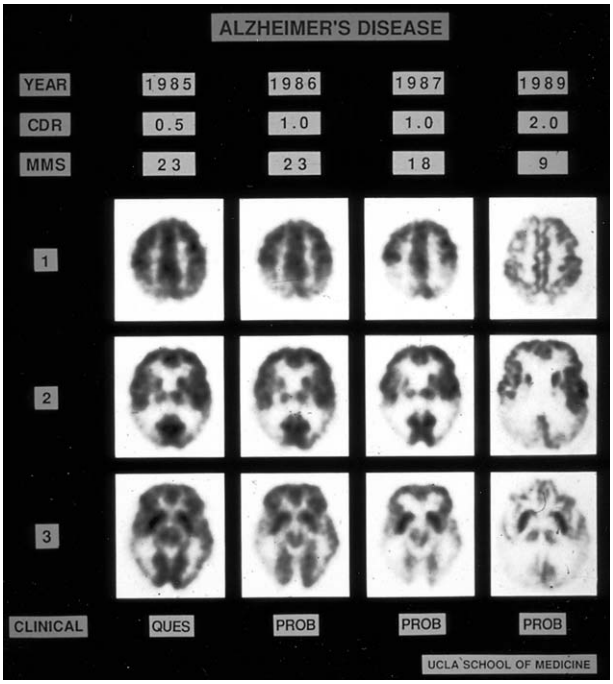

Figure 6 PET studies of cerebral glucose metabolism in a patient with Alzheimer's disease demonstrating the characteristic pattern of hypometabolism that occurs in the parietal and superior temporal cortices. As the disease progresses (from left to right), hypometabolism worsens in both spatial extent and magnitude, ultimately involving all neocortical structures.

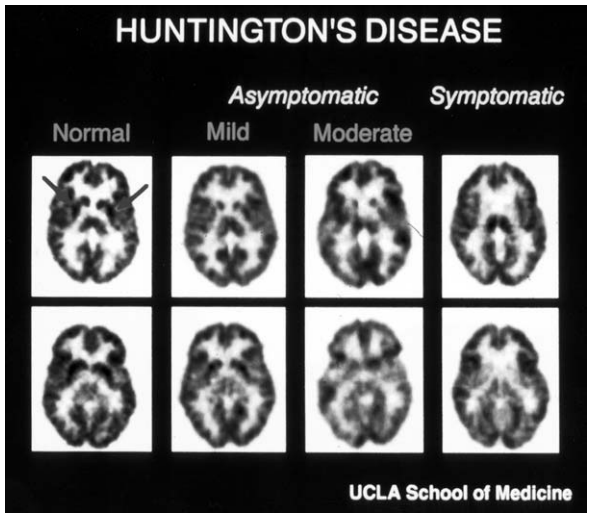

Figure 7 Glucose metabolism measured with PET in Huntington's disease. Two anatomical levels (rows) of a normal subject demonstrating glucose metabolism in the caudate and putamen as compared with three patients, two with mild or moderate asymptomatic Huntington's disease and one with frank symptoms. Note that in the symptomatic patient there is profound hypometabolism of the caudate and most of the putamen, whereas in the asymptomatic, gene-positive subjects, there is progressive loss of metabolism in the caudate. Such changes can be identified 5–7 years prior to the onset of symptoms in patients who carry an expanded triplet repeat sequence of the Huntington's disease gene. With advancing disease, hypometabolism extends throughout the striatum and can also involve the frontal cortices (courtesy of Scott Grafton and John Mazziotta, UCLA School of Medicine).

b. MR Spectroscopy Concentrations of a wide variety of compounds can be estimated using MR spectroscopy. Proton spectra provide information about lactate as a measure of carbohydrate metabolism. Other chemical species as well as spectra obtained from other isotopes can provide additional clues about various chemical pathways. In addition, "tracer" techniques can be employed, e.g., using $^{17}O_2$, ^{13}C-labeled glucose, analogous to those used with PET or SPECT.

5. Ligands and Neuroreceptor Imaging

a. PET Ligands have been developed for PET to image both pre and postsynaptic neuroreceptors. Since one or both sides of a synapse can be affected by neuropsychiatric disease, the ability to image the integrity of both components of synaptic structure and function is useful. There are a large number of neurotransmitter systems in the human brain but

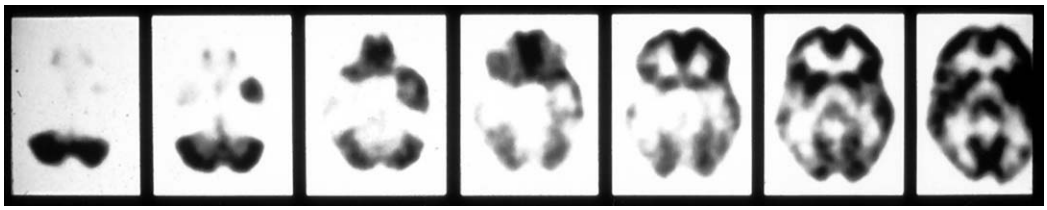

Figure 8 Interictal hypometabolism of the temporal lobe in a patient with complex partial epilepsy referable to that structure. Note the profound asymmetry of metabolism, particularly in the medical but also in the lateral portion of the temporal lobe, in six out of the seven axial images. Such studies are typically performed in the evaluation of patients who are candidates for surgical treatment of their epilepsy. In many patients, brain mapping techniques have obviated the requirement for depth electrodes and subdural grids in the presurgical evaluation of such individuals (courtesy of Jerome Engel, Jr., *et al*., UCLA School of Medicine; J. Engel, P. H. Crandall, and R. Rausch (1983). The partial epilepsies. In *Clinical Neurosciences* (R. N. Rosenberg, Ed.), pp. 1349–1380. Churchill Livingstone, New York).

PET ligands have been developed for only some of these. Fewer still have been completely validated and are in clinical use.

The most extensively studied neurochemical system is the dopaminergic network. Presynaptic imaging of dopamine synthesis and reuptake have been evaluated with fluorinated (^{18}F) ligands. The uptake, metabolism, and flux of ^{18}F-labeled L-DOPA in presynaptic dopaminergic terminals have been used to evaluate movement disorders, particularly Parkinson's disease (Fig. 9), and a number of neuropsychiatric syndromes. The same is true for the evaluation of presynaptic dopaminergic reuptake sites (e.g., with the WIN compounds). On the postsynaptic side, numerous ligands have been developed with a range of affinities for the different postsynaptic dopaminergic receptors. These tracers include raclopride, spiperone, and ethylspiperone. They have provided data for the movement disorders, schizophrenia, pituitary tumors, and other disorders of the brain. In addition, the labeling of drugs of abuse, such as ^{11}C-labeled cocaine, that bind to receptors in the dopaminergic system has

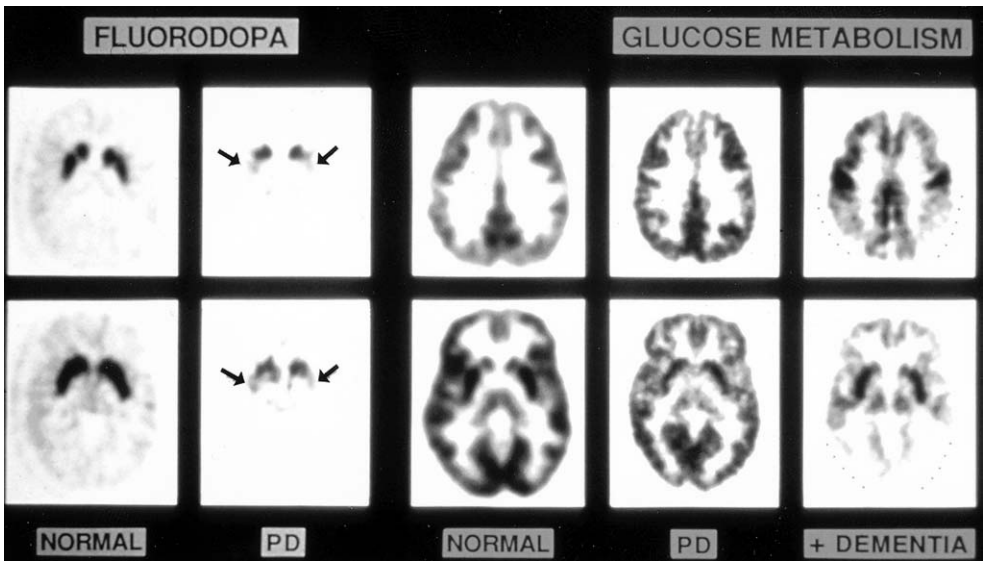

Figure 9 Evaluation of patients with Parkinson's disease using PET. Glucose metabolism in Parkinson's disease demonstrates a normal pattern in such patients (PD label) when compared to a normal control (middle column). When the dopamine-specific ligand [^{18}F]fluoro-L-DOPA is employed, however, a striking reduction in the uptake of this tracer is identified in the posterior putamen of patients with Parkinson's disease when compared to normals (columns 1 and 2). This is because the majority of the presynaptic dopaminergic terminals in Parkinson's disease are lost from the putamen at the onset of Parkinson's disease symptoms. Nevertheless, this population of synapses represents only a minority of all the synapses in this structure. As such, glucose metabolism remains normal but the uptake of fluoro-L-DOPA is dramatically reduced since this tracer images only that subpopulation of cells that have dopamine as their neurotransmitter. In patients with Parkinson's disease plus dementia, some patients also show hypometabolism of neocortex (+ DEMENTIA) similar to patients with Alzheimer's disease (see Fig. 6).

been helpful as a means of exploring the neurobiology of chemical addiction.

Cholinergic tracers are in use for the study of neurodegenerative disorders such as Alzheimer's disease and markers of the serotonin system and have been employed in the evaluation of psychiatric disorders. The central benzodiazepine system can be scanned with flumazenil labeled with carbon-11. Important findings have been made with this tracer in patients with epilepsy (Fig. 10A). Finally, opioid receptors have been studied with a host of ligands that bind with varying affinities to the many subclasses of opiate receptor. These compounds have been used in the exploration of eiplepsy, psychiatric disease, and movement disorders.

b. SPECT A number of iodinated compounds have been developed and serve as analogs of the PET tracers described previously. Used in a similar fashion, relative estimates of binding and receptor uptake can be obtained with SPECT (Fig. 10B). Although the number of compounds of this type is few compared to the inventory of PET ligands, interest in their development and use will result in an ever-increasing set of SPECT tracers.

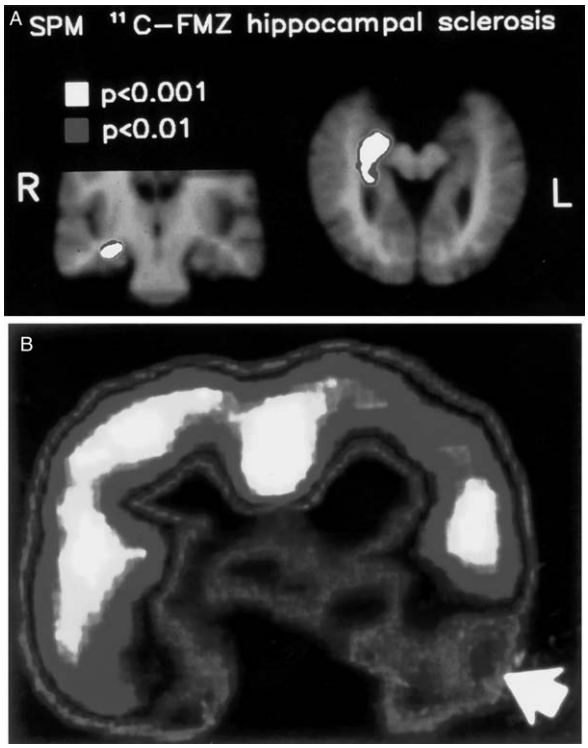

Figure 10 Benzodiazepine receptor imaging in patients with focal epilepsy. (A) PET evaluation with [^{11}C]flumazenil. In patients with focal temporal lobe epilepsy from hippocampal sclerosis producing complex partial seizures, flumazenil uptake is reduced in the medial temporal lobe. These changes are typically smaller in spatial extent than hypometabolism detected with FDG–PET. Comparison of the two studies may ultimately lead to more selective surgical resections of medial temporal lobe structures in such patients. [courtesy of John Duncan, National Hospital for Neurologic Disease, Queen Square, London. From *Brain* (1996), **119,** 1677–1687, with permission of Oxford University Press]. (B) Similar imaging can be performed using SPECT and the iodinated compound iomazenil. Although slightly lower in spatial resolution, such studies provide information comparable to that discussed for flumazenil PET imaging in patients with focal epilepsy [courtesy of A. C. van Huffelen, University of Utrecht (van Huffelen *et al.* 1990). From Berkovic *et al.* (1993). In *Surgical Treatment of the Epilepsies* (J. Engel, Jr., Ed.), 2nd ed., p. 238. Raven Press, New York].

6. Electrophysiology

a. EEG Electrophysiological techniques provide the best temporal resolution for studying neuronal activity in patients with neurosurgical, neurological, and psychiatric disorders. Although more limited in spatial resolution than the tomographic techniques, EEG data provide the investigator and clinician an opportunity to learn about the timing of events and their synchronicity. Particularly important in the investigation of patients with seizures, EEG has been the mainstay of diagnostic evaluation of such patients. The limited spatial resolution of scalp EEG can be overcome by the use of more invasive techniques when patients are surgical candidates. In that setting, subdural grid electrodes, depth electrodes, and cortical surface electrodes can be used to obtain local extracellular field potential recordings and electrocorticograms.

System-specific information can be obtained with EEG when recording is accompanied by specific sensory, motor, or cognitive stimulation, a technique known as ERP recording. The resultant ERP maps are used to identify the general location and relative timing of a cortical representation of such functions in the brain. This approach has been used extensively to evaluate interruptions of the visual, auditory, or somatosensory systems (e.g., in multiple sclerosis) noninvasively and to provide more detailed cortical maps intraoperatively, or with subcortical or depth electrodes, in the evaluation of patients with seizure foci. Analysis of power spectra from scalp EEG and ERP recordings have also provided information of clinical use in neurodegenerative disorders and psychiatric syndromes.

b. MEG The measurement of minute magnetic fields in the brain with MEG is analogous to the measurement of electrical fields with EEG. Requiring far more complex equipment, the MEG method may have greater spatial resolution and greater accuracy in identifying electrophysiological dipoles, both at the surface and in the depths of the brain. Clinically, the method has been used to identify seizure foci and in a research setting has been employed for the experimental investigation of a wide range of neuropsychiatric disorders. Data with this technique are limited in number due to the fact that only a small number of MEG installations are currently operational and evaluating patients clinically.

c. Transcranial Magnetic Stimulation The creation of an intense focal magnetic field in the human cerebral cortex results in the induction of an electrical current that discharges cells lying tangentially within that volume of tissue. The discharge can result in a pseudophysiologic response. That is, if the motor cortex is stimulated, the appropriate contralateral muscle groups will contract. If the visual cortex is stimulated, a subject or patient will see a flash or phosphene in the contralateral visual field. Transient high-frequency stimulation of the cortex by magnetic stimulation will temporarily and reversibly deactivate it.

This approach has been used to create reversible lesions and has also been used as a therapeutic maneuver in the treatment of chronic depression, in a fashion analogous to electroconvulsive shock therapy delivered focally to the frontal cortex. When linked to a tomographic functional imaging technique, TMS can be used to map functional pathways directly in patients and normal subjects. There are guidelines for the safe use of this technique, which must be used with caution in epileptic patients.

7. Optical Intrinsic Signal (OIS) Imaging

The newest brain mapping technique to be used in a clinical setting is optical intrinsic signal imaging. This method provides information about cortical blood flow, blood volume, and metabolism in an integrated fashion. The approach is straightforward. White light is shone onto the exposed cortex and the amount of light of different wavelengths reflected from the cortex is measured. The reflectance and wavelength composition of light changes as a function of the neural activity of the illuminated tissue as a function of blood volume, blood flow, cell swelling, and the oxidative state of the tissue (among other variables). An invasive technique, OIS is used in the operating room to provide functional maps in which neuronal activity is varied by stimulation of peripheral nerves or, in the awake patient, by the performance of behavioral (e.g., language) tasks. The method has the best spatial and temporal resolution of all the functional imaging techniques, approaching 50 μm in the spatial domain and 50 ms in the temporal domain.

B. Multiple Modality Imaging

There are two types of multimodal integrative imaging studies that are important in the clinical evaluation of patients. The first is the within-subject integration of information from multiple brain mapping techniques, or the serial integration of multiple imaging studies in time using the same technique in the same individual. The second approach is the averaging or integration of information from multiple subjects, a much more difficult problem due to the great anatomical and functional variability that exists between individuals. The within-subject integration problem has yielded to a variety of excellent and elegant mathematical approaches for the alignment and registration of data. The between-subject problem is a more difficult one that is being resolved through the use of warping and morphing techniques.

1. Within-Subject Registration

A composite image of a patient derived from imaging using multiple imaging modalities or serial studies over time is a critical indicator of the clinical picture from an imaging perspective-for example, in a patient with a brain tumor in whom the natural history of the enlargement of the lesion can be evaluated quantitatively and objectively. Similarly, the integrated image of functional activation in cortical regions surrounding a lesion that is to be surgically resected can predict the relative risk of functional damage due to resection of normal cortex in the process of tumor ablation (Fig. 11).

Images of interictal spikes can be obtained by combining EEG and fMRI. Such images capitalize on the excellent temporal resolution of EEG and the complementary high spatial resolution of MRI. The relationship between hypometabolism in a seizure focus, determined with PET measurements of glucose metabolism, can be compared with benzodiazepine receptor binding, thereby increasing the specificity and

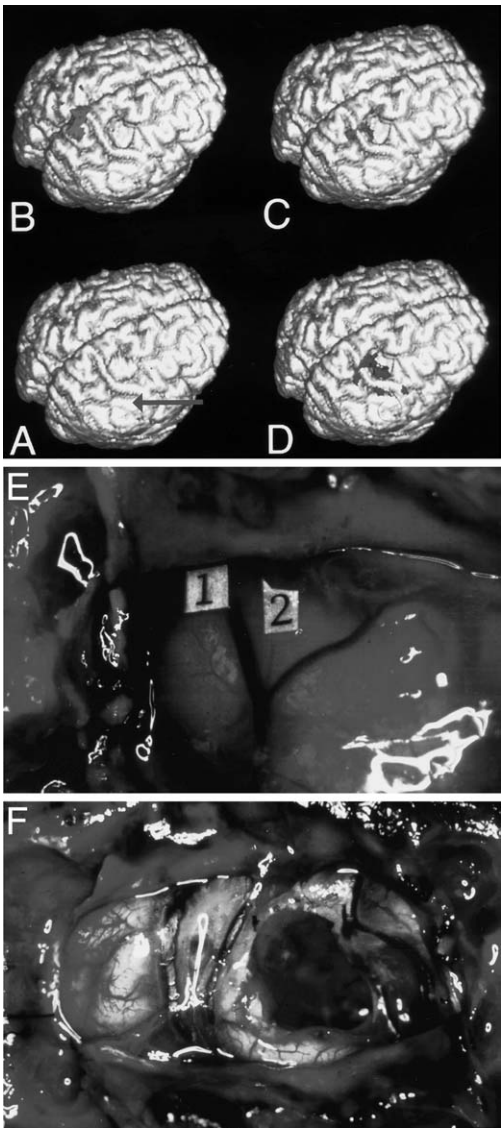

Figure 11 Within-subject registration techniques. (A) Three-dimensional reconstruction of a patient's brain with a cortical tumor in the region of the sensorimotor cortex (arrow). The structural data set, reconstructed from MRI, can then be combined with functional information about cerebral blood flow changes associated with motor tasks, derived from ^{15}O-labeled water PET studies when the patient moved the left leg (B), shoulder (C), or fingers (D). (E) Intraoperative view of the hand area of the motor cortex where the localization of sensorimotor hand function was identified intraoperatively with electrophysiologic techniques and labeled "1" and "2." (F) Operative view of site following resection of tumor. Because of the close proximity of the tumor to the activation site for finger movement, identified with preoperative PET imaging, it was predicted that this patient would have loss of fine motor control of the hand following complete resection of the lesion. This was in fact the case and is indicative of the accuracy and predictive power of preoperative mapping in patients with cortical lesions close to vital cortical structures (courtesy of Roger Woods, ULCA School of Medicine, and Scott Grafton, Emory University School of Medicine).

sensitivity of the combined result. One can also combine electrophysiologic data sets with tomographic data from PET, MRI, and MRS to provide a composite preoperative assessment of patients with epilepsy. PET measurements of cerebral blood flow, oxygen extraction, and oxygen metabolism in the same subject and comparison with diffusion-weighted MRI and MR angiography (or helical CT) provide a very complete picture of the supply–demand relationships of the brain parenchyma in patients with ischemic cerebrovascular disease. Such combined studies will undoubtedly become a clinical norm rather than an exception in the future.

Comparisons of scans between individual patients will become increasingly important. Such comparisons require that the scans be spatially normalized to account for individual differences in brain structure. The ability to normalize a scan to a standard brain space means that individual patient scans can be compared with a representative scan from a population of normal subjects that takes into account a realistic estimate of the anatomical variability in that population. In the structural domain, this ability may increase the sensitivity with which subtle heterotopias or other migrational abnormalities are identified in patients with focal epilepsy. Similarly, selected patterns of atrophy in neurodegenerative diseases should be detected in a more sensitive and specific fashion. The ability to compare representative scans across patient groups could also have importance for clinical trials where a patient group on an experimental therapy could be compared with a control group in an objective and quantifiable manner.

II. SURGICAL STRATEGIES

A. Preoperative

The preoperative investigation of patients with cerebral lesions falls into two general categories. The first is targeting areas for the purpose of stimulation or ablation. These circumstances occur in patients with movement disorders in which parts of the basal ganglia or other subcortical regions are selected for lesioning (e.g., pallidotomy) as a means of improving symptoms. Lesioning using stereotactic focal radiation or direct surgical ablation, by heating or freezing, are of interest for the treatment of cerebral neoplasms and vascular malformations. In a similar fashion, stimulating electrodes are now being employed in the treatment of Parkinson's disease and certain types of tremors.

The exact location for the placement of these electrodes requires knowledge of the structural anatomy and local electrophysiology or function to obtain maximal therapeutic benefit.

1. Targeting

Brain mapping techniques have already been employed for targetting. Currently, these approaches are limited to obtaining better definition of a patient's structural anatomy and developing better atlases to identify selected portions of the brain, given the individual variability among patients. With high-resolution structural imaging, specific locations for potential lesions can be identified anatomically and a frameless stereotactic approach can be used to direct an ablation probe or stimulation electrode. Once located, electrophysiological recordings can be used to verify the local functional environment of a given anatomical site.

Functional activation of deep brain sites (e.g., medial globus pallidus) is an important area of current investigation. Ideally, such sites should be located both structurally and functionally to identify a surgical target more accurately preoperatively. Such a facility would mean less retargeting and repositioning of electrodes and probes, thus reducing operating room time and morbidity, resulting in a higher success rate. Currently, there are no validated clinical examples of such an approach.

2. Differentiation of Normal from Abnormal Brain

Another important aspect of presurgical investigation of patients with brain mapping techniques is the identification of normal cortex or deep brain structures so that they may be avoided during surgical resection or ablation of cerebral lesions. The goal is to remove an abnormality in its entirety without removing normal brain tissue. Preoperative evaluation with PET, SPECT, fMRI, or transcranial magnetic stimulation may be employed to identify the functional anatomy of an individual's brain to determine the safety of surgery and a strategy for reaching an abnormal brain region to remove pathologic tissue.

Such functional imaging techniques may ultimately replace procedures such as the Wada test or reversible pharmacologic interruptions of brain function. The selective administration of barbiturates to brain regions that produce transient deficits has long been used to determine the relative safety associated with removal of a portion of the brain. Nevertheless, such tests are difficult to perform, particularly in younger children, and the exact distribution of the pharmacologic agent can be difficult to verify. If the same information can be obtained through presurgical use of functional imaging, it is hoped that both the accuracy and the ease of obtaining such data will be enhanced (Fig. 11).

The combined use of all of the noninvasive scanning methods, both current and experimental, resulting in integrated and composite images linked to interactive graphics stations in the operating room or the interventional neuroradiological suite, will surely become a part of such interventional procedures in the future. To be successful, these approaches need to be less costly, more accurate, and associated with lower eventual morbidity than conventional surgery without such ancillary noninvasive procedures.

B. Intraoperative Mapping

The most frequently used intraoperative brain mapping techniques are electrophysiological. These include electrocorticography for the identification of epileptic foci. Where cortical resections are indicated, evoked potential recordings with cortical electrodes are combined with peripheral nerve stimulation in anesthetized patients. Such an approach is frequently used to identify sensory and motor cortices. When more complex information is needed, particularly about language areas of the cortex, anesthesia is reversed and the patient is awakened during surgery. Direct electrical stimulation of the cortex is then used to reversibly disrupt local neuronal function while the patient performs behavioral tasks. In this setting, a patient must be psychologically able to accept the disturbing aspects of awake neurosurgery. Ideally, the examiner and the patient should have good rapport so that behavioral testing can proceed in an efficient and cooperative manner.

Optical intrinsic signal imaging, currently used in a research setting, may soon augment intraoperative electrophysiological measurements by directly providing visualization of cortical maps and functional responses seen ultimately through the operating microscope in real time. The high spatial and temporal resolution of this approach can be used to validate preoperative images of functional anatomy from individual patients. In addition, the functional brain maps can be updated as they become distorted from the preoperative state by changes in brain shape resulting from osmotic dehydration, ventricular

drainage, or local edema during the course of the operation.

As more interventional neuroradiology and neurosurgery are performed within imaging devices, the reacquisition of structural and functional information as an invasive procedure unfolds will become possible and realistic. The most likely source of these data will be from MRI devices, where either patients are moved in and out of the device to update imaging data or the interventional procedure is performed within the magnetic field directly. In either case, direct updates of structural and, potentially, functional information can be provided to the clinical team performing the procedure.

III. ATLASES

The advent of modern mathematical and computational approaches to averaging imaging data across subjects has led to the generation of population-based probabilistic atlases. Such atlases are already in existence for the normal brain at different age ranges and for other regions of the body. Disease-based atlases may be useful for the differential diagnosis of human cerebral disorders.

The basic approach to generating such atlases is to obtain images from a large number of subjects (i.e., typically hundreds or even thousands) in a mathematical framework that produces a database that is probabilistic. Such an atlas allows the user to obtain relative information that takes into account the variance in structure and function in the human population (Fig. 12). Once established, such an atlas can interact with new data sets derived from individual subjects and patients or groups of subjects or patients. Thus, a clinician or investigator who performs an MRI scan of a single patient with focal epilepsy could call on a digital probabilistic atlas of normal subjects and compare the patient with the average normal atlas. The atlas will use the normal variance information estimated from the population of normals from which it is generated to determine whether a patient's scan falls within or outside normal morphometric limits. If the atlas is constructed from sufficient subjects, a subpopulation could be selected that more closely resembles a patient's demographic profile. In such a case, one might ask for only those normal subjects from the atlas who are right-handed, of a particular racial origin, and females ages 25–30. An increasing number of variables can be included in such a prior specification depending on the size of the data set constituting the atlas and the range of demographic information collected about the contributing subjects. As a result, it would become possible to detect subtle abnormalities of diagnostic importance that would not be identified by the less sensitive conventional approach of qualitatively examining two-dimensional image sets by eye. In addition, such an atlas-based approach will give an objective and quantifiable magnitude to any detected abnormality. The scan data from any patient can be added to an atlas database, increasing its value with regard to particular patient groups.

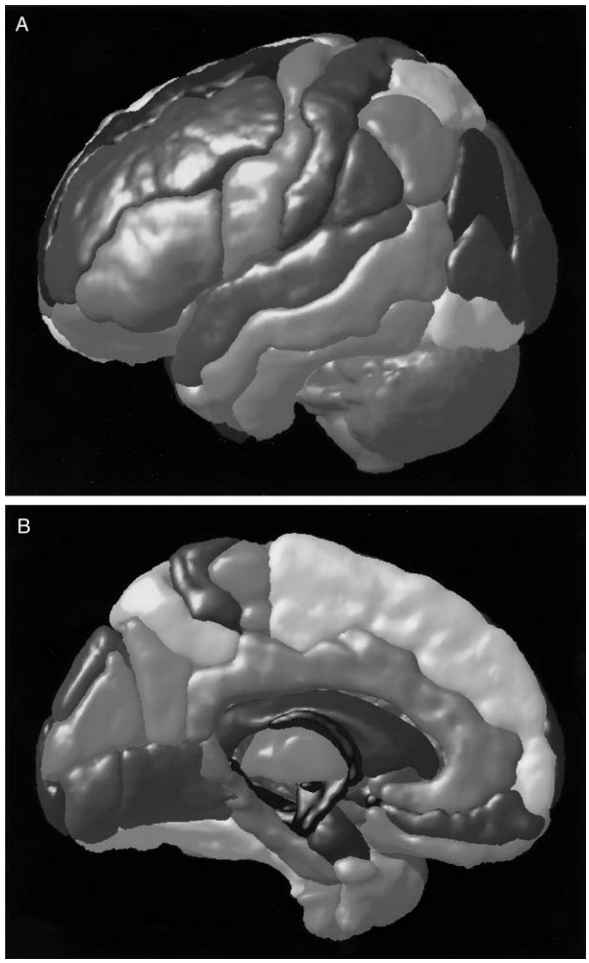

Figure 12 Probabilistic atlases. Population-based probabilistic atlas of the normal human brain derived from 67 subjects, ages 20–40 years, seen from the lateral (A) or midsagittal (B) views. The structures have been segmented to show cortical regions at a 50% confidence limit in the population [courtesy of Alan Evans and colleagues. Montreal Neurologic Institute].

Disease-based atlases, thus generated, are currently being assessed. It is possible to imagine morphometric or functional atlases for Alzheimer's (Fig. 13) and

Parkinson's disease, schizophrenia, and other disorders. Such atlases would also provide a population and disease-based opportunity to examine the natural history of morphometric or functional abnormalities as a function of disease progression, age of onset, or other variables. Such atlases could also be used to identify changes in natural course as a function of therapeutic intervention. Consider, for example, a clinical trial with a new drug for Alzheimer's disease. The Alzheimer's disease population atlas would provide estimates of morphometric changes in focal atrophy as well as, for example, alterations in crerebral glucose metabolism as a function of disease progression. A population of patients at a certain stage of the disease could be divided into two groups, one given an experimental therapy and the other given placebo. Serial imaging of both groups with the appropriate techniques would then provide longitudinal imaging data. Comparisons of morphometric and metabolic changes as a function of time between the two groups would be undertaken to detect objective and quantitative differences between the two groups. Any differences would represent a measure of the effect of the therapeutic intervention on progressive atrophy or glucose metabolism due to the natural history of the disease. It is probable, although currently unproven, that such an approach will be more sensitive in detecting differences between control and experimental groups, thereby requiring either fewer subjects or shorter time frames for therapeutic assessment, thus resulting in lower costs of clinical trials.

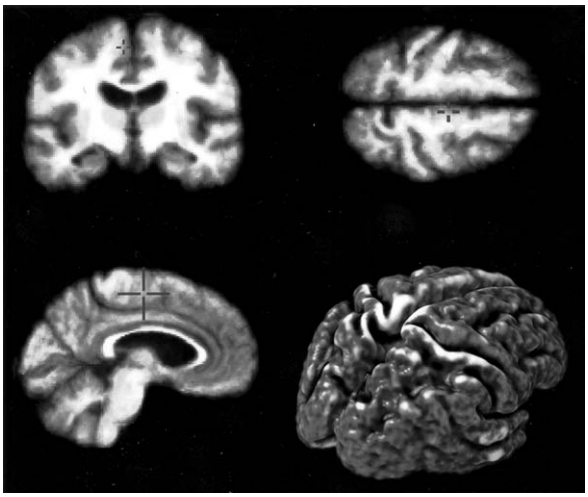

Figure 13 Probabilistic population atlas derived from nine individuals with Alzheimer's disease. This atlas is presented as a set of two-dimensional orthogonal views plus a three-dimensional rendering (bottom right) and is produced using a continuum-mechanical approach. Note the influence of atrophy on the composite image demonstrating widening of the major fissures of the brain as well as sulci in the neocortex. Such disease-based population atlases will be useful not only in tracking the natural history of cerebral disorders but also in providing objective and quantifiable information about structural and functional changes associated with experimental therapy for these disorders (courtesy of Paul Thompson and colleagues. UCLA School of Medicine).

IV. PLASTICITY

One of the most exciting and dramatic observations to come from human brain mapping with a wide range of structural and functional techniques has been the dynamic plasticity of function in both normal brains and the brains of patients with neurological and neuropsychiatric disorders. Brain maps must therefore be viewed as dynamic, changing with development, disease progression, and normal learning and in the recovery of function after acute injury. The dynamic plasticity of functional brain maps provides an exiting opportunity to study these processes. It also means that the use of brain maps must take into account such variability in the design of brain mapping studies for patients with cerebral disorders.

For example, just as structural and functional studies must be normalized for spatial variability in the population, disease-based maps must be normalized in time to account for dynamic changes that occur with progression. Thus, a comparison of patients with Alzheimer's disease or other neurodegenerative disease should be stratified by time of onset or other variables that take into account the pattern of changing functional maps. The same is true after an acute brain injury, such as trauma or cerebral infarction. The complex interaction and highly variable changes in blood flow, blood volume, water diffusion, oxygen, and glucose extraction and metabolism will all be more appropriately interpreted if they are stratified by time from onset of cerebral injury. So too will plastic changes associated with recovery and reorganization after irreversible damage. Compensatory properties of the human nervous system have been clearly demonstrated in studies of patients following stroke who recover motor function (Fig. 14). The study of drug-induced, behaviorally associated and surgically promoted plasticity will, we predict, be an important part of brain mapping in the study of patients with neurological, neurosurgical, and psychiatric disorders.

The value of imaging data depends on an appreciation of the changing landscape of functional patterns.

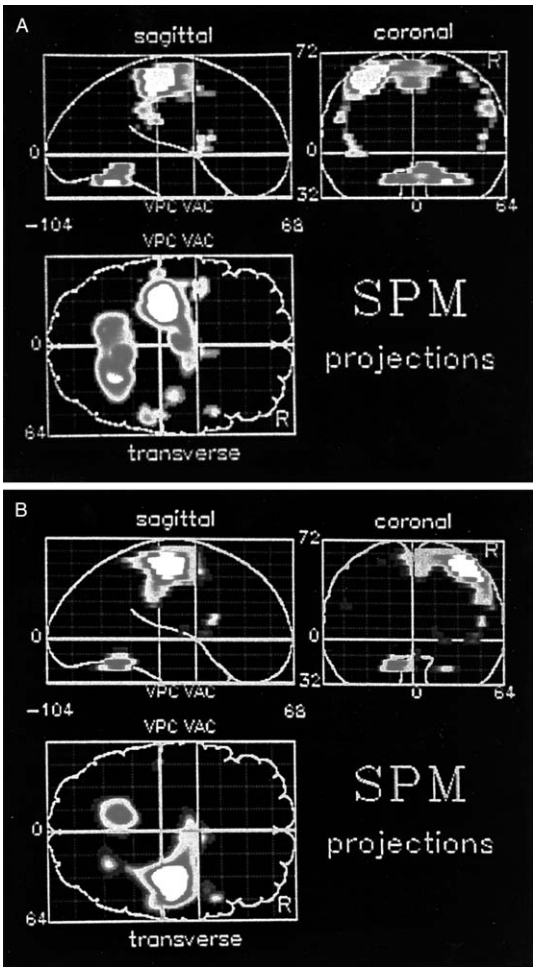

Figure 14 Compensatory reorganization of the brain after acute injury induced by cerebral infarction. (A) Normal response of a group of control subjects performing a motor task with the right upper extremity. Relative increases in cerebral blood flow derived from PET measurements demonstrating increased perfusion in the contralateral hand area of the motor cortex and the ipsilateral cerebellum. (B) The same motor task and methods were applied to a group of patients who had small subcortical cerebral infarctions associated with upper extremity paresis, all of whom recovered in the days to week following the acute ischemic injury. Note that when these subjects perform the same task, not only are there responses in the expected areas previously identified in the normal controls—that is, the contralateral hand area of the motor cortex and ipsilateral cerebellum—but also there are relative increases in cerebral blood flow in the ipsilateral hand area of the motor cortex and the contralateral cerebellum. Such studies provide useful insights into how the brain reorganizes following acute injury and can also be used to study compensation in more chronic states such as might be encountered in neurodegenerative disorders. These types of insights may be useful for designing more efficient, effective, and timely neurorehabilitation protocols employing behavioral, pharmacologic, or, potentially, surgical interventions for the restoration of function or its maintenance following acute or, chronic injury to the brain [courtesy of Francois Chollet and colleagues, Toulouse, France. From Chollet *et al.* (1991). *Ann. Neurol.* **29,** 63–71].

This is particularly true for techniques that make relative measurements. For example, relative cerebral blood flow measurements obtained with fMRI, SPECT, or PET may be misleading in patients with large cerebral infarctions. The evaluation of motor reorganization after cerebral infarction in a patient or group of patients must take into account a variable cerebral blood flow baseline in the setting of hemodynamically unstable tissue. Cerebral blood flow may be very low acutely, rise dramatically soon thereafter, and then reach some stable new level days, weeks, or months later. Currently, it is uncertain how increments or decrements in blood flow associated with neuronal firing changes that are task induced will behave under these different conditions of baseline blood flow. Is it valid to compare motor task activation in a cortical region when the "resting state" blood flow is altered from the normal value by 50–200%? Are there ceiling or floor effects in these responses? These issues need to be addressed before a proper interpretation of scans from such patients will be possible.

We predict that the ability to image plastic reorganization, both in normal and in pathologic states, will provide new insights, previously unavailable, about the constant reorganization of the human brain. Such information will be valuable in the design of behavioral, surgical, and pharmacological interventions in patients that facilitate and maximize the efficiency of the natural recovery processes. The imaging techniques should also provide a means to evaluate specific rehabilitation interventions, to determine their appropriateness, effectiveness, and timing, and to select patients for them. These abilities are currently lacking because the necessary information about the variables discussed has not been previously available.

Information Processing

JOE L. MARTINEZ, Jr., STEPHEN A. K. HARVEY, ADRIA E. MARTINEZ, and EDWIN J. BAREA-RODRIGUEZ

University of Texas, San Antonio

GLOSSARY

amygdala A group of nuclei in the anterior–medial part of the brain that are involved in emotional memory.

declarative memory Memory that involves the conscious recollection of events.

DNA (deoxyribonucleic acid) The central library of an organism's genetic information.

DNA microarray Technique used to investigate thousands of genes from the same tissue sample.

engram The memory trace laid down in the brain. It is believed to be formed by changes in the synapse.

Hebbian synapse When a signal between two neurons is strengthened due to the simultaneous activation of the presynaptic and postsynaptic neurons.

hippocampus A structure located in the medial temporal lobe that is involved in spatial learning.

learning A change in behavior as a result of experience.

long-term potentiation A form of synaptic plasticity induced by brief high-frequency stimulation.

memory The ability to store and recall an experience.

nondeclarative memory Memory usually measured by performance, such as automatic motor skills.

RNA (ribonucleic acid) Short-lived molecule that contains information about the DNA.

transduction The change of physical energy into neural signals.

The neuron is the principal functional unit of the brain. Neurons both transform physical energy such as pressure and temperature into neural energy and conduct light and sound energy transformed by the eyes and ears. This transformation is the first step in information processing. Because we all have slightly different perceptual worlds and experiences, our individual identity is based on our memories of perceptions. This article presents learning and memory as an example of an information processing system. The article takes a cognitive and molecular biology approach in understanding how memories are formed.

> *The world first exists, and then the states of mind; and these gain a cognizance of the world which gets gradually more and more complete.*
>
> William James (1892)

Understanding movement of sensation from the external environment to the inside of one's head as useful information is a process that has consumed philosophers and scientists for hundreds of years. Think of the Challenger space shuttle explosion. In your mind's eye you can visualize the twin plumes of smoke streaking higher into the sky that represented the end of the mission. How did this image get into your brain and why will it be with you for the rest of your life? These are two questions this article seeks to address.

The human body exists in a sea of physical stimuli, only a tiny fraction of which we are aware. Consider

the electromagnetic spectrum, which includes X-rays able to permeate solid objects and ultra-low-frequency radio waves with which we can contact submerged submarines thousands of miles away. We see only a tiny fraction, from 400 to 760 nm. We do not see cosmic rays or television transmissions. Perhaps our tiny range of vision allows us to focus on those external objects necessary for our survival. Our senses, then, are transducers that convert physical energy to neural energy. Ears convert sound, nerve endings convert temperature and pressure, the labyrinth converts gravity, the tongue converts acids and sugars, and the nose captures molecules from the air and gives them each a unique sensation. Consider the curious life of synasthets, people who hear light or see sound when their neural energies are crossed at the level of the thalamus so that hearing neural energy goes to the visual areas and *vice versa*.

We do not all perceive the same world because physical energy is transduced by biological systems that have many states and conditions. A person who walks into a darkened movie theater does not see nearly as clearly as the person who has been in the theater for a long time and who is dark adapted. At that moment their perceptual worlds differ. A person unable to distinguish red and green, a dichromatic, sees a different world, and a blind person does not see the world at all. Because we all have slightly different perceptual worlds and experiences, our individual identity is based on our memories of perceptions. As William James said, cognizance of the world is an iterative process that depends on perception and memory; together, perception and memory allow information processing. Everyone agrees that the brain is the organ that perceives the world and stores our individual memories, and the computational unit of a brain is the neuron (Fig. 1). As a cell, the neuron exhibits continuous metabolic activity but exists in only one of two transmission states, "on" and "off." Thus, it is analogous to a computer memory address, which contains a bit of information—either 1 or 0. Although the content of a computer memory address is set by a central processor, a neuron is much more complicated, gathering information from its dendrites and deciding whether and how many on states, called action potentials, it will generate. Neurons connect through special contacts called synapses at the end of axons. As depicted in the Fig. 1, a neuron connects with many other neurons, usually on a part of the neuron called a dendrite.

Figure 2 shows that neurons are organized into units called nuclei and these nuclei perform functions and communicate with other nuclei. Neuroanatomy is the study of the organization of nuclei. Continuing our computer analogy, nuclei function like integrated circuits. Note that in Fig. 2, neurons become more complex as one moves up the phylogenetic scale from mouse to human. Because it is more complex, the human neuron has more computational power. This is the basis of superior information processing in humans. Note that rat and human brains are similar in architecture. Both have cerebral hemispheres, both have a thalamus, and both have a cerebellum. Based on this similarity, we expect humans and rats to have similar functions, and both are capable of learning mazes, for example.

Now we can ask a difficult question: How can a perception become a memory and vice versa? Figure 3 shows a most intriguing result. In this experiment, a monkey was trained to look at a fixed point in the center of the circular pattern, and this was followed by

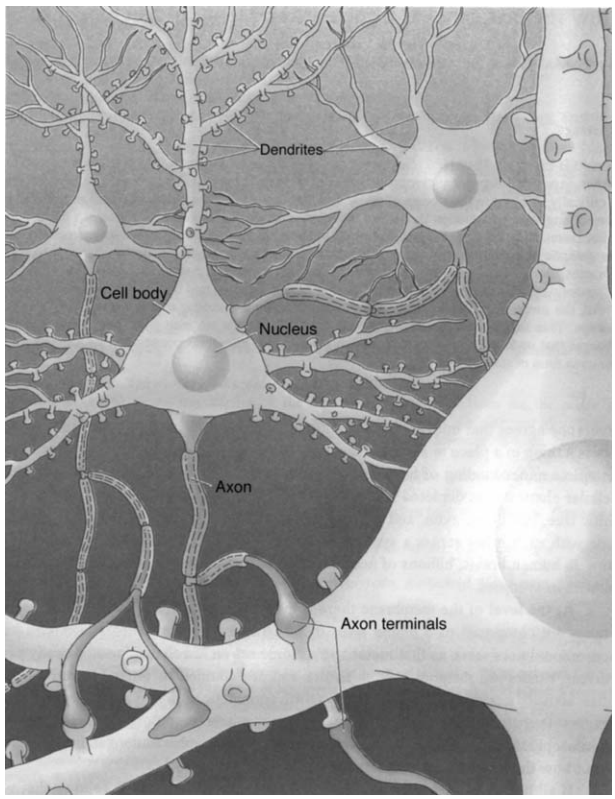

Figure 1 The neuron is the basic signaling unit of the nervous system. There are 10^{12} neurons in the brain and most have a cell body that gives rise to the axon, dendrites, and synaptic boutons or terminals [reproduced with permission from Rosenzweig, M. R., Leiman, A. L., and Breedlove, S. M. (1996). *Biological Psychology*. Sinauer Associates, Sunderland, MA].

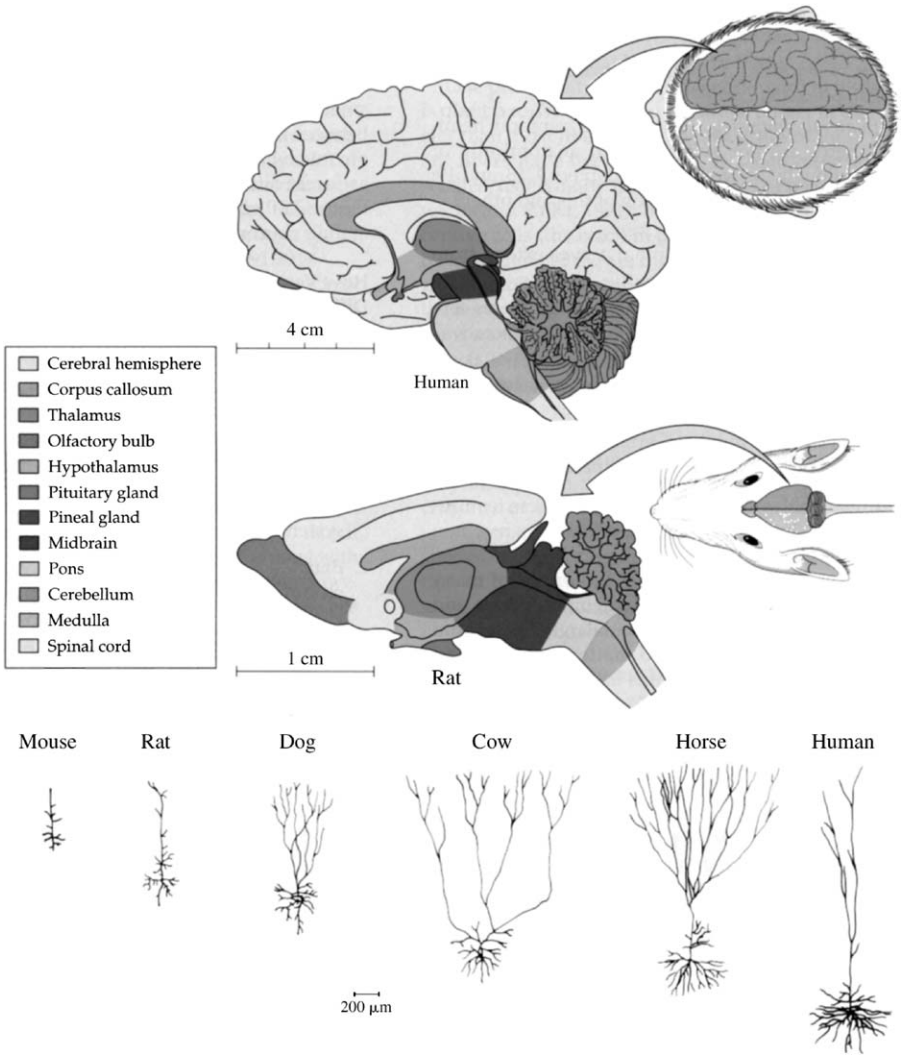

Figure 2 Midsagittal view of human and rat brains. The structures observed contain neurons and each performs different functions [reproduced with permission from Rosenzweig, M. R., Leiman, A. L., and Breedlove, S. M. (1996). *Biological Psychology*. Sinauer Associates, Sunderland, MA].

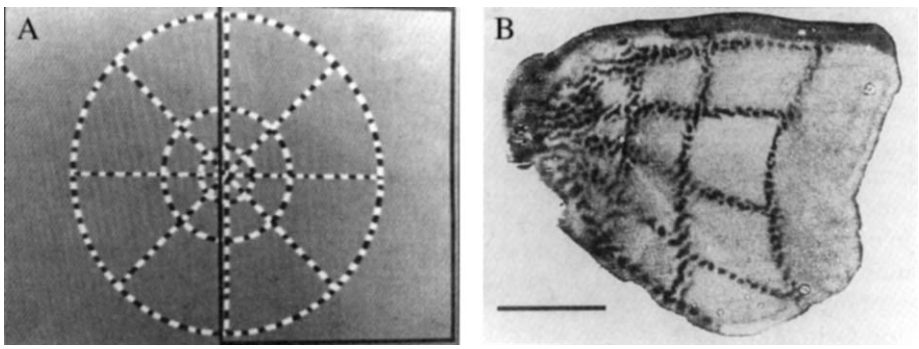

Figure 3 (A) A pattern of flickering lights shown in the visual field of a macaque monkey (B) Pattern is mapped in the striate cortex using 2-deoxyglucose (reproduced with permission from Tootell *et al.*, 1988. Deoxyglucose analysis of retinotopic organization in primate striate cortex. *Science* **218,** 902–904).

an injection with a synthetic form of glucose. Neurons that were metabolically active look darker. The circular pattern is recreated on the cortex of the monkey. A network of interconnected neurons represents the perception. The pattern can be stored in the monkey brain and made into a memory if the network that represents the circle can be made permanent. Hebb proposed this idea in 1949, but he called the network of neurons a cell assembly. In order for the monkey to re-experience the pattern, the network has to be reactivated in its brain.

Hebb proposed that the pattern could be made permanent if the connections between neurons were made stronger in a functional sense. That is, if neuron A, the first in the network representing the circle pattern, persistently fires neuron B, and so on, then some process takes place in either A or B and all the neurons that represent the pattern so that the efficiency of A firing B is increased. In other words, when neuron A fires the pattern is recreated. Today, the phenomenon by which one cell creates a larger response in the second by repeated stimulation is called long-term potentiation (LTP), and it is considered to be the best model of how the brain may store information.

