corticobasal degeneration (CBD) The extrapyramidal variety of PiD. It is clinically defined as unilateral extrapyramidal symptoms, apraxia, and the alien hand syndrome, but many of these patients develop features of FTD and PPA and they often present with cognitive syndromes. Therefore, the pathological entity of CBD and the clinical syndrome of CBDs are also part of the PC.

frontotemporal dementia (FTD) Clinical PiD or PC. It is also used for the apathy–disinhibition presentation or the pathology without Pick bodies.

FTDP-17 Frontotemporal dementia and parkinsonism linked to chromosome 17. Most of these families have τ mutations and a range of pathological and clinical phenotypes that are similar to sporadic cases of PC.

motor neuron type of FLD This was initially described as a separate entity with ubiquitin-positive, τ-negative inclusions, but there is considerable overlap between these cases and other members of the PC.

Pick bodies Round, argyrophilic, compact inclusions in the dentate gyrus and the neocortex. At one time they were considered the defining pathology of PiD, but there are a variety of inclusions in PC and sometimes there are no inclusions in the clinical syndrome (see Section III).

Pick cells Ballooned neurons. This is a feature of all varieties of the PC and was originally described with PiD but later also as a cardinal feature of CBD.

Pick complex (PC) Clinical PiD encompassing all the syndromes of frontotemporal dementia, primary progressive aphasia, corticobasal degeneration, and frontal lobe dementia with motor neuron disease and all of the pathological varieties, including PiD, CBD, dementia lacking distinctive histology, etc.

Pick's disease (PiD) Clinical frontotemporal dementia or pathology with Pick bodies.

primary progressive aphasia (PPA) This presenting syndrome is also part of the Pick complex or clinical Pick's disease. It has a variety of pathologies just like FTD. By definition, the patient exhibits slowly progressive aphasia before anything else develops.

semantic dementia Semantic aphasia or a fluent type of transcortical sensory aphasia in which the patient has difficulty with comprehension and naming, especially comprehending nouns, with well preserved repetitions, spontaneous speech, and syntax. The loss of meaning extends to visually presented stimuli; therefore, the term semantic dementia is applied. However, because these patients are not truly demented at the beginning and the condition is more related to PPA, semantic aphasia would be a preferable term.

Pick's disease (PiD) has been used to describe either the clinical syndrome of frontotemporal dementia (clinical

Pick's disease), or as a pathological description of frontotemporal atrophy with silver staining, globular inclusion (Pick bodies), swollen neurons (Pick cells), superficial cortical spongiosis, neuronal loss, and gliosis. However, only a small percentage of cases, about 25%, with clinical PiD will have the typical inclusions. This has created a nosological dichotomy, but more recent and advances in neuroimaging, histochemistry and genetics have highlighted the importance of frontotemporal dementia.

I. INTRODUCTION

Arnold Pick described the clinical picture associated with focal atrophy in the frontal and temporal lobes around the turn of the twentieth century. Pick's initial description of a patient with progressive aphasia and behavioral disturbances and cases of frontal lobe dementia included only a gross examination without any microscopic data, but the clinical descriptions and their relationship to focal atrophy form the basis of the syndrome. Gans suggested the eponymic term and considered a predilection for the phylogenetically younger frontal and temporal lobes in the etiology. A reexamination of a series of cases of Pick and others emphasized the histological picture particularly the "pick bodies" described by Alois Alzheimer. However, it soon became apparent that cases of clinical PiD with frontal and temporal lobe symptomatology may not show the typical "Pick bodies" on autopsy. Publications of PiD were often based on post mortem examination, and the clinical features were either variable depending on the locus of disease or described incompletely because of the retrospective nature of these studies. This gave rise to the notion that PiD is difficult to diagnose *in vivo*. The restriction of the pathological diagnosis to the finding of typical Pick bodies created the second misconception that PiD is rare.

Whereas PiD continued to be diagnosed clinically and pathologically, the emphasis on the pathological diagnosis impaired the clinical recognition. Nevertheless, interest in the entity continued, mainly in Europe. Constantinidis *et al.* classified PiD as (A) with Pick bodies, (B) only with swollen neurons, and (C) only gliosis. They felt that "in spite of the dissimilarities between these forms, considering the absence of sufficient knowledge about pathogenesis, it seems prudent at present to maintain the uniqueness of Pick's entity." They thought that the clinical differences between these forms were not related to the nature of histological alterations but rather to the temporal or frontal prominence.

With the development of neuroimaging, frontotemporal atrophy was demonstrated with increasing frequency *in vivo*, first with air studies, then with CT scans, and with MRI scan and SPECT more recently. The clinical diagnosis of PiD is based on recognizing complex frontal and temporal symptomatology: mainly disinhibition dementia and aphasia with relatively preserved memory and visuospatial function (in contrast to Alzheimer's disease, AD) in younger individuals supported by focal atrophy on imaging and normal EEG. However, instead of shifting the diagnosis of PiD back to the clinic, new labels were applied to the syndrome, such as frontal lobe dementia (FLD), primary progressive aphasia (PPA), and frontotemporal degeneration (FTD), as new and separate entities while reserving the diagnosis of PiD for increasingly restricted histological criteria. Further development of histochemistry contributed to the fractionation of the pathological variations neglecting or underemphasizing the similarities. The glossary of the proliferating terminology is summarized in order of historical appearance (Table I).

Two European groups described frontal lobe dementia (FLD) as a distinct entity and contrasted the clinical features with those of AD. They estimated its relative incidence to be 15–20% of degenerative dementias. Both groups recognized that, even though some of the cases had Pick bodies and the majority did not, the clinical syndrome was the same, regardless of the pathological variant. They called the pathology without Pick bodies "frontal lobe dementia type," consisting of neuronal loss and gliosis in the frontal cortex with or without spongiform changes or ballooned neurons. Shortly thereafter, a similar clinicopathological picture was called "dementia lacking distinctive histology (DLDH)". More recently, occasional association with motor neuron disease (MND) has been increasingly recognized. Ubiquitin-positive, τ-negative inclusion bodies in the dentate gyrus and cortex were described as a marker of this syndrome.

The Lund and Manchester groups described dementia of the frontal lobe type changed the terminology to frontotemporal degeneration (FTD), and later to frontotemporal lobar degeneration (FTLD), and summarized the consensus criteria for diagnosis. The term frontotemporal degeneration or frontotemporal dementia does not include the frequent subcortical involvement, parietal pathology, and extrapyramidal symptomatology. Furthermore, it does not distinguish between the behavioral presentation of FLD and

aphasic presentation of PPA, which is one of the most valuable contributions of the descriptions of the clinical picture in these conditions. We proposed the term Pick complex (PC) to encompass this family of related disorders. The glossary of these is summarized in order of their historical appearance (Table I).

II. THE CLINICAL PRESENTATIONS OF PICK'S DISEASE

A. The Apathetic–Disinhibition Syndrome of Frontal Lobe Dementia (FLD)

The behavioral and personality changes of the "frontal lobe syndrome" often begin with apathy and disinterest, which may be mistaken for depression. On the other hand, symptoms of disinhibition may suggest a manic psychosis or a personality disorder. Cases of PiD–FTD with behavioral manifestations, therefore, are more likely to be presented to a psychiatrist than to a neurologist.

Socially inappropriate comments, rude, childish, or selfish behavior appear as a significant change of personality. Patients can be strikingly indifferent and unemotional. Stubbornness and insistence on routines resemble obsessive/compulsive behavior. When they are opposed, irritability and aggression appear. Poor judgment in spending, driving, social interaction, and bizarre behavior, such as hoarding or pilfering, can be very disruptive and lead to criminal charges.

Over-eating, cravings of sweets, or other food fads may occur. Table manners deteriorate. In the later stages, patients may touch everything and compulsively put objects in their mouth. Perseverative humming, clapping, and decreased language appear. Incontinence may come relatively early.

Some of the behavioral syndrome of PiD resembled the so-called Kluver–Bucy syndrome, which is produced in monkeys by bilateral ablation of the temporal neocortex and the amygdala and can be seen in humans after encephalitis. It consists of hyperorality, hypersexuality, and compulsive touching or "hypermetamorphosis."

Further distinctions have been made between clinical behavioral syndromes, such as the "apathetic, disinhibited, and stereotypic." The disinhibited type mainly involves the orbitofrontal region of the frontal lobes. In the apathetic type, the dorsal lateral convexity appears to be more affected. The stereotypic type appears to have more extrapyramidal involvement and striatal pathology. These distinctions tend to become blurred as the disease progresses, and not all patients can be easily categorized into these subtypes. Severe disinhibition syndrome may be seen with nondominant temporal lobe atrophy. It is difficult to separate the contributions of the temporal and frontal lobes in these cases.

The highly complex symptomatology requires a pattern recognition. Early cases often remain puzzling for first-time observers. Even dementia authorities claimed at one time or another that AD and PiD are similar clinically and cannot be distinguished reliably by clinical or neuropsychological methods. On the contrary, the pattern of disengagement–disinhibition is characteristic, once it is recognized. Neuropsychological testing often reveals relatively preserved episodic memory and visuospatial function, but a caregiver providing history or response to a questionnaire, such as the *Frontal Behavioral Inventory*, is even more useful. Neuroimaging, especially MRI, completes the differential diagnosis.

B. Primary Progressive Aphasia (PPA)

The dominant temporal lobe variety of PiD presenting with progressive aphasia has been described quite early, and these descriptions are similar to those of primary progressive aphasia (PPA) appearing later. Many cases had histology characterized by gliosis, neuronal loss, and layer II and III spongiosis in the cortex, which was initially considered specific and later described as identical to FLD. Some had classical PiD with Pick bodies and some subcortical involvement with neuronal achromasia similar to CBD.

Several varieties of PPA have been described: (1) the more common nonfluent variety leads to mutism (the majority of published cases); (2) the aphemic variety initially presents with verbal apraxia and stuttering; and (3) semantic aphasia (dementia) in which speech output remains preserved whereas the meaning of objects as tested by naming and comprehension appears to be lost. PPA is defined as a progressive language impairment without dementia for at least 2 years, although it is recognized that other modalities are affected subsequently, particularly behavior changes suggesting frontal deficit. At times extrapyramidal complications or MND supervenes. The variety associated with MND tends to be more rapidly progressive. PPA has been frequently described with progressive apraxia. FTD and CBD, in turn, also have a progressive language disturbance. Eventually most cases of FTD followed long enough develop progressive language loss and mutism. Therefore, not only the pathology but also the symptomatology of PPA overlaps among the entities belonging to the Pick complex.

Those who are more interested in behavioral disorders are less likely to report the language disorder in great detail, often describing the end stage of the progressive language disorder as mutism. Neurologists, on the other hand, may see the primarily aphasic disorder more often, as focal symptoms may be referred for investigation of a slowly growing tumor or even a stroke.

C. Corticobasal Degeneration (CBD)

There have been several case descriptions of PiD in which the patients had prominent extrapyramidal features. This became known as the "Akelaitis" variety of PiD. Sometimes unilateral rigidity and parkinsonism were the first symptoms to attract attention. It was recognized that subcortical changes occur in PiD, even without extrapyramidal symptomatology. Constantinidis *et al.* described extrapyramidal involvement particularly in group B Pick patients and in FLD patients. Changes in the basal ganglia, especially in the striatum and the substantia nigra, in addition to cortical pathology occurred in the majority of 30 cases in one review.

The authors initially describing corticodentatonigral degeneration recognized the similarity of the pathology to PiD, and this was subsequently confirmed by several investigators who also contributed further clinical details. The condition was relabeled corticobasal or corticobasal ganglionic degeneration. Most of the literature concerning this condition acknowledges the clinical and pathological overlap between CBD and PiD. CBD suffers from a dichotomy similar to that of PiD, in that the pathological and clinical descriptions do not fully match. There are some case reports describing patients presented clinically as CBD, as defined by unilateral rigidity, apraxia, and alien hand syndrome, but who have the pathological findings of PiD with Pick bodies. Other cases pathologically typical of CBD have a frontal type of dementia without extrapyramidal features. Typical CBD pathology can be seen with a clinical picture of PPA. We suggested that the clinical syndrome of prominent apraxia, unilateral extrapyramidal syndrome, and alien hand phenomenon should be designated as corticobasal degeneration syndrome (CBDS) and CBD as a pathological description. Progressive supranuclear palsy (PSP) has a great deal of clinical, biochemical, pathological, and genetic overlap with CBD and CBDs and can be considered along with CBD and CBDS as part of the Pick complex.

III. NEUROPATHOLOGY

The key feature of all forms of Pick complex is a gross pattern of focal atrophy that is initially often asymmetrical (Fig. 1). Combined frontotemporal atrophy is most common, followed by predominantly frontal, temporal, and finally parietal atrophy in this order. Involvement of an area does not allow predictions about the degree of involvement of another, in contrast to the sequential involvement of cortical areas in AD. The introduction of the Gallyas silver stain and the ubiquitin and synuclein immunohistological techniques has revealed several unsuspected lesions and allowed the separation of others.

The characteristic lesions affect neurons and glial cells. There is a common underlying theme of neuronal

Figure 1 MRI of a patient with Pick's disease. The arrow shows severe frontotemporal atrophy bilaterally. The posterior half of the brain is normal in appearance. The frontal horns and ventricles are also much enlarged.

loss, gliosis, and superficial linear spongiosis in affected cortical areas in all variations. All can show Pick cells or ballooned neurons, so-called because of the swollen, homogeneously pink appearance of the cytoplasm on routine Hematoxyllin and Eosin (H&E) stains. These cells regularly express Aβ crystallin and phosphorylated neurofilament epitopes, in contrast with the absence or at most weak and scarce immunoreactivity for τ. The consistent location of these cells in the deep layers of the cortex indicates that they likely are not the precursors of the other neuronal inclusions.

The presence of τ immunoreactivity in oligodendrocytes, demonstrated on Gallyas stains (coiled bodies), is also a common feature to all varieties, although their abundance varies. In our series, dementia lacking distinctive histopathology and dementia with ITSNU are the most common variants, followed by CBD, dementia with Pick bodies, and basophilic inclusion body disease contributing to the underlying spectrum of pathology of Pick complex.

A. Pick Body Dementia

Pick bodies are large, round inclusions located in the neuronal cytoplasm (Fig. 2). Barely visible on H&E, they are best demonstrated with traditional silver stains, such as Bodian or Bielchowsky, but do not stain with the Gallyas method. There is considerable heterogeneity in the composition of Pick bodies, not only between cases but even within a single case, as shown in the variable labeling obtained with τ antibodies and antibodies to the synaptic protein chromogranin A. Similarly, electron microscopy has revealed bodies made up of 15-nm straight fibrils, long-period twisted, and even paired helical filaments and neurofilaments. Neocortical Pick bodies are preferentially located in small neurons, as well as in the neurons in the granular cell layer of the dentate gyrus. Their presence in the latter location is pathognomonic of dementia with Pick bodies, whereas traditional silver stains and τ antibodies will identify scattered Pick bodies in the neocortex in CBD as well.

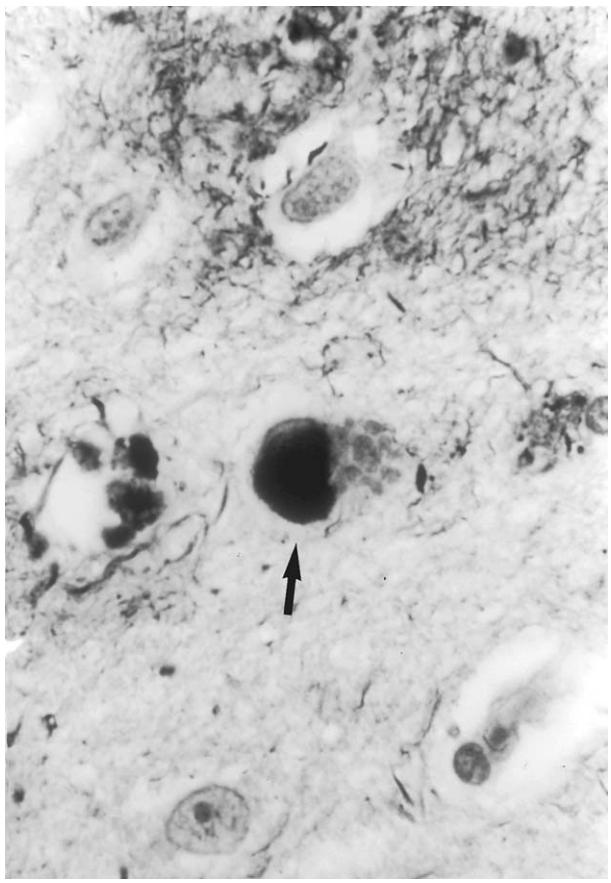

Figure 2 Bielchowsky silver stain shows (arrow) round, compact, neuronal inclusion or Pick body on autopsy.

The role of inflammatory mechanisms in PiD is not well-understood. Complementary proteins and inhibitors are detected in the neuronal cytoplasm, suggesting that complementary activation is interrupted prior to reaching completion and causing neuronal lysis. Additionally, Pick-body-bearing neurons, but not Pick cells, are surrounded by activated microglia cells and T-lymphocytes.

B. Corticobasal Degeneration (CBD)

Since the original pathological description, changes in our understanding of the pathological substrate have been substantial. The neuronal inclusions are best seen in Gallyas stains. In the neocortex, they seem to involve the same neurons as dementia with Pick bodies and adopt a variety of forms, including round lesions like Pick bodies but more characteristically ringlike tangles around the nucleus. CBD inclusions are made up of straight 15-nm fibrils, as in the common form of Pick bodies. Oligodendroglial τ expression and argyrophilic inclusions are substantial, but the pathognomonic glial inclusion occurs in astrocytes, which accumulate aberrantly phosphorylated τ protein in curlicue processes emanating raylike from the cell body, giving rise to the so-called glial plaques that are not associated with amyloid. The neuronal inclusions in the substantia nigra neurons, called corticobasal bodies in the original publications, are now recognized as no more than globose neurofibrillary tangles. They are part of the extensive subcortical involvement that usually accompanies frontal, temporal, or central cortical atrophy in CBD.

Although the absence of immunoreactivity with ubiquitin has been proposed as a method to distinguish the inclusions in CBD from those in dementia with Pick bodies, we have not found this method to be useful because ubiquitin immunoreactivity is often extremely weak in Pick bodies. CBD inclusions lack the chromogranin A immunoreactivity of Pick bodies. Pick bodies' absence of staining in the Gallyas technique may be a more practical criterion of differentiation.

C. Dementia Lacking Distinctive Histopathology (DLDH)

The uninspiring name may be preferable to such confusing terms as frontal lobe dementia or frontotemporal degeneration, which may refer to a clinical presentation, to the other varieties in Pick complex, or to this specific variety. It corresponds to Pick's disease types B and C of Constantinidis. The variation in the distribution of cortical and subcortical atrophy is manifested in clinical syndromes of frontal dementia, aphasia, and extrapyramidal movement disorders.

Histological examination reveals characteristic neuronal loss and gliosis, superficial linear spongiosis, and a variable degree of atrophy and gliosis of the white matter. The presence of ballooned neurons in the deep layers of the cortex and scattered oligodendrocytes expressing τ does not alter the diagnosis. Occasional cases demonstrating diffuse τ immunoreactivity in the neuronal cytoplasm without the formation of Pick bodies or neurofibrillary tangles, as well as the demonstration of abnormal τ proteins, emphasize the uncertainty concerning the precise margins of this entity.

D. Dementia with ITSNU

Inclusion, tau and synuclein negative, ubiquitinated (ITSNU) defines this entity, which otherwise blends with dementia lacking distinctive histopathology. The inclusions bear a resemblance to Pick bodies in size and shape, but so far are revealed only by ubiquitin immunostains. They occur in the dentate gyrus of the hippocampus and the scattered neurons in the atrophic frontal or temporal cortex. The ultrastructural appearance of ITSNU, with fibrils of variable diameter associated with granular material, is reminiscent of Lewy bodies from which they can be distinguished by the absence not only of eosinophilia but also of α-synuclein immunoreactivity. In addition, motor neurons in the brain stem and spinal cord show the skein-like ubiquitinated inclusions characteristic of amyotrophic lateral sclerosis; thus, the term "dementia of motor neuron disease type" has been applied to this condition. However, many of these patients have no record of motor weakness in the course of their disease, and as many as 25% of nondemented patients with amyotrophic lateral sclerosis also show cortical ITSNU. Vertically oriented, ubiquitinated, enlarged neurites can also be seen in the neocortex, and cell loss in the substantia nigra is consistently found. The suggestion of considering dementia with ITSNU as a subset of dementia lacking specific histopathology is not historically unreasonable, because several series of the latter variant were described without the benefit of ubiquitin immunohistochemistry.

E. Basophilic Inclusion Body Disease

This variant was described as the generalized variant of PiD, whereas other authors have reported it as a form of juvenile or adult motor neuron disease. The characteristic inclusion is round in neocortical, hippocampal, neostriatal, subthalamic, and nigral neurons. However, it adopts irregular shapes in the motor neuron. The basophilia is due to the content of RNA, derived from the rough endoplasmic reticulum. The inclusions express ubiquitin immunoreactivity but, unlike Lewy bodies, are not labeled by antibodies to α-synuclein. The ultrastructural appearance is remarkably similar to ITSNU. Although the flamboyant look of the inclusions contrasts with the drab appearance of ITSNU, we have observed two patients of the same family, each showing one form consistently throughout the brain. It is thus likely that basophilic inclusions represent ITSNU with additional RNA.

F. Progressive Subcortical Gliosis

The claim that progressive subcortical gliosis represents a distinct condition is based on the discrepancy between the severe loss of volume and gliosis of the white matter and the relative sparing of the cortex. However, careful reading of modern series reveals no substantial differences with DLDH, in which white matter degeneration can be severe. The variant has been given prominence by a report of a family in which this pathological diagnosis was linked to chromosome 3 and in which abnormal prion proteins were identified by immunohistochemistry and Western blots in the absence of mutations of the prion protein gene.

In conclusion, it seems likely that DLDH, dementia with ITSNU, basophilic inclusion body disease, and progressive subcortical gliosis are manifestations of the same pathological process. The other two pathological substrates of the Pick complex, Pick body dementia and CBD, are distinct, but their lesions show much greater overlap than review articles suggest. For example, most cases of Pick body dementia show neurofibrillary tangles in the substantia nigra indistinguishable from corticobasal bodies, and neocortical Pick bodies are a feature of most cases of CBD. The marked case to case variation in each subgroup of Pick complex (ignored in review articles) and the multiple pathological expressions of chromosome-17-linked dementia further argue for considering the varieties described here as diverse of appearances of shared pathological processes, rather than as unrelated diseases.

IV. BIOCHEMISTRY

Although the etiology and biochemical basis of PiD remain unknown, it has become clear that alterations of the cytoskeletal protein τ play a fundamental role, as they do in several other degenerative disorders. τ proteins are involved in the modulation of microtuble assembly and, thus, in the regulation of axonal transport and neuronal plasticity. Six different τ isoforms are generated in the adult brain by splicing a single gene, located in chromosome 17.

Pathological τ proteins (PTPs), formed by aberrant phosphorylation and other modifications, can be recovered from the brains of patients with AD, PiD, and progressive supranuclear palsy (PSP). Western blots detect distinct profiles of PTP: a triplet at 55, 64, and 69 kDa in AD; a doublet at 55 and 64 kDa in PiD; and a different doublet at 64 and 69 kDa in CBD and PSP. Furthermore, site-specific monoclonal antibodies have shown that, although PTPs in PiD and AD share similar phosphorylated residues, others are distinct such as serine 262, which is phosphorylated in AD but not in PiD. Moreover, PTPs in PiD do not incorporate exon 10, unlike those in AD. The combined use of Western blot of PTPs and antibodies specific for each of the six isoforms of τ has revealed that, whereas all six isoforms are present in AD PTPs, only the three isoforms lacking the domain coded by exon 10 (3-repeat τ) are found in PiD and only the three isoforms incorporating the domain coded by exon 10 (4-repeat τ) are present in CBD. PTPs have somatoaxonal distribution in PiD and somatodendritic distribution in AD.

The demonstration of PTP in DLDH, even in the absence of argyrophilic or τ-immunoreactive inclusions, supports the concept of Pick complex by suggesting that alterations in τ are common to all variants. More recently, cases of DLDH were found to be deficient in normal τ on Western blot.

A. Genetics, Chromosome-17-Linked FTD

It was recognized that PiD at times occurred in families. Wilhelmsen *et al.* have linked an autosomal-dominant family with frontotemporal dementia to chromosome 17. Most patients in this family presented with behavioral disinhibition and subsequently developed a language disturbance, parkinsonism, and amyotrophy; the syndrome was called disinhibition dementia, parkinsonism, amyotrophy complex (DDPAC). Report of a large family with PiD, in

which 25 of 51 examined members were affected with mostly behavioral presentation, was published in Holland. Subsequently, this family was found to have genetic linkage to chromosome 17. Descriptions of what could be classified as familial PiD continue, but there is a tendency to reclassify these because of the lack of Pick bodies. PiD generally has a presenile onset before age 65, in contrast to the majority of AD patients. Familial cases tend to have an even earlier onset in the 40s or 50s.

Other families received various designations, such as pallidopontonigral degeneration (PPND), hereditary dysphasic disinhibition dementia (HDDD2), and multiple system tauopathy with presenile dementia (MSTD). Other families are described by their place of origin such as the Dutch, Australian, Duke Seattle, and Karolinska families. A consensus conference on chromosome-17-linked dementia decided on using the acronym FTDP-17. There is a family with progressive subcortical gliosis (PSG) with probable linkage to chromosome 3.

Several mutations were found in τ in FTD families linked to chromosome 17. A Val337 Met change has been found in exon 12 of the τ gene in the Seattle A family. Other τ mutations have been found in common with PSP in the intron between exons 9 and 10 in association with PSP. Several additional families with P301L mutations on exon 10 have been described with a variety of clinical manifestations, all compatible with Pick's disease. τ polymorphisms, but not mutations, so far have been found in PSP.

The clinical features of chromosome-17-linked dementia are very similar to the sporadic cases of Pick complex and PiD discussed earlier, even though the connection is not always fully recognized or explicitly stated. There is a tendency to report each of these families as being distinct. Disinhibition syndrome and behavioral disturbances are most common. Language difficulties and extrapyramidal symptoms are also frequent. Some patients had signs of motor neuron disease. Prominent psychosis similar to schizophrenia has been reported, which may represent a distinction, but the descriptions are not sufficiently detailed to allow certainty in this regard.

The neuropathology of FTDP-17 is similar to the range of pathological findings described in sporadic Pick complex. τ-positive silver staining neuronal inclusions were numerous in the neocortex, basal ganglia, hypothalamus, and midbrain in some of the families reported. Some of these autopsied cases also had glial cell argyrophilic and τ positive deposits. The most detailed neuropathological studies have been reported for the DDPAC and Seattle family A. All of the pathological reports indicate atrophy of the frontal and temporal lobes of varying degrees and the of parietal lobes to a lesser extent, in addition to atrophy of the basal ganglia such as the caudate, putamen, globus pallidus, amygdala, and hypothalamus. A family with typical Pick bodies has now been reported to have a τ mutation. One of the chromosome-17-linked families had ubiquitin-positive, τ-negative neuronal inclusions, but some τ was found in the glia. There seems to be a whole range of τ deposits in FTDP-17 families from the very severe in the MSTD cases to the very mild or none mentioned earlier. On electromicroscopy, neurofilaments appeared similar to those of AD in the Seattle family, and unique in the MSTD family, suggesting a heterogeneity of τ alterations in the cytoskeleton in FTDP-17.

V. CONCLUSIONS

We suggested the term *Pick complex* to avoid the confusion that continues to surround the terms PiD and FTD. PC designates both the pathological and the clinical overlap between the variations. It avoids the restriction of pathology and clinical symptomatology to the frontotemporal cortex and acknowledges the relationship to PiD. PC is a unifying concept of overlapping clinical syndromes and neuropathological findings underlying the commonalities rather than differences between them.

If one considers all of the cases of FLD, PPA with and without MND, and CBD as part of PC, the entity becomes much less of a rarity. According to some estimates including all pathological variants, the incidence of FTD or clinical PiD may be as high as 20% of degenerative dementias, and PPA reports may represent another 10% even considering the substantial overlap with FTD. This number would be further increased by the inclusion of CBD cases. The incidence matches or surpasses that of pure vascular dementia in our experience. The ratio of PC to AD may turn out to be 1:4 or about 25% of degenerative dementias rather than the estimates of PiD based on autopsy material using restrictive histological criteria. This ratio may be even higher if only patients whose illness starts under age 65 are considered. Apart from a survey of Dutch specialists, which seems to underestimate the incidence probably due to insufficient diagnostic experience, true population-based epidemiological studies are lacking. A selection bias may be playing a role in centers with an interest in the disease.

An increasing number of clinicians and pathologists believe that many, if not all, of the preceding labels describe diseases that clinically and most probably biologically are related to PiD. However, as new immunohistological techniques are applied to varieties of PC, the fractionation of the entity continues. It is difficult to resist the urge to describe a new disease when a new stain or an interesting biochemical marker is discovered. Nevertheless, the clinical, pathological, biochemical, and genetic evidence for the cohesion of the syndrome is compelling, and excessive fractionation may be misleading.

Prefrontal Cortex

ROBERT J. MORECRAFT* and EDWARD H. YETERIAN†
University of South Dakota and Colby College†*

GLOSSARY

association cortex Extremely well-developed and interactive regions of the cerebral cortex involved in the integration of highly processed sensory information and the formation of perception and cognition. The anatomical construct of association cortex is formed in part through local feedforward and feedback projections, as well as widespread projections preferentially interconnecting association areas of the frontal, parietal, temporal, occipital, and limbic cortices.

cognitive functions The mental activities associated with the execution of thinking, learning, and memory requiring computational strategies to acquire knowledge and effectively solve complex problems or situations.

frontal lobe Major subdivision of the cerebral cortex located anterior to the central sulcus, including the medial and ventral surfaces of the cerebrum. The frontal lobe is formed by various components of the primary motor cortex, premotor cortices, frontal eye fields, and prefrontal cortex.

prefrontal cortex The most rostral portion of the frontal lobe, characterized as being involved in cognitive and emotional brain functions.

working memory The ability to plan and sequence an adaptive behavior utilizing on-line or actively stored and processed information from both the external and internal environments.