Are there any nuclei in the brain whose function is to make memories? In the 1950s, a patient H.M. had his hippocampus removed on both sides of his brain to control his grand mal epilepsy. Following the surgery, H.M. could remember the past, but he could not remember anything new. He was said to have a deficit in his ability to consolidate or make permanent new memories. Interestingly, Fig. 4 shows that H.M. could learn a backward mirror drawing task, even though he did not remember the apparatus from day to day. It is thought that the hippocampus is a brain structure whose function is to lay down new declarative memories or "knowing that" (the apparatus) rather than "knowing how" (to draw backwards). In Section III.A, we take a closer look at the hippocampus and determine whether its organization or arrangement of

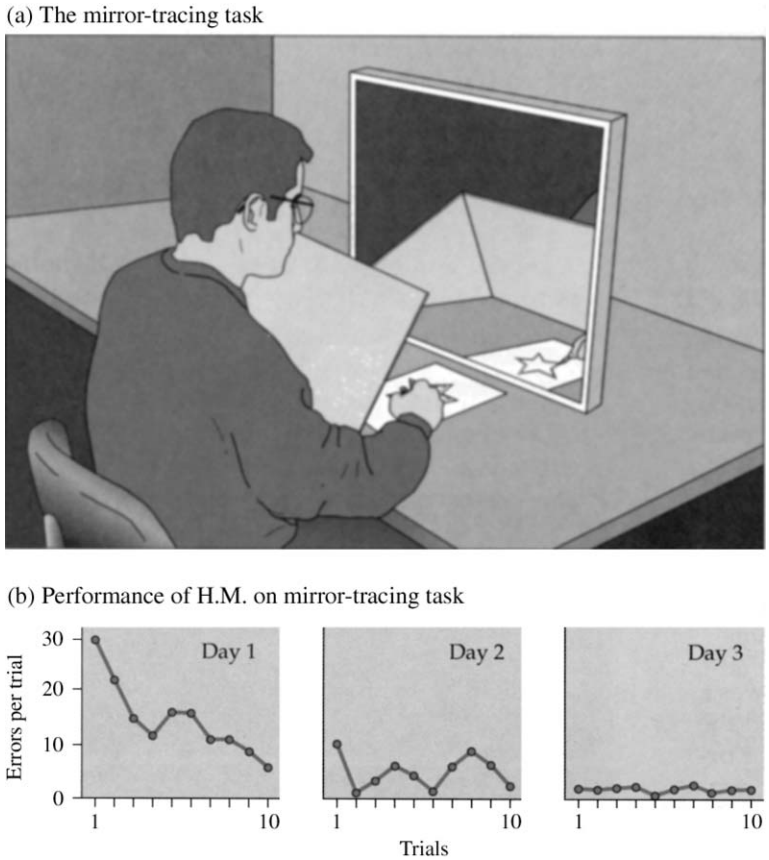

Figure 4 (a) The mirror-tracing task used to test memory in patient H.M. (b) Performance of H.M. on this task. Despite the improvement over days in this task, H.M. did not remember having performed this task in the previous days [reproduced with permission from Rosenzweig, M. R., Leiman, A. L., and Breedlove, S. M. (1996). *Biological Psychology*. Sinauer Associates, Sunderland, MA].

cells provide clues as to how it might lay down memories. In Section III.G, we examine the phenomenon of LTP in the hippocampus. If the hippocampus really is a nucleus designed to lay down memories, then LTP should abound in this structure. Finally, we examine an interesting phenomenon of memory: Many are permanent. What could possibly change in a neuron so that you remember the first time you rode a bicycle?

I. LEARNING AND MEMORY AS AN INFORMATION PROCESSING SYSTEM

In the morning an employee arrives to work and realizes that her usual parking spot is taken. She parks in another parking area, but before she leaves she inspects the area looking for landmarks that will help her find her parked car at the end of the day. At the end of the day she searches for her car in the parking lot by looking for specific landmarks. The ability to find the location of the car by searching for landmarks is possible because the person makes an association between the location of the parked car and the landmarks.

It is 12 noon, you are feeling hungry but still have work to do. You know that when the bell of the microwave oven sounds, your coworker, who is a great cook, is warming up food. Today, you hear the bell and your mouth waters. Sometime in the past an association was established between the bell and the food. In both the cases of using landmarks to one's car (declarative/spatial learning) and the sounding of the microwave oven bell causing one's mouth to water (nondeclarative/classical conditioning learning), it is said that learning occurred. Both visual and auditory stimuli were processed and associated in memory.

Using the spatial learning example (this also applies to auditory information), we can construct a model that explains how the person establishes an association between landmarks and the parked car. This model can be divided into a set of stages. The first stage involves the registration of the cues and the location of the car in the visual system. Thus, as described earlier, physical energy, light, which is used by the visual system to form the images (light pole, trees, or a sign with the lot number) that surround the car, is transformed by the sensory register into neural energy. Transduction is the first step in information processing—the transformation of physical energy into a type of energy that the brain understands. The second stage involves the processing of neural energy by the neural structures involved with establishing the association (the hippocampus). In the third and final stage, the information is retrieved as needed.

The information processing model constructed previously uses two approaches to explain the surrounding landmarks–parked car associations: cognitive psychology and computer science. The cognitive psychology approach seeks to understand the mental processes that take place during the time that a stimulus is perceived and the behavior that it elicits in an individual. The computer science approach helps us understand how information is processed so that it can be used at a later time. Interestingly, we can borrow many concepts from computer science. For instance, in order for perceived information to be used it needs to be encoded, stored, and retrieved. One major difference between the brain and a computer is that the brain uses billions of neurons in parallel fashion to process information. The computer has a main processor that allows the processing of a number of serial operations. You know that you have never seen the word "tedinu" (united backwards); you do not have to scan your memory from aardvark to zygote, as a computer does.

Humans are processors of information and human memory is an exemplar information processing system. In the past four decades we have learned a great deal about memory and the underlying mechanisms that subserve the encoding of information, and we are learning more about the mechanisms involved in the storage and retrieval of information. Next, we discuss the concept of the memory trace and current evidence that shows how a number of neural structures are involved in mediating the processing of information that leads to the formation of spatial and emotional memories.

II. IN SEARCH OF THE MEMORY TRACE (ENGRAM)

Curiosity in the understanding of the ability to remember information (memory) dates back as far as 800 BC, when memory was considered a virtue. Interestingly, even in those days teachers and philosophers recognized the importance of the sense of sight to develop strategies to remember information, also known as mnemonic techniques. The context became associated with all the information acquired in a place. Although an engram, the memory trace, was formed with a given experience, little was speculated about the localization of the engram.

III. ANATOMICAL BASIS OF THE MEMORY INFORMATION SYSTEM

Here, we focus on two types of learning presented previously—spatial (declarative) and classical conditioning (nondeclarative) learning that allow us to empirically understand the role of the brain in information processing. Interestingly, both humans and animals utilize these forms of learning. Furthermore, one type of learning may exist without the other. Before we discuss different types of learning, it is important to describe two structures believed to be involved in learning and memory—the hippocampus and the amygdala.

A. Anatomy of the Hippocampus and Amygdala

As noted earlier, the hippocampus was found to be involved in memory when H.M.'s hippocampi were removed and he exhibited anterograde amnesia. Figure 5 shows a view of the hippocampus and the amygdala using a transparent model of the human brain. The hippocampus was so named because it has a close resemblance to a sea horse ("hippo" means horse, and "kampos" is Greek for "sea monster"). The hippocampus is an elaborate infrastructure of computational systems. However, the complex basis on which the hippocampus functions can be understood in a simpler way by describing its trisynaptic structure.

The hippocampal formation is composed of the hippocampus proper and is formed by layers of neurons that form areas CA1–CA3 (cornu ammonis 1–3), the dentate gyrus, the entorhinal cortex, and the subiculum. The hippocampal formation has an internal circuit known as the trisynaptic circuit. First projection is from the entorhinal cortex to the dentate gyrus. Second, the dentate gyrus neurons give rise to the mossy fibers (axons) that project to CA3 cell fields. Third, the CA3 neurons give rise to the Schaffer collaterals (axons), which project to the CA1 cell field. In addition, the hippocampal formation receives projections from many subcortical structures (e.g., amygdala). Neuroanatomy is replete with nerve tracts that run from one physical location in the brain to another, but the hippocampus can be thought of as a loop that returns its signals to a location close to their cortical origin.

The amygdala, derived from the Greek word for "almond," is a collection of nuclei located in the temporal pole of the cerebral hemisphere rostral to the hippocampal formation. The amygdala comprises the lateral, medial, basolateral, and central nuclei. These nuclei have a number of functional roles, from receiving and processing olfactory information to sending projections to areas involved in autonomic responses. Studies suggest that the amygdala is directly involved in classical conditioning associated with fear.

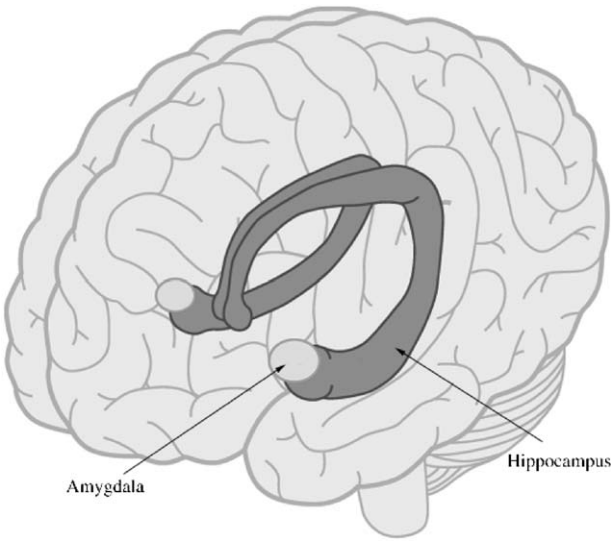

Figure 5 Studies from human and rodents show that the hippocampus mediates declarative information. Studies derived from rodents show that the amygdala is involved in classical conditioning (reproduced with permission from *www.brainconnection.com*).

B. Declarative Learning and the Hippocampus

Remember H.M.; imagine not being able to remember what you ate for breakfast, lunch, and dinner. Picture yourself at a dinner party unable to recognize any of the faces of the people whom you had met only minutes earlier. Recall that because H.M. suffered from epileptic seizures, doctors suggested that his hippocampus be removed. The result was both successful and unfortunate. H.M.'s seizures ended, but H.M. could not form any new memories. In addition to H.M.'s anterograde amnesia, he was unable to remember the 3 years of his life prior to the surgery (retrograde amnesia). Through endless studies and tests performed on H.M., many theories about learning and memory were revolutionized. Previous views focused on the concept of functional localization; this meant that specific brain regions were responsible for particular functions. This view (for some) was

modified. Research from H.M. suggested that although functional localization is legitimate, there is a more complex circuitry associated with memory than once believed. It could have been hypothesized that because H.M. was incapable of transferring short-term memories into long-term memories, he could not have learned anything new. This was not entirely true. Remember that H.M. could learn skills such as the backwards mirror-drawing task. H.M. illustrated learning by improving at the task, despite his inability to recognize the test each day. This gave much insight into the process of converting short-term into long-term memory, a process called consolidation. H.M.'s ability to learn and improve at a task but to have no recollection of tracing the lines in the star gave novel insight into the role of the hippocampus in storing declarative memories.

C. The Role of the Hippocampus

Think of the hippocampus as the place where short-term memories are processed until they turn into long-term memories. Because H.M. lacked any ability to "remember" postsurgery, doctors and researchers deduced that the hippocampus was the locale where short-term memories turned into long-term memories. Keep in mind that H.M. could recall his life 3 years prior to the removal of his hippocampus. This illustrated the fact that long-term memories were not stored in the hippocampus; they were subsequently believed to be stored in another part of the brain called the neocortex.

D. Declarative Memory: One Type of Memory

Declarative memory is what we most often think of as memory. Remembering where you were when you first rode your bicycle or where you were when the Challenger exploded are examples of declarative memory. What defines declarative memory is the ability to consciously recollect the situation in which you learned something new. Declarative memory is context based. H.M. was able to recall experiences before his retrograde amnesia. H.M. had intact declarative memory to an extent, but he was unable to form any new declarative memories because he lacked the anatomical structure to do so.

E. The Animal Model

These findings provided an understanding about the hippocampus as a whole, but structurally there was much more to learn. Because of H.M. and considerable research on amnesic patients, we know now that the hippocampus is critical in transferring new memories into stored ones. How does this system work? Researchers needed to first find a model to test that was comparable to humans. Rats have similar nervous systems to humans, but unlike humans they are not able to verbally recall (declarative) what they have learned. They do use spatial cues to find their way in the environment (spatial learning). Spatial learning is mediated by the hippocampus, and thus used as a model for declarative learning in animals. The Morris water maze tests spatial memory by placing rats in a pool of opaque water. The rats have to find a submerged platform only by using cues (a large black star on the wall or an inflated beach ball) which are placed around the pool. Rats must first make a choice about what they did before (how they found the platform) and then use visual cues. Because the time spent finding the platform decreases with each new trial, it is believed that they have learned to find the platform by using the visual cues. Research on spatial information processing in the hippocampus shows that there are cells, known as place cells, that code for specific cues in the environment. Animal studies have shown that the dorsal hippocampus is specifically required for spatial learning, and the equivalent (posterior) part of the human hippocampus shows increased metabolic activity when navigational information is being recalled. Some species actually show an increased hippocampal volume during periods when they need to bury and retrieve cached food. Is there an equivalent change in humans? A professional requirement for London taxi drivers is a detailed knowledge of the tortuous streets of that large city. Interestingly, these taxi drivers have an increase in volume of the posterior hippocampus relative to a matched control population. Moreover, the longer they have been taxi drivers, the more pronounced is this change.

F. Nondeclarative Learning and the Amygdala

Previously, we used the example of a microwave bell and mouth watering to introduce nondeclarative learning. Physiologist Ivan Pavlov was the first to investigate classical conditioning. His studies showed

that by repetitive pairing of a conditioning stimulus (bell) with an unconditional stimulus (food), dogs salivated at the sound of the bell. It was Pavlov's idea that the cerebral cortex was involved in classical conditioning.

Studies with animals show that the amygdala is involved in classical conditioning. In this case, the pairing of a tone with a foot shock elicits a freezing response when the tone is presented alone. That is, the tone predicts the presentation of the shock. Neurons in the amygdala respond to a shock-related tone only. Furthermore, damage to the amygdala eliminates the physiological changes associated with the freezing response. What is the circuit involved in this type of information processing? Studies by LeDoux and coworkers suggest that auditory information arriving at the auditory cortex travels to the basolateral nucleus and the central nucleus of the amygdala; first the auditory information arrives at the basolateral nucleus, then to the central nucleus. The central nucleus then sends information to the hypothalamus, which mediates autonomic responses (increased in heart rate); periaqueductal the gray area the brain stem, which mediates the actual emotional response (freezing); and the cerebral cortex, which mediate the emotional experience.

In the next section, we show that information processing can also be studied at the cellular and molecular level. Indeed, as suggested by Semon, Santiago Ramon y Cajal, and William James, the engram is formed by physiological changes in neurons. Neurons in both the hippocampus and the amygdala display physiological changes that are believed to mediate information storage.

G. Long-Term Potentiation Is a Form of Synaptic Plasticity That May Be Involved in Information Processing

As addressed earlier, Hebb increased our understanding of how information processing occurs in neurons by suggesting that activity in groups of neurons mediates memory formation. Because neurons communicate with each other only at synapses, changes in activity of groups of neurons likely occur at the synapses, and therefore memories are stored through LTP. The NMDA receptor is involved in forming LTP. Activation of the NMDA receptor requires both the release of the neurotransmitter glutamate and stimulation of the postsynaptic cell. That is, the NMDA receptor must be activated by glutamate and simultaneously there must be sufficient depolarization of the postsynaptic membrane to relieve a magnesium block in the NMDA-associated ion channel, which allows entry of the ion calcium (Ca^{2+}) into the postsynaptic terminal. Ca^{2+} activates a number of changes in the cells. Thus, this receptor acts as a coincidence detector, informing the neuron that it was activated in rapid succession. This is an example of a cellular mechanism that may be involved in information processing.

IV. RELATIONSHIP BETWEEN LTP AND LEARNING

The first evidence to associate LTP with learning was derived from studies that used drugs to block the activity of the NMDA receptor. The rationale behind these studies was that the blockade of the NMDA receptor would prevent changes in synaptic function. In the most comprehensive studies, the drugs were administered directly into the ventricles. This procedure allows the drugs to diffuse to the hippocampus in addition to other brain areas. The behavioral task investigated was the Morris water maze task, which is a spatial learning task. Blocking the NMDA receptor indeed affected spatial learning and also blocked LTP. Presumably, the blockade of changes in synaptic function prevented learning. As expected, LTP is also found in the amygdala, and NMDA receptor blockade in the amygdala prevents both nondeclarative learning and LTP.

A. LTP or Memory Formation Causes Changes in Gene Expression

Previously, we presented LTP as a model of information processing that leads to memory storage. We also considered the idea that information processing is associated with changes in synaptic function. However, changes in synaptic function alone cannot account for the permanence of memory storage. That is, there must be other mechanisms associated with information processing that allow for memories to remain for days to years. Many believe that the permanent storage of information involves a signal cascade that begins at the level of the synapse and includes the activation of a receptor and the activation of cellular changes known as second messenger

systems. Then, at the level of the cell body, it involves the transcription of genes that have a short-lasting function (immediate early genes) and the activation of genes that have a longer lasting function. The activation of the latter may account for a more stable memory. The molecular biological revolution has taught us that long-term changes of cell function, as must occur in long-term memory storage, are controlled by gene expression and resultant protein production. Interestingly, almost every aspect of the signal cascade has been investigated in both learning and LTP.

How might changes in the synapse and then at the nucleus be involved in LTP and learning? If one accepts the hypothesis that long-term potentiation subserves memory, then one can alter information processing either by inducing LTP or by training an animal so that it forms a memory (task acquisition). After either of these experimental perturbations, electrophysiological and morphological responses are known to occur in the brain. For example, the electrical properties of a neuron could be changed by altered production of ion channel proteins, and dendritic morphology in neurons could be altered by changes in cytoskeletal and/or surface adhesion proteins.

Changes in gene expression can be measured in a number of ways. In "fishing" for the expression of genes that are unknown, two techniques have been used successfully: subtractive hybridization and differential display. Subtractive hybridization permits a mathematical subtraction of gene expression in control tissue from expression in treated or perturbed tissue, allowing isolation of mRNA specifically from genes that have been upregulated or downregulated. Differential display involves amplification of both control and perturbed sequences and subsequent separation of the amplified products, which permits one to determine directly which sequences have been increased. However, with the completion of the Human Genome Project and with other entire mammalian genomes in reach, a technique called DNA microarray analysis has become increasingly important. In principle, DNA microarray techniques can measure expression of all known genes at one time, and it likely will become the method of choice for some investigations. DNA microarray techniques have already been applied to studies of alcoholism, Alzheimer's disease, schizophrenia, and multiple sclerosis; they have examined the changes wrought in the brain by aging, sleep, environmental enrichment chemically induced seizures, and amphetamine.

Indications so far are that these conditions cause altered expression of a small subset of genes (approximately 12). One possibility is that this altered expression is sufficient to cause profound changes in a complex system such as the brain. Another possibility, which has yet to be examined, is that DNA microarray analysis of a relatively large piece of tissue containing millions of cells misses the changes that occur in a small subset of those cells. After all, neuroanatomy tells us that changes in highly localized nuclei or tracts within the brain will have profound effects. Other molecular biological techniques have been used to examine gene expression in a single cell, and it seems likely that DNA microarray analysis will be adapted to provide the same kind of specificity.

B. Restriction or Enhancement of Gene Expression Changes LTP and/or Memory Formation

Previously, we considered perturbing brain function and measuring the consequent changes in gene expression. Conversely, one can perturb normal gene expression and determine what effect this has on the ability of the brain to support LTP or the ability of the animal to acquire a task. For instance, single genes, controlling what are hoped to be specific events within cells, can be eliminated and the resultant effect can be studied simultaneously in whole animals minus one gene (so-called knockouts) for LTP and learning.

One reason to target genes is that these genetic procedures have the potential to overcome the current limitations of pharmacology. As mentioned previously, drugs used to block the NMDA receptors affected not just the NMDA receptors located in the hippocampus but also those all over the brain. In addition, drugs used to block second messenger systems are not specific. Thus, the idea of gene manipulation is to delete genes in local areas. Homologous recombination, a process that gives rise to natural diversity, is used to create knockout animals. To use this technique *in vitro*, one must know the DNA sequence bracketing the gene in question; also, the efficiency of recombination is low. In the first studies of genes related to LTP and learning, an area of focus was proteins known as kinases. Kinases are important because they activate other proteins (e.g., receptors). This presented a problem because the kinase family is composed of a number of subtypes, which appear to have varied functions. However, we can selectively impair the

function of a specific kinase isoform by using knockout mutants.

The first kinase targetted was α-CaMKII, the type II α-calcium/calmodulin kinase. This kinase is important because it is activated when calcium enters through the NMDA receptor. Mice lacking this kinase had difficulty learning the Morris water maze. In the mutant mice, only the probability of LTP induction was altered; LTP induction was not abolished.

Protein kinase C is another kinase investigated using the knockout technology. In these mice the probability of LTP induction was reduced in the mutants much as it had been in previous studies employing knockouts. However, if the mutant mice were first treated with low-frequency stimulation, then the LTP was indistinguishable from that observed in wild-type controls. Regarding behavior, there were interesting findings in these mice. The mutant mice learned the Morris water maze at the same rate as did the normal mice; however, they had a deficit in contextual fear conditioning, a task that requires intact hippocampal function.

One potential function of kinases is to activate transcription factors, which are molecules that activate other genes and are found in the nucleus. Transcription factors are interesting because they mediate cellular and molecular mechanisms downstream of receptor activation (i.e., the cell body). One transcription factor involved in learning and memory is CREB. Previous studies indicated that better learning occurs when spaced trials are given as opposed to massed trials. One group used this finding to investigate learning in mice lacking CREB. Unique to these animals is impairment in long-term but not short-term memory. In this elegant study, it was found that in a number of behavioral tasks, including contextual conditioning, socially transmitted food preferences, and spatial learning, there was no impairment in learning when the animals were trained using spaced trials. The impairment observed with massed trials is explained by the fact that there is insufficient CREB to activate the long-term regulatory genes, whose proteins are essential for long-term memory. The use of spaced trials allows a limited amount of CREB to initiate sufficient transcription to allow long-term memory. These findings are important because they indicate the complexity that is inherent in the mechanisms involved in information processing in the brain. That is, since the deletion of CREB occurs throughout the entire animal, it is difficult to separate its primary effects in the central nervous system from effects outside the central nervous system. Since the animal's entire development occurs in the absence of the gene product, a viable adult likely indicates that compensatory changes have been made in the levels of other gene products. DNA microarray analysis provides a means of measure for these compensatory changes.

Recently, second-generation knockouts have been created in which the gene deficiency can be localized to a specific region of the brain or can be turned on or off by treatment with a specific drug. Spatial localization within the brain is performed using two distinct genetically engineered animals. In one animal, part of the target gene is replaced by an identical sequence that is flanked by short, highly specific sequences of DNA (called lox sequences); these sequences do not affect gene function. In the second animal, the gene for a bacterial enzyme called Cre is inserted under the control of a promoter that is known to be activated in the brain. For example, the enzyme calcium/calmodulin kinase is highly expressed in the forebrain; therefore, inserting the promoter sequence for calcium/calmodulin kinase in conjunction will cause a high level of Cre expression. When these two mice are mated, some progeny will possess both the Cre enzyme and the lox-bracketed gene. The normal function of the Cre enzyme is to locate two lox adjacent sequences and join them together, excising the portion of the DNA that lies between them. In so doing, Cre inactivates the target gene. This inactivation will occur only in cells that express Cre, and since the expression of Cre is different among strains of engineered mice, workers were able to obtain a strain in which expression was highly localized to the principal cells of hippocampal region CA1. Studies accomplished with the first target gene—NMDAR1 or subunit 1 of the NMDA receptor—illustrate the elegance of this system. Conventional first-generation knockouts of NMDAR1 die shortly after birth. Since normal calcium/calmodulin kinase expression (and therefore Cre expression) does not occur until later in development, the second-generation knockouts have NMDAR1 present during critical early periods and are viable adults. However, the adults are deficient in long-term potentiation in area CA1 and have a greatly reduced ability to learn a spatial task.

The genetic techniques mentioned previously are all implemented in the mouse. Although behavioral training of mice is well established, the induction of LTP *in vivo* is technically more challenging in these smaller animals. The advantage of antisense oligonucleotides is that they can be used in the rat, which is the neurophysiologist's animal of choice. There is still no satisfactory explanation as to why this technique works, but it is particularly successful in the brain.

The target in this case is not the gene but the transcribed messenger RNA (mRNA), which directs protein synthesis. An oligonucleotide sequence approximately 20–25 bases long is synthesized that is complementary to part of the target mRNA. This antisense oligonucleotide is injected stereotaxically into the brain, where it enters the cells. Within the cytosol the antisense binds specifically to the target mRNA. The resultant nucleic acid duplex is vulnerable to cellular enzymes (e.g., RNase H) that cut both strands, inactivating the target mRNA. One disadvantage is that to ''knock down'' the levels of proteins that are constitutively expressed, a number of injections have to be given, often over several days. The antisense technique is best used against proteins that are expressed transiently, such as immediate early genes (IEGs). A further disadvantage is that to ensure that any effects seen are due to the specific antisense sequence used, it is useful to use more than one control sequence.

C. Transgenic Mice

As mentioned previously, the predominant form of LTP in the brain is dependent on the NMDA receptor. Functional NMDA receptors comprise more than one subunit and usually more than one type of subunit. For example, NMDAR1 subunits seem to be absolutely required for the survival of mice and are capable of assembling to form a working receptor. However, most receptors also contain NMDAR2 subunits, of which these are four different kinds (2A–2D). The NMDAR2 subunits do not form functional receptors on their own but modify the characteristics of NMDAR1 when they associate with it; each of the four subtypes combines with NMDAR1 to produce a receptor with slightly different characteristics. In the rat, NMDAR2A and NMDAR2B are strongly expressed in the hippocampus. The hippocampus has essentially no NMDAR2C (which is predominantly located in the cerebellum) or NMDAR2D (which is found in the thalamus and hypothalamus). Mice with targeted disruptions (knockouts) of NMDAR1 or NMDAR2B show no gross anatomical abnormalities in the brain but die after birth of respiratory failure and impairment of suckling response, respectively. Of the hippocampal NMDAR2s, electrophysiological studies suggest that NMDAR2B should be more effective than NMDAR2A in causing LTP. In a recent study, a transgenic mouse overexpressing the NMDAR2B was created and evaluated; the researchers called their transgenic ''doogie'' after a precocious fictional medical student Doogie Hauser. These mice show enhanced retention of spatial memory and of both context (hippocampal-dependent) and cued (hippocampal-independent) fear conditioning, and they were dubbed ''supermice'' by the media. However, these mice show faster extinction (i.e., forgetting) of fear conditioning and enhanced novel-object exploratory responses, which are not traits likely to enhance survival in the wild. Between 20 days of age and adulthood, the amounts of NMDAR2A and NMDAR2B in the hippocampus decline slightly. A better name for this transgenic mouse might be Peter Pan since the decreased expression of the 2B subunit in adulthood is counteracted by overexpression, keeping the complement of 2B in a ''child-like'' state.

D. The Temporal Control of Gene Expression

Specialized proteins bind to the control regions of a gene (called promoters or operators) and increase or decrease the probability of transcription. In bacteria, genes to counter tetracycline antibiotics are kept switched off by the binding of a repressor protein to the appropriate operon (bacterial control sequence). Tetracyclines bind to the repressor and release it from the operon, permitting gene expression. A useful mutation of this system works in reverse: An activator of transcription does not bind the control region unless tetracycline is present so that antibiotic switches the system on. Insertion of these bacterial genes into mammals can be used to provide precise temporal control of gene expression. In one mouse, the activator protein (called rtTA) is placed under the control of calcium/calmodulin kinase, so it is expressed abundantly, but only in the forebrain. A second mouse has a transgene inserted that is under the control of tetO, the region of DNA to which rtTA binds. Progeny of these two mice will show elevated gene expression in the forebrain in response to a tetracycline-class antibiotic, such as doxycyclin. A proof-of-concept study used calcineurin as the transgene. Calcineurin is a protein phosphatase, and as a simplistic model it predicts that if protein phosphorylation by specific kinases is critical for the induction of LTP and for memory, then overexpression of phosphatases such as calcineurin should neutralize the kinase effects by dephosphorylating some of the critical proteins. This is indeed the case: The mutant progeny show normal LTP and a

normal ability to recall their spatial training until doxycyclin is added to their food. Doxycyclin treatment significantly decreases both LTP and the ability to retrieve (recall) spatial training. When doxycyclin is withdrawn and the antibiotic clears from the animals' bodies, their LTP and ability to recall training revert to normal. Doxycyclin treatment does not alter the characteristics of the parental strains, which contain the individual components of the expression control system.

V. THE STORY OF ARC: A MOLECULAR BIOLOGICAL EXPLORATION OF LTP AND MEMORY

IEGs are expressed rapidly (within 30–60 min) after a stimulus. They include transcriptional factors, which act as intracellular signals, switching the expression of other genes on or off. However, IEGs also include proteins necessary for rapid extracellular signaling or for structural changes.

As an example of how molecular biology can be used to probe the processes underlying memory, consider the discovery and characterization of an IEG called *Arc* (activity-regulated cytoskeleton-associated protein) by Lyford and associates and Link and associates. Messenger RNA was extracted from the hippocampi both of control rats and of rats subjected to electroconvulsive stimulation. Subtractive hybridization was performed to isolate genes that were upregulated by stimulation. In order to confirm that the identified Arc DNA sequence could code for a functional protein, it was subjected to *in vitro* transcription/translation, which uses a mixture of the appropriate isolated cellular components to produce protein in a cell-free system. The predicted protein sequence of Arc indicated that it had no signal sequence for export outside the cell. Nor did it have long hydrophobic sequences or glycosylation sites, which are often diagnostic of a membrane protein; long hydrophobic sequences permit a protein to span the cell membrane, and glycosylation is a common feature of the extracellular domains of proteins. Sequence comparisons showed that one-half of Arc is closely related to α-spectrin, a cytoskeletal protein. The other half interacts with calcium/calmodulin-dependent protein kinase II. Measurement of Arc mRNA using Northern blot analysis showed that the unstimulated brain was enriched in Arc relative to other tissues, and that following electroconvulsive stimulation hippocampal Arc was elevated between 30 min and 8 hr, returning to basal levels by 24 hr.

When a gene product shows increased expression, the following is one of the first questions asked: Where in the tissue of interest is this expression taking place? This question is answered by *in situ* hybridization: Tissue slices are taken and exposed to radioactive nucleic acid sequences that are complementary to the mRNA of interest and therefore bind to it specifically. Exposure to film results in an autoradiograph that localizes the mRNA to anatomic structures and even to subcellular regions. At 15 and 30 min after electroconvulsive stimulation, Arc was expressed principally in the cell bodies of the dentate gyrus granule cells. After 1 hr, Arc was also found in the dendrites (see Fig. 2).

In order to confirm that the expression of mRNA is paralleled by protein production, bacterial expression systems are used to generate large quantities of pure protein from the mRNA sequence. Immunizing animals with the protein yields antibodies that react specifically with the protein. These antibodies can be used to localize proteins in a tissue slice, a technique called immunohistochemistry. The general pattern of Arc protein localization in unstimulated tissue matched that obtained by *in situ* hybridization. Four hours after electroconvulsive stimulation the number of granule cells in the dentate gyrus that expressed Arc protein increased from 1–2 to nearly 100%. Moreover, protein was not expressed in axons or synaptic terminals but was expressed in cell bodies and also in dendrites. In these regions, Arc protein was subplasmalemmar (i.e., just inside the cell membrane), and this localization resembles that of spectrin and F-actin, important cytoskeletal components. Since Arc resembles a cytoskeletal protein in structure and localization, its ability to interact with other cytoskeletal proteins was measured. Arc did not interact with highly purified actin, but it did bind to a less purified preparation containing actin and actin-associated proteins.

The behavior of Arc, a protein rapidly synthesized in the nerve dendrites and capable of interacting with the cytoskeleton, would be interesting if it occured only in response to a pathological stimulus such as electroconvulsive stimulation. Does synthesis of Arc occur under conditions that more closely resemble normal physiology? Stimulation that leads to LTP induction *in vivo* causes changes in Arc mRNA expression similar to those seen in response to electroconvulsive stimulation. Blocking the induction of LTP in this model with an NMDA receptor antagonist also blocks the changes

in Arc expression. Further analysis demonstrates that Arc is actually localized to the dendrites that are stimulated. As dentate granule cells extend into the molecular layer, they are contacted first (proximal to the cell body) by commissural/associational neurons, then (at an intermediate distance) by the medial perforant path, and finally (distal from the cell body) by the lateral perforant path. When electroconvulsive stimulation is used to generate Arc, there is no specific localization within the granule cell dendritic tree. However, when the afferent paths are stimulated separately, Arc mRNA is increased in the appropriate region of the dendritic tree. Immunohistochemistry confirms that Arc protein is localized in a similar way.

Are the increased expression of Arc and its subsequent localization distinct processes or are they related? Also, how is Arc targeted? As mRNA alone, with translation to protein occurring only at its dendritic destination, or as a polyribosome complex, with the newly synthesized protein required for localization? When Arc expression is increased by electroconvulsive stimulation (a process that causes no specific localization in the dendritic tree), subsequent high-frequency stimulation of the medial perforant path causes appropriate localization of the Arc mRNA within the dendritic tree, suggesting that localization is a process distinct from increased expression. Moreover, localization occurs in the presence of the protein synthesis inhibitors cycloheximide and puromycin, demonstrating that the signal sequence for localization is in Arc mRNA. An important negative control for all these data is that no other IEG so far discovered shows dendritic localization: mRNAs for these IEGs are retained in the cell body. A logical speculation is that Arc is required for the postsynaptic remodeling that occurs in the dendrite following high-frequency stimulation and that is necessary for synaptic plasticity.

It is known that the survival time of cellular mRNA is markedly decreased if it encounters a sequence that is complementary (antisense). The precise mechanism for this decreased survival time is incompletely understood, although it likely involves RNase H, an enzyme that specifically cleaves double-stranded RNA. If our speculation about the function of Arc is correct, treatment with oligonucleotide sequences (ODNs) antisense to Arc should change the pattern of LTP seen as a result of high-frequency stimulation. This proves to be the case: Direct injection of Arc antisense ODNs into the dorsal hippocampus significantly decreases the induction of LTP in the perforant path to dentate gyrus in the awake, behaving rat. In this experiment animals are injected in one hippocampus with antisense ODN; as a control, a scrambled-sequence ODN is injected in the other hippocampus. Both sides show the same initial LTP, but from 4 hr up to 5 days a significant difference is apparent, with antisense-treated hippocampi showing only 30–60% of control LTP.

Given the likely correspondence between LTP and memory, it is interesting that the injection of Arc antisense ODNs also impairs the ability of rats to retain a spatial memory. In this experiment, rats receive bilateral injections of either Arc antisense ODNs or the scrambled control; three hours later, they receive training in the spatial Morris water maze for 1 hr. It is known that this spatial training, like the different forms of electrical stimulation mentioned previously, normally causes an increase in Arc expression in the hippocampus. Both sets of rats acquire the task successfully, but when they are tested 2 days later control animals can successfully distinguish the target location, whereas the rats treated with Arc antisense ODNs cannot. Since Arc-dependent consolidation of the memory likely occurs between 1 and 2 hr after training, antisense ODNs can actually be injected immediately after the spatial training and still interfere with the 2-day long-term memory; when injected 8 hr after training, the antisense has no long-term effect.

It is well-known from electrophysiological experiments that the hippocampus contains "place" cells, whose electrical activity increases when the animal is in a particular spatial environment. If Arc is involved in spatial memory, then whenever the animal is placed in a particular environment Arc expression should be increased in the corresponding place cells. Placing the animal in a different environment should activate Arc in a different set of place cells. As noted previously, microscopic localization of Arc in tissues can be achieved using *in situ* hybridization; if the visualization process uses fluorescent instead of radioactive probes, the acronym FISH (fluorescence *in situ* hybridization) is used. The method used to measure the increased expression of Arc very shortly after environmental stimulation is denoted compartmental analysis of temporal FISH (catFISH). Like all mRNAs, Arc originates in the nucleus but is rapidly exported to the cytoplasm of the cell body. Unlike other IEG mRNAs, Arc is then cleared from the cell body by targeting to the dendrites. By examining Arc's distribution relative to the nucleus, one can determine how recently a given cell was stimulated. For example, taking an animal from its home cage and placing it in a particular environment (e.g., environment A) 5 min before sacrifice yields a subpopulation of hippocampal cells

with only nuclear labeling. If the sacrifice of the animal is delayed for more than 30 min, then there is a subpopulation of cells with only cytoplasmic labeling. How do we know that these subpopulations in different animals are comparable, or even that they are truly place cells? If an animal is exposed to environment A, returned to its home cage, and then reexposed to environment A immediately before sacrifice, a single subpopulation of cells shows both nuclear and cytoplasmic labeling—that is, the *same* subpopulation has been stimulated twice, at different times in the past. In hippocampal region CA1, this subpopulation represents about 40% of all cells. A completely different pattern is seen if the animal is exposed to environment A, returned to its home cage, and then exposed to environment B. Only 16% of cells in the CA1 show both nuclear and cytoplasmic labeling. If another 40% (fraction 0.4) of CA1 cells are activated by any given environment, then the number of cells stimulated in common by two different environments will be $(0.4)^2$ or 0.16 (i.e., 16%). We predict that 24% (40%−16%) of cells will be uniquely stimulated by environment A and the same number by environment B. The cells corresponding to environment A will show exclusively cytoplasmic labeling because of the delay prior to sacrifice. The cells corresponding to environment B will show exclusively nuclear labeling because no delay ensued. The experimentally determined values are 22 and 23%, respectively, showing the model to be internally consistent.

Given that the Arc story began in the dentate gyrus, it is interesting that although hippocampal regions CA1 and CA3 and the parietal cortex all show similar results using catFISH, the dentate gyrus shows essentially no Arc response to environmental change, or that ARC is not involved in storing spatial information in the dentate gyrus. This suggests that spatial data pass through the dentate gyrus without causing a change.

In summary, studies show that cellular and molecular events are the underlying mechanisms associated with the processing of information that leads to the permanent storage of memory. Interestingly, as suggested by Hebb, these cellular and molecular events are initiated by the activity between neurons.

GLOSSARY

anterior cingulate cortex A region of the medial frontal lobe involved in a variety of cognitive, motor, and emotional–motivational functions, including Brodmann's area 24 and perhaps the closely associated area 25.

attention A class of cognitive processes involving prioritization or selection among stimuli to be processed, tasks to be performed, or responses to produce.

frontal eye field A region centered at the intersection of the precentral sulcus with the superior frontal sulcus, that is, Brodmann's area 6. This region is involved in generation and control of eye movements.

reaction time The time elapsed from onset of the imperative stimulus to initiation of the subject's response.

saccade Rapid eye movement that changes the point of fixation from one location to another.

stimulus onset asynchrony The time elapsed from the onset of the first stimulus (or the cue) to the onset of the imperative stimulus.

Inhibition refers to mechanisms by which the nervous system suppresses information, restricts its use, or restrains its transmission from one place in the brain to another. This article addresses hypotheses about the role of inhibition at the systems level, considering the possible functional consequences of inhibitory processes for cognition and behavior. Ultimately, one might guess that at the neuronal level, inhibitory processes would be implemented via neuron-to-neuron communication in which release of inhibitory neurotransmitters reduces the probability of action potentials in postsynaptic target neurons of brain structures whose activity needs to be curtailed. As will be shown, however, reduction or suppression of activation is not the only way in which a systems-level inhibitory outcome can be achieved in cognition or behavior, although it is the most commonly proposed mechanism.

I. THE ROLE OF INHIBITION IN COGNITION AND BEHAVIOR

Cognition and the control of overt behavior rely on real-time orchestration of component cognitive processes or "mental operations." Each operation achieves a step in the sequence of steps leading from stimulus to response, intention to action, or thought to thought. A major distinction is made between reflexive or "automatic" operations and voluntary or "controlled" operations. The more automatic an operation is, the more able it is to occur without intention, needing only the appropriate stimulus conditions or information inputs to trigger it; to occur outside of

conscious awareness, without being noticed phenomenologically; and to run in parallel with other mental operations.

Automatic operations gain these properties either from genetic hardwiring or, more frequently, from repetition under relatively unchanging conditions. Hence, they sometimes occur as reflexes, and they become quite prominent in familiar situations and well-practiced tasks. Controlled operations are the opposite. The more voluntary or controlled an operation is, the more its execution is intentional, conscious, and demanding of serial attention. Controlled processes become prominent when dealing with novel situations to which reflexes and habits are poorly adapted or when pursuing particular goals in situations that are likely to trigger reflexes and habits that would produce incorrect or inappropriate behavior if unrestrained.

To achieve flexibility in dealing with both the familiar, unchanging aspects of the world and with novel events, it is important to make automatic and controlled processes work in concert. Inhibition provides a tool for curbing or regulating automated responses in the service of controlled assessment and reaction.

Just how fundamental a role is played by inhibition of automated responses can be appreciated by thinking about the developmental trajectory of reflexes across the life span. One of the central principles of neurology is that disease processes affecting higher brain centers, especially the cerebral cortex, are revealed by reappearance of primitive reflexes. The knee jerk of a normal person is tonically inhibited, but it can become hyperactive after damage to the spinal cord that interrupts descending inhibitory pathways from the motor cortex. The sucking reflex of infants disappears after the nursing years but can reappear in a patient with Alzheimer's disease. Presumably, with the development of the nervous system, these primitive reflexes are inhibited throughout adulthood but may be disinhibited and reappear due to nervous system insult.

Other reflexes remain active throughout the life span. Among the most common are reflexive orienting reactions that involve the automatic deployment of attention to a suddenly appearing visual stimulus or a loud sound. Because these are very common occurrences, such attentional reactions are frequent and do not always occur at convenient times. When controlled deployment of attention is required by task performance, disruptive reflexive deployments may need to be inhibited.

Analogous problems can arise in controlling responses that are not reflexes but have become automated through practice. Attention deficit and hyperactivity disorder is a persistent individual difference characterized by an impulsive inability to resist engaging in prepotent or automated actions triggered by task-irrelevant stimuli in the environment or task-irrelevant thoughts in the mind. Intrusion of an unwanted or inappropriate automatic response occasionally occurs in normal children and adults as well. This can be seen in "slips of action" in which distraction of attention while carrying out a low-frequency task can result in inadvertently executing a different task that is higher in frequency given the situation and stimulus environment.

Other inhibitory functions are aimed at suppressing unwanted or incorrect perceptions and thoughts rather than controlling attention or inhibiting overt actions. These extraneous mental representations may become activated through relatively automatic processes of generalization because they are similar to correct perceptions and thoughts, or they may become activated because the environmental situation is ambiguous and admits multiple interpretations, only one of which is relevant to the task at hand. It is obvious that the wrong interpretation can be reached in an ambiguous situation, and if so it will need to be replaced. Less obvious, perhaps, is the possibility that all the interpretations of an ambiguous stimulus might be computed relatively automatically at an early stage of processing on every occasion, with one chosen for further processing at a later stage. In either case, contextually inappropriate interpretations will be active at some point in task performance and will need to be put aside or eliminated. This may involve inhibition. In this regard, Sir John Eccles wrote the following in 1977:

> *I always think that inhibition is a sculpturing process. The inhibition, as it were, chisels away at the diffuse and rather amorphous mass of excitatory action and gives a more specific form to the neuronal performance at every stage of synaptic relay.*

In this article, we present several examples representing the types of inhibitory function we have just described. Some are examples of inhibition regulating the deployment of attention. Others are examples of inhibition enabling disengagement from ongoing or automatically triggered responding so that overt behavior can be under voluntary and strategic control.

Still others are examples of inhibition tuning and sharpening the representation of the stimulus produced by perception or the interpretation of the situation produced by higher cognitive processes.

II. ATTENDING TO A SPATIAL LOCATION

Orienting of visual attention to a point of interest is commonly accompanied by overt movements of the head, eyes, or body. Attending may originate at will, such as when we decide to look at a particular location where something of interest is expected, or it may originate reflexively without intention when something captures our attention, such as when we orient to a flash of light in the dark or to a movement in the periphery of our vision. In everyday life there are constantly competing demands on attention by the outside world as well as from internally generated goals. The need for mechanisms to arbitrate between these competing demands is straightforward: This must be done so that they can be integrated, prioritized, or selected among to provide coherent and adaptive behavior.

Michael Posner developed a paradigm widely employed to study visual spatial attention. Figure 1 shows the basic features of this paradigm. In a typical experiment, the subject is first presented with three boxes on a computer screen. A trial begins with a fixation cross at the middle box. After a short interval, one of the boxes may flash briefly, and a target (an asterisk) appears in one of the peripheral boxes. The subject is asked to respond as quickly as possible, by pressing a key, to the appearance of the target. Reaction time (RT) is measured (in milliseconds) from target onset until the subject's response. It is possible to study covert attention by asking the participants not to move their eyes and by measuring keypress responses (rather than saccade latencies).

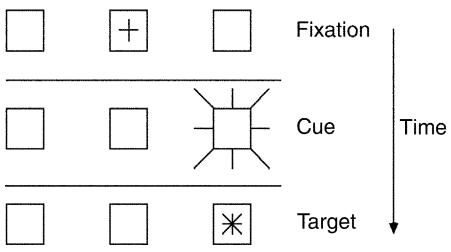

Figure 1 Basic paradigm for spatial attention, showing an exogenous cue and a valid trial.

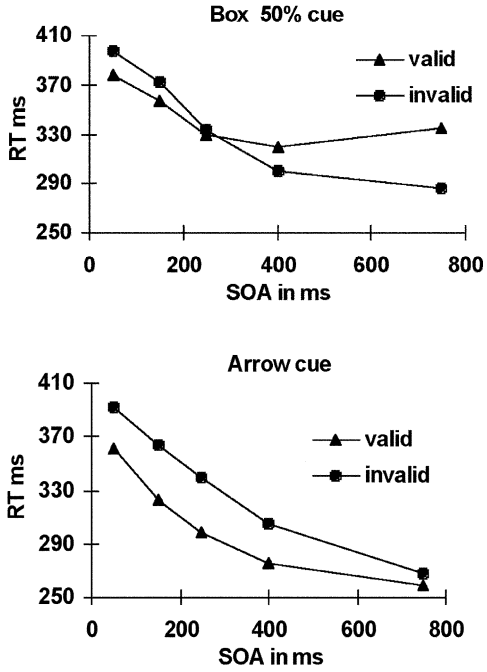

Figure 2 Typical time course for effects of a peripheral nonpredictive luminance cue (box 50% cue) and a central predictive arrow cue. The task is a simple RT key press response to the appearance of the target. Mean detection RTs are presented as a function of cue–target interval (SOA) for valid and invalid cue conditions.

The cue may summon attention to the target location, in which case it is a *valid* cue, or it may summon attention to the wrong location, in which case it is an *invalid* cue. For volitional goal-directed shifts of attention, often called *endogenous* shifts of attention, a central arrow serves as a cue and predicts where the target is likely to occur in most trials. That is, in 80% of the trials the target will appear at the valid cue location and in 20% of the trials the target will occur at the invalid cue location. For reflexive stimulus-driven shifts of attention, often called *exogenous* shifts of attention, the peripheral luminance change that serves as a cue has no predictive value with respect to where the target will occur (e.g., in 50% of the trials the target will occur at the valid cue location and in 50% of the trials the target will appear at the invalid cue location). In order to measure the effectiveness of the cue in summoning attention, researchers have manipulated the time interval between cue onset and target onset [the stimulus onset asynchrony (SOA)]. The typical effects of the two types of cues are depicted in Fig. 2. The top panel of Fig. 2 shows the time course of a

nonpredictive peripheral luminance cue on summoning reflexive exogenous attention, and the bottom of Fig. 2 shows the time course of a predictive central arrow. These results were achieved in a covert attention experiment, with no movement of the eyes. The two cues are similar in the sense that in both types of cues the facilitory effects begin at 50 msec. However, there are differences. With endogenous cueing, the facilitory effect appears to be more sustained. With peripheral cueing, the advantage at the cued location changes, after a few hundred milliseconds, into an inhibition resulting in longer RTs for the cued location. No such inhibition is seen with endogenous cueing. These features of Fig. 2 will be discussed next, each related to a different mechanism of inhibition generated by the deployment of spatial attention.

A. Noise Reduction and Suppression of Competing Stimuli

Figure 2 shows that for about 200 msec after an exogenous cue and for 600 msec or longer following an endogenous cue, RT to detect the onset of a target is shorter when a target appears at the valid cue location compared to the invalid cue location. This RT effect indicates that attention has been drawn to the location of the cue, thereby facilitating the detection of the target at the valid location compared to the invalid location.

It is generally agreed that the presence of attention due to valid cueing increases the signal-to-noise ratio or sensitivity of information processing at the cued location. Of course, this could happen either if the signal from the attended location were enhanced (a facilitatory process) or if noise that might interfere with that signal were reduced or suppressed (an inhibitory process). The available evidence supports a combination of these two effects.

First, valid cueing can increase sensitivity even when a single target appears in an otherwise blank visual field. Since there are no other stimuli around to produce any noise or distraction, it would appear that attention is enhancing the signal from the attended location. However, the effect of cueing a target in an otherwise blank field is often small and sometimes disappears. The impact of cueing is usually greater when the target is accompanied by distracting stimuli at other spatial locations. From such evidence it has been argued that the primary contribution of spatial attention, especially in real-world visual environments, is to reduce noise or cross talk from unattended stimuli that if unsuppressed would interfere with processing the attended stimulus.

Direct evidence for inhibition of cross talk-based interference from unattended stimuli comes from single-cell recording in extrastriate cortical areas of the ventral object-processing pathway of monkeys. When two stimuli are present in the receptive field of a cell in one of these areas (e.g., V4 or TEO), the cell's response is less than if only one of them was present. This reduction in activity shows that the two stimuli interfere with each another's ability to activate the cell. However, if the monkey attends to one of the stimuli for the purpose of performing an experimental task, the cell's response returns to approximately the same level as if the attended stimulus were presented alone. This restoration of responsiveness shows that the unattended stimulus is being filtered out of the cell's receptive field and hence no longer interferes with processing the other stimulus. Analogous evidence that humans have a similar attention-driven mechanism of noise reduction through suppression of competing stimuli comes from functional magnetic resonance imaging (fMRI) experiments reported by Kastner and colleagues.

B. Inhibition of Return

A second important feature of Fig. 2, (seen only in the top), is that when SOA's following an exogenous cue are longer than 2–300 msec RT to detect a target is *longer* when a target appears at the valid location compared to the invalid location. That is, facilitation is transformed into inhibition. This is a standard outcome of experiments with nonpredictive cues, in which subjects have no reason to use the cue to guide attention and would prefer to keep attention focused at fixation or spread diffusely across the display.

Michael Posner and Yoav Cohen analyzed the effect of nonpredictive cues at the longer SOA durations, now known as the inhibition of return (IOR) phenomenon. Facilitation changes to inhibition (i.e., IOR) 200–300 msec after cue onset. IOR lasts for about 3 or 4 sec; it works in environmental rather than in retinal coordinates, it is not generated by endogenous cues unless the oculomotor system has been activated, and it declines as the distance from the original cued location increases.

What is the explanation for this counterintuitive transformation of facilitation into inhibition? Exogenous cueing commonly produces a reflexive shift of attention to the cued location or object (producing the

early facilitation in Fig. 2). Even when people are asked not to pay attention to the cued location or it is in their favor to ignore the cued location, they find it difficult to avoid reacting to a peripheral luminance change and often cannot refrain from orienting to this kind of cue. As much as such efficient and rapid orienting is important for predatory and defensive behavior, voluntary control of reflexive orienting and the ability to strategically search the environment are also critical for survival. It appears that IOR is a mechanism that enables the organism to disengage from reflexive orienting and switch to the control of a more voluntary attentional system. How does it work? It seems that a location (or an object) that was recently cued or searched is tagged and IOR biases attention away from responding to events occurring at the tagged locations. Avoidance of tagged locations encourages search in new spatial locations. Accordingly, IOR seems to be a mechanism that supports efficient foraging behavior, which involves strategic search of the environment and use of knowledge about previous searched locations or objects.

Several lines of evidence point to the midbrain superior colliculus (SC) as the neural substrate for the implementation of IOR. IOR is abnormal in patients with damage to the SC. This has been shown in patients with midbrain degeneration due to progressive supranuclear palsy and in a patient with unilateral lesion to the SC. IOR is preserved in the presence of hemianopia, in which only the extrageniculate pathways are available to process visual information. It is present in newborn infants in whom the geniculostriate pathway is not yet developed. It is generated asymmetrically in the temporal and nasal visual fields. The temporal hemifield has stronger collicular representation than the nasal hemifield; accordingly, for monocular presentations of stimuli, IOR is larger for stimuli presented to the temporal than to the nasal hemifield. However, it seems that cortical structures play a role in the generation of IOR. In particular, the parietal lobe has been suggested as a structure that conveys the spatial coordinates of the tagged locations to the SC.

C. Inhibition of Reflexive Orienting

As suggested previously, other cortical structures in addition to the parietal lobes regulate activation of the SC. In 1966, James Sprague reported that occipitotemporal cortical ablation in cats produced stable hemianopia. However, visually guided behavior was restored by ablation of the dorsal midbrain contralateral to the cortical lesion. He noted,

> *This initial hemianopia is apparently due to depression of function of the colliculus ipsilateral to the cortical lesion, a depression maintained by influx of inhibition from the crossed colliculus. Thus, removal of the contralateral tectum, or splitting of the collicular commisure, abolishes this inhibition and allows the return of function in the ipsilateral colliculus, and with it the recovery from hemianopia.*

This phenomenon is called the Sprague effect. A reversed version of the Sprague effect can be found with lesions to the frontal lobe, which will be described later.

The SC is involved in triggering reflexive saccades, whereas cortical mechanisms are needed for generating voluntary saccadic eye movements under strategic guidance. Early work showed that patients with frontal cortex lesions have difficulty executing saccades in response to verbal commands. When these patients scan pictures their eye movements are controlled by external stimuli rather than by instructions. In addition, lesions of the frontal lobes produce a deficit in inhibiting ''reflexive glances.'' The patients seem unable to resist moving their eyes in the direction of a peripheral stimulus even when instructed to prevent such eye movements. It appears that the frontal eye fields (FEFs) are critical components of the frontal circuitry underlying inhibition of reflexive saccades and endogenous control of eye movements. Unilateral lesions of the FEF may shorten latencies of reflex saccades to targets in the contralesional field. Moreover, single cell recordings show that the FEF contains cells that respond in temporal correlation with purposive saccades even in the absence of an exogenous visual stimulus.

In line with these reports, Henik, Rafal, and Rhodes found that lesions to the FEF have opposite effects on endogenously activated and visually guided saccades to external stimuli. In a typical trial of an experiment examining saccades in FEF patients, subjects saw a visual cue (''get ready'') followed by a target (''go''). The cue was informative (a small arrow) or neutral (a double-headed arrow). There were two types of target go signals: an asterisk appearing at the periphery (used to elicit reflexive, exogenously triggered saccades) or a large arrowhead in the center of the display pointing left or right (used to measure voluntary, endogenously generated saccades). The efficacy of saccade

preparation was measured as facilitation in saccade latency in the informative cue condition compared to the neutral cue condition. Patients with FEF lesions presented slower endogenous saccades (in response to the central arrow) to the contralesional field, whereas exogenously triggered saccades (in response to the peripheral targets) were faster to the contralesional field (a reversed Sprague effect). These results indicate that the FEF is involved in generating endogenous saccades and therefore lesions in this region increase their latency. In addition, the FEF is involved in visually guided saccades through inhibitory connections to the SC. It seems that the FEF has the opposite effect on the extrageniculate visual system from occipital lesions. That is, whereas occipital lesions reduce activation of the ipsilesional SC (producing increased activation of the contralateral SC), FEF lesions disinhibit the ipsilesional colliculus, producing suppression of collicular function contralateral to the cortical lesion.

Taken together, this evidence indicates hierarchical control over eye movements. A relatively automatic system depending on SC is stimulus driven, responding to the appearance of new objects in the visual field and to movement, especially in the periphery. This system is also sensitive to sound via interactions between superior and inferior colliculus. Barry Stein and colleagues have shown that reflexive saccades and head turning are elicited when a movement that is subthreshold for triggering an orienting response is accompanied by a sound from the same spatial location that is also too weak by itself to cause orienting. The second level of control is cortical, depending on FEF. It exerts endogenous control rather than responding reflexively to stimulus inputs, implementing voluntary eye movements, and inhibiting the responses of the automatic system when such responses would conflict with the intended voluntary movement.

Interactions between automatic orienting and voluntary control have been studied extensively in the *antisaccade* task. This task requires subjects to move their eyes *away* from a stimulus that appears abruptly in the visual field—a stimulus that would ordinarily *attract* a reflexive saccade. Endogenous control is far from perfect in this difficult task. Errors occur in which the eyes move toward the abruptly appearing stimulus, and changes in error rate with experimental manipulations and subject characteristics can be used to diagnose the effectiveness of endogenous control. More evidence is provided by the latencies of correct responses away from the stimulus, which are slower than either reflexive saccades toward the same stimulus or voluntary saccades toward stimuli that do not elicit reflexive saccades (either because they are already present in the visual field or because they are new but their onset is ''ramped up'' slowly to eliminate visual-onset transients). In general, factors that increase the perceptual salience of the stimulus, such as brightness, tend to increase errors and slow latencies, as do factors that reduce the subject's ability to concentrate on the task, such as attentional load, and factors that reduce the subject's ability to predict when effortful control will be needed, such as randomly varying foreperiods prior to stimulus onset. Furthermore, patients with frontal lobe damage have great difficulty with the antisaccade task.

III. ''SELECTION FOR ACTION'' AND CONFLICT RESOLUTION

The antisaccade task involves more than inhibiting the reflexive response toward the abruptly appearing stimulus. The subject must successfully implement another response at the same time the reflex is being inhibited. This second response is less well learned or less natural than the one that must be inhibited. Hence, the competition created by the automatic response is powerful, and resolving the conflict in favor of the less well-learned response is difficult. The antisaccade task is one example of a common method for studying the regulatory processes of cognitive control. This method involves creating a conflict situation in which the subject has to respond to one stimulus or to one aspect of the stimulus and ignore another stimulus or another aspect of the stimulus. In these situations, the subject needs to focus on the target (a stimulus or an aspect of a stimulus) and ignore all the rest of the display. Failures in attention are commonly revealed in two ways: (i) reduction in efficiency of responding to the target when the irrelevant features of the display are present and (ii) indications for processing of the irrelevant material, especially when it clearly interferes with processing of the target. The two most widely used paradigms for studying this type of selection are *Stroop color naming* and *negative priming*.

A. Stroop Color Naming

J. Ridley Stroop, a theologist with a side interest in psychology, sought an experimental method that would enable him to measure the interference of one stimulus dimension on attempts to process another. In

1935, he published a seminal paper describing three experiments. The second experiment asked subjects to name the color of the ink of color words (e.g., the word ''red'' printed in green ink) or the color of colored squares. The first condition is called ''incongruent'' and the second ''neutral.'' Stroop found that the words interfered with naming the color. That is, RT to the incongruent condition was slower than RT to the neutral condition. Later, researchers added a congruent condition to the task (e.g., the word ''green'' printed in green ink). The congruent condition enabled one to look at facilitation, which is the difference in RT between congruent and neutral trials. It is commonly found that although facilitation in the congruent condition is small and on many occasions not significant, interference in the incongruent condition is robust and significant. Since 1935, this type of conflict has been studied extensively using variations of Stroop's color-naming task and in other Stroop-like situations with a wide variety of different stimuli and task demands. All studies converge on the conclusion that people cannot suppress the irrelevant dimension if it is heavily practiced and consequently overlearned (like reading words). Hence, the Stroop effect is considered a powerful example of automatic processing.

Nevertheless, several studies have shown that readers can modulate and partially control the impact of the word. Increasing the proportion of congruent trials relative to incongruent trials produces a larger Stroop effect. Moreover, even when the numbers of congruent and incongruent trials are kept constant while the proportion of neutral trials changes, the effect can be altered. It seems that the expectation to face a relatively large proportion of conflict trials prompts the adoption of a strategy that helps reduce interference. In addition, it seems that language competence may modulate the effect. When bilinguals are tested, under certain conditions they can reduce the effect in their first language but not in their second language. Note that they experience interference in both their first and their second language, but they are better able to control reading (i.e., reduce Stroop interference) in the language in which they are more competent.

Neuropsychological studies of brain-injured individuals suggest that the left frontal lobe is crucial to successful performance of the Stroop task. In particular, it has been reported that injury to the left dorsolateral prefrontal cortex results in enlarged Stroop interference. This result suggests that the Stroop interference presented by noninjured individuals is an underestimate of the potential interference. Stroop interference presented by the noninjured individuals is the product of automatic intrusion of the irrelevant word and their ability (admittedly not perfect) to inhibit this reading. In addition, it points to the involvement of the left dorsolateral prefrontal cortex in the control processes by which Stroop interfence is modulated. Consistent with this lesion evidence, neuroimaging studies of blood flow and changes in blood oxygenation during task performance show that the incongruent condition of the Stroop task activates left dorsolateral prefrontal cortex more than the neutral or congruent conditions. Even more noticeable in neuroimaging studies is differential activation of the anterior cingulate gyrus. Barch, Braver, Sabb, and Noll suggested that this medial–frontal structure is also active in a variety of other tasks in which selections must be made among competing stimuli, stimulus properties, and responses to them.

Of course, the crucial question in the present context is whether resolution of conflict in the Stroop task involves inhibition. Many theorists interpret the task in this way, although a well-known computational model of Stroop performance suggested by Cohen, Dunbar, and McClelland is able to account for many aspects of performance in the Stroop task by facilitation of the less automated process of color naming rather than inhibition of the more automated process of word reading. The phenomenon discussed next offers a more demanding and therefore more analytic test.

B. Negative Priming

In the incongruent or conflict condition of Stroop color naming, an additional slowing of performance is observed, over and above the usual interference, if the color name to be produced on any given trial is the same as the color word that had to be ignored on the immediately preceding trial. This effect, which has been dubbed *negative priming*, can be found in a wide variety of task situations in which two stimuli occur on each trial, one to be ignored and the other requiring a response. When a just-ignored distractor becomes the target on the next trial, responding is slowed relative to not having ignored the current target item in the recent past. Similar slowing occurs when there is just one stimulus on each trial to which subjects must produce a newly learned arbitrary response. Suppose that subjects must say ''car'' whenever they see ''bike'' or a picture of a bike, ''plane'' whenever they see ''car'' or a picture of a car, and ''boat'' whenever they see ''plane''

or a picture of a plane. Now suppose that as a prime the subject sees "car" and correctly says "plane." If the succeeding target is "bike," production of the correct response "car"—the overlearned response that had to be avoided when processing the prime—will be slower than if the prime was an unrelated stimulus that required an unrelated arbitrary response, such as "plane"–"boat."

The dominant interpretation of negative priming invokes a selective process that occurs while processing the prime. To respond appropriately, subjects must select against the distracter item that is the nonimperative component of the prime (or, in a task such as that of Shiu and Kornblum's just described, they must select against the overlearned but contextually inappropriate response that the prime tends to elicit). The act of selection leaves the distractor or the overlearned response in a state that makes it more difficult to process if it recurs as the target.

Two sorts of hypotheses have been offered about how this act of selection could be implemented. According to the distractor inhibition hypothesis, attentional operations actively inhibit either the prime's perceptually activated mental representation, in order to prevent it from competing for access to response selection operations, or the link between the prime's mental representation and the action ordinarily associated with the prime, in order to make that response unavailable. Inhibition takes time to dissipate. Therefore, if the inhibited representation or response link is needed soon thereafter for processing a target, more time and effort will be required for its activation. George Houghton and Steven Tipper constructed a simulation model embodying such processes.

According to an alternative proposal, the episodic retrieval hypothesis of W. Trammell Neill and colleagues, attentional operations mark the distractor item with a "do not respond to this stimulus" tag or the overlearned response with a "do not produce this response" tag. The tag provides an instruction that guides decision and response selection, and it remains a part of the experience of having processed the prime that is stored in episodic memory. When the target appears it acts as a cue to retrieve this memory. The tag that served the subject well when the tagged stimulus or response needed to be ignored causes confusion and interferes with performance when the tagged item becomes the target.

Note that the episodic retrieval hypothesis does not propose inhibition in the classic sense of reduction or suppression of activation. Its inhibitory process is "symbolic" rather than "analog," acting through an influence on a mental representation's informational content rather than its level of activity. Considerable effort has been expended attempting to distinguish these two underlying mechanisms by which an overtly inhibitory behavioral outcome might arise. Arguments have begun to appear that both mechanisms may be at work, and partly as a solution to the dilemma, in 1998 Milliken *et al.* made an important attempt to reinterpret negative priming in terms of the difficulty of deciding whether retrieved episodic memories of past processing should or should not be used to guide current performance rather than whether they have been inhibited or tagged with negative content. This debate illustrates a crucial point mentioned earlier. Inhibition of behavior (i.e., slowing of overt performance) does not necessarily signal inhibition of mental processing, if what one means by "inhibition of mental processing" is reduction or suppression of activation. Considerable theoretical analysis and empirical investigation are often required to make this determination.

IV. PRIMING AND RETRIEVAL FROM MEMORY

It is often possible to retrieve information from memory at will (though sometimes, of course, such intentional attempts at retrieval fail). At the same time, there are often occasions when thoughts come to mind without any apparent intention. Here again, we are dealing with two fundamental aspects of cognition: controlled and automatic processing. In the domain of retrieval of information from memory (general knowledge as well as specific episodes of experience), these two aspects of cognition have been investigated by exploiting *priming effects*. "Priming" consists of an alteration in the speed or accuracy of responding to a stimulus such as a word or object due to a previous encounter with that stimulus or with related stimuli.

A. Repetition Priming

Repetition priming refers to the change in responding to a word or an object as a result of a previous encounter with that same item, either in the same task or in a different task. Responding to words or objects is typically improved due to this previous experience (usually more so when the task as well as the stimulus item remains the same). For example, if a word appears for a second time in a task that requires reading the target aloud (naming task) or deciding whether the

target is a word or a nonword (lexical decision task), responding is faster and more accurate than for words appearing for the first time at the same level of overall practice in the task. In addition, repetition priming can influence the probability of producing a previously encountered item as a response when a task allows multiple possible answers on each trial. For example, suppose that in the study phase of a two-phase experiment subjects are asked to study a series of words. After a delay that can range from minutes to hours they are given three-letter word stems and asked to complete each stem with the first word that comes to mind (e.g., gre_ for green). In this word stem completion task, the repetition priming effect appears when subjects respond more frequently with words that had been studied earlier than with words that were not encountered in the study phase.

As can be seen from the examples, repetition priming is commonly examined using tasks that do not require conscious recollection of past experience with the stimulus item to complete. Therefore, it potentially represents a nonconscious or unintended effect of that experience. Such effects are called implicit memory in the repetition priming literature. When it can be documented that repetition priming has occurred without conscious recollection, the priming is called implicit memory, and as such it represents another example of automatic processing.

Brain imaging studies using positron emission tomography (PET) and fMRI have shown that priming is accompanied by reduced neural activity within areas that were initially activated to perform the task. Reduced neural activity was found in occipital visual cortex (Brodmann's area 19), left frontal cortex, and inferior temporal cortex. Whereas the reduced neural activity in visual cortex is specific to visually presented stimuli, the activity reductions in left frontal cortex occur regardless of cue modality (visual or auditory). The reduced activity within the left frontal cortex suggests an amodal priming effect that represents access to the meaning of the word rather than to its visual or orthographic representation. Analogous modality-specific and amodal effects have been observed with objects.

Single cell recording in monkeys provides evidence about the neural mechanisms that might mediate these repetition priming effects, at least for nonverbal stimuli. Repeated experience with the same visual stimulus leads to suppression of neuronal responses in subpopulations of visual neurons. This "repetition suppression" was found in the delayed matching-to-sample task. In these studies a monkey was presented with a sample stimulus followed by a sequence of test stimuli. The animal was rewarded for indicating which test stimulus matched the sample. For example, the monkey was presented with the sequence A … B … C … A and was supposed to respond to the final A. Under these conditions, the common type of neural response was suppressive, and it was graded by similarity. The more similar the test stimulus was to the sample, the more the neural response was suppressed. Moreover, repetition suppression was associated with item repetition, whether the repeated item was the target or a distractor. Repetition suppression was found to be stimulus specific and long-lasting. In addition to visual cortex, this effect was recorded in the inferior temporal cortex and also in some regions of the prefrontal cortex.

Robert Desimone suggested that the reduction in cortical activation in human neuroimaging studies such as those described earlier was due to a repetition suppression effect such as that documented in monkeys. This repetition suppression effect at the neuronal level would result in a decrease in the total number of activated cells (and hence in a reduced demand for oxygenated blood, producing the signal change measured in PET and fMRI). This reduced population of neurons, according to Desimone, provides a sharpened stimulus representation. The prime tunes the population of neurons so that a selective subpopulation that carries the critical features of the stimulus gives a robust response when the stimulus recurs, whereas other neurons, which are probably related to other stimuli, are suppressed. The more selective representation allows for a more efficient responding upon the next encounter with the stimulus. Desimone's argument recalls the words of Sir John Eccles quoted earlier.

B. Semantic Priming

Semantic priming arises because the brain makes use of relations among similar or related stimuli in addition to using past experiences with the same stimulus. In the basic version of the semantic priming paradigm, subjects are presented with two successive stimuli called the prime and the target. They are usually asked to respond overtly only to the target. When words are the stimuli, the task may be naming or lexical decision. Supposing that the target is the word "nurse," the prime can be a related word (e.g., "doctor"), an unrelated word (e.g., "bread"), or a neutral stimulus (e.g., a row of X's). Under these conditions, the

semantic priming or relatedness effect emerges. This effect can be described as a greater speed and accuracy of performance in the response to a target word when it is presented after a semantically related prime word than when it is presented after an unrelated prime word or after a neutral stimulus. This effect has been documented in a variety of situations. The semantic priming effect can occur when people are asked to pay attention to the prime and also when they do not pay attention to the prime, or even when they are unaware of its identity and do not phenomenologically realize that a prime has occurred. That is, semantic priming effects still exist when the target is presented very briefly and masked by visual noise presented immediately following the prime so that people believe they have seen only the visual noise and are not aware of the presence of the prime.

James Neely studied automatic and controlled processes by examining the ability of subjects to switch between semantic categories in an arbitrary fashion. He asked his subjects to think of parts of a building when the prime was the category name "body" (e.g., "body"–"door"). Subjects were able to follow the instructions when the time between the prime and the target (i.e., SOA) was long enough (e.g., 750 msec). That is, they responded faster to "door" following "body" relative to "door" following an unrelated prime (e.g., "tree") or even a neutral prime (e.g., XXXX). However, they were not able to switch from one category to another when the SOA was short (e.g., 250 msec). What was the fate of the rejected category? That is, when the prime was "body" and the subject made an effort to think of the category "building," what happened to parts of the body such as "arm"? "Arm" appearing after "body" was facilitated at short SOAs (<300 msec) and inhibited at long SOAs (between 500 and 2000 msec)—that is, RTs for related trials ("body"–"arm") were longer than RTs for neutral trials and equivalent to those for unrelated trials ("bird"–"arm").

Hence, priming can be achieved both by unintentional automatic activation, as shown by priming from masked words of which subjects are unaware, and from consciously perceptible words at short SOAs even when subjects are trying to think of unrelated words. However, priming can also be achieved by intentionally focusing on a concept and generating possibilities following some rule, even an arbitrary rule as in Neely's "switch condition," although such intentional focusing takes more time than automatic activation. Thus, these findings support the existence of two mechanisms of semantic priming. The first is automatic, nonconscious, and can work without attention. By analogy to repetition priming, one might wonder if it is mediated by reduction of neural response in structures that store semantic knowledge. The second is voluntary, conscious, and occupies attention. One might expect that this mechanism would be associated with neural structures involved in the executive control operations of working memory, and that invoking this mechanism would increase neural activation in those structures. To date, however, we do not know of any neuroimaging studies of semantic priming.

C. Inhibitory Semantic Priming and the Center–Surround Theory of Retrieval Operations

Neely's evidence for inhibition of related words in his switch condition is one of the few instances in the literature in which semantic relatedness between successive stimuli harms performance in speeded tasks, such as naming or lexical decision. Another instance was reported by Dale Dagenbach and colleagues. They found that in certain circumstances lexical decisions following semantically related primes are slower than lexical decisions following unrelated primes—an absolute inhibition effect associated with semantic relatedness. This inhibitory priming occurs as a consequence of attempting to retrieve the meaning of a perceptually presented word when the meaning is weakly activated—either because the word is masked and hence perceptual input is easily confused with other input or because the word is newly learned and hence its representation in semantic memory is weak and easily confused with or overwhelmed by other representations. In either case, the weakly activated meaning is likely to suffer interference because other representations are activated that are similar but incorrect. Dagenbach and colleagues proposed that in such circumstances, the attempt to retrieve the weakly activated semantic code is accompanied by active inhibition of the related information that is producing the interference. This inhibition reflects the operation of a center-surround attentional mechanism, which works to facilitate a semantic code on which it is focused or "centered" while inhibiting "surrounding" codes. These are codes that are similar or related to but different from the desired code and are competing with it for retrieval. The center-surround hypothesis predicts that repetition priming should be facilitatory at the same time that semantic priming is

inhibitory—a prediction that has been confirmed. Analogous findings have been reported by Steven Lehmkuhle and colleagues in the domain of spatial rather than semantic processing, suggesting that inhibition of similar or closely related representations may be a generalizable strategy for conflict resolution in the central nervous system.

V. EXECUTIVE CONTROL OF TASK PERFORMANCE: STOPPING AN ONGOING THOUGHT OR ACTION

Sometimes we start thinking about something or start to perform an action, only to realize it does not fit with our primary goal or our general plan at the moment or that our goal has changed and it is no longer appropriate. Such situations call for a change in the course of thought or action. We must stop the current thought or action in order to be able to switch to another one. An experimental method for studying this common example of executive control is the *stop signal paradigm* developed by Gordon Logan.

In this paradigm subjects are engaged in a primary task. In a relatively small proportion of trials they are signaled to stop before executing the response to the primary task. For example, participants can be asked to respond in each trial by pressing a button to an X and another button to an O. In addition, they are asked to withhold their response if a tone is presented at any point during a trial. The tone is presented in 25% of the trials at various delays after onset of the primary stimulus. Performance in this task can be successfully modeled as a race between a "go process" (perceiving and responding to the primary stimulus) and a "stop process." The stop process is conceived to be a separate sequence of mental operations that involves perceiving the stop signal and intervening in the ongoing sequence of operations involved in the go process or primary task. If participants finish the stop process before the go process, they inhibit their response to the primary stimulus. If they finish the go process before the stop process, they produce a response to the primary stimulus, failing to inhibit it. RT to the go signal can be measured directly, whereas stop-signal RT (the time needed to cancel the planned response) cannot be measured directly (since its behavioral signature is the absence of action and hence there is nothing overt to measure). However, Logan's race model provides quantitative methods for estimating the stop-signal RT.

Research applying this model shows that young adults can stop a wide variety of actions (key presses, hand movements, squeezes, and speech) very quickly, with an estimated latency from the stop signal of about 200 msec. Williams and colleagues reported that the ability to stop improves developmentally throughout childhood (i.e., stop-signal RT decreases) and then remains approximately constant across much of adulthood, falling off slightly but nonsignificantly in old age. Interestingly, speed of responding in most tasks that would be used as a primary task in this paradigm—the go process—also improves throughout childhood, but peak performance in young adulthood is followed by significant slowing beginning in middle adulthood. Thus, there appears to be a difference between the developmental trajectory of the execution of primary tasks and that of the type of inhibitory control represented by stopping. This supports Logan's hypothesis that processes governing inhibition are separate from those governing execution of speeded primary processing. Other research, however, shows that in old age the probability of stopping successfully does deteriorate, even if stop-signal RT remains fairly constant on those trials in which the stopping process succeeds. This suggests that old age may involve a loss of concentration in which inhibitory control processes are less likely to be implemented appropriately, even though they may still work effectively once deployed. Although this conclusion is consistent with the available data from the stopping paradigm, there is more to the relationship between age and inhibition. As will be discussed later, a major theory of cognitive aging proposes that most inhibitory functions decline in old age.

In addition to developmental changes, the ability to inhibit one's actions in the stopping paradigm is related to some personal characteristics and individual differences. Stop-signal RT varies with impulsivity, being longer for more impulsive individuals. Hyperactive children have trouble stopping. Their stop-signal RT is longer than that of normal controls and they fail to inhibit responding on many occasions. This pattern is not due to a failure to detect the stop signal itself but rather to a deficit in the inhibitory mechanism that implements stopping. Moreover, stimulant medication (methylphenidate) that improves behavioral symptoms of hyperactive children also improves their stopping performance.

Event-related potentials suggest two loci at which the stop process exerts its impact—a central locus in frontal cortex that acts on motor planning and execution operations and a more peripheral process that acts on descending motor commands after they have left cortex. Evidence on the frontal locus comes

from application of the stop-signal paradigm to examine gaze control in the FEF of monkeys by Jeffrey Schall and colleagues. Recording from single neurons in FEF showed that movement-related activity, which began to increase when a signal to move the eyes was presented, decreased when a signal to cancel the saccade was presented. The activity associated with this inhibition began to decrease before the stop-signal RT was over. It seems that the preparation of a movement is a controlled process composed of both execution and inhibition processes. FEF is involved in the generation of saccades, as mentioned earlier; in addition, neurons in the FEF can specify saccade cancellation—a specific and well-documented example of inhibitory function.

VI. DEVELOPMENTAL ASPECTS

A. Development of Reaching and the "A Not B Error"

Studies of reaching behavior in human infants and monkeys suggest that development of such behavior involves both the ability to plan and execute sequences of action and the ability to inhibit certain reflexive actions or dominant response tendencies.

Piaget suggested that infants have difficulty in understanding objects and their properties, including spatial relations. However, it seems that infants, even as young as 5 months old, can understand the object concept but they have difficulty demonstrating this understanding by their reaching behavior. Reaching behavior of infants has been studied by Adele Diamond and colleagues using several paradigms. In one paradigm infants were presented with a Plexiglas box with a building block inside or outside the box. Infants were able to retrieve the object when a direct line of reach was possible (the object was in front of the box touching its front wall or in the middle of the box, away from its front wall). However, when the object was placed inside the box touching its front wall infants were unsuccessful in retrieving it. To retrieve the object in the latter situation there is a need to execute a sequence of two movements in order to avoid touching the front wall of the box—one away from the object and a second in the direction of the object. Moreover, when the infants touched the front of the box they reflexively grasped it or withdrew their hands. Seven-month-old infants rarely continued their reaching toward the object. In contrast, 10-month-old infants were much less likely to show these reflexive behaviors upon touching the edge of the box. These infants were able to retrieve the object in these circumstances. It seems that the older infants developed the ability to execute a reach that requires a change of direction and to inhibit reflexive reactions of the hand.

Infants also have difficulty detouring around a barrier to retrieve an object. Here, the infant's task is to retrieve the object from a transparent box that has an open side. Infants 6.5–7 months old reach straight through the side at which they are looking at the object. If they see the object through the open side, they can retrieve it. Otherwise, they cannot retrieve the object and they do not try alternative reaching behaviors. Toward the end of the first year of life they can look through a closed side but retrieve the object from any open side of the box. In order to develop this ability infants need to inhibit the tendency to reach according to the line of sight.

In another paradigm the infant is presented with an object in one of two places, A or B. The locations are covered to hide the object from sight and the infant is then allowed to search for it by lifting the covers. After the infant retrieves the object, the object is again placed in one of the two locations and the search task continues. Suppose the object is first hidden at location A and the infant retrieves it successfully. If the object is then hidden at the second location B, the infant will often try to retrieve the object from A, even though the infant watched the experimenter hiding the object at B. This is the A not B error. Infants continue to make the A not B error from about 7.5 to 12 months of age, as long as the delay between hiding and retrieval is incremented as the infant gets older. Perhaps the most striking aspect of the phenomenon is that infants appear to know that the object is at B despite the fact that they reach toward A. Visual habituation and other visual memory tests indicate that infants remember the correct location. Sometimes, in the search task, the infant fixates B while he or she is reaching toward A. Moreover, infants show the A not B error even when the covers are transparent and the object can be seen. In order to prevent this type of error there is a need to hold details of the task and the situation briefly in short-term memory, and there is a need to inhibit the tendency to reach to A. The tendency to reach to A develops because reaching to A was reinforced earlier by successful finding of the object, and it increases with the number of times the infant has retrieved the object from location A before it is hidden at location B. The ability to meet both of these needs imposed by the task improves during infancy. Short-term memory improves as evidenced by the longer retention interval between

hiding and allowing the infant to reach for the object needed to elicit the A not B error, and inhibition of the incorrect response tendency improves as evidenced by the eventual disappearance of the A not B error.

It seems from this evidence that during the second half of the first year of life infants begin to gain control over their reaching actions. They can inhibit interfering automatic tendencies and demonstrate planned and goal-directed control over manual behavior. The gradual ascendance of planned and goal-directed behavior over reflexive or practiced stimulus-action routines has been modeled both by Diamond and colleagues and Stuart Marcovitch and Philip Zelazo as changes with age in the relative strength or dominance of competing systems, one like working memory and the other like conditioned or procedural learning. Evidence from lesions and single-cell recordings suggests that the increase in dominance of the working memory-like system is achieved, at least in part, through the maturation of several components of frontal cortex: the supplementary motor area (SMA) and the dorsolateral prefrontal cortex. Reflexive grasping is released in adult humans following lesions of the SMA, and the same is true in the case of lesioned monkeys. Lesions of the dorsolateral prefrontal cortex in monkeys produce the A not B error and difficulties inhibiting the urge to reach straight ahead to retrieve an object.

B. Development of Selection and Conflict Resolution

It is possible to view the previously mentioned studies as conflict situations in which habitual or endogenous tendencies compete for control of behavior. Throughout early childhood there is development in the ability to resolve such conflict and select among competing stimuli, stimulus properties, and responses. Several researchers have suggested that central to this achievement is the development of the ability to effectively inhibit stimuli or associations that are irrelevant to the task. Moreover, it has been suggested that such a development relies on maturation of the frontal lobes.

The Stroop task and its many variations have played a major part in the study of this development. For example, when preschool children are asked to say ''day'' to a picture of a moon and ''night'' to a picture of a sun, their accuracy is reduced relative to a neutral condition (e.g., responding ''day'' or ''night'' to a checkerboard). In addition, their accuracy decreases across the experimental session. Older children are able to maintain above-chance accuracy throughout a session. Similar trends have been found in latency of responding. Other conflict situations present similar results and document continued development of inhibitory function during childhood. For example, when Stroop color naming is examined across the school years, intrusion of the irrelevant word in place of the color name decreases in the incongruent or conflict condition, as does the impact of the irrelevant word on latency of correct responding.

Combining this evidence on conflict resolution with the evidence on stopping discussed previously suggests a general improvement in the ability to inhibit prepotent and automated responses from infancy to adulthood. This ability frees the system from stimulus-driven control, enabling strategic control and planning to play a more dominant part in behavior. Moreover, it seems that such development is dependent on high levels of cortical maturation. Other trends in development are consistent with this idea that inhibitory function depends on cortical input. One example is IOR, discussed earlier. The SC, which seems to be the generator of IOR, is already developed in infancy. However, there appears to be a need for the parietal lobes to provide this system with the spatial coordinates necessary for producing IOR. Although in some circumstances IOR can be observed even in infants only a few days old, the appearance of robust and widespread IOR in the eye movement patterns of infants awaits parietal development, rather than depending only on maturation of the SC.

C. Cognitive Aging

Lynn Hasher, Rose Zacks, and colleagues have amassed a considerable body of evidence that inhibitory functions decline in old age. As a consequence, the cognitive processes of older adults are increasingly susceptible to interference from irrelevant or unwanted perceptions, thoughts, and tendencies toward action that are more successfully ignored by younger adults. Hasher, Zacks, and May suggested that the deleterious impact of interference appears to occur in addition to the generalized slowing observed in a wide variety of speeded task performances. Older adults produce more errors and slower correct responses in antisaccade tasks. They suffer greater interference in conflict resolutions tasks such as Stroop color naming, and they find it more difficult to inhibit primary task performance in the stopping paradigm. They suffer greater proactive interference in short-term memory

tasks. They make more errors and retrieve answers more slowly in associative learning tasks when more than one response item is associated with a stimulus item (and in analogous "fan effect" fact-learning tasks in which multiple facts are learned about a single entity or topic item). They show less evidence of intentional or controlled forgetting in directed forgetting tasks, and they show less evidence of inhibiting irrelevant or inappropriate senses of ambiguous words and interpretations of ambiguous referring expressions in sentence reading and text comprehension. In many area of cognitive activity, older adults are susceptible to what Hasher, Zacks, and colleagues call "mental clutter."

Given the role played by prefrontal cortex in a number of the inhibitory functions reviewed in this article, one might wonder whether aging is particularly damaging to the integrity or efficiency of processing in frontal tissue. There is considerable evidence to support such an idea.

There are factors that moderate the impact of aging on cognitive activities with strong inhibitory components. One is practice, with task- and stimulus-specific practice being the most effective. Another is the level of circadian arousal. It is well-known that arousal levels vary systematically with time of day, and that individual differences in the time of occurrence of periods of optimal arousal create "morning people" and "evening people." These individual differences extend to task performance. Both younger and older adults perform a wide variety of tasks better during their optimal periods of arousal than during off-peak periods, and the impact of variation in circadian arousal is greater for older adults. Indeed, if testing is done in the morning when older adults are more likely to be in an optimal period and younger adults are more likely to be in an off-peak period, age differences in task performance are minimized and in some cases nearly eliminated. Testing in the evening, when older adults are likely to be in an off-peak period and younger adults in an optimal period, exaggerates age differences. Thus, circadian variation in locus coeruleus activity and right-prefrontal activity related to vigilance and preparation interact with other aging-induced changes in cortical efficacy.

Finally, there are a number of tasks in which performance does not appear to decline with age, at least in healthy adults free of nervous system insult such as stroke or Alzheimer's disease. Many of these are related to language use. Vocabulary scores continue to increase with age, although word-finding problems during real-time speech production and question answering may also increase. Sentence completion scores in fill-in-the-blank cloze tasks are not affected by age, nor is the accuracy of semantic categorization. All these language tasks that show little or no decline in old age are also affected little if at all by variation in circadian arousal. Perhaps the most surprising of the spared language functions is the ability to select one out of several possible and hence competing syntactic structures for application during real-time sentence production, which has been studied by Douglas Davidson in Zacks' laboratory. Here, the integrity of older adults' performance extends to speed as well as accuracy, violating both of the two best-established outcomes of cognitive aging—susceptibility to interference in conflict resolution situations and generalized slowing in speeded performances of many kinds. Thus, as has often been argued, language skills represent a domain-specific specialization whose operating principles seem to depart from those in many other areas of human cognition.

VII. CONCLUSIONS

Inhibitory functions are part and parcel of the cognitive processes that generate and control behaviors designed to provide specific solutions to dealing with environmental demands. In reviewing examples of inhibitory functions, we have seen that inhibition helps create coherent experience of the world along with the flexibility and efficiency required for skilled behavior.

The ability to inhibit prepotent or reflexive attentional and behavioral reactions and to stop unnecessary or inappropriate behavior develops throughout childhood. These developments free us from interference by otherwise dominant tendencies. This, in turn, enables us to exercise choice and intention over our actions. It seems that such changes are achieved through the development of various brain structures such as regions of the frontal lobes, including anterior cingulate, SMA, dorsolateral prefrontal cortex, and FEF. In doing their jobs, these control structures may interact or cooperate with regions of orbitofrontal cortex and amygdala involved in emotional regulation and sensitivity to delayed and long-term reinforcement contingencies. Note, however, that the ability of higher cortical structures to control reflexive behaviors by inhibiting them is not the only development that takes place. In some functional domains, inhibition already being produced by lower brain structures is made accessible to the influence of higher levels in the system.

An example of this type of development is IOR, which appears to occur in retinal coordinates early in development when SC alone is responsible for it, but it occurs in environmental and object-based coordinates once parietal cortex becomes sufficiently mature to contribute. Here, inhibition is already produced by certain brain structures but the development of cortical mechanisms allows this inhibition to be modulated by the higher brain mechanisms.

In addition, we presented results from memory and language processing suggesting that inhibition helps focus on an object or a concept by sharpening the activated representation. Moreover, it seems that this sharpening can sometimes proceed automatically, with no involvement of attention, and can be achieved without awareness, at least in some circumstances. In other circumstances, deployment of inhibitory tuning mechanisms appears to be under the control of intentions to process a particular kind of information.

In conclusion, inhibitory processes are ubiquitous in human cognition and vary in terms of the levels at which they operate and in terms of their relationship to various mental operations carried out in order to produce behavior.

GLOSSARY

biological approaches to intelligence Approaches emphasizing the anatomical and physiological substrates of intelligence.

cognitive approaches to intelligence Approaches emphasizing thinking and learning processes in intelligence.

intelligence The ability purposively to adapt to, shape, and select real-world environments.

psychometric approaches to intelligence Approaches emphasizing measurement operations for intelligence.

Intelligence can be defined as the ability purposively to adapt to, shape, and select real-world environments. However, most investigators of intelligence want to go beyond simple dictionary-like definitions to a deeper understanding of the construct.

I. DEFINING INTELLIGENCE

If you ask people what intelligence is, the answer depends on whom you ask and the answer differs widely across disciplines, time, and place. We begin this article by discussing the diversity of views regarding what intelligence is because empirical studies often assume rather than explore the nature of the construct they are investigating—in this case, intelligence.

A. Western Psychological Views

How have Western psychologists conceived of intelligence? Almost none of the Western views are adequately expressed by Boring's 1923 operationistic view of intelligence as what intelligence tests test.

For example, in a 1921 symposium on experts' definitions of intelligence, researchers emphasized the importance of the ability to learn and the ability to adapt to the environment. Sixty-five years later, Sternberg and Detterman conducted a similar symposium, again asking experts their views on intelligence. Learning and adaptive abilities retained their importance, and a new emphasis crept in—metacognition or the ability to understand and control one's self. Of course, the name is new but the idea is not because long before Aristotle emphasized the importance for intelligence of knowing oneself.

B. Cross-Cultural Views

In some cases, Western notions about intelligence are not shared by other cultures. For example, at the mental level, the Western emphasis on speed of mental processing is not shared in many cultures. Other cultures may even be suspicious of the quality of work that is done very quickly. Indeed, other cultures emphasize depth rather than speed of processing. They are not alone: Some prominent Western theorists have

pointed out the importance of depth of processing for full command of material.

Yang and Sternberg reviewed Chinese philosophical conceptions of intelligence. The Confucian perspective emphasizes the characteristic of benevolence and of doing what is right. As in the Western notion, the intelligent person spends a great deal of effort in learning, enjoys learning, and persists in life-long learning with a great deal of enthusiasm. The Taoist tradition, in contrast, emphasizes the importance of humility, freedom from conventional standards of judgment, and full knowledge of oneself as well as of external conditions.

The difference between Eastern and Western conceptions of intelligence may persist even in the present day. A study of contemporary Taiwanese Chinese conceptions of intelligence found five factors underlying these conceptions: (i) a general cognitive factor, much like the *g* factor in conventional Western tests; (ii) interpersonal intelligence; (iii) intrapersonal intelligence; (iv) intellectual self-assertion; and (v) intellectual self-effacement.

The factors uncovered in both studies differ substantially from those identified in U.S. people's conceptions of intelligence—practical problem solving, verbal ability, and social competence—although in both cases, people's implicit theories of intelligence seem to go far beyond what conventional psychometric intelligence tests measure.

Another study varied only language. It explicitly compared the concepts of intelligence of Chinese graduates from Chinese-language versus English-language schools in Hong Kong. It was found that both groups considered nonverbal reasoning skills as the most relevant for measuring intelligence. Verbal reasoning and social skills were considered second in importance, followed by numerical skill. Memory was viewed as least important. The Chinese-language-schooled group, however, tended to rate verbal skills as less important than did the English-language-schooled group. Moreover, an earlier study found that Chinese students viewed memory for facts as important for intelligence, whereas Australian students viewed this skill as of only trivial importance.

A review of Eastern notions of intelligence suggested that, in Buddhist and Hindu philosophies, intelligence involves waking up, noticing, recognizing, understanding, and comprehending, but it also includes determination, mental effort, and even feelings and opinions in addition to more intellectual elements.

Differences between cultures in conceptions of intelligence have been recognized for some time. One study noted that Australian university students value academic skills and the ability to adapt to new events as critical to intelligence, whereas Malay students value practical skills as well as speed and creativity. Another study found that Malay students emphasize both social and cognitive attributes in their conceptions of intelligence.

The differences between East and West may be due to differences in the kinds of skills valued by the two kinds of cultures. Western cultures and their schools emphasize what might be called "technological intelligence"; thus, things such as artificial intelligence and so-called smart bombs are viewed, in some sense, as intelligent or smart.

Western schooling also emphasizes generalization or going beyond the information given, speed, minimal moves to a solution, and creative thinking. Moreover, silence is interpreted as a lack of knowledge. In contrast, the Wolof tribe in Africa views people of higher social class and distinction as speaking less. This difference between the Wolof and Western notions suggests the usefulness of examining African notions of intelligence as a possible contrast to U.S. notions.

Studies in Africa in fact provide another window on the substantial differences. Some psychologists have argued that in Africa conceptions of intelligence revolve largely around skills that help to facilitate and maintain harmonious and stable intergroup relations; intragroup relations are probably equally important and at times more important. For example, one study found that Chewa adults in Zambia emphasize social responsibilities, cooperativeness, and obedience as important to intelligence; intelligent children are expected to be respectful of adults. Kenyan parents also emphasize responsible participation in family and social life as important aspects of intelligence. In Zimbabwe, the word for intelligence, *ngware*, actually means to be prudent and cautious, particularly in social relationships. Among the Baoule, service to the family and community and politeness toward and respect for elders are seen as key to intelligence.

Similar emphasis on social aspects of intelligence has been found among two other African groups—the Songhay of Mali and the Samia of Kenya. The Yoruba, another African tribe, emphasize the importance of depth—of listening rather than just talking—to intelligence and of being able to see all aspects of an issue and to place the issue in its proper overall context.

The emphasis on the social aspects of intelligence is not limited to African cultures. Notions of intelligence

in many Asian cultures also emphasize the social aspect of intelligence more than does the conventional Western or IQ-based notion.

It should be noted that neither African nor Asian notions emphasize exclusively social notions of intelligence. A current project is studying conceptions of intelligence in rural Kenya. The Kenyans that have been studied have variegated conceptions of intelligence, distinguishing school intelligence (*rieko*) from other nonschool kinds of intelligence (such as *luoro*, which has more of the quality of character). Near one village (Kisumu), many and probably most of the children are at least moderately infected with a variety of parasitic infections. As a result, they experience stomachaches quite frequently. Traditional medicine suggests the usefulness of a large variety (actually, hundreds) of natural herbal medicines that can be used to treat such infections. Children who learn how to self-medicate via these natural herbal medicines are viewed as being at an adaptive advantage over those who do not have this kind of informal knowledge. Clearly, the kind of adaptive advantage that is relevant in this culture would be viewed as totally irrelevant in the West and vice versa. Children who do better on tests of adaptive knowledge of this kind actually do worse on Western tests of intelligence and in Western schooling in English and mathematics.

These conceptions of intelligence emphasize social skills much more than do conventional U.S. conceptions of intelligence, while simultaneously recognizing the importance of cognitive aspects of intelligence. However, it is important to realize that there is no one overall U.S. conception of intelligence. Indeed, one study found that different ethnic groups in San Jose, California, had different conceptions of what it means to be intelligent. For example, Latino parents of schoolchildren tended to emphasize the importance of social-competence skills in their conceptions of intelligence, whereas Asian parents tended to heavily emphasize the importance of cognitive skills. Anglo parents also emphasized cognitive skills. Teachers, representing the dominant culture, emphasized cognitive more than social-competence skills. The rank order of children of various groups' performance (including subgroups within the Latino and Asian groups) could be perfectly predicted by the extent to which their parents shared the teachers' conception of intelligence. In other words, teachers tended to reward those children who were socialized into a view of intelligence that happened to correspond to the teachers' own view. However, as we shall argue later, social aspects of intelligence, broadly defined, may be as important as or even more important than cognitive aspects of intelligence in later life. Some, however, prefer to study intelligence not in its social aspect but in its cognitive one.

II. COGNITIVE APPROACHES TO INTELLIGENCE

In 1957, Cronbach called for a merging of the two disciplines of scientific psychology—the differential and experimental approaches. Serious responses to Cronbach came in the 1970s, with cognitive approaches to intelligence attempting this merger. One team introduced the cognitive-correlates approach, whereby scores on laboratory cognitive tests were correlated with scores on psychometric intelligence tests. Another psychologist introduced the cognitive-components approach, whereby performance on complex psychometric tasks was decomposed into elementary information processing components.

In the 1990s, cognitive and biological approaches began to merge. A prototypical example is the inspection-time task. In this task, two adjacent vertical lines are presented tachistoscopically or by computer, followed by a visual mask (to destroy the image in visual iconic memory). The two lines differ in length, as does the amount of time for which the two lines are presented. The subject's task is to say which line is longer. However, instead of using raw response time as the dependent variable investigators typically use measures derived from a psychophysical function estimated after many trials. For example, the measure might be the duration of a single inspection trial at which 50% accuracy is achieved. Correlations between this task and measures of IQ appear to be about 0.4, slightly higher than is typical in psychometric tasks. There are differing theories as to why such correlations are obtained, but such theories generally attempt to relate the cognitive function of visual inspection time to some kind of biological function, such as speed of neuronal conduction. Next, we consider some of the biological functions that may underlie intelligence.

III. BIOLOGICAL APPROACHES TO INTELLIGENCE

An important approach to studying intelligence is to understand it in terms of the functioning of the brain, in particular, and of the nervous system, in general. Earlier theories relating the brain to intelligence tended

to be global in nature, although not necessarily backed by strong empirical evidence.

A. Early Biological Theories

Halstead suggested that there are four biologically based abilities, which he called the integrative field factor, the abstraction factor, the power factor, and the directional factor. Halstead attributed all four of these abilities primarily to the functioning of the cortex of the frontal lobes.

More influential than Halstead has been Hebb, who distinguished between two basic types of intelligence: intelligence A and intelligence B. Hebb's distinction is still used by some theorists today. According to Hebb, intelligence A is innate potential; intelligence B is the functioning of the brain as a result of the actual development that has occurred. These two basic types of intelligence should be distinguished from intelligence C—intelligence as measured by conventional psychometric tests of intelligence. Hebb also suggested that learning, an important basis of intelligence, is built up through cell assemblies, by which successively more complex connections among neurons are constructed as learning takes place.

A third biologically based theory is that of Luria, which has had a major impact on tests of intelligence. According to Luria, the brain comprises three main units with respect to intelligence: a unit of arousal in the brain stem and midbrain structures; a sensory-input unit in the temporal, parietal, and occipital lobes; and an organization and planning unit in the frontal cortex.

B. Modern Biological Views and Research

1. Speed of Neuronal Conduction

Recent theories have dealt with more specific aspects of brain or neural functioning. For example, one view suggested that individual differences in nerve conduction velocity are a basis for individual differences in intelligence. Conduction velocity has been measured either centrally (in the brain) or peripherally (e.g., in the arm).

Some investigators tested brain nerve conduction velocities via two medium-latency potentials, N70 and P100, which were evoked by pattern-reversal stimulation. Subjects saw a black-and-white checkerboard pattern in which the black squares would change to white and the white squares to black. Over many trials, responses to these changes were analyzed via electrodes attached to the scalp in four places. Correlations of derived latency measures with IQ were small (generally in the 0.1 to 0.2 range of absolute value) but were significant in some cases, suggesting at least a modest relation between the two kinds of measures.

Other investigators reported on two studies investigating the relation between nerve conduction velocity in the arm and IQ. In both studies, nerve conduction velocity was measured in the median nerve of the arm by attaching electrodes to the arm. In the second study, conduction velocity from the wrist to the tip of the finger was also measured. Vernon and Mori found significant correlations with IQ in the 0.4 range as well as somewhat smaller correlations (approximately -0.2) with response time measures. They interpreted their results as supporting the hypothesis of a relation between speed of information transmision in the peripheral nerves and intelligence. However, these results must be interpreted cautiously because a later study did not successfully replicate these earlier results.

2. Glucose Metabolism

Some of the most interesting recent work using the biological approach has been done by Richard Haier and colleagues. For example, their research showed that cortical glucose metabolic rates as revealed by positron emission tomography scan analysis of subjects solving Raven matrix problems were lower for more intelligent than for less intelligent subjects, suggesting that the more intelligent subjects needed to expend less effort than the less intelligent ones to solve the reasoning problems. A later study showed a similar result for more versus less practiced performers playing the computer game of Tetris. In other words, smart people or intellectually expert people do not have to work as hard as less smart or intellectually expert people at a given problem.

What remains to be shown, however, is the causal direction of this finding. One could sensibly argue that the smart people expend less glucose (as a proxy for effort) because they are smart rather than that people are smart because they expend less glucose. Also, both high IQ and low glucose metabolism may be related to a third causal variable. In other words, we cannot always assume that the biological event is a cause (in the reductionistic sense). It may be, instead, an effect.

3. Brain Size

Another approach considers brain size. Investigators correlated brain size with Wechsler Adult Intelligence

Scale (WAIS-R) IQs, controlling for body size. They found that IQ correlated 0.65 in men and 0.35 in women, with a correlation of 0.51 for both sexes combined. A follow-up analysis of the same 40 subjects suggested that, in men, a relatively larger left hemisphere better predicted WAIS-R verbal ability than it predicted nonverbal ability, whereas in women a larger left hemisphere predicted nonverbal ability better than it predicted verbal ability. These brain size correlations are suggestive, but it is currently difficult to determine what they indicate.

4. Behavior Genetics

Another approach that is at least partially biologically based is that of behavior genetics. The literature is complex, but it appears that about half the total variance in IQ scores is accounted for by genetic factors. This figure may be an underestimate because the variance includes error variance and because most studies of heritability have been performed with children, but it is known that heritability of IQ is higher for adults than for children. Also, some studies, such as the Texas Adoption Project, suggest higher estimates: 0.78 in the Texas Adoption Project, 0.75 in the Minnesota Study of Twins Reared Apart, and 0.78 in the Swedish Adoption Study of Aging.

At the same time, some researchers argue that effects of heredity and environment cannot be clearly and validly separated. Perhaps, future research should focus on determining how heredity and environment work together to produce phenotypic intelligence, concentrating especially on within-family environmental variation, which appears to be more important than between-family variation. Moreover, peers seem to have a particularly large effect on the development of various personal attributes, probably including cognitive skills. Such research requires, at the very least, very carefully prepared tests of intelligence—perhaps some of the newer tests described in the next section.

IV. PSYCHOMETRIC APPROACHES TO INTELLIGENCE

The psychometric approach to intelligence is among the oldest of approaches and dates back to Galton's 1883 psychophysical account of intelligence, which attempts to measure intelligence in terms of psychophysical abilities (such as strength of hand grip or visual acuity), and to Binet and Simon's 1916 account of intelligence as judgment, involving adaptation to the environment, direction of one's efforts, and self-criticism.

A. Theoretical Developments: Carroll's and Horn's Theories

Two of the major new theories proposed during the past decade are Carroll's and Horn's theories. The two theories are both hierarchical, suggesting more general abilities higher in the hierarchy and more specific abilities lower in the hierarchy. Carroll's theory will be described briefly as representative of these new developments.

Carroll proposed his hierarchical model of intelligence based on the factor analysis of more than 460 data sets obtained between 1927 and 1987. His analysis encompasses more than 130,000 people from diverse walks of life and even countries of origin (although non-English-speaking countries are poorly represented among his data sets). The model Carroll proposed, based on his monumental undertaking, is a hierarchy comprising three strata: stratum I, which includes many narrow, specific abilities (e.g., spelling ability and speed of reasoning); stratum II, which includes various group-factor abilities (e.g., fluid intelligence, which is involved in flexible thinking and seeing things in novel ways, and crystallized intelligence, the accumulated knowledge base); and stratum III, which is a single general intelligence, much like Spearman's 1904 general intelligence factor.