The prefrontal cortex is a major subdivision of the cerebral cortex, which plays a critical role in mediating complex processes such as attention, planning, decision making, emotion, and personality (Fig. 1). The prefrontal cortex, in part, provides us with our power of intellect, reasoning, and rationality, distinguishing elements of human cognition and behavior. This article will present a general overview of basic structural, functional, and clinical features that characterize the prefrontal cortex based upon an extensive body of information developed from studies of humans and nonhuman primates.

I. ANATOMICAL ORGANIZATION OF THE PREFRONTAL CORTEX

A. Surface Features and Major Subdivisions

The prefrontal cortex is located on the medial, lateral, and orbital surfaces of the most anterior portion of the frontal lobe (Figs. 1 and 2). It has been estimated that prefrontal cortex occupies approximately one-third of the entire human cerebral cortex. Unique cytoarchitectonic, connectional, electrophysiological, behavioral, and clinical features distinguish the prefrontal cortex on each surface. This complex and distributed organization reflects the characterization of this brain area as a protean and heterogeneous entity, dedicated to sustaining rapid computations required to accomplish a wide range of mental activities.

1. Lateral Organization

On the lateral convexity, the frontal lobe lies rostral to the central sulcus, extending to and including the frontal pole. From caudal to rostral, the frontal lobe is subdivided into primary motor cortex, premotor cortex, frontal eye fields, and lateral prefrontal cortex

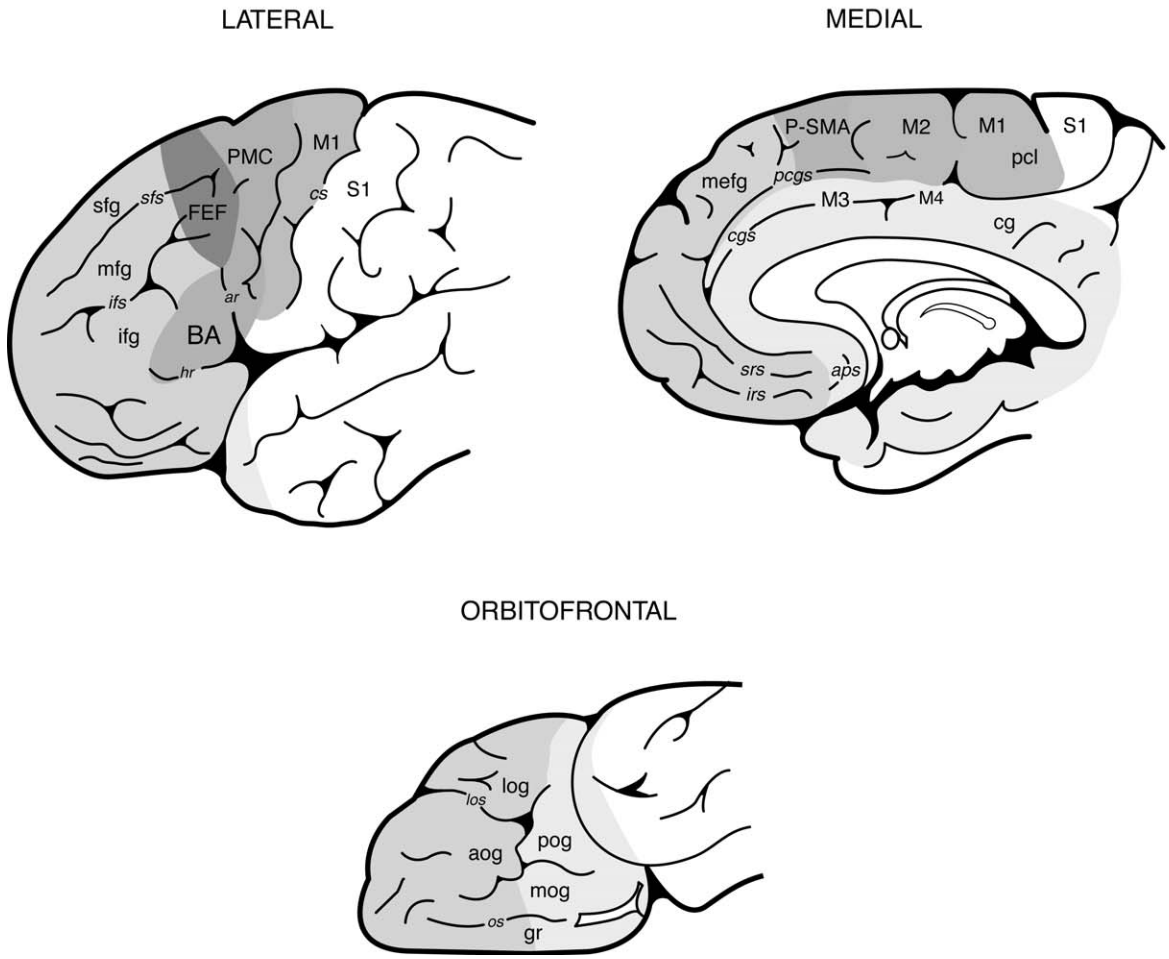

Figure 1 Schematic diagrams of the lateral, medial, and orbital surfaces of the human frontal region illustrating the general anatomical and functional organization. Granular prefrontal cortex is located rostrally and darkly shaded. Limbic cortex is lightly shaded. All other divisions are specifically identified. aog, anterior orbital gyrus; *ar*, ascending ramus; *aps*, anterior parolfactory sulcus; BA, Broca's area; cg, cingulate gyrus; *cgs*, cingulate sulcus; *cs*, central sulcus; FEF, frontal eye fields; gr, gyrus rectus; *hr*, horizontal ramus; ifg, inferior frontal gyrus; *ifs*, inferior frontal sulcus; *irs*, inferior rostral sulcus; log, lateral orbital gyrus; *los*, lateral orbital sulcus; M1, primary motor cortex; M2, supplementary motor cortex; M3, rostral cingulate motor cortex; M4, caudal cingulate motor cortex; mefg, medial frontal gyrus; mfg, middle frontal gyrus; *mog*, medial orbital gyrus; *os*, olfactory sulcus; *pcgs*, paracingulate sulcus; pcl, paracentral lobule; PMC, lateral premotor cortex; pog, posterior orbital gyrus; P-SMA, presupplementary motor area; S1, primary somatosensory cortex; sfg, superior frontal gyrus; *sfs*, superior frontal sulcus; *srs*, superior rostral sulcus.

(Fig. 1). On the lateral convexity, interposed between the dorsolateral prefrontal and the ventral portion of premotor cortex, is Broca's area. This area is involved in the abstract mediation of the verbal expression of language. In humans, there is no primary sulcus demarcating the posterior limit of the prefrontal cortex. However, occasionally there are two distinct sulci within the prefrontal region designated as the superior frontal sulcus and inferior frontal sulcus. They are often discontinuous and extend horizontally to subdivide the rostral part of the frontal cortex, including the prefrontal region into superior frontal, middle frontal, and inferior frontal gyri.

2. Medial Organization

The cortex lining the medial wall of the hemisphere, located directly above the anterior portion of the paracingulate and/or cingulate sulci is divided into the paracentral lobule caudally and the medial frontal gyrus rostrally (Fig. 1). The division between the paracentral and medial frontal gyri is occasionally

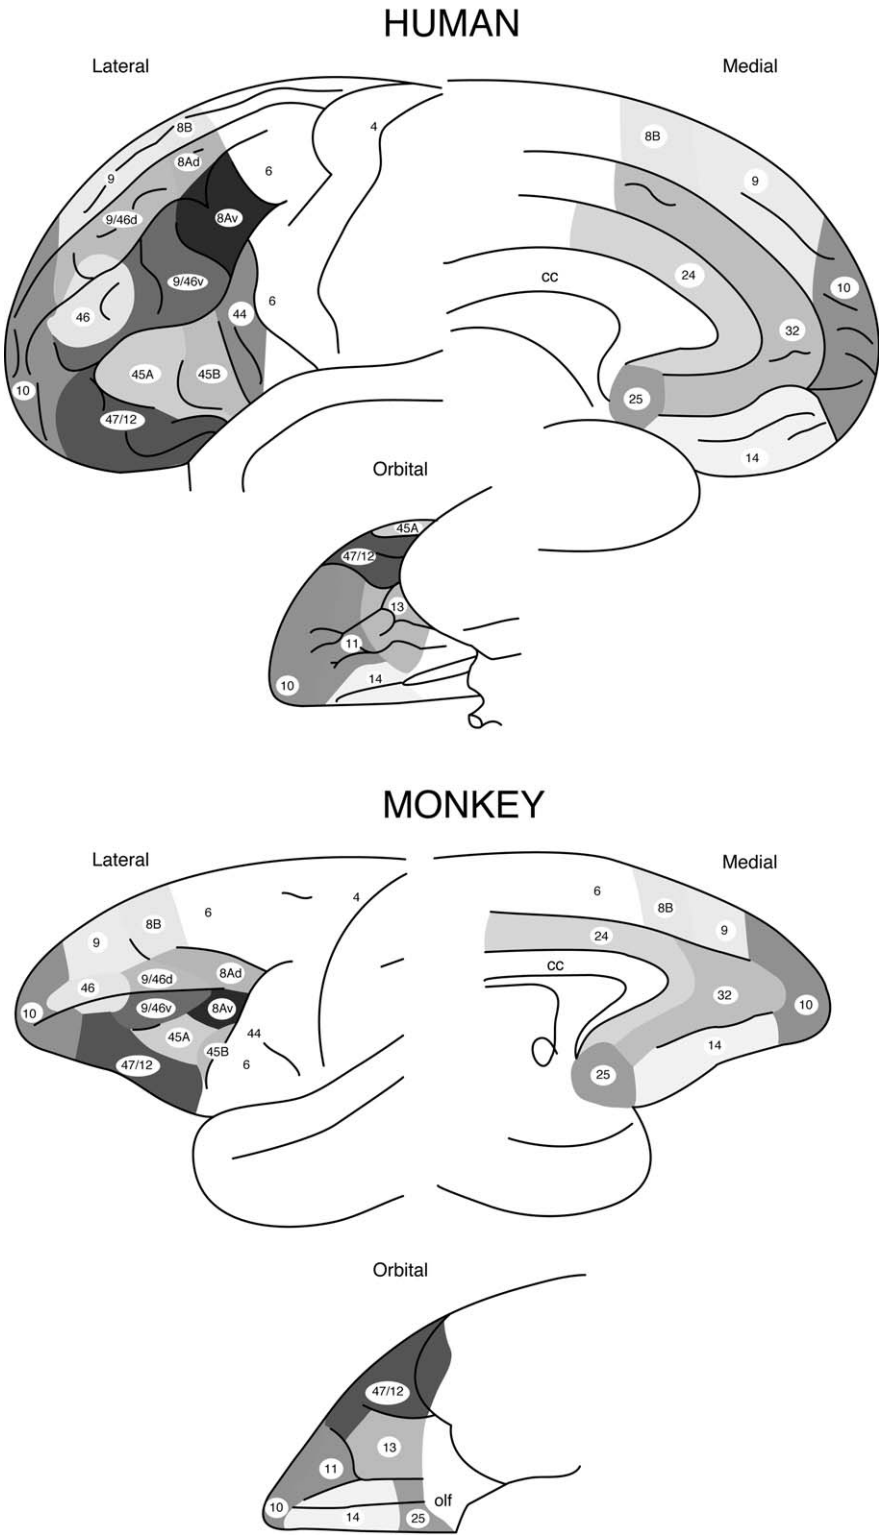

Figure 2 Schematic diagram illustrating the cytoarchitectonic organization of the lateral, medial, and orbital surfaces of the frontal region in the human (top) and monkey (bottom) cerebral cortices. Studies indicate that area 13 is more restricted, or limited in size, than illustrated on the orbital surface of the human brain. [From Petrides and Pandya, 1994, Comparative architectonic analysis of the human and the macaque frontal cortex. *Handbook of Neuropsychology*, Vol. 9. pp. 28, with permission from Elsevier Science.] (See color insert in Volume 1).

formed by a vertical sulcus emerging from the cingulate sulcus above the midpoint of the corpus callosum. The primary somatosensory (S1) and primary motor (M1) cortices occupy caudal and rostral portions of the paracentral lobule, respectively. The supplementary motor cortex (M2), presupplementary motor cortex (P-SMA), and prefrontal cortex comprise the caudal to rostral components of the superior frontal gyrus. Bordering the medial frontal gyrus ventrally is the cingulate gyrus and its affiliated subcallosal extension. In a majority of cases, the paracingulate sulcus roughly defines the border between the frontal lobe and the cingulate cortex of the limbic lobe. Ventral to the paracingulate sulcus is the cingulate sulcus. Rarely, an intralimbic sulcus is located ventral to the cingulate sulcus. Rostral (M3) and caudal (M4) cingulate motor cortices are located in the dorsal portion of the cingulate cortex.

3. Orbitofrontal Organization

The orbitofrontal cortex lines the ventral surface of the frontal lobe in the floor of the anterior cranial fossa (Figs. 1 and 2). The posterior portion of the orbitofrontal cortex is formed by agranular cortex, and the intermediate portion is formed by dysgranular cortex. This general region of cortex is categorized by some authorities as limbic or paralimbic cortex. It is continuous with the agranular and dysgranular cortices of the insula caudally and the temporal pole laterally. It is also continuous with the agranular–dysgranular cortices of the medial wall (e.g., areas 25 and 32). In the caudolateral region of the right dysgranular orbitofrontal cortex is a postulated secondary gustatory or taste region. Caudal to the secondary gustatory is the orbital extension of piriform (primary olfactory) cortex. Granular cortex forms the rostral portion of the orbitofrontal cortex, including the frontal pole. Unlike the lateral and medial surfaces of the frontal lobe, premotor cortex is absent from the orbitofrontal surface. Major sulci in this region include the olfactory sulcus, which is oriented rostrocaudally and demarcates the anatomical boundary between the gyrus rectus medially and orbitofrontal cortex proper laterally (Fig. 1). The orbitofrontal region is subdivided by irregular medial and lateral sulci that occasionally form an H shape. The medial and lateral orbital gyri occupy medial and lateral regions, respectively. Interposed between the medial and lateral orbitofrontal gyri are anterior and posterior orbitofrontal gyri.

B. Cytoarchitecture

Cytoarchitecture is the study of the structural arrangement of neurons within the central nervous system. Neuronal size, shape, packing density, and staining intensity are all features that are used to characterize a specific cytoarchitectural area, region, or trend. Historically, the prefrontal region is characterized cytoarchitecturally as "frontal granular cortex," referring to the fact that a large portion of the prefrontal cortex has a well-developed granular layer IV. Although this view is widely accepted when considering the more rostral parts of the frontal lobe, more complex features reflecting dysgranular and agranular types of cortex are also recognized in the more caudal portions of the transitional prefrontal region. Dysgranular refers to cortex having a poorly developed layer IV, and agranular refers to cortex lacking a layer IV.

Among the many cytoarchitectonic maps of the prefrontal cortices in both humans and monkeys, the general location of medial areas 24, 25, 32, and 10 are very similar in terms of location and nomenclature. However, many differences exist in the various interpretations of the cytoarchitectonic organization of the lateral and orbital areas. On the basis of cytoarchitectural commonalities, Pandya and co-workers have developed a working model of regional cytoarchitectonic homologies in the human and nonhuman primate cortices (Fig. 2). This approach is intended to assist in the interpretation, comparison, and integration of information obtained from the vast number of studies conducted in both species. A condensed version of this view is presented later. Although individual numerically assigned cytoarchitectonic areas are designated, it is important to call attention to the fact that two general, progressive trends in frontal architectonic development can be recognized (Fig. 3). They include the medial and ventral frontal trends. The medial trend originates from the hippocampal system (archicortical lineage) and progresses mediodorsally. In other words, the trend emanates from cortex lining the medial wall along the corpus callosum to cortex forming the dorsolateral frontal surface. The ventral trend originates from the olfactory system (paleocortical lineage) and progresses ventrally from the orbitofrontal region and laterally onto the ventrolateral frontal convexity. Thus, both trends originate from a simple, primitively organized moiety that is relatively undifferentiated in terms of laminae. This is followed by a continuous, stepwise progression of cortical development in which there is a

gradual increase in the number, size, and complexity of cortical layers (from agranular to dysgranular cortex), culminating in the formation of a well-developed six-layered organization (granular cortex) (Fig. 3).

Area 44 is located immediately anterior to the ventral portion of lateral area 6. In humans, area 44 comprises a major portion of Broca's area and is involved in mediating the control of speech. Architecturally, area 44 is dysgranular, referring to the fact that it has a poorly developed layer IV. This cortex is also characterized by the presence of large pyramidal neurons located in the deep portion of layer III.

Area 8 plays a major role in mediating complex eye movements and resides on the dorsolateral surface of the frontal lobe, rostral to the dorsal portion of lateral area 6 and caudal to granular areas 9–46. Area 8 extends medially, where it is located anterior to the presupplementary motor area (pre-SMA) and caudal to area 9. On the lateral convexity, a well-developed layer IV with large pyramidal cells in layer III characterizes the ventral portion of area 8. Progressing dorsally and medially, layer IV becomes less prominent and the number of large pyramids in layer III diminish.

Area 45 corresponds to pars triangularis of the inferior frontal gyrus. Area 45 forms the rostral portion of Broca's expressive speech area, whereas area 44 forms the caudal portion. Structurally, area 45

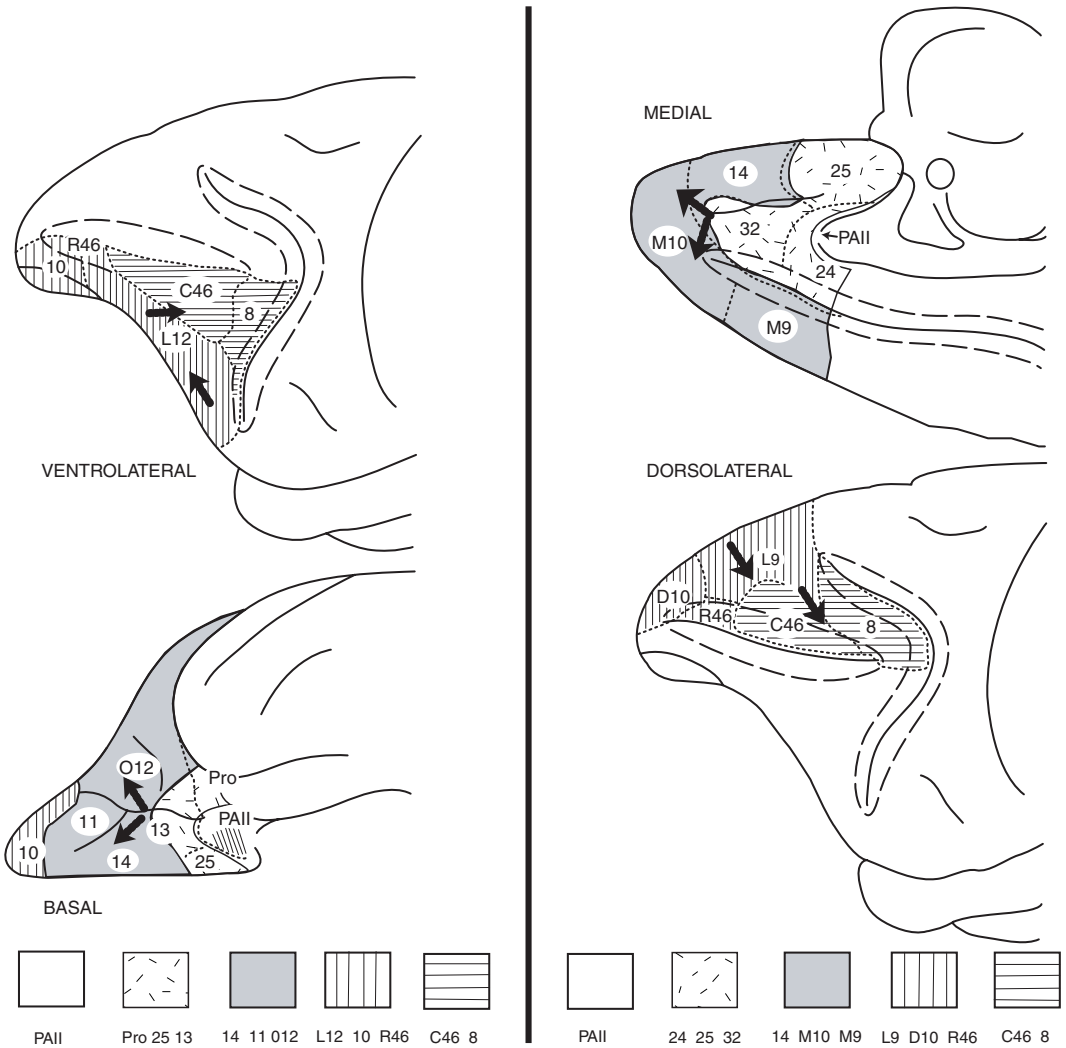

Figure 3 Diagrams depicting the cytoarchitectonic areas in the prefrontal cortex of the rhesus monkey arranged in progressive stages within the orbital and ventral paleocortical trends (left) and medial and dorsolateral archicortical trends (right). [From Barbas and Pandya, 1989, Architecture and intrinsic connections of the prefrontal cortex in the rhesus monkey. *J. Comp. Neurol.* **286,** 372. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.]

is characterized by a well-developed layer IV, a hallmark feature of granular frontal cortex. Like adjacent area 44, the lower portion of layer III contains large pyramidal neurons.

Area 9 is located in the dorsal-most portion of the lateral prefrontal cortex and extends medially onto the medial frontal gyrus. **Area 46** is located rostral to area 9, where it occupies the rostral portion of the middle and superior frontal gyri. Morphologically, the lateral portion of area 9 is characterized as dysgranular to moderately granular. Medially, however, granular layers II and IV are less developed. In contrast, area 46 is highly granularized, referring to the fact that layers II and IV are well-developed. Furthermore, area 46 contains medium-sized pyramidal cells in layers III and V.

Area 10 occupies the frontal pole. Layer II, although not prominent, is distinguishable. Layer III is the widest layer in area 10, and layer IV is thin, but prominent. Sublamination is evident in layer V.

Areas 47/12 are located ventrally along the lateral surface and extend onto the lateral portion of the orbital surface. Layer III contains small and medium-sized pyramidal cells and is clearly separated from layer V by layer IV. The lateral and orbital components are further distinguishable. Layer IV is less developed on the orbital surface, and the pyramidal cells are less densely packed in this location.

Area 13 occupies the centrocaudal portion of the orbitofrontal surface. The rostral portion of area 13 is characterized as dysgranular due to its poorly developed layer IV. It contains a poorly differentiated layer II that is difficult to distinguish from adjacent layer III. Similarly, a distinct border between layers V and VI is difficult to recognize. The caudal region is agranular, lacking discernible granular cells in layers II and IV, thus forming a primitive, two-cell-layer arrangement (e.g., bilaminate organization).

Area 14 is located in the gyrus rectus on the orbitofrontal surface. The rostral portion of area 14 is dysgranular. Like adjacent area 13, layers II and IV diminish in size progressing caudally until this cortex becomes agranular. In the agranular sector, inner and outer strata (e.g., bilaminate organization) characterize area 14.

Areas 25 and 32 are located below the genu of the corpus callosum. In both areas, layer I is thick and there is a discernible layer IV. In area 25, layer III is broad, whereas layer V is densely packed. In contrast, layer V in area 32 widens and sublaminates where medium-sized pyramidal neurons are situated superficially.

C. Connections

1. Corticocortical Connections

a. Local Connections Local, or intrinsic, connections of the frontal lobe form important feedforward and feedback circuits, which modulate the neurotransmission of pyramidal and nonpyramidal neuron ensembles. These, in part, form the core elements of prefrontal information processing. These connections are organized such that each architectonic area has a connection with a more differentiated region, on the one hand (e.g., rostral or dorsal), and with a less differentiated region on the other (e.g., caudal or ventral) (Fig. 3). The orbital proisocortical area of the ventral trend projects mainly to orbital areas 11, 13, and 14, as well as to inferior prefrontal area 12. Area 13 in turn projects back to the proisocortical area, as well as to areas 11, 14, and 12. Area 12 projects to orbital areas 11, 13, and 14 and to ventral prefrontal areas 10 and 46. Ventral area 46 sends connections to areas 12 and 10 rostroventrally and to ventral area 8 caudally. Area 8 projects to ventral area 46 rostrally and to dorsal area 8 and lateral premotor area 6 caudally. Similarly, the dorsal trend proisocortical area 32 projects to areas 25 and 14 ventrally, area 24 caudally, and areas 9 and 10 dorsally. Area 9 in turn sends connections to proisocortex (areas 32 and 24) medially and to dorsal areas 10 and 6 laterally. Dorsal area 46 projects to areas 9 and 10, on the one hand, and to dorsal area 8 on the other. In addition, dorsal area 8 projects to areas 46 and 9 rostrally, dorsal area 6 caudally, and area 8 ventrally.

Thus, within both the dorsal and the ventral frontal trends, a systematic pattern of connectivity interrelates more differentiated regions of cortex with less differentiated regions. In addition, it is important to recognize that dorsal and ventral regions are interconnected at certain critical levels. For example, the orbital (ventral trend) and medial (dorsal trend) proisocortical areas are interconnected, as are areas 9 and 12, which reside above (dorsal trend) and below (ventral trend) the principal sulcus, respectively. Finally, there is a specific pattern of connectivity between dorsal and ventral area 8 as well as between dorsal and ventral area 6.

b. Long Association Connections Long association connections represent an integral part of the extended prefrontal system linking the prefrontal cortex with distant and widely dispersed parts of the

association and limbic cortices. With regard to afferent connections of the frontal lobe, the lateral extrastriate and caudal inferotemporal regions project to the ventral part of the arcuate cortex (ventral area 8) and to area 46 below the principal sulcus. In contrast, the rostral inferotemporal region projects to orbital area 11 and area 12 of the inferior prefrontal convexity. The proisocortical area of the superior temporal gyrus (area Pro of the temporal pole) and the caudally adjacent portion of the gyrus (area Ts1) are connected preferentially with the orbital and medial prefrontal cortices. The caudal portion of the superior temporal gyrus (areas Tpt and paAlt) projects to area 8 of the caudal prefrontal cortex. The intermediate portion of the superior temporal gyrus is related to the lateral prefrontal cortices. The superior and medial parietal association regions project preferentially to the dorsal and medial prefrontal cortices, which also receive afferents from visual areas PG-Opt and POa of the inferior parietal lobule. The inferior parietal areas, including the dorsal Sylvian opercular cortex and the gustatory cortex, project mainly to the ventrolateral and orbital prefrontal cortices. The visual association areas of the ventral and dorsomedial occipitotemporal cortices, relating to the peripheral visual field, project mainly to the dorsal prefrontal region. In contrast, the areas of the inferotemporal region involved in central vision project preferentially to the ventral prefrontal region.

The combined entorhinal and perirhinal region, which comprises the rostral part of the parahippocampal gyrus, projects to the orbital and medial (area 25) prefrontal cortices. The caudal part of the parahippocampal gyrus sends efferent connections to the medial prefrontal, caudal orbital, and ventrolateral prefrontal regions. The rostral (agranular–dysgranular) insula projects to the ventrolateral and orbital prefrontal regions (areas 12 and 13). The caudal (granular) insula has efferent connections to the dorsolateral prefrontal cortex (area 8). The cingulate and retrosplenial cortices project to the dorsal prefrontal region.

Within the prefrontal region are specific multimodal areas that receive input from more than a single sensory modality. Area 45 of the ventral prefrontal cortex has afferents from the rostral visual area of the inferotemporal cortex, the ventral somatosensory area, and the auditory cortex of the superior temporal gyrus. In addition, area 45 receives input from multimodal area TPO of the superior temporal sulcus, the insula, and the parahippocampal gyrus. The caudal orbitofrontal cortex receives input from visual association cortices as well as from the olfactory and gustatory areas. Other multimodal frontal regions include dorsal area 8, which receives input from both visual and auditory modalities, and areas 9 and 10, which receive input from multimodal cortices of the superior temporal sulcus.

The efferent connections of the frontal lobe are largely reciprocal to the afferent connections. For example, the dorsal prefrontal cortex projects to cingulate areas 24 and 23 (including the rostral, M3, and caudal, M4, cingulate motor cortices), retrosplenial cortex, as well as the medial parietal and caudal inferior parietal regions. In addition, dorsal prefrontal cortex projects to the presupplementary motor area (P-SMA) and the face representation of the supplementary motor cortex, M2 (Fig. 4). The transitional region between areas 6 V and 12 also projects to the face–head representation of the primary motor cortex, M1. The ventral prefrontal region projects mainly to the inferotemporal cortices, the ventral somatosensory cortex, and the rostral superior temporal region. Finally, the orbitofrontal cortex projects to the entorhinal, perirhinal, and parahippocampal cortices.