Of these strata, the most interesting is perhaps the middle stratum, which includes, in addition to fluid and crystallized abilities, learning and memory processes, visual perception, auditory perception, facile production of ideas (similar to verbal fluency), and speed (which includes both sheer speed of response and speed of accurate responding). Although Carroll does not break much new ground, in that many of the abilities in his model have been mentioned in other theories, he does masterfully integrate a large and diverse factor-analytic literature, thereby giving great authority to his model.

B. An Empirical Curiosity: The Flynn Effect

We know that the environment has powerful effects on cognitive abilities. Perhaps the simplest and most

potent demonstration of this effect is the Flynn effect, named after its discoverer, James Flynn. The basic phenomenon is that IQ has increased over successive generations throughout the world during most of the past century—at least since 1930. The effect must be environmental because, obviously, a successive stream of genetic mutations could not have taken hold and exerted such an effect over such a short period of time. The effect is powerful—about 15 points of IQ per generation for tests of fluid intelligence. Also, it occurs throughout the world. The effect has been greater for tests of fluid intelligence than for tests of crystallized intelligence. The difference, if linearly extrapolated (a hazardous procedure, obviously), suggests that a person who in 1892 was at the 90th percentile on the Raven Progressive Matrices, a test of fluid intelligence, would in 1992 score at the 5th percentile.

There have been many potential explanations of the Flynn effect, and in 1996 a conference was organized by Ulric Neisser and held at Emory University to try to explain the effect. Some of the possible explanations include increased schooling, greater educational attainment of parents, better nutrition, and less childhood disease. A particularly interesting explanation is that of more and better parental attention to children. Whatever the answer, the Flynn effect suggests we need to think carefully about the view that IQ is fixed. It probably is not fixed within individuals, and it is certainly not fixed across generations.

C. Psychometric Tests

1. Static Tests

Static tests are the conventional kind in which people are given problems to solve and they solve them without feedback. Their final score is typically the number of items answered correctly, sometimes with a penalty for guessing.

Psychometric testing of intelligence and related abilities has generally advanced evolutionarily rather than revolutionarily. Sometimes, what are touted as advances seem cosmetic or almost beside the point, as in the case of newer versions of the Scholastic Assessment Test (SAT), which are touted to have not only multiple-choice but also fill-in-the-blank math problems. Perhaps the most notable trend is a movement toward multifactorial theories, often hierarchical ones, and away from the notion that intelligence can be adequately understood only in terms of a single general or g factor. For example, the third edition of the Wechsler Intelligence Scales for Children offers scores for four factors (verbal comprehension, perceptual organization, processing speed, and freedom from distractibility), but the main scores remain the verbal, performance, and total scores that have traditionally dominated interpretation of the test. The fourth edition of the Stanford–Binet Intelligence Scale also departs from the orientation toward general ability that characterized earlier editions, yielding scores for crystallized intelligence, abstract visual reasoning, quantitative reasoning, and short-term memory.

Two new tests are also constructed on the edifice of the theory of fluid and crystallized intelligence of Cattell: the Kaufman Adolescent and Adult Intelligence Test and the Woodcock–Johnson Tests of Cognitive Ability–Revised. Although the theory is not new, the tendency to base psychometric tests closely on theories of intelligence is a welcome development.

The new Das–Naglieri Cognitive Assessment System is based not on fluid-crystallized theory but rather on the theory of Luria. It yields scores for attention, planning, simultaneous processing, and successive processing.

2. Dynamic Tests

In dynamic testing, individuals learn at the time of test. If they answer an item correctly, they are given guided feedback to help them solve the item until they either get it correct or the examiner runs out of clues to give them.

The notion of dynamic testing appears to have originated with Vygotsky and was developed independently by Feuerstein and colleagues. Dynamic assessment is generally based on the notion that cognitive abilities are modifiable, and that there is some kind of zone of proximal development, which represents the difference between actually developed ability and latent capacity. Dynamic assessments attempt to measure this zone of proximal development or an analog of it.

Dynamic assessment is cause both for celebration and for caution. On the one hand, it represents a break from conventional psychometric notions of a more or less fixed level of intelligence. On the other hand, it is more a promissory note than a realized success. The Feuerstein test, the Learning Potential Assessment Device, is of clinical use but is not psychometrically normed or validated. There is only one formally normed test available in the United States, by Swanson, which yields scores for working memory before and at various points during and after training as well

as scores for the amount of improvement with intervention and the number of hints that have been given and a subjective evaluation by the examiner of the examinee's use of strategies.

3. Typical Performance Tests

Traditionally, tests of intelligence have been maximum-performance tests, requiring examinees to work as hard as they can to maximize their scores. Ackerman recently argued that typical performance tests, which, like personality tests, do not require extensive intellectual effort, should supplement maximal-performance ones. On such tests, subjects might be asked to what extent they agree with statements such as "I prefer my life to be filled with puzzles I must solve" or "I enjoy work that requires conscientious, exacting skills." A factor analysis of such tests yielded five factors: intellectual engagement, openness, conscientiousness, directed activity, and science/technology interest.

Although the trend has been toward multifaceted views of intelligence and away from reliance on general ability, some have bucked this trend. Among those who have are Herrnstein and Murray.

D. The Bell Curve Phenomenon

A momentous event in the perception of the role of intelligence in society occured with the publication of *The Bell Curve* by Herrnstein and Murray. The impact of the book is demonstrated by the rapid publication of a number of responses. A whole issue of *The New Republic* was devoted to the book, and two edited books of responses were quickly published. Some of the responses were largely political or emotional in character, but others attacked the book on scientific grounds. A closely reasoned attack appeared a year after these collections. The American Psychological Association also sponsored a report that although not directly a response to *The Bell Curve* was largely motivated by it.

Some of the main arguments of the book are that (i) conventional IQ tests measure intelligence, at least to a good first approximation; (ii) IQ is an important predictor of many measures of success in life, including school success, but also economic success, work success, success in parenting, avoidance of criminality, and avoidance of welfare dependence; (iii) as a result of this prediction, people who are high in IQ are forming a cognitive elite, meaning that they are reaching the upper levels of society, whereas those who are low in IQ are falling toward the bottom; (iv) tests can and should be used as a gating mechanism, given their predictive success; (v) IQ is highly heritable and hence is passed on through the genes from one generation to the next, with the heritability of IQ probably in the 0.5–0.8 range; (vi) there are racial and ethnic differences in intelligence, with blacks in the United States, for example, scoring about one standard deviation below whites; (vii) it is likely, although not certain, that at least some of this difference between groups is due to genetic factors; and (viii) tests can and should be used as a gating mechanism, given their success.

Herrnstein and Murray attempted to document their claims using available literature and also their own analysis of the National Longitudinal Study of Youth data that were available to them. Although their book was written for a trade (popular) audience, it was unusual among books for such an audience in its use of fairly sophisticated statistical techniques.

It is not possible to review the full range of responses to Herrnstein and Murray. Among psychologists, there seems to be widespread agreement that the social policy recommendations of Herrnstein and Murray, which call for greater isolation of and paternalism toward those with lower IQs, do not follow from their data but rather represent a separate ideological statement. Beyond that, there is a great deal of disagreement regarding the claims made by these authors.

Our view is that it would be easy to draw much stronger inferences from the Herrnstein–Murray analysis than the data warrant and perhaps even than Herrnstein and Murray would support. First, Herrnstein and Murray acknowledge that, in the United States, IQ typically accounts only for approximately 10% of the variation, on average, in individual differences across the domains of success they survey. In other words, about 90% of the variation, and sometimes much more, remains unexplained.

Second, even the 10% figure may be inflated by the fact that U.S. society uses IQ-like tests to select, place, and, ultimately, to stratify students so that some of the outcomes that Herrnstein and Murray mention may actually be results of the use of IQ-like tests rather than results of individual differences in intelligence per se. For example, admission to selective colleges in the United States typically requires students to take either the SAT or the American College Test, both of which are similar (although not identical) to conventional tests of IQ. Admission to graduate and professional programs requires similar kinds of tests. The result is that those who do not test well may be denied access to

these programs and to the routes that would lead them to job, economic, and other socially sanctioned forms of success in our society.

It is thus not surprising that test scores would be highly correlated with, for example, job status. People who do not test well have difficulty gaining access to high-status jobs, which in turn pay better than other jobs to which they might be able to gain access. If we were to use some other index instead of test scores (e.g., social class or economic class), then different people would be selected for the access routes to societal success. In fact, we do use these alternative measures to some degree, although less so than in the past.

Finally, although group differences in IQ are acknowledged by virtually all psychologists to be real, the cause of them remains very much in dispute. What is clear is that the evidence in favor of genetic causes is weak and equivocal. We are certainly in no position to assign causes at this time. Understanding of group differences requires further analysis and probably requires examining these differences through the lens of broader theories of intelligence.

V. BROAD THEORIES OF INTELLIGENCE AND KINDS OF INTELLIGENCE

In recent years, there has been a trend toward broad theories of intelligence. We consider some of the main such theories next.

A. Multiple Intelligences

Gardner proposed that there is no single, unified intelligence but rather a set of relatively distinct, independent, and modular multiple intelligences. His theory of multiple intelligences (MI theory) originally proposed seven multiple intelligences: linguistic, as used in reading a book or writing a poem; logical–mathematical, as used in deriving a logical proof or solving a mathematical problem; spatial, as used in fitting suitcases into the trunk of a car; musical, as used in singing a song or composing a symphony; bodily–kinesthetic, as used in dancing or playing football; interpersonal, as used in understanding and interacting with other people; and intrapersonal, as used in understanding oneself.

Recently, Gardner proposed one additional intelligence as a confirmed part of his theory—naturalist intelligence, the kind shown by people who are able to discern patterns in nature. Charles Darwin would be a notable example. Gardner has also suggested that there may be two other "candidate" intelligences: spiritual intelligence and existential intelligence. Spiritual intelligence involves a concern with cosmic or existential issues and the recognition of the spiritual as the achievement of a state of being. Existential intelligence involves a concern with ultimate issues. Gardner believes the evidence for these latter two intelligences is less powerful than the evidence for the other eight intelligences. Whatever the evidence may be for the other eight, we agree that the evidence for these two new intelligences is speculative.

In the past, factor analysis served as the major criterion for identifying abilities. Gardner proposed a new set of criteria, including but not limited to factor analysis, for identifying the existence of a discrete kind of intelligence: potential isolation by brain damage, in that the destruction or sparing of a discrete area of the brain may destroy or spare a particular kind of intelligent behavior; the existence of exceptional individuals who demonstrate extraordinary ability (or deficit) in a particular kind of intelligent behavior; an identifiable core operation or set of oeprations that are essential to the performance of a particular kind of intelligent behavior; a distinctive developmental history leading from novice to master, along with disparate levels of expert performance; a distinctive evolutionary history, in which increases in intelligence may be plausibly associated with enhanced adaptation to the environment; supportive evidence from cognitive experimental research; supportive evidence from psychometric tests; and susceptibility to encoding in a symbol system.

Since the theory was first proposed, a large number of educational interventions have arisen that are based on the theory, sometimes closely and other times less so. Many of the programs are unevaluated, and evaluations of others seem to be ongoing, so it is difficult to say at this point what the results will be. In one particularly careful evaluation of a well-conceived program in a large southern city, there were no significant gains in student achievement or changes in student self-concept as a result of an intervention program based on Gardner's theory. There is no way of knowing whether these results are representative of such intervention programs, however.

B. Successful Intelligence

Sternberg suggested that we should pay less attention to conventional notions of intelligence and more to

what he terms successful intelligence—the ability to adapt to, shape, and select environments so as to accomplish one's goals and those of one's society and culture. A successfully intelligent person balances adaptation, shaping, and selection, doing each as necessary. The theory is motivated in part by repeated findings that conventional tests of intelligence and related tests do not predict meaningful criteria of success as well as they predict scores on other similar tests and school grades.

Successful intelligence involves an individual's discerning his or her pattern of strengths and weaknesses and then figuring out ways to capitalize on the strengths and at the same time compensate for or correct the weaknesses. People attain success, in part, in idiosyncratic ways that involve their finding how best to exploit their own patterns of strengths and weaknesses.

Three broad abilities are important to successful intelligence: analytical, creative, and practical abilities. Analytical abilities are required to analyze and evaluate the options available to oneself in life. They include identifying the existence of a problem, defining the nature of the problem, setting up a strategy for solving the problem, and monitoring one's solution processes.

Creative abilities are required to generate problem-solving options in the first place. Creative individuals are ones who "buy low and sell high" in the world of ideas: They are willing to generate ideas that, like stocks with low price–earnings ratios, are unpopular and perhaps even deprecated. Having convinced at least some people of the value of these ideas, they then sell high, meaning that they move on to the next unpopular idea. Research shows that these abilities are at least partially distinct from conventional IQ, and that they are moderately domain specific, meaning that creativity in one domain (such as art) does not necessarily imply creativity in another (such as writing).

Practical abilities are required to implement options and to make them work. Practical abilities are involved when intelligence is applied to real-world contexts. A key aspect of practical intelligence is the acquisition and use of tacit knowledge, which is knowledge of what one needs to know to succeed in a given environment that is not explicitly taught and that usually is not verbalized. Research shows that tacit knowledge is acquired through mindful utilization of experience, that it is relatively domain specific, that its possession is relatively independent of conventional abilities, and that it predicts criteria of job success about as well as and sometimes better than does IQ.

The separation of practical intelligence from IQ has been shown in different ways in different studies. Scribner showed that experienced assemblers in a milk processing plant used complex strategies for combining partially filled cases in a manner that minimized the number of moves require to complete an order. Although the assemblers were the least educated workers in the plant, they were able to calculate in their heads quantities expressed in different base number systems, and they routinely outperformed the more highly educated white-collar workers who substituted when the assemblers were absent. Scribner found that the order-filling performance of the assemblers was unrelated to measures of academic skills, including intelligence test scores, arithmetic test scores, and grades.

Ceci and Liker carried out a study of expert racetrack handicappers and found that expert handicappers used a highly complex algorithm for predicting post time odds that involved interactions among seven kinds of information. Use of a complex interaction term in their implicit equation was unrelated to the handicappers' IQ.

In a series of studies by Lave and colleagues, it was shown that shoppers in California grocery stores were able to choose which of several products represented the best buy for them, even though they did very poorly on the same kinds of problems when they were presented in the form of a paper-and-pencil arithmetic computation test. The same principle that applies to adults appears to apply to children as well: Carraher, Carraher, and Schliemann found that Brazilian street children who could apply sophisticated mathematical strategies in their street vending were unable to do the same in a classroom setting. In study by Grigorenko and Sternberg, practical intelligence was found to be a better predictor of everyday adaptation than was academic intelligence among adults in contemporary Russia.

One more example practical intelligence was provided by a study in which individuals were asked to play the role of city managers for the computer-simulated city of Lohhausen. Dorner and colleagues presented a variety of problems to these individuals, such as how best to raise revenue to build roads. The simulation involved more than 1000 variables. No relation was found between IQ and complexity of strategies used.

There is also evidence that practical intelligence can be taught, at least to some degree. For example, children in middle school given a program for developing their practical intelligence for school

(strategies for effective reading, writing, execution of homework, and taking of tests) improved more from pretest to posttest than did control students who received an alternative but irrelevant treatment.

None of these studies suggest that IQ is unimportant for school or job performance or other kinds of performance, and indeed, evidence suggests the contrary. The studies do suggest, however, that there are other aspects of intelligence that are relatively independent of IQ and that are important as well. A multiple-abilities prediction model of school or job performance would probably be most satisfactory.

According to the theory of successful intelligence, children's multiple abilities are underutilized in educational institutions because teaching tends to value analytical (as well as memory) abilities at the expense of creative and practical abilities. Sternberg, Ferrari, Clinkenbeard, and Grigorenko designed an experiment in order to illustrate this point. They identified 199 high school students from throughout the United States who were strong in analytical, creative, or practical abilities, all three kinds of abilities, or none of these kinds of abilities. Students were then brought to Yale University to take a college-level psychology course that was taught in a way that emphasized memory, analytical, creative, or practical abilities. Some students were matched, and others mismatched, to their own strength(s). All students were evaluated for memory-based, analytical, creative, and practical achievements.

Sternberg and colleagues found that students whose instruction matched their pattern of abilities performed significantly better than did students who were mismatched. They also found that prediction of course performance was improved by taking into account creative and practical as well as analytical abilities. In the broader test of abilities they used, confirmatory factor analysis failed to reveal a general factor. In a separate study, Sternberg, Torff, and Grigorenko found that fourth-graders and eighth-graders taught either social studies or science in a way that emphasized analytical, creative, and practical thinking performed better on tests of achievement than did children taught in a way that emphasized primarily memory, even if the children's achievement was measured by memory tests.

C. True Intelligence

Perkins proposed a theory of what he refers to as true intelligence, which he believes synthesizes classic views as well as new ones. According to Perkins, there are three basic aspects to intelligence: neural, experiential, and reflective.

Neural intelligence concerns what Perkins believes to be the fact that some people's neurological systems function better than do the neurological systems of others, running faster and with more precision. He mentions "more finely tuned voltages" and "more exquisitely adapted chemical catalysts" as well as a "better pattern of connecticity in the labyrinth of neurons," although it is not entirely clear what any of these terms mean. Perkins believes this aspect of intelligence to be largely genetically determined and unlearnable. This kind of intelligence seems to be similar to Cattell's idea of fluid intelligence.

The experiential aspect of intelligence is what has been learned from experience. It is the extent and organization of the knowledge base and thus is similar to Cattell's notion of crystallized intelligence. The reflective aspect of intelligence refers to the role of strategies in memory and problem solving, and it appears to be similar to the construct of metacognition or cognitive monitoring.

D. The Bioecological Model of Intelligence

Ceci proposed a bioecological model of intelligence, according to which multiple cognitive potentials, context, and knowledge are all essential bases of individual differences in performance. Each of the multiple cognitive potentials enables relationships to be discovered, thoughts to be monitored, and knowledge to be acquired within a given domain. Although these potentials are biologically based, their development is closely linked to environmental context; hence, it is difficult if not impossible to cleanly separate biological from environmental contributions to intelligence. Moreover, abilities may express themselves very differently in different contexts. For example, children given essentially the same task in the context of a video game and in the context of a laboratory cognitive task performed much better when the task was presented in the context of the video game. Part of this superiority may have been a result of differences in emotional response.

E. Emotional Intelligence

Emotional intelligence is the ability to perceive accurately, appraise, and express emotion; the ability to

access and/or generate feelings when they facilitate thought; the ability to understand emotion and emotional knowledge; and the ability to regulate emotions to promote emotional and intellectual growth. The concept was introduced by Salovey and Mayer and popularized and expanded upon by Goleman.

There is tentative evidence for the existence of emotional intelligence. For example, researchers found that emotional perception of characters in a variety of situations correlates with SAT scores, with empathy, and with emotional openness. Full convergent–discriminant validation of the construct, however, appears to be needed.

Some scholars still hold a relatively simple view of intelligence not much different from the view proposed by Spearman in 1904. However, with the introduction of emotional intelligence and all the other kinds of intelligences, it seems like a simple view may fail to capture intelligence in all its richness.

Ion Channels

B. ALEXANDER YI and LILY Y. JAN
University of California, San Francisco

GLOSSARY

complementary DNA DNA that is synthesized from mRNA and therefore contains the coding sequence of the gene with no introns.

equilibrium potential The membrane potential at which there would be no net movement of ions across the membrane.

ligand A molecule that binds a protein.

neurotransmitter A chemical substance that is stored in vesicles at the nerve terminal and released to cause a change in the postsynaptic membrane, usually a change in the membrane to ions.

protease An enzyme that cleaves proteins.

resting potential The membrane potential of the cell in its quiescent state.

second messenger A molecule that is generated by the activation of surface receptors in response to hormones or neurotransmitters that lead to changes in the functional state of the cell.

In one sense, a cell is similar to a battery. Approximately one-third of the cell's metabolic energy is stored as an electrical potential in the form of ionic gradients across the plasma membrane. This energy is released at precise moments by "holes" in the membrane that allow ions to move down their electrochemical gradients across the membrane. These holes are ion channels. In the brain, a diverse array of ion channels coordinates their actions to generate complex waveforms that are used to transmit signals across long distances or between cells.

I. ROLE OF ION CHANNELS IN PHYSIOLOGY

Ion channels are membrane proteins that catalyze the transfer of ions down their electrochemical gradients across the plasma membrane. Ion channels are necessary because the plasma membrane is hydrophobic and thus by themselves they are impermeable to ions. In this article, we review what is known about the role of ion channels in physiology and their structure and function. More is known about some ion channels than others. In the last section, we introduce some of the major ion channel families that have attracted the interest of scientists who study ion channels.

There are two types of proteins that are able to move ions across the plasma membrane: ion pumps and ion channels. There are several features that distinguish them. Ion pumps are able to perform thermodynamic work (i.e., they are able to move an ion against its electrochemical gradient). This is accomplished by consuming energy in the form of ATP hydrolysis or the concentration gradients of other ions. Ion channels cannot perform thermodynamic work and the direction of ions traveling through an open channel is solely dependent on the electrochemical gradient. Sometimes ion pumps are said to carry out active transport, whereas ion channels carry out passive transport. Another major difference is the rate at which ions move through these proteins. Ion channels are essentially pores in the plasma membrane and the throughput of an ion channel can be fast—up to 100 million ions per second. The turnover rate of ion pumps is typically orders of magnitude slower.

Ion channels are found in nearly all cells in nature and play integral roles in a cell's basic physiology. It is likely that ion channels were among the proteins found

in the earliest forms of life on this planet. Through millions of years of evolution, the number and diversity of ion channels have expanded to take on more complex functions such as those involved in learning and memory in the nervous system. Classically, ion channels are introduced via a discussion of neuronal action potentials that transmit signals down an axon. Beyond action potentials, ion channels play roles in other processes too many to enumerate. On a fundamental level, the activity of ion channels can change the membrane potential of the cell or alter the concentrations of ions inside the cell. These processes are basic to the cell's physiology; therefore, it is easily imagined that ion channels may be involved, directly or indirectly, in virtually all cellular activities. More directly, some of these activities may include setting the membrane potential, allowing the entry of ions for nutritive needs, allowing the entry of Ca^{2+}, which is used as a second messenger, and controlling cell volume.

In other cases, the physiological role of an ion channel is unknown. We have often learned about the function of ion channels by discovering instances when their activity goes awry—namely, disease states. It is becoming apparent that defective ion channels underlie the pathogenesis of many human diseases. The term channelopathy has been coined to refer to the expanding list of diseases in this class. For example, cystic fibrosis stems from a mutation in a chloride channel, cystic fibrosis transmembrane regulator (CFTR). In the lung, mutations in CFTR disrupt normal Cl^- efflux, which is necessary for the secretion of fluid that coats the airway epithelium. Consequently, patients with cystic fibrosis develop viscous mucus secretions that can obstruct the airways and are prone to acquiring life-threatening pulmonary infections. Another example is long-QT syndrome. Individuals with long-QT syndrome have abnormally prolonged action potentials in the heart and are at risk for ventricular arrhythmias that can lead to sudden death. Some individuals with long-QT syndrome have mutations in potassium channels that repolarize the cardiac muscle. The direct importance of ion channels in cardiac function is underscored by the effectiveness of antiarrhythmic drugs, many of which act on ion channels.

II. PRINCIPLES OF ION CHANNEL MECHANISMS

A. The Electrochemical Gradient

The electrochemical gradient determines the direction that ions will flow through an open ion channel and is a combination of two types of gradients: a concentration gradient and an electrical field gradient. We can consider these two gradients separately. Figure 1a shows two compartments that contain an aqueous solution of ions separated by a membrane. It is apparent that there is a concentration gradient, since the left side contains more ions than the right. Assuming the membrane is permeable to the ion, there will be a net movement of ions from the right to left side until the concentrations of ions on both sides are the same. In this case, when the concentrations on both sides equalize, the solution will have reached

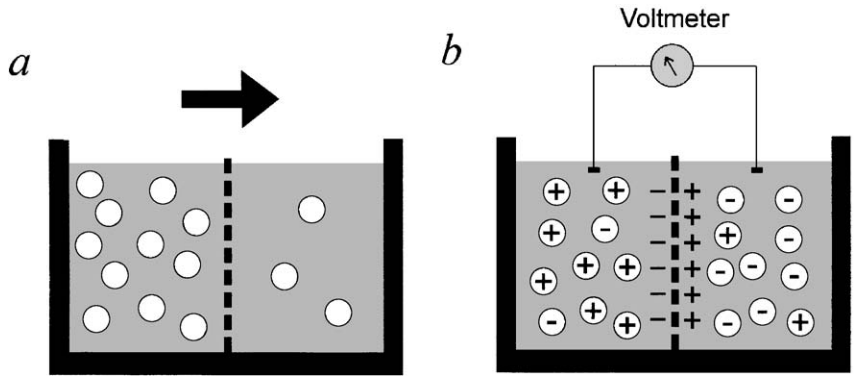

Figure 1 The electrochemical gradient is a combination of the concentration gradient and the electrical potential. The panels show two compartments that contain a solution of ions (circles). An ion-permeable membrane separates the two compartments. (a) There is a higher concentration of ions on the left side; therefore, ions will tend to diffuse from the left to the right (direction of arrow). It is also apparent that there is an osmotic gradient. Initially, water will tend to flow from the right to the left. At equilibrium, however, the two sides will be isoosmotic. (b) A voltage has been applied across the membrane. As a consequence, positively charged ions are drawn to the left and negatively charged ions to the right.

equilibrium. At equilibrium, an equal number of ions will diffuse across the membrane in both directions, and the concentrations of ions on either side will not change.

The electrical field gradient takes into account the charge on the ion. In Fig. 1b, an electrical potential has been applied so that the left side is negatively charged and the right side is positively charged. Ions that are positively charged will flow into the left compartment until it reaches a new equilibrium, in which the electrostatic forces that pull the cations into the left side are balanced by the tendency for the ions to move down its concentration gradient. Negatively charged ions will tend to flow into the right compartment. In this equilibrium, the final concentrations of ions on both sides are not equal.

The relationship between the electrical potential and the magnitude of the concentration gradient that is created is intuitive: The stronger the electrical potential, the greater the concentration gradient. The Nernst equation describes this relationship:

$$E_x = \frac{RT}{zF} \ln \frac{[X]_{\text{out}}}{[X]_{\text{in}}} \qquad (1)$$

where E_x is the electrical potential with units of millivolts, R is the gas constant, T is the temperature, z is the valence of the ion, and F is Faraday's constant. In words, the Nernst equation states that an electrical potential, E_x, will produce a concentration gradient with the ratio $[X]_{\text{out}}/[X]_{\text{in}}$ when the membrane is permeable to the ion. The converse is also true; a concentration gradient, $[X]_{\text{out}}/[X]_{\text{in}}$, will generate an electrical potential, E_x. Near room temperature (20°C), the Nernst equation simplifies to

$$E_x = \frac{58}{z} \log_{10} \frac{[X]_{\text{out}}}{[X]_{\text{in}}} \qquad (2)$$

E_x is also referred to as the equilibrium potential or the Nernst potential.

The cell is similar to the compartments in Fig. 1, only more ions need to be considered. The membrane potential is determined by the permeability of the membrane to a given ion. Figure 2 gives the concentrations of Na^+, K^+, Cl^-, and Ca^{2+} inside and outside a typical cell. Two processes work to maintain the concentration gradients of these ions. The action of ion pumps helps keep the cytoplasmic concentrations of Na^+, Cl^-, and Ca^{2+} low and the K^+ concentration high. Second, the presence of macromolecular anions inside the cell, such as proteins, tends to produce gradients of ions on their own. The redistribution of ions due to fixed charges in the cell is referred to as the Donnan effect.

At rest, the membrane is permeable to K^+; therefore, the resting potential of the cell is near E_K (in Fig. 2, approximately −84 mV). The flow of ions through the membrane is not large enough to affect changes in the ionic composition inside or outside the cell. Experimentally, currents can be elicited by changing the electrical potential across the membrane in short pulses. At membrane potentials of approximately −84 mV, there will be small K^+ currents since the membrane potential is near E_K, at which there is no net flow of K^+ across the membrane. Above E_K, there will be a net flow of K^+ outward because the electrical field gradient is not large enough to balance the concentration gradient. This results in an outward current (Fig. 3a). Below E_K, there will be a net inward current because the stronger electrical field gradient will tend to pull more K^+ into the cell. With the opening of sodium channels, the membrane becomes predominantly permeable to Na^+ rather than K^+. The low concentration of Na^+ inside the cell and the negative

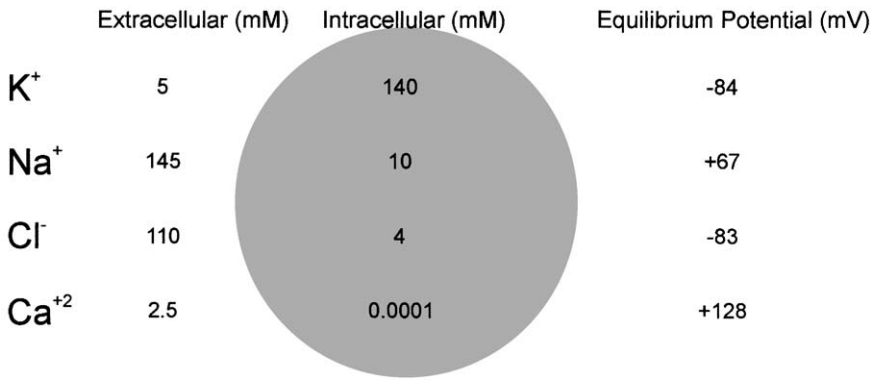

Figure 2 The concentration of ions inside and surrounding a typical mammalian cell. The equilibrium potentials were calculated using Eq. (2).

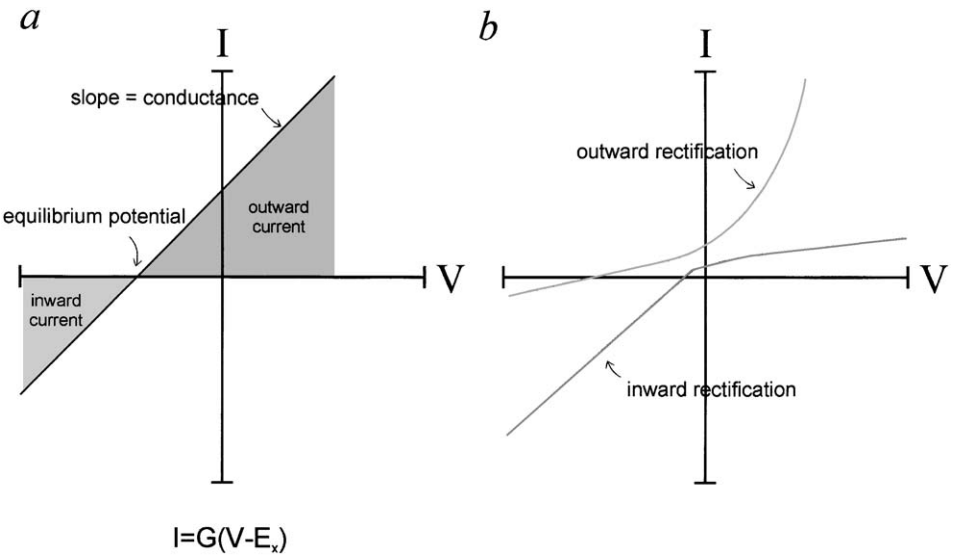

Figure 3 Current–voltage plots of ion channels. (a) An *I–V* curve of an ion channel that conducts positively charged ions. Above the equilibrium potential, there is outward current; below the equilibrium potential, there is inward current. An ohmic ion channel has a linear *I–V* relationship. (b) Rectifiers pass more current in one direction. *I–V* curves of ion channels that rectify curve upwards or downwards.

membrane potential initially create a strong driving force for Na^+ to enter the cell and can cause the membrane potential to approach E_{Na}, (e.g., at the peak of action potentials).

B. Current–Voltage Relationships

Current is the movement of charge, and in cells the flow of ions through ion channels can be measured. By expressing cloned ion channels in heterologous systems or by silencing other channels with chemical blockers, the current from a single ion channel can be isolated. In these settings, it is often useful to apply different electrical potentials to the membrane and measure the magnitude and direction of the current as a function of voltage. If current through the ion channel is linearly related to the membrane potential as in Fig. 3a, then the ion channel is said to be ohmic because it behaves like a resistor and follows Ohm's law:

$$V = IR \tag{3}$$

where V is voltage, I is current, and R is the resistance. For the purposes of studying ion channels, it is useful to modify Ohm's law into the form

$$I = G(V - E_x) \tag{4}$$

Here, V is replaced with $(V-E_x)$ because $I=0$ at the equilibrium potential, and R is replaced with its inverse, the conductance G. The conductance is the ease with which ions will flow through an ion channel, which is more intuitive since ion channels with a high conductance will conduct larger currents. $(V-E_x)$ constitutes the driving force, which together with the conductance determines the amount of current that flows through the ion channel. From Fig. 3a or Eq. (4), we can see that G represents the slope of the *I–V* curve. Ion channels with a higher conductance will have steeper *I–V* curves.

I–V curves show the sensitivity of an ion channel to voltage. One should bear in mind that all ion channels are not ohmic. Ion channels that conduct more ions in one direction are said to rectify. For example, inward rectifier potassium channels preferentially conduct more K^+ into the cell than out of the cell (Fig. 3b). Other ion channels display outwardly rectifying currents.

C. Anatomy of a Typical Ion Channel

In the early 20th century, ion channels as we know them were considered nothing more than "holes in the membrane" that allowed ions to pass through them. We now know that ion channels are more complex than simple holes. In particular, there are two properties that distinguish them from simple holes: They exhibit selectivity for certain ions, and they open and close in response to stimuli.

All ion channels display many of the same basic properties. All ion channels are integral membrane proteins that form a pore in the lipid bilayer (Fig. 4). Like other membrane proteins, ion channels contain stretches of hydrophobic amino acids called transmembrane segments that anchor the protein within the lipid bilayer. These transmembrane segments pack against each other to stabilize the basic pore structure. Part of the pore is narrow and forms a barrier beyond which impermeant ions cannot cross. This region is lined with amino acid sidechains or backbone atoms that interact with the ion briefly as it crosses the pore. A flexible region of the ion channel forms a gate that acts to open and close access to the pore. The opening and closing of the ion channel is referred to as gating. The position of the gate can be influenced by regions that are modified by enzymes such as kinases or phosphatases. Finally, many ion channels extend processes that dock onto intracellular scaffolding proteins that are part of the cellular architecture. These interactions help direct those ion channels to specific locations within the cell such as the synapse or an intracellular organelle.

D. Ion Selectivity

All ion channels conduct certain ions over others—a property referred to as ion selectivity. Some ion channels are permeable to a class of ions; cation channels are one example, though most ion channels conduct a single type of ion. The selectivity of some ion channels is extraordinary. Voltage-gated calcium channels are 1000 times more selective for Ca^{2+} over other cations and pass Ca^{2+} almost exclusively. This is remarkable considering that the concentrations of other ions such as Na^{+} can be much higher than that of Ca^{2+}. The mechanism by which ion channels pick and choose certain ions is still not fully understood.

At the molecular level, ions are little more than point charges with different valences. For ions with the same charge the only distinguishing feature is their ionic radius. Na^{+} and K^{+}, which both have a charge of $+1$, have radii of 0.95 and 1.33 Å, respectively. Another feature is the water molecules that surround and interact with the ion. In solution, ions are surrounded by multiple layers of water molecules that are continuously exchanging with other "free" waters around it. Based on the mobility of ions in solution, Na^{+} behaves as though they are larger than K^{+}. This is because its charge is concentrated in a smaller space and thus binds its waters of hydration more tightly.

The narrowest part of the pore has been termed by Bertil Hille as the ion selectivity filter. A filter with a fixed diameter is one way of explaining ion selectivity. In this view, ion channels are like sieves that allow small ions to pass but retain large ions. Although this mechanism is certainly at work in ion channels, an ion selectivity filter does not explain how an ion channel could be permeable only to large ions.

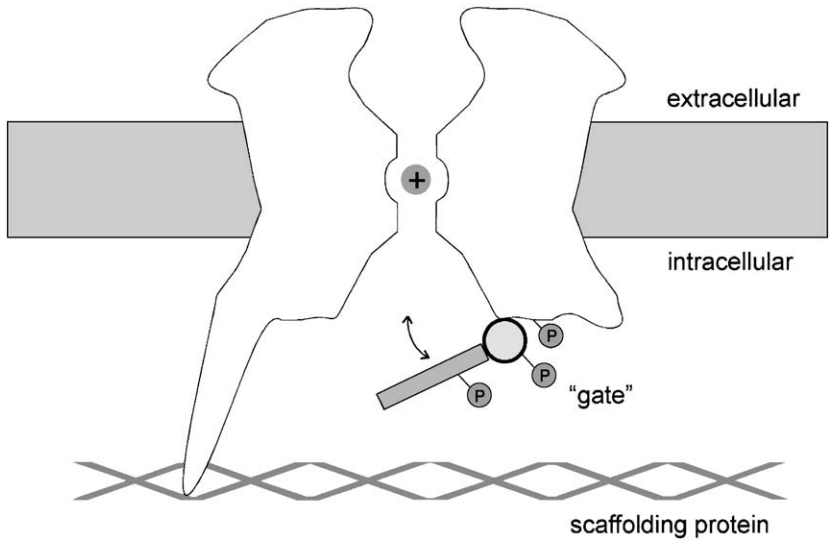

Figure 4 The "anatomy" of a typical ion channel. Ion channels are integral membrane proteins that sit in the plasma membrane. An ion is drawn sitting in a binding pocket in the ion selectivity filter (narrow part) as it passes through the ion channel. A gate (drawn as a door) swings open and closed.

It is likely that the permeant ion makes direct contact with the ion channel at some points during its passage. These interactions at specific binding sites may explain how an ion channel can be selective for large ions or discriminate between ions of similar radii. The binding sites can be depicted with the aid of an "energy landscape" diagram (Fig. 5a). Unfavorable locations are represented as regions of high energy, or peaks, whereas stable regions such as binding sites are represented by valleys. It is clear that some ion channels have more than one binding site within the channel. Multiple binding sites in close proximity may explain the high turnover rate of ion channels by setting up electrostatic repulsion between ions.

All potassium channel genes share a P region. The P region can be easily identified in potassium channel sequences since it contains the signature amino acid sequence GYG. The P region forms a part of the pore that is involved in ion selectivity since mutations in this region can alter the ion selectivity of potassium channels. The physical nature of the binding sites formed by the pore regions of most ion channels is unknown; however, it is likely that they are assembled from polar and charged amino acid sidechains or carbonyl oxygens from the protein backbone. These moieties could mimic the waters that may have been stripped away when the ion enters the pore. These interactions are likely to be transient and of low affinity given the high rate of turnover of an ion channel. One measure of the affinity can be obtained by measuring the current size at given ion concentrations (Fig. 5b). With no permeant ions present, an open ion channel will conduct zero current. As the concentration of ions is increased, the current will increase since the greater number of permeant ions will allow more ions to flow through the channel. Eventually, the current will reach a plateau or saturate. Plotted on a graph, the current can be fit with the Michaelis–Menton equation, and a constant (K_M), a measure of the affinity of the ion channel for the ion,

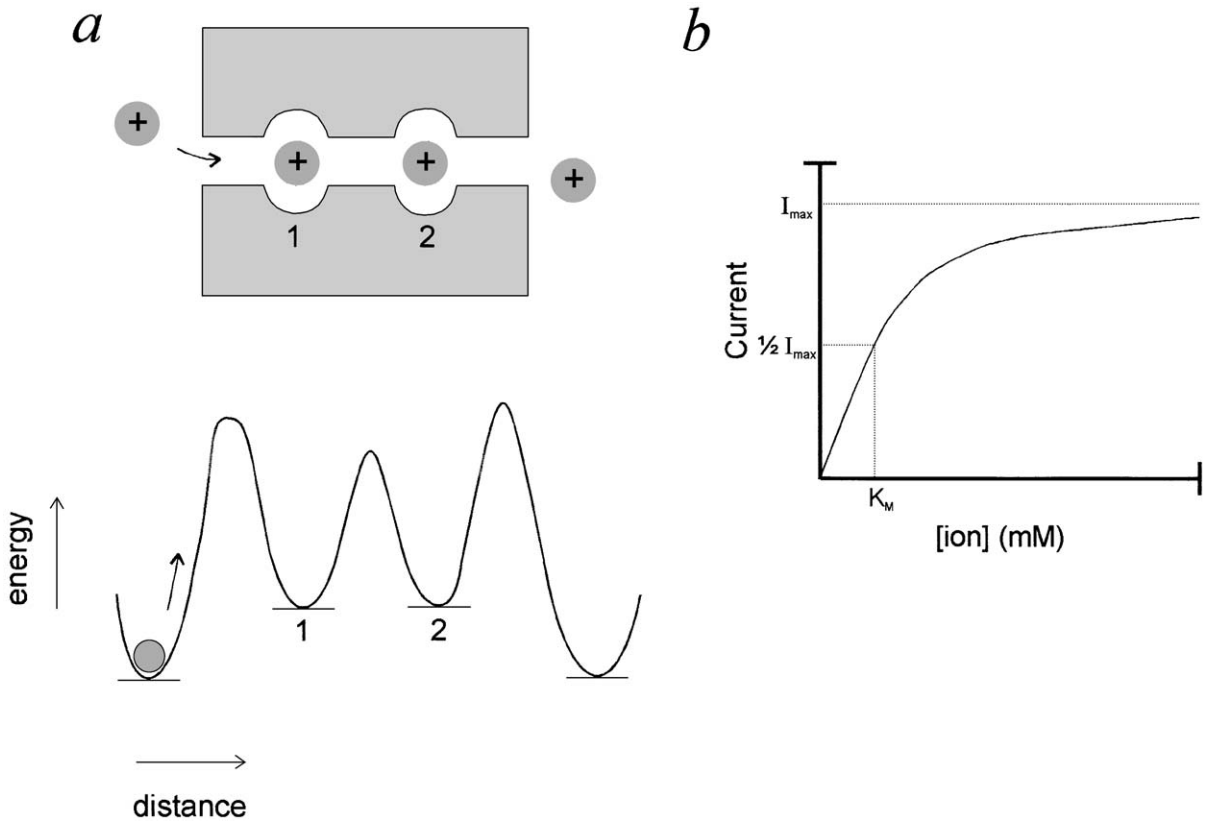

Figure 5 Ion channels contain binding sites for ions in the pore. (a) Ions move through the pore in single file from left to right. Binding sites 1 and 2 are places where the ions make interactions with the ion channel. The procession through the pore can be represented on an energy landscape diagram in which the binding sites are drawn as valleys. (b) The current amplitude eventually plateaus as the concentration of permeant ions is increased. This data can be fit using the Michaelis–Menton equation to derive the K_d, a measure of affinity.

can be obtained. Typically, ion channels show a K_M in the millimolar range.

E. Ion Channel Gating

Ion channels undergo a conversion between two types of states—closed and open—in a process referred to as gating. The gating behavior of an ion channel defines its functional role in physiology and is typically tied to the name of the ion channel. Ion channels are able to respond to a wide range of stimuli. The binding of a neurotransmitter (ligand-gated ion channels), a change in the membrane potential (voltage-gated ion channels), a physical pull on the ion channel protein (mechanosensitive ion channels), and heat are known to activate certain ion channels.

An ion channel with two states, one closed and one open, can be represented by a state diagram:

$$C \leftrightarrow O \tag{5}$$

where C stands for closed and O stands for open. The $C \rightarrow O$ transition is referred to as activation; the reverse process, $O \rightarrow C$, is called deactivation. Since ion channels are metastable and can exist in multiple states, there is no way of knowing a priori which state a single ion channel will be in at any moment in time. After observing the activity of an ion channel for some length of time, however, one can collect statistics that describe the probability that an ion channel will be in the closed or open state, the average duration of each closing and opening, and the frequency of switching between states. These parameters are part of a set of fundamental variables that uniquely describe the activity of an ion channel. A stimulus can activate the ion channel by destabilizing the closed state or stabilizing the open state and thus increase the probability that an ion channel will be in the open state. A closed state that is accessed after the ion channel opens is referred to as the inactive state (I). An ion channel with three states may have the following state diagram:

$$C \leftrightarrow O \leftrightarrow I \tag{6}$$

The $O \rightarrow I$ transition is referred to as inactivation. Often, the state diagrams of ion channels are complex and can contain multiple interconnecting closed, open, and inactive states.

The physical change in the ion channel structure that is responsible for gating remains an area of active research. Studies of several model ion channels have revealed a range of mechanisms by which ion channels may gate. For one channel, the nicotinic acetylcholine receptor (nAChR), scientists have been able to get a glimpse of the gating process with the use of the electron microscopy. Thus far, this has only been possible for the nAChR because the *Torpedo* electric ray produces abundant amounts of this protein that can form crystalline arrays in the membrane. These images revealed that this ion channel has an outer vestibule that makes it a great deal longer than the vertical height of the plasma membrane. Images taken before and after treatment with acetylcholine have been used to model the conformational changes that occurred after ligand binding. The binding site for acetylcholine lies on the outer vestibule, and the binding of ligand is transduced as a signal to the transmembrane segments that then undergo a concerted change in structure to open the pore. Unfortunately, the resolution of these images is too low to provide a detailed view of the gating process. One model postulates that the pore is lined by "kinked helices" whose vertices project into the pore in the closed state. After treatment with acetylcholine, the kinked helices appear to rotate away from the pore. This rotation may move hydrophobic residues that block the pore out of the way and replace them with polar residues.

Another well-studied gating mechanism is the inactivation gating of voltage-gated potassium channels (Fig. 6b). Inactivation can be eliminated, while other properties are left intact, by treating the inside of the channel with proteases. This and other experimental observations of the inactivation process can be explained by a "ball-and-chain" mechanism. In this model, part of the ion channel that binds the pore (ball) is tethered to the ion channel by a linker (chain) and blocks the pore once the channel has been activated. The region of the ion channel that forms the ball can be expressed by itself. As further evidence of this mechanism, when the ball is directly applied onto protease-treated ion channels, inactivation can be restored.

Inward rectifier potassium channels illustrate that the gate does not need to be an intrinsic part of the ion channel (Fig. 6c). Inward rectifying potassium channels pass larger currents into the cell than out of the cell. The channel alone, however, exhibits little or no rectification but displays rectification when it is brought near a cell, suggesting that a soluble factor is involved. In the case of inward rectifier potassium channels, it was discovered that Mg^{2+} and

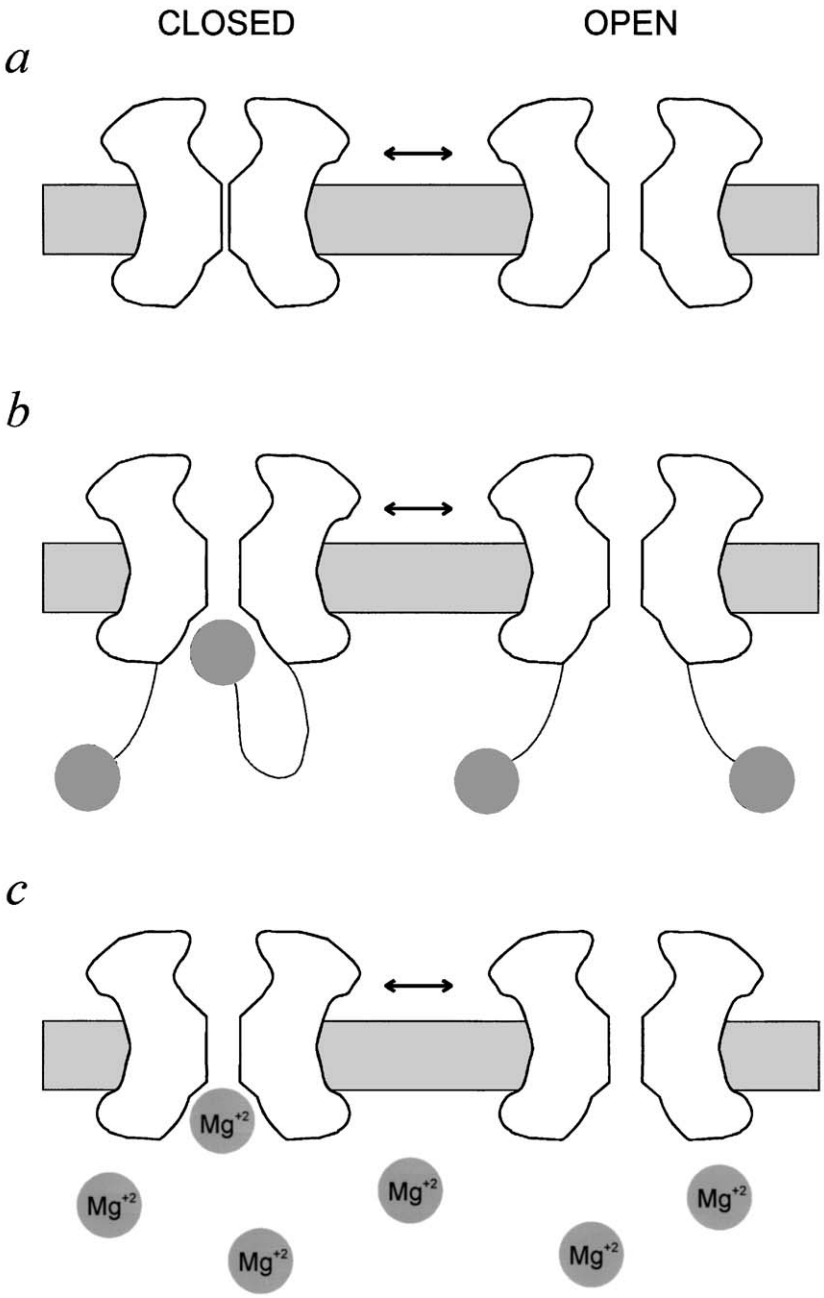

Figure 6 Three examples of ion channel gating mechanisms depicted as a cartoon. (a) Gating occurs via a generalized change in the structure in the region of the pore. The nicotinic acetylcholine receptor undergoes a conformational change of its M2 segment that closes the ion conduction pathway. (b) "Ball-and-chain" mechanism of inactivation gating in voltage-gated potassium channels. (c) Inward rectifiers are gated by extrinsic factors (e.g., Mg^{2+}) that block the pore. The block is voltage dependent; therefore, inward rectifiers conduct more current below E_K and little current above E_K.

polyamines, amino acid metabolites, produced rectification by binding to the pore of the channel at depolarized membrane potentials but not at hyperpolarized membrane potentials.

F. Ion Channel Modulation

Aside from the binding of a ligand or other stimuli that activate the ion channel, the gating of the ion channel

can be affected by other factors that affect the ease of opening the ion channel. This process is loosely referred to as modulation and can occur through the binding of a second messenger or a covalent modification of the ion channel such as phosphorylation. The role of modulation is to tweak or fine-tune the gating of an ion channel, although in some instances the line between modulation and gating can be blurred. For example, the phosphorylation of CFTR is necessary for channel openings to occur.

In general, modulation events originate at receptors that are at a distance from the ion channel. The response is usually slower in onset because a second messenger needs to be generated and then diffuse to the ion channel. The signal transduction cascade also branches off to influence other effectors that produce major changes in a cell's functioning. The modulation of ion channels can be part of long-lasting changes in the cell.

III. MOLECULAR PROPERTIES OF ION CHANNELS

A. Primary Structure of Ion Channels

What do ion channels look like? Although ion channel currents have been measured for many decades, only recently with advancements in molecular biology have their structures been determined in any detail. The goal of understanding ion channel structure is a biochemical one. Usually, the initial step is to determine the primary structure of the ion channel protein. Currently, this is achieved by first cloning the ion channel gene and then reading the protein sequence from its cDNA. The nicotinic acetylcholine receptor was the first ion channel to have its sequence identified through the work of Shosaku Numa and colleagues in 1982. They first purified the ion channel protein from the *Torpedo* electric ray and obtained small bits of protein sequence. Then they designed short oligonucleotides that corresponded to their protein sequence and hybridized them to a cDNA library that contained genes from *Torpedo*. In this way, they obtained the entire cDNA sequence and read the entire amino acid sequence of nAChR.

Ion channels have also been identified using genetic methods. *Shaker*, a voltage-gated potassium channel from *Drosophila melanogaster*, was cloned by Lily and Yuh Nung Jan and colleagues in 1987. *Shaker* derives its name from the behavior of mutant flies when exposed to ether and was long suspected to be an ion channel based on biophysical studies. *Shaker* had already been localized to a region of the X chromosome. To identify part of the gene sequence, the Jan group performed Southern blots on a series of *Shaker* mutant flies with chromosomal rearrangements. Then, they were able to obtain the entire *Shaker* sequence by probing a *Drosophila* cDNA library with their partial DNA sequence.

Once a member of an ion channel family has been identified, other members of the same family can be identified by sorting through DNA libraries for genes that have related sequences. What was in the past done with petri dishes and nitrocellulose membranes is now being done using computers. With the growing information collected from genome sequencing projects, it is increasingly common for new ion channel genes to be identified through the Internet. Once a putative ion channel sequence has been found, a relatively straightforward sequence of steps can be used to clone the gene by amplifying from a sample of genomic DNA.

A great deal of information about what the ion channel looks like can be obtained from the primary structure. For example, it is known that membrane proteins contain discrete stretches of hydrophobic amino acids that span the lipid bilayer. These transmembrane segments can be identified with computer programs that search the protein for long stretches of hydrophobic residues. Combined with other information, one can derive a model of the membrane topology of the ion channel. The models that are generated, however, can be imperfect. There are several experimental methods by which scientists can test whether a region of the protein lies on the extracellular or intracellular face of the membrane. One is to identify sites that are glycosylated since they are known to be present only on the extracellular parts of a protein. Another is to raise antibodies against specific stretches of the protein and determine whether the antibodies bind from the inside or the outside surface of the cell.

The membrane topography is a useful scheme for classifying ion channels (Fig. 7). For example, there are three classes of potassium channels. The gene for voltage-gated potassium channels has six transmembrane segments, numbered S1–S6, and another hydrophobic region between S5 and S6 called the P region, which does not cross the plasma membrane. The P region contributes to the pore of the ion channel. The inward rectifier potassium channels have two transmembrane segments with a P region between M1 and M2. A third class of potassium channels is called two-pore channels because each gene contains two P regions. Two-pore channels have four transmembrane

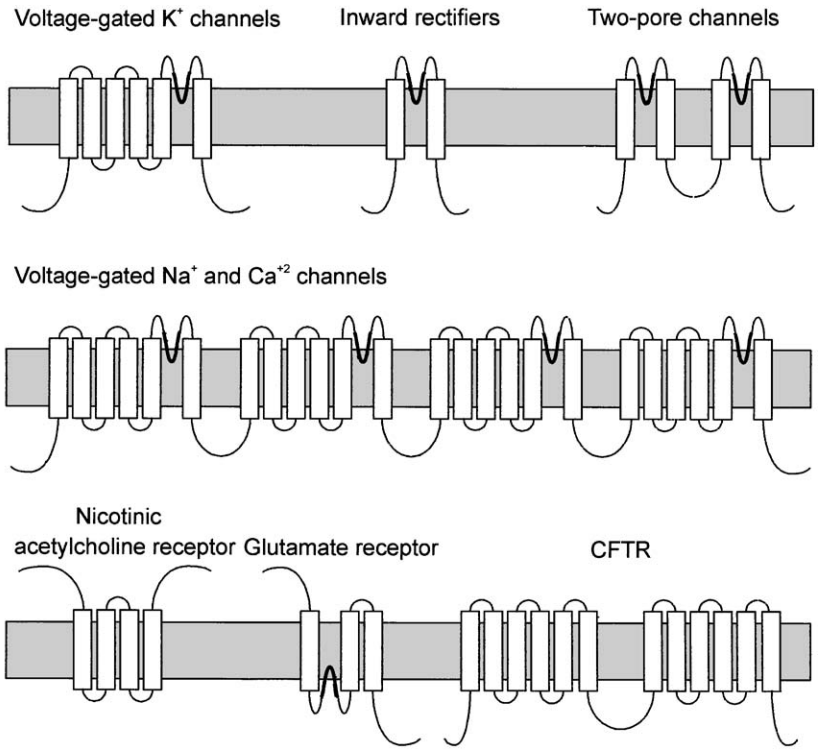

Figure 7 The membrane topology of ion channels. Voltage-gated sodium and calcium channels resemble four voltage-gated potassium channel subunits linked together. The nicotinic acetylcholine receptor and the glutamate receptor are both ligand-gated ion channels but have different membrane topologies. Two-pore channels look like two inward rectifiers fused together. Among ion channels, CFTR belongs to a unique class of membrane proteins.

segments, M1–M4. The membrane topology also gives clues about the function of different parts of the ion channel. For example, the binding site for acetylcholine in nAChR would be limited to those regions that faced the extracellular side.

Sequence analysis of different ion channel families suggests that ion channels are evolutionarily related. Two-pore channel genes resemble two inward rectifier potassium channel genes linked together, and voltage-gated sodium channels and voltage-gated calcium channels resemble four voltage-gated potassium channel genes linked in tandem.

The cloning of ion channels has revolutionized the study of ion channels by allowing scientists to make changes in the amino acid sequence and then test them. One particular strategy of making mutations—making chimeric ion channels—has been especially powerful in determining ion channel structure and function. In one well-known example, Numa, Sakmann, and colleagues used this method to conclude that M2 in the nicotinic acetylcholine receptor is important for determining the conductance of nAChR. In this strategy, one starts with two related ion channels that have different properties. In this case, it was known that nAChR expressed with the δ subunit from calf has a conductance of 65 pS, whereas the δ subunit from *Torpedo* has a conductance of 87 pS. In order to identify the residues that were responsible, Numa and colleagues made hybrid genes by splicing parts of the gene for the calf δ subunit to the *Torpedo* δ subunit and measured their conductance. With successive chimeras that contained increasingly smaller parts of the *Torpedo* gene, they were able to determine that the M2 segment is the region that determines the difference in conductance between the calf and *Torpedo* δ subunits.

This approach has been instrumental in assigning functional roles to parts of ion channels. Using this approach, it has been revealed that ion channels are modular in design (Fig. 8). One caveat, however, is that one cannot exclude the involvement of other regions of the gene since replacement of those regions would not be detected if they shared a similar sequence or function.

Our understanding of ion channels has facilitated efforts to find more ion channel genes in computer

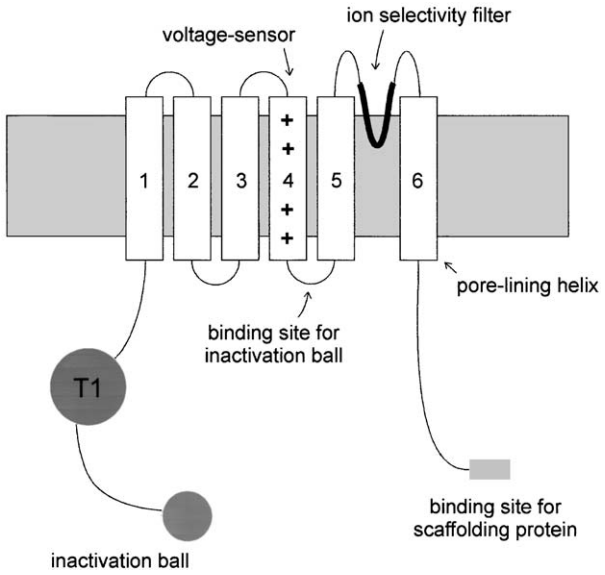

Figure 8 The modular design of voltage-gated potassium channels. Regions of the gene perform separate functions. Some of these functions can be transferred to other ion channels by transplanting that region alone.

databases. The parts of the ion channel that are functionally important are more likely to be conserved through evolution; therefore, database searches that are weighted to these residues are more likely to find homologs that may otherwise have little sequence conservation. The completion of the genomes of organisms with nervous systems, such as the fruit fly, *D. melanogaster*, or the worm, *Caenorhabditis elegans*, has ushered in a new set of more complex questions to be addressed. What are all the ion channels in a nervous system or in an animal? Given the redundancy of ion channel genes, what is the minimum set of ion channels needed for a functional nervous system?

B. Ion Channel Assembly

Ion channels are typically assembled from many subunits that form the pore-lining structure. The number of subunits that form ion channels varies from subfamily to subfamily. For example, four subunits of voltage-gated potassium channels assemble to form a single ion channel. Likewise, inward rectifier ion channels are tetramers. Most ligand-gated ion channels are pentamers, and gap junction ion channels are hexamers.

Ion channels that are members of the same subfamily can assemble with each other because they share molecular determinants that allow them to interact. For example, there are four subfamilies of voltage-gated potassium channels, Kv1–Kv4, related to *Shaker*. It is known that members of one Kv subfamily can coassemble together, but not with members of the other subfamilies. By carefully designing chimeras between the different Kv genes, the Jan group identified a stretch of amino acids in the N-terminal cytoplasmic domain before S1 that determines whether two Kv channels can interact with each other. This region, called the T1 domain, appears to form a structural domain that by itself can form a stable tetrameric structure. The T1 domain has been solved by X-ray crystallography. Analysis of the structure of the T1 domain from different Kv subfamilies shows that the interface between the T1 domain from each subfamily differs structurally. This suggests that members of different Kv subfamilies cannot coassemble because their T1 domains are incompatible.

Ion channels assembled from different subunits will exhibit different functional properties. Because ion channels can assemble from several genes of a given subfamily, the number of potential ion channels is expanded combinatorially. The reason for this potential diversity is unknown. One possibility is that the incorporation of certain subunits is used to regulate ion channel selectivity, gating, or biosynthesis. The inclusion of a subunit with certain sequence motifs has been shown to be able to target an ion channel to specific compartments within the cell or alter the stability of an ion channel on the plasma membrane.

In vivo, ion channels are often part of a complex with accessory proteins that can modify its functional properties or stability in much the same way that mixing subunits can do so. These other proteins are often referred to as β subunits, with the ion channel being the α subunit. β subunits can be soluble or integral membrane proteins. In some cases, the ion channel cannot be expressed in heterologous systems without its accessory subunits, suggesting that the β subunit is an essential part of the functional ion channel complex.

C. The Three-Dimensional Structure of Ion Channels

The final frontier is to be able to visualize the three-dimensional structure of ion channels. In 1998, Rod MacKinnon and colleagues reported the three-dimensional structure of a potassium channel and Doug Rees

and colleagues reported the structure of a mechanosensitive channel using X-ray crystallography. High-resolution structural studies of ion channels are difficult to perform because it is difficult to obtain sufficient quantities of ion channel protein for crystallization experiments and it is harder to coax membrane proteins into forming crystals than it is to coax soluble proteins. Both MacKinnon and Rees used bacterial ion channels that are easier to produce recombinantly.

Rod MacKinnon and colleagues determined the structure of the KcsA potassium channel from the bacteria *Streptomyces lividans* (Fig. 9a). KcsA has two transmembrane segments, which might place it in the same category as inward rectifier potassium channels. However, sequence analysis of KcsA suggests that it is more closely related to voltage-gated potassium channels than inward rectifiers. In support of this view, KcsA interacts with a peptide toxin, agitoxin2, that blocks *Shaker* but not inward rectifiers. One of the most satisfying aspects of the channel structure has been how well it agrees with predictions from functional studies of potassium channels. The structure is 45 Å long and the pore is narrow at the top, where the selectivity filter is predicted to be located. The helical structure resembles an "inverted teepee," and in the center of the ion channel there is a wide cavity that MacKinnon refers to as the "lake." As predicted by earlier experiments, the ion selectivity filter is formed from residues in the P region, and the carbonyl oxygens of GYG are held at a diameter that is optimal for allowing K^+ to pass. Previously we stated that ion channels catalyze the transfer of ions across an electrostatic barrier, the plasma membrane. The KcsA structure depicts two elegant mechanisms by which an ion channel overcomes the barrier. First, a water-filled lake reduces the electrostatic barrier by simply surrounding the ion in an aqueous environment. Second, the negative ends of the dipoles formed by four pore helices point toward the center of the lake, forming a point of negative electrostatic potential in the center of the membrane that is favorable for a cation.

Doug Rees and colleagues determined the structure of a mechanosensitive ion channel, MscL, from *Mycobacterium tuberculosis* (Fig. 9b). MscL is activated when lateral tension is applied to the lipid bilayer and is used by bacteria to rapidly release intracellular solutes when they are placed in a hypoosmotic environment. One motivation for studying MscL was to understand how mechanical stress could gate this ion channel. Since the open MscL channel has been shown to be able to pass a whole protein, thioredoxin, it is likely that the structure in Fig. 9b represents the closed channel. It is possible that normally lateral pressure in the membrane clamps the ion channel shut. When this pressure is released, MscL may expand into the open state.

IV. ION CHANNELS BY FAMILY AND FUNCTION

So far, we have discussed ion channels in the general sense. In the short time since the cloning of the nicotinic acetylcholine receptor, scientists have cloned and identified many ion channels, but it is clear that there are more ion channels that have yet to be discovered. An equally daunting task is to investigate the role that ion channels play in physiology. Although a complete review of the ion channel literature is beyond the scope of this articles in this section we introduce the major ion channel families and attempt to explain why some of these ion channels have attracted the interest of scientists.

A. Voltage-Gated Ion Channels

Broadly, voltage-gated ion channels are involved in the generation of electrical signals in excitable cells such as neurons (Table I). Voltage-gated sodium channels are activated when the membrane potential reaches a certain threshold potential, and they contribute to the rapid depolarization of the membrane potential. Some invertebrate species lack voltage-gated sodium channels. In these animals, voltage-gated calcium channels may partially fulfill the roles of voltage-gated sodium channels. Voltage-gated calcium channels also mediate the entry of Ca^{2+} in response to depolarization. In nerve terminals, activation of voltage-gated calcium channels by axonal action potentials is a critical step in the release of synaptic vesicles.

The voltage-gated ion channels are related in structure. Potassium channels contain one domain of six transmembrane segments per subunit, whereas sodium and calcium channels contain four domains in one large α subunit. The distinguishing feature of this group of ion channels is that they are sensitive to changes in the membrane potential. A remarkable feature of these ion channels is that they contain basic amino acids interspersed in the fourth transmembrane segment (S4). These charges could potentially sense the electric field across the membrane, and movement of S4 could transmit changes in the membrane potential to the gate. Although S4 is likely a part of the

Table I
Voltage-Gated Ion Channels

Ion channel	Ion selectivity	Function
Voltage-gated sodium channel	Na^+	Generates the upstroke in action potentials
Voltage-gated calcium channel	Ca^{+2}	Maintains the plateau of action potentials; allows the entry of Ca^{+2} in nerve terminals and muscle cells
Voltage-gated potassium channel	K^+	Generates the downstroke in the action potential; controls the frequency of action potentials; transports K^+ across membranes
Hyperpolarization-activated cation channel	Na^+, K^+	Mediates I_h and I_f; generates synchronous firing patterns in cells

mechanism by which ion channels sense voltage, precisely how voltage-gated ion channels respond to changes in the membrane potential and how this change is transmitted to the gate are still not completely understood.

Voltage-gated sodium channels and calcium channels are important targets of drugs used in the treatment of hypertension, cardiac arrhythmias, epilepsy, and pain. Voltage-gated sodium channels are famous for being the target of tetrodotoxin (TTX), a naturally occurring toxin most commonly associated with the pufferfish *Fugu* (it has been proposed that tetrodotoxin is actually synthesized by microorganisms living on the pufferfish). TTX blocks voltage-gated sodium channels with high affinity and thus inhibits action potentials, making it a potent neurotoxin. Marine species use TTX either to paralyze prey or to discourage natural predators. In Japan, fugu is treasured as a delicacy since low doses of TTX can produce paresthesia around the mouth when consumed (ironically, encouraging a predator). Fugu can only be prepared by licensed chefs; however, deaths from fugu poisoning are still reported.

In addition to their role in generating action potentials, voltage-gated potassium channels are involved in a wide array of other functions. This is reflected by the expression of voltage-gated potassium channels by cells outside the nervous system. The voltage-gated potassium channel family is much more diverse than the voltage-gated sodium and calcium channel families. Since the cloning of *Shaker*, the family of voltage-gated potassium channels has grown to include at least nine different subfamilies. One group, the calcium-activated potassium channels, is sensitive to changes in intracellular Ca^{2+} concentration as well as membrane potential. This feature allows them to help control the frequency of firing of action potentials. The entry of Ca^{2+} following repeated action potentials helps to activate these channels, which prolongs the duration of the undershoot of the membrane potential following the spike. Longer afterhyperpolarizations can slow the rate of action potential firing or stop it.

A new class of voltage-sensitive ion channels that mediates a hyperpolarization-activated cation current was recently identified. This current, I_h or I_f, is also referred to as the pacemaker current because it is important in establishing the rhythmic oscillatory firing of action potentials. In the heart, I_f regulates the beat-to-beat variations in the heart rate, and in the brain it helps generate synchronous oscillations in neuronal networks that can be observed in electroencephalograms. The gene that encodes the pacemaker current appears to be a cousin of voltage-gated potassium channels; however, it is not apparent how this channel is activated by hyperpolarization while other voltage-gated ion channels are activated by depolarization.

B. Ligand-Gated Ion Channels

Ligand-gated ion channels are activated upon the binding of a neurotransmitter to the ion channel and are involved in fast synaptic transmisssion in the nervous system. Many of the ion channels in Table II have a wide tissue distribution outside of the nervous system and have other functions beyond synaptic transmission. These neurotransmitters include acetylcholine, γ-aminobutyric acid (GABA), glycine, glutamate, and serotonin (5-hydroxytryptophan), and the ion channels are more commonly referred to as receptors. Several of these neurotransmitters also activate a second distinct type of receptor. This second receptor type is a heptahelical receptor that produces intracellular second messengers through the modulation of G proteins. Most commonly in the context of glutamate receptors, the ligand-gated ion channel is referred to as an ionotropic receptor, whereas the G

Table II
Ligand-Gated Ion Channels

Ion channel	Ion selectivity	Function
Nicotinic acetylcholine receptor	Na^+, K^+	Fast synaptic transmission in the nervous system and at the neuromuscular junction
$GABA_A$ receptor	Cl^-	Fast inhibitory transmission in the brain
Glycine receptor	Cl^-	Fast inhibitory transmission, predominantly in the brain stem and spinal cord
Serotonin receptor	Na^+, K^+	Fast synaptic transmission
Glutamate receptor	Na^+, K^+, (Ca^{+2})	Fast excitatory transmission in the central nervous system; mediates ischemic neuronal cell death; involved in learning and memory?
P_{2X} receptor	Na^+, Ca^{+2}	Fast synaptic transmission; sensation of pain in the trigeminal system

protein-coupled receptor is referred to as a metabotropic receptor. A familiarity with the nomenclature is helpful in determing whether a neurotransmitter receptor is ionotropic or metabotropic.

On the basis of sequence similarity, it was originally assumed that these ligand-gated ion channels formed one superfamily. The current view is that glutamate receptors have a different transmembrane topology and belong to a distinct family of ligand-gated ion channels.

The nicotinic acetylcholine receptor is a pentamer, and each subunit contains four transmembrane segments with the N and C termini outside of the membrane. Among ligand-gated ion channels, the nicotinic acetylcholine receptor has been the most thoroughly characterized. This is due to the fact that the *Torpedo* electric ray has been a source of abundant amounts of the protein and this receptor mediates synaptic transmission at the neuromuscular junction, which is a synapse that has been amenable to biophysical studies. At the neuromuscular junction, acetylcholine is released from the motoneuron and diffuses across the synaptic cleft to activate the receptor. The opening of ion channels depolarizes the membrane and generates an action potential in the muscle that initiates muscle contraction.

The nicotinic acetylcholine receptor derives part of its name from nicotine, which is an agonist of this ion channel. The nicotine in tobacco products mediates the stimulatory and addictive effects of smoking and suggests that nACh receptors in the brain play a role in cognition as well as the activation of reward pathways. Along similar lines, experimental evidence suggests that patients with Alzheimer's disease have depleted levels of acetylcholine, indicating the importance of nicotinic acetylcholine receptors in normal cognitive functioning.

GABA is the major inhibitory neurotransmitter in the brain. $GABA_A$ receptors are ligand-gated ion channels, whereas $GABA_B$ receptors are G protein-coupled receptors. In the brain stem and spinal cord, glycine is also used as a neurotransmitter in inhibitory synapses. Both $GABA_A$ and glycine receptors are chloride channels that when activated hyperpolarize the cell and make it more difficult for excitatory neurotransmitters to depolarize the membrane. Clinically, $GABA_A$ receptors are the target of benzodiazepines, which are used as sedatives, muscle relaxants, and anticonvulsants. Benzodiazepines work by a distinctive mechanism. They do not activate $GABA_A$ receptors by themselves. Instead, they facilitate the action of GABA that is released by binding to an allosteric site on the ion channel.

Glutamate is the major excitatory neurotransmitter in the brain, and many scientists believe that glutamate receptors are involved in learning and memory. Under pathological conditions, glutamate receptors also mediate the neurotoxicity associated with cerebral ischemia. By analogy to the nicotinic acetylcholine receptor, glutamate receptors were originally believed to have four transmembrane segments. This model has since been revised so that the second transmembrane segment does not traverse the plasma membrane, leaving three membrane-crossing segments—M1, M3, and M4 (the numbering of the transmembrane segments was not changed). This moved the M3–M4 loop to the outside of the cell and the C terminus to the interior of the cell.

The glutamate receptors are heterogeneous and classified based on sequence and pharmacological profile into NMDA receptors, AMPA receptors, and kainate receptors. Many of the glutamate receptors have been cloned. The distinctive features of NMDA receptors versus non-NMDA receptors fit well with

proposed mechanisms of neuronal plasticity. Near the resting potential, the majority of fast excitatory neurotransmission is mediated by AMPA receptors, which are permeable to Na^+ and K^+. NMDA receptors carry little current since they are blocked by Mg^{2+} at resting potentials. With a strong stimulus, however, enough AMPA receptors are activated to depolarize the cell and relieve the Mg^{2+} block of NMDA receptors. This is significant because NMDA receptors are highly permeable to Ca^{2+}. The entry of Ca^{2+} can initiate a signal transduction cascade that produces a long-lasting potentiation in subsequent synaptic potentials. Mechanisms of use-dependent enhancement of synaptic efficacy are often implicated in models of learning and memory.

Given the significance of Ca^{2+} permeability in glutamate receptors, the low Ca^{2+} permeability of AMPA receptors is achieved by a remarkable genetic mechanism. Sequencing of the gene and cDNAs of a particular AMPA receptor subtype (GluRB) revealed a discrepancy in the codon at a position in the second transmembrane segment. The gene contains a glutamine (Q) codon, whereas the cDNA contains an arginine (R) codon. It was later discovered that this codon is edited posttranscriptionally by the action of an enzyme in the nucleus that converts an adenine base into inosine. This single position, referred to as the Q/R site, also controls the Ca^{2+} permeability of AMPA receptors. In heterologous systems, AMPA receptors with Q in the Q/R site display high Ca^{2+} permeability, whereas AMPA receptors with R in the Q/R site display low Ca^{2+} permeability.

C. Inward Rectifiers and Two-Pore Potassium Channels

Inward rectifier potassium channels constitute another family of potassium channels distinct from voltage-gated potassium channels. Inward rectifiers are involved in maintaining the resting membrane potential near E_K or mediating the transport of K^+ across membranes (Table III). Some subfamilies of inward rectifiers respond to intracellular effectors that are produced by the activation of surface receptors. The activity of GIRKs (Kir3.0) is activated by the binding of the $G\beta\gamma$ subunits of G proteins. The activation of GIRKs is associated with the generation of slow inhibitory postsynaptic potentials in the brain and the slowing of the heart rate in response to vagal stimulation.

Inward rectifiers have the simplest structural plan of any ion channel. Like voltage-gated potassium channels, they are tetramers and contain a P region that forms part of the ion selectivity filter, but they contain only two transmembrane segments, M1 and M2. Inwardly rectifying potassium channels, as the name implies, allow more K^+ to enter the cell than to leave the cell. This property is a result of blocking of the pore from the intracellular side by polyamines or Mg^{2+} at depolarized potentials. Two acidic amino acid residues in M2 and the C terminus of inward rectifiers have been identified as part of the binding sites for the blocking particles.

Members of the Kir6.0 subfamily associate with the sulfonylurea receptor, a member of the ABC family, and form K_{ATP} ion channels that are sensitive to intracellular levels of ADP and ATP. Therefore, these ion channels link the membrane potential to the metabolic state of the cell. This property at work is best illustrated in the feedback regulation of blood glucose levels by the controlled release of insulin. In pancreatic β cells, the metabolism of glucose generates ATP, which inhibits K_{ATP}. This depolarizes the membrane potential and activates voltage-sensitive calcium channels that allow Ca^{2+} to enter the cell. The entry of Ca^{2+} then triggers the release of vesicles containing insulin, which stimulates glucose uptake by other tissues. Clinically, this pathway is utilized to help

Table III
Inwardly Rectifying Potassium Channels

Ion channel	Ion selectivity	Function
ROMK (Kir 1.0)	K^+	Salt reabsorption in the distal kidney
IRK (Kir 2.0)	K^+	Setting the resting membrane potential
GIRK (Kir 3.0)	K^+	Slowing the heart rate and slow inhibitory postsynaptic potentials in the brain
Kir 6.0	K^+	With the sulfonylurea receptor, forms K_{ATP}; regulates hormone release; cardioprotection during ischemia; regulates vascular tone

manage individuals with diabetes mellitus with oral hypoglycemics drugs that block K_{ATP} and stimulate the release of insulin.

Two-pore channels are a newly identified family of potassium channels. Their name derives from the presence of two P regions per gene. They have four transmembrane segments and resemble two inward rectifier subunits fused together. By analogy to inward rectifiers, it is believed that two-pore channels are dimers and not tetramers. Unlike inward rectifiers, two-pore channels display an outwardly rectifying current and are active at rest. Two-pore channels can be modulated by arachidonic acid or other unsaturated fatty acids, and inhibition of two-pore channels is a potential mechanism of excitatory neurotransmission. Evidence suggests that activation of two-pore channels may mediate some of the anesthetic effects of volatile gases such as chloroform or ether.

D. Chloride Channels

In addition to the $GABA_A$ and glycine receptors described previously, the chloride channels include the CLC family, CFTR, and other channel families that have yet to be identified. Chloride channels are involved in the regulation of cell volume, the transport of Cl^-, pH homeostasis, and membrane excitability. The CLC channels contain numerous hydrophobic stretches; however, the membrane topology of the CLC channels is unknown, with various models having 8–12 transmembrane segments.

The CFTR is a chloride channel that was cloned from molecular genetic studies of patients with cystic fibrosis. Its major role is in the transport of Cl^- across epithelial cells in many organs, such as the pancreas, lung, sweat glands, and kidneys. CFTR is a member of the ATP-binding cassette (ABC) family of ion transporters. ABC proteins are generally known for mediating the ATP-driven transport of substances; for example, the MDR protein pumps chemotherapeutic drugs out of the cell. Therefore, the CFTR ion channel is a unique member of this family.

Ion channels are fantastic molecular machines. Their functions are fundamental—they act as valves for ions to move into or out of the cell—and thus they play important roles in many physiological processes. The study of ion channels is challenging but rewarding since it ranges from exploring the function of ion channels on the cellular and systems level down to the atomic level to investigating how ion channels as proteins work. The first crystal structures of ion channels have ushered in a new era in ion channel research. With more structures and functional studies of ion channels and the cloning of ion channels involved in channelopathies, the next decade promises to be an exciting time for ion channel research.

Language Acquisition

HELEN TAGER-FLUSBERG
Boston University School of Medicine

GLOSSARY

binding principles According to the syntactic theory, known as government binding theory, these are the rules of our grammar that dictate the relation between words, for example, pronouns and their referents.

communicative competence Linguistic competence and knowledge of the social rules for language use.

constraints Limits or biases that children bring to the task of language acquisition. A constraint may dictate a cognitive or pragmatic strategy in the interpretation of words.

grammar The finite set of rules shared by all speakers of a language that allows all possible sentences to be generated.

intentional communication Any communicative act that a person engages in purposefully.

language A symbolic system, based on syntactic, semantic, and phonetic features, that allows mutually intelligible communication among a group of speakers.

learnability Various models of language acquisition based on several assumptions concerning the nature of children, known learning mechanisms, the structure of language, and the logical inferences that can be drawn from these assumptions.

morphology The rules that govern the use of free or bound morphemes, the minimal meaningful units of language.

overregularization errors A common error among children that involves applying regular and productive grammatical rules to words that are irregular or exceptions.

parameter A type of linguistic switch that is set after children are exposed to particular forms in their native language; it is one of a finite number of values along which languages are free to vary.

phoneme A speech sound that can signal a difference of meaning in a language.

semantics The study of the meaning system of language.

speech acts Aspects of the pragmatic systems referring to different functions of utterances, such as requesting or promising.

theory of mind Knowledge about the mind and mental states of other people that is used to interpret their actions and the intended meaning of utterances.

universal grammar Hypothetical set of restrictions governing all forms that human languages may take.

Language acquisition refers to the process of achieving the ability to speak and understand the particular language or languages to which a child has been exposed. By the time most children reach the age of 5, they are highly competent speakers of their native language. During these early years of development, children acquire the ability to perceive and produce the speech sounds of the language to which they are exposed and the phonological rules for combining them to create words. They also acquire a large and varied vocabulary and the rules for combining them into complex grammatical sentences with correct morphology to mark tense, mood, number, and so forth. Finally, they become proficient users of this linguistic system to perform a range of different speech acts appropriate to varied social contexts. These remarkable achievements in the acquisition of language occur without explicit instruction or even significant feedback from others. Language is a complex, componential system composed of an abstract phonological rule system and lexicon, syntax, morphology, pragmatic, and discourse rules. These components depend on the development of different cognitive and neural mechanisms that interact over the course of acquisition.

I. PRELINGUISTIC DEVELOPMENTS

A. Speech Perception

Infants come into the world prepared to acquire language. At birth they are able to distinguish speech from other sounds and, indeed, to perceive and discriminate speech sounds in the same way as adults. They can discriminate between syllables that differ by a single phonetic feature (e.g., ba vs pa). Studies have demonstrated that during the first months of life infants discriminate all phonetic contrasts between speech sounds in their native language as well as those occurring in other languages to which they have not been exposed.

During the second half of the first year speech perception abilities undergo significant changes and reorganizations. As a result of continued exposure to the sound properties of their native language, infants show a reduction and eventual loss in the capacity to discriminate speech sound contrasts that are present only in foreign languages. At the same time, by the age of 6 months infants become more attuned to the sound structure of their native language, preferring the prosodic patterns of their own language as opposed to those found in languages they have not heard. By the age of 9 months, infants also prefer listening to word lists in which the words follow the constraints on ordering phonetic segments in their native language over those in which the words violate those constraints.

B. Social Developments

From the start, these sophisticated speech perceptual abilities are closely tied to the infant's social experience. Studies of newborns have shown that they distinguish their own mothers' voices from those of other mothers, which is most likely related to prenatal exposure to the acoustic properties of the mothers' speech. In the visual domain, newborns also show a preference for human faces and can even imitate facial expressions. Thus, from the beginning, the social niche for language is clearly established.

During the first few months of life, rapid changes take place. Mothers and their infants begin to interact in a finely tuned way with one another. They synchronize their patterns of eye gaze, movements, and facial expressions of affect in ways that resemble turn-taking patterns in conversations. By the age of 4 months, there is a marked increase in vocal turn-taking during these rich interactions between infants and their caretakers. Toward the end of the first year of life, vocalizations as well as other nonvocal behaviors again become genuinely integrated into social interaction as infants' developing social cognitive capacities lead to the onset of intentional communication. At this point, infants becomes capable of coordinating their attention to objects or events with other people through eye gaze patterns (joint attention), gestures, and vocalizations. This developmental achievement is generally viewed as a critical step in language acquisition, with the onset of communicative intent. Infants at this stage are able to communicate a variety of meanings, including protodeclaratives, which involve pointing or other gestures to draw another person's attention to an object of interest, and protoimperatives, meaning a gesture or vocalization to express a request or demand for an object. The significance of these communicative attempts is that they suggest the infant is capable of understanding the intentions of others (the beginning of a theory of mind), at least in a rudimentary or implicit form.

C. Speech Production

During the first year of life the infant's vocal abilities are also changing. Initially, because of anatomical limitations, newborns produce mostly cries or occasional gurgling. Infants begin producing sounds at approximately the age of 2 months, with the onset of cooing—vocalizations produced in the back of the mouth. By 4 months, most infants engage in vocal play, including a broad range of different kinds of sounds such as some rudimentary consonant–vowel (CV) syllables. By 6 months, infants produce canonical babbling, consisting of systematic CV syllables with adult-like timing. During this stage, infants are sensitive to the feedback they receive from their own babbling, and there are increases in the variety of consonants produced. By 10 months, infants babble in a conversational or modulated manner, with more complex strings of sounds that have varied intonation. These stages form the backdrop against which phonological development takes off during the second year of life.

One question that has been addressed in research on babbling is whether there is a connection between the sounds that an infant selects to produce and those in the target language in the infant's environment. A

second question concerns the relationship between babbling and the onset of language. There is growing evidence suggesting that there is important continuity between prelinguistic babbling and the first words produced by infants. Not only do these stages overlap but also there is considerable overlap in sounds incorporated in babbles and early words. Furthermore, research on the development of vocal babbling in deaf infants suggests that the auditory feedback that infants receive from their own as well as others' sounds is crucial in shaping the course of development. Thus, recent studies have shown that deaf infants begin babbling later than hearing infants and in a more limited way. Even the sounds are somewhat different, presumably because deaf infants lack auditory feedback from their own sounds and have no access to the speech sounds in their environment. At the same time, deaf infants exposed to sign language during the first year of life begin manual babbling: They produce repetitive sequences of sign-language formatives that parallel the syllabic units of vocal babbling.

D. Mechanisms Underlying the Capacity for Language Acquisition

The development of the basic capacities that form the foundation of language acquisition in infancy is largely determined by the maturation of linguistic, motor (articulatory or manual), and social mechanisms that undergo developmental changes as a result of exposure to and feedback from particular language environments. Two distinct biologically based mechanisms are considered crucial for language acquisition: a domain-specific language system and a social mechanism that is dedicated to the development of understanding of other minds. Normal development of language depends on the integration of these distinct mechanisms, both of which depend on stimulation from the linguistic and social environment.

II. PHONOLOGICAL ACQUISITION

A. Stages of Development

As noted previously, it is generally agreed that there is essential continuity between prelinguistic babbling and the earliest stages of phonological development evidenced in the child's first words. The majority of sounds produced in the earliest words of children are the same as those preferred in their babbles. Initially, children's words are composed of simple CV syllable structures, using a relatively small inventory of sounds. Gradually, over time and with growth in the child's vocabulary, there is an expansion in the range of sounds produced by children. Although there is no universal order in the acquisition of phonological features, certain regularities have been found in the phonological sounds that are used across children. Mastery over vowels occurs before consonants. The main consonant classes that are used earlier in development include stops (e.g., b and d), nasals (e.g., m and n), and glides (e.g., w). Later developing consonants include fricatives (e.g., v) and liquids (e.g., l and r).

B. Systematic Error Patterns

As children begin producing more elaborated syllable structures and a wider range of sounds, they begin producing speech sound errors. The most striking feature of these errors is that although there are individual differences in the particular kinds of errors made, the errors are not random but instead fall into common patterns. In children with more severe articulation difficulties, words may be produced that involve combinations of different error patterns.

1. Omissions

Children will often omit syllables or specific sounds as they attempt to reproduce more complex adult words. Typically, unstressed syllables will be omitted—those occurring at the beginning of words (e.g., "mato" for "tomato") or in the unstressed medial position (e.g., "e'phant" for "elephant"). Consonant clusters will lead to omissions. For example, in English, one common error is to omit the /s/ in /s/ + stop consonant clusters (e.g., "top" for "stop"). Sometimes, final consonant sounds will be omitted (e.g., "go" for "gone").

2. Feature Changes

Another class of error patterns is the changing of sounds at the level of individual articulatory features. For example, voiced consonants may be changed to unvoiced consonants (e.g., bot for pot or gat for cat). Place changes also may be found in some children, with back consonants becoming more frontal (e.g., dame for game and bup for cup). These kinds of errors demonstrate the significance of features in children's phonological representations.

3. Assimilation Errors

A third class of errors illustrates how the child's representation of the target word may influence the kinds of sound substitutions that are made. Assimilation errors entail the change in one sound in the target word to make it more similar to another sound in that word. Such errors may involve assimilation in different feature classes, such as voicing (e.g., "doad" for "toad") or place ("gog" for "dog").

C. Theoretical Explanations

One of the main debates in the literature on phonological development has been between those advocating the view that very early phonological development is a discontinuous stage, which does not map onto the adult system, and those who argue that from the beginning young children's phonological systems share properties of the adult system. More evidence has accrued in favor of the latter view, called the continuity hypothesis, which suggests that the same underlying mechanisms are used in phonological acquisition as in the adult speaker.

One important piece of evidence for the continuity hypothesis is that infants are capable of perceiving speech in a mature, adult-like way before they even begin producing their first words. Furthermore, it is clear from the developmental and error patterns described here that children's attempts at producing target words are guided by abstract representations of speech sounds, including representations of syllable structures and distinctive articulatory features. At the earliest stages, the representations of syllable structures are very simple (e.g., simple CV structures referred to as minimal words), and these become more elaborate and complex over time. Similarly, children's earliest words may only include a small group of distinctive features that are considered marked (such as labials). Again, these expand over time, until by age 3 or so, the majority of children have mastered the phonology of their native language.

III. LEXICAL–SEMANTIC DEVELOPMENT

A. Stages of Development

Lexical development can be divided into three periods. The first period covers the acquisition of the initial 50 words or so, during which children are learning what words do. At this stage, some words appear to be tied to particular contexts and serve primarily social or pragmatic purposes. Word learning during this initial phase is relatively slow and uneven. A word may be equivalent to a child's holistic representation of an event. Especially in Western middle-class children, the child's vocabulary at this stage is dominated by names for objects, including animals, people, toys, and familiar household things. There will also be some social words (e.g., "hi" and bye), modifiers (e.g., "more" and "wet"), and relational terms that express success, failure, recurrence, direction and so forth.

By the middle of the second year, there is a significant increase in the rate at which children acquire new words. This new period is usually referred to as the vocabulary spurt, or naming explosion, and may be punctuated by many requests from children for adults to label things in the world around them. Words are learned very quickly, often after only a single exposure that may take place without any explicit instruction. This process of rapid word learning is referred to as "fast mapping." This phase of vocabulary growth is marked by a close relationship between lexical and grammatical development.

By the time children reach their third birthday, they begin to develop a more organized lexicon, in which the meaning relations among groups of words are discovered. For example, at this time children begin to learn words from a semantic domain, such as kinship, and they are able to organize the words according to their similarities and differences on dimensions of meanings. For nouns labeling concrete objects, children begin to organize taxonomies, also learning words at the superordinate and subordinate levels and understanding the hierarchical relations among terms such as dachshund, dog, and animal. Semantic developments at this stage will often lead to reorganizational processes as these kinds of relationships among words are realized by the child. The rate of word learning continues to be very rapid, with estimates suggesting that children acquired about 15–20 new words a day during the preschool years and beyond.

B. Developmental Processes

1. Conceptual Development

The fact that children can grasp the meaning of a word without explicit instruction, and in a variety of circumstances, suggests that there is a significant role played by preexisting or ongoing developing conceptual representations. During the early phases of word

learning, studies demonstrate how specific conceptual developments at this stage are closely related to the acquisition of particular words. For example, infants develop the ability to retrieve hidden objects within a few weeks of acquiring words such as "*gone*" that encode the concept. In some children the words were acquired before the concept, in others the reverse was found. This suggests that at this early phase, while conceptual development can influence semantic development, it is also the case that semantic development can influence conceptual change. Thus, the relationship between language and conceptual development, or more generally between language and thought, is highly complex, with each system placing constraints on the other and both dependent on the social environment for their elaboration in development.

During the toddler years, objects tend to be named at the so-called basic object level (e.g., dog or car) rather than at the subordinate (e.g., dalmatian and Mercedes) or superordinate (e.g. animal and vehicle) levels. Objects within the same category at the basic object level tend to share perceptual and functional features, and they do not overlap with related semantic categories. Thus, this level may be the most useful for children for both functional and cognitive reasons. Parents also have been shown to name objects for children at the basic object level and this too might explain why this is the preferred level for children's early words.

Once a new word is learned it is quickly generalized to new contexts. Much of the focus of research on word meanings has been on the extension of a word. At this stage, children will sometimes overextend the meaning of a word, broadening the use of a term beyond its semantic boundaries. Typical examples include calling all women "Mommy" or using "ball" to name any round object. Overextension errors may be made on the basis of functional or, more frequently, perceptual similarity, or they may involve an associative complex of features. Another kind of extension error that is not so easily noticed occurs when the child *underextends* the use of word, not using a word to label an appropriate referent. Underextension errors tend to be noted at earlier stages of lexical development, whereas overextension errors are more typical of this period, after the naming explosion.

The most widely accepted view of what guides the acquisition of word meanings at this stage is the child's conceptual representations. The initial representation may be of a particular referent to which new examples are compared. Later, this semantic representation becomes more abstract and may be composed of a composite image or set of features for a prototype or best exemplar. This theory can explain both underextension and overextension errors; however, it is a theory of lexical development that is most usefully applied to the child's acquisition of names for concrete objects but not to other kinds of word classes.

2. Contextual Influences

Even during the earliest stages of word learning, children rarely make errors about the mapping between a word and its referent. Despite the fact that children may not have words for most concepts in the world, they almost always hone in on the correct meaning of a word learned in various social contexts. One important developmental process that makes this possible is that children understand other peoples' intentions and bring this knowledge of other minds to the task of word learning. Thus, they will carefully observe what a speaker is looking at or playing with when a new word is spoken. Children monitor the speaker's line of regard and assume that a novel word refers only to the object that is in the attentional focus of the speaker, indicating that they are sensitive to subtle cues to a speaker's referential intentions.

3. Constraints on Word Meaning

A number of researchers have argued that what makes word learning possible, especially when the child is capable of fast mapping, is a set of constraints that guides the child's hypotheses about the possible meanings of words. Eve Clark proposed a very general kind of constraint, called the *principle of contrast*, which states that every two words in a language contrast in meaning. This principle operates in conjunction with the *principle of conventionality*, which states that there are conventional words that children expect to be used to express particular meanings so that if a speaker does not use the conventional word, then the child assumes that the new word must have a somewhat different meaning. A different version of the principle of contrast is called the *mutual exclusivity constraint*. This constraint leads the child to assume that each object only has a single name, and that a name can only refer to one category of objects. When children hear a new word, they will look around for a referent for which they do not currently have a label. This explains why young children are reluctant to accept superordinate labels for individual objects. Other constraints that have been proposed include the *whole-object constraint*, which states that new words

refer to whole objects rather than parts of objects (if, however, the child already knows the name of the object, then the word might be considered as labeling a part or property of the object), and the *taxonomic constraint*, which states that words refer to categories of objects.

Although some view these kinds of constraints as innate principles that are specific to lexical development, others view them as more general biases that may be an aspect of broader pragmatic or cognitive processes. Although there are still disagreements about how to characterize constraints on the child's hypotheses about the meanings of new words they encounter, most researchers agree that children use these heuristics to help them with the rapid mapping of words onto underlying meaning representations.

4. Syntactic Bootstrapping

Much of the research on semantic development has focused on the acquisition of nouns. Verbs, on the other hand, pose a different kind of problem because there is often not enough information in the context to help the child distinguish between related verbs such as "look" and "see." Children need to use syntactic information to help them figure out the meanings of verbs. The particular kinds of information that children can use include the number and kind of arguments that occur with the verb. Thus, transitive verbs take object arguments, whereas intransitive verbs do not. This kind of information is useful in helping the child interpret verb meaning. Syntactic bootstrapping is also useful for helping the child distinguish mass nouns (e.g., spaghetti) from count nouns (e.g., a potato) or common nouns from proper names, and very young children have been shown to be able to use this information when they hear new words in ambiguous contexts. As children's language progresses and they begin acquiring knowledge about the syntactic frames in which words occur, they begin to integrate syntactic and semantic information in this way. This process underscores the interrelationships that drive both semantic and syntactic development.

IV. THE ACQUISITION OF SYNTAX AND MORPHOLOGY

A. Stages of Development

Before the end of the second year, soon after the spurt in vocabulary development, children reach the next important milestone in language development: They begin to combine words together to form their first sentences. This is a crucial turning point because even the simplest two-word utterances show evidence of early grammatical development. The child's task in acquiring the grammar of her native language is complex. First, children need to segment the stream of language into morphemes (the minimal unit of language that carries meaning), phrases, and sentences. They must then discover the major word classes, such as noun, verb, and determiner, and map the appropriate lexical terms into these word classes. Children then learn how to grammatically encode tense, plurality, gender, and so forth, often using morphemes that are attached to verbs or nouns. At the same time, they acquire the major rules for organizing basic phrasal units such as noun phrase (e.g., article + adjective + noun—"*The tall man*") and verb phrase (e.g., verb + tense + prepositional phrase—"*walk-ed to the park*") as well as for organizing basic sentence structures for declaratives, questions, and negation. In the final stages, children figure out the syntactic rules for complex sentences involving coordinating and embedding multiple clauses.

B. Measuring Grammatical Development

1. Production

One of the obvious ways that children's sentences change over time is that they gradually grow longer. This fact is the basis for one of the most widely used measures of grammatical development, the mean length of utterance (MLU), which is the average length of a child's utterances as measured in morphemes. The assumption underlying this measure is that each newly acquired element of grammatical knowledge adds length to the child's utterances. Studies confirm that MLU increases gradually over time, and that it is a better predictor of the child's language level than chronological age. Nevertheless, it is only valid as a measure of development up to an average sentence length of four morphemes, and it may not be useful without significant modifications as a measure for languages other than English.

2. Comprehension

It is much more difficult to measure the child's comprehension of syntactic and morphological structures. Although in naturalistic contexts young children

give the impression they understand significantly more that they say, this may reflect the child's use of nonlinguistic context and other cues rather than knowledge of abstract linguistic structure to compute the underlying semantic relations of sentences.

Methods to assess comprehension include a variety of paradigms, each of which has both advantages and disadvantages. The oldest method is the use of diary studies, which document the conditions and contexts in which a child understands or fails to understand a particular structure. Experimental procedures may include act-out tasks, in which an experimenter asks the child to enact a sentence or phase using a set of toys and props, or direction tasks, in which the child is asked to act out an event or command. Choice selection paradigms have also been developed, including picture-choice tasks, in which the child selects from a set of pictures the one that best represents the linguistic form presented by the experimenter, and preferential-looking tasks that have successfully been used with infants. In this kind of task infants listen to a linguistic message and have the choice of two videos to observe, only one of which matches the message. Infants who look reliably longer at the matching scene are credited with understanding the linguistic structure that was presented.

C. Early Word Combinations

When children begin to combine words to form the simplest sentences, most are limited in length to two words, although a few may be as long as three or four words. These early sentences are often unique and creative, composed primarily of nouns, verbs, and adjectives. In English, function words (such as articles or prepositions) and other grammatical morphemes, such as noun (e.g., plural –s) and verb inflections (e.g., past tense -ed or present progressive –ing), are usually omitted, making the child's productive speech sound "telegraphic"; however, this is less true for children learning other languages, such as Italian or Hebrew, that are rich in inflectional morphology.

1. Semantic Relations

Cross-linguistic studies of children at this stage have shown that there is a universal small set of meanings, or semantic relations, that are expressed, including agent + action, action + object, entity + location, entity + attribute, and demonstrative + entity. Children talk a lot about objects by naming them and by discussing their locations or attributes, who owns them, and who is doing things to them. They also talk about people, their actions, their locations, their actions on objects and so forth. Objects, people, actions, and their interrelationships preoccupy young children universally.

2. Limited Scope Formulae

Initial studies of utterances produced in the two-word stage found that children used highly consistent word order. Indeed, the semantic relations approach assumed that the child uses a productive word order rule that operates on broad semantic rather than syntactic categories. This research was limited by focusing primarily on languages that make extensive use of order to mark basic relations in sentences and on a small number of children. It is now acknowledged that there is considerable individual variation among children learning different languages, and even for children learning English. Nevertheless, word order rules are used at this early stage of grammatical development, but they are more limited and more narrowly defined in semantic scope than is suggested by the semantic relations approach and therefore have been called *limited scope formulae*. For some children ordered combinations of words may even be based on specific lexical items rather than on semantic categories. Over time, these more limited rules expand to encompass broader semantic and later syntactic categories and begin to resemble the adult grammar.

3. Null Subjects

One characteristic of children's two-word sentences is that they often omit the subject. Recently, this has been interpreted from the perspective of current linguistic theory, which proposes a parameter-setting approach. Some theorists argue that all children begin with the subject parameter set in the null position (which holds for languages such as Italian or Spanish) so that children learning English must eventually switch the parameter setting to the position marked for required subjects.

Although this proposal is attractive because it connects early grammar to linguistic theory, there are several criticisms of this approach. Although English-speaking children do omit subjects, in fact they include them significantly more often than Italian-speaking children, which suggests that they know that subjects need to be expressed. Subjects are probably omitted

because young children have limited processing capacity, and for pragmatic reasons subjects are more readily omitted than objects because they are often provided by the context.

D. Development of Grammatical Morphology

1. Invariant Order of Acquisition

As children progress beyond the two-word stage, they gradually begin to fill in the inflectional morphology and function words that are omitted in their early language. The process of acquiring the major grammatical morphemes in English is gradual and lengthy and some are still not fully controlled until the child enters school. Studies have found that the order in which English morphemes are acquired (e.g., articles, past tense, prepositions, or auxiliary verbs) is strikingly similar across children. The order of acquisition is not accounted for by frequency of use by the child or mother; instead, it is related to measures of both semantic and syntactic linguistic complexity.

2. Overgeneralization and Rule Productivity

One striking error that children make in the process of acquiring grammatical morphemes is the overregularization of regular forms to irregular examples. For example, the plural *-s* is frequently added to nouns that take an irregular plural, such as "*mans*" instead of "*men*" or "*mouses*" instead of "*mice*," and the regular past tense ending *-ed* is sometimes used on verbs that are marked with an irregular form, such as "*falled*," "*goed*," or "*teached*." These errors may not be frequent, but they can persist well into the school years and are quite resistant to feedback or correction. They are taken as evidence that the child is indeed acquiring a rule-governed system rather than learning these inflections on a word-by-word basis.

Other evidence for the productive use of morphological rules comes from an elicited production task introduced by Jean Berko Gleason called the Wug test. The child is shown drawings depicting novel creatures, objects, and actions and asked to supply the appropriate description that would require the inclusion of noun or verb inflections. For example, a creature was labeled a wug, and then the child had to fill in the blank for "*there are two* ____." Preschool aged children performed well on this task, demonstrating their internalized knowledge of English morphological rules that can be applied productively.