2. Corticostriatal Connections

The corticostriatal projection is nonreciprocal and represents the initial stage of the classic striatopallidothalamic pathway, or loop, that is largely directed back to the cortex via thalamocortical projections (see the following section). In general, this pathway is topographically organized throughout the entire loop and is typically directed back to the cortex (e.g., via thalamocortical projections to the dorsal lateral prefrontal region) from which the pathway originated (e.g., lateral prefrontal projections to the caudate nucleus of the striatum). The corticostriatal projection from prefrontal cortex to the caudate nucleus has a distinctive medial–lateral topography that is systematically related to the origin of the projection in the frontal lobe (Fig. 5, top). Medial and orbital prefrontal regions project mainly to the medial and intermediate portions of the head and body of the caudate nucleus. This projection also includes the nucleus accumbens of the ventral striatum. The ventral striatum has been the focus of an increasing number of studies, suggesting that the nucleus accumbens plays a prominent role in mediating reward and motivation. Of clinical relevance is the potential involvement of the nucleus accumbens in drug addiction and mental disorders such as schizophrenia and Tourette's syndrome. The

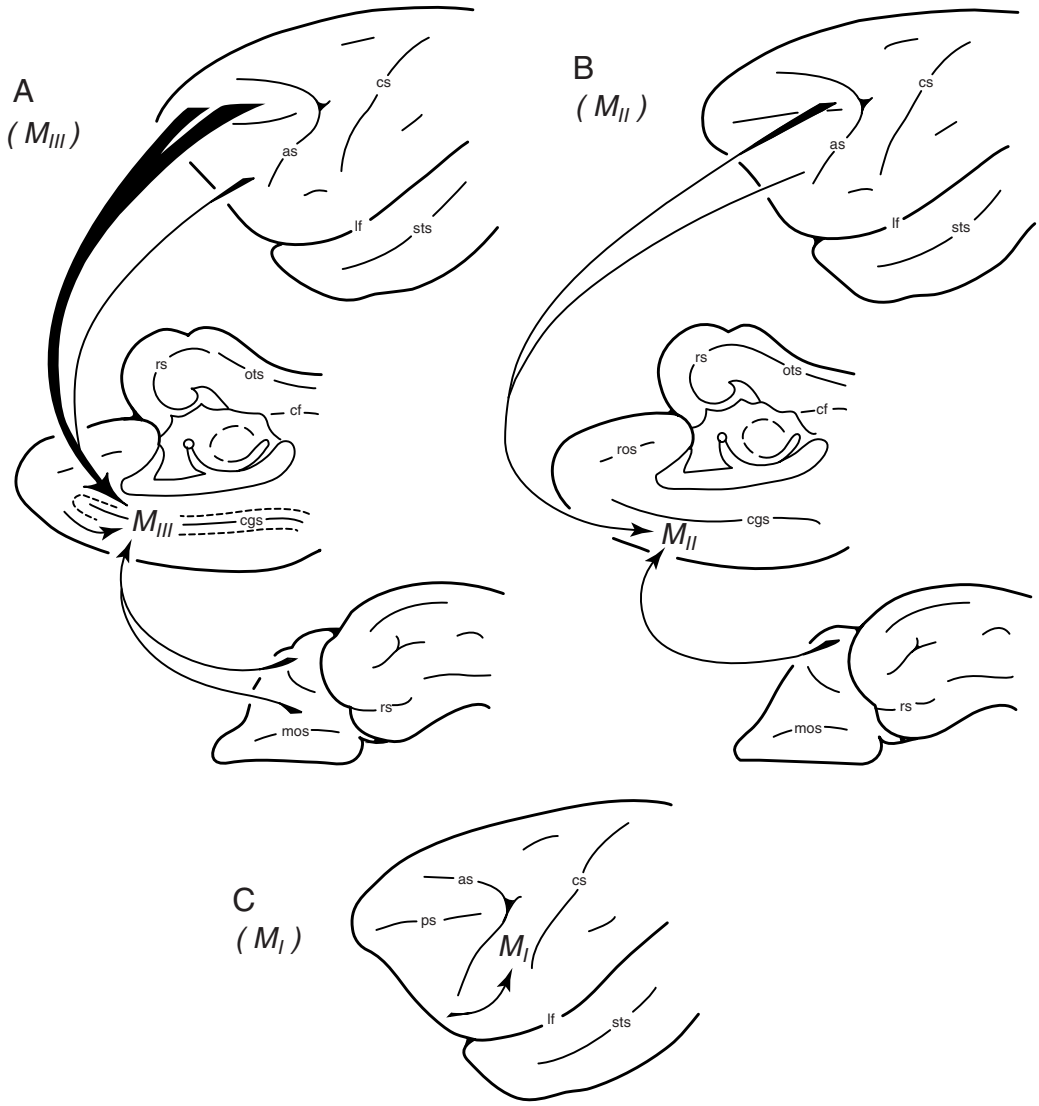

Figure 4 Line drawings summarizing prefrontal inputs to the motor cortices. The rostral (M3) and caudal (M4; not shown) cingulate motor areas receive significant prefrontal inputs primarily from the dorsolateral sector. The supplementary motor cortex (M2) receives weak inputs from the same prefrontal region that targets only the face–head representation. The face–head representation of the primary motor cortex (M1) receives input from the transition prefrontal region that is formed in part by the rostral portion of ventral area 6. as, arcuate sulcus; cf, calcarine fissure; cgs, cingulate sulcus; cs, central sulcus; lf, lateral fissure; M_I, primary motor cortex; M_{II}, supplementary motor cortex; M_{III}, rostral cingulate motor cortex; mos, medial orbital sulcus; ots, occipitotemporal sulcus; ps, principal sulcus; ros, rostral sulcus; rs, rhinal sulcus; sts, superior temporal sulcus. [from Morecraft and Van Hoesen, 1993, Frontal granular cortex input to the cingulate (M3), supplementary (M2), and primary (M1) motor cortices in the rhesus monkey. *J. Comp. Neurol.* **337,** 13. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.]

lateral prefrontal cortex is related preferentially to the intermediate portions of the head and body of the caudate nucleus, whereas the caudal prefrontal region (area 8) projects mainly to the lateral and intermediate portions of the nucleus. A dorsal–ventral topography is evident as well (Fig. 5, top). Dorsal prefrontal areas are related predominantly to the dorsal portions of the head and body of the caudate nucleus, whereas ventral prefrontal areas are connected preferentially with the ventral portion. Nevertheless, there is a certain degree of intermingling of projections from the dorsal and ventral prefrontal cortices, specifically within the central sector of the head of the caudate nucleus. The topography of prefrontal projections to the tail of the

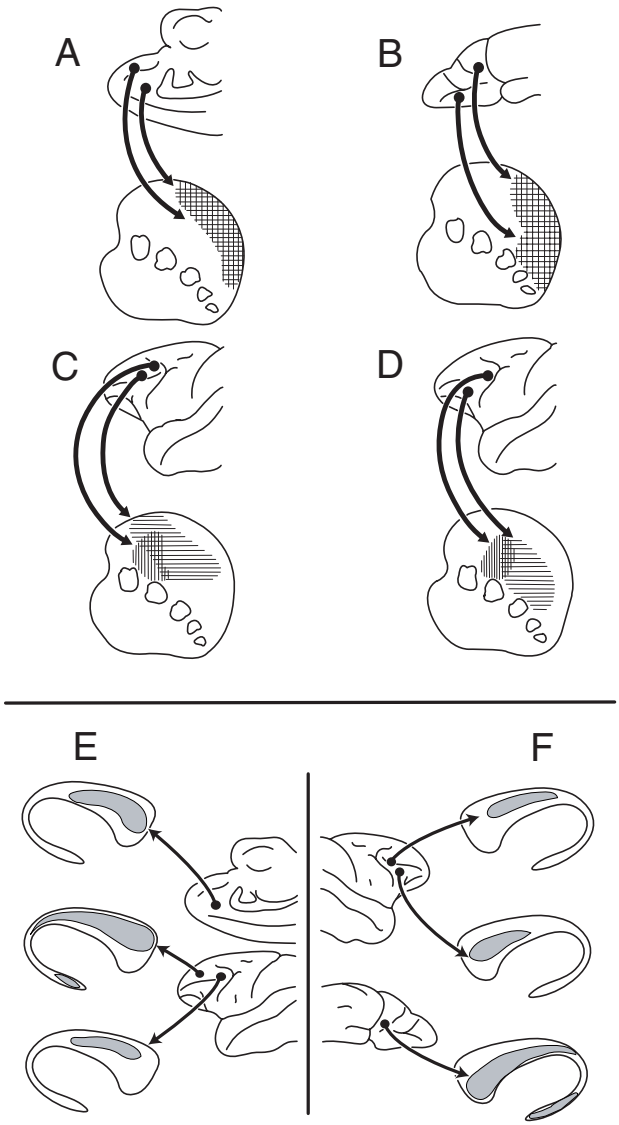

Figure 5 Summary diagrams showing the mediolateral (A–D) and rostrocaudal (E and F) connectional relationships of the dorsal or archicortical (A, C, and E) and ventral or paleocortical (B, D and F) architectonic trends of the prefrontal cortex and the caudate nucleus. [from Yeterian and Pandya, 1991, Prefrontostriatal connections in relation to cortical architectonic organization in rhesus monkeys. *J. Comp. Neurol.* **312,** 60–61. Reproduced by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.]

caudate is less distinct. The medial portion of the tail receives projections from the dorsal and ventral proisocortical regions, as well as from the dorsomedial (dorsal area 10) and dorsolateral (dorsal areas 9 and 46) portions of the prefrontal cortices.

In comparison to prefrontocaudate connections, the prefrontal projections to the putamen nucleus are less extensive. In most instances, these appear to be continuous with connections to the caudate nucleus and have a dorsoventral topography. Dorsal trend regions (areas 10, 9, 46, and 8) project mainly to dorsal and central parts of the putamen nucleus. In contrast, ventral trend regions (areas Pro, 13, 12, 14, 10, and 46) project to ventral and central portions of the putamen, with the exception of ventral area 8, which projects to the dorsal part of the putamen. In general, the projections to the putamen from prefrontal regions with highly differentiated laminar organization (e.g., areas 46 and 8) tend to be more dorsal.

The distribution of prefrontal projections to the striatum, when viewed sagittally, appear to be longitudinal, although the projections tend to be patchy

rather than continuous (Fig. 5, bottom). Moreover, not all prefrontal regions have the same rostrocaudal extent of projections. For example, the prefrontocaudate projection from the dorsal arcuate region is less extensive than the projection from dorsal areas 9 and 46. Similarly, the prefrontocaudate projection from the ventral arcuate region is less extensive than those from the orbitofrontal region.

3. Corticothalamic Connections

The prefrontal cortex is interconnected with many thalamic nuclei, but the most prominent prefrontothalamic connection is established with the mediodorsal thalamic nucleus (MD). This connection represents another major outflow pathway of the prefrontal cortex that is largely reciprocated by thalamoprefrontal connections. Studies conducted by many investigators demonstrate that the connections with specific subdivisions of MD follow the mediolateral and rostrocaudal topography of the frontal lobe (Fig. 6). Thus, the medial prefrontal and orbitofrontal proisocortical areas are reciprocally interconnected with the medial portion (magnocellular division) of MD, maintaining their respective dorsal and ventral topographies in this subnucleus. The lateral prefrontal region, above and below the principal sulcus, is linked with the middle part (parvocellular division) of MD, again showing a dorsal to ventral topography. Finally, dorsal area 8 and ventral area 8 are reciprocally interconnected, respectively, with dorsal and ventral portions of the most lateral part (multiformis division) of MD. In summary, prefrontal projections to and from MD correspond to the established patterns of prefrontal cytoarchitectonic differentiation within the dorsal and ventral trends.

4. Corticofugal and Corticopetal Connections

In addition to the corticostriatal and corticothalamic projections discussed earlier, prefrontal interconnections with the amygdala, hypothalamus, midbrain, and pons represent important subcortical linkages of the extended prefrontal neural system. These are likely to integrate higher order brain functions mediated by the prefrontal cortex with more developmentally fundamental brain activities, such as emotion and visceral, or autonomic, functions. Related are important, chemically specific projections to various parts of the prefrontal cortices that arise from the nucleus basalis of Meynert (cholinergic), raphe nuclei (serotonin), hypothalamus (histamine), ventral tegmental area (dopamine), and locus ceruleus (norepinephrine). These projections are thought to play a vital role in cortical arousal, motivational valence, and the overall effectiveness of learning.

a. Amygdala The amygdala plays a central role in processing the emotional significance of complex situations based upon previous and current experiences. Under normal circumstances, cognitive functions such as abstract reasoning, decision making, and planning are greatly affected by previous emotional experiences as well as our current emotional state. The amygdala exerts a direct influence on prefrontal cortex through widespread and reciprocal projections preferentially interconnecting the amygdala with less differentiated cortices of the medial and lateral trends. This cortex includes the agranular and dysgranular portions of the medial and orbitofrontal cortices. Cortex ventrolateral to the principal sulcus is also moderately interconnected with the amygdala. The amygdala projection to the prefrontal cortex arises from the basolateral and accessory basal nuclei and to a lesser extent from the cortical and lateral nuclei. The amygdala projection terminates primarily in superficial cortical layers, namely layers I and II, as well as the superficial portion of layer III. Therefore, the various patterns of connectivity suggest that cognitive operations mediated by the prefrontal cortices are influenced by emotional context through selective amygdaloprefrontal pathways.

b. Hypothalamus The hypothalamus is a major subdivision of the diencephalon that is well-known for mediating core autonomic functions, including feeding, fluid regulation, heart rate, respiratory rate, reproduction, and self-defense. The agranular and dysgranular portions of the prefrontal cortex are reciprocally interconnected with the hypothalamus. For example, medial areas 25 and 32 are reciprocally connected with anterior and ventromedial hypothalamic regions, whereas the posterior orbitofrontal cortex is interconnected primarily with the posterior hypothalamic region. There is also a mediolateral topography suggesting that lateral parts of the hypothalamus are connected with the posterior orbitofrontal cortices, whereas the medial hypothalamus is interconnected with the medial prefrontal cortices. Lateral prefrontal connections with the hypothalamus are weaker than those established with the orbitofrontal and medial prefrontal cortices and primarily target the posterior hypothalamic region. The patterns of descending projections indicate that

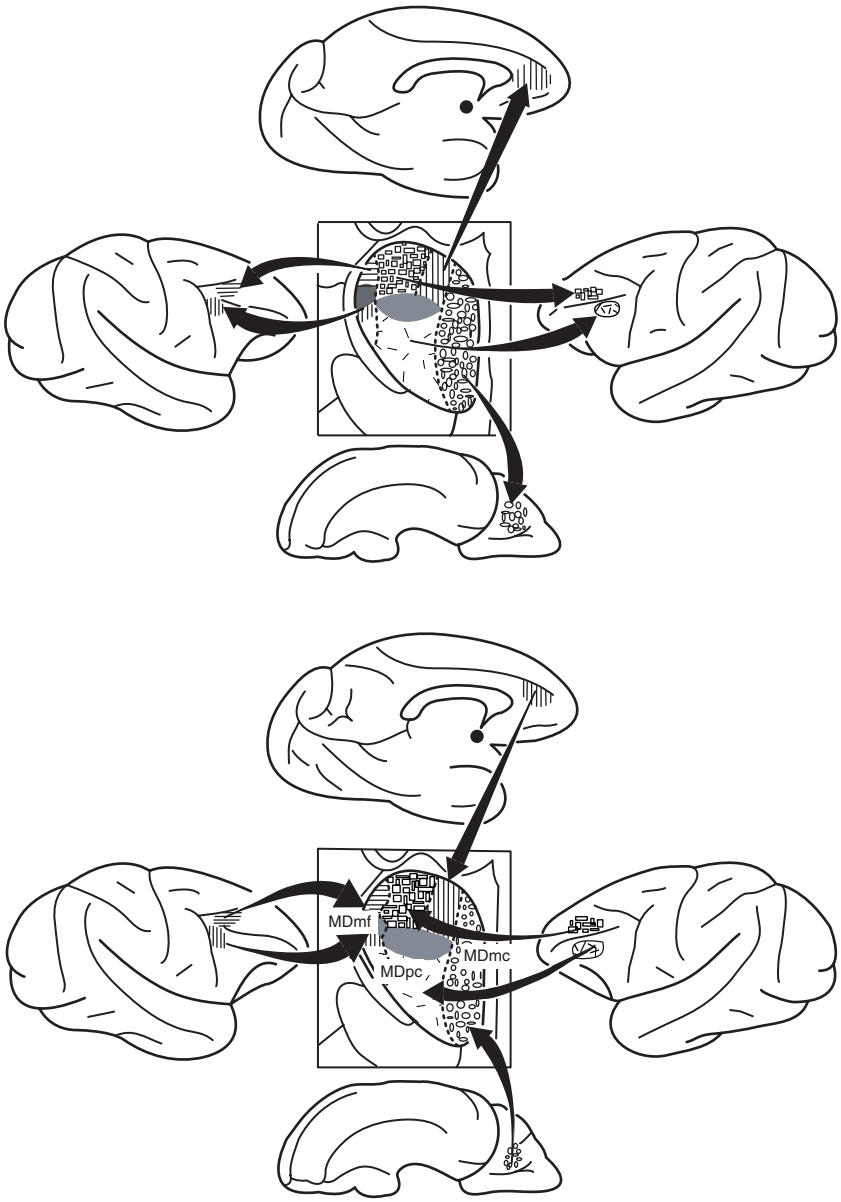

Figure 6 Summary diagram illustrating the topographic organization of thalamocortical (top) and corticothalamic (bottom) connections between the prefrontal cortex and the mediodorsal nucleus. [from Siwek and Pandya, 1991, Prefrontal projections to the mediodorsal nucleus in the rhesus monkey. *J. Comp. Neurol.* **312,** 519. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.]

prefrontal activity may directly initiate autonomic responses accompanying stressful and important decision-making processes. Similarly, direct ascending hypothalamic projections to the prefrontal cortex indicate that basic and powerful physiological drives are likely to affect the outcome of higher order behavior. These connections may be involved in recruiting a prefrontal contribution to appropriately address the autonomic needs of the body in general (e.g., maintenance of physiological homeostasis) or to solve a potentially life-threatening situation.

c. Midbrain Prefrontal projections terminate in several major midbrain structures, which include the substantia nigra, periaqueductal gray (PAG), cuneiform nucleus, median raphe nucleus, and reticular formation. Collectively, prefrontomesencephalic projections are thought to play a major role in influencing

vocalization, autonomic mechanisms, and pain-related responses. Medial, lateral, and orbital projections to the PAG are highly organized and terminate in distinct columns. The prefrontal projection to the PAG is heaviest from the medial and posterior orbital regions and terminates, respectively, in the dorsolateral and ventrolateral columns. In addition, projections from dorsomedial areas 9 and 24b end mainly in the lateral column. The prefrontal projection to the PAG from lateral areas 9, 46, and 8 is weak and directed mainly to the dorsolateral column. Finally, the rostral cingulate motor cortex (M3) projects to the lateral and ventrolateral sectors of the PAG.

d. Pons The pontine nuclei receive ipsilateral input from many parts of the cerebral cortex. The pontine nuclei in turn project to the contralateral cerebellar hemisphere. The cerebellum has long been known to mediate aspects of motor behavior, and projections from motor cortex to the pontine nuclei represent a critical contribution to this function in higher primates. However, several new observations suggest a cerebellar role in mediating cognitive processes. Possibly related is the more recent observation of sizeable and highly organized corticopontine projections arising from selected parts of the prefrontal cortex. Massive corticopontine projections originate from dorsolateral prefrontal areas 8d, 9, 46d, and 10 and terminate in the paramedian and medial parts of the peripeduncular pontine nuclei. Medial areas 32, 9, 8B, and possibly 10 give rise to corticopontine projections ending primarily in the medial and paramedian nuclei and the medial portion of the peduncular and peripeduncular nuclei. In contrast, the ventrolateral prefrontal cortices do not project to the pontine nuclei, with the exception of area 45. Similarly, the available evidence indicates that orbitofrontal cortex does not project to the pontine nuclei.

II. FUNCTIONAL ORGANIZATION OF THE PREFRONTAL CORTEX

Prefrontal cortex is often classified as association or multimodal association cortex. This refers to the fact that highly processed information from multiple sensory modalities is integrated or combined within the prefrontal region in a precise, temporally ordered fashion to form the physiological constructs of perception, memory, and complex action. Specific processes mediated by the prefrontal cortex include attention, planning, decision making, emotion, and personality. In general terms, these functions are loosely categorized as higher order, executive, or cognitive functions. Although it is clear that prefrontal cortex as a whole mediates complex behaviors, there is considerable evidence for functionally distinct subregions within the various prefrontal territories.

A. Lateral Prefrontal Cortex

The peri-principalis region in monkeys correlates to the dorsal lateral prefrontal cortex in humans and is generally thought to play a role in tasks that depend upon memory and spatial information, that is, in spatial working or representational memory. Different functional roles for the peri-principalis region and the adjacent dorsolateral prefrontal cortex have been proposed. These include the integration of spatial and visual information, the motivational evaluation of sensory stimuli, the monitoring of the serial order of stimuli during the performance of self-ordered tasks, and the performance of tasks dependent upon tactile and auditory as well as visual working memory. The peri-principalis region has also been shown to have a role in the control of saccadic eye movements and visual attention. The inferior prefrontal convexity, ventral to the peri-principalis region, is known to be involved in processes relating to the behavioral significance of stimuli as well as in reward. Damage to this region results in strong perseverative tendencies, indicating a role in the control of responses to specific stimuli. It has also been suggested that the cortex of the inferior convexity is involved in stimulus selection and attention, immediate visual memory, and the appreciation of faces. In contrast, the cortex of the superior convexity, dorsal to the peri-principalis region, has been implicated in kinesthetic function as well as in the performance of self-ordered and externally ordered tasks.

The caudal-most portion of the lateral prefrontal region includes the frontal eye fields and has a distinctive functional role (Fig. 1). It is well established that this region serves processes important for attention and orientation, particularly in the visual sphere and in the auditory and somatosensory modalities as well. For example, this region mediates smooth-pursuit eye movements, the control of visual scanning and fixation, and auditory orientation as well as aurally guided saccades. In addition, the arcuate region has been implicated in integrative functions such as cross-

modal matching and in intermodal association and conditional associative learning. The ventral periarcuate cortex has also been shown to mediate aspects of vocal control including the laryngeal musculature, which would be consistent with the vocal conduction abnormalities that occur following damage to the homologous region in humans.

B. Medial Prefrontal Cortex

Recent advances in behavioral methodologies, and the ever-expanding application of functional imaging have led to unprecedented advances in our understanding of medial prefrontal region functions. Specifically, the medial frontal region (anterior cingulate area) appears to be involved in bimanual coordination, attention to demanding cognitive tasks, modulation of body arousal, spatial memory, self-initiated movement, conflict resolution, and the retrieval of information from long-term memory (medial prefrontal and medial orbital regions). The anterior cingulate cortex is also involved in the perception of pain (e.g., perceived unpleasantness of painful stimuli) and possibly in mediating the emotional response that is initiated by our perception of pain. The rostral cingulate motor cortex (M3) is a higher order motor area that is involved in selecting an appropriate voluntary motor act on the basis of the consequences and the value of the associated reward. Reward and goal-related activity is thought to correspond to the unique patterns of connections that link the rostral cingulate motor cortex with the prefrontal and limbic cortices, on the one hand, and many classically affiliated motor targets including the isocortical motor areas (e.g., M1 and M2), brain stem (e.g., facial nucleus), and spinal cord on the other (Fig. 7). The presupplementary motor area (pre-SMA) plays a role in generating a motor plan or strategy in response to an instructional signal. In comparison, activity in the adjacent supplementary motor area (M2) is related to the onset or initiation of movement. Finally, it has also been shown that medial frontal damage results in perseverative behavior.

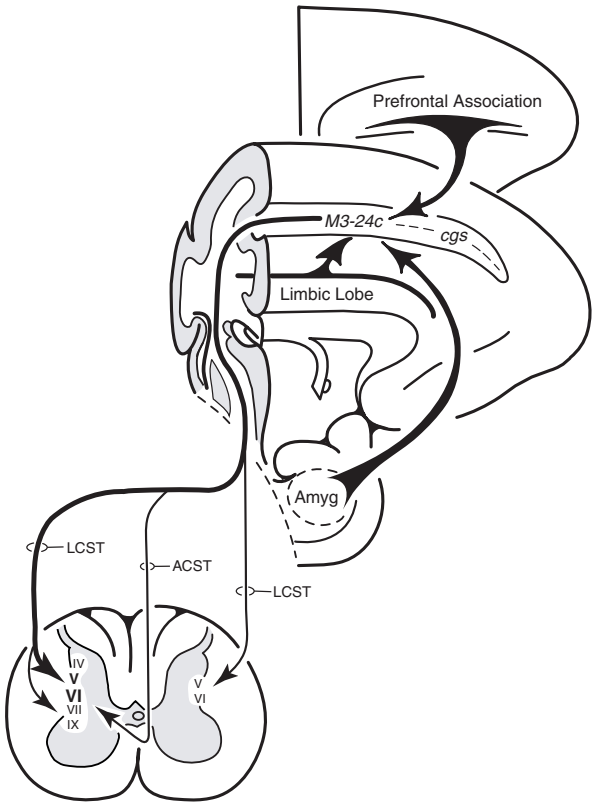

Figure 7 Summary diagram illustrating important higher order inputs from prefrontal and limbic cortices (top, right) to the rostral cingulate motor area (M3–area 24c), which projects directly to the spinal cord (bottom, left) and facial nucleus (not shown). Also illustrated is amygdala input to M3, which may play an important role in coupling emotional relevance and complex motor activity. ACST, anterior corticospinal tract; Amyg, amygdala; cgs, cingulate sulcus; LCST, lateral corticospinal tract. Copyright Lippincott, Williams and Wilkins.]

C. Orbitofrontal Cortex

The orbital prefrontal region appears to be involved in autonomic, emotional, response inhibition, and stimulus significance functions. This region has been shown to have a significant role in social and emotional behavior and in the formation of new memories. The orbitofrontal cortex is involved in olfactory and gustatory processing and in the appreciation of the emotional significance of stimuli. In addition, this region has been shown to serve the processing of facial information, the relation of specific stimulus features to reinforcement in learning paradigms, and the regulation of behavior in response to reward and punishment. From neuropsychological, neurophysiological, and clinical studies, it can be concluded that these functions are consistent with the distinctive and heavy orbitofrontal connections established with numerous cortical and subcortical limbic system structures.

III. CLINICAL SYNDROMES

The precise origin of the phrase "frontal lobe syndrome" remains obscure, but it has been used as an umbrella term to characterize patients with deficits in executive or intellectually related functions. These deficits cover a wide spectrum of complex behavioral changes, including impairments in foresight, judgment, initiative, creativity, problem-solving, social conduct, and attention. However, experimental data, lesion-based behavioral analyses and functional imaging observations demonstrate that the executive functions managed by the brain depend not only on prefrontal cortex but also on the integrity of other cortical and subcortical structures that are interconnected with the prefrontal cortex (as reviewed in this article). Although the various parts of the extended prefrontal neural system are not equivalent in their contribution to the overall cognitive process, their participation is essential for appropriate and skilled execution of higher order tasks. The clinical relevance of a "distributed neurocognitive network" is that lesions located within the extended cortical and subcortical neural system may produce functional deficits similar to those that occur when damage is isolated to a specific prefrontal region. For example, patients with lesions involving parts of the basal ganglia or mediodorsal thalamic nucleus that are topographically interconnected with dorsolateral prefrontal cortex may present with behavioral disorders essentially the same as those occurring in patients with damage restricted to the dorsolateral prefrontal cortex.

Related is the fact that brain lesions are often difficult to delineate precisely and are rarely confined to the cortical gray matter. Therefore, higher order behavioral deficits associated with prefrontal lesions are often too complex to fit a simple unified description such as frontal lobe syndrome. In the case of prefrontal damage, this has led to the development of more specific terminology based on structural, functional, and clinical features, which recognize *dorsolateral*, *medial*, and *orbital* prefrontal regions as described next. This view not only takes into consideration the unique contributions of the various and highly specific corticocortical and subcortical prefrontal interconnections but also reinforces the functional heterogeneity and specialization of each prefrontal subdivision. This conceptual framework provides a useful reference point for interpreting patient conditions and for advancing our functional understanding of this complex brain region and its inherent circuitry. However, caution should be exercised because lesions are rarely confined to any one prefrontal system, and clinical features of more than one "syndrome" are likely to occur in an individual patient.

A. Lateral Dysexecutive Syndrome

Common sources of damage to the dorsolateral frontal cortex include infarction of the lateral prefrontal branches of the middle cerebral artery, infarction of the internal frontal and frontopolar branches of the anterior cerebral artery, lateral frontal gliomas, convexity meningiomas, and head trauma. Central nervous system infections, demyelinating disorders, and degenerative diseases resulting in neuronal loss and gliosis of the frontal lobe, such as Pick's disease and frontotemporal dementia, alter prefrontal executive functions. In addition, schizophrenia and depression are associated with dorsolateral dysexecutive syndrome characteristics. For example, during verbal episodic memory retrieval tasks, schizophrenic patients show enhanced activity in the dorsolateral prefrontal cortex and reduced activity in the hippocampus when compared to controls. This indicates that normal recruitment of the hippocampus, a central structure in neural systems related to memory, is altered during memory retrieval in schizophrenics.

Patients with dysexecutive syndrome are characterized by deficits in many cognitive domains. This syndrome has been described as a metacognitive disorganization reflecting a reduced state of mental control. Working memory (regulating actions based upon on-line internal and external environmental stimuli) and the temporal ordering of recent events are impaired. The ability to recall or retrieve information is altered despite evidence of intact recognition. Patients present with diminished judgment, planning, insight, and self-care, and there is often a general reduction in verbal and nonverbal fluency.

B. Medial Apathetic Syndrome

The most common cause of medial apathetic syndrome is infarction of the anterior cerebral artery and its branches, which is a rare cardiovascular accident in itself. This syndrome is also associated with midline meningiomas of the falx cerebri, multiple sclerosis, central nervous system infections, and frontotemporal dementia. Occasionally, penetrating wounds whose

trajectory is directed along the midline of the skull, such as that reported in the landmark case of Phineas Gage, damage medial as well as ventromedial sectors of prefrontal cortex.

The hallmark feature of medial apathetic syndrome is a severe reduction in spontaneity and motivation. For example, medial syndrome patients are able to generate internally organized plans for action but lack the impetus to carry them out. This syndrome is also characterized by a reduced interest in the environment. Memory of recent events is relatively intact, as is the ability to recollect principal events. Although few neuropsychological deficits accompany this disorder, the patient has a flattened affect, illuminated by a blunted facial expression. It is thought that the overall alteration in motivation and motor activity is a result of the lesion involving the medial motor cortices. Medial motor areas considered to be of particular importance include the rostral (M3) and caudal (M4) cingulate motor areas and the supplementary (M2) motor area (Figs. 1 and 7). All three motor areas are known to project to the primary motor cortex, lateral premotor cortex, facial nucleus, and spinal cord. In addition, the cingulate motor areas directly receive widespread dorsolateral prefrontal, limbic, and amygdalar inputs, which under normal conditions are likely to provide the appropriate motivational impetus to carry out an internally generated plan of action (Fig. 7).