Steven Pinker has argued that two different mechanisms are involved in acquiring regular and irregular forms. Regular forms involve a linguistic rule-governed mechanism, whereas irregular forms are retrieved directly from the lexicon and thus involve a memory storage system. This dual-mechanism hypothesis has been challenged by models developed within connectionist frameworks, in which only a single mechanism is needed to compute the correct form for regular and irregular examples, after being trained on mixed input. The debate between these camps continues.

3. Cross-Linguistic Evidence

There is a growing literature on the acquisition of morphology in other languages. Overgeneralization errors have been recorded in children learning many different languages suggesting this is a universal pattern for this aspect of grammatical development. However, the slow and gradual development of English morphology does not hold up for languages that have richer morphological systems. For example, children acquiring Turkish use suffixes on nouns that mark the noun as either the subject or object of the sentence, at even the earliest stages of language development, and children learning Italian acquire verb inflections marking person, tense, and number very rapidly and in a less piecemeal fashion than has been found for English morphology. These cross-linguistic variations seem to reflect differences among languages in the amount of inflectional morphology within a language and the degree to which inflections are optional. For example, English marks verbs only for the past tense, third person singular present tense (e.g., "*he walk-s*"), or progressive aspect (e.g., "*he is walk-ing*"), whereas Italian verbs are always marked in various ways. Children appear to be highly sensitive to these differences from the beginning stages of acquiring grammar.

E. The Acquisition of Sentence Modalities

1. Simple Declaratives

As children progress beyond the two-word stage, they begin combining words into three- and then four-word sentences. In doing so, they link together two or more basic semantic relations that were prevalent early on. For example, *agent* + *action* and *action* + *object* may be linked to form *agent* + *action* + *object*. These simple

declarative sentences include all the basic elements of adult sentences. Gradually these may become enriched with the addition of prepositional phrases, more complex noun phrases that include a variety of modifiers, and more complex verb phrases including auxiliary and modal verbs. All these additions add length to the declarative sentences of young children.

2. Negation

Although children do express negation even at the one-word stage (e.g., using the word "*no!*"), the acquisition of sentential negation is not fully acquired until much later. There are three stages in the acquisition of negation in English: (i) The negative marker is placed outside the sentence, usually preceding it (e.g., "*not go movies*" and "*no Mommy do it*"); (ii) the negative marker is sentence internal, placed adjacent to the main verb but without productive use of the auxiliary system (e.g., "*I no like it*" and "*don't go*"); and (iii) different auxiliaries are used productively and the child's negations approximate the adult forms (e.g., "*you can't have it*" and "*I'm not happy*"). Although the existence of the first stage has been questioned by some researchers, there does appear to be cross-linguistic support for an initial period when negative markers are placed outside the main sentence.

Negation is used by children to express a variety of meanings. These emerge in the following order, according to studies of children learning a wide range of languages: "nonexistence," to note the absence of something or someone (e.g., "*no cookie*,"); "rejection," used to oppose something (e.g., "*no bath*"); and "denial," to refute the truth of a statement (e.g., "*that not mine*"). Some children show consistent patterns of form–meaning relations in their negative sentences. For example, one child used external negation to express rejection while at the same stage reserved sentence internal negation forms to express denial. These patterns may have had their source in the adult input.

3. Questions

There are several different forms used to ask questions, including rising intonation on a declarative sentence; yes–no questions, which involve subject–auxiliary verb inversion; *wh-* questions, which involve *wh-* movement and inversion; and tags, which are appended to declaratives and may be marked lexically (e.g., "*we'll go shopping, okay*?") or syntactically ("*we'll go shopping, won't we*?"). Children begin at the one- or two-word stage by using rising intonation and one or two fixed *wh-* forms, such as "*what that*?" Gradually, over the next couple of years syntactic forms of questions develop with inversion rules acquired simultaneously for both yes–no and *wh-* questions. Some data suggest that for *wh-* questions, inversion rules are learned sequentially for individual *wh-* words, such as "*what*," "*where*," and "*who*," "*why*," and may be closely linked in time to the appearance of those words used as *wh-* complements. Thus, syntactic rules for question formation may be *wh-* word specific in early child language.

Several studies of English and other languages have investigated the order in which children acquire various *wh-* questions and the findings have been consistent. Children generally begin asking and understanding "*what*" and "*where*" questions, followed by "*who*," then "*how*," and finally "*when*" and "*why*" questions. One explanation for this developmental sequence is that it reflects semantic and cognitive complexity of the concepts encoded in these different types of questions. Thus, questions about objects, locations, and people (i.e., *what, where*, and *who*) involve less abstract concepts than those of manner, time, and causality (i.e., *how, when*, and *why*). The early emerging *wh-* questions are also syntactically less complex in that they involve simple noun phrase replacement, whereas the later developing questions involve prepositional phrases or full sentence complements.

4. Passives

Despite the rarity of the passive construction in everyday conversations in English, a good deal of attention has been paid to how children use and understand passive sentences. Because the order of the agent and patient is reversed, this particular construction can reveal a great deal about how children acquire word order rules that play a major role in English syntax.

Elicited production tasks have been used to study how children construct passive sentences, typically using sets of pictures that shift the focus to the patient. Younger children tend to produce primarily truncated passives (e.g., "*the window was broken*") in which no agent is specified. These truncated passives generally have inanimate subjects, whereas full passives are produced by children when animate subjects are involved, suggesting that full and truncated passives may develop separately and be unrelated for the younger child. It has been suggested

that truncated passives are really adjectival, whereas the later appearing full forms are complete verbal passives.

Numerous studies have used an act-out procedure to investigate children's comprehension of passive voice sentences. Typically, these studies compare children's comprehension of passive sentences to active sentences that are either reversible, in which either noun could plausibly be the agent (e.g., "*the boy kisses the girl*" or "*the boy is kissed by the girl*"), or semantically biased, in which one noun is more plausibly the agent than the other (e.g., "*the girl feeds the baby*" or "*the girl is fed by the baby*"). Studies find that children correctly interpret the plausible passive sentences before they do the reversible sentences. Preschoolers acquiring English tend to make errors systematically on the reversible passive sentences, suggesting the use of a processing strategy, called the word-order strategy whereby noun–verb–noun sequences are interpreted as agent–action–object. Children learning languages other than English may develop different processing strategies that closely reflect the canonical ways of organizing the basic relations in a sentence in their native language. For example, Japanese is a verb-final language that marks the agent with a suffix *-ga* rather than with a fixed word order, although there is a preference for an *agent–object–verb* order. Preschool-aged Japanese children tend to use a strategy that takes the first noun marked with *-ga* as the agent of the sentence. Thus, children's processing strategies are tailored to the kind of language they are acquiring and show that preschoolers have already worked out the primary ways that their language marks the basic grammatical relations.

Studies of the acquisition of other languages such as Sesotho, in which the passive construction is very frequent because subjects always mark sentence topic, have found that children acquire the passive much earlier and use it much more productively than do English-speaking children. Again, this suggests that children are sensitive to the typology of their language and that these factors influence the timing of development for the passive.

The semantic characteristics of the verb also influence the child's comprehension of passive sentences. Although 5-year-olds do correctly understand passive sentences that have action verbs, they find it more difficult to interpret passive sentences with nonaction verbs (e.g., "*Donald was liked by Goofy*"). Thus, the acquisition of passive voice continues into the school years as the child's knowledge becomes less constrained by semantic aspects of the verb.

F. Complex Sentence Structures

1. Coordinations

As early as 30 months of age, children begin combining sentences to express compound propositions. The simplest and most frequent method children use to combine sentences is to conjoin two propositions with "*and*". One question that has been investigated in numerous studies regards the order in which different forms of coordination develop. Both sentential (e.g., "*Mary went to school and Peter went to school*") and phrasal coordinations (e.g., "*Mary and Peter went to school*") tend to emerge at the same time in development, suggesting that these forms develop independently and are not, for young children, derived from one another. Children form phrasal coordinations by directly conjoining phrases, not via deletion rules.

Semantic factors influence the course of development of coordination. Children use coordinations first to express additive meaning, where there is no dependency relation between conjoined clauses (e.g., "*maybe you can carry this and I can carry that*"). Later, temporal relations (e.g., "*Joey is going home and take her sweater off*") and then causal relations (e.g., "*she put a Band-aid on her shoe and it maked it feel better*") are expressed, suggesting that children begin demonstrating greater semantic flexibility even while limiting themselves to the use of a single connective, "*and*."

2. Relative Clauses

Sometime after children begin using coordination, relative clauses emerge in their spontaneous speech. Initially, they are used to specify information exclusively about the object of a sentence (e.g., "*let's eat the cake what I baked*"), and often the relative pronoun is omitted or incorrect. The use of relative clauses in the spontaneous speech of young children is quite rare, perhaps because children avoid these syntactically complex constructions or because they lack the occasion to use them when the context is shared by the speaker and listener.

Elicited production techniques have been used successfully with preschoolers. These studies have also found that children find it easiest to add relative clauses to the ends of sentences rather than to embed them within the matrix clause. This suggests that some processing constraints operate on young children's productive capacities.

3. Anaphoric Reference

Children's knowledge of grammar continues to develop beyond the preschool years. One area that has received a good deal of attention from researchers is their knowledge of coreference relations within sentences, especially how anaphoric pronouns and reflexives link with referents. This research has been conducted primarily within a government-binding theoretical framework, investigating children's knowledge of the main binding principles. Spontaneous productions of pronominal forms suggest that quite young children use them correctly in their productive speech, however, the limits of their knowledge cannot be accurately assessed in naturalistic contexts.

Generally, children appear to develop knowledge of the main principles in the following order. By age 6 children know principle A, which states that reflexives are bound to referents within the same clause (e.g., "*John watched Bill wash himself*"; "*himself*" must refer to Bill, not John). Sometime later, knowledge of principle B emerges, which states that anaphoric pronouns cannot be bound to referents within the same clause (e.g, "*John asked Bill to hit him*"; "*him*" him must refer to John in the "*ask*" clause, not Bill in the "*hit*" clause). The last principle to emerge sometime during middle childhood is principle C, which states that backward coreference is only allowed if the pronoun is in a subordinate clause to the main referent (e.g., "*when he came home, John made dinner*"). Some researchers have argued that the grammatical knowledge of these principles is acquired much earlier that the research would suggest but that children's performance on tasks that tap this knowledge is limited by processing factors, pragmatic knowledge, or lexical knowledge. This debate continues in the developmental psycholinguistic literature.

G. Theoretical Explanations

1. Semantic Bootstrapping

Current theories in language acquisition attempt to address the central question of how the young child acquires the abstract and formal syntactic system of his or her language so rapidly, without formal instruction and with no feedback about whether he or she is using correct or incorrect forms. In the past two decades, one idea that has gained prominence in the literature is that children may use semantics or meaning to help break into the grammar of their language. Steven Pinker has been the main proponent to argue that children may use semantics as a bootstrap into syntax, particularly to acquire the major syntactic categories on which grammatical rules operate. Thus, children can use the correspondence that exists between names and things to map onto the syntactic category of noun, and they can use physical attributes or changes of state to map onto the category of verb. At the initial stages of development all sentence subjects tend to be semantic agents, and so children use this syntactic–semantic correspondence to begin figuring out the abstract relations for more complex sentences that require the category of subject.

2. Functionalism

A very different theoretical approach has been taken by those who view the central task of the child as gaining communicative competence. Much of the research conducted within this framework has focused on the acquisition of pragmatic aspects of language, including the functions of utterances and their use in discourse and other communicative contexts. Within research on grammatical development the functional approach does not take formal syntactic theory as its primary model. Instead, the structure of language is viewed from a functional or processing perspective. One example is the competition model of language acquisition proposed by Elizabeth Bates and Brian MacWhinney. In this model, the child begins by establishing the basic functional categories: topic–comment and agent. Different surface representations of these functional categories then compete for expression and initially the child may use a simple one form–one function mapping. Eventually, children move toward the adult system of form–function mappings.

3. Distributional Learning

At some point, all theories of acquisition need to consider how the child learns the major syntactic categories, even if they begin with a simple lexically specific, functional, or semantic approach. Thus, from the stream of words that children hear around them they must figure out which ones belong to the different major word classes, such as nouns, verbs, or adjectives. One important approach to this learning problem is the distributional learning view, according to which children not only use semantic mappings to acquire a category such as verb but also use distributional factors, such as it takes an *-ed* ending to express pastness or an *-ing* or *-s* ending in present tense

contexts, it occurs with auxiliary verbs, and so forth. In this view, children come to know that a particular morpheme is a verb because they hear that morpheme cooccurring with inflections that mark tense, for example. This kind of approach argues that children are sensitive to all kinds of distributional patterns in the linguistic input to which they are exposed.

4. Parameter-Setting Theory

Linguists working within a government-binding framework who have taken an interest in the question of how children acquire the grammar of their language claim that the central task of acquisition is to set the parameters of universal grammar in the direction appropriate for the language that is being acquired. Some argue that the parameters are initially set in one position, which may then have to be switched. An alternative view holds that parameters start off neutrally—that is, they are not set in any position. As children are exposed to their native language, they use linguistic evidence present in the environment to set the parameters accordingly.

V. PRAGMATIC DEVELOPMENT

In recent years, there has been increased interest in investigating how children acquire the ability to use language to fulfill a range of functions and in a variety of communicative contexts. This emphasis reflects the notion that to become a competent speaker requires not only knowledge of the structural forms and meanings of a language but also the ability to communicate using those forms in a competent, flexible, and appropriate manner. Some researchers have argued that language forms develop to serve new communicative functions, not *vice versa*. This aspect of language development is closely tied to the child's developing theory of mind and related social knowledge.

A. Communicative Functions

1. Speech Act Theory

What are the communicative functions expressed in children's speech? This approach to the child's language is based on the theory of speech acts proposed by Austin and Searle, among others, and has been very influential in child language research. These philosophers argue that many utterances do not simply make an assertion, but they also operate as *performatives*—that is, they perform an act (e.g., promise or refuse). Each utterance has three components: the *illocutionary intent*, or goal of the speaker; the *locutionary act*, or the actual form of the utterance; and the *perlocutionary effect*, the influence on the listener. In this way, we can account for the many different utterances that can be used, both direct and indirect, literal or metaphorical, to convey the same message. Thus, one of the questions that derives from this approach to language is how children come to use and interpret indirect and nonliteral uses of language.

2. The Development of Speech Acts

A number of researchers have focused on identifying and classifying the functions of early language, investigating the development of illocutionary intent and its relation to locutionary acts, and several systems have been developed. Children less than age 2 use language to fulfill a number of different functions, including getting people to do things, regulating their own or other's behavior, for social interaction, and as part of their imaginative play. By the time children are 3 years old, new functions emerge, including the use of language to describe objects or events and to assert an opinion, and also a range of conversational devices. At this point, children are also able to express each of these functions using a variety of different syntactic forms.

There is a more protracted period of development for indirect forms, such as indirect requests. Although 2-year-olds use terms such as "*want*" or "*need*" as a way of asking for something (e.g., "*I need new ball*"), genuine indirect requests do not emerge until approximately age 3 (e.g., "*Where is the truck?*"). By age 4, children can use polite forms, including modal verbs to make their request (e.g., "*Would you give me a cookie?*"), but hints or oblique indirect requests are not used until the early school years. Children aged 2 do not discriminate between requests for action and requests for information; however, throughout the preschool and early school years children gradually become able to understand increasingly more oblique levels of indirect speech acts.

B. Social Use of Language

A number of studies have focused on children's developing awareness of the perlocutionary effect of

their utterances and the ability to modify locutionary acts to take into account their listeners' knowledge. Although 5-year-olds know when to use definite and indefinite articles ("*the*" and "*a*"/"*an*"), depending on the listener's presuppositional knowledge about an object, children younger than age 7 or 8 do not perform well on referential communication tasks, in which they are required to describe a scene or unusual object that is hidden from the listener's view. Using more naturalistic data, such as spontaneous speech, other studies have found that even 4-year-olds change the way they speak. For example, they use simpler language if they are talking to 2-year-olds, which shows some awareness of the distinct needs of a very young conversational partner.

C. Conversational Abilities

Communicative competence also entails knowing how to engage in conversations in appropriate and informative ways. A number of studies have focused on the development of conversational abilities, especially the ability to take turns and maintain the topic of conversation. From the earliest stages children are able to take turns in conversation, following their mothers' utterance with their own, usually, although not always, in a semantically related way. This ability to maintain topic increases during the preschool years and the child is now able to respond to his or her mother by expanding on the information in her utterances. This ability to add new information correlates highly with the child's developing linguistic skills, as measured by MLU, and leads to the ability to maintain a topic over longer chains of conversational turns.

The use of language in various contexts provides the interactive, communicative framework within which children acquire knowledge of the linguistic structures available in their native language so that they can express more fully the ideas that are generated by their developing cognitive and social systems.

GLOSSARY

aphasia Disorder of language production and/or comprehension following brain damage.

Broca's area Area in the frontal lobe traditionally thought to contain the motor representations for words.

discourse processing Deriving meaning from conversation and text.

dissociation Preserved performance in one cognitive domain and impaired performance in another. A double dissociation occurs when one patient shows a disruption of one domain and preservation of the other, whereas another patient shows the reverse.

functional level First level of linguistic encoding in sentence production in which nonverbal conceptual information is used to select words and represent their relations.

immediacy of processing theory of comprehension Syntactic analysis and semantic interpretation are carried out on a word-by-word basis as each word is perceived.

lexicon The mental dictionary in which sound, spelling, meaning, and grammatical aspects of words are represented.

modularity hypothesis Hypothesis that different cognitive subsystems (i.e., modules) function independently.

orthography The written representations and rules for spelling of words.

parser A processing module that assigns syntactic structure to a sentence.

phoneme The basic unit of speech sounds.

phonological system The sound system of language.

positional-level Second level of linguistic encoding in sentence production in which the syntactic structure of the sentence is created and phonological representations are selected.

proposition Representation of part of a text that specifies the relations between actions and entities (people or objects) and between entities and their states or properties.

semantic system System that represents word and sentence meaning.

syntactic system System that represents grammatical information in the language.

thematic roles The roles that entities play with respect to a verb, such as agent, theme, or recipient.

Wernicke's area Area in the posterior temporal lobe traditionally thought to contain sound representations for words.

Within the realm of understanding and producing language, the brain is responsible for a wide range of tasks, from recognizing written words to understanding narrative. There is a fairly long history of behavioral studies of normal and brain-damaged populations that has delineated the organization of the component processes involved in various language tasks. Recently, lesion data have been supplemented by electrophysiological and neuroimaging data to reveal the regions of the brain that support language functions. A comprehensive view of language processing must take into account the theoretical developments from both behavioral and neuroimaging approaches.

The task of language comprehension is to transform written words or speech input into a conceptual representation, whereas that of language production is to translate a conceptual message into its spoken or written forms. Language processing can be examined

at the word level, sentence level, or at higher discourse levels (e.g., text and narrative). Various models of language processing have been proposed to represent these levels of analysis. These models vary in scope and detail, but most assume that processing at a given level is carried out by a set of systems. For example, spoken sentence comprehension involves lexical, syntactic, and semantic systems. The lexical system includes the mental lexicon (or mental dictionary), which contains all the information about individual words. In the lexical subsystem, acoustic input is matched to a sound representation of a word (termed a lexical phonological representation). A match to a phonological representation then allows access to other aspects of a word's representation, including its meaning and its grammatical features (such as noun vs verb). A syntactic system uses the grammatical information from each word to construct a representation of the relationships among words within the sentence (i.e., syntactic relationships). The semantic system uses individual word meaning, syntactic information (e.g., which noun is the subject of the verb), and general world knowledge to construct an overall interpretation of sentence meaning.

Some researchers have hypothesized that the separate systems within a domain are modular—that is, they function independently. According to a strong version of the modularity hypothesis, once a module (i.e., system) receives input from another module (e.g., the syntactic system receives grammatical information about a word from the lexical system), the module carries out its computations (e.g., determines how the word fits into the syntactic structure) without further influence from any other modules (termed discrete processing). The output from the module is then passed on to the next module. According to a weaker version of the modularity hypothesis, each module may be represented independently in the brain; however, while a module is carrying out its computations, it may receive input from other modules that influences its processing (termed interactive processing). For example, compare the sentences "Mary saw the bird with binoculars" and "Mary saw the bird with red feathers." Both have the same syntactic structure but semantic information most likely causes listeners to assume that the prepositional phrase "with binoculars" modifies "saw" in the first sentence, whereas "with red feathers" modifies "the bird" in the second. The strong version of modularity would assume that this semantic information only comes into play after a syntactic decision has been made, perhaps leading to a reinterpretation of syntactic structure. The weaker version of modularity would assume that semantic information influences the initial decisions that are made regarding syntactic structure (i.e., that the semantic and syntactic systems interact during early stages of processing). A completely nonmodular theory of language processing would assume that there is no distinction between syntactic and semantic representations—that is, both are represented in the same system, obey the same principles, and have been learned according to the same principles. As discussed later, the evidence from brain-damaged patients supports some form of modularity.

Many current models of language processing are instantiated in a network framework—that is, a network consisting of nodes that represent different types of units (e.g., letters, phonological representations, and concepts) and connections among these nodes. These network models are sometimes referred to as neural networks because the nodes and connections are argued to be analogous to neurons and their synaptic connections. The nodes of a certain type are all represented at the same level and the connections may be between levels or between units at the same level. For example, in written word recognition, there are layers of nodes representing visual features (e.g., straight line and curve), letters, and written word forms. In this type of model, processing is carried out via activation that spreads throughout the network. Stimulus presentation activates the first layer of nodes, and then activation spreads to subsequent layers. For example, if the word "bear" were presented, the visual features corresponding to each letter would be activated; activation would then spread along the connections between features and letters so that the appropriate letters would be activated. Activation of the letters would then lead to a spread of activation along connections between letters and words so that the appropriate word would be activated. In this type of model, partially consistent but incorrect letters and words would be activated, at least temporarily. For example, since "pear" shares features and letters with "bear," this word would be activated to some extent from presentation of "bear." In purely "feedforward" network models, activation flows in only one direction (in this case, from visual features to words). In "feedback" models, activation flows in both directions. In a feedback version of this model, activation from letters would activate corresponding words; however, in addition, activation at the word level would flow back to the letter level, boosting the activation of letters consistent with activated words.

I. LEXICAL PROCESSING

A. Word Recognition

In visual word recognition, a whole word may be viewed at once (provided that it is short enough), and recognition is achieved when the characteristics of the stimulus match the orthography (i.e., spelling) of an entry in the mental lexicon. Speech perception, in contrast, is a process that unfolds over time as the listener perceives subsequent portions of the word. Upon hearing the first syllable of a spoken word such as the "un" in "understand," several words may be consistent with the input (e.g., "under," "until," and "untie"). As subsequent portions are perceived the pool (or "cohort") of words will be narrowed down, until only one word remains.

Despite these differences in the temporal course of processing, there are many commonalities in spoken and written word recognition. In both cases, the goal is to go from the perceptual information to the lexical form in order to access semantic and syntactic information about the word. In visual word recognition, a letter level intervenes between visual processing and lexical access. In auditory word perception, it is often assumed that a phoneme level intervenes between the acoustic input and lexical access. Phonemes are assumed to be the basic sound units of speech perception (and production). In English there are approximately 40 different phonemes, corresponding to the consonant and vowel sounds. The phonemes of other languages overlap those of English to a large degree, although some languages may lack some of the phonemes in English or may contain phonemes that do not exist in English. For example, Chinese does not distinguish between the "l" and "r" phonemes, and some African languages include clicking sounds as phonemes.

There is general agreement that spoken and written word recognition involve access to the same semantic and syntactic representations. There has been some disagreement, though, about whether there are separate lexical representations for spoken and written words. Some researchers have argued that written words have to be transformed into a sound representation in order to access semantic and syntactic information about the word. If so, then only a phonological representation (e.g., one that indicates the sequence of constituent phonemes and the stress pattern) is needed for each word. However, considerable neuropsychological evidence suggests that there are separate phonological and orthographic representations for words, and that access to word meaning can proceed for written words without conversion to a phonological form. Nonetheless, it is the case that for normal individuals the phonological representation of a written word appears to be computed automatically (through an implicit "sounding out" or "letter–sound" conversion process) when a written word is perceived. This derived phonological information can influence the time course of lexical access, making word recognition slower for words that have an unusual letter–sound correspondence, particularly if these words appear infrequently in print (e.g., "yacht"). Despite this slowing, the correct word is typically accessed, indicating that readers cannot be relying solely on letter–sound correspondences in accessing the meaning of written words.

B. Word Production

Spoken and written word production involve the reverse of the processing steps in word perception: conceptual processing to lexical to phonological or orthographic. Motor execution stages involved in articulation and writing would complete the output process.

More research has been devoted to speech production than to writing. In the domain of speech production, a distinction has been made between a nonverbal conceptual representation of the message to be expressed and a semantic representation that is specific to words. Speech production begins with the formulation of the nonverbal conceptual representation, followed by two steps of lexical access. In the first step, a lexical–semantic representation is selected (which also contains syntactic information about the word), and in the second step the phonological form corresponding to the semantic representation is accessed. In a strict modular approach with nonoverlapping stages, only one lexical–semantic representation is selected before processing proceeds to the phonological level. Other approaches assume what is termed "cascaded processing," in which activation spreads from the lexical–semantic level to the phonological level before a single lexical–semantic representation is chosen. Suppose that the speaker wishes to communicate the concept "cat." The conceptual representation for cat would serve to activate most highly the lexical–semantic representation for "cat" but would also activate related lexical–semantic representations to some extent, such as "dog" and "lion," because of

shared conceptual features. In the cascaded model, the phonemes in "dog" and "lion" would also be activated to some extent, even though "cat" might eventually be the most activated at the lexical–semantic level. In a cascaded model with feedback, the activation of the phonemes in "cat" would cause backwards activation of words that shared phonemes with "cat," such as "mat," even though such words had no semantic relationship to "cat."

In writing, as in reading, some have argued that the orthographic forms are dependent on the phonological forms. That is, the writer is assumed to have followed similar steps in written word production as in spoken word production and has accessed a phonological form. This phonological form is then translated into a written form through a phoneme–grapheme conversion process. However, it is even clearer in writing than in reading that orthographic knowledge specific to individual words (i.e., a lexical orthographic representation) is needed for correct spelling. Even for a word with a regular correspondence between sounds and letters, there may be several alternative "regular" spellings (i.e., spellings that follow typical sound-to-letter conversion patterns in English). For example, "kat" or "cat" would be regular spellings for "cat," and "leaf," "leaph," "leef," and "leeph" would be regular spellings for "leaf." Thus, producing the correct spelling depends on having stored knowledge about the sequences of letters in words.

C. Neuropsychological Evidence on Lexical Processing

Evidence for independent modules in lexical processing can be obtained from individuals with brain damage due to a stroke or other injury who can competently produce or understand some types of linguistic information but not others. On the other hand, evidence that the same module is involved in performing two different tasks can be obtained by showing strong correlations between the factors affecting performance on each. In the domain of word recognition, double dissociations between written word and spoken word comprehension have been reported. That is, some patients who show a deficit in recognizing printed words can nonetheless recognize spoken words, whereas other patients show the reverse. For some of these patients, the deficit in spoken or written word perception cannot be attributed to difficulties with basic aspects of visual or auditory perception because the patient can recognize nonverbal materials in both modalities. Instead, the deficit is specifically in the phonological or orthographic processing systems. The existence of patients who can understand written words but who cannot understand spoken words because of disrupted phonological representations argues against the necessity of converting written words to phonological forms in order to access meaning. Evidence that the same lexical–semantic system is involved in comprehending spoken and written words comes from patients who show comprehension difficulties for certain words or certain semantic categories (such as animals or tools), and the same words are affected irrespective of whether the input is spoken or written. If there were separate semantic representations for spoken and written words, it would be highly unlikely that the same categories of words would be affected for both modalities.

Category-specific deficits have been noted for many patients and raise interesting questions concerning the nature of semantic representations in the brain. Although more specific deficits have been observed, these deficits tend to occur in the categories of animals, plants, and artifacts (i.e., man-made objects), with the most common deficit for animals or, more generally, for living things. One possible explanation of category-specific deficits is motivated by the fact that semantic properties of an object tend to be interrelated (e.g., having eyes usually occurs with having a nose) and that objects in the same superordinate category (e.g., tools or fish) share properties. If constellations of shared properties are organized together in the brain, then when damage occurs to a region in which semantic properties are stored, deficits that affect certain categories will result. The only difficulty with this account is that it does not explain why deficits tend to occur in three categories—that is, any constellation of shared properties should be subject to damage and we should observe patients with highly specific deficits such as a deficit for vehicles but not other artifacts.

Another possible explanation for category-specific deficits is that there are two separate semantic systems in the brain—one that represents sensory knowledge and another that represents functional knowledge (i.e., the functions that objects perform). Researchers have argued that knowledge of animals is mainly sensory, whereas knowledge of artifacts is mainly functional. Consequently, damage to the sensory knowledge system results in a deficit specific to animals, whereas damage to the functional system results in a deficit

specific to artifacts. However, findings from some brain-damaged patients are problematic for this sensory/functional explanation. For example, some patients have been reported who have semantic deficits for only some subsets of living things (e.g., fruits and vegetables), and others have been reported who have a disruption of knowledge of both sensory and functional attributes of animals but a preservation of both sensory and functional knowledge for artifacts.

As discussed earlier, models of word production take either a discrete stage or interactive activation approach. Some data from speech errors in normal subjects (either spontaneous or experimentally elicited) support the interactive view. For example, sound exchange errors are more likely to occur if the exchange results in two words (saying "barn door" for "darn bore") than if the exchange results in nonsense words (saying "beal dack" for "deal back"). This effect of lexical status of the resulting error can be attributed to feedback from the phoneme level to the lexical level. The word production errors of aphasic patients can also be better accounted for by an interactive approach. Such an approach provides a means of accounting for some patients' tendency to produce words phonologically related to a target word (so-called "formal errors," such as saying "mat" for "cat") and for some patients' tendency to produce a large proportion of errors that are both semantically and phonologically related to a target (saying "rat" for "cat").

Double dissociations between deficits in written and spoken word production have been observed. Again, in many of these cases, basic deficits in the motor processes involved in speaking or writing can be ruled out, indicating that the modality-specific deficit is specific to phonological or orthographic output processing. Further evidence for the separation of phonology and orthography comes from patients who make semantic errors in only one output modality—for example, producing "pillow" as the name for a picture of a bed when speaking but producing "bed" correctly in writing. Such a pattern would not be expected if it were necessary to use the phonological form to guide spelling.

Evidence from speech production deficits provides information about the representation of grammatical information. Deficits specific to certain grammatical categories have been reported because some patients have selective difficulties in the production of function words (i.e., words such as prepositions, pronouns, and auxiliary verbs that play primarily a grammatical role in a sentence). Such difficulties are remarkable given that these grammatical words are often quite short and easy to pronounce (e.g., "to" and "will") and are the most frequently occurring words in the language. Some patients have demonstrated greater difficulty in producing nouns than verbs, and others have demonstrated the reverse. As with the semantic category deficits, there is no consensus on the explanation for these grammatical class deficits. In some cases, these apparent grammatical class effects have a semantic basis. For example, better production of nouns than verbs and better production of verbs than grammatical words may be observed because the patient is better able to produce more concrete words. However, for some patients, it appears that grammatical class effects cannot be reduced to a semantic basis; consequently, these deficits suggest that at some level in the production system words are distinguished neurally with regard to the grammatical role that they play in a sentence. The separability of grammatical information from other types of lexical information is supported by other findings showing that some patients with picture-naming deficits can provide grammatical information about a word, such as its gender (in a language such as Italian or French), even though they are unable to retrieve any of the phonemes in the word.

Neuropsychological research with brain-damaged patients, more so than research with normal subjects, has addressed the issue of the relation between the phonological processing systems involved in speech perception and production and the relation between the orthographic systems involved in reading and writing. Some patients show an excellent ability to recognize and remember input phonological forms (e.g., being able to decide whether a spoken probe word rhymes with any of the words in a preceding list but have great difficulty in producing output phonological forms (e.g., naming a picture). Other patients show the reverse pattern of great difficulty in holding onto input phonological forms (performing at chance on the rhyme probe task) but showing normal speech production. Similar double dissociations have been documented for orthographic processing. Thus, input and output forms in both speech and writing appear to be represented in different brain areas. However, although the input and output forms may be different, they are linked to each other. For example, individuals can repeat nonwords, converting an input to an output form. A close coupling between input and output forms appears to be involved in the development of speech production and in the maintenance of accurate speech production throughout adulthood.

D. Localization of Word Comprehension and Production

As we have seen, patient studies can be used to posit the nature of the functional components of language comprehension and production and their connections. Studies of localization reveal where in the brain those components may lie. Models of brain areas and their functions can be traced back to the late 1800s, beginning with Lichtheim and Wernicke. Wernicke's model assumed that language was represented in the left hemisphere. Findings since that time have indicated that although the left hemisphere is dominant for language in most individuals, the right hemisphere also plays some role. In addition, the right hemisphere is dominant in some individuals. The model incorporated a concept center that received input from sensory word images and provided output to motor word images. The sensory word images were thought to be represented in Wernicke's area, found in the superior (upper), posterior (near the back), left temporal lobe, and the motor images in Broca's area, found in the left frontal lobe near the motor cortex. Damage to Wernicke's area was thought to result in an inability to recognize and understand spoken words, although speech was thought to be fluent. Broca's aphasics were thought to have an impairment in articulating speech (i.e., "essentially mute, except for the repetition of the same few utterances"), but their comprehension was intact. Wernicke's and Broca's areas, though separate, were thought to be connected through a neural fiber tract (i.e., the arcuate fasciculus). This fiber tract was thought to be involved in translating an auditory word representation into a motor word representation. Based on Wernicke's model, one would predict that patients who had intact Broca's and Wernicke's areas but damage to this fiber tract should have good language comprehension and production but have difficulty repeating words and sentences. Patients were reported who showed this pattern (termed conduction aphasics), which seemed to provide a strong confirmation of the model.

There are a number of observations that cause difficulties for the classical model. For example, Broca's aphasics are not equally impaired on all types of words, typically being better able to produce nouns than verbs. Although they have difficulty producing function words, function words occurring in the middle of sentences are omitted less frequently than those that occur in the beginning of sentences. An additional complication for the Wernicke/Lichtheim models is that although Wernicke's aphasics' speech is fluent it shows numerous aberrations, such as misordered phonemes, incorrect words, and nonsense words such as "tarripoi" in the statement spoken by one Wernicke's aphasic, "I can't mention the tarripoi." Moreover, current studies suggest that among individuals classified into any traditional syndrome category (Broca's, Wernicke's, and conduction aphasia), there are wide variations in the nature of their deficits. For example, within conduction aphasics, some patients produce fluent and appropriate speech output but make semantic substitutions or paraphrases in repeating sentences, suggesting that they have difficulty retaining phonological information on the input side. Other conduction aphasics make numerous phonemic errors in their speech output but do not make semantic substitutions in repeating, suggesting that they have difficulty constructing and maintaining phonological representations on the output side. Thus, localization of function on the basis of classical syndromes appears to be a misguided effort. However, careful examination of a series of individual cases who show similar behavioral deficits allows for the determination of the lesion site that is affected in all such individuals. On the basis of these data, one can look to behavior–lesion correspondences to draw conclusions about localization.

Recently, using methods that measure the physiological changes that occur in the brain, it has been possible to determine the brain areas activated in normal individuals while they are performing language tasks. Electrical activity occurring in the brain during various tasks [i.e., event-related potentials (ERPs)], can be measured. These ERPs show negative and positive electrical potentials that are time locked to the onset of the presentation of verbal stimuli. The brain distribution of these potentials can be plotted. The flow of blood into different regions of the brain can be detected through via positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). The use of PET and fMRI for functional localization thus assumes that greater blood flow is observed in brain areas with greater neural activity. Although all these methodologies provide information about when and where activation occurs in the brain, ERPs are known for their good temporal resolution, whereas the strength of fMRI lies in its spatial resolution. The spatial resolution of PET is also substantially better than that from ERPs but worse than that of fMRI.

The traditional model of language processing predicts that processing of phonological information of heard words should occur in the posterior left

temporal lobe (Wernicke's area) and phonological activation for spoken words should occur in left frontal lobe (Broca's area). Although the brain areas implicated in the traditional model have been confirmed by imaging studies, additional areas have been found to be active. That is, although neuroimaging studies show consistent evidence of Wernicke's area activation during phonological encoding, temporoparietal and frontal activation have been found as well. Similarly, studies have found activation both in Broca's area and in the lower portion of the posterior temporal lobe (Wernicke's area is the upper portion of the posterior temporal lobe) during language production. One caveat regarding the role of Broca's area is that it has been activated when research participants are asked to make hand and tongue movements, suggesting that activation of this area reflects general motor programming rather than motor programming specific to phonological output.

If visually presented words are converted into their phonological representations, then activation should occur in areas similar to those implicated for auditory word processing. Studies have found activation during reading of visually presented words in left temporoparietal cortex, which is also active during auditory word processing. The left posterior middle temporal gyrus, in addition to the occipital–temporal and left inferior temporal/fusiform regions, has also been shown to be active during word reading.

A variety of areas have also been implicated for semantic processing. Two tasks meant to measure semantic processing, categorizing words and generating actions that can be performed with objects, have shown activation in left frontal regions of Broca's and surrounding areas. Other research has suggested that the frontal cortex is involved in retrieving and maintaining semantic information rather than being the locus of representation of semantic knowledge. Recent studies with normal and brain-damaged research participants have suggested the role of temporal areas in semantic processing, including left posterior temporoparietal, inferior temporal, and anterior temporal cortex. Researchers investigating the localization of categorical knowledge with neuroanatomical and neuroimaging studies found a wide variety of brain areas to be involved during tasks that test knowledge of different categories. Even within a category, various brain areas have been activated. For example, the left temporal lobe, the right temporal lobe, and even the frontal and inferior parietal areas have all been reported to be active during processing of animals and living things. Areas responsible for processing nonliving things also appear to be diverse. Despite the varied areas that have been reported to be involved in semantic function, one area that has shown activation across several different studies is the temporal lobe. Work with Alzheimer's patients who have semantic impairment suggests a further category distinction. Alzheimer's patients whose knowledge of the perceptual features of objects is disrupted tend to have temporal region damage, and those whose knowledge of how objects function tend to have frontoparietal impairment.

More consistent findings have been obtained regarding different localization for words of different grammatical classes. Neuropsychological and neuroimaging results suggest that nouns are represented in the temporal lobe and verbs in the frontal lobe. Some ERP studies have indicated that content words and function words elicit different timing of brain potentials and the involvement of different brain areas. For instance, one study showed early frontal activation from both word types with a similar pattern brain distribution at approximately 200–300 msec after the onset of the word. Approximately 150 msec later, however, differences for the word types were observed, with a different timing of the potential waveforms for the two word types and greater left hemisphere activation for the function words than for the content words. However, because this study measured processing of these word types in a sentence context, the different patterns may be due to the different roles that these words play in sentence processing rather than to different localization of lexical representations. For example, function words may lead to more predictions about the syntactic structure of upcoming words in a sentence.

Recent behavioral and neuroimaging data suggest that the right hemisphere may play more of a role in language processing than was previously assumed. Behavioral studies on this issue have used a priming paradigm in which word recognition (as measured by time to pronounce a word or to make a word–nonword decision) is facilitated by the prior presentation of a related word. To study hemispheric contributions, written words are presented to the left or right visual field, which engages processing in the contralateral cerebral hemisphere first. Priming studies have shown that priming occurs for only the most highly related words in the left hemisphere but for a broader range of related words in the right hemisphere. Also, for ambiguous words such as "bank" that have a dominant meaning (money) and a subordinate meaning (river), priming results indicate that immediately

following presentation of an ambiguous word both meanings are activated in both hemispheres. However, within a short time, only the dominant meaning is available in the left hemisphere, whereas both meanings are still available in the right hemisphere. Taken together, the evidence suggests that the meanings of words are more coarsely coded in the right hemisphere. Neuroimaging studies of word processing have also often found activation in the right hemisphere in areas corresponding to the traditional language areas on the left, although the activation is often less than that obtained in the left hemisphere.

II. SENTENCE PROCESSING

A. Sentence Comprehension

Sentence comprehension processes involve more than combining the meaning of individual words in a sensible fashion. Even though the sentence "the girl chased the dog" has the same content words as "the dog chased the girl" and "the girl was chased by the dog," it is clear that the first sentence means something different than the latter two. Clearly, the grammatical roles that nouns play (e.g., subject vs object) and sentence structure (e.g., active vs passive) play a role in determining sentence meaning. Most models of sentence comprehension assume that in order to understand a sentence, the constituents (e.g., noun phrase, verb phrase, and prepositional phrase) of a sentence must be identified and related to each other structurally. The "parser" is the term used to describe the module that assigns syntactic structure to a sentence. Parsing allows the determination of the grammatical roles, such as subject, direct object, and indirect object. These grammatical roles are assumed to be mapped onto "thematic roles"—that is, conceptual roles that entities play with respect to a verb such as the agent (i.e., the entity carrying out the action), theme (i.e., the entity being acted upon), recipient, or location. The mapping between grammatical roles and thematic roles varies for different verbs and may vary for the same verb depending on the sentence. For example, the thematic roles of the subjects of the phrases "the boy received," "the girl opened," and "the key opened" are "recipient," "agent," and "instrument," respectively. Because of this variation in mapping, the lexicon needs to contain verb-specific information concerning the possible mappings between grammatical and thematic roles.

It is often the case that the syntactic structure to be assigned to a sequence of words is ambiguous. For example, for a sentence beginning with "The defendant examined," "examined" could be the main verb or could be part of a reduced relative clause construction (e.g., "The defendant examined by the lawyer was innocent"). A major issue in research on sentence processing has been whether a strict modular approach applies in which the parser assigns syntactic structure purely on the basis of syntactic rules of thumb (e.g., "choose the simplest structure") or whether an interaction between semantic and syntactic information affects parsing decisions. For example, if semantic information influences parsing, then "examined" should be less likely to be taken as the main verb in a sentence beginning "The evidence examined" since "evidence" is unlikely an agent of "examine." Current evidence supports the interactive view.

During comprehension, it is necessary to integrate different constituents of a sentence, sometimes over distances spanning several words. For example, in the sentence "The truck that the car splashed was green," it is necessary to retrieve "truck" as the direct object of "splashed" and to integrate "green" with "truck" rather than "car." Consequently, researchers have assumed that comprehension makes demands on working memory resources. The concept of working memory is similar to that of short-term memory, involving the temporary maintenance of information. The term "working" is used to signify that this capacity is used in carrying out computations in addition to maintaining information. Individual differences in working memory capacity of normal individuals have been found to correlate with aspects of sentence comprehension performance. However, neuropsychological findings suggest that there are different components of working memory that play different roles in sentence comprehension.

B. Sentence Production

In sentence production, as in comprehension, the mapping between thematic and grammatical roles and the construction of syntactic structure must be included in the processing stages. The processing stages in sentence production include the message level stage, in which a conceptual representation of the sentence is formed, two stages of linguistic encoding, and an articulatory stage. Thematic role relations between actions and entities are assumed to be represented at the message level. At the first level of linguistic encoding (termed the functional level), the message level information is used to select lexical representations

(i.e., semantic–syntactic lexical representations) and to construct grammatical relations among these lexical representations based on the thematic role and other semantic information in the message. The prosodic structure of the sentence is also encoded during this stage. Prosodic factors such as word stress (the emphasis given to words) and intonation (using pitch to signify different meanings) are important methods of varying speech to facilitate communication. The second level of linguistic encoding (called the positional level) creates the syntactic structure for the sentence in terms of word order, function words, and grammatical markers (e.g., plural markers and past tense inflections). The phonological forms for the content words are also retrieved at this stage. Once the phonological representations have been retrieved, plans for articulation can be formed.

C. Neuropsychological Evidence on Sentence Processing

1. Sentence Comprehension

In the 1970s and 1980s, researchers demonstrated that some aphasic patients who understood the content words in a sentence might nonetheless show a failure of comprehension for the sentence as a whole if comprehension depended on the correct analysis of syntactic information. For example, these patients might have difficulty understanding ''reversible'' sentences—that is, sentences in which either noun could play the thematic roles of agent or theme, as in ''The dog was chased by the girl'' or ''The truck that the car splashed was green.'' This comprehension difficulty could be demonstrated by asking the patient to choose between a picture depicting the correct thematic role relations and one depicting the reverse role relations (e.g., a girl chasing a dog vs a dog chasing a girl). Although the patients might perform at chance with such picture contrasts, they would do well if one of the pictures substituted an incorrect noun or verb (e.g., a girl chasing a cat or a girl walking a dog). One early hypothesis about the nature of such a comprehension deficit was that it derived from a general failure of syntactic processing because patients who showed this comprehension problem also produced ''agrammatic speech.'' That is, their speech production was marked by simplified syntactic structure and the omission of function words and grammatical markers. However, recent findings have demonstrated that some patients may show only one side of this deficit (i.e., impaired syntactic comprehension but not agrammatic speech, or the reverse). In addition, several studies have shown that patients who show this comprehension problem on sentence–picture matching may do well on judging the grammatical acceptability of sentences. Thus, rather than a global deficit in all aspects of syntactic processing, these patients may have a more restrictive comprehension deficit, such as a deficit in mapping between the grammatical structure of the sentence and the thematic roles that entities play in the sentence. For instance, for the sentence ''The truck that the car splashed was green,'' the patient might be able to determine that ''car'' is the grammatical subject of the verb ''splashed'' but be unable to determine that the car is doing the splashing.

Other findings indicate that although agrammatic speakers may not provide the clearest evidence of a dissociation between syntactic and semantic knowledge, other patients do provide such evidence. Some patients with Alzheimer's dementia demonstrate very impaired knowledge of word meanings but show preserved grammatical knowledge. For example, they might be unable to realize that a phrase such as ''The jeeps walked'' is nonsensical but be able to detect the grammatical error in a phrase such as ''The jeeps goes.'' Other case studies of aphasic patients show the reverse pattern of preserved semantic knowledge but disrupted grammatical knowledge. Thus, the findings indicate some degree of modularity in the sentence comprehension system, with separate modules for semantic and syntactic processing. However, other evidence from patients comports with the findings from normal subjects in showing that these modules do not typically operate in isolation but instead interact. That is, patients may use the grammatical structure of sentences when there are weak semantic constraints (e.g., understanding that ''tiger'' is the agent of ''chased'' in ''The lion that the tiger chased'') but fail to use the grammatical structure when there are strong semantic constraints (e.g., mistakenly interpreting the ''woman'' as the agent of ''spanked'' in ''The woman that the child spanked''). These findings support the view that information from both semantic and syntactic sources typically combines during comprehension, but when one of these systems is weakened due to brain damage, the other system may override its influence.

As discussed previously, theories of comprehension often assume a role for a short-term or working memory system that is used to hold partial results of comprehension processes while the rest of a sentence is processed and integrated with earlier parts. Aphasic patients often have very restricted short-term memory

spans, being able to recall only one or two words from a list compared to normal subjects' ability to recall five or six words. Many of these patients appear to have a deficit specifically in the ability to retain phonological information. Although it may seem intuitively plausible that restricted short-term memory capacity would impede comprehension, a number of studies have shown that patients with very restricted memory spans may show excellent sentence comprehension even for sentences with complex syntactic structures. Such findings support immediacy of processing theories of comprehension that state that syntactic analysis and semantic interpretation are carried out on a word-by-word basis, to the extent possible. Recently, some patients have been identified whose short-term deficit appears to be due to a difficulty in retaining semantic information rather than phonological. For such patients, their restricted ability to retain semantic information does impede comprehension for certain sentence types—that is, those that put a strain on the capacity to retain individual word meanings. Specifically, these patients have difficulty comprehending sentences in which the structure of the sentences delays the integration of word meanings into larger semantic units. One sentence type causing difficulty includes sentences with several prenominal adjectives, such as "The drab old red swimsuit was taken to the beach." In this example, the meaning of "drab" cannot be integrated with the noun it modifies until two intervening words have been processed. These patients do not have difficulty comprehending similar sentences in which word meanings can be integrated immediately. For example, these patients can understand sentences in which several adjectives follow the noun (e.g., "The swimsuit was old, red, and drab, but she took it along anyway"), because these sentences allow for the immediate integration of each adjective with the preceding noun.

2. Sentence Production

Sentence production deficits have also been a focus of research in aphasia, although in this domain much of the work has originated from a syndrome-based approach, concentrating on patients showing agrammatic speech. Agrammatism occurs predominantly in patients with articulatory disturbances who are typically classed as Broca's aphasics. However, several studies have documented that some features of agrammatism may appear in patients who are fluent speakers. Moreover, other studies have shown that the sentence structure and function word difficulties of agrammatic patients may dissociate, with some patients demonstrating reduced sentence complexity but accurate production of function words and inflections and others showing the reverse. In order to accommodate the dissociation between sentence structure and function word difficulties, deficits at different levels in the production process have been postulated. Several different suggestions have been made as to what these different deficits might be. An interesting recent approach relates deficits in sentence structure to deficits in the knowledge of verb representation. The verb plays a major role in structuring the roles of nouns (such as agents, patients, and recipients) with respect to the action in the sentence. The specific verb to be used dictates what grammatical role a noun with a specific thematic role will play (e.g., the recipient will be the subject of an active sentence using the verb "receive" but the indirect object of an active sentence using "give"). A deficit in knowledge of the relations of semantic and grammatical roles entailed by verbs could lead to a reduction in sentence structure, such as the failure to produce a required indirect object.

The disruption in the production of function words and inflections might be a result of a disruption at a different stage, specifically the stage at which the syntactic structure of the utterance is specified in terms of word order and grammatical markers (i.e., the positional level). Of course, many patients might have a disruption both in representing the relations of the verbs to the nouns and in constructing a syntactic specification, resulting in prototypical agrammatic speech.

D. Localization of Sentence Processing Mechanisms

Because of the association of Broca's aphasia with agrammatism and difficulties comprehending reversible sentences, some researchers have tried to link the frontal lobe, specifically Broca's area, to syntactic parsing. However, as discussed earlier, patients who are not Broca's aphasics have been shown to have difficulties understanding reversible sentences and to make grammatical errors in language production. With regard to comprehension, a study of lesion overlap among a group of aphasic patients with syntactic comprehension difficulties revealed that the critical area appeared to be in the anterior temporal lobe rather than Broca's area. ERP studies have revealed different patterns of brain potentials in response to semantic and syntactic errors in a sentence,

supporting the independence of these processes. The semantic anomalies elicit negative-going waves approximately 400 msec after the onset of the anomalous word, whereas the syntactic anomalies elicit positive-going waves approximately 600 msec after the onset of the ungrammatical word. Both the negative semantic wave and the positive syntactic wave have central or posterior brain distributions, with a somewhat more posterior distribution for the positive syntactic wave.

There have so far been relatively few neuroimaging studies of sentence comprehension. All of the traditional left hemisphere language areas (i.e., areas surrounding the Sylvian fissure, including Broca's area and Wernicke's area) are activated; however, activation in the anterior temporal lobe is also observed in some studies. Given the many processing components involved in sentence comprehension (e.g., syntactic parsing, thematic role determination, semantic integration, and maintenance in working memory), it is unclear exactly what function is carried out in which part of this broad network of activation. Some studies have suggested a specific role for Broca's area in the comprehension of syntactically complex sentences; however, not all types of complex sentences induce activation in this area. It is possible that, instead, this area carries out a working memory function related to maintaining words that have not yet been assigned a thematic role. Only certain types of syntactically complex sentences would place a demand on such a working memory function.