C. Orbitofrontal Disinhibited Syndrome

The orbitofrontal cortex rests on the floor of the anterior cranial fossa directly above the paired orbital and nasal cavities. It is separated from the orbital cavity by a relatively thin and fragile sheet of bone formed by the orbital plate of the frontal bone and cribriform plate of the ethmoid bone. This spatial association and the potential for fragmentation of the orbital plate render the orbitofrontal cortex highly vulnerable to injury following acceleration–deceleration head trauma, which is common, for example, in automotive collisions. Other common causes of orbitofrontal damage include rupture of the anterior communicating artery (often producing concomitant medial wall damage) and ventral frontal meningiomas. Orbitofrontal cortex is also adversely affected in frontotemporal dementias, viral infections (e.g., herpes encephalitis and Creutzfeldt–Jacob disease), and demyelinating disorders such as multiple sclerosis. Many neuroimaging studies have implicated the orbitofrontal cortex in the pathophysiology of obsessive-compulsive disorder and depression.

Patients with orbitofrontal damage are characterized generally by an acquired disturbance of personal and social behaviors. Remarkably, intellect is not grossly impaired. For example, learning and retention of factual knowledge are relatively preserved. Therefore, working memory is intact. The ability to use logic to solve problems and the ability to articulate verbally are preserved. However, there are marked abnormalities in the realms of reasoning, personal and social decision-making, emotional control, and feeling. Disruption in the ability to control feelings and emotions often results in explosive aggressive outbursts characterized by socially unacceptable, tactless, and vulgar presentation. The overwhelming feature of impulse dyscontrol underscores the classification—disinhibited syndrome. Depending upon the posterior extent of the lesion, patients may have impairments in identifying odors (olfactory damage) and tastes (gustatory involvement).

IV. CONCLUSIONS

The prefrontal cortex is regarded as a critical portion of the cerebral cortex that mediates intellectual or executive functions. Its diverse but specific connectivity patterns, electrophysiological properties, neuroimaging correlates, and associated clinical sequelae all reinforce the complex role of the prefrontal cortex in mediating higher order behaviors. The prefrontal cortex can be viewed as a major component of a large-scale neurocognitive network where complex behaviors are organized at the interactive level of multifocal neural systems. This network contains a variety of anatomical projections for transferring informational content to and from the prefrontal cortex. Also important is complex local circuitry involved in the short-term storage of information, encoding of this information, and synthesis of the associated mental representations to achieve an appropriate goal-directed response. The significance of the prefrontal cortex, which is extensively developed in primates, is related to its involvement in dynamic mental functions that underlie behaviors in response to novel and challenging demands.

GLOSSARY

declarative memory Forms of long-term memory that may be consciously recollected or explicitly expressed, including memory for facts, ideas, and events, and supported by a medial–temporal and diencephalic neural network. Tests of declarative memory, such as free recall and recognition, are also termed direct or explicit probes of memory.

global amnesia Condition involving marked impairments in declarative memory for recently encountered facts and events, together with intact immediate memory and perceptual and linguistic functions within the normal range.

nondeclarative memory Forms of long-term memory expressed as a change in behavior, rather than by conscious recollection, and including skill learning, conditioning, and priming. Tests of nondeclarative memory, particularly tests of priming, are also termed indirect or implicit probes of memory.

Priming refers to facilitative changes in the ability to identify, generate, or process an item due to a specific prior encounter with the item. This article will consider theoretical accounts of priming, surveying the extensive evidence regarding this form of nondeclarative memory that has been derived from behavioral, neuropsychological, neuroimaging, and electrophysiological approaches.

I. WHAT IS PRIMING?

Historically, the term ''priming'' has been used in several areas of psychology to refer to conditions or stimuli that change an organism or system into a state of increased readiness or preparedness for action or response. Within cognitive psychology and cognitive neuroscience, priming refers to instances in which an earlier encounter with a given stimulus (e.g., a word, face, or other object) alters (''primes'') subsequent responses to that same stimulus or to a related stimulus by increasing the speed of responding, increasing accuracy, or biasing the nature of the response given. For example, participants are more accurate at identifying briefly exposed, masked, or degraded words during a perceptual identification task if they have earlier encountered those words during an unrelated study phase than if the words were not previously exposed. Critically, findings from both brain-damaged individuals and neurologically intact populations demonstrate that this alteration in performance may occur under conditions where the task itself does not involve or require any reference to memory: where the individual has no explicit or overt intention to remember the earlier occurrence and where the individual may remain entirely unaware of the earlier occurrence and its effects on behavior.

A. Initial Insights

Prior to the 1960s, a number of philosophers and psychologists had proposed a distinction between forms of learning involving conscious awareness of the past and forms of learning that occur independent of recollection, using such terms as knowing how vs knowing that (Gilbert Ryle), memory vs habit (William James), explicit vs implicit recognition (William McDougall), and mechanical or sensitive memory vs representative memory (Maine de Biran). However, these distinctions and related clinical findings were based largely on informal observation and introspection and did not clearly map onto questions regarding the possible brain regions that might support these different forms of learning. Two key findings—derived from experimental investigation of patients with global amnesia—radically altered this state of affairs and eventually prompted intensive investigation into multiple forms of long-term "learning without awareness".

The first key finding, reported by Milner and colleagues in the early 1960s, involved the famous amnesic patient H.M. Following bilateral removal of the hippocampi and adjacent medial temporal lobe regions as treatment for intractable epilepsy, H.M. was found to show profoundly impaired memory for recently experienced events: if his attention was momentarily diverted from an event such that it was no longer in working memory, it was, for him, as if the event had never occurred, even though it happened only minutes earlier and had been fully attended and comprehended. Yet, despite this severe impairment in the ability to consciously recollect and report recently experienced events, H.M. showed some forms of preserved long-term memory, including normal learning and retention on a perceptual–motor skill task involving tracing the outline of a figure reflected in a mirror. Even though H.M. had no conscious recollection of having performed this task before, with practice he became increasingly adept at the task, tracing the figure more quickly and more accurately. This practice-related improvement was similar in magnitude to that shown by normal individuals without impaired memory. These observations provided a clear demonstration that different kinds of long-term memory can be distinguished in amnesia.

The second key finding, reported by Warrington and Weiskrantz in 1968 and 1974, showed that amnesics also could (indirectly) manifest evidence of recent learning in a cognitive–perceptual domain. If, instead of asking amnesic patients to explicitly or directly recall or recognize previously encountered words, the task was simply to try to complete a "word stem" with possible words (e.g., TAB__might be completed as TABLE or TABOO), then—just like individuals with intact memory—amnesics more often completed stems with words that had been presented earlier in the experiment. This priming effect, or increased likelihood of completing word stems with studied items, was subsequently clarified by Graf, Squire, and Mandler, who showed that amnesic patients demonstrated normal priming when the task instructions were to complete each stem with the first word that comes to mind but impaired performance when the same cues were given but with the instruction to use the cues to help intentionally remember a previously studied item.

Priming thus refers to instances in which prior experience with a specific stimulus influences subsequent behavior in the absence of intentional remembrance—a form of indirect, nonconscious, nondeclarative, or implicit memory. In everyday life, priming may take many forms. For example, if, in casual conversation, an acquaintance uses a relatively low-frequency word, such as "ebullient,' then, should an appropriate situation later arise, this word might be more likely to simply "spring to mind" and be used than if the earlier exposure had not occurred. Priming may also lead to errors, as when, in written composition, a word may appear particularly apt because it was recently used in an earlier sentence (yielding unintended repetition) or when an idea generated by someone else may be remembered without awareness of its earlier occurrence, leading the "unknowing rememberer" to fail to credit the original source (i.e., cryptomnesia or inadvertent plagiarism).

B. Forms of Priming

Priming is one of several types of learning that do not depend on conscious, explicit recollection of prior episodes, with classical conditioning and skill learning also comprising classes of nondeclarative learning. Further, the term priming is used to refer to several somewhat different phenomena, including repetition priming, semantic priming, and new association priming. Subtypes of priming within these broad classifications may also be distinguished.

1. Repetition Priming

Repetition priming is the chief focus of this article and refers to instances where exactly the same stimulus (or

a very similar stimulus) repeats after an initial occurrence. Tests of repetition priming may be subdivided in multiple ways, but one broad distinction is that between tests that primarily place demands on *perceptual* processes (tasks in which performance depends on analysis of stimulus form) and tests that rely more heavily on *conceptual* processes (tasks in which performance depends on analysis of stimulus meaning).

2. Semantic Priming

Semantic priming refers to a facilitation of responding that occurs as a result of the presentation of a semantically related word, as when presentation of the word ''nurse'' facilitates access to or decisions regarding ''doctor.'' Semantic priming effects are one of the most robust findings in cognitive psychology and have been reported for a variety of tasks, including lexical decision (participants are presented words and nonwords and decide whether each comprises a word), perceptual identification, and speeded word reading (naming). A primary difference between semantic priming and repetition priming concerns the longevity of the effects. Whereas repetition priming may be quite long-lasting, persisting for hours, days, or, in some instances, many months, semantic priming was—until relatively recently—believed to be much more transient, dissipating over the course of several seconds or after more than one intervening item between the prime and target stimulus. However, other data suggest that, particularly under conditions requiring more extensive or ''deeper'' encoding, semantic priming may span several intervening items. Long-term forms of semantic priming also may be more readily observed on tasks that require deeper semantic processing. The literature on semantic priming is not reviewed further here.

3. New Association Priming

New association priming, in contrast to priming of individual stimuli, refers to priming of the relationship or *association* between unrelated stimuli. Priming for new associations is measured by presenting pairs of preexperimentally unrelated stimuli, such as words, in a study phase (e.g., MUSTARD–SATELLITE, TABLE–REASON) and then presenting three types of pairs during a subsequent test phase: intact pairs (words presented in their original context or pairing, as in MUSTARD–SATELLITE), recombined pairs (TABLE–SATELLITE), and new baseline pairs. Measures of new association priming are based on a comparison of performance for intact pairs relative to recombined pairs. If intact pairs show greater facilitation than recombined pairs, this can be attributed to the retention and use of associative information because the individual items in both types of pairs were encountered previously—what differs is their conjunctive or associative pairing.

New association priming can be examined with a variety of verbal and nonverbal materials and tasks (e.g., word-stem completion, lexical decision, naming, color naming of nonwords or novel objects). From both a theoretical and a pragmatic viewpoint, studies of new association priming are important because they may serve to delineate the limits of repetition priming: can priming occur, not only for already familiar or learned individual items but also for new relationships or associations between items? This also has implications for understanding the neural substrates of priming and the extent to which damage to brain substrates believed to contribute to declarative memory may be necessary to support the acquisition of contextual associations between items.

4. Skill Learning vs Priming

Skill learning refers to an improvement in speed and/or accuracy of performance that arises with increased practice on a task, where this improvement not only is observed for specific items that were encountered previously (as in repetition and new association priming) but *generalizes* to new stimuli within a domain of processing. Skill learning may assume several forms, including enhanced performance on sensorimotor tasks (e.g., mirror tracing, rotary pursuit), perceptual tasks (e.g., reading mirror-reversed or inverted text), and cognitive tasks (e.g., artificial grammar learning, probabilistic classification learning). Although several studies comparing skill learning and priming in different neuropsychological populations have demonstrated that these two forms of learning rely on distinct neural mechanisms, it is important to note that these studies have often compared different types of tasks and stimuli for priming vs skill learning. Thus, the observed dissociations may reflect dissociations across domains of processing (e.g., sensorimotor vs lexical–conceptual) rather than between skill learning and priming *within a given domain*. Work by Poldrack and others examining skill learning and item-specific priming within the same task (e.g., mirror reading, digit entry) suggests that —at least under some conditions and for some types of

tasks—skill learning and priming may partially rely on common learning and neural bases.

C. An Important Methodological and Interpretive Caveat

As noted earlier, priming refers to instances in which prior experience with a stimulus influences subsequent behavior in the absence of "conscious, intentional subjective remembering." Initial theoretical considerations and subsequent empirical findings have underscored the need to differentiate between two aspects of subjective remembering: *intention* or effort to remember and *awareness* of remembering. Particularly for individuals with intact memory function, awareness that one has experienced something previously might arise even though one did not intentionally attempt to remember, that is, one may "involuntarily" or spontaneously notice that one's current experience is similar to, or has been influenced by, past experience. Priming involves changes in performance as a result of past experience with a particular stimulus in the absence of an intention to remember. However, should persons become aware of the relation between study and test items, it is possible that they may alter the way that the task is performed, changing a nominally "implicit" test, which makes no reference to the past, into an "explicit" test, in which there are deliberate attempts to retrieve items that correspond to those encountered earlier.

Attention to the possible confounding influences of explicit retrieval is important when designing and interpreting the outcome of priming studies. Researchers have developed a number of informal procedures to reduce the likelihood of contributions from explicit volitional memory on implicit tests and have proposed various criteria to more confidently infer that observed facilitative effects reflect priming rather than explicit contamination (e.g., the effects are observed in amnesics, the effects of an encoding factor differ when retrieval is volitional or intentional relative to when it is implicit, and the effects are observed on speeded tests that make intentional retrieval difficult or less likely). Although no one of these approaches, in isolation, provides unequivocal support for the unintentional nature of memory on a given task or occasion, collectively they can provide convergent evidence of the manner in which nonconscious, unintentionally expressed memory (particularly priming) may differ from intentional, conscious recollection of the past.

II. THEORETICAL ACCOUNTS

Five general classes of accounts of repetition priming have been proposed: activation–elaboration, transfer appropriate processing, memory systems, components of processing, and perceptual or response bias.

A. Activation–Elaboration

Among the earliest accounts of repetition priming were activation theories, which posited that prior experience facilitates subsequent word processing because it temporarily activates preexisting abstract representations in semantic memory. From this perspective, identification of a word was thought to involve activating an abstract lexical–orthographic word code above some threshold, with priming reflecting experience-induced modification in the lexical entry such that repeated words were more readily activated beyond threshold. These early accounts, proposed by Graf, Mandler, Morton, and others, contrasted *activation* of abstract lexical units, which was thought to be especially important for priming, with *elaboration* (e.g., processing the stimulus for meaning or forming associations to it), which was thought to be especially important for the formation, retention, and conscious recollection of events from long-term memory.

Early activation accounts involved three central propositions: (a) the representations involved were abstract (i.e., not modality-specific), (b) activation was temporary, and (c) activation occurred only for preexisting representations. Two empirical findings conclusively refuted the early activation accounts: study-to-test modality changes (e.g., visual presentation at study, auditory presentation at test) reduce or eliminate priming on perceptual tasks, and priming effects can be observed across relatively long delays. However, later activation accounts developed by Morton, J. S. Bowers, and others are not susceptible to these objections because they propose that there are modality-specific representations (that is, different representations for visually and auditorily presented words) and have differentiated between two forms of activation (and repetition priming): short-term priming, lasting only a few seconds and reflecting the activation of abstract orthographic codes or access to abstract lexical entries, and long-term priming, which can persist for minutes, hours, or longer and is viewed as reflecting a structural change in orthographic representations. The revised activation account (see also the reactivation theory proposed by G. H. Bower),

however, has difficulty with evidence demonstrating *within-modality* specificity effects in priming, as in reduced priming for words presented in different type fonts or presented auditorily in different voices relative to items presented in the same font or same voice at study and test. These findings led to the further suggestion that there may be two different perceptual systems involved in identifying information, one abstract and one specific (possibly partially lateralized to the left and right cerebral hemispheres, respectively). Most importantly, the activation account also does not provide a clear explanation for priming effects that have been demonstrated for stimuli other than words, particularly novel forms of information for which no preexisting representation exists, including novel configurations of dots or lines, novel objects, unpronounceable letter strings, novel faces, and novel melodies. This suggests that explanations in terms of activation cannot provide a comprehensive account of all priming effects. Some further mechanism or process that allows for priming involving novel representations is also necessary.

B. Transfer Appropriate Processing

According to this view, the magnitude of priming observed on a given task depends on the ''congruency'' or ''match'' between the forms of cognitive processing that are engaged during an individual's initial encounter with a word, object, or other stimulus (the ''study'' phase) and the forms of cognitive processing elicited during the subsequent (repeated) processing of that stimulus (the ''test'' phase). Greater match or congruency between the forms of processing engaged at study and those demanded at test yields greater priming, whereas mismatch tends to decrease or eliminate priming. (Such transfer appropriate processing—a term proposed by Morris, Bransford, and Franks in the late 1970s—is consistent with the notion of encoding specificity, proposed by Tulving and Thomson in the early 1970s with regard to retrieval processes in episodic memory.)

Much initial work from this framework focused on the broad distinction between ''perceptually driven'' tasks and ''conceptually driven'' tasks. Perceptually driven tasks, such as those requiring the identification of briefly exposed words or fragmented objects, are construed as being heavily reliant on sensory perceptual analyses, whereas conceptually driven tasks, such as producing words from a specified category (category–exemplar generation) or deciding whether words or objects belong to a given semantic category (e.g., making animate–inanimate decisions), are construed as being dependent on conceptual analyses. Roediger and colleagues proposed three primary criteria to operationally define tasks as conceptual vs perceptual, including sensitivity to (a) the ''read–generate'' study manipulation, (b) manipulations of study–test modality, and (c) levels-of processing manipulations at study. Tasks that show (a) a ''generation'' effect, that is, superior performance under conditions where the target items, during study, are not physically presented but must be produced (''generated'') by the participant in response to a conceptual cue (e.g., an antonym), (b) relative immunity to changes in study–test modality, and (c) superior performance for items that were semantically processed relative to items that were nonsemantically processed during study are considered to be conceptual tasks. By contrast, tasks that show (a) a ''reverse-generation'' effect, that is, superior performance for items that are simply read (from physically presented cues) rather than generated, (b) reduced or eliminated priming for items studied in one modality but tested in another modality, and (c) equivalent or near-equivalent levels of priming for items that were semantically vs nonsemantically processed at study are considered to be perceptual tasks.

Early proponents of the data-driven vs conceptually-driven distinction advanced this as an alternative to the implicit–nondeclarative vs explicit–declarative distinction regarding the forms of memory that were preserved vs impaired in amnesia, proposing that the performance of amnesics could be explained as involving the preservation of perceptual memory processes but impaired conceptual processing. However, extant data indicate that this distinction is an inadequate account of memory failure in amnesia (see later discussion). Nevertheless, distinctions relating to transfer appropriate processing continue to inform task analyses, particularly in across-task comparisons (under what conditions does across-task facilitation occur, what aspects of processing might be common across different tasks) and in attempts to specify the neural substrates that support specific task components.

C. Memory Systems

As noted earlier, there have been numerous attempts by psychologists, philosophers, and others to differentiate between different forms of learning and

memory that are subject to conscious awareness and recollection and forms of learning that may occur without such awareness. On the basis of dissociations in the performance of amnesic patients vs normal controls for tasks that require conscious recollection vs motor and cognitive tasks that may show facilitation from past experience without requiring such recollection, Cohen and Squire proposed a distinction between a hippocampally based declarative memory system and a procedural (or nondeclarative) memory system that supports the acquisition of skills and other forms of preserved learning in amnesics. Declarative memory includes memory for events (episodic memory) and factual knowledge (semantic memory) where these forms of information may be consciously recollected, subjected to verbal reflection, or explicitly expressed. Nondeclarative memory includes skill learning, repetition priming, and conditioning.

Other researchers have proposed similar broad divisions, such as that between explicit memory and implicit memory, but with further subdivisions of the latter. For instance, Schacter, Tulving, and others suggest that performance on (implicit) perceptual priming tests is mediated by perceptual representation systems, including a word form system (further differentiated into visual and auditory word form systems representing visual and spoken words, respectively) and a structural representation system for objects. These perceptual representation systems encode and retain presemantic perceptual information (in the form of perceptual records) about words and objects but do not represent semantic or associative information about them (though these systems are connected to semantic systems where such information is represented). By contrast, performance on conceptual priming tests is mediated by a semantic system, separate from the perceptual representation systems, and is sensitive to semantic variables. Within the domain of semantics, further distinctions have been posited such as that between lexical systems and more abstract semantics. Critically, these various memory systems are thought to differ not only in their operating characteristics but also in their underlying neural substrates.

D. Components of Processing

Although researchers began by emphasizing the broad characterization of tasks as perceptually driven vs conceptually driven, evidence from a variety of sources suggested that most tasks involved elements of both types of processing, thereby pointing to the need to move beyond this comparatively coarse characterization to a more precise understanding of which processes are necessary components of which tasks. The components of processing approach holds that memory depends on the operation of various components, depending on the particular processing demands of a task. This approach emphasizes the overlap in critical components of the task at study and test (as in the transfer appropriate processing approach), but also views the components of processing as *structural units*, each performing a particular function with some components shared across tasks and some unique to a given task (as in the memory systems approach). In this approach, the unit of analysis is not a large-scale system, but smaller components that comprise networks of connections with other components, where a single component may belong to a number of different systems.

E. Perceptual or Response Bias

Each of the three preceding theoretical accounts —transfer appropriate processing, memory systems, components of processing—provides a different framework from which to consider priming, but all three agree in their basic characterization of the phenomenon to be explained, specifically: priming reflects facilitation in the processing of repeated relative to nonrepeated items. In contrast, according to a perceptual or response bias account, as proposed and developed by Ratcliff, McKoon, and colleagues, priming does not reflect enhanced sensitivity in processing repeated materials but rather reflects a *bias* to interpret test items as previously studied materials, i.e., a change in the likelihood of guessing the studied item that gives rise both to benefits in performance (when the biased response matches the test item) and to costs (when the biased response leads to the incorrect identification of a test item that, though similar to the studied stimulus, differs from it). This bias is postulated to occur at a perceptual level in tasks such as forced-choice perceptual identification, but it is thought to occur at the response level in other tasks (e.g., a tendency to respond ''possible'' for all studied items in the possible–impossible object decision paradigm developed by Schacter, Cooper, and colleagues). Evidence that bias may *contribute* to priming phenomena has been obtained in several experiments, but there is also evidence to suggest that a ''pure bias'' account —without also allowing for changes in sensitivity—is

incomplete. Theoretical and empirical interpretations of findings in relation to bias continue to be a matter of debate but will not be reviewed further here.

III. BEHAVIORAL EVIDENCE

Studies of priming in neurologically healthy individuals, using behavioral paradigms with the dependent variables of response latency or accuracy, will be considered in relation to four types of priming: perceptual, lexical–phonological, conceptual, and new association priming. Although the distinctions between these types of priming are, in part, relatively crude, and often tasks involve more than one form of priming, they provide an initial classification that can serve as a general guide. More importantly, these distinctions appear to be necessary in mapping to the neural substrates of task performance, as indicated by a convergence of data from neuropsychological, electrophysiological, and neuroimaging methods (reviewed later).

A. Perceptual Priming

As noted earlier, perceptual tasks involve processing of stimulus form (rather than stimulus meaning). Research has primarily focused on perceptual priming for visual stimuli (visually presented words, faces, objects, patterns, nonwords) and, to a lesser extent, auditory stimuli (auditorially presented words or sounds). However, perceptual priming also may occur for tactile stimuli (raised letters, forms) and is reliably found for novel stimuli for which individuals do not have preexisting representations, such as novel dot patterns, novel three-dimensional objects, and novel letter strings that do not obey orthographic or phonological rules.

A given task is thought to involve a substantial perceptual component when priming is reduced or eliminated following changes between study and test modality (modality specificity) or symbolic form (e.g., picture to word changes; format specificity). On the basis of this criterion, a number of tasks have been found to involve a substantial perceptual component, including perceptual word identification, word-stem completion, word-fragment completion (participants are asked to generate a word that conforms to partially provided letter cues, as in –E–S—X, for ''beeswax''), picture-fragment completion (similar to word-fragment completion but involving line drawings of common objects, with some of the contours of the picture omitted), picture naming (participants are shown pictures of common objects and asked to name them), speeded word reading, naming, and lexical decision.

Although priming is reduced by changes in study-to-test modality or stimulus form on these tasks, cross-modal and cross-form priming have also been observed. For example, whereas both positive and negative findings have been reported, significant cross-modal priming has been found when the modality changes both from vision to audition and from audition to vision for perceptual identification, lexical decision, and word-stem completion. Priming from pictures at study to verbal tests (e.g., word-fragment completion) and from words to pictorial tests (e.g., generating words and then later identifying fragmented pictures) has also been found. More recently, several instances of significant cross-modal priming across vision and touch have been documented for words (words were presented as a raised line drawing on a card) and for two-dimensional and three-dimensional objects using such tasks as naming, picture-fragment completion, and object decision.

Cross-modal and cross-form facilitation may be attributable to explicit recollective processes (i.e., ''explicit contamination'') or to nonperceptual abstract aspects of processing that are repeated across the modality change. These latter processes may include lexical access or selection for words and access to structural descriptions for visually and haptically processed common objects (structural representations may be abstracted similarly across these modalities). For haptic-to-visual priming, results showing that cross-modal priming is not affected by elaborative processing, whereas explicit memory is, argue against an explicit contamination account. For words, evidence that cross-modal priming is not enhanced by deep compared with shallow processing—provided that the shallow encoding task requires lexical access—likewise argues against an explicit contamination account and suggests that priming operates at the lexical level. Consistent with this interpretation, neuropsychological data from amnesic patients also indicate that cross-modal priming may not necessarily reflect intentional, conscious retrieval as amnesics show normal cross-modal word-stem completion priming.

The magnitude of perceptual priming may also be evaluated in relation to changes in stimulus form *within* a given modality, as where visually presented words are presented in different type fonts, auditorially presented words are presented in different voices, or alternative exemplars or tokens of an object are presented (e.g., two different chairs). The extent to

which such item-specific changes in stimulus form attenuate priming depends on the task and stimuli. For example, for visually presented common objects, changes in the size, right–left reflection, texture, color, contrast polarity, or illumination of the object have little effect; however, changes in exemplar form (different tokens of an object) consistently produce attenuation of priming (see Fig. 2 for a neural correlate). The insensitivity of object priming to changes in size is particularly noteworthy because changes in this attribute have been found to significantly depress conscious recognition of studied items (though size changes may also affect object priming under conditions where size is highly relevant to the task). For words, changes in font, size, and script often have little effect on such tasks as lexical decision and naming; however, specificity effects may be observed for words presented in unusual or nonstandard fonts or under study conditions that focus attention on the visual appearance of the words. Additionally, the direction of the difference between conditions even in situations involving less salient changes, although not significant, is most often consistent with specificity (see Fig. 1 for relevant neuropsychological data). Specificity effects also tend to emerge more frequently for stimuli that are presented in a degraded or fragmented form.

In contrast to the clear detrimental effects of modality change and stimulus form that are observed on perceptual implicit tests, changes in stimulus form often show relatively little effect on explicit tests of recall and (somewhat less consistently) on explicit tests of recognition, though these tests markedly benefit from semantic processing. However, although many perceptual priming tests show relatively modest or nonsignificant effects of level of processing, particularly compared with the extremely robust effects of this factor on tests of conscious recollection, meta-analyses indicate that it is not possible to conclude that perceptual priming tests are entirely immune to the effects of encoding manipulations: small, often statistically insignificant, but nonetheless relatively consistent benefits for semantic compared with nonsemantic processing on perceptual tasks may, in some instances, reflect explicit retrieval strategies but may also reflect contributions of semantic or conceptual processes to task performance under certain conditions.

B. Lexical–Phonological Priming

Models of single-word reading distinguish between different possible stages of processing, including visual feature analysis, and access to a word-form (lexical) system, semantic system, and phonological output system. Although different models do not necessarily treat these stages as invariably sequential, there is evidence that access to the word-form or lexical system need not be accompanied by access to the semantic system. Consistent with this, repetition priming paradigms have shown asymmetrical transfer on a number of tasks, such that tasks that depend on access to *both* the lexical and the semantic systems (e.g., judging whether something is man-made or is abstract or concrete) may show transfer benefits to a task requiring only access to the lexical system (e.g., lexical classification), but tasks that require *only* access to the lexical system do not show transfer benefits to tasks requiring access to both the lexical system and the semantic system. Transfer across different tasks that require access to the same level, as in two lexical tasks such as lexical classification vs naming, also has been observed, but such across-task facilitation has been found to be less strong than the facilitation found for within-task repetition. Moreover, there is evidence pointing to a specific contribution of phonological similarity to repetition priming: for example, priming transfers across interpretations of a homophone, that is, words that are pronounced identically but that differ in both spelling and meaning (e.g., seeing or hearing "week" primes both "week" and "weak"). Depending on task conditions, multiple aspects of the representation of a word—lexical, orthographic, phonological, and semantic (discussed next)—may contribute to repetition priming.

C. Conceptual Priming

Conceptual priming tasks require access to semantic memory, including abstract knowledge about the structural, functional, and associative information about a stimulus: how the object is constructed or formed, its uses, and the situations or contexts in which it occurs. In a strict sense, conceptual tests might be construed as those in which there is *no* overlap of perceptual information between the target items presented in the initial study exposure and the cues presented in the subsequent test exposure, as in the case of tests of general knowledge (e.g., at study, exposed to the word "cheetah;" at test, queried "What is the fastest animal on earth?") or category–exemplar generation (e.g., at study, exposed to the word "mango;" at test, given the category name "fruit" and asked to generate appropriate exemplars of that

category). However, the term conceptual priming also has been used more broadly to refer to various tasks in which performance during the test phase relies on semantic analysis, including semantic classification or verification tasks (e.g., tasks requiring animate–inanimate or abstract–concrete decisions), and in which, depending on experimental conditions, the item may recur in the same perceptual form at study and test. Support for the notion that it may, nonetheless, be appropriate to consider the latter type of task as "conceptual" is provided by evidence that priming in this instance is largely unaffected by a change in study modality or format but is influenced by levels of processing. Neuropsychological and neuroimaging findings (see later discussion) also support this distinction.

An important question regarding conceptual priming concerns the extent to which it can be dissociated from explicit memory. Because explicit memory performance is often enhanced through deeper, "conceptual" analysis, in many instances manipulations of conceptual processing affect performance on implicit conceptual and explicit tasks in a parallel manner, raising the possibility that there is no need to differentiate between them. However, as noted later, several neuropsychological dissociations between explicit memory and conceptual priming have been observed. Moreover, dissociations between category–exemplar priming and explicit memory performance have been observed in young normal controls relative to older normal controls. Compared to normal young controls, older normal controls show impaired category-cued recall (explicit test) but intact category–exemplar priming (conceptual implicit test), together with normal benefits (increases) in both category-cued recall and category–exemplar priming for semantic relative to nonsemantic encoding.

Further evidence that explicit retrieval (indexed by category-cued recall) and conceptual implicit memory (indexed by category–exemplar generation) may reflect distinct processes even in individuals with intact memory includes the following: (a) findings of a "picture-superiority effect" (i.e., enhanced performance for items studied as pictures relative to items studied as words) during explicit retrieval but not in conceptual priming, (b) results showing that, whereas exemplar frequency and retention interval (varied between immediate testing and 24-hr delay) influenced explicit recall, they did not affect conceptual priming, (c) findings that perceptual interference at study (presenting words very briefly followed by a mask) enhanced explicit retrieval but had no effect on conceptual implicit memory, (d) results showing within-category serial position effects for explicit recall (greater recall for the first and second items that were presented in a category at study than for the later items when categories were studied in blocks) but not for conceptual priming, and (e) pharmacological evidence demonstrating preserved conceptual priming following the administration of the benzodiazepine lorazepam but impaired explicit retrieval.

Earlier, several criteria used to designate a task as conceptual were outlined. The feasibility of this approach, however, has been undermined by the finding that the various experimental manipulations believed to indicate conceptual processing do not invariably converge for a given task. For example, although a number of sources of evidence point to a conceptual processing component in word-stem completion priming (e.g., there is often a strong cross-modal component), this form of priming is not always enhanced by semantic encoding and is not greater after generation than after reading. Other conceptual tasks have also been shown to dissociate in relation to conceptual elaboration, with some tasks showing enhanced priming with conceptual elaboration (e.g., word-cued association with weak associates and category-cued association) but others not showing such enhancement (e.g., word-cued association with strong associates, category verification). This suggests the need to further differentiate types of conceptual processing.

One distinction focuses on tasks that involve semantic *verification* or classification as opposed to the actual generation or *production* of a response. Consistent with this, whereas semantic processing at study enhanced priming on production tasks, it did not facilitate verification responses; likewise, division of attention at study did not affect verification responses. However, there also is evidence of differences within conceptual production tasks: whereas semantic encoding and division of attention may not affect priming on the word association task when the words are highly associated (e.g., TABLE–CHAIR), semantic encoding does yield benefits for words that are weakly related (e.g., TABLE–STOOL).

Rather than distinguishing between verification vs production, an alternative account of these differing patterns focuses on the question of whether the task involves response competition during retrieval: such competition may be minimal or absent in cases where the stimulus is itself presented at test (in verification) or where the target word is strongly associated with the cue word. By contrast, response competition may be considerable in exemplar production tasks where the category cue is consistent with multiple legitimate

responses or for weak associates. Whereas, under conditions where the retrieval cue directly activates relevant knowledge, elaborative processing during study might not be needed or useful, under conditions where the retrieval cue is consistent with multiple responses, elaborative encoding may make a difference. This distinction between competitive and noncompetitive access also coheres with findings in neuropsychology and neuroimaging. For example, compared with matched controls, patients with focal left inferior frontal lesions made more errors on a verb generation task (generate a verb associated with a noun) when the noun had multiple possible responses (high demands on selection or competitive access) relative to when the noun had few possible responses (low demands on selection).

One further posited differentiation between conceptual tasks focuses on the distinction between item-specific encoding (processing related to individual items that tends to enhance the differentiation of that item from others) and relational encoding (processing emphasizing features that are shared among items). It has been suggested that, whereas explicit tasks can benefit from both types of processing, some conceptual implicit tasks rely especially on relational processing. This distinction suggests that minimal effects of divided attention on category–exemplar generation under conditions where the category items are blocked at study, but detrimental effects when category items are presented randomly, may arise because blocking allows the extraction of relational information even under division of attention. A somewhat similar distinction is that between initial interpretative encoding (encoding that occurs during perception) and elaborative encoding.

D. New Association Priming

The question of whether facilitation of performance occurs for "new associations," i.e., novel pairings of stimuli or stimuli that provide a context for one another, is important regarding the generalizability of priming. Measures of new association priming are based on the comparison of performance for repeated items that occur accompanied by the same item as at study (intact pairs) relative to items that are paired with different study items (recombined pairs) with findings of greater facilitation for intact than for recombined pairs taken as evidence for the formation, retention, and use of associative or contextual information.

Early studies of new association priming primarily used a word-stem completion task in which individuals initially study unrelated pairs of words (e.g., MUSTARD–SATELLITE, TABLE–REASON) and then are tested, using either explicit cued-recall instructions or implicit word-stem completion instructions, for intact pairs (MUSTARD–SAT___), recombined pairs (TABLE–SAT___), and entirely new pairs. These initial studies suggested that new association priming only emerged under conditions of elaborative encoding, specifically when the task required relational encoding of the items in the pair (e.g., forming a sentence using the words) rather than encoding that focused on each item individually (e.g., judging each word for pleasantness). These findings suggested that new association priming might require the "unitization" of stimuli in memory, such that items or components formed a single unit. Subsequent work has, however, shown that new association priming can occur even under shallow encoding, at least under conditions where the items in the pair are presented simultaneously rather than sequentially (e.g., for the stem completion task, copying the two words next to one another at study; for lexical decision, deciding whether the two words in a pair have the same number of vowels at study).

Depending on the nature of the task, there is evidence pointing to both perceptual and conceptual contributions to new association priming. For example, evidence of a perceptual contribution has been reported for the relatively perceptual tasks of word-stem completion and lexical decision, including attenuation or elimination of associative priming for unrelated word pairs under cross-modal relative to unimodal study–test conditions, and little effect of levels-processing on lexical decision. Evidence for perceptual or other lower level contributions to new association priming (such as factors relating to the phonological or articulatory production of items) also has been reported for a word reading task, such that interposition of the irrelevant intervening word "and" between the members of each word pair—while keeping the pair and order within the pair intact—virtually eliminated the new association priming effect. However, findings pointing to a conceptual contribution to new association priming have been reported both for the word-stem completion paradigm (performance was influenced by the inclusion of conceptual context words that were not presented during study though they biased interpretation toward one of two possible meanings of a homograph, both of which had been presented at study) and for a more conceptual

task (semantic relatedness judgments: no attenuation of associative priming for unrelated word pairs under cross-modal conditions).

Several early studies, particularly those using the word-stem completion paradigm, raised the possibility that new association priming might only be found in individuals with intact memory who were "test aware" (i.e., aware of the purpose of the task). However, because several subsequent studies have shown new association priming in neurologically intact individuals using tasks involving speeded responses (e.g., masked word identification, reading time for words and nonwords, color naming for compound nonwords and novel line figures), it is unlikely that new association priming entirely or exclusively reflects conscious retrieval processes. Other evidence, including differences in response times as a function of task (longer for explicit recognition than for lexical decision) and as a function of encoding condition and task (little effect of level of processing on associative priming in lexical decision but a strong effect on explicit recognition), also suggests that associative priming does not always reflect explicit contamination. (Even for the associative stem completion paradigm there is evidence of a dissociation between explicit and implicit tests as a function of encoding task.)

That said, evidence for new association repetition priming in neurologically intact individuals is less extensive and more qualified than for item-specific repetition priming, with this form of priming appearing to be quite sensitive to the particular parameters used at study and test (e.g., encoding tasks that encourage some form of relational or at least "integrative" processing; simultaneous presentation of the new associate pair at both study and test; for unfamiliar or novel stimuli, physical integration of the to-be-associated elements). There are also several demonstrations that new association priming—at least in the word-stem completion paradigm—does not occur in densely amnesic patients, although the evidence here, too, is not altogether straightforward, and associative priming *has* been found in amnesics using other tasks such as word identification, color word naming, and reading time (see later discussion).

IV. NEUROPSYCHOLOGICAL EVIDENCE

Arguably, perhaps the most fundamental development in the theoretical understanding of memory's organization was the observation that lesion or insult to specific regions of the brain can result in the impairment of some forms of long-term memory, while leaving other forms preserved. As noted earlier, the initial influential reports of such dissociations between forms of long-term memory began to appear in the 1960s and early 1970s. These studies revealed that, despite considerable impairments on explicit tests of memory, individuals with global amnesia learn new motor skills and sometimes demonstrate intact levels of facilitated word-stem completion due to recent experience with a word. These observations motivated extensive efforts in the 1980s and 1990s to understand the functional and anatomical organization of long-term memory, with significant insights being derived through studying patients with focal lesions and patients with neurodegenerative disorders. Emerging from this literature was evidence indicating that perceptual and conceptual forms of repetition priming are neuroanatomically dissociable from declarative memory, from each other, and from other forms of nondeclarative memory.

A. Perceptual Priming

Beginning with patient H.M., considerable research has revealed that declarative memory is subserved by a medial temporal and diencephalic neural network that includes the hippocampal formation, adjacent parahippocampal, entorhinal and perirhinal cortices, and medial thalamus and mammillothalamic tract. Insult to these structures results in a global amnesia characterized by a specific impairment of declarative memory, as evidenced by deficits on explicit memory tests.

Extensive neuropsychological evidence demonstrates that, in contrast to declarative memory, perceptual priming is not dependent on medial temporal structures. Since Warrington and Weiskrantz's initial reports that amnesics demonstrate intact priming on word-stem completion, numerous studies have extended these observations by revealing intact levels of perceptual priming on various implicit memory measures. For example, amnesics demonstrate normal levels of priming on visual and auditory word identification, picture naming, and word-fragment completion measures. Moreover, on implicit tests that index perceptual representations, amnesics demonstrate an intact sensitivity to the degree of perceptual match between study and test stimuli, showing reduced priming when there is mismatched study–test modality

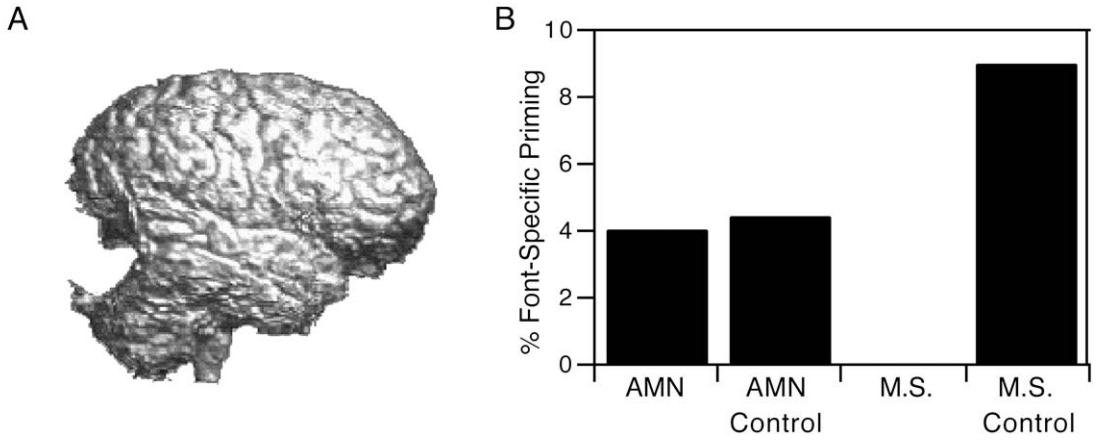

Figure 1 MRI rendering of patient M.S.'s right cerebral hemisphere and measures of font-specific behavioral priming. (A) The MRI reveals the extent of right occipital cortex resected in M.S. (B) Research by Vaidya, Gabrieli, and colleagues has revealed font–specific priming (same font-different font) in amnesic patients (AMN) and their controls (AMN control), as well as in the controls for patient M.S. (M.S. control), but not in M.S. himself.

and when the font in which a word is presented differs across study and test exposures (see Fig. 1).

Perceptual priming in amnesia is not restricted to the priming of stimuli that have preexisting memory representations. For example, levels of priming for novel visual patterns, unfamiliar objects, and novel verbal units (e.g., pseudo-words and orthographically illegal nonwords) are comparable in amnesics and healthy controls. Similarly, amnesics have been observed to demonstrate intact "new association" priming on word identification tasks, where greater priming is observed for previously encountered word pairings. However, priming of novel associations is limited following medial temporal damage. For example, data suggest that healthy individuals demonstrate priming for visual contextual information as revealed through facilitated visual search performance when the context is identical across initial and repeated search trials. Amnesic patients, in contrast, fail to show such priming, which is thought to require the formation of associations across multiple cues.

From a "memory systems" perspective, intact perceptual priming in amnesia has been hypothesized to reflect the operation of a distinct form of long-term memory from that supporting performance on explicit memory tasks. Alternatively, some theorists have suggested that intact priming derives from residual declarative memory in amnesia, rather than from nondeclarative memory. Multiple lines of evidence appear to be inconsistent with the latter interpretation, including the observation by Squire and colleagues that a patient (E.P.) who suffers from such a dense amnesia that he does not demonstrate above chance recognition memory nevertheless shows entirely intact levels of perceptual priming. Thus, perceptual priming can remain intact despite evidence suggesting an absence of residual declarative memory. Such data are consistent with the proposal that perceptual priming derives from perceptual representation systems that process information about the form and structure of stimuli. From this perspective, priming reflects the "tuning" of such a system as a result of prior perceptual processing of a stimulus. Importantly, this tuning or forming of perceptual nondeclarative memory traces does not depend on the medial temporal memory system implicated in declarative memory.

Perceptual priming appears to be subserved by modality-specific sensory cortices, with insult to such regions resulting in a selective impairment of modality-specific nondeclarative memory. For example, lesion of right visual cortex yields spared declarative memory but impaired visual priming. Specifically, in the mid-1990s, Gabrieli and colleagues reported a patient (M.S.) who, due to an extensive lesion of the right occipital lobe, fails to demonstrate visual repetition priming but who nevertheless demonstrates normal visual recognition memory. M.S.'s visual repetition priming deficits include: (a) the failure to demonstrate visual word-identification priming, (b) an absence of modality-specific priming in visual word-stem completion but normal across-modality word-stem priming

(suggesting that priming at an abstract lexical level is intact), and (c) the failure to demonstrate font-specific priming in word-stem completion (see Fig. 1). This dissociation suggests that a nondeclarative perceptual memory system in the right occipital cortex may be involved in memory for visual word form information that is necessary for visual repetition priming but not for visual declarative memory. Moreover, this dissociation between impaired perceptual priming and intact explicit memory complements the reverse dissociation in the densely amnesic patient E.P., providing further evidence against the interpretation that perceptual priming in amnesia reflects residual declarative memory.

B. Conceptual Priming

Whereas some theorists have interpreted intact perceptual priming in amnesia as indicative of multiple long-term memory systems, others have posited an alternative "process" account. This alternative perspective, which derives from the transfer appropriate processing hypothesis, posits that the dissociation between perceptual priming and performance on explicit memory tests reflects a distinction between perceptual and conceptual processes in long-term memory, rather than multiple forms of long-term memory. Accordingly, the explicit memory deficits observed in amnesia are thought to arise from the fact that these memory measures are heavily dependent on conceptually driven processes, which are posited to be impaired following medial–temporal insult, rather than perceptually driven processes, which are posited to be preserved in amnesia.

This position initially appeared viable because most early implicit tests (on which amnesics showed intact performance) were perceptual in nature, whereas the explicit tests (on which amnesics showed impaired performance) were conceptual in nature. However, findings from studies that examined amnesics' performance on all four types of test (i.e., implicit and explicit perceptual tests and implicit and explicit conceptual tests) unambiguously demonstrated that, contrary to this account, amnesic patients show intact conceptual priming (e.g., priming on word–associate generation, category–exemplar generation, and conceptual classification) and impaired performance on perceptually cued tests of conscious recall or recollection (e.g., graphemically cued recall: study the word "treason," at test probe with the visually similar but semantically unrelated word "treasure"). Amnesics also show sensitivity to manipulations of conceptual priming that parallel those found in neurologically intact individuals (e.g., conceptual priming that is uninfluenced by modality change, but sensitive to changes in semantic processing). Thus, extant data indicate that both conceptual and perceptual priming remain intact following medial–temporal and diencephalic insult, revealing dissociations between these memory phenomena and declarative memory.

Conceptual priming appears to be dependent on amodal association cortices. In contrast to amnesia, individuals with Alzheimer's disease (AD) demonstrate impaired explicit memory and impaired conceptual priming together with preserved perceptual priming (two exceptions to impairment of conceptual priming in AD may include category exemplar *verification* and word association for highly associated word pairs). AD is characterized by pathology to frontal, temporal, and parietal neocortical areas, as well as to medial–temporal regions, with a relative sparing of sensory cortices, including occipital regions. This pathology, combined with the accompanying behavioral pattern, suggests that processes mediated by frontal and temporal regions may support conceptual priming phenomena. Thus, across studies of patients with AD, amnesia, and focal lesions to sensory-specific cortices, neuropsychological evidence points to single and double dissociations between conceptual priming, perceptual priming, and declarative memory. Moreover, the preservation of skill learning, which is impaired following the disruption of basal ganglia structures as in Huntington's disease, in amnesia and AD supports the hypothesis that conceptual and perceptual priming reflect the operation of nondeclarative memory systems that are distinct from those supporting skill acquisition.

V. ELECTROPHYSIOLOGICAL AND NEUROIMAGING EVIDENCE

Neuropsychological investigation of the lesioned or injured brain has been the keystone of the cognitive neuroscientific revolution in understanding human memory. Patient studies have provided critical evidence regarding the forms of memory that are impaired and those that remain intact following a specific neural insult. However, whereas lesion studies remain a principal means for determining whether a neural region is necessary for a specific form of memory, the inferences permitted by this approach are limited for a number of reasons, including (a)

difficulties associated with drawing inferences from small samples, (b) interpretative complications arising from possible neural plasticity or reorganization, (c) challenges due to the fact that lesions often do not obey functional boundaries, and (d) the absence of information about the timing of neural processes. In the 1990s, complementary evidence about mind–brain relations, including the neural underpinnings of priming, began to be consistently derived from other approaches, including electrophysiological studies with nonhuman and human primates and neuroimaging studies with humans.

A. Electrophysiological Studies in Nonhuman Primates

One approach to studying memory processes in the primate brain is to use implanted microelectrodes to directly record from single (or, more recently, multiple) neurons while a nonhuman primate is engaged in a memory task. For example, to investigate visual memory, researchers have frequently recorded from neurons in the inferior temporal cortex while a monkey performs some variant of the delayed matching-to-sample (DMS) task. In the DMS task, a sample stimulus is initially presented followed by some number of intervening stimuli and then a repetition of the sample stimulus. Depending on the variant of DMS, all of the intervening stimuli may be novel (i.e., none of them repeat), or some of the intervening stimuli may themselves repeat prior to the repetition of the sample stimulus. In both variants of DMS, the monkey's task is to respond whenever a test stimulus matches the sample stimulus. Thus, only repetitions of the sample stimulus are task-relevant and should elicit a behavioral response from the monkey; repetitions of the intervening stimuli are irrelevant and should be ignored.

With respect to priming, the central outcome from such electrophysiological studies of DMS is the observation that many inferior temporal neurons, and to a lesser extent prefrontal neurons, demonstrate reduced or suppressed neural firing rates during repeated stimulus presentation relative to initial stimulus presentation. These changes in neural firing have been observed very early in the processing stream, with onset occurring within 100 msec or less after presentation of the repeated stimulus. Critically, in the mid-1990s, Miller and Desimone demonstrated that this "repetition suppression" is observed for both task-relevant stimuli (i.e., matches to the sample stimulus) and task-irrelevant stimuli (i.e., matches to an intervening stimulus), indicating that these repetition-induced reductions are not necessarily dependent on goal-related processes. Indeed, repetition suppression is observed even when the primate is not actively engaged in a task (e.g., during passive fixation of visually presented stimuli or when the animal is under anesthesia).

As noted by Wiggs and Martin, accumulating evidence across extant single-unit studies of repetition suppression points to similarities between this neural phenomenon and the behavioral manifestation of priming. First, repetition suppression appears to generalize across retinal locations and is observed following changes in stimulus size, indicating that these reductions, as with behavioral perceptual priming, derive from higher level representations rather than low-level visual representations. Second, repetition suppression is stimulus-specific rather than a general change associated with performance of a task. Third, suppression effects have been observed following long temporal lags between the two presentations of a stimulus, surviving lags of 24 hr (the longest tested) and the presentation of more than 100 intervening stimuli. Fourth, repetition suppression appears to be intact even when operations thought to be dependent on medial–temporal structures are impaired. For example, repetition suppression is intact when monkeys are administered scopolamine, which is thought to hinder declarative memory operations.

One account of repetition suppression is that it reflects a tuning of the neural system such that a smaller population of neurons is activated during the repeated presentation of a stimulus relative to its initial presentation. This trimming of the neuronal representation of a stimulus has been posited to reflect a sharpening within long-term memory due to the initial processing of the stimulus. This sharpening may give rise to more efficient neural computations during subsequent stimulus processing, and this increased neural efficiency may yield the behavioral manifestations of priming (decreased response latencies and increased accuracy). Although additional evidence is required, this putative link between repetition suppression in the nonhuman primate and behavioral and neural priming effects in humans (see later discussion) is theoretically enticing.

B. Functional Neuroimaging

In the human primate, direct recording of single-unit activity is constrained for obvious reasons. However,

investigation of the neural correlates of priming in the human brain has dramatically advanced over the past decade partially due to the application of more recently developed functional neuroimaging methodologies. Two principal neuroimaging methods—positron emission tomography (PET) and functional magnetic resonance imaging (fMRI)—have been adopted to explore the relation between neural and cognitive function, including studies of priming and the brain. As is reviewed elsewhere, PET and fMRI provide indirect measures of neural activity by indexing changes in regional cerebral blood flow (PET) or blood-oxygenation levels (fMRI) that are correlated with changes in neural firing. These techniques have proven to be powerful because they provide a means of determining structure–function relations in the healthy human brain with relatively high spatial resolution. However, unlike electrophysiological and magnetoencephalographic approaches, these methods do not provide millisecond temporal resolution as they depend on a temporally sluggish hemodynamic response.

1. Perceptual and Lexical Priming

Over the past decade, neuroimaging has been adopted to investigate the neural correlates of multiple forms of nondeclarative memory, including phonological, lexical, and conceptual priming. The most frequent observation across PET and fMRI studies of priming is that the specific brain regions that are recruited during initial (unprimed) stimulus processing demonstrate decreased activation during repeated (primed) stimulus processing. For example, in the early 1990s, Squire and colleagues reported the first neuroimaging observation of priming-related reductions in neural activity. In this landmark PET study, neural activations during the performance of two visual word-stem completion conditions were compared. In the primed condition, subjects were presented word stems that could be completed with words that had been encountered visually prior to PET scanning, whereas in the unprimed condition the stems could not be completed with a previously encountered item. As in behavioral studies of word-stem completion priming, here subjects were faster at completing the primed relative to the unprimed stems, and primed stems were completed more often with target items than were unprimed stems. Functional neuroanatomically, the PET data revealed a neural correlate of these behavioral priming effects: there was less activation in extrastriate visual cortex during primed relative to unprimed stem completion.

Subsequent PET and fMRI studies of perceptual priming have extended this initial observation of reduced posterior cortical activation during primed stimulus processing. As with visual stem completion priming, reduced extrastriate activation accompanies primed relative to unprimed visual word-fragment completion. Moreover, decreases in activation have been observed in fusiform and inferior temporal regions during repeated relative to initial processing of visually presented objects. For example, fMRI work in our laboratory has revealed that, when subjects attend to a novel visually presented object, there is greater activation in bilateral fusiform and inferior temporal cortices relative to when they attend to an object that has been encountered recently. However, left and right inferior temporal regions do not demonstrate identical priming patterns. As Fig. 2 illustrates, whereas both left and right fusiform gyri demonstrate priming reductions during repeated relative to initial object processing, the right fusiform gyrus is more sensitive to the recapitulation of specific perceptual details than is the left fusiform gyrus, suggesting a differential role for the two hemispheres in visual object priming.

Posterior cortical activation reductions during repeated stimulus processing have been interpreted as neural correlates of visual repetition priming. As with behavioral priming, these changes in neural firing reflect item-specific mnemonic effects rather than general task learning, because they derive from a specific prior encounter with an item. Moreover, these neural priming effects survive filled retention delays of multiple minutes, indicating that they depend on long-term memory representations. It has been hypothesized that these neural priming effects reflect the facilitated reprocessing of the visual form of words or the structural characteristics of objects as a consequence of nondeclarative memory for prior perceptual processing. These activation reductions resemble the phenomenon of repetition suppression observed in electrophysiological studies with nonhuman primates. As with repetition suppression, neuroimaging demonstrations of priming-related activation reductions are consistent with a representational sharpening mechanism, where the neural representation of an item becomes sparser with experience. This tuning may result in only a subset of the neurons that are initially involved in processing the perceptual properties of the item being engaged during subsequent reprocessing of these perceptual attributes. Thus, one possibility is that the reduction in activation observed in PET and fMRI priming studies reflects a

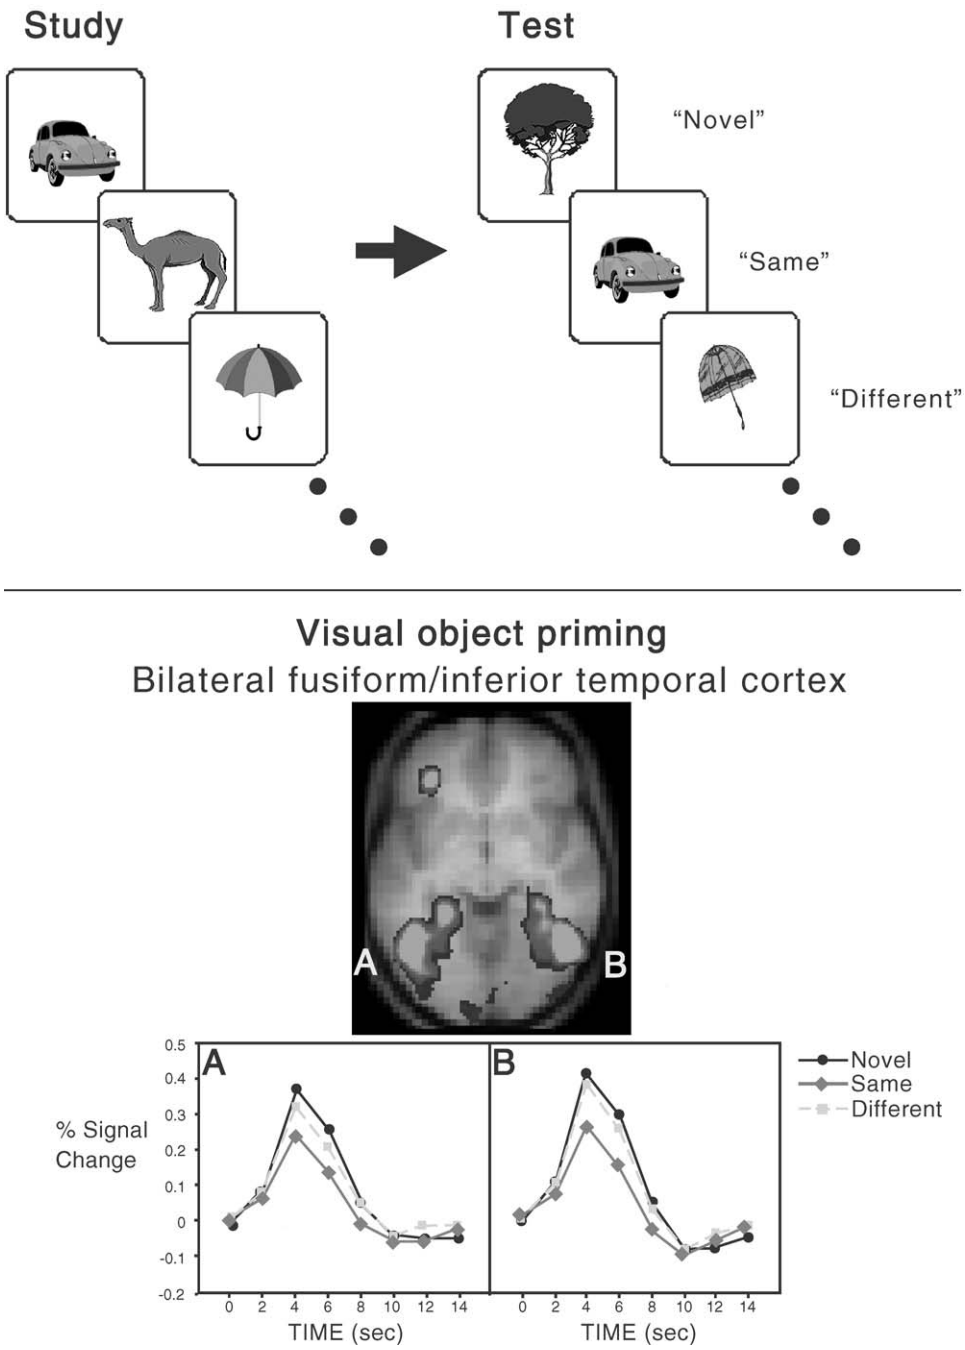

Figure 2 Repetition priming for objects is associated with reduced activation in fusiform and inferior temporal cortices. At top is the task paradigm illustrating the relation between study and test exemplars for the novel, same repetition, and different repetition conditions. At bottom are statistical activation maps showing left (A) and right (B) fusiform–inferior temporal regions that demonstrated reduced activation for both types of repetition trials. The plotted measures of neural activation in these regions revealed that, whereas there was reduced activation in bilateral fusiform regions for both same and different exemplar repetition trials (relative to novel trials), the right fusiform was particularly sensitive to study–test perceptual match (as revealed by very modest priming in this region for different repetition items).

decrease in the number of neurons engaged during repeated stimulus processing. Alternatively, it is possible that the number of neurons engaged does not change, but rather there is a decrease in either the rate or duration of firing of a static population of neurons with repetition.