With regard to sentence production, there have been few studies using lesion localization that have attempted to isolate different aspects of production. One well-established finding is that there are frontal areas involved in speech articulation. However, for more central linguistic encoding aspects of language production, the data are scarce. Some patients with frontal lesions who show difficulty comprehending sentences in which integration of meanings is delayed (i.e., sentences with several adjectives preceding a noun) also have difficulty producing similar sentence constructions. These findings suggest that the same frontal working memory area is involved in maintaining semantic representations in comprehension and production. Clearly, neuroimaging data would be useful in helping to localize aspects of language production. However, there are methodological difficulties in obtaining such data. If subjects move during PET and fMRI studies, this movement can induce the appearance of activation in brain areas that are in fact not activated. Thus, having subjects overtly produce speech could introduce movement artifacts in such studies. Having subjects speak silently to themselves would prevent the experimenter from monitoring what the subject was saying. Future research may find means to obviate these difficulties.

III. HIGHER LEVEL LANGUAGE PROCESSING

A. Discourse Comprehension

The comprehension of continuous discourse involves more than word recognition, syntactic parsing, and deriving the meaning of individual sentences. Successful comprehension requires an understanding of the relationships among the various parts of the discourse context and is dependent on the reader's or listener's general world knowledge. Many researchers have argued that story comprehension implies the derivation of propositional representations. Propositions derived from a story specify relations between actions and participants in the actions, the states and attributes of the participants, the time and locations of the actions, etc. Propositions are specified in terms of entities (typically nouns) and predicates (such as actions or states) that apply to these entities. For example, consider a story titled "The Picnic," beginning with the following: "The sky was cloudy and the weather forecast was not encouraging. There was a 70% probability of showers. However, the Brown family had no intention of renouncing their plan." Propositions derived from these sentences might include time (past), sky (cloudy), forecast [not (encouraging)], and renounce (agent, family; object; plan). It is clear, however, that comprehension of the story depends not only on deriving propositions but also on relating propositions to each other and to world knowledge. Even for the first sentence in this example, not only are "sky" and "cloudy" linked, such that "cloudy" specifies the state of the sky, but also it is likely that this information would to be related to the title and to long-term knowledge that people prefer sunny skies for picnics. Moreover, this information is reinforced by propositions derived from the following sentences. Overlap among the propositions and their associations in long-term memory makes the text more easily comprehended and remembered.

Propositions can be related to each other by various means. A person or object mentioned earlier can be referred to again using an anaphor, such as a pronoun. For example, "she" is an anaphor for "The little girl" in the passage "The little girl wanted to play ball. She got the bat out of the car." Propositions can also be

related via inferences. An inference is the drawing of a conclusion that is not explicitly mentioned in a discourse but, rather, is based on general world knowledge. In the picnic example discussed previously, someone hearing this story is likely to infer that it was the Browns who were planning the picnic mentioned in the title and that, contrary to usual expectations, they were not going to cancel because of the weather. In some cases, discourse or narrative texts (such as a mystery novel or an adventure story) may follow a familiar structure (termed a schema or script), and the presence of this structure may help the comprehender to organize the information.

B. Discourse Production

Narrative production requires that the speaker (or writer) produce a sequence of sentences that is coherent and comprehensible to the conversational partner (or the reader). The speaker has to be able to keep in mind what has already been stated and what remains to be stated and have some plan regarding the order in which information should be presented. Thus, in order to study narrative, measures beyond those of the individual phrase or sentence must be used in order to determine whether speakers are producing coherent narratives. Measures such as the overlap in propositions between utterances and the use of appropriate anaphors have been employed. Researchers may elicit target narratives by having the subjects view pictures or films and then asking the subject to tell the story of what happened. In such cases, the subjects' production can be assessed regarding whether the major elements of the story are present (such as introduction of people and situation, discussion of sequence of events and complication of the events, and resolution of the complication). Other measures can be used that assess whether the speaker uses vocabulary appropriate to the target audience and provides enough information, given the listener's knowledge, to allow for appropriate inferences.

C. Neuropsychological and Localization Evidence on Discourse Processing

As opposed to the dominance of the left hemisphere in carrying out single-word and sentence processing, the right hemisphere appears to play an important role in discourse comprehension and production. Research with right hemisphere-damaged patients demonstrates an impaired understanding of various forms of discourse, including indirect requests ("Can you reach the bowl?"), jokes, ironic comments, and metaphors. This problem with discourse materials is not limited to verbal materials, but may be observed with stories that are told through cartoons or other pictures. Left hemisphere-damaged patients, in contrast, perform better than the right hemisphere-damaged patients and may even display normal levels of performance, particularly if the material is presented in a nonverbal format.

As discussed earlier, research on single-word and sentence processing indicates that multiple meanings or senses of words are activated and maintained by the right hemisphere. This has led to the proposal that semantic coding in the right hemisphere is coarse, allowing for a broad but weak activation of semantic representations that are distantly related to the word or context being processed. Weak activation of a broad semantic field may be of little use when the literal meaning of a word is required or when the most likely inference is the correct one. However, the activation and maintenance of multiple representations may allow the comprehension system to recognize and capitalize on distant semantic relationships in the comprehension of jokes or metaphors or in instances in which the comprehender has to revise an initial interpretation.

Like discourse and text comprehension, narrative production can be impaired even when production at the single-word or sentence level is preserved. That is, a speaker may fail to have an organized plan for communicating information, going off on topics tangential to the central one. The speaker might also fail to make coherent anaphoric reference between sentences or omit information that would be critical to the listener for drawing the appropriate inferences. Patients with right hemisphere brain damage and those with frontal damage have been shown to have discourse production deficits that are disproportionate to any deficits in vocabulary and grammar. Although relatively few studies have been carried out with right hemisphere-damaged patients, their deficits include an underspecification of information and a failure to take into account the listener's point of view. A larger number of studies have examined discourse deficits in individuals with closed head-injury (e.g., from a car accident). Individuals with closed-head injury often have frontal damage, and it has been assumed that the discourse deficits displayed by these patients are due to damage to this region. These individuals also display reduced information content and a lack of cohesion among the sentences in a story.

Some caveats should be kept in mind when considering the findings on discourse deficits. Much of this research has been carried out using group studies, even though researchers have found wide variation in the discourse deficits exhibited by right hemisphere-damaged or closed-head injury patients, with some patients showing no deficits. Clearly, the right hemisphere and the frontal lobes (both left and right) are very large cortical regions, and it is likely that only specific regions within these large areas are critical for discourse processing. Moreover, there are a variety of aspects of discourse processing that could be affected in different subgroups. Some individuals might have difficulty with the working memory demands involved in maintaining information across sentences during discourse comprehension or in planning a narrative to produce. Other patients might have difficulty taking into account other individuals' points of view, which makes their discourse production lack cohesion. Still others might have difficulty inhibiting irrelevant information that becomes activated during comprehension or production. Yet others might have subtle deficits at the level of lexical retrieval that become critical when several words have to be kept active simultaneously in planning discourse production. Carefully designed case studies testing for all these possibilities are necessary to delineate which components of discourse production are functionally isolable and which brain areas provide the cortical substrate for these functions.

IV. CONCLUSIONS

A substantial body of behavioral data has been amassed concerning language and lexical processing. Studies of brain-damaged patients indicate that considerable modularity of processing components exists in these domains. Although there is some knowledge concerning the brain areas involved in various aspects of language processing, the knowledge is currently at a broad rather than fine-grained level. Some of the same brain areas are implicated in a variety of language functions. For example, the temporal lobe appears to be involved in phonological, semantic, and syntactic processing. It is possible, however, that further study will reveal that nonoverlapping areas within the temporal lobe are involved in these different aspects. Future research using series of case studies with well-identified functional deficits and neuroimaging studies with normal subjects should provide a better specification of the localization and interaction of brain areas involved in word, sentence, and discourse processing.

GLOSSARY

agrammatism Omission of function words, prefixes, and suffixes from speech.

agraphia Disturbance of writing.

alexia Disturbance of reading.

anomia Difficulty producing words, often nouns.

aphasia Disorders of language due to disease of the brain.

Broca's aphasia A type of aphasia with nonfluent speech and relative preserved comprehension.

paragrammatism Production of incorrect function words, prefixes and suffixes.

phonemic paraphasia Sound substitution in speech.

Wernicke's aphasia A type of aphasia with fluent error-containing speech and impaired comprehension.

Language is a code that relates different types of forms to semantic meanings. The forms of the code and their associated meanings are activated in the tasks of speaking, comprehension of spoken language, reading, and writing. Disorders of the brain can affect the ability to activate these representations in these tasks. Neurological and psychiatric disorders can also affect the use of language to accomplish tasks such as communicating ideas, storing information in long-term memory, reasoning, and solving problems. Language disorders that have been most extensively studied neurologically are those that affect language processing in the tasks of language use.

I. LANGUAGE STRUCTURE AND PROCESSING

Human language can be viewed as a code that links linguistic representations to aspects of meaning. The basic types of representations of language (or language levels) are simple words (the lexical level), words with internal structure (the morphological level), sentences, and discourse. The lexical level of language makes contact with the categorial structure of the world. Lexical items (simple words) designate concrete objects, abstract concepts, actions, properties, and logical connectives. The basic form of a simple lexical item consists of a phonological representation that specifies the segmental elements (phonemes) of the word and their organization into metrical structures (e.g., syllables). The form of a word can also be represented orthographically. Words are associated with syntactic categories (e.g., noun and verb). The morphological level of language allows the meaning associated with a simple lexical item to be used as a different syntactic category (e.g., noun formation with the suffix *-tion* allows the semantic values associated with a verb to be used as a noun, as in the word "destruction" derived from "destroy") and thus avoids the need for an enormous number of elementary lexical items in an individual's vocabulary. The sentential level of language makes use of the syntactic categories of lexical items to build hierarchically organized syntactic structures (e.g., noun phrase, verb phrase, and sentence) that define relationships between words relevant

to the propositional content of a sentence. The propositional content of a sentence expresses aspects of meaning, such as thematic roles (who did what to whom), attribution of modification (which adjectives go with which nouns), the reference of pronouns, and other referentially dependent categories. Propositional meanings make assertions that can be entered into logical and planning processes and that can serve as a means for updating an individual's knowledge of the world. The discourse level of language includes information about the general topic under discussion, the focus of a speaker's attention, the novelty of the information in a given sentence, the temporal order of events, causation, and so on. Information conveyed by the discourse level of language also serves as a basis for updating an individual's knowledge of the world and for reasoning and planning action.

The forms of language and their associated meanings are activated in the usual tasks of language use—speaking, auditory comprehension, reading, and writing. There is wide agreement among linguists, psychologists, and computer scientists that these different forms are activated by different "components" of a "language processing system." Components of the cognitive processing system are devices that accept as input a certain type of representation and operate on these inputs to activate another type of representation, where at least one of these representations is part of the language code. For instance, a component of the language processing system might accept as input the semantic representation (meaning) activated by the presentation of a picture and produce as output a representation of the sound pattern of the word that corresponds to that meaning.

The operations of the components of the language processing system are obligatory and largely unconscious. The obligatory nature of language processing can be appreciated intuitively by considering that we are generally unable to inhibit the performance of many language processing tasks once the system is engaged by an appropriate, attended input. For instance, we must perceive a spoken word as a word, not just as a nonlinguistic percept. The unconscious nature of most of language processing can be appreciated by considering that when we listen to a lecture, converse with an interlocutor, read a novel, or engage in some other language processing task, we usually have the subjective impression that we are extracting another person's meaning and producing linguistic forms appropriate to our intentions without paying attention to the details of the sounds of words, sentence structure, etc.

In general, cognitive processes that are automatic and unconscious are thought to require relatively little allocation of mental resources. However, many experimental results indicate that language processing does require the allocation of attention and/or processing resources. The efficiency of each of the components of the language processing system is thought to be a function of the resources available to that component, up to the maximum level of resource utilization of which the component is capable. Components of the system are remarkably efficient. For instance, it has been estimated on the basis of many different psycholinguistic experimental techniques that spoken words are usually recognized less than 125 msec after their onset (i.e., while they are still being uttered). Similarly, normal word production in speech requires searching through a mental word production "dictionary" of over 20,000 items, but it still occurs at the rate of about three words per second with an error rate of about one word misselected per 1 thousand and another one word mispronounced per 1 thousand. The efficiency of the language processing system as a whole reflects the efficiency of each of its components but also is achieved because of the massively parallel computational architecture of the system, in which many components of the system are simultaneously active.

Functional communication involving the language code occurs when people use these processors to undertake language-related tasks to accomplish specific goals—to inform others, to ask for information, to get things done, etc. The language code is remarkably powerful with respect to the semantic meanings it can encode and convey, and psycholinguistic processors are astonishingly fast and accurate. The ability to use this code quickly and accurately is critical to human success, both as a species and as individuals.

II. CLASSICAL APHASIC SYNDROMES

The language disorders that are best understood are those that affect the representation and processing of language in the usual tasks of language use. These disorders are known as "aphasia." By convention, the term aphasia does not refer to disturbances that affect the functions to which language processing is put. Lying (even transparent, ineffectual lying) is not considered a form of aphasia, nor is the garrulousness of old age or the incoherence of schizophrenia.

Neurologists and speech–language pathologists often describe aphasic patients as having one of a number of syndromes, which were first described in the second half of the nineteenth century. Because these syndromes are the foundation for contemporary descriptions of language impairments, and because they are still widely used by clinicians, I shall describe them here.

The paper that first led researchers to these syndromes was written by Paul Broca in 1861. Broca described a patient, Leborgne, with a severe speech output disturbance. Leborgne's speech was limited to the monosyllable "tan." In contrast, Broca described Leborgne's ability to understand spoken language and to express himself through gestures and facial expressions, as well as his understanding of nonverbal communication, as being normal. Broca claimed that Leborgne had lost "the faculty of articulate speech." Broca related this impairment to the neural tissue most badly damaged in Leborgne—the posterior portion of the inferior frontal convolution of the left hemisphere, which became known as Broca's area.

During the ensuing years, many cases of language impairments were described. In some, speech impairments were related to lesions in the left frontal lobe. Other speech impairments were associated with more posterior lesions. In 1874, Carl Wernicke, then a medical student, published a paper that appeared to reconcile many of these different findings. Wernicke described a patient with a speech disturbance, but one that was very different from that seen in Leborgne. Wernicke's patient was fluent; her speech, however, contained words with sound errors, other errors of word forms, and words that were semantically inappropriate. Also unlike Leborgne, Wernicke's patient did not understand spoken language. Wernicke related the two impairments—the one of speech production and the one of comprehension—by arguing that the patient had sustained damage to "the storehouse of auditory word forms." Under these conditions, speech would be expected to contain the types of errors that were seen in this case, and comprehension would be affected. Establishing the location of the lesion in this case was more problematic, however. Wernicke did not have the opportunity to perform an autopsy on his patient. However, he did examine the brain of a second patient, whose language had been described prior to her death by her physician in terms that made Wernicke think that she had a set of symptoms that were the same as those he had seen in his patient. The lesion in this second patient occupied the posterior portion of the first temporal gyrus, also on the left. Wernicke suggested that this region, which came to be known as Wernicke's area, was the locus of the storehouse of auditory word forms.

These two seminal papers gave rise to a model of the relation of language processing to the brain. In this model, speaking involves activating the forms of words (in Wernicke's area) from concepts and transmitting these word forms to Broca's area to plan speech; Broca's area is also directly activated by concepts. Comprehension involves activating word forms from auditory input and then activating word meanings. Repetition involves transmitting the forms of words from Wernicke's area to Broca's area. Based on this model, researchers identified a number of aphasic syndromes, summarized in Table I.

The first two of these syndromes are Broca's and Wernicke's aphasia. Broca's aphasia, which affects primarily expressive language and leads to nonfluent speech, is due to lesions in Broca's area, the center for motor speech planning adjacent to the motor strip. Wernicke's aphasia follows lesions in Wernicke's area that disturb the representations of word sounds. Pure motor speech disorders arise from lesions interrupting the motor pathways from the cortex to the brain stem nuclei that control the articulatory system. These disorders differ from Broca's aphasic because they are not linguistic; they affect articulation, not the planning of speech. Pure word deafness affects the transmission of sound input into Wernicke's area. It therefore disrupts word recognition but not speech since words are intact and accessible for speech production purposes. Transcortical motor aphasia results from the interruption of the pathway from the concept center to Broca's area. This affects speech but not repetition or comprehension. Transcortical sensory aphasia follows lesions between Wernicke's area and the concept center. Repetition of words is intact, but comprehension is affected. Finally, conduction aphasia follows from a lesion between Wernicke's area and Broca's area. Repetition is affected, but comprehension is intact. Speech is also affected, in the same way as it is affected in Wernicke's aphasia, because the sound patterns of words, though activated, are not transmitted properly to Broca's area to be used to plan speech.

These syndromes have defined the domain of aphasia as a description of performances in the usual tasks of language use—speaking, understanding spoken language, reading, and writing. In terms of the linguistic elements, the disorders affect words, sounds of words, word endings, and classes of words such as function words that are produced, recognized, or understood. In this content, they contrast with other

Table I
Classical Aphasic Syndromes

Syndrome	Clinical manifestations	Postulated deficit	Classical lesion location
Broca's aphasia	Major disturbance in speech production with sparse, halting speech, often misarticulated, and frequently missing function words and bound morphemes	Disturbances in the speech planning and production mechanisms	Posterior aspects of the third frontal convolution (Broca's area)
Wernicke's aphasia	Major disturbance in auditory comprehension; fluent speech with disturbances of the sounds and structures of words (phonemic, morphological, and semantic paraphasias)	Disturbances of the permanent representations of the sound structures of words	Posterior half of the first temporal gyrus and possibly adjacent cortex (Wernicke's area)
Pure motor speech disorder	Disturbance of articulation; apraxia of speech, dysarthria, anarthria, aphemia	Disturbance of articulatory mechanisms	Outflow tracts from motor cortex
Pure word deafness	Disturbance of spoken word comprehension	Failure to access spoken words	Input tracts from auditory system to Wernicke's area
Transcortical motor aphasia	Disturbance of spontaneous speech similar to Broca's aphasia, with relatively preserved repetition	Disconnection between conceptual representations of words and sentences and the motor speech production system	White matter tracts deep to Broca's area connecting it to parietal lobe
Transcortical sensory aphasia	Disturbance in single word comprehension, with relatively intact repetition	Disturbance in activation of word meanings despite normal recognition of auditorily presented words	White matter tracts connecting parietal lobe to temporal lobe or portions of inferior parietal lobe
Conduction aphasia	Disturbance of repetition and spontaneous speech (phonemic paraphasias)	Disconnection between the sound patterns of words and the speech production mechanism	Lesion in the arcuate fasciculus and/or corticocortical connections between Wernicke's and Broca's areas
Anomic aphasia	Disturbance in the production of single words, most marked for common nouns with variable comprehension problems	Disturbances of concepts and/or the sound patterns of words	Inferior parietal lobe or connections between parietal lobe and temporal lobe; can follow many lesions
Global aphasia	Major disturbance in all language functions	Disruption of all language processing components	Large portion of the peri-Sylvian association cortex
Isolation of the language zone	Disturbance of both spontaneous speech (similar to Broca's aphasia) and comprehension, with some preservation of repetition	Disconnection between concepts and both representations of word sounds and the speech production mechanism	Cortex just outside the peri-Sylvian association cortex

approaches to the description of aphasia. For instance, Hughlings Jackson described a patient, a carpenter, who was mute but who mustered the capacity to say "master's" in response to his son's question about where his tools were. Jackson's poignant comments convey his emphasis on the conditions that provoke speech rather than on the form of the speech:

> *The father had left work; would never return to it; was away from home; his son was on a visit, and the question was directly put to the patient. Anyone who saw the abject poverty the poor man's family lived in would admit that these tools were of immense value to them. Hence we have to consider as regards this and other occasional utterances the strength of the accompanying emotional state.*

Jackson and others sought a description of language use as a function of motivational and intellectual states and tried to describe aphasic disturbances of language in relationship to the factors that drive language production and make for depth of comprehension. This is a vital aspect of understanding language impairments. In many ways, it is more humanly

relevant than a description of language impairments in terms of which phonemes are produced in spontaneous speech or repetition. Unfortunately, it is a very intractable goal, both in terms of psychological descriptions and in terms of relating these specific motivational states to the brain. The researchers who conceived and developed the framework of the classical syndromes focused aphasiology on the description of the linguistic representations and psycholinguistic operations that are responsible for everyday language use.

III. PROBLEMS WITH THE CLASSICAL APHASIC SYNDROMES

A major limitation of the classical syndromes is that they stay at arm's length from the linguistic details of language impairments. The classical aphasic syndromes basically reflect the relative ability of patients to perform entire language tasks (speaking, comprehension, etc.), not the integrity of specific operations within the language processing system. This is not to say that there are no linguistic or qualitative descriptions of language in the characterizations of the classical aphasic syndromes, only that they are incomplete and unsystematic.

A second problem with these syndromes is that they do not classify many aphasic patients very well. In practice, most applications of the clinical taxonomy result in widespread disagreements as to a patient's classification and/or to a large number of "mixed" or "unclassifiable." The criteria for inclusion in a syndrome are often arbitrary: How bad does a patient's comprehension have to be called a Wernicke's aphasic instead of a conduction aphasic or a global aphasic instead of a Broca's aphasic? Part of the problem is that patients can only be assigned to a single syndrome instead of being thought of as having multiple deficits.

A third problem that the classical aphasic syndromes face is that they are not as well correlated with lesion sites as the theory claims they should be. The correlations do not apply to many types of lesions, such as various sorts of tumors, degenerative diseases, and others. The classical syndromes are only related to lesion sites in cases of rapidly developing lesions, such as stroke; even in these types of lesions, they are not related to acute and subacute phases of the illness. Even in the chronic phase of diseases such as stroke, as many as 40% of patients have lesions that are not predictable from their syndromes according to some studies.

IV. PSYCHOLINGUISTIC DESCRIPTIONS OF APHASIC IMPAIRMENTS

Modern psycholinguistic analyses have greatly amplified the descriptions of aphasic syndromes. This work seeks to describe the aspects of language that are affected in individual patients. It differs from the syndrome approach in that a patient can have (and usually will have) more than one deficit. This work is far too extensive to review in detail here; I shall illustrate it with a few selective descriptions of analyses undertaken in this framework.

A. Disturbances of Word Meanings

Most recent research on disturbances of word meanings in brain-damaged patients has focused on words that refer to objects. Disturbances of word meanings cause poor performance on word–picture matching and naming tasks. However, the combination of deficits in word–picture matching and naming may be due to separate input- and output-side processing disturbances that affect word recognition and production. Cooccurring deficits in naming and word–picture matching are more likely to result from a disturbance affecting concepts when (i) the patient makes many semantic errors in providing words to pictures and definitions, (ii) he or she has trouble with word–picture matching with semantic but not phonological foils, (iii) he or she fails on categorization tasks with pictures, and (iv) the same words are affected in production and comprehension tasks.

Disorders affecting processing of semantic representations for objects may be specific to certain types of inputs. Elizabeth Warrington first noted a discrepancy between comprehension of words and pictures in two dementing patients. Dan Bub and colleagues described a patient who showed very poor comprehension of written and spoken words but quite good comprehension of pictures. These impairments have been taken as reflections of disturbances of "verbal" and "visual" semantic systems, although others have disputed this conclusion.

Semantic disturbances may also be category specific. Several authors have reported a selective semantic impairment of concepts related to living things and foods compared to man-made objects. The opposite pattern has also been found. Selective preservation and disruption of abstract versus concrete concepts, and of nominal versus verbal concepts, have also been reported.

Disturbances may affect the unconscious activation of semantic meanings or their conscious use. There are patients who cannot match words to pictures or name objects but who are unconsciously influenced by a word's meaning. For instance, in a word/nonword decision task, they will respond faster to the word "doctor" when it follows "nurse" than when it follows "house," indicating they are able to appreciate the relations between words unconsciously, even when they cannot indicate understanding of word meaning in conscious, controlled tasks such as word–picture matching. Conversely, some patients who appear to understand words well have abnormalities in tasks that examine unconscious processing of the meanings of words.

B. Disturbances of Oral Word Production

Disturbances affecting the oral production of single words are extremely common in language-impaired patients. There are three basic disturbances affecting word production (other than semantic deficits). They follow the stages of word sound production: accessing the forms of words from concepts, planning the form of a word for articulation, and articulation.

A disturbance in activating word forms from concepts is manifest by an inability to produce a word from a semantic stimulus (a picture or a definition), coupled with intact processing at the semantic and phonological levels (determined by answering questions about pictures, picture categorization tests, and repetition). The form of a patient's errors is not a good guide to whether he or she has an impairment at this level of the production process since disturbances in accessing word forms may appear in a variety of ways, ranging from pauses to neologisms (complex sequences of sounds that do not form words) and semantic paraphasias (words related to the meaning of the target item). Rarely, patients show an inability to name objects presented in one modality only (e.g., visually) even though they demonstrate understanding of the concept associated with that object when it is presented in that modality (optic aphasia). Because disorders of basic sensory and motor functions can be ruled out in these patients, these modality-specific naming disorders have been taken to reflect a failure to transmit information from modality-specific semantic systems to the processor responsible for activating the forms of words.

Disturbances of a patient's ability to convert the representation of the sound of a word into a form appropriate for articulatory production are usually manifest as phonemic paraphasias (substitutions, omissions, and misorderings of phonemes). Three features of a patient's performance suggest a disturbance in word sound planning. First, some phonemic paraphasias are closely related to target words (e.g., "befenit" for "benefit"). Second, some patients make multiple attempts that come increasingly closer to the correct form of a word. Third, some patients make similar phonological errors in word repetition, word reading, and picture naming. Because the form of a word is presented to the output system in very different ways in these three tasks, the errors in such patients most likely arise in the process of planning the form of the word that is suitable for articulation.

Patients with sound planning problems tend to be more affected on longer words and on words with consonant clusters. The frequency of occurrence of a word in the language has a variable effect on the occurrence of these types of errors. Planning disturbances only rarely affect function words compared to nouns, verbs, and adjectives. Some patients have trouble planning the sounds of words only when words are inserted into sentences, making phonemic paraphasias in sentence production but not naming or repetition tasks. In these cases, the errors probably arise when words are inserted into syntactic structures.

Patients often have disturbances of articulation, as shown by abnormalities in the acoustic waveform produced by a patient and in the movement of the articulators in speech. Investigators have identified two major disturbances of articulation—dysarthria and apraxia of speech. Dysarthria is marked by hoarseness, excessive nasality, and imprecise articulation, and it has been said to not be significantly influenced by the type of linguistic material that the speaker produces or by the speech task. Apraxia of speech is marked by difficulty in initiating speech, searching for a pronunciation, better articulation for automatized speech (e.g., counting) than volitional speech, abnormal prosody, omissions of syllables in multisyllabic words, and simplification of consonant clusters (often by adding a short neutral vowel sound between consonants). Both dysarthria and apraxia of speech result in sounds that are perceived as distorted. Apraxia of speech often cooccurs with dysarthria or with the production of phonemic paraphasias, and the relations between these disorders and the empirical basis for distinguishing one from another are the subject of active research.

C. Disturbances of Recognition of Auditorily Presented Simple Words

Disturbances affecting auditory comprehension of simple words have been attributed to impairments of semantic concepts, as discussed previously, and/or to an inability to recognize spoken words. The latter disturbances have, in turn, been thought to have two possible origins: disturbances affecting the recognition of phonemes in the acoustic signal and disturbances affecting the ability to recognize words despite good acoustic–phonetic processing.

Disturbances of acoustic–phonetic processing may affect the ability to discriminate or to identify phonemes. It is unclear, however, whether these disturbances lead to problems in recognizing or understanding spoken words. Several studies suggest that they do, but other researchers have found weak correlations between comprehension capacities and phoneme discrimination capacities in language-impaired patients.

Many researchers believe that patients can have disturbances of spoken word recognition despite good acoustic–phonetic processing. Such a disturbance was originally postulated by Carl Wernicke. However, there is no clear case of a patient who has intact acoustic–phonetic processing and who cannot recognize spoken words. In most cases, single-word comprehension problems are probably multifactorial in origin and result from a complex interaction of acoustic–phonetic disturbances, disturbances in recognizing spoken words, and disturbances affecting word meanings.

D. Disorders of Repetition of Single Words

Repetition of a word can be carried out in three ways: (i) nonlexically by repeating sounds without recognizing the word (as if one were imitating a foreign language), (ii) lexically by recognizing the stimulus as a word and uttering it without understanding it, and (iii) semantically by understanding the word and reactivating its form from its meaning. Any of these routes to repetition may be disturbed. For instance, one patient could only repeat by the semantic route; this patient made many semantic paraphasias in repetition and could not repeat nonwords. Patients with relatively isolated disturbances affecting the repetition of nonwords have been described, reflecting disruption of the nonlexical route. In most cases, patients have a more complicated picture, with lexical status (whether a stimulus is a word or a nonword), word frequency, and stimulus length affecting performance differently in different patients.

E. Disturbances of Processing Morphologically Complex Words

Disturbances affecting both the comprehension and the production of morphologically complex words have been described. With respect to recognition of morphologically complex words, researchers have observed that some patients who make derivational paralexic errors (e.g., "write" → "wrote," "fish" → "fishing," and "directing" → "direction") in the oral reading of complex words have particular difficulty with the recognition and analysis of written morphologically complex words compared to morphologically simple words. A patient with a disturbance affecting the auditory processing of words with inflectional but not derivational morphology has been described.

Disturbances affecting morphological processing also appear in single-word production tasks. In one study, patients had difficulties in producing plural, possessive, and third-person singular forms of nonwords. The fact that this disorder arose with nonwords that the patients were given by the experimenters suggests that the impairment affected the ability to construct new morphological forms. Such disturbances can arise in patients who perform well on tasks that require recognition and comprehension of written morphologically complex words.

Disturbances affecting the production of morphologically complex words are most commonly seen in sentence production, where they are known as "agrammatism" and "paragrammatism." The most noticeable deficit in agrammatism is the widespread omission of function words and affixes and the better production of common nouns. This disparity is always seen in the spontaneous speech of patients termed agrammatic, and it often occurs in their repetition and writing as well. Patients in whom substitutions of these elements predominate, and whose speech is fluent, are called paragrammatic. Recent observations have emphasized the fact that these two patterns cooccur in many patients. They may result from a single underlying deficit that has different surface manifestations.

Agrammatism and paragrammatism vary considerably, with different sets of function words and bound morphemes being affected or spared in different cases. In some patients, there seems to be some systematicity to the pattern of errors. For instance,

English agrammatic patients frequently produce infinitives (e.g., "to walk") and gerunds (e.g., "walking") because these are the basic forms in the verbal system. In other cases, substitutions are closely related to the correct target. Agrammatics' errors also tend to follow the tendencies seen in normal subjects with respect to errors that "strand" affixes (e.g., "I am going to school" → "I am schooling to go") and the "sonorance hierarchy" that establishes syllabic forms as easier to produce than simple consonants. Agrammatics generally produce real words, which makes for different patterns of errors in different languages that differ with respect to whether or not they require inflections to appear on a word. The fact that in almost all cases errors do not violate the word-formation processes of the language suggests that most agrammatic and paragrammatic patients retain some knowledge of the rules of word formation.

F. Disorders of Sentence Production

Disturbances at the sentence production level are the inevitable results of disturbances affecting the production of simple or complex words. In addition, many patients have problems in the sentence planning process.

Agrammatic patients usually produce only very simple syntactic structures. In one study, virtually no syntactically well-formed syntactic constructions were found in the utterances produced by one agrammatic patient. All the agrammatic patients studied in a large contemporary cross-language study showed some impoverishment of syntactic structure in spontaneous speech. The failure to produce complex noun phrases and embedded verbs with normal frequency were the most striking features of the syntactic simplification shown by these patients.

The ability to express the thematic roles of noun phrases requires the ability to use verbs. Many agrammatic patients have problems with verbs; in one, a category-specific degradation of the meaning of verbs resulted in almost no production of verbs in speech and limited the ability to convey thematic roles of nouns. In other studies, patients' inabilities to produce verbs were only partially responsible for the shortened phrase length found in their speech. It thus appears that in some patients a disturbance affecting the ability to produce verbs affects the production of a normal range of syntactic structures, whereas in others at least some syntactic structures are built despite poor verb production. Yet other patients cannot produce normal syntactic structures despite relatively good verb production.

Several studies suggest that syntactic errors in sentence production differ in paragrammatic and agrammatic patients. Five characteristic paragrammatic patients each produced many long and complex sentences, with multiple interdependencies of constituents, but tended to produce many types of syntactic errors, including errors in tag questions, illegal noun phrases in relative clauses, and illegal use of pronouns to head relative clauses. A type of error that has often been commented on in paragrammatism is a "blend," in which the output seems to reflect a conflation of two different ways of saying the same thing (e.g., "They are not prepared to be of helpful," which is a combination of "They are not prepared to be helpful" and "They are not prepared to be of help"). Some paragrammatic patients can solve anagram tasks according to syntactic constraints (whereas agrammatic patients solved them using semantic constraints). Because of the evidence that paragrammatic patients retain some ability to use syntactic structures, some researchers have suggested that the syntactic and morphological errors in paragrammatism result from the failure of these patients to monitor their speech production processes and their output.

The various disturbances that affect sentence production usually cooccur. A complex disturbance that results from the combination of the deficits in producing syntactic forms, disturbances in accessing and planning word forms, and impairments in producing morphologically complex words is known as "jargonaphasia."

Many patients have difficulty producing prosodic aspects of speech. These disturbances may be secondary to motor output disorders or associated with other sentence production disorders. However, these disturbances may occur in isolation. These are different from the aprosodias related to emotional display described after right hemisphere disease. They reflect a primary disturbance of production of intonation in right hemisphere-damaged patients that differs as a function of lesion location in the hemisphere.

G. Disorders of Sentence Comprehension

When a subject understands a sentence, he or she combines the meanings of the words in accordance with the syntactic structure of the sentence into a propositional content. There are many reasons why a patient might fail to understand the propositional

content of a sentence. In addition to the carryover effect of disturbances affecting comprehension of simple and complex words, there are disturbances affecting the ability to understand aspects of propositional meaning despite good single-word processing.

The greatest amount of work in the area of disturbances of sentence comprehension has gone into the investigation of patients whose use of syntactic structures to assign meaning is not normal. The first researchers to show that some patients have selective impairments of this ability described patients who could match "semantically reversible" sentences such as "The apple the boy is eating is red" to one of two pictures but not "semantically irreversible" sentences such as "The girl the boy is chasing is tall." The difference between the two types of sentences resides in the fact that a listener can understand a sentence such as "The apple the boy is eating is red" via the lexico-pragmatic route, whereas understanding "The girl the boy is chasing is tall" requires assigning its syntactic structure since both boys and girls are capable of chasing one another.

Disorders of syntactic comprehension have since been examined in considerable detail. Patients may have very selective disturbances affecting the use of particular syntactic structures or elements to determine the meaning of a sentence. For instance, patients may understand sentences with reflexives ("himself") but not pronouns ("him") and vice versa. Some patients can understand very simple syntactic forms, such as active sentences ("The man hugged the woman"), but not more complex forms, such as passive sentences ("The woman was hugged by the man"). Many of these patients use strategies such as assigning the thematic role of agent to a noun immediately before a verb to understand semantically reversible sentences, leading to systematic errors in comprehension of sentences such as "The boy who pushed the girl kissed the baby." Other patients have virtually no ability to use syntactic structure. Most of these patients rely on inferences based on their knowledge of the real world and their ability to understand some words in a sentence.

Some patients can assign and interpret syntactic structures unconsciously but cannot use these structures in a conscious, controlled fashion. For instance, one patient's word-monitoring performances indicated that he was sensitive to certain syntactic anomalies but could not make judgments regarding these same anomalies at the end of a sentence. Some patients who have syntactic comprehension problems (e.g., who cannot match reversible sentences to pictures) can make judgments as to whether or not a sentence is grammatical. For instance, some patients can indicate that the utterance "The woman was watched the man" is ill formed and the utterance "The woman was watched by the man" is acceptable, despite not being able to match sentences such as "The woman was watched by the man" to one of two pictures. These results suggest that these patients can construct syntactic structures but cannot use them to determine propositional meaning (a so-called "mapping" problem). As with other areas of language functioning, it appears that patients may retain unconscious, on-line sentence comprehension processes but lose the ability to use the products of these processes in a controlled, conscious fashion in some tasks.

Some researchers maintain the view that short-term memory is used in comprehending more complex sentences and have pointed out a variety of sentence comprehension disturbances in patients with short-term memory limitations. Sentence length has been shown to affect certain comprehension tasks in some patients who do not show disturbances of syntactic comprehension. However, case studies show that patients with short-term memory impairments can have excellent syntactic comprehension abilities. Although many short-term memory patients have trouble in comprehension tasks, the relationship of these short-term memory disorders to sentence comprehension impairments remains unclear.

H. Disorders of Reading Single Words

The contemporary study of acquired dyslexias has largely focused on impairments in the ability to read single words aloud. One model of the mechanisms involved in reading a word aloud claims that there are three separate and partially independent routines in the brain for converting a written word into its spoken form: The first pathway (the semantic route) involves recognizing a word visually, gaining access to its meaning, and then activating the sound of the word from its meaning. The second pathway (the whole word route) translates the orthography of the entire word directly into a pronunciation, without first contacting the word's meaning. Finally, a third pathway (the sublexical route) decomposes the word into orthographic segments (graphemes and other spelling units) and derives a pronunciation by assigning each of them a spoken (phonemic) value. Other models of the reading-aloud process combine the second and third processes into one highly interactive system.

Brain damage can selectively affect a particular routine without impairing the function of the remaining branches of the system. Certain patients (phonological alexics) lose the operation of the sublexical route, which acts on subword units to assemble a response, leaving the semantic and whole word routes available. A patient with damage to the sublexical route is impaired in the reading aloud of nonwords, whereas legitimate words are mostly read correctly. Other reading disorders appear to be the outcome of severe damage to both the whole word route and the sublexical route. Patients with this pattern or impairment, termed deep dyslexics, are unable to pronounce written nonwords (indicating severe impairment to the sublexical route) but also make semantic paralexias (e.g., they read "chair" as "table") and are poor at reading abstract words aloud relative to concrete words. The failure to read nonwords combined with the presence of semantic errors and the influence of a semantic variable on the ability to read a written word aloud is consistent with the interpretation that the patient has lost the use of both the routines from whole words and subword units to sound and is forced to use a defective routine from the visual description of the word through meaning to pronunciation. Yet other dyslexic readers (surface dyslexics) have lost the ability to use both the semantically mediated reading route and the whole-word route but retain the translation of subword units into sound (the sublexical route). These patients can still read words aloud that obey regular correspondences between spelling and sound (e.g., "hint," "mint," and "stint"), but not those that do not (e.g., "pint"). Finally, some patients with dementia show the ability to use the whole-word reading route without the benefit of semantics. These patients can read irregularly spelled words correctly that they do not understand.

The fact that a patient has difficulties in reading words and/or nonwords aloud does not necessarily imply that he or she does not recognize or understand a printed word. Some patients have a severe disturbance of reading aloud known as "letter-by-letter reading" because they name each letter in a word before attempting (often with incomplete success) to pronounce the word. These patients take longer to read longer words, and it can take them many seconds to pronounce a printed word. Several of these patients have been tested for their abilities to recognize and comprehend words that are presented for short periods of time—far less than the time needed for them to read the words aloud. One such patient could recognize words and familiar letter strings as visual patterns, and other letter-by-letter readers can extract at least some semantic information from briefly presented words. Most of these patients denied that they were able to recognize or understand these briefly presented words. These performances suggest that some reading problems arise after words have been recognized, and also that some alexic subjects, such as the patients with disturbances affecting auditory–oral processing described previously, may retain abilities to recognize and understand words without being aware that they do so.

I. Disorders of Writing Single Words

The acquired dyslexias have their counterparts in the acquired agraphias. Patients with phonological agraphia are severely impaired in their ability to spell or write nonsense words but are capable of very good performance on legitimate words, even words that are low in frequency and contain unusual spelling patterns (e.g., "leopard"). The deficit is these cases appears to lie in the ability to convert sublexical phonological units to orthographic units (graphemes and letters). The converse impairment—an inability to access the written forms of whole words with preserved ability to convert sublexical phonological units to orthographic units, termed surface agraphia or lexical agraphia—has also been described. A third disturbance, known as "asemantic writing," consists of the inability to write spontaneously but the retained ability to write to dictation. This suggests that the contents of the visual word-form system can be addressed from spoken input but not from the meaning of a word.

These disorders of writing can be strikingly different from patients' reading performances. For instance, one patient was unable to write nonsense words to dictation but read these items aloud without difficulty; another produced numerous misspellings when attempting to write orthographically irregular or ambiguous words but accurately read the majority of legitimate words perfectly. These dissociations have led researchers to infer that the orthographic knowledge necessary for word recognition in reading is different from the orthographic knowledge necessary for correct spelling in writing.

The abstract graphemic representation of familiar and unfamiliar words is ultimately converted by the writing mechanism into a sequence of rapid movements that generate letters on the page. A specialized working memory device is needed to maintain the graphemic code in a buffer zone while the spatial

identity of each letter is chosen at the next processing stage. One patient made the same kind of errors in writing, oral spelling, and typing, a result that justifies the conclusion that the disturbance arose while these items were in the planning buffer and before the programming and execution of a particular motor act began.

Written production takes place by generating the spatial form of each letter (allographs) in the correct order. A few agraphic cases have been documented in which the impairment is plainly confined to the retrieval of elements in the allographic code. In these patients, adequate knowledge of the word's orthography can be demonstrated because oral spelling is carried out extremely well. When tested, other methods of forming a printed word that do not require a written response (typing or use of block letters) may also yield a high degree of accuracy. Writing, however, is characterized by numerous errors of omission, substitution, reversals, and insertions. The agraphia is not merely a disturbance in the production of a graphic motor pattern because patients can write single letters to dictation, and their writing of words, although flawed, is clearly legible.

Finally, the motor schema for a letter appears to distinguish between the movements denoting the shape of a letter and the parameters that govern scale factors such as magnitude and orientation. Cases of apractic agraphia reveal a loss of the motor programs necessary for producing letters. Written characters are poorly formed and may be indecipherable, although even severely affected patients maintain the distinction between cursive and printed letters and between upper- and lowercase. Evidence indicates that the disturbance need not be associated with limb apraxia. Certain patients with right hemisphere damage have no difficulty constructing written letters or words, but they exceed the correct number of strokes on letters that require repetitive movements.

V. CONCLUSION

This brief overview of the major acquired language disorders reveals their heterogeneity and specificity. It also highlights the fact that patients may have trouble with conscious, controlled use of the products of language processing, but retain the ability to compute certain language structures unconsciously on-line. Additional disorders, and further characterization of the impairments of the operating characteristics of psycholinguistic processors, continue to be documented in psycholinguistic aphasiological research. Most patients with language disorders have more than one primary language disorder and often have disorders of these processors due to other cognitive impairments as well (such as attentional deficits or problems with searching through semantic memory).

There is no simple, one-to-one relationship between impairments of elements of the language code or of psycholinguistic processors, on the one hand, and abnormalities in performing language-related tasks and accomplishing the goals of language use, on the other hand. Most patients who have disturbances of elements of the language code or psycholinguistic processors experience limitations in their functional communicative abilities. However, individuals with language processing disorders adapt to their language impairments in many ways, and some of these adaptations are remarkably effective at maintaining at least some aspects of functional communication. Time, rehabilitation, support, and a positive attitude can allow many aphasic patients to be productive and happy.

Language, Neural Basis of

DAVID CAPLAN
Massachusetts General Hospital

GLOSSARY

cortex The nerve cells along the outside edge of the brain; the most advanced part of the brain.

holism Models of the neural basis of cognitive functions that maintain that these functions depend on large areas of the brain (i.e., that they are not narrowly localized).

lateralization The fact that some cognitive functions rely on one hemisphere of the brain more than another.

localization The fact that sensory, motor, and cognitive functions are supported by small areas of the brain.

Perisylvian cortex The cortex around the Sylvian fissure in the brain.

Language is a distinctly human symbol system that relates a number of different types of forms to aspects of meaning. The forms of language and their associated meanings are activated in the processes of speaking, understanding speech, reading, and writing. Several types of data provide information about the way the brain is organized to represent and process language in these tasks. These include correlations between language processing deficits and brain lesions, regional cerebral blood flow and other hemodynamic responses to language processing in normal subjects, electrophysiological and magnetoecephalographic responses to language processing in normal subjects, and the effects of electrocortical stimulation on language. These sources of data indicate that language is primarily represented and processed in perisylvian association cortex, with possible contributions from other brain areas. They indicate that different aspects of language processing are localized in different parts of the perisylvian cortex and lateralized differently in the two hemispheres. They also indicate that both localization and lateralization show some degree of variability across individuals.

I. LANGUAGE STRUCTURE

Language is a distinctly human ability that is vital to the cognitive and communicative abilities that underlie the success of humans both as individuals and as a species. Although many people think of language as a form of communication, it is more accurate to think of language as a code that can serve many functions, one of which is communication. The language code links linguistic representations to aspects of meaning. The types of representations of the language code include simple words, words with internal structure, sentences, and discourse. These types of representations are also called the lexical, word-formation, sentential, and discourse levels of language.

The lexical level of language consists of simple words. The basic form of a simple word (or lexical item) consists of a phonological representation that specifies the segmental elements (phonemes) of the word and their organization into metrical structures such as syllables. The form of a word can also be

represented orthographically. Simple words are assigned to different syntactic categories, such as nouns, verbs, adjectives, articles, and prepositions. The semantic values associated with the lexical level primarily consist of concepts and categories in the nonlinguistic world. Simple words tend to designate concrete objects, abstract concepts, actions, properties, and logical connectives.

The word-formation level of language allows words to be formed from other words. In English, word formation can take place via affixation (e.g., the word "destruction" is derived from the word "destroy") and compounding (e.g., the word "paper tray" is formed from the words "paper" and "tray"). There are two basic types of affixation in English. Derivational morphological processes allow the meaning associated with a simple lexical item to be used as a different syntactic category without coining a large number of new lexical forms that would have to be learned (e.g., "destroy" → "destruction"). Inflectional morphological processes play roles in encoding syntactic relationships (e.g., subject–verb agreement: "destroy" → "destroys").

The sentential level of language consists of syntactic structures—hierarchical sets of syntactic categories (e.g., noun phrase, verb phrase, and sentence)—into which words are inserted. The meaning of a sentence, known as its propositional content, is determined by the way the meanings of words combine in syntactic structures. Propositions convey aspects of the structure of events and states in the world. These include thematic roles (who did what to whom), attribution of modification (which adjectives go with which nouns), and the reference of pronouns and other anaphoric elements (which words in a set of sentences refer to the same items or actions). For instance, in the sentence "The big boy told the little girl to wash herself," the agent of "told" is "the big boy" and its theme is "the little girl," "big" is associated with "boy" and "little" with "girl," and "herself" refers to the same person as "girl." Sentences are a crucial level of the language code because the propositions they express make assertions about the world. These assertions can be entered into logical systems and can be used to add to an individual's knowledge of the world.

The propositional meanings conveyed by sentences are entered into higher order structures that constitute the discourse level of linguistic structure. Discourse includes information about the general topic under discussion, the focus of a speaker's attention, the novelty of the information in a given sentence, the temporal order of events, causation, and so on. Information conveyed by the discourse level of language also serves as a basis for updating an individual's knowledge of the world and for reasoning and planning action. The structure and processing of discourse involve many nonlinguistic elements and operations, such as search through semantic memory, logical inferences, and others.

II. LANGUAGE PROCESSING

Current models of language processing subdivide functions such as reading, speaking, and auditory comprehension into many different, semiindependent components, which are sometimes called modules or processors. These components of the language processing system perform highly specialized operations. For instance, the process of mapping the acoustic waveform onto phonemes and other phonological units involves a large number of highly specific operations that relate specific features of the acoustic signal to linguistically relevant units of sound. We may think of these operations as all being part of an "acoustic–phonetic" processor or module, or we may consider each of these operations as a distinct cognitive function. An analogy in the area of visual perception might be the claim that one function of the system is the identification of the three-dimensional shape of an object, which involves the identification of lines, surfaces, angles, and other geometric elements of shape; we may think of each of these more elementary perceptual operations separately or consider them as a whole with respect to their contribution to shape recognition. Different aspects of language involve different operations: The operations that have been postulated to be involved in constructing the syntactic structure of a sentence from words are different from those involved in recognizing linguistically relevant sounds. The visual system provides an analogy for this multiplication of different types of processors in that it has separate mechanisms for the perception of shape, color, texture, movement, and other visually perceptible elements. In the language system, as in the visual system, these different processing components, each composed of a variety of elementary operations, are semiindependent of the others in that each yields a particular type of representation. Each representation is finally integrated with others to achieve the overall goal of the processing system.

Information processing models of language can be expressed as flow diagrams (often called functional

architectures) that indicate the sequence of operations of the different components that perform a language-related task. These models become extremely detailed and complex when all the operations and components used in a task are specified. For present purposes, it is adequate to identify the major components of the language processing system as those processors that activate units at the lexical, word-formation, sentential, and discourse levels of the language code in the usual tasks of language use—speech, auditory comprehension, reading, and writing. This approach to defining language processing components groups together different operations that all activate a similar type of linguistic representation in a given task into a single processor.

The major components of the language processing system that can be identified at this level of detail for simple words are listed in Table I, and those for the word-formation and sentence levels are listed in Table II. Figure 1 presents a model indicating the sequence of activation of components of the lexical processing system, and Fig. 2 presents a similar model of the processing system for word formation and sentences. These tables and figures are based on the results of experimental psychological research in both normal subjects and patient populations.

Table I
Components of the Language Processing System for Simple Words

Component	Input	Operation	Output
		Auditory–oral modality	
Acoustic–phonological processing	Acoustic waveform	Matches acoustic properties to phonetic features	Phonological segments (phonemes, allophones, syllables)
Input-side lexical access	Phonological units	Activates lexical items in long-term memory on basis of sound; selects best fit to stimulus	Phonological forms of words
Input-side semantic access	Words (represented as phonological forms)	Activates semantic features of words	Word meanings
Output-side lexical access	Word meanings (“lemmas”)	Activates phonological forms of words	Phonological forms of words
Phonological output planning	Phonological forms of words (and nonwords)	Activates detailed phonetic features of words (and nonwords)	Speech
		Written modality	
Written lexical access	Abstract letter identities	Activates orthographic forms of words	Orthographic forms of words
Lexical semantic access	Orthographic forms of words	Activates semantic features of words	Word meanings
Accessing orthography from semantics	Word meanings	Activates orthographic forms of words	Orthographic forms of words
Accessing lexical orthography from lexical phonology	Phonological representations of words	Activates orthographic forms of words from their phonological forms	Orthographic forms of words
Accessing sublexical orthography from sublexical phonology	Phonological units (phonemes, other units)	Activates orthographic units corresponding to phonological units	Orthographic units in words and nonwords
Accessing lexical phonology from whole-word orthography	Orthographic forms of words	Activates phonological forms of words from their orthographic forms	Phonological forms of words
Accessing sublexical phonology from orthography	Orthographic units (graphemes, other units)	Activates phonological units corresponding to orthographic units	Phonological units in words and nonwords

Table II
Components of the Language Processing System for Derived Words and Sentences[a]

Component	Input	Operation	Output
		Processing affixed words	
Accessing morphological form	Word forms	Segments words into structural (morphological) units; activates syntactic features of words	Morphological structure; syntactic features
Morphological comprehension	Word meanings; morphological structure	Combines word roots and affixes	Meanings of morphologically complex words
Accessing affixed words from semantics	Word meanings; syntactic features	Activates forms of affixes and function words	Forms of affixes and function words
		Sentence-level processing	
Lexico inferential processing	Meanings of simple and complex words; world knowledge	Infers aspects of sentence meaning on basis of pragmatic plausibility	Aspects of propositional meaning (thematic roles, attribution of modifiers)
Syntactic comprehension	Word meanings; syntactic features	Constructs syntactic representation and combines it with word meanings	Propositional meaning
Construction of sentence form	Word forms; propositional meaning	Constructs syntactic structures; inserts word forms into structures	Sentence form (including positions of lexical items)

[a]Collapsed over auditory–oral and written modalities

Tables I and II and Figs. 1 and 2 outline the way information—in this case, sets of related linguistic representations—flows through the tasks of speaking, understanding spoken language, reading, and writing. The model depicted in these tables and figures simplifies this information flow in three ways: (i) It does not specify the nature of the operations in each of the major components of the system, (ii) it does not fully convey the extent to which the components of the system operate in parallel, and (iii) it does not convey the extent of feedback among the components of the system. Despite these simplifications, the model captures enough aspects of information processing in the language system to constitute an adequate starting place for a psycholinguistic approach to the neural basis of language.