Neuroimaging has begun to highlight the neural correlates of priming deriving from more abstract, nonperceptual lexical representations. The observation in Fig. 2 that priming in the left fusiform cortex is less sensitive to changes in perceptual detail between the initial and repeated encounter of an object suggests that priming in this region may derive from more abstract, nonvisual representations. Other fMRI evidence converges with this interpretation. For example, activation reductions in a very similar left fusiform–inferior temporal region (as well as in left inferior frontal cortex) have been observed in both visual-to-visual and auditory-to-auditory word-stem completion priming. The colocalization of visual and auditory word priming in a region that also demonstrates priming across perceptually distinct objects that share a common lexical code indicates that priming in this region likely does not reflect (or solely reflect) the recapitulation of visual processing. Rather, left fusiform priming may at least partially derive from facilitated access to abstract lexical representations as a consequence of prior access to these representations. This interpretation is consistent with evidence from human neuropsychological and depth-electrode recording studies, which point to a role for the basal temporal region in lexical processing.

2. Conceptual Priming

PET and fMRI studies have also elucidated the nature of experience-induced changes in neural activation during comparatively more conceptually driven tasks, such as judging whether a presented word refers to an abstract or concrete entity or generating a semantic associate of a stimulus. Considerable evidence indicates that, relative to baseline tasks, semantic processing tasks, which typically require access to and evaluation of both semantic and phonological stimulus attributes, are associated with activation in the posterior and anterior left inferior prefrontal cortices (LIPCs). Posterior LIPC activation has been shown to be more sensitive to the processing of phonological or lexical codes associated with a stimulus, whereas anterior LIPC activation has been shown to modulate as demands on semantic attribute processing vary.

Both posterior LIPC [at or near Brodmann's areas (BA) 44/6] and anterior LIPC (at or near BA 45/47) demonstrate decreased activation during repeated relative to initial semantic processing of a stimulus. In the first neuroimaging report of repetition-induced changes in LIPC activation, Raichle and colleagues observed greater LIPC activation during the initial (unpracticed) generation of semantic associates of nouns relative to that found for highly practiced generation of the associates (participants had previously practiced generating the associates nine times). Subsequent studies extended this result to different semantic processing paradigms and various classes of stimuli and demonstrated that LIPC priming effects can be observed at the individual subject level even following a single presentation. For example, as Fig. 3 illustrates, reduced LIPC activation accompanies semantic classification of a word that was primed by a single prior classification of the item. Whereas these reductions decline with the temporal delay between the initial and repeated presentations of an item, nevertheless they appear to be long-lasting, having been observed even after 24 hr delays (the longest delay tested). Importantly, although only limited evidence is currently available, initial investigations of the status of LIPC priming in amnesic patients indicate that amnesics also demonstrate repetition-related reductions in frontal cortex. These latter data are consistent with the hypothesis that these changes reflect nondeclarative memory.

Available data do not directly implicate a specific underlying mechanism through which prior experience results in decreased LIPC activation. However, a number of theorists have posited that these reductions reflect decreased demands on prefrontally mediated control mechanisms due to nondeclarative memory. Specifically, activation in inferior prefrontal cortex during conceptual processing tasks may reflect directed attention to task-relevant stimulus features (e.g., those semantic features that enable the semantic classification of a word). This allocation of attention to task-relevant features may result in the subsequent priming of these features. During reprocessing of the stimulus, implicit memory representations for the initial processing may serve to make the task- or goal-relevant features more readily available than task-irrelevant features. This greater accessibility of task-relevant features would reduce the computational demands on prefrontally mediated attentional or biasing operations, thus resulting in decreased LIPC activation and faster and more accurate behavioral responses. Thus, neural priming effects may reflect

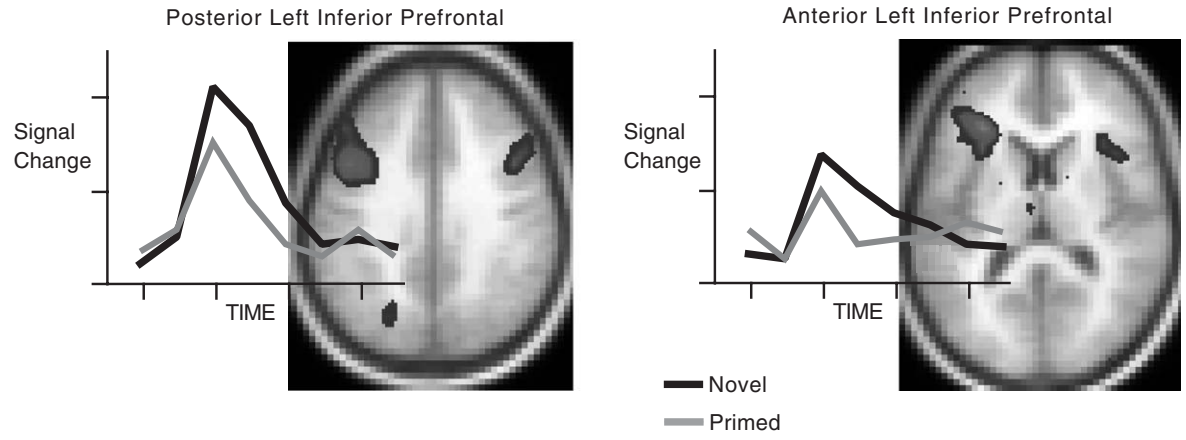

Figure 3 Conceptual repetition priming is associated with reduced activation in left frontal regions, including posterior and anterior left inferior prefrontal cortices. Displayed are the posterior and anterior LIPC regions typically observed to demonstrate greater activation (fMRI signal change) during initial (novel) semantic classification of a stimulus relative to repeated (primed) classification of the same stimulus.

enhanced efficiency in accessing, selecting, and/or evaluating target semantic knowledge necessary to achieve the goal of semantically categorizing a word, with this efficiency deriving from increased availability of the target attributes as a result of earlier processing. From this perspective, priming tends to yield a stereotyped or sparser reprocessing experience because the same semantic features are more likely to be processed during the subsequent encounter with a stimulus as were processed during the initial encounter.

C. Event-Related Potentials

A complementary approach for investigating the neural correlates of cognition in humans is the recording of event-related potentials (ERPs). ERPs, which are recorded using scalp electrodes, reflect changes in neural electrical activity (EEG) that are time-locked to the onset of a specific event. Within the context of priming paradigms, these events typically consist of the presentation of a novel or repeated stimulus. ERPs are complementary to PET and fMRI as they offer high temporal resolution (on the order of milliseconds) but poor spatial resolution. The comparison of ERPs elicited by two different experimental conditions provides measures of if and when (in terms of poststimulus onset time) the underlying neural activity associated with the conditions diverges.

A number of ERP studies have begun to unambiguously identify some of the neural signatures of priming. Common across most extant studies is the recording of ERPs during the performance of implicit or indirect memory tasks and the comparison of ERPs elicited during the processing of repeated items to ERPs elicited during the processing of novel items. Such comparisons provide candidate electrophysiological responses (ERP repetition effects) that might reflect the neural signatures of priming. The inference that a repetition effect reflects priming rather than incidental or intentional explicit remembrance can be drawn when the repetition effect varies with task parameters known to influence priming but not explicit memory (e.g., study–test modality).

Repetition effects often present as a more positive-going shift in ERPs during the processing of repeated relative to novel items (although reduced ERP amplitudes have also been observed during item repetition). For example, in the late 1990s, Paller and colleagues explored the neural correlates of visual word priming by manipulating the perceptual match between the initial and repeated presentation of a word. In this study, words initially were visually presented either in a whole-word format (e.g., APPLE) or in a letter-by-letter format (e.g., exposing each of the letters in a sequential manner: AP__, followed by __P__, __L__, and __E). During the critical poststudy lexical decision test, all words were presented in a whole-word format. The results revealed an ERP repetition effect at occipital electrode sites with onset approximately 400–500 msec poststimulus. Critically, this effect was greatest for studied items that were perceptually identical at study and test (whole-word format items) and was dramatically diminished for items studied in a

letter-by-letter format, thus revealing an effect of the match between study–test perceptual form. Interestingly, other data indicate that ERP repetition effects occur for visually integrated or unitized stimuli (e.g., words, pronounceable nonwords, and pictures) but not for stimuli that lack a higher level unitized representation (e.g., orthographically illegal nonwords and meaningless pictures).

Diminished ERP repetition effects as a result of a mismatch between study–test sensory modality also have been observed at other electrode sites and at earlier temporal latencies. Specifically, Rugg and colleagues reported more modest repetition effects occurring around 200–400 msec poststimulus over frontal and temporal scalp sites when the study–test modality of words was auditory–visual relative to visual–visual. These effects indicate that ERP-indexed neural activity can reflect sensitivities to both repetition and study–test sensory similarity, suggesting that the effects derive from perceptual repetition priming.

Although accurate source localization is difficult with ERP, the observation of ERP repetition effects in occipital and temporal regions broadly converges with visual word-form priming in extrastriate and temporal cortices, as indexed with PET and fMRI, and with impaired visual word-form priming following right occipital resection. Further linkage between these effects comes from a combined neuropsychological–ERP investigation of visual word priming on a lexical decision task, where control subjects and patients with focal lesions in right temporal–occipital cortices were compared. Relative to controls, the repetition-related positive ERP deflections and reaction time priming effects were reduced in the patients, especially when there was a moderate-to-long lag between the initial and repeated occurrences of a word. Collectively, these data further implicate right occipital–temporal cortices in visual word-form priming.

In contrast to perceptual priming, unambiguous ERP indices of conceptual priming remain elusive. The principal challenge for obtaining such evidence is the fact that behavioral task manipulations, such as varying the extent of conceptual elaboration at encoding, often have similar effects on both conceptual priming and explicit remembrance. Given the difficulty of differentially affecting conceptual priming and explicit memory and the absence of relevant ERP data from amnesic patients, researchers have yet to determine whether ERP repetition effects on implicit or indirect tests of conceptual processing reflect priming or explicit contamination. For example, ERP repetition effects have been observed using a semantic generation paradigm previously implemented in PET and fMRI studies of item repetition. As discussed earlier, PET and fMRI studies have revealed that repeated generation of a verb associated with a noun yields reduced left frontal and temporal activation relative to initial generation of the associate. In a subsequent ERP study, it was observed that, relative to ERPs elicited by word reading, ERPs elicited by novel semantic generation were more positive in left frontal regions at approximately 250 msec poststimulus onset and in left temporal–parietal regions at approximately 700 msec poststimulus onset. Broadly consistent with the neuroimaging literature, these ERP repetition effects were reduced during repeated semantic generation. However, repeated semantic generation also was associated with an additional response over right anterior frontal regions previously observed in PET, fMRI, and ERP studies of explicit retrieval, suggesting possible explicit contamination. (To date, no such increase has been reported in PET and fMRI studies of conceptual priming using this paradigm, although similar frontal activations have been reported in cross-modal stem-completion and cross-exemplar object-decision priming paradigms; it is possible that such activation reflects involuntary explicit memory). Although behavioral data indicate that amnesics demonstrate intact behavioral priming in the repeated semantic generation paradigm, in the absence of any ERP data clearly demonstrating that these repetition-related ERP reductions are dissociable from explicit memory effects, it is not possible to conclude that such ERP changes reflect conceptual priming. Thus, unambiguous ERP signatures of conceptual priming await further investigation. Such investigations will ultimately allow an increased understanding of the neural networks and processes that support facilitated performance, not only as a result of prior perceptually based processing of specific stimuli but also from prior conceptually based processing involving the retrieval, manipulation, and representation of the meaning of specific stimuli.

VI. CONCLUSIONS

The past four decades have witnessed a multileveled and ever-deepening convergence of findings that provide insight into the brain processes that subserve the apparently simple manner in which a repeated encounter with a stimulus enhances subsequent processing. Behavioral outcomes documenting increased

accuracy and/or increased speed of response to previously encountered words, objects, faces, and other stimuli may mesh with electrophysiological findings suggesting that repeated presentation of a stimulus may give rise to a form of representational tuning or sharpening, wherein the stimulus is represented in an increasingly sparse or efficient manner. Enhanced neural efficiency is also suggested by findings from functional brain imaging, showing reduced activation in brain regions that are initially involved in stimulus processing and including both modality-specific perceptual processing regions (especially visual word and object processing in, for example, regions of occipitotemporal cortex) and more abstract conceptual processes (e.g., in evaluating stimuli for classification on the basis of meaning, particularly in left prefrontal cortex). However, the precise interrelations between perceptual and conceptual processing still remain somewhat unclear, and refinement and articulation of subcomponents of processing in the conceptual domain are still necessary.

Theoretical analyses have likewise yielded increasing convergence. Although analyses from the perspective of perceptual or response bias underscore the notion that forms of facilitation may not necessarily or exclusively reflect increased "sensitivity," key notions advanced from the transfer appropriate processing perspective are routinely incorporated into task analyses and the interpretation of dissociations across tasks and populations. Theoretical accounts positing the activation of preexisting lexical–semantic representations, separable memory systems, and components of processing all—in different ways—recognize the need for further subdivision and acknowledge the possible interplay and contribution of any one neural or representational component to multiple tasks. The upcoming decades, particularly with further evidence drawn from *conjunctive application* of neuroimaging, neuropsychological, behavioral, and electrophysiological approaches, will continue to increase our understanding of the brain and different forms of long-term memory, including instances where we may benefit from or be influenced by the past—primed for responding—without intentional remembrance.

Prion Diseases

HANS A. KRETZSCHMAR
Ludwig-Maximilians-Universität, München

GLOSSARY

BSE Bovine spongiform encephalopathy.

CJD Creutzfeldt–Jakob disease.

FFI Fatal familial insomnia, a hereditary human prion disease.

(n)vCJD New variant of Creutzfeldt–Jakob disease.

prion Infectious agent of prion diseases, derived from *pro*teinaceous *in*fectious particle.

Prnp The prion protein gene of mammals.

***Prnp*$^{0/0}$** Ablation of *Prnp* (in *Prnp* knockout or *Prnp*-null mice).

PRNP *The human prion protein gene.*

PrP^{C} Cellular isoform of the prion protein. PrP^{C} is a normal protein expressed on the surface of many cell types of mammals (and birds). It is a copper-binding protein whose exact function is not known.

PrP^{Sc} Scrapie isoform of the prion protein. This protein shows increased resistance to digestion with proteinase K. It is closely associated with infectivity, and in terms of the prion hypothesis it is part of the infectious agent, the prion.

PrPres Proteinase K (pK) resistant form of PrP derived *in vitro* from PrP^{C}. (PrPres to date has not been shown to be infectious. Unfortunately this term is also used by some groups to denote the pK-resistant PrP found in infectious brain tissue, thus creating confusion with PrP^{Sc}.)

scrapie Prion disease naturally occurring in sheep.

TSE Transmissible spongiform encephalopathy, often used as a synonym for prion disease.

Prion diseases are rapidly progressing, invariably fatal, neurodegenerative diseases associated with dementia and neurological deficits such as ataxia, visual disturbances, or myoclonus. Histologically, nerve cell loss, spongiform change, and various forms of prion protein deposits are found in the brain. They are a heterogeneous group of diseases that can be acquired, hereditary, or idiopathic. All prion diseases are experimentally transmissible with a relatively long incubation time and a comparatively short clinical duration. Human prion diseases were shown to be transmissible after intracerebral inoculation of brain tissue from kuru and CJD patients into chimpanzees in 1966 and 1968. The nature of the infectious agent of prion diseases such as Creutzfeldt–Jakob disease (CJD) in humans, scrapie in sheep, and BSE in cattle has been the subject of numerous studies for many years. The assumption, which seemed natural in the early 1970s, that the agent must be a slow virus or a virino was challenged by the failure to detect viral nucleic acids and by the resistance of the agent to radiation, nucleases, and other reagents that damage nucleic acids. In contrast, infectivity was closely associated with a protein, PrP^{Sc}, and if any nucleic acid is to be associated with the infectious agent it cannot contain more than 50 nucleotides. The term "prion" was proposed by Stanley Prusiner to distinguish the infectious pathogen from viruses and viroids. Albeit not formally proven, the prion hypothesis is supported by many lines of evidence. Prions were originally defined as small, proteinaceous infectious particles that resist inactivation by procedures that modify nucleic acids, and they have been redefined as a proteinaceous particle that lacks nucleic acid (Prusiner, 1998). The change in conformation of a normal protein encoded by the host genome, the cellular isoform of the prion protein (PrP^{C}), into an altered

isoform, the scrapie isoform of the prion protein (PrP^{Sc}), is the core of this hypothesis. The term PrP^{Sc} is used for the isoform of the prion protein that is closely associated with infectivity and that is part and parcel of the prion. Whether PrP^{Sc} is the only necessary constituent of prions is at present unknown. According to the prion hypothesis, the infectious agent, the prion, would require PrP^{C} molecules for its propagation, and organisms devoid of PrP^{C} should not be susceptible to prion diseases. Indeed, this has been shown experimentally by the resistance of PrP gene knockout mice ($Prnp^{0/0}$ mice) to scrapie.

I. THE PRION PROTEIN

A. PrP Structure and PrP Genes

Human PrP^{C} is a glycoprotein of 253 amino acids before cellular processing. There is an 85–90% homology to prion proteins of other mammalian species. PrP^{Sc} is a membrane protein expressed mainly in neurons, but also in astrocytes and a number of other cells. It has an N-terminal signal sequence of 22 amino acids, which is cleaved off the translation product. Twenty-three terminal amino acids are removed when glycosylphosphatidylinositol (GPI) is attached to serine residue 230. Mature PrP^{C} is attached to the cell surface by this GPI anchor and undergoes endocytosis and recycling. It seems, however, that PrP may exist in alternative membrane topologies (^{ctm}PrP and ^{ntm}PrP), whose implications for the function of PrP^{C} and its role in pathogenesis are just beginning to be elucidated. There are two N-glycosylation sites that are glycosylated differently in different human CJD variants. The N-terminal moiety of the protein contains an octapeptide repeat, (PHGGGW-GQ) $\times$ 4, which has been suggested to function in copper binding.

Whereas PrP^{C} is found on the surface of many cell types in all mammals and birds studied so far, PrP^{Sc} is generated from PrP^{C} in a posttranslational process and is closely associated with infectivity. In terms of the prion hypothesis, it is part and parcel of the infectious agent, the prion. NMR structural studies have shown that the C-terminal half of PrP^{C} contains a two-stranded antiparallel β-sheet (S1 and S2) and three α-helices, whereas the N-terminal moiety is thought to have no definite structure in aqueous solution. PrP^{C} and PrP^{Sc} seem to differ mainly in their folded structures. PrP^{C} purified from hamster brain consisted of 42% α-helical and only 3% β-sheet structure, whereas PrP^{Sc} purified from scrapie-infected hamster brain is composed of 30% α-helix and 43% β-sheet. PrP^{Sc} shows increased protease resistance, is insoluble in aqueous solution, and tends to form fibrils that show birefringence after binding of Congo red.

The human PrP gene (*PRNP*) is located on the short arm of chromosome 20. It has a simple genomic structure and consists of two exons and a single intron 13 kb in length. The entire protein-coding region is located in exon 2. In families with inherited prion diseases, a large number of different point mutations and insertion mutations have been described in the open reading frame of *PRNP* (Fig. 1). The insertional mutations are situated in the N-terminal half of the protein in an octapeptide repeat region, whereas the point mutations cluster in the central and C-terminal regions of the protein.

The common polymorphism at amino acid position 129 of the prion protein, where humans carry a methionine (M) or valine (V), clearly influences susceptibility to the sporadic and iatrogenic types of prion diseases and, furthermore, determines in part the phenotype of the sporadic as well as of some inherited prion diseases. Several studies have revealed a marked over-representation of homozygotes (mainly for methionine) at this position in cases of sporadic CJD compared to the normal population. CJD homozygotes at codon 129 also show a higher susceptibility to iatrogenic CJD and a shorter incubation time as well. There is also a strong correlation of codon 129 genotype and clinicopathological phenotype (see later discussion).

A *Prnp*-like gene was identified in the mouse genome. This gene, *Prnd*, is located 16 kb downstream of *Prnp*, and it encodes a protein, named Dpl (Doppel, German for double), that is composed of 179 amino acids. Dpl has a 25% identity with the carboxy-terminal two-thirds of PrP^{C}, but it lacks the N-terminal copper-binding octarepeat and the central region between amino acids 114 and 121 that is needed for prion replication. It is expressed at high levels in testis, at lower levels in other organs, and at very low levels in the brain of wild-type mice. It is overexpressed in certain $Prnp^{0/0}$ mouse lines lacking the entire PrP-coding region and 5′- and 3′-flanking regions. In these animals, overexpression of Dpl leads to ataxia that can be cured by expression of PrP from a cosmid introduced containing *Prnp*. The physiological function of Dpl and its possible role in prion disease are unknown.

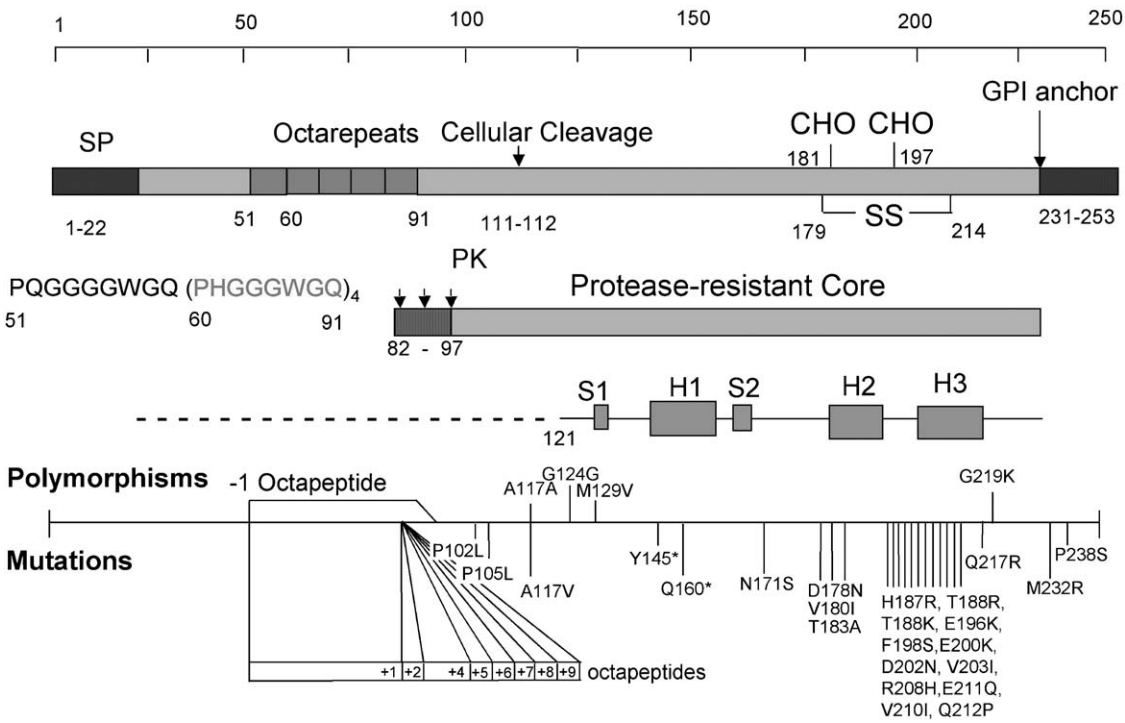

Figure 1 Structural features of the human prion protein. Shown are the cellular isoform of PrP (PrP^C), the protease-resistant core of PrP^{Sc}, and secondary structural features, as well as mutations and polymorphisms of the prion protein gene (*PRNP*). The numbers indicate amino acid residues. Abbreviations: SP, signal peptide; GPI, glycosylphosphatidylinositol anchor; CHO, glycosylation sites; S1, S2, β-sheets; H1, H2, H3, α-helices; PK, proteinase K digestion sites. The dotted line indicates the unstructured N-terminus.

B. The Physiological Function of PrP^C

By using conventional biochemical and molecular biological approaches, it has not been possible to identify a binding partner or a functional role of PrP^C. An attempt to unravel the physiological role of PrP^C in the course of infection and its normal function was undertaken by destroying the murine PrP gene (*Prnp*) by homologous recombination ($Prnp^{0/0}$ mice). $Prnp^{0/0}$ mouse lines proved to be resistant to infection with mouse-adapted scrapie. Therefore, the presence of PrP^C is necessary for agent replication. Also, neuronal loss in prion disease seems to depend on the expression of PrP^C, as shown by two different experimental approaches using transplants of normal mouse brain in $Prnp^{0/0}$ mice or primary neuronal cultures derived from $Prnp^{0/0}$ mice.

$Prnp^{0/0}$ mice appeared to be behaviorally normal. However, several subtle phenotypes were detected. Electrophysiological examination of $Prnp^{0/0}$ mice revealed slight changes in hippocampal long-term potentiation (LTP) and $GABA_A$-receptor-mediated responses. Whereas changes in LTP were confirmed in two $Prnp^{0/0}$ lines, other findings were seen in only one of the $Prnp^{0/0}$ lines created by different research groups. There is, however, morphological, biochemical, and physiological evidence that PrP^C is involved in synaptic transmission. PrP^C is known to be transported axonally to synaptic boutons, where it was localized immunohistochemically and biochemically in normal brains and where PrP^{Sc} was identified in scrapie-infected brain tissue. PrP^C influences the synaptosomal calcium concentration and calcium-dependent potassium channels. Two further phenotypes have been reported. In two of the three $Prnp^{0/0}$ mouse lines there were subtle changes in the circadian rhythm, and in the third line there was loss of Purkinje cells in aged animals.

Because the N-terminal octarepeat, (PHGGGWGQ) $\times$ 4, of recombinant PrP shows cooperative binding of 5–6 Cu(II) ions in the micromolar range compatible with estimates for copper concentrations in the synaptic cleft, comparative studies of wild-type and $Prnp^{0/0}$ mice were undertaken to investigate the

hypothesis of functional synaptic Cu(II) binding to PrP^C. Biochemical preparations of synaptosomes showed a 50% reduction in copper concentration in *Prnp*$^{0/0}$ animals. In brain slice preparations, synaptic transmission is severely disturbed by the addition of excess copper in *Prnp*$^{0/0}$ animals. Synaptic transmission in the presence of H_2O_2, which is known to be decomposed to highly reactive hydroxyl radicals in the presence of iron or copper, was found to correlate with the level of PrP^C expression in the presynaptic neuron. Further evidence of a role for PrP^C in cerebral copper metabolism comes from the finding that the activity of the copper-dependent cytoplasmic enzyme Cu,Zn superoxide dismutase (Cu,Zn-SOD) is significantly reduced in the brains of *Prnp*$^{0/0}$ mice.

C. The Conversion Process of PrP^C to PrP^{Sc}

Conversion of PrP^C to PrP^{Sc} seems to be a late posttranslational process, which in scrapie-infected cells occurs after PrP^C has reached its normal location on the cell surface or even later during endocytosis. Why this is such a rare event and how PrP^{Sc} triggers the conversion of PrP^C are not understood. In the nucleation model, PrP^C and PrP^{Sc} are in equilibrium. PrP^{Sc} is stable only when it adds onto a seed or PrP^{Sc} aggregate, a process that has been compared to crystal formation. The spontaneous formation of an initial PrP^{Sc} aggregate (seed) would be a very rare event. Once the seed has been formed, the ensuing addition of PrP monomers could follow at a fast rate. In contrast, the refolding model holds that PrP^C is unfolded and that the conversion process consists of a refolding of the molecule under the influence of a PrP^{Sc} molecule. In this process, a high activation energy barrier must be overcome and chaperones and an energy source may be required. The two hypotheses, which have also been named the Lansbury and the Prusiner mechanisms, are by no means mutually exclusive.

The conversion process has also been studied in cell-free conditions *in vitro*. Incubation of ^{35}S-labeled hamster PrP^C with a 50-fold excess of PrP^{Sc} from scrapie-infected hamster brain resulted in the conversion of some labeled protein into proteinase K (pK) resistant PrP (PrPres). Because of the large surplus of infectivity associated with PrP^{Sc} necessary to initiate the conversion process, this experimental approach has not been conducive to showing that the abnormal PrP formed *in vitro* (PrPres) is infectious. PrPres, therefore, is not necessarily identical to PrP^{Sc}. A surprising finding was that this cell-free conversion process was species-specific and correlated well with known barriers to cross-species transmission in animals. Thus, PrP^C from mouse was readily convertible to protease-resistant PrPres by murine PrP^{Sc} but poorly convertible by bovine PrP^{Sc} and vice versa.

II. PRION PATHOGENESIS

A. Neuroinvasion

Acquired prion infection such as scrapie is an oral infection; iatrogenic CJD may be peripherally acquired. For invasion of the central nervous system, two possible routes are discussed: (1) transport in blood cells, possibly after amplification of prions in the lymphoreticular system (LRS), and (2) transport in peripheral nerves. Possibly a combination of amplification in the LRS and transport by peripheral nerves is what actually happens in acquired prion disease. The importance of the LRS has been known for a long time.

In experimentally infected mice, infectivity has been shown in the spleen 4 days after intraperitoneal and even after intracerebral inoculation. In these cases, prion replication in the spleen precedes intracerebral replication even after intracerebral inoculation. In nvCJD, PrP^{Sc} accumulates in lymphoid tissues of the tonsils and in the appendix, in one case 8 months before the outbreak of clinical disease. The nature of the cells supporting prion replication in the LRS has not been established beyond doubt. Follicular dendritic cells (FDCs) would be prime candidates. Indeed, PrP^{Sc} accumulation has been observed in these cells. In mouse scrapie, functional B lymphocytes are necessary for neuroinvasion, but PrP^C expression in these cells is not required. B lymphocytes may indirectly influence neuroinvasion by allowing the development of mature spleen FDCs as sites of agent replication. Because lymphocytes do not normally cross the blood–brain barrier, it seems questionable, however, whether immune cells are sufficient to transport the agent from the periphery to the CNS.

Prion replication in the CNS first takes place in areas that relate to the site of peripheral inoculation or oral uptake. This implies that the agent spreads along the peripheral nervous system. The importance for neuroinvasion of PrP^C positivity of peripheral nerves has been demonstrated in experiments where transgenic

mice expressing PrP^C only in neurons developed scrapie after oral or intraperitoneal infection with high doses of the infectious agent. A scenario in which the agent is first transported to FDCs by mobile immune cells, where it amplifies and spreads to the peripheral nervous system, also seems possible and may be of particular importance in cases of low-dose infection.

B. Neuronal Cell Death

Two basic types and mechanisms of cell death have been described in the brain and other organs: necrosis and apoptosis. Necrosis often results from severe and sudden injury and leads to rapid cell lysis and a consecutive inflammatory response. In contrast, apoptosis proceeds in an orderly manner following a cellular suicide program involving active gene expression in response to physiological signals or types of stress. It is usually not accompanied by an inflammatory response. The *in situ* end-labeling technique (ISEL), which is based on the incorporation of labeled nucleotides in fragmented DNA by terminal transferase, is thought to be highly characteristic of apoptosis and has been used to investigate neuronal cell death in a scrapie model in the mouse. ISEL revealed nuclei containing fragmented DNA in the granule cell layer of the cerebellum in mice infected with the 79A strain of scrapie from day 120 onward. The number of labeled cells increased from days 120 to 150 and was highest in terminally ill mice (day 166). Electron microscopy of specimens from the cerebellum of terminally ill mice identified cells that showed homogeneously condensed chromatin, dark cytoplasm, membrane blebbing, and, occasionally, nuclear fragmentation, all of which are morphological changes characteristic of apoptosis. Two mechanisms are discussed as causing neuronal cell death in prion diseases: loss of function of PrP^C and gain of function of PrP^{Sc}. Whereas some of the electrophysiological data in $Prnp^{0/0}$ mice were interpreted as indicating that progressive loss of PrP^C in prion disease might lead to impaired synaptic transmission and neuronal cell death, other experiments showed that PrP^{Sc} has toxic effects on neurons in primary cell culture. Arguing that this toxic effect could reside in a part of the protein that is deposited in brain tissue in human prion disease, Forloni and co-workers identified a peptide corresponding to human PrP amino acid residues 106–126 (PrP106–126), which elicited maximal neurotoxic effects in rat hippocampal cultures. The involvement of different cell types present in mixed cerebellar cultures in the neurotoxic mechanism of PrP106–126 was investigated by using L-leucine methyl ester (LLME), which significantly reduces the number of microglia in mixed cultures. After this treatment, 10-day administration of PrP106–126 was no longer toxic to cerebellar cells. When cerebellar cells from $Prnp^{0/0}$ mice were treated with PrP106–126, the peptide showed no toxic effect. These experiments have also been performed with PrP27–30, the protease-resistant core of PrP^{Sc} isolated from scrapie-infected hamster brains. The results show that cellular expression of PrP^C and the presence of microglia are necessary for the neurotoxicity of PrP27–30 and PrP106–126 *in vitro*. This interpretation was confirmed by experiments using normal brain tissue transplanted into $Prnp^{0/0}$ mice. In these animals, only $Prnp^{+/+}$ cells were prone to the toxic effect of PrP^{Sc}.

To investigate the neurotoxic effect of microglia, the supernatants of microglial cultures were assayed for nitrite production, and a high increase in production after the application of PrP106–126 was found. The increased nitrite most likely is a stable reaction product of sort-lived superoxide radicals and nitric oxide, which can be produced by microglia to induce oxidative stress. This result strongly suggests that PrP106–126 acts directly on microglia and gives strong support to the notion that microglia induce neuronal death by oxidative stress as a result of PrP106–126 stimulation.

As far as the role of microglial activation *in vivo* is concerned, it has been well-documented that there is an intense microglial reaction in mice terminally ill with scrapie, which corresponds to the pattern of neurodegeneration. The question of whether microglial activation is secondary to neuronal cell death or whether microglial activation precedes neuronal cell death and is possibly involved in inducing neuronal cell death has been addressed in a large time course study using three different strains of scrapie in mice. It appeared that microglial activation was present early in the incubation period in all models studied. The pattern of microglial activation closely paralleled the pattern and time course of PrP^{Sc} accumulation. Microglial activation clearly preceded apoptotic neuronal cell death in all strains studied. Furthermore, quantitative analysis of microglial activation and cell death in the cerebellum showed that the time course and extent of neuronal cell death correlated with the time course of microglial activation. Taken together with the data derived from cell-culture studies, this indicates that

microglial activation is also involved in mediating PrP^{Sc} toxicity *in vivo*.

III. THE PRION DISEASES

A. Animal Prion Diseases

Scrapie, a disease that naturally occurs in sheep and goats, has been known for more than 200 years and was the first prion disease to be shown to be infectious in 1936 by two French scientists, Cuillé and Chelle. Affected sheep clinically show abnormal behavior, such as excessive scraping as well as trembling and ataxia and other motor disturbances. There are no known hereditary prion diseases in animals; however, allelic variations in the ovine PrP^{C} sequence exert a strong influence on susceptibility to natural and experimental scrapie. Although the disease has been known for centuries and its infectious nature was recognized more than 60 years ago, the exact mode of natural transmission is not known. Maternal transmission seems to be an established fact, but there are also reports of transmission by keeping sheep on pastures that were previously occupied by scrapie-infected flocks. Scrapie is experimentally transmissible to many mammalian species. Epidemiological studies show that scrapie apparently is not transmissible to humans by the oral route.

BSE is a disease of cattle that was first described in Great Britain in 1986. It is estimated that since then almost 1 million animals have been infected. The mean incubation time is about 5 years; therefore, most animals did not manifest disease because they were slaughtered at age 2 or 3 years. Nonetheless, more than 160,000 affected animals were diagnosed and killed over the years. It is now clear that BSE was spread by feeding cattle with contaminated meat and bone meal (MBM) prepared from the offal of sheep, cattle, and pigs. However, the origin of BSE is still obscure. It is now thought that changes in the hydrocarbon extraction method, including temperature changes, that were made in the rendering of offal in the late 1970s allowed the infectious agent to survive the manufacturing process and pass from sheep to cattle. Because by strain typing and PrP^{Sc} banding pattern in Western blots all scrapie strains tested so far are different from BSE, an alternative hypothesis, i.e., transmission of preexisting natural BSE at low incidence as a consequence of the preceding changes in the rendering process, cannot be dismissed. BSE is experimentally transmissible to many species and seems to have passed the species barrier to humans (see later discussion).

In addition, a number of other prion diseases exist (see Table I), some of which are of unknown origin such as chronic wasting disease in mule deer and elk, others are transmitted by contaminated offal from sheep or cattle such as transmissible mink encephalopathy, feline spongiform encephalopathy, and exotic ungulate encephalopathy.

B. Human Prion Diseases

CJD and Gerstmann–Sträussler–Scheinker syndrome (GSS) were first described as neurodegenerative diseases in the 1920s, whereas kuru was first reported in 1957. CJD and kuru were successfully transmitted to chimpanzees in the 1960s. The exceptional nature of GSS as a hereditary disease that is experimentally transmissible to laboratory animals was discovered in 1981. In 1989, the first mutation of the prion protein gene was identified in a GSS family. Neuropathology has played a lead role in defining the various entities that are now known as human prion diseases and is still of particular importance in routine diagnosis. The classical neuropathological changes consist of (1) spongiform degeneration, (2) PrP^{Sc} deposition, (3) neuronal loss, and (4) astrocytic gliosis (Fig. 2). There is some confusion as to the exact definition of such terms as "spongiform change" and "spongiosis." Spongy changes or spongiois describes small parenchymal vacuoles predominantly in the cerebral or cerebellar gray matter in various diseases. Out of this group, spongiform changes are really specific for prion diseases. They are small, often opaque vacuoles of 2–10 μm in diameter. They are found as single vacuoles or in small groups in the neuropil in practically all human prion diseases (Fig. 2a). Confluent vacuoles are 10–50 μm in diameter, found in grapelike accumulations (Fig. 2b), and characteristic of MM patients with PrP^{Sc} type 2 (see later discussion). Both spongiform changes and confluent vacuoles are only found in prion diseases. In contrast, status spongiosus, which is characterized by almost complete nerve cell loss, extreme astrocytic gliosis, and tissue disintegration with pericellular formation of holes, is found in prion diseases and late stages of various neurodegenerative and metabolic diseases. Spongy degeneration of the first and second cortical layers is a result of vacuolar shrinkage, often in the late stages of neurodegenerative

Table I
Prion Diseases

Type	Disease	Etiology
	Human Diseases	
Idiopathic	Sporadic Creutzfeldt–Jakob disease (sCJD)	Unknown. Possibly spontaneous conversion of PrP^{C} into PrP^{Sc} or somatic *PRNP* mutation.
	Sporadic fatal insomnia (SFI)	Unknown. Possibly spontaneous conversion of PrP^{C} into PrP^{Sc} or somatic *PRNP* mutation. Found only in 129 MM patients with PrP^{Sc} type 2.
Hereditary	Familial CJD	Various *PRNP* mutations.
	Gerstmann–Sträussler–Scheinker syndrome	Various *PRNP* mutations.
	Fatal familial insomnia (FFI)	*PRNP* mutation D178N with M129.
Acquired	Iatrogenic CJD	Accidental transmission through treatment with prion-contaminated preparations of human growth hormone, dura mater grafts, etc.
	(New) variant CJD, (n)vCJD	Infection by bovine prions (BSE-contaminated food or other products).
	Kuru	Infection through ritualistic cannibalism in the Fore population in New Guinea (historical).
Disease	**Host**	**Etiology**
	Animal Diseases	
Scrapie	Sheep (and goats)	Oral–maternal infection in genetically susceptible sheep.
Bovine spongiform encephalopathy (BSE)	Cattle	Infection with contaminated meat and bone meal (MBM).
Feline spongiform encephalopathy (FSE)	Felidae (cats)	Infection with contaminated feed.
Exotic ungulate encephalopathy	Nyala, kudu, onyx	Infection with contaminated feed.
Transmissible mink encephalopathy (TME)	Mink	Infection with contaminated feed.
Chronic wasting disease (CWD)	Mule deer and elk	Unknown.

diseases with strong cortical atrophy such as prion diseases, Alzheimers's disease, and Pick's disease. PrP^{Sc} deposition is found as diffuse delicate accumulations in the gray matter in areas of high synaptic density and in a distribution similar to that of synaptophysin (Fig. 2c). This type of PrP^{Sc} deposition therefore has been called synaptic. Other forms are described as pericellular, perivacuolar, in kuru plaques that are visible in routine H&E stains, and plaquelike, i.e., in small plaques that are only visible after immunohistochemical staining of PrP^{Sc}.

1. Kuru

Kuru was first described as a deadly neurodegenerative disease affecting the Fore people in the eastern highland of New Guinea. This disease was mainly characterized by ataxia and predominantly affected women and children. William Headlow, a veterinary pathologist, noted the neuropathological similarities of scrapie and kuru and suggested that infection experiments be performed in apes. Gajdusek and Gibbs were successful in transmitting the disease to chimpanzees in 1966. Later, ritualistic cannibalism of deceased clan members was identified as the mode of transmission in the Fore population. After cannibalistic practices ceased, the disease disappeared. Kuru incubation times of more than three decades were reported. The pathological similarities of kuru and CJD led Gibbs and Gajdusek to perform further transmission experiments and to show that CJD is transmissible to apes.

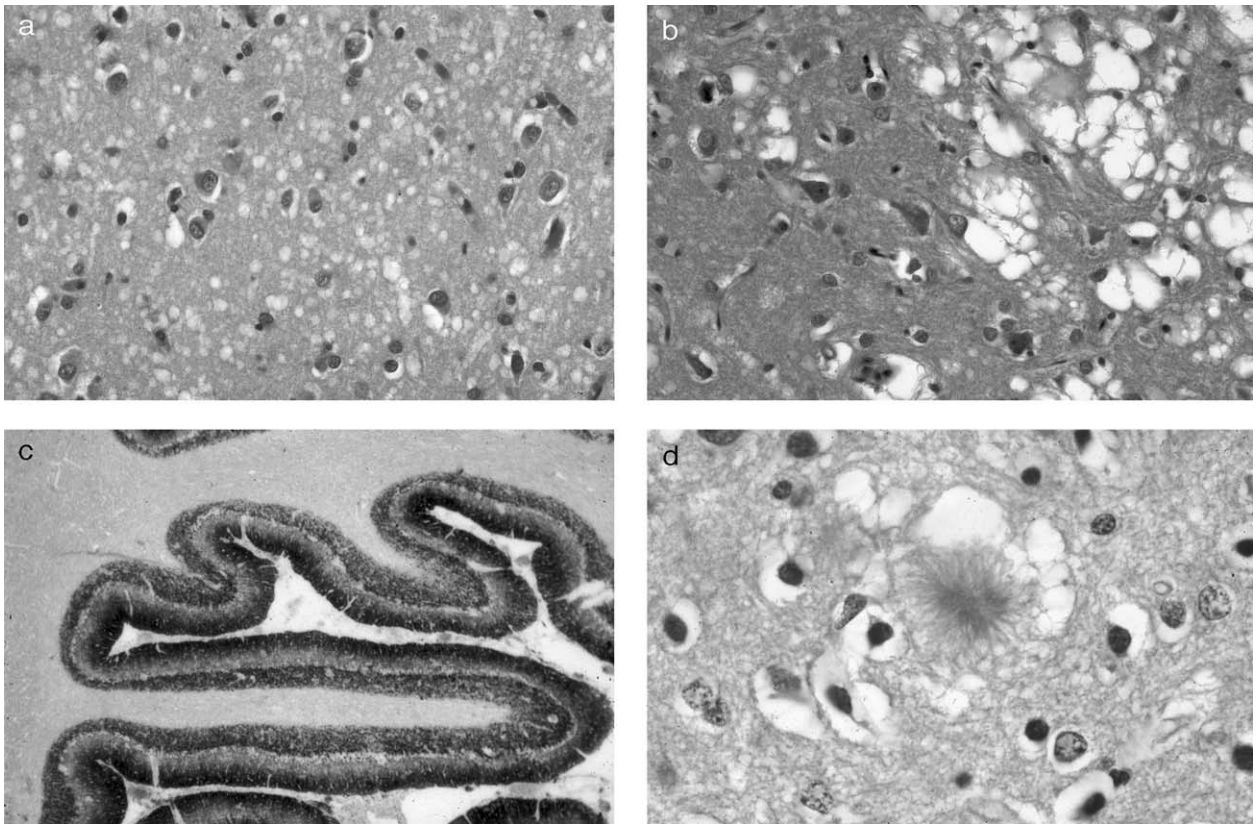

Figure 2 Histological findings in Creutzfeldt–Jakob disease. (a) Typical spongiform changes with small transparent or opaque vacuoles in the neocortex of a sporadic CJD case (MM, PrP^{Sc} type 1). Hematoxylin and eosin stain, × 20 (original magnification). (b) Large, confluent vacuoles are seen in the neocortex of this sporadic CJD case (MM, PrP^{Sc} type 2 cortical). Hematoxylin and eosin, × 40 (original magnification). (c) Paraffin-embedded tissue blot (PET blot) of the cerebellum of a sporadic CJD case (MM PrP^{Sc} type1). In this technique, formalin-fixed and paraffin-embedded tissue is digested with proteinase K and blotted onto a nitrocellulose membrane. PrP^{Sc} detection is then achieved by labeling with PrP-specific antibodies. In this case, synaptic-type deposition in the cerebellum is stained dark brown. (d) A typical florid plaque consisting of delicate strands and surrounded by confluent vacuoles in a case of nvCJD. Hematoxylin and eosin, × 40. (Courtesy of Dr. James Ironside, Edinburgh, Scotland.)

2. Sporadic (Idiopathic) Creutzfeldt–Jakob Disease

Sporadic CJD (sCJD) most often affects patients in their 60s. It usually presents with dementia and various neurological signs and runs a relentless course, leading to death usually within 6 months. Diagnostic criteria established by Masters have been modified (Table II). A definite diagnosis can only be made by neuropathologic or biochemical examination of the brain.

Well-documented phenotypic heterogeneity of sCJD in the absence of a genome of the infectious agent has been a puzzling observation that now seems to be resolved. Parchi and co-workers described two different molecular types of PrP^{Sc} associated with distinct clinical and pathological phenotypes in sCJD. On transmission to laboratory animals, the properties of PrP^{Sc} types 1 and 2 have been shown to propagate faithfully. The two types of PrP^{Sc} are distinguished by their different physicochemical properties, particularly their appearance on Western transfers after digestion with proteinase K. The unglycosylated forms of PrP^{Sc} are seen as proteins of approximately 21 (type 1) and 19 kDa (type 2) relative molecular mass (Fig. 3). Proteinase K has two preferential, if not exclusive, cleavage sites at codons 97 and 82 of PrP^{Sc}, most likely related to two different conformations of PrP^{Sc}. In addition, the common methionine and valine polymorphism at codon 129 of *PRNP* was shown to modify the phenotype of the disease. The full spectrum of sCJD

Table II
Diagnostic Criteria for CJD from the World Health Organization

The clinical criteria define possible and probable cases:

1. Sporadic CJD

   Probable CJD

   Progressive dementia

   Typical EEG (periodic sharp wave complexes) during an illness of any duration and/or

   Positive 14-3-3 assay and clinical duration to death <2 years

   At least two out of four clinical features listed:

   1. Myoclonus
   2. Visual or cerebellar disturbance
   3. Pyramidal or extrapyramidal dysfunction
   4. Akinetic mutism

   Routine investigations should not suggest an alternative diagnosis.

   Possible CJD

   Clinical features identical to those for probable CJD, but no typical EEG and no positive 14-3-3 assay.

2. Accidentally transmitted CJD

   Progressive cerebellar syndrome in a pituitary hormone recipient

   Sporadic CJD with a recognized exposure risk (e.g., dura mater transplant)

3. Familial CJD

   Definite or probable CJD plus definite or probable CJD in a first degree relative

   Neuropsychiatric disorders plus disease-specific *PRNP* mutations

4. NvCJD

   NvCJD cannot be diagnosed with certainty using clinical criteria at present. The diagnosis of nvCJD should be considered as a possibility in a patient with a progressive neuropsychiatric disorder with at least five out of the following six clinical features: (1) early psychiatric symptoms, (2) early persistent paresthesia–dysesthesia, (3) ataxia, (4) chorea–dystonia or myoclonus, (5) dementia, (6) akinetic mutism. The suspicion of nvCJD is strengthened by the following criteria: (7) absence of a history of potential iatrogenic exposure, (8) clinical duration >6 months, (9) age at onset <50 years, (10) absence of a *PRNP* mutation, (11) EEG not showing the typical periodic appearance, (12) routine investigations do not suggest an alternative diagnosis, (13) MRI showing abnormal bilateral signal from the pulvinar on axial T2- and/or proton density-weighted images. A patient with a progressive neuropsychiatric disorder and five out of clinical features 1–6 and all criteria 7–13 should be considered as a suspect case of nvCJD for surveillance purposes. A definite diagnosis is established only by neuropathological examination.

   The definite diagnosis is based on the examination of brain tissue:

   1. Neuropathological examination including immunohistochemistry
   2. Western blot analysis with antibodies against PrP
   3. Isolation of scrapie-associated fibrils or prion rods

variants was defined in a large series of 300 CJD patients and was compared with molecular and pathological phenotypes. Six distinct types of sCJD were described by molecular analysis. Almost 90% of sCJD patients were homozygous at codon 129, the vast majority being MM homozygotes, whereas only half of the normal population in Europe and the United States is homozygous. PrP^{Sc} types 1 and 2 were found to be associated with all *PRNP* genotypes. However, there was a strong association between PrP^{Sc} type 1 and MM homozygosity as well as between PrP^{Sc} type 2 and VV or MV patients.

A detailed analysis of the pathologic lesion pattern (lesion profile) and PrP immunohistochemistry defined six pathological variants of sCJD, which by and large were associated with the six groups of sCJD as defined by molecular analysis (Table III). Among the MM2 patients, one subgroup, termed MM2-C (cortical), had a pathological phenotype that closely resembled that of MM1 patients, with the exception that they lacked cerebellar pathology, whereas another subgroup, termed MM2-T (thalamic), showed a striking resemblance to the fatal familial insomnia (FFI) phenotype. Immunohistochemistry for PrP^{Sc}

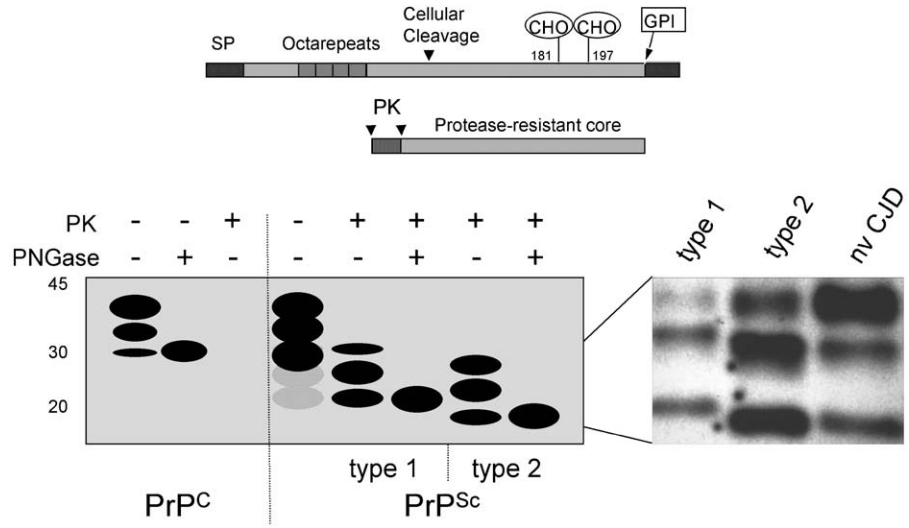

Figure 3 Western blot analysis of human prion proteins. Shown are the primary structure of PrP^{C} and the protease-resistant core of PrP^{Sc}, as well as their appearance on Western blots. The insert in the right lower corner shows an original Western blot with the three PrP^{Sc} bands after pK digestion of two sporadic CJD cases (PrP^{Sc} type 1 with the unglycosylated PrP^{Sc} at 21 kDa, PrP^{Sc} type 2 with the unglycosylated PrP^{Sc} at 19 kDa) and an nvCJD case in which the three PrP bands correspond in size to PrP^{Sc} type 2 but show a different glycosylation pattern.

was positive in all subgroups of sCJD, though it may be extremely weak and hardly recognizable or reliable in VV1 and MM2-T cases.

As for the clinical signs at onset, the absence of cognitive impairment in a large group of VV2 patients and the absence of ataxia in the VV1 and MM2-C subgroups were remarkable. During the course of the disease, dementia was found in all subjects except a small group of patients who rapidly lapsed into a stupor after a short initial phase with exclusively neurological signs. Ataxia was always more common in VV2 and MV2 subjects. Visual signs and myoclonus were prominent in the MM1 and MV1 subgroups.

Electroencephalography (EEG) showed typical periodic sharp wave complexes (PSWC) in MM1 and MV1 subjects, but these were rare in MV2 and VV2 patients and absent in VV1, MM2-C, and MM2-T patients. As a consequence, these patients are classified as possible CJD according to classic clinical diagnostic criteria. The 14-3-3 proteins in the CSF have proven to be good surrogate markers for most variants of sCJD, with the exception of MV2 subjects.

MM1 and MV1 subjects comprise 70% of sCJD cases, exhibiting features that have been recognized as typical of CJD, i.e., these subjects show dementia, myoclonus, and PSWC. On histologic examination, they show delicate spongiform changes in the cerebral cortex, particularly the occipital cortex, neostriatum, thalamus, and cerebellum. Brain stem nuclei and the hippocampus are usually spared. Immunohistochemistry shows synaptic PrP^{Sc} deposition in the cortex and cerebellum. The second most common subgroup is VV2 patients (16%), who are clinically characterized by prominent ataxia and a lack of PSWC upon EEG. Histology is characterized by spongiform degeneration of the deep cortical laminae of the neocortex, limbic cortex, and subcortical nuclei. Immunohistochemically, plaquelike deposits of PrP^{Sc} and prominent perineuronal staining are found. With 9% of all cases, MV2 patients are the third most common group that is clinically similar to the VV2 type. These patients show no typical EEG, and in most cases the proteins 14-3-3 are also negative in the CSF. Histologically there is involvement of cortical and subcortical structures. The most prominent feature is cerebellar kuru plaques, which are homogeneous eosinophilic structures that, in contrast to plaquelike deposits are visible on routine H&E-stained sections. The rare MM2-T phenotype (2%) is indistinguishable from the FFI phenotype clinically and neuropathologically. There is prominent atrophy of the thalamus and the inferior olivary nucleus, minimal focal cortical spongiform change, and minimal and unreliable immunohistochemical staining for PrP^{Sc}. Progressive insomnia, absence of PSWC, and visual hallucinations are found in the MM2-T group, which has also been termed

Table III
Molecular and Phenotypic Features of sCJD Variants

sCJD variant	Other classification	Percent of cases	Duration (months)	Age at onset (years)	Clinical features	Neuropathological features
MM1 or MV1	Myoclonic, Heidenhain variant	70	3.9 (1–18)	65.5 (42–91)	Rapidly progressive dementia, early and prominent myoclonus, typical EEG; visual impairment or unilateral signs at onset in 40% of cases.	"Classic" CJD pathology: Spongiform change with small (2–10 μm) round to oval vacuoles, predominantly located to neuronal processes; often predominant involvement of occipital cortex; "synaptic" type PrP staining; in addition, one third of cases shows confluent vacuoles and perivacuolar PrP staining
VV2	Ataxic variant, Brownell-Oppenheimer variant	16	6.5 (3–8)	61.3 (41–80)	Ataxia at onset, dementia late in the disease, no typical EEG in most cases.	Prominent involvement of subcortical nuclei including brain stem; in neocortex, spongiosis is often confined to deep layers; PrP staining shows plaque-like focal deposits as well as prominent perineuronal staining
MV2	Kuru plaque variant	9	17.1 (5–72)	59.4 (40–81)	Ataxia and progressive dementia, no typical EEG, long duration (>2 years) in some cases.	Cerebellar kuru plaques, other pathological changes similar to VV2 with more consistent plaque-like deposits
MM-2 thalamic	Thalamic variant, sporadic fatal insomnia (SFI)	2	15.6 (8–24)	52.3 (36–71)	Insomnia and psychomotor hyperactivity in most cases, in addition to ataxia and cognitive impairment, no typical EEG.	Prominent atrophy of the thalamus and inferior olive with little pathology in other areas; spongiosis may be absent or focal, minimal PrP^{Sc} deposition
MM-2 cortical	—	2	15.7 (9–36)	64.3 (49–77)	Progressive dementia, no typical EEG.	Large confluent vacuoles with perivacuolar PrP^{Sc} staining in all cortical layers; cerebellum is relatively spared
VV1	—	1	15.3 (14–16)	39.3 (24–49)	Progressive dementia, no typical EEG.	Severe pathology in the cerebral cortex and striatum with sparing of brain stem nuclei and cerebellum; no large confluent vacuoles, and very faint synaptic PrP^{Sc} staining

sporadic fatal insomnia (SFI). The cortical MM-2 phenotype is also rare (2%). It shows progressive dementia and no PSWCs. Histologically there are large confluent vacuoles with coarse perivacuolar PrP^{Sc} deposits. VV1 patients are the smallest subgroup of sCJD (1%). There are very young patients in this group. Clinically they show progressive dementia with no typical EEG. Histologically there is massive spongiform degeneration with numerous small vacuoles in the neocortex and striatum in these cases. Immunohistochemical detection of PrP^{Sc} is minimal and sometimes unreliable.

The detailed analysis of molecular and phenotypic variants of sCJD thus forms the basis for the recognition of unusual subtypes, which in the past may not have been diagnosed as CJD because of their early age at onset, their unusual clinical course, and even their atypical pathology. Thus, there should be

much greater clinical awareness of sCJD cases in young patients with a long clinical course and progressive dementia but no PSWC, as represented by MM2-C and VV1 cases.

3. Hereditary Prion Diseases

About 10–15% of all prion disease cases are hereditary. A large number of different point mutations and insertion mutations of the prion protein gene have been identified in familial prion diseases. Insertion mutations represent additional repeats of the N-terminal Cu^{2+}-binding octapeptide (Fig. 1). Depending on their clinical and neuropathological characteristics, familial prion diseases are designated as familial CJD, GSS, or fatal familial insomnia (FFI).

Familial CJD often is indistinguishable from sporadic CJD and is most often associated with the E200K mutation and less often with D178N-129V, V180I, R208H, V210I, M232R, and insertion mutations. GSS is thought to be distinguishable from CJD by the predominance of ataxia, whereas dementia and myoclonus are more prominent in CJD. Neuropathologically, GSS is quite distinct and is characterized by large, multicentric PrP-containing amyloid plaques; spongiform change is variable. It is found most often in families with the P102L mutation and less often with P105L, A117V, F198S, D202N, Q212P, Q217R, and insertion mutations. Fatal familial insomnia (FFI) often presents with insomnia and dysautonomia and later shows signs of ataxia, dysarthria, myoclonus, and pyramidal tract dysfunction. Neuropathologically, FFI is characterized by neuronal loss and astrocytic gliosis preferentially affecting the ventral anterior and medial dorsal nuclei of the thalamus and the inferior olive. FFI is caused by a D178N mutation of *PRNP* associated with a methionine codon at position 129 of the same allele.

4. Iatrogenic CJD

The first possible person-to-person transmission of CJD was reported in a recipient of a corneal transplant from a donor with CJD in 1974. Other modes of accidental iatrogenic transmission were reported in the following years, including the use contaminated EEG depth electrodes, neurosurgical instruments, cadaveric pituitary-derived gonadotrophin and human growth hormone (hGH), and dura mater grafts. Transmission by contaminated hGH has raised major concern because of the large number of possibly affected persons. Worldwide more than 120 hGH-associated cases have been reported to date, whereas 8000 persons received hGH between 1963 and 1985 in the United States alone. The affected patients commonly present with gait abnormalities and ataxia, whereas dementia is a late manifestation and is mild. The incubation time in these cases has been estimated to be 12 years or longer.