The operations of the language processing system are regulated by a variety of control mechanisms, including both those internal to the language processor and those that are involved in other aspects of cognition. The first category, language-internal control mechanisms, probably consists of a large number of operations that schedule psycholinguistic operations on the basis of the ongoing nature of a given psycholinguistic task. The second category of control mechanisms, those that are related to cognitive processing outside the language system, determines what combinations of processors become active in order to accomplish different tasks, such as reading, repeating what one has heard, and taking notes on a lecture.

Processing components are activated in serial and in parallel to accomplish language tasks such as reading a word aloud, producing a spoken sentence, and writing a word from dictation. Different tasks require different processors. For instance, referring to Table I and Fig. 1, reading a word aloud can be accomplished in several ways. All these ''reading routes'' begin with the processor that recognizes visual patterns as letters. One route then uses these letter identities to activate phonological units, which are assembled into a pronunciation. A second route uses letter identities to activate the orthographic forms of words, which in turn activate the phonological forms of words. A third route also activates the orthographic forms of words, which in turn activate meanings of words, and these then lead to the activation of the phonological forms of words. In all cases, the resulting phonological sequence is sent to the processor labeled ''output phonological

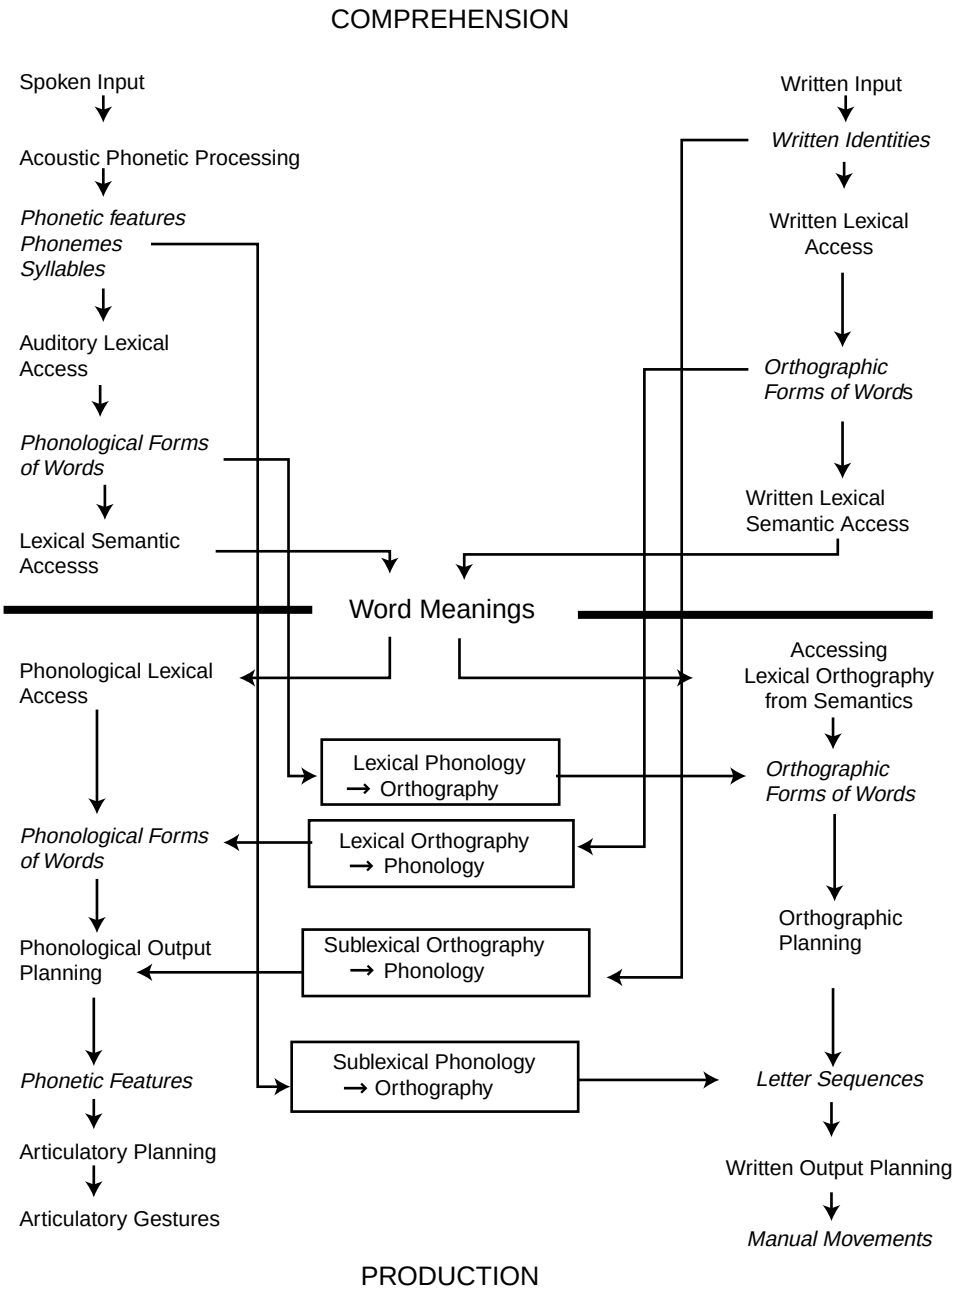

Figure 1 A model of the language processing system for single words. Processing components, indicated in boxes, activate linguistic representations in the sequences indicated by arrows. [from Caplan (1992). *Language, Structure, Processing, and Disorders*. Reproduced with permission of MIT press].

planning" to be turned into a form appropriate to activate motor speech activity. These three routes are thought to become active simultaneously. The processors used in reading aloud can be used in other language tasks. For instance, the processors involved in activating the phonological forms of words from their meanings and in output phonological planning are also used in naming pictures.

Functional communication involving the language code occurs when people use these processors to

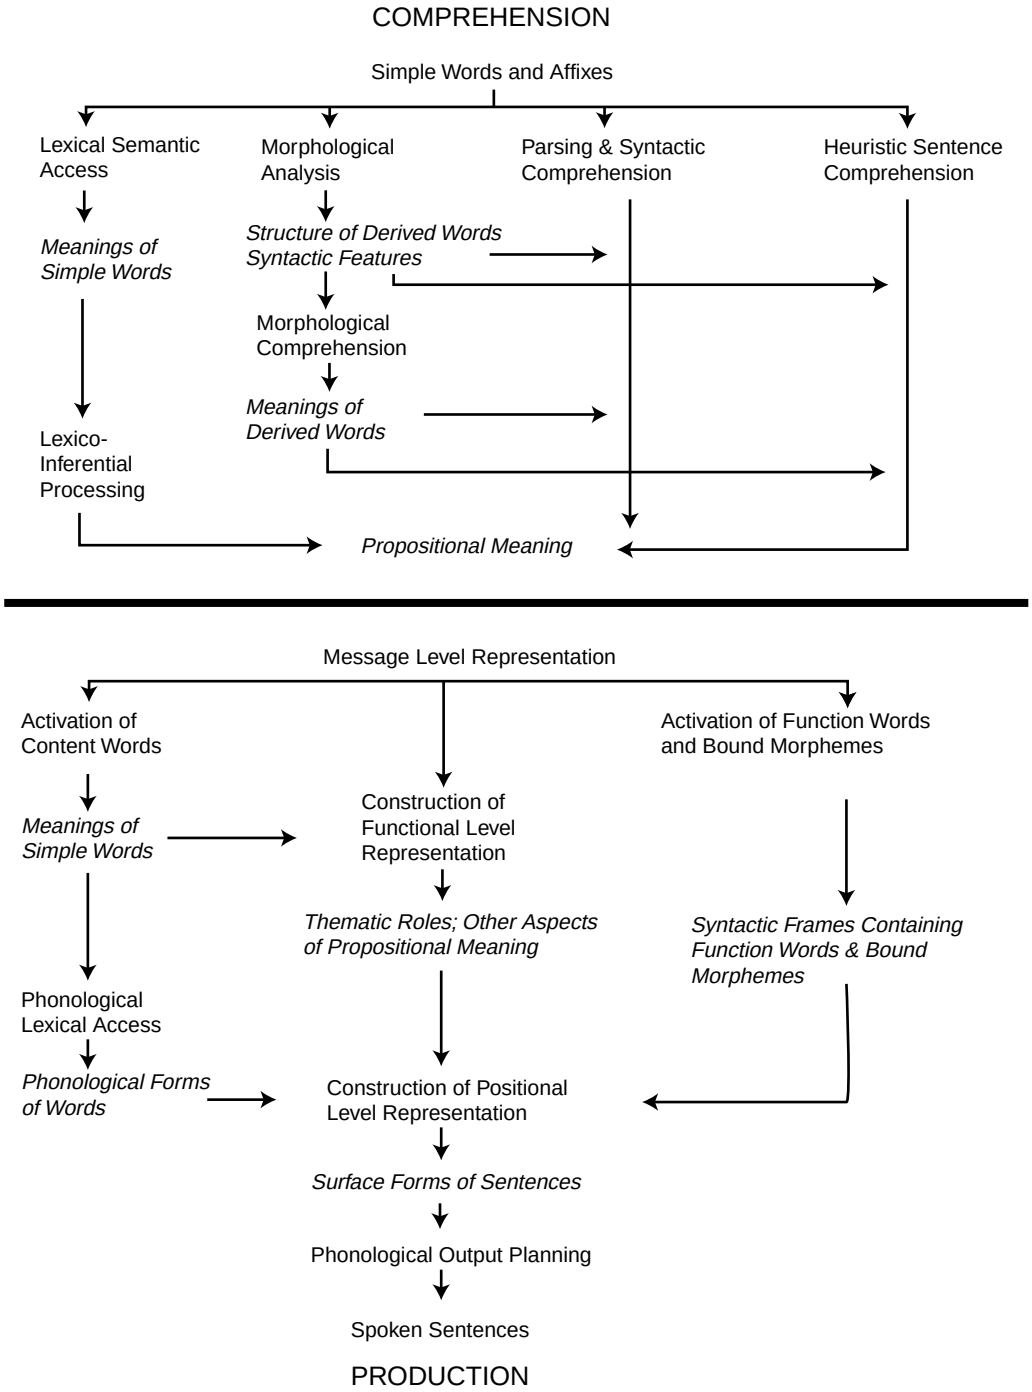

Figure 2 A model of the language processing system for derived words and sentences. Processing components, activate linguistic representations in the sequences indicated by arrows. [from Caplan (1992). *Language, Structure, Processing, and Disorders*. Reproduced with permission of MIT press].

undertake language-related tasks to accomplish specific goals—to inform others, to ask for information, to get things done, etc. It was previously noted that language is subject to control from other cognitive domains; conversely, one of the most important functions of language is to operate as a control mechanism for both intra- and interpersonal thought and action.

III. OVERVIEW OF NEURAL STRUCTURES SUPPORTING LANGUAGE

There is evidence that language processing involves the perisylvian association cortex—the pars triangularis and opercularis of the inferior frontal gyrus [Brodman's areas (BA) 45 and 44 (Broca's area)], the angular gyrus (BA39), the supramarginal gyrus (BA40), and the superior temporal gyrus (BA22: Wernicke's area) —in the dominant hemisphere. Data regarding the functional neuroanatomy of language processing were originally derived from deficit–lesion correlations and, recently, have been obtained from functional neuroimaging and electrophysiological studies in normal subjects. All these sources of data indicate that the perisylvian association cortex is involved in this function.

Patients with lesions in parts of this cortex have been described who have had long-lasting impairments of this function. Disorders affecting language processing after perisylvian lesions have been described in all languages that have been studied, in patients of all ages, with written and spoken input, and after a variety of lesion types, indicating that this cortical region is involved in syntactic processing, independent of these factors. Functional neuroimaging studies have documented increases in regional cerebral blood flow (rCBF) using positron emission tomography (PET) or blood oxygenation level-dependent (BOLD) signal using functional magnetic resonance imaging (fMRI) in tasks in associated with language processing. Event-related potentials (ERPs) whose sources are likely to be in this region have been described in relationship to a variety of language processing operations. Stimulation of this cortex by direct application electrical current during neurosurgical procedures interrupts language processing. From these data, it can be concluded that language processing is carried out in the dominant perisylvian cortex.

Regions outside the perisylvian association cortex might also support language processing. Working outwards from the perisylvian region, there is evidence that the modality of language use affects the location of the neural tissue that supports language, with written language involving cortex closer to the visual areas of the brain and sign language involving brain regions closer to those involved in movements of the hands than movements of the oral cavity and its contents. Some ERP components related to processing improbable or ill-formed language are maximal over high parietal and central scalp electrodes. This may suggest that these regions are involved in language processing, but two factors have to be considered before such a conclusion is drawn: The location in the brain of the tissue that generates an ERP wave is not easy to identify on the basis of the scalp location of that wave and may not be right below that wave, and some of these waves may reflect general processes related to detection of pragmatically implausible or unlikely events in general, not language processing per se.

Both lesion studies in stroke patients and functional neuroimaging studies suggest that the anterior temporal lobe, primarily in the dominant hemisphere, is involved in aspects of language processing. The leading candidate for such a function is the accessing of the sounds of words from their meanings in speech production. However, electrocortical stimulation studies and the effects of neurosurgical resections do not support this conclusion. On the other hand, both functional neuroimaging and electrocortical stimulation studies indicate that the inferior temporal lobe is involved in aspects of word processing, particularly the representation of meanings of nouns. Activation studies implicate the frontal lobe just in front of Broca's area in word meaning as well, although these activations may reflect switching sets rather than processing semantic representations. Injury to the supplementary motor cortex along the medial surface of the frontal lobe can lead to speech initiation disturbances; this region may be important in activating the language processing system, at least in production tasks. Activation studies have shown increased rCBF and BOLD signal in the cingulate gyrus in association with many language tasks. This activation, however, appears to be nonspecific because it occurs in many other, nonlinguistic, tasks as well. It has been suggested that it is due to increased arousal and deployment of attention associated with more complex tasks. The cerebellum also has increased rCBF in some activation studies involving both language and other cognitive functions. This may be a result of the role of this part of the brain in processes involved in timing and temporal ordering of events or because it is involved in many cognitive functions.

Subcortical structures may also be involved in language processing. Several studies report aphasic disturbances following strokes in the deep gray matter nuclei (the caudate, putamen, and parts of the thalamus), but studies of other diseases affecting the same nuclei fail to show significant language impairments. For instance, aphasias follow some caudate strokes, but language disorders are minimal in patients with Huntington's disease, even at the stage of the illness at which memory impairments are readily

documented. It has been suggested that subcortical structures involved in laying down procedural memories for motor functions, particularly the basal ganglia, are involved in "rule-based" processing in language, such as regular aspects of word formation, as opposed to the long-term maintenance of information in memory, as occurs with simple words and irregularly formed words.

Some abnormal language behaviors seen after deep gray matter lesions probably reflect the effects of disturbances in other cognitive functions on language. An example of this is the fluctuation between neologistic jargon and virtual mutism seen after some thalamic lesions. This corresponds to a more general fluctuation between states of delirium and near akinetic mutism, and it most likely reflects the effects of some thalamic lesions on arousal, alerting, and motivational functions, some of which are seen in the sphere of language. Intraoperative stimulation studies of the interference with language functions following dominant thalamic stimulation also suggest that the language impairments seen in at least some thalamic cases are due to disturbances of attentional mechanisms. Perhaps the most important consideration regarding language disorders following subcortical lesions is the question of whether they result from altered physiological activity in the overlying cortex and not from disorders of the subcortical structures. In general, subcortical lesions cause language impairments when the overlying cortex is abnormal (often, the abnormality can only be seen with metabolic scanning techniques), and the degree of language impairment is much better correlated with measures of cortical rather than subcortical hypometabolism. It may be that subcortical structures serve to activate the language processing system but do not process language.

The other major component of the subcortical region of the cerebral hemispheres is the white matter. White matter tracts transmit representations from one area to another. Lesions of white matter tracts disconnect regions of the brain from others and make the operations performed in one region unavailable to others. This can cause language disorders. The best known such disturbance is a pure alexia, in which a patient can write but not read–not even his or her own writing. This can result from a lesion that destroys the primary visual cortex in the dominant hemisphere and extends forward in the white matter to cut off visual information coming to the nondominant hemisphere from the dominant hemisphere language area. In addition to these "disconnection" syndromes, language disturbances of all sorts occur with lesions affecting many white matter tracts, whereas sparing of language functions can follow lesions in identical subcortical areas. The fact that multiple language processing disturbances occur following subcortical strokes affecting white matter is consistent with the existence of many information transfers carried out by white matter fibers, suggesting that many of the areas of cortex and/or subcortical nuclei that carry out sequential language processing operations are not contiguous.

In summary, a large number of brain regions are involved in representing and processing language. Ultimately, they all interact with one another as well as with other brain areas involved in using the products of language processing to accomplish tasks. In this sense, all these regions are part of a "neural system," but this concept should not obscure the fact that many of these regions appear to compute specific linguistic representations in particular tasks. The most important of these regions is the dominant perisylvian cortex.

IV. ORGANIZATION OF THE PERISYLVIAN CORTEX FOR LANGUAGE PROCESSING

Two general classes of theories of the relationship of portions of the perisylvian association cortex to components of the language processing system have been developed—one based on "holist" or distributed views of neural function and one based on localizationist principles. Although theories within each of these two major groupings vary, there are a number of features common to theories within each class.

The basic tenet of holist/distributed theories of the functional neuroanatomy for language is that linguistic representations are distributed widely and that language processing conmponents rely on broad areas of perisylvian association cortex. Karl Lashley identified two functional features of holist/distributed models that determine the effects of lesions on performance: equipotentiality (every portion of a particular brain region can carry out a specific function in every individual) and mass action (the larger the neuronal pool that carries out a particular function, the more efficiently that function is accomplished). The features of equipotentiality and mass action jointly entail that lesions of similar sizes anywhere in a specified brain region have equivalent effects on function, and that the magnitude of any functional deficit is directly proportional to the size of a lesion in

this specified area. Recently, models of lesions in parallel distributed processing simulations of language and other cognitive functions have provided a mathematical basis for these properties of these systems.

All the traditional theories that postulate localization of components of the language processing system maintain the view that, discounting lateralization, the localization of components of the language processing system is invariant across the normal adult population. Thus, all the traditional localizationist theories have as a corollary that lesions in particular areas of the perisylvian association cortex interrupt the same language processing components in all individuals. Many localizationist theories also maintain that the specific localization of language processing components results from a computational advantage inherent in juxtaposing particular language processing components to each other or to cortex supporting arousal, sensory, and motor processes. Modern localizationist models relax these assertions, incorporating the ideas of individual variability and some degree of specialization wthin large-scale neural nets.

Because of the plethora of specific theories within each of these two general camps, it is impossible to critically review the empirical basis of all theories that have present-day adherents. I focus on the most widely cited theories as examples of each class.

A. Holist Theories

Unlike narrow localizationist theories, there is no one holist model that has emerged as the major example of this class of theories. However, several lines of evidence are adduced as evidence for holist theories, and all holist theories suffer from similar inadequacies in accounting for certain empirical findings.

The first line of evidence supporting holist theories consists of the ubiquity of general factors in accounting for the performance of aphasic patients. For instance, factor analyses of the performances of groups of patients both on general aphasia tests and on tests of specific language abilities almost always result in first eigenvectors (usually accounting for more than half of the variance in performance) that are approximately equally weighted for most of the subtests used to test the population. Such vectors are usually taken to reflect disruption of a single factor that affects performance on all measures, such as a limited amount of mental resources available for psycholinguistic computations. The existence of such factors would be the immediate consequence of a system in which functions were disruptable by lesions in a variety of locations, and they have therefore been widely taken as evidence for a distributed basis for language functions. A second finding supporting holist theories is the frequent observation of so-called ''graceful degradation'' of performance within specific language domains after brain damage. An example of such degradation is the strong tendency of certain dyslexic patients to read irregularly spelled words according to a regularization strategy (e.g., ''pint'' is read with a short ''i''), a tendency that is inversely proportional to the frequency of the word. Graceful degradation reflects the preservation of the simplest (in many cases, the most commonly occurring) aspects of language processing after brain damage. Modern work with parallel distributed processing models, which provide formal models of holist concepts, indicates that such patterns of performance can arise following focal lesions in systems in which information is represented and processed in massively parallel, distributed forms. A third source of empirical support for holist theories comes from the finding of an effect of lesion size on the overall severity of functional impairments in several language spheres. This would follow from the principle of mass action. Therefore, these results therefore are consistent with some form of holism in the neural basis for linguistic representations and processes.

Against the complete adequacy of any holist model is the finding that multiple individual language deficits arise in patients with small perisylvian lesions, often in complementary functional spheres. For instance, studies of acquired dyslexia have documented patients who cannot read by a whole-word route (i.e., by using the entire form of a written word to gain access to the mental representation of that word) and others who cannot read by the application of spelling–sound correspondences at the letter and grapheme level. The existence of these isolated complementary deficits in different single cases indicates that at least one abnormal performance cannot result from the relative complexity of processing required by one of these tasks. Double dissociations of this sort abound in the contemporary psycholinguistic aphasiological literature. They indicate that the mode of organization of language in the brain must be one that allows focal lesions to disrupt specific aspects of psycholinguistic processing, not simply a mode of organization that produces complexity effects and degrades gracefully. Although some selective disruptions of function can occur when ''lesions'' are produced in simulated language processing systems that operate in parallel

and distributed fashion, to date no mechanism of lesioning a distributed neural system has been shown to produce the range of specific patterns of language breakdown observed in patients.

B. Localizationist Theories

Although many localizationist models exist, the connectionist model of language representation and processing in the brain, revived by Norman Geschwind and colleagues in the 1960s and 1970s, is probably the best known localizationist model of the functional neuroanatomy of language, at least in medical circles in North America. This model is based on observations of aphasic patients and the interpretation of those observations that were first made more than a century ago.

Figure 3 represents the basic connectionist model of auditory-oral language processing and its relation to areas within the dominant perisylvian cortex. This model postulates three basic "centers" for language processing, all in cerebral cortex. The first (Fig. 3A), located in Wernicke's area, stores the permanent representations for the sounds of words (what psycholinguists would now call a "phonological lexicon"). The second (Fig. 3M), located in Broca's area, houses the mechanisms responsible for planning and programming speech. The third (Fig. 3C), diffusely localized in cortex in the 19th-century models, stores the representations of concepts. A major innovation proposed by Geschwind is in the location of one aspect of the concept center. Geschwind proposed that the inferior parietal lobule—the supramarginal and angular gyri—is the location at which the fibers projecting from somesthetic, visual, and auditory association cortices all converge and that as a consequence of this convergence, associations between word sounds and the sensory properties of objects can be established in this area. Geschwind argued that these associations are critical aspects of the meanings of words and that their establishment is a prerequisite of the ability to name objects.

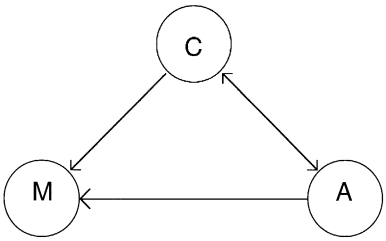

Figure 3 The classical connectionist model. A represents the auditory center for the long-term storage of word sounds. M represents the motor center for speech planning, and C represents the concept center. Information flow is indicated by arrows. The location of these centers in the brain is described in the text.

Language processing in this model involves the activation of linguistic representations in these cortical centers and the transfer of these representations from one center to another, largely via white matter tracts. For instance, in auditory comprehension, the representations of the sound patterns of words are accessed in Wernicke's area following auditory presentation of language stimuli. These auditory representations of the sounds of words in turn evoke the concepts associated with words in the "concept center." Accessing the phonological representation of words and the subsequent concepts associated with these representations constitutes the function of comprehension of auditory language. In spoken language production, concepts access the phonological representations of words in Wernicke's area, which are then transmitted to the motor programming areas for speech in Broca's area. In most versions of this model, the proper execution of the speech act also depends on Broca's area receiving input directly from the concept center. Repetition, reading, and writing are modeled as involving similar sequences of activation of centers via connections.

Recently, these aphasic syndromes have been related to the brain using a series of neuroimaging techniques—first T^{99} scanning and then computed tomography MRI, and PET. All have confirmed the relationship of the major syndromes to lesion locations. Broca's aphasia is associated with anterior lesions; Wernicke's aphasia is associated with posterior lesions, centered in the temporal–parietal juncture; pure motor deficits of speech are associated with subcortical lesions; pure word deafness is associated with lesions in the auditory association areas and surrounding white matter tracts, often bilaterally; transcortical motor and transcortical sensory aphasia are associated with watershed infarcts between the anterior and middle cerebral arteries and middle and posterior cerebral arteries; and conduction aphasia is associated with smaller lesions that often appear to affect the arcuate fasciculus. However, despite these general correlations, the classical aphasic syndromes are not as well correlated with lesion sites as the theory claims they should be. Virtually all studies exclude many types of lesions, such as various sorts of tumors, degenerative diseases, and others.

The classical syndromes are best related to lesion sites in cases of rapidly developing lesions, such as stroke. Even in these types of lesions, the syndromes are never applied to acute and subacute phases of the illness and, in the chronic phase of diseases such as stroke, between 15 and 40% of patients have lesions that are not predictable from their syndromes.

Lesion-deficit correlations have been studied in patients with more specific functional impairments than are captured by the classic aphasic syndromes (e.g., semantic memory, whole-word writing and the conversion of sounds to their corresponding orthographic units, short-term memory, and word comprehension). For the most part, these studies have involved relatively small numbers of subjects because of the difficulty in obtaining large numbers of subjects with specific deficits. For instance, one study of disorders affecting semantic memory in stroke patients could only identify three patients with a selective deficit in this function from the many patients that were screened; many other patients had problems in naming objects or in matching spoken words to pictures but not with semantic memory.

These more focused studies have provided evidence for localization of function, but the picture that emerges is complex. The localizations found have often not been consistent with the classical connectionist model. For instance, semantic memory (word meaning) appears to be disrupted after temporal, not inferior parietal, damage, and auditory–verbal short-term memory appears to be disrupted after parietal, not temporal, lesions.

An important aspect of the database relating specific language functional deficits to lesions is the finding that individual components of the language processing system can be either affected or spared following lesions in particular parts of the perisylvian association cortex. This variability in the effects of lesions at particular sites ranges across all areas of the perisylvian association cortex and is true of components of the language processing system responsible for activating any of the linguistic representations described in Section I (i.e., lexical, morphological, and sentential representations). For instance, most studies have reported phoneme discrimination deficits after both anterior and posterior lesions, in both real words and in computer-synthesized stimuli. At the same time, some studies have found that most lesions producing these impairments occur with posterior lesions. Similar individual variability has been documented in the localization of the lesions responsible for the comprehension of single words, the production of morphological forms, aspects of sentence comprehension, the production of function words in sentence production, and the production of phonemic errors in spontaneous speech, picture naming, repetition, and reading, in some cases with "central tendencies" toward deficits following lesions in specific locations. This pattern has led some rsearchers to view the entire perisylvian cortex as a neural net that supports all aspects of language processing, with some degree of specialization of parts of this net for specific functions. Models of this type cannot account for severe impairments of a single langauge operation following small lesions in different parts of this region in different individuals, however.

The finding of variability in the effects of lesions on language functions also emerges from electrocortical stimulation studies, which have studied phoneme discrimination, picture naming, sentence comprehension, and other language functions. Each of these language tasks was most likely to be interrupted with stimulation in particular regions of the perisylvian cortex across all patients, but considerable variation in sites associated with interruption of each task was also noted. For instance, phoneme discrimination was interrupted by stimulation throughout the entire central region of the perisylvian association cortex in approximately 80% of cases and in sites within the language zone that are further removed from the Sylvian fissure (such as the more dorsal regions of the inferior parietal lobule) in the remaining 20% of cases.

This variability suggests that language operations are localized in small parts of the perisylvian association cortex, but that the areas in which they are localized are different in different people. The fact that lesions restricted to specific parts of the perisylvian cortex are each associated with all levels of performance of a language processing operation, from normal performance to the worst performances seen in aphasic patients, implies that for some individuals a lesion in each of these lobar regions does not affect the operation at all, whereas for others some or all of the operation is impaired by a lesion in the same region. It is difficult to understand how this could result from anything other than individual variability in the premorbid location of these operations.

On the other hand, to the extent that specific lesions tend to be associated with certain deficits, as may be the case for some impairments, these studies also support the view that there are central tendencies in the localization of these language processing components within the perisylvian cortex. A reasonable conjecture is that the functional neuroanatomy of language in the

perisylvian association cortex has three features: (i) localization of language functions in individuals, (ii) tendencies for functions to be localized in specific portions of the perisylvian association cortex, and (iii) at least 20% of normal adults (and often many more) showing significant deviations from these central localizationist tendencies for each language processing component.

In the past 10 years, a considerable number of studies of the neural correlates of language processing have been published that employed PET, fMRI, and other "activation" techniques. As noted previously, some of these studies have led to the appreciation of possible roles for brain regions outside the perisylvian cortex in carrying out language operations. These studies also provide evidence about the organization of the perisylvian cortex for language. Many studies claim to find evidence for the localization of particular language representations, such as the phonological forms of words used in speech recognition, or language operations, such as transforming letters into their corresponding sounds, in particular parts of this cortex. Some of these localizations depend on specific tasks; for instance, the exact part of the perisylvian cortex in which blood flow changes during tasks that require comparison of sequences of phonemes has varied considerably in different studies in which different tasks were used. In other cases, there is more consensus about the areas that increase their vascular responses as a function of particular operations. Verbal rehearsal, which appears to involve Broca's area and adjacent parts of the frontal lobe, and maintenance of phonological representations in verbal short-term memory, which seems to activate the inferior parietal lobe, are examples of such functions; however, even here, different studies show some variation in the areas activated. Very few studies have examined patterns of vascular responsivity in individual subjects, which will be necessary to address the issue of variability. Much more work using these techniques can be expected, with consequent increases in the database relevant to our understanding of these issues.

V. LATERALIZATION

Most language processing occurs in one hemisphere called the "dominant" hemisphere. Which hemisphere is dominant shows considerable individual differences, which bear a systematic relationship to handedness. In approximately 98% of right-handed individuals, the left hemisphere is dominant, with the extent to which left hemisphere lesions cause language disorders influenced by the degree to which an individual is right-handed and the number of non-right-handeders in his or her family. Approximately 60–65% of the non-right-handed individuals are left hemisphere dominant, approximately 15–20% are right hemisphere dominant, and the remainder appear to use both hemispheres for language processing. The relationship of dominance for language to handedness suggests a common determination of both, probably in large part genetic (although the nature of the genetic effect remains unclear).

Although language was the first function known to be lateralized and is still the best example of a lateralized function, it is not completely lateralized. Although not as important in language functioning as the dominant hemisphere, the nondominant hemisphere is involved in many language operations. Evidence from the effects of lesions and split-brain studies, experiments using presentation of stimuli to one or the other hemisphere in normal subjects, and activation studies indicates that the nondominant hemisphere understands many words, especially concrete nouns, and suggests that it is involved in other aspects of language processing as well, such as syntactic processing. Some language operations may be carried out primarily in the right hemisphere. The best candidates for these operations are ones that pertain to processing the discourse level of language, interpreting nonliteral language such as metaphors, and appreciating the tone of a discourse as is manifest in, for instance, its being humorous. Some scientists have developed models of the sorts of processing that the right hemisphere carries out. For instance, it has been suggested that the right hemisphere codes information in a course way compared to the left hemisphere. This and other suggestions provide the bases for ongoing research programs on the nature of language processing in the right hemisphere.

Lateralization of language functions can be seen as a broad form of localization—the localization of a function in one of the two cerebral hemispheres. As noted previously, lateralization varies as a function of handedness and even within populations with similar handedness profiles. These facts suggest intriguing similarities between the phenomena of localization and lateralization of language. In both localization and lateralization, the location of a particular language processing component varies across the adult population as a whole. In both cases, however, there are

central tendencies with respect to the location of particular language processing components: There appear to be preferred sites for particular language processing functions within the perislyvian region, and there is a strong preference for language processing components to be left hemisphere based. These patterns would result from any area of either perisylvian association cortex being capable of supporting any subcomponent of the language processing system at the initial stage of language development, and from different areas of cortex assuming particular language processing roles as a function of intrinsic, genetically determined, developmental patterns, modified by other factors such as the internal organic milieu and the nature of exposure to language.

VI. CONCLUSION

Our newly acquired abilities to identify specific language processing deficits in patients, to characterize lesions with modern imaging techniques, and to use technologies such as intraoperative electrocortical stimulation, event-related potentials, and metabolic scanning to study the neural basis for language position us to investigate the neural basis for language at a level of detail previously unattainable. Research using these techniques is likely to continue to change our ideas of the way the human brain supports language functions.

Laterality

JOSEPH B. HELLIGE
University of Southern California

GLOSSARY

corpus callosum Largest fiber tract that connects the left and right cerebral hemispheres.

handedness The tendency to prefer the use of one hand over the other and for motor performance to be better for the preferred hand.

hemispheric asymmetry Biological and functional differences between the left and right sides of the cerebral cortex.

hemisphericity Indication of the extent to which an individual is more reliant on the left or on the right cerebral hemisphere, inferred from measurement of the individual's cognitive skills and biases.

laterality Behavioral and biological manifestations of left–right brain differences or of hemispheric asymmetry.

manual praxis Purposeful, sequential actions in which spatial constraints imposed by the environment are minimal.

planum temporale Cortical area located on the superior surface of the temporal lobe posterior to the transverse auditory gyrus of Heschl.

split-brain patients Individuals whose left and right cerebral hemispheres have been surgically disconnected by severing the corpus callosum and other connecting fibers.

Sylvian fissure Deep groove on the lateral surfaces of the cerebral hemispheres that marks the boundary between the frontal and parietal lobes above and the temporal lobe below.

Laterality refers to the behavioral and biological manifesta-tions of asymmetry between the left and right cerebral hemispheres. The cerebral cortex of the human brain is divided anatomically into two hemispheres, the left and the right. Although the two hemispheres are similar in appearance and structure, they are not biologically identical and they have different information processing abilities and propensities. This article provides an overview of this brain laterality and its consequences for perception, cognition, emotion, and action.

I. LEARNING ABOUT LATERALITY: TECHNIQUES AND TOOLS

Brain laterality has been studied in a variety of populations using several research techniques and tools. In fact, the existence of so many converging techniques is a very positive feature of research in this area. I begin by reviewing the major techniques on which later conclusions rest and, for the sake of example, indicate briefly how each technique provides information about laterality for aspects of human language. The oldest technique for studying brain–behavior relationships is the observation of behavioral deficits after localized brain damage. If the brain were completely symmetric in terms of structure and function, then injury to homologous areas of the two hemispheres should have equivalent effects. However, this is not the case. For example, specific language

deficits are more common and more severe after damage to certain temporal and parietal areas of the left hemisphere than after injury to corresponding areas of the right hemisphere. The deficits for which this is true include speech production and perception, phonetic analysis of printed text, the use of syntactic cues, and access to certain types of word meaning. As discussed later, certain other deficits (e.g., processing intonation cues) are associated more with right hemisphere damage. This is important because such double dissociations rule out the possibility that the left hemisphere is simply dominant for everything. Note that identification of deficits after localized brain damage can indicate the extent to which an area within one hemisphere is necessary for performing a particular task or executing a particular process. However, such studies do not indicate the extent to which one hemisphere is sufficient for performing the task or process or that the impaired process is localized within the damaged area.

Dramatic demonstrations of brain laterality come from the study of so-called split-brain patients whose hemispheres have been surgically disconnected in order to control the spread of epileptic seizures. This is done by cutting the corpus callosum, the largest fiber tract connecting the two hemispheres, as well as other connecting fibers. By using clever techniques of stimulus presentation and response measurement it is possible to examine the positive competence of each hemisphere in split-brain patients and thereby identify tasks and processes for which each isolated hemisphere is sufficient. These techniques take advantage of the fact that human sensory projections are organized so that input from one side of the body or one side of space is transmitted directly to the contralateral cerebral hemisphere. This includes sensory input from fingers of the left and right hands, the left and right halves of each retina (so that each visual half field projects directly to the contralateral visual cortex) and, under appropriate conditions, the left and right ears. With respect to certain aspects of language, the study of split-brain patients indicates that the isolated left hemisphere is far more competent than the isolated right hemisphere. For example, a split-brain patient can say the name of a common object (e.g., pencil) when it is placed into the right hand or when its picture or printed name is projected to the right visual field (i.e., to the left hemisphere) but not when it is placed into the left hand or when its picture or printed name is projected to the left visual field (i.e., to the right hemisphere). Of course, generalizing from such patients to neurologically intact individuals is tricky, in part because brain laterality may not operate the same way in the presence of extensive interhemispheric connections.

In neurologically intact individuals, it is not possible to test the competence of each hemisphere in isolation, but it is possible to measure speed and accuracy of performance as a function of which hemisphere receives information directly and must at least initiate processing. The techniques for studying this sort of behavioral laterality in neurologically intact individuals are the same as those used to lateralize stimuli for split-brain patients. When used with appropriate methodological care, such studies provide an important converging technique for learning about functional hemispheric asymmetry in the intact brain. Although often smaller, laterality effects in intact individuals are typically in the same direction as those found in split-brain patients. For example, there is a right visual field (left hemisphere) advantage for the identification of printed words and nonwords as well as a right ear (left hemisphere) advantage for the identification of spoken words and syllables.

In recent years there have been significant advances in brain imaging techniques that permit measurement of various structures in the living brain and of the relative amounts of neural activity in different cortical regions as individuals perform experimental tasks. The techniques include computerized axial tomography scans, magnetic resonance imaging (MRI) and functional MRI, measures of regional cerebral blood flow, positron emission tomography scans, event-related potentials, and magnetoencephalography. Among other things, brain imaging has provided a great deal of converging information about brain laterality. Later, I discuss certain well-established structural asymmetries as well as individual variation in the size of the corpus callosum. With respect to language, functional imaging techniques have shown greater activation in temporoparietal areas of the left hemisphere than in the right hemisphere when normal individuals speak, identify printed words, and so forth, with the specific areas of greatest activation depending on exactly which processes are relevant to the task. Furthermore, monitoring a list of words for semantic content also produces activation of frontal areas within the left hemisphere. In addition, verbal working memory tasks produce primarily left hemisphere activation, whereas spatial working memory tasks produce primarily right hemisphere activation. Of course, increased activity in a specific brain area does not indicate exactly what that area is doing or how well it is doing it. Nor is it possible to determine whether

increased activation reflects excitatory or inhibitory neural processes. Nevertheless, functional imaging techniques have produced important results that are consistent with conclusions suggested by classical neuropsychology and clearly constitute a converging operation that will grow in importance.

II. BEHAVIORAL ASYMMETRIES IN HUMANS: LATERALITY FOR COMPONENTS OF ACTION AND COGNITION

The tools and techniques described in the preceding section have been used to identify and confirm a great many behavioral asymmetries in humans. Before summarizing a number of the most well-established asymmetries, it is useful to consider three general characteristics of laterality effects: ubiquity, subtlety, and complementarity. Ubiquity refers to the fact that the two cerebral hemispheres have different levels of ability and different processing propensities in a great many domains. In this section, I review examples in the domains of motor activity, language, perception, and emotion. Subtlety refers to the fact that it is rarely the case that one hemisphere can perform a task or accomplish a specific process quite well, whereas the other hemisphere cannot perform the task or process at all. Instead, both hemispheres typically have some ability, though they may go about a task in different ways and one hemisphere may do a better job than the other. A notable exception to this is speech production, which tends to be controlled exclusively by a single hemisphere (usually the left). Complementarity refers to the fact that in many domains, the roles for which each hemisphere is dominant can be described as complementary. Consequently, both hemispheres normally play a role in virtually all complex activities, such as understanding language or identifying faces, with their contributions fitting together like two pieces of a puzzle. Several examples of complementarity are given in the remainder of this article.

The most obvious behavioral asymmetry in humans is handedness, with approximately 92% of women and 88% of men favoring and being more proficient with the right hand for performing a variety of skilled activities, such as writing, drawing, eating, and using a needle to sew. Of the remaining non-right-handed individuals a few exhibit strong and consistent left-handedness, a few are truly ambidextrous, and others show hand preferences that vary from one skilled activity to another. In general, for both right-handed and left-handed individuals, hand differences are weaker for unskilled activities such as picking up a small object. Furthermore, for tasks that require the coordinated activity of both hands, their roles are often complementary. In general, for right-handed individuals the left hand (controlled by the right hemisphere) performs movements of relatively low spatial and temporal frequency, whereas the right hand (controlled by the left hemisphere) performs movements of relatively high spatial and temporal frequency. An example of this complimentary arrangement is handwriting, during which the left hand arranges and steadies the paper while the right hand makes more frequent and smaller movements with the writing instrument. Though handedness is the most obvious example, there are also other motoric asymmetries. For example, for right-handed individuals the left side of the body is frequently preferred for postural support. In addition, the right side of the face (controlled by the left hemisphere) is superior for making certain oral movements associated with language and other precisely sequenced activities, whereas the left side of the face (controlled by the right hemisphere) is more emotionally expressive.

Left hemisphere dominance for many aspects of language is the most obvious and cited asymmetry outside of the motor domain. From clinical neurological data as well as other sources, it is estimated that speech production is limited to the left hemisphere in approximately 95% of right-handed individuals. As noted in the preceding discussion of research tools and techniques, the left hemisphere is also dominant for many aspects of language perception and for the verbal processing of stimulus material, although in these cases left hemisphere superiority is more a matter of degree than of the all-or-none asymmetry that is characteristic of speech production. In addition, when we consider understanding language for the purpose of communication, there is growing evidence that both hemispheres make important contributions. Whereas the left hemisphere is dominant for the perception of phonetic information, for the use of syntax and for certain aspects of semantic processing, the right hemisphere is dominant for processing the sort of intonation cues and prosody that communicate such things as emotional tone (e.g., anger versus surprise). The right hemisphere is also involved in processing narrative-level linguistic information. Some of these complementary, language-related asymmetries may be related to hemispheric differences in the efficiency of processing different aspects of acoustic signals. For example, identification of many spoken phonemes requires

efficient processing of rapid changes in the acoustic signal over brief periods of time, a type of processing for which the left hemisphere is hypothesized to be superior. In contrast, identification of the emotional tone of voice requires efficient processing of much slower modulations of the acoustic signal over longer periods of time, a type of processing for which the right hemisphere is hypothesized to be superior. The two hemispheres also appear to access word meanings in complementary ways. When a word is presented, the left hemisphere restricts processing very quickly to one possible meaning, usually the dominant meaning or the meaning most consistent with the present context, whereas the right hemisphere maintains activation of multiple meanings and remotely associated words for a more extended period of time.

Neither hemisphere is uniformly superior for processing nonverbal perceptual information. Instead, both hemispheres contribute to perceptual processing and do so in ways that could be described as complementary. For example, in studies of the identification of visual patterns there is evidence of right hemisphere dominance for processing global aspects of stimuli (e.g., the outer contour of a face) and left hemisphere dominance for processing local details (e.g., small features of a face). Specifically, global and local processing are associated with the posterior superior temporal areas of the right and left hemispheres, respectively (though this may be affected by the relative sizes and perceptual clarity of the global and local levels within a stimulus). These effects may be related to hemispheric differences in the efficient use of information carried by visual channels tuned to relatively high versus relatively low spatial frequencies. Specifically, the left and right hemispheres are biased toward more efficient use of higher and lower frequencies, respectively, with at least three aspects of spatial frequency being relevant: the absolute range of frequencies contained in a stimulus, the range of frequencies that is most relevant for the task being performed, and whether the relevant frequencies are high or low relative to other frequencies contained in the stimuli used in the experiment. It has been hypothesized that analogous hemispheric differences extend to the processing of relatively high and relatively low temporal frequencies in audition and, perhaps, to movements of different temporal frequencies and spatial extent.

In the spatial domain, the brain computes at least two kinds of spatial relation representations—a categorical representation used to assign a spatial relation to a category such as ''connected to'' or ''above'' and a coordinate representation used to represent precise distances and locations. The right hemisphere makes more effective use of this latter coordinate system, whereas there is either no hemispheric difference or a left hemisphere advantage for processing categorical spatial relationships. Neural network simulations suggest that hemispheric asymmetry for making categorical versus coordinate judgments may be related to the nature of visual information that is most useful for processing categorical versus coordinate properties. For example, networks constructed to simulate relatively large overlapping receptive fields compute coordinate spatial information better than do networks constructed to simulate relatively small, nonoverlapping receptive fields. Exactly the reverse has been found for the computation of categorical spatial information. From this perspective, it is interesting that categorical spatial processing is disrupted by manipulations (blurring of stimuli) that selectively interfere with information carried by channels with small, discrete receptive fields, whereas coordinate spatial processing is disrupted by manipulations (use of a diffuse red background) that selectively interfere with information carried by channels with large, overlapping receptive fields. Additional neural network simulations have examined the possible importance of receptive field sizes for encoding information about shape. The same networks that favored coordinate spatial processing also favored coding the identify of specific shapes, whereas the same networks that favored categorical spatial processing also favored the assignment of shapes to categories. Interestingly, there is evidence of right hemisphere superiority for processing the sort of specific shape information that would be needed to distinguish among the exemplars of a single category but left hemisphere superiority for classifying the prototypes used to define different categories. Of course, it is possible to devise alternative ways of tying these different laterality effects together (e.g., in terms of left and right hemisphere attentional biases toward different ranges of spatial frequency) and more empirical as well as theoretical work is needed before we fully understand the mechanisms that underlie these complementary hemispheric specializations.

As noted earlier, the right hemisphere is superior to the left in using the intonation cues of speech to identify emotional tone of voice. The same tends to be true of identifying the emotion displayed on a face, though in both cases it is difficult to rule out interpretations in terms of the kind of auditory or visual information that is most useful for identifying

emotion. With respect to the production or experience of emotions, hemispheric differences seem to be more complementary. For example, the balance of activation between the frontal lobes of the two hemispheres is related to the valence of an experienced emotion. Specifically, positive emotions are accompanied by relatively greater left hemisphere activation and negative emotions are accompanied by relatively greater right hemisphere activation. Emotions of negative versus positive valence (e.g., sadness versus happiness) are typically characterized by states of low versus high arousal, respectively, leading some researchers to suggest that it is the difference in arousal, rather than valence per se, that accounts for the observed hemispheric asymmetries.

These representative examples of behavioral asymmetries in humans are admittedly illustrative rather than exhaustive. Nevertheless, they illustrate that laterality is a pervasive characteristic of human behavior, that computational differences between the hemispheres are often subtle, and that each hemisphere makes important contributions to most aspects of behavior.

III. BIOLOGICAL ASYMMETRIES IN THE HUMAN BRAIN

At first glance, the left and right hemispheres appear to be biologically identical, leading one to wonder why there are so many functional asymmetries. However, postmortem studies of anatomy and structural imaging studies of the living brain have documented a number of consistent physical asymmetries. For example, in the majority of human brains the frontal region is wider and extends farther forward in the right hemisphere and the occipital region is wider and extends farther rearward in the left hemisphere, giving the brain a kind of counterclockwise torque. Because the temporoparietal areas of the left hemisphere are important for language, it may not be surprising that a number of anatomical and cytoarchitectonic hemispheric differences have been found in those areas. For example, consider the Sylvian fissure, which marks the boundary between the frontal and parietal lobes, which lie above the fissure, and the temporal lobe, which lies below the fissure. This fissure tends to be longer and straighter in the left hemisphere than in the right hemisphere, in which it tends to curl upward. In addition, the planum temporale, which is an extension of Wernicke's area in the left hemisphere (known to be important for language), tends to be larger in the left hemisphere than in the right hemisphere.

There is evidence that individual variation in these structural asymmetries is related to individual variation in functional asymmetry. As noted earlier, handedness is the most obvious motoric expression of laterality. Therefore, it is interesting that the foregoing structural asymmetries are related to handedness. For example, for right-handed individuals the planum temporale is larger in the left hemisphere in approximately 65% of the cases, larger in the right hemisphere in approximately 10% of the cases, and approximately equal in 25% of the cases. The corresponding percentages for non-right-handers are approximately 25, 10, and 65%, respectively. Similar distributions characterize asymmetry of the Sylvian fissure. The ability to measure structure within the normal, living brain has also made it possible to search for relationships between structural asymmetry and a variety of other nonmotoric behavioral and perceptual asymmetries, but no clear-cut picture has emerged. Perhaps this is not surprising in view of the fact that structural characteristics revealed by contemporary imaging techniques are still relatively gross (e.g., the length of a fissure).

Despite the fact that structural characteristics such as length and size are difficult to interpret, some of the structural characteristics that have been observed are related to other aspects of individual variation. For example, the extent of leftward asymmetry of planum temporale size is greater in musicians with perfect pitch than in either nonmusicians or musicians who do not have perfect pitch. Also, although it is impossible to reach strong conclusions from the study of only one brain, there is something intriguing about the fact that neurons in areas that are known to be involved in spatial reasoning and mathematics received greater metabolic support in the brain of the great physicist Albert Einstein than in the brains of other individuals. However, it should be noted that attempts to relate structural asymmetries to other dimensions, such as sex, psychopathology, and cognitive deficit, have produced mixed results.

Though not as well established as the gross structural asymmetries, there are also indications of cytoarchitectonic and biochemical differences between the two hemispheres. For example, the extent of higher order dendritic branching seems to be greater in certain speech areas of the left hemisphere (e.g., Broca's area) than in corresponding regions of the right hemisphere. Conversely, lower order dendritic branches seem to be longer in the right hemisphere than in the left

hemisphere. It has also been hypothesized that the distribution of two important neurotransmitters is asymmetric in the human brain, with dopamine being more prevalent in the left hemisphere and norepinephrine being more prevalent in the right hemisphere.

Structural imaging has also been used to study the correlates of more or less callosal connectivity between the two hemispheres by measuring such things as the midsagittal area of the corpus callosum. Although the size of the corpus callosum increases with the size of the brain, the relative extent of callosal connectivity (e.g., corpus callosum size relative to brain size) seems to decrease with increases in the size of the brain. Furthermore, there is some indication that fewer callosal fibers connect more asymmetric regions of the two hemispheres, although the functional significance of these relationships is not clear. Studies have also begun to examine the relationship between callosal connectivity as measured from brain images and various perceptual asymmetries. One hypothesis is that as the extent of callosal connectivity increases, interhemispheric transfer of information is facilitated, thereby decreasing the size of behavioral laterality effects. Despite a certain intuitive plausibility, the experimental evidence for this hypothesis is mixed, perhaps because increases in callosal connectivity also permit more inhibition from one hemisphere to the other.

IV. UNITY OF PROCESSING FROM THE LATERALIZED BRAIN: VARIETIES OF INTERHEMISPHERIC INTERACTION

One of the most striking and consistent observations in studies that involve functional brain imaging is that many areas within both brain hemispheres are activated by even very simple tasks. This reflects the fact that the behavior of neurologically intact individuals is virtually always the result of processing in both hemispheres as well as in a variety of subcortical structures. In this section, I consider a variety of ways in which the left and right hemispheres interact and the biological mechanisms that support those interactions.