In February 1987, the first CJD case related to a dura mater graft (Lyodura, B. Braun Melsungen, Germany) was reported. The same year, representatives of the company announced that they had changed their procedures for collecting and processing dura mater in order to reduce or eliminate the risk of CJD transmission. Subsequent case reports from Germany, Italy, Spain, New Zealand, the United Kingdom, the United States, and Japan suggested that Lyodura processed before 1987 was indeed associated with an increased risk of developing CJD. Worldwide more than 100 dura-mater-associated CJD cases have been reported to date. The mean incubation time in these cases was 5.8 years, and the patients' mean age was 38.5 years. A total of 57 cases were reported as having received Lyodura, with 43 reported from Japan alone. The Japanese cases go back to a survey study with little information on the details revealed in a publication. Thus, the diagnosis was confirmed in only 10 patients by neuropathological examination. The number of clinically possible and clinically probable cases is not reported. The mean incubation period in the Japanese cases was 89 months, and the mean age was 53 years. In June 1998, 21 unpublished Lyodura-associated cases in various countries were identified. In contrast to the cases transmitted by contaminated hGH (see earlier discussion), there is no difference in the symptomatology of sporadic CJD and dura-mater-associated cases.

5. New Variant CJD and the Transmission of BSE to Humans

A new variant of CJD was described in 10 patients in the United Kingdom in 1996. These patients had a mean age of 29 years and presented with psychiatric disturbances, whereas signs more typical of CJD developed later in the course of disease. Neuropathology at autopsy was exceptional, showing extensive depositions of PrP^{Sc} in various areas of the brain in a fashion that had only been described in hereditary disease before 1996. In addition, there were florid plaques with a central PrP accumulation and surrounding vacuoles (Fig. 2d) that had not been seen in human prion disease before. From 1996 to date, 100 cases of this variant were identified in the United

Kingdom, 3 were found in France, and the search in other countries was not successful. Information on the clinical appearance has been compiled, and a definition for suspect nvCJD cases is now available (see Table II). All nvCJD patients to date have been methionine homozygotes at codon 129 of the prion protein gene; the youngest patient was 15 years old and the oldest was 54 years old at death. It is not possible at present to define the clinical and pathological features to be expected in codon 129 valine homozygotes or in heterozygotes that are likely to be observed in the future. nvCJD has shown significantly new features in the pattern of extracerebral deposition of PrP^{Sc} in the tonsils, lymph nodes, spleen, and appendix. This has raised concern that blood cells may also harbor the infectious agent and that the disease might be spread by blood transfusions. Although this suspicion is unsubstantiated to date, measures have been taken to prevent the spread by blood transfusion in various countries.

It is hypothesized that nvCJD cases have been caused by the consumption of food or other products containing large amounts of the BSE agent (BSE prions). This hypothesis is strengthened by epidemiological and experimental findings. The appearance of nvCJD 10 years after BSE in the country with the highest incidence of BSE is highly consistent with this hypothesis. The banding pattern of PrP^{Sc} in nvCJD has been shown to be different (see Fig. 3) and resembles the pattern in BSE. Although BSE and nvCJD show significant differences pathologically, upon transmission to genetically homogeneous animals (inbred mice) they elicit practically identical patterns, whereas in these strain-typing experiments all tested scrapie strains and sporadic CJD cases were different. These findings have been confirmed in transgenic animals expressing bovine PrP.

If we assume that nvCJD is caused by transmission of the BSE agent to humans, the available epidemiological data are insufficient to predict the number of cases that must be expected to occur in the future, because neither the mean incubation time nor the shape of the epidemiological curve, the exact mode of transmission, or any other parameter that might possibly be important is known at present.

C. Models in Transgenic Animals

Many transgenic mouse models have been developed to study susceptibility, prion pathogenesis, species barrier, prion propagation, and other problems. The nature of the species barrier was examined by introducing the hamster PrP gene into the germ line of mice. These transgenic mice became readily susceptible to the hamster agent and produced the homologous type of agent when infected with the material from either hamster or mouse. The situation was more complicated when human *PRNP* was introduced into mice. Only after a chimeric gene with murine N- and C-termini and the central part of *PRNP* (codons 96–167) was expressed in transgenic animals did these mice become susceptible to human prions. This has led to the postulate of the existence of a species-specific protein X that interacts with PrP. There are conflicting findings from another group who succeeded in breaking the species barrier by introducing unmodified *PRNP* into mice. Transgenic mice expressing the bovine PrP^{C} have shown short incubation times after inoculation with BSE and practically no decrease in incubation time at second transmission, i.e., they seem to have no species barrier and thus should be an ideal model to study the infectivity of various organs of BSE-infected cattle. Exciting data concerning inherited prion diseases were provided by experiments with mice overexpressing a murine *Prnp* with a homolog of the P102L-GSS mutation [Tg(MoPrP-P101L)H]. These mice spontaneously developed a neurodegenerative disease reminiscent of other prion diseases in mice. However, an accumulation of protease-resistant PrP was not found. The infectious nature of the disease generated was shown by serial transmission to hamsters (10% of animals) and transgenic mice expressing low levels of the mutated protein (40% of animals), whereas the disease could not be transmitted to normal mice. Again, protease-resistant PrP was not detectable in the brains of any of the infected animals. Some transgenic lines overexpressing various normal PrP genes develop a lethal spontaneous disease late in life. This disease is characterized by the degeneration of skeletal muscles and peripheral nerves and by spongiform changes in the brain. It was claimed that this disease may be transmissible, yet no protease-resistant PrP was found. To complicate the matter, another transgenic line expressing P101L at normal levels does not spontaneously develop disease.

D. New Diagnostic Approaches

Although transmission studies indicate the presence of low levels of infectivity, it has not been possible to detect PrP^{Sc} aggregates in the CSF using generally

available techniques such as the Western blot or ELISA. On the basis of a setup for confocal dual-color fluorescence correlation spectroscopy (FCS), a technique suitable for single-molecule detection, a novel and highly sensitive detection method, was developed: the scanning for intensely fluorescent targets (SIFT) technique for PrP^{Sc}. In this technique, pathological prion protein aggregates are labeled by specific antibody probes tagged with fluorescent dyes, resulting in intensely fluorescent targets (PrP^{Sc} aggregates) that are measured by dual-color fluorescence intensity distribution analysis in a special scanning setup. In a diagnostic model system, PrP^{Sc} aggregates were detectable down to a concentration of 2pM PrP^{Sc}, corresponding to an aggregate concentration of approximately 2 f*M*. This was more than one order of magnitude more sensitive than Western blot analysis. PrP^{Sc}-specific signal was detected in a number of CSF samples from CJD patients. Thus, for the first time PrP^{Sc} was directly detected in the CSF, providing the basis for a rapid and specific test for CJD and other prion diseases. Improvements in scanning as well as sample handling and preparation may significantly improve sensitivity.

E. Therapy

Interference with the conversion reaction from PrP^{C} to PrP^{Sc} would seem to be the most promising therapeutic approach. This would entail stabilization of PrP^{C} or destabilization of PrP^{Sc} by direct or indirect means. In that vein, experiments in cell-free conversion systems and in scrapie-infected neuroblastoma cell cultures have shown that PrP^{C} conversion can be inhibited by synthetic peptides composed of amino acids 109–141 and 119–136. Because the region from 119 to 136 is conserved in most mammalian species, this peptide may be of practical use for therapy in many prion diseases. In addition, a number of substances such as Congo red, amphothericin B, porphyrins, pentosan phosphate, and phthalocyanins have empirically been found to prolong the incubation time in experimental scrapie systems. Some of these substances have been shown to inhibit PrPres formation *in vitro*. The availability of analogs of macrocyclic compounds such as porphyrins and phthalocyanins in large numbers that vary in structure and that can be modified in a number of ways offers the opportunity for rational drug development and, thus, may become potent therapeutic agents. New avenues of research arise from observations indicating that prions may be transported by cells of the lymphoreticular system. The search for effective approaches to therapy for prion diseases seems most prudent at a time when the total number of nvCJD cases is slowly increasing, whereas we have no means to predict the total number of individuals that may be affected by this new and deadly disease.

Problem Solving

RICHARD E. MAYER
University of California, Santa Barbara

GLOSSARY

ill-defined problem Problem in which the given state, goal state, and/or operators are not clearly stated.

insight When a problem solver suddenly moves from a state of not knowing how to solve a problem to a state of knowing how to solve a problem.

nonroutine problem Problem for which the problem solver does not know a solution method.

problem When a problem solver wants to change a situation from its given state to a goal state but there are obstacles.

problem solving Cognitive processing directed at transforming a given situation into a goal situation when no obvious solution is available to the problem solver.

routine problem Problem for which the problem solver knows a solution method.

well-defined problem Problem that has a clearly stated given state, a clearly stated goal state, and a clearly stated set of operators.

A *problem* occurs when a person has a goal but does not know how to achieve that goal. This definition has three components: the problem is in the *given state*, the problem solver wants the problem to be in the *goal state*, and there are *obstacles* blocking the path between the given and goal states. Problem solving involves finding a way of moving from the given state to the goal state when there is no obvious path between them. For example, a problem occurs when a person wants to find the area of a parallelogram but does not know the solution formula. Problem solving occurs when the problem solver invents a way to solve the problem, such as cutting the triangle off one side and placing it on the other side to form a rectangle.

I. INTRODUCTION

Problem solving is cognitive processing directed at transforming a given situation into a goal situation when no obvious solution method is available to the problem solver. This definition consists of three parts. First, problem solving is *cognitive*—it occurs in the learner's mind. Because problem solving is an internal event, its occurrence can only be inferred indirectly by observing external events such as the learner's behavior. Observable changes in physiological state that happen while a problem solver is thinking are not the same as problem solving, but rather are physiological correlates or indicators of problem solving. Second, problem solving is a *process*—it involves a series of mental manipulations (or computations) performed on mental representations (or knowledge). A premise of cognitive science—the multidisciplinary study of cognition—is that the working of the mind can be characterized as a series of computations. Third, problem solving is *directed*—it is aimed at accomplishing a goal. Thus, directed thinking—including reasoning—is the same as problem solving, but

Portions of this article are adapted from Mayer, R. E., "Problem Solving," in the *Encyclopedia of Creativity* (1999), pp. 437–447, with permission.

nondirected thinking such as daydreaming is not problem solving. In short, problem solving is directed, cognitive processing. This definition is broad enough to include a wide array of cognitive activities, ranging from solving a puzzle to discovering a cure for a disease or from composing an essay to figuring out how to resolve an interpersonal conflict.

II. TYPES OF PROBLEM SOLVING

A. Routine versus Nonroutine Problems

It is customary in the problem-solving literature to distinguish between routine and nonroutine problems. A *routine problem* is a problem for which the problem solver knows a solution method. For example, for most adults, $567 \times 789 =$ ____, is a routine problem because they know the procedure for long multiplication. Routine problems can also be called exercises because they involve exercising procedures that the problem solver already knows. Routine problems depend on reproductive thinking; in reproductive thinking, problem solvers must reproduce responses that they have used in the past. Technically, routine problems do not fit the definition of a problem because the problem solver knows a solution method, so that there is no obstacle between the given and goal states.

A *nonroutine problem* is a problem for which the problem solver does not know the solution method. For example, for most adults, the following problem proposed by the Gestalt psychologist, Karl Duncker, is a nonroutine problem: "Why is it that all six-place numbers of the type abcabc, for example, 276276, are divisible by 13?" The solution occurs by realizing that all numbers of the form abcabc can be expressed as abc $\times$ 1001 and that 1001 is divisible by 13. Nonroutine problems are called insight problems because the problem solver must invent a new approach to the problem, that is, the problem solver must see the problem in a new way. Nonroutine problems depend on productive thinking in which problem solvers create a novel solution that they have never produced before. The cognitive processes involved in solving nonroutine problems may be different from those involved in solving routine problems, which may be reflected in different patterns of brain activity.

B. Well-Defined versus Ill-Defined Problems

It is also customary to distinguish between well-defined and ill-defined problems. A *well-defined* problem has a clearly stated given state, a clearly stated goal state, and clearly stated set of operations. For example, the game of chess is a well-defined problem because it has a clear given state (the board is set the same way for the start of every game), a clear goal state (the opponent's queen is unable to move), and clear operators (each piece can move in a certain way). In an *ill-defined problem*, the given state, goal state, and/or operators are not clearly stated. For example, the problem of how to have a good life is an ill-defined problem because the goal state (i.e., a good life) is not clearly stated and the operators (i.e., the things you are allowed to do to achieve this goal) are not clearly stated. Well-defined problems can be either routine or nonroutine; ill-defined problems can be either routine or nonroutine.

III. PROCESSES IN PROBLEM SOLVING

A. Problem Representation

There are two major processes in problem solving: problem representation and problem solution. In *problem representation*, a problem solver builds an internal mental representation of the problem based on a statement or presentation of the problem. In short, the problem solver comprehends the problem. Cognitive psychologists have further analyzed problem representation into two subprocesses: translation and integration. *Translation* involves mentally representing each sentence or portion of the problem. For example, we have the problem, "John has two marbles. Pete has three more marbles than John. How many marbles does Pete have?" In listening to this problem, a problem solver may mentally represent the first sentence as, "John's marbles = 2" and the second sentence as, "Pete's marbles = John's marbles + 3." *Integration* involves putting knowledge together into a coherent structure that can be called a situation model; the situation model is the problem solver's mental model of the problem situation. For example, in the marble problem the problem solver may construct a set–subset relation in which one set, "Pete's marbles" consists of two subsets: "John's marbles" and "the difference between Pete's and John's marbles."

B. Problem Solution

In *problem solution*, the problem solver devises and carries out a plan for solving the problem. In short, the

problem solver produces a solution to the problem. The process of problem solution includes the subprocesses of planning, executing, and monitoring. *Planning* involves devising a solution plan, that is, a method for solving the problem. For example, in the marble problem, the problem solver may decide to add 3 to 2. *Executing* involves carrying out the steps in the solution plan, that is, engaging in behaviors based on a plan. In the marble example, this involves determining that 5 is the sum of 3 and 2. *Monitoring* involves awareness and control of one's cognitive processing, including determining the extent to which the problem solution phase is successful and altering one's course if necessary. Monitoring is a metacognitive process because it involves awareness and control of one's cognitive processing. In the marble example, the problem solver may check to see that if Pete has 5 marbles, then the story in the problem makes sense. In addition, after completing the problem-solving process, the problem solver may engage in the subprocess of *evaluating*—reviewing the process of how the problem was solved, reflecting on its merits, and considering how it could be used in the future. For example, the problem solver may note that it is a "compare" problem in which one set is compared to another, so that the same solution procedure will work in other "compare" problems even if the sets do not involve marbles.

C. Example of the Processes in Problem Solving

George Polya analyzed the processes in solving the following geometry problem: "Find the volume F of the frustrum of a right pyramid with square base given the altitude h of the frustrum, the length a of a side of its upper base, and the length b of a side of its lower base." According to Polya, the first step is *understanding the problem*, which corresponds to the translation subprocess in problem representation. In this step, the problem solver asks, "What do I want?" and "What do I have?" In answering these questions, the problem solver mentally represents that the goal is to find the value of F and the givens are the values of a, b, and h. Polya's second step is *devising a plan*, which includes both the integration subprocess of problem representation and the planning subprocess of problem solution. This is the step in problem solving where creative insight occurs. To help the problem solver build a situation model of the problem, the problem solver can ask, "What is a related problem I can solve?" and "Can I restate the goal or givens differently?" In this step, the problem solver might already know a related problem —how to find the volume of a pyramid—and may realize that the goal may be stated differently as the difference between a full pyramid (including the frustrum) and the smaller pyramid on top of the frustrum. After building this coherent representation of the structure of the problem, the problem solver is able to create a plan: compute the volume of the large pyramid and subtract the volume of the small pyramid. Polya's third step, *carrying out the plan*, corresponds to the execution subprocess of problem solution. In this step, the problem solver makes the needed arithmetic calculations to compute the answer. Finally, Polya's last step, *looking back*, involves examining what has been done. This corresponds to the monitoring and evaluating subprocesses. In this step, the problem solver evaluates the logic of the solution.

Although the subprocesses in problem solving can be neatly defined, they rarely occur in a linear order. In most complex problem solving the subprocesses interact with one another; for example, a problem solver may begin by trying to represent the problem, then try to plan, then go back to modify the problem representation, then try to execute the plan, then monitor, then revise the plan, and so on. Most of the difficulty in problem solving concerns building a coherent problem representation (i.e., integrating) and devising and monitoring a solution plan (i.e., planning and monitoring).

IV. APPROACHES TO PROBLEM SOLVING

For more than a century, psychologists have grappled with the thorny question of how the human mind works. What goes on inside someone's mind when they are thinking, that is, when they come up with a solution to a problem? Three different ways of answering this question come from the associationist, Gestalt, and cognitive science approaches.

A. Associationist

In the early 1900s, associationist theory developed as psychology's first large-scale account of how the human mind works. The approach received a large boost from the landmark work of Edward L. Thorndike, including his classic book, *Animal Intelligence*, which was published in 1911. According to this view, knowledge is a network consisting of nodes and associations among them. The strength of the

association between two nodes depends on the experience of the learner. Problem solving involves beginning at one of the nodes and following a chain of associations to other nodes, always taking the association that is the strongest.

For example, in a classic set of studies, Thorndike placed a hungry cat in a puzzle box. If the cat performed a simple response, such as pulling a loop of string, a door would open and the cat could escape to a bowl of food sitting nearby. On the first trial, the cat performed many unsuccessful responses, such as clawing through the bars, pouncing against the walls, and meowing, until it accidentally pulled the string and got out. However, across many trials, the time needed to get out of the puzzle box declined as did the number of unsuccessful responses. On the basis of results like these, Thorndike devised the law of effect: if a response is followed by satisfaction, it is more likely to recur, and if a response is followed by dissatisfaction, it is less likely to recur. Thus, each time the cat engaged in an unsuccessful response, the association between the problem situation and that response was automatically weakened, and each the cat performed the successful response the association between the problem situation and the response was automatically strengthened. Thus, Thorndike characterized the cat's problem-solving process as learning by trial and error and accidental success. According to the associationist view, problem solving is simply a matter of exercising existing associations. One of the major criticisms of this approach to problem solving is that it fails to adequately account for creative problem solving.

B. Gestalt

In the 1930s and 1940s, Gestalt theory provided an important alternative to associationist theory, culminating in psychology's second account of how the human mind works. The approach is reflected in the work of the Gestalt psychologists such as Wolfgang Kohler's *The Mentality of Apes* originally published in 1925, Karl Duncker's *On Problem Solving* published in 1945, and Max Wertheimer's *Productive Thinking* originally published in 1945. According to this view, problem solving occurs when the problem solver mentally reorganizes the problem situation in a new way. Problem solving is not a matter of following preexisting associations but rather requires structural insight—seeing how the parts of the problem fit together to achieve the goal. *Insight* occurs when a problem solver suddenly moves from a state of not knowing how to solve a problem to a state of knowing how to solve a problem.

For example, in a classic set of studies, Kohler observed apes as they attempted to solve problems. In one problem, bananas were hung high in a cage beyond the reach of the ape, and crates were scattered about the floor of the cage. The ape looked around the room and then, in a flash of insight, stacked the crates on top of one another to form a ladder that he then climbed to reach the bananas. According to Kohler, the ape had a flash of insight in which he mentally organized the parts of the problem by seeing how the crates could be used as a ladder. Whereas Thorndike had observed problem solving as following preexisting associations, Kohler observed problem solving by insight. A reconciliation of these apparently conflicting views is that associationist theory explains one kind of problem solving, whereas Gestalt theory explains a different kind of problem solving. A major criticism of the Gestalt approach is that it is too imprecise.

C. Cognitive Science

During the second half of the 20th century, psychology produced a third approach containing elements of the preceding two—the cognitive science approach. Cognitive science is the multidisciplinary study of cognition and is based on the idea that cognition involves mental computations—operations carried out on mental representations. Cognitive science has its roots in the information-processing approach to problem solving, in which humans are assumed to be processors of information. For example, in their classic book, *Human Problem Solving*, Allen Newell and Herbert Simon showed how a computer program could simulate the problem-solving processes of humans on a wide variety of problems. According to this view, an important goal of cognitive science is to understand the ways that knowledge is represented and how it is transformed by mental operations.

V. TOPICS IN PROBLEM SOLVING

A. Problem-Solving Expertise

What do expert problem solvers know that novices to not know? This is the question that motivates research on problem-solving expertise. For example, classic research comparing expert and nonexpert chess

players has shown that they differ on domain-specific skills, such as being able to remember the location of pieces in an actual game, but not on domain-general skills, such as having a better memory in general. Similarly, experts in computer programming outperform beginners in being able to read and reconstruct a computer program from memory but not in being able to remember a random list of programming commands. This line of research is consistent with the idea that problem solving is domain-specific, that is, the knowledge and skills required for problem solving in one domain (such as chess or programming) are not the same as the knowledge and skills required for problem solving in another domain (such as essay writing).

B. Thinking by Analogy

All problem solving involves thinking by analogy. This is the hypothesis that is examined by research on thinking by analogy. For example, when people are asked to solve a problem about electrical flow, such as what happens to the rate of flow of electrons when there are two resistors in series rather than one, they tend to use a familiar analogy such as thinking of the circuit as water flowing in pipes. Research on analogical thinking shows that people often have difficulty in recognizing that the problem they are currently trying to solve is similar to a problem they already know. Thus, a major factor in successful problem solving is the ability to find a problem analog, that is, to be able to think of a related problem that the problem solver already knows how to solve.

C. Teaching Thinking

Another way to study problem solving is to analyze the processes in problem solving and teach them to people. If the instruction improves people's problem-solving skills, then this validates the processes as being important components in problem solving. Research on teaching thinking shows that successful programs generally focus on teaching specific problem-solving processes that fit within a specific domain rather than trying to improve the mind in general for all problem-solving domains.

D. Subject-Based Cognition

How do students think mathematically? How do students think scientifically? How do students think historically? These questions reflect a growing research literature on the psychology of subject matter. Importantly, the cognitive processes involved in each subject appear to be different from one another—mathematical problem solving is different from scientific problem solving, which is different from historical problem solving, and so on. For example, even Polya's analysis of problem-solving processes (summarized in a previous section) seems to be closely tied to the domain of solving geometry problems. Thus, planning a solution to a geometry problem might be quite different from planning how to write an historical essay, even though both involve the problem-solving process of planning.

E. Everyday Thinking

Do people use the same problem-solving processes in their everyday lives as they use in school or laboratory situations? Increasingly, research on problem solving in naturalistic contexts reveals that people's problem-solving strategies are dependent on the situations in which the problems are encountered. When asked to determine the best buy (e.g., 4oz for 45¢ or 10oz for 90¢), most people compute the unit cost in a mathematics class (11.25¢ per ounce versus 9¢ per ounce), but use a ratio strategy in a real supermarket (the larger one costs exactly twice as much but contains more than twice as many ounces). This research contributes to theories of situated cognition in which all cognitive activity depends on its context rather than on applying general cognitive procedures.

VI. CONCLUSION

Some dominant themes in current research on problem solving include the domain specificity of cognition, the focus on component cognitive processes, the situated nature of thinking, and the role of metacognitive control in cognitive processing. Although the field of problem solving has not yet achieved a single perspective or unifying theory, progress continues to be made in understanding how people solve problems.

Prosopagnosia

EDWARD H. F. DE HAAN
Utrecht University

GLOSSARY

affective prosopagnosia An impairment in the appreciation of facial expressions.

agnosia A recognition disorder that cannot be explained by sensory–perceptual, language, or amnestic deficits or general confusion. Agnosias are often modality-specific, i.e., pertaining to one sensory modality (e.g., visual agnosia).

anomia A naming impairment.

apperceptive agnosia A recognition disorder that is caused by a higher order perceptual impairment.

associative agnosia A recognition disorder that is caused by a problem in accessing stored information about objects and faces.

covert face recognition The experimental demonstration of preserved face recognition in prosopagnosia despite a complete absence of acknowledged awareness.

ERP Event-related potential.

fMRI Functional magnetic resonance imaging.

GSR Galvanic skin response.

metamorphopsia The clinical condition in which patients perceive faces in a distorted manner.

object agnosia A recognition disorder for common objects. In pure cases, other stimulus categories such as text or faces may remain unaffected.

person identification deficit The clinical condition in which a patient is able to distinguish between familiar and unfamiliar people but cannot access biographical information.

PET Positron emission tomography.

priming An experimental procedure in which the processing of a particular stimulus is influenced by a previous presentation of that stimulus (repetition priming) or a related stimulus (semantic priming).

speech reading The perception of the movements of the lips and the tongue to aid the understanding of spoken speech.

within-category discrimination The ability to identify specific exemplars of stimulus category with many visually similar items (e.g., motor cars).

The term *prosopagnosia* refers to the inability to recognize familiar people via visual inspection of the face. It is a modality-specific impairment, and other recognition routes, such as via the voice, remain spared. In addition, reading and object recognition may remain unaffected in selective cases. The inability cannot be explained by perceptual, language, or amnestic deficits or by general confusion.

I. BACKGROUND

Anecdotal observations of face recognition deficits date back to ancient Greek literature. For instance, the Greek general Thucydides described intriguing behavior, such as the inability to recognize friends, in soldiers who recovered from the plague. Clinical case studies published in the second half of the nineteenth century sometimes mentioned problems in this domain in patients who have suffered neurological disease. But it was not until the early twentieth century that clinicians suggested that face recognition might be a

separate function that can be selectively impaired after brain injury.

In 1947, the German neurologist Joachim Bodamer published a report on a number of patients who experienced a particular selective difficulty in recognizing faces. Bodamer named the condition prosopagnosia with reference to the Greek *prosopon* (face) and *agnosis* (without knowledge). His patients complained bitterly about the problem. In severe cases, even the faces of family members and close friends were affected and sometimes the patient's own face when seen in a mirror. When Bodamer asked his patient to inspect his own face in the mirror, it was clear that, although he knew he was looking at his own face, there was no sense of familiarity. This problem does not appear to be directly caused by an impairment in the perception of facial features. All of his prosopagnosic patients knew when they were looking at a face, and they could identify and describe separate features such as the eyes and mouth. Thus, although prosopagnosic patients know that they are looking at a human face, it has lost its value as a cue for the identification of a person, and not even a vague feeling of familiarity is evoked when the patient is looking at a known face. Prosopagnosic patients often describe faces as all looking similar, unattractive, and having lost their individuality. Another common comment from these patients is that faces are not perceived as an integrated whole and appear fragmented.

In order to suggest that prosopagnosia constitutes a separate clinical entity, it is important to look in more detail at the claim that these deficits in the recognition of familiar faces dissociate from visual object agnosia in general. There are many case descriptions suggesting that the patient is unable to recognize any familiar faces, whereas his or her ability to recognize common objects is spared. However, it should be noted that the task demands in face and object recognition are not comparable. Instead of recognizing a hammer as a tool, a more comparable situation would be to recognize one's neighbor's hammer among many other exemplars.

The ability to recognize faces is probably the most difficult visual recognition task that we are able to perform, despite the subjective ease with which we do it. In a lifetime, we learn thousands of faces, most of which we are able to recognize relatively unaffected by changes due to age and variable additions such as spectacles and facial hair. These faces, however, only differ very slightly in visual appearance. This is a point well-illustrated by the general experience that faces from another race than one's own are difficult to remember. When prosopagnosic patients are tested on within-class recognition tasks, such as flower or car recognition, that approach the task demands involved in face recognition, they often show impairments. However, there is evidence that within-class discrimination problems do not always co-occur in prosopagnosia.

An extensive investigation of prosopagnosia by the Italian neurologist Ennio de Renzi is illustrative here. He described a prosopagnosic patient who was able to perform recognition tasks that are visually very demanding. For instance, this patient was able to recognize his own car in the car park, his own wallet from an array of similar wallets, and his own handwriting amid that of others. In addition, he was very apt at distinguishing Italian coins from foreign ones. Until very recently, the controversy about a dedicated cortical system for face recognition continued because the other half of the necessary double dissociation was still lacking, despite a number of clinical reports that described a statistical trend toward relatively more severe problems in recognizing objects than faces. Convincing evidence for this position was provided by a number of reports on a patient who performed normally on tests of familiar face recognition while remaining severely impaired in the recognition of common objects.

Other indirect evidence comes from the clinical phenomenon of metamorphopsia, where the patient sees faces—and only faces—in a distorted manner. For example, one patient reported that his visual world appeared to be completely unaffected by his brain damage apart from the fact that all faces looked like "fish heads." Despite this distortion, he was able to recognize most familiar faces without any problems. The fact that this phenomenon is restricted to faces supports the notion of a separate cognitive system that is dedicated to the perception of faces.

II. PROSOPAGNOSIA AND SENSORY STATUS

Visual recognition disorders as a result of brain disease have created theoretical controversies since they were first described in the latter half of the nineteenth century. Regarding impairments in object recognition, Heinrich Lissauer suggested a distinction between apperceptive and associative Seelenblindheit, where the former results from visuosensory deficits, whereas the latter was thought to represent a difficulty in associating meaning with a relatively intact percept. A few years later, Sigmund Freud coined the term

agnosia to describe these recognition disturbances. It is the viability of the concept of associative agnosia, or as Hans-Lukas Teuber put it, "a normal percept stripped of its meaning" that has been questioned. Notably, Eberhard Bay claimed that the so-called higher order recognition deficits are secondary to sensory impairment, general intellectual loss, language problems, or a combination these factors.

More recent investigations have convincingly demonstrated that visual recognition disorders can occur in patients with normal, or even above average intelligence. Also, it has now been clearly established that language difficulties are not instrumental in causing associative agnosias. However, the question of whether subtle sensory impairment or a certain constellation of sensory deficits can produce the clinical symptoms of associative agnosia remains controversial.

The debate is fueled by the fact that even the most "pure" cases of agnosia often show some mild problems on tasks of visual perception. A seminal study by George Ettlinger in 1956 set out to test Bay's hypothesis. He carried out a careful assessment of sensory status in patients with and patients without recognition deficits, and he argued that sensory status alone could not explain the presence or absence of a recognition disorder. The crux of his argument is that, although patients with a recognition deficit may have sensory impairments, other patients who do not experience recognition problems can show equal or worse impairments on the sensory tests. George Ettlinger was subsequently criticized for using a composite sensory score and for using tests that might not have covered all of the relevant sensory abilities for visual recognition. There is now strong evidence for relatively independent functional components in human visual processing.

Neuropsychological research has shown highly selective disorders of color, luminance, shape, location, and movement. In a study with three densely prosopagnosic patients, the evaluation of primary visual proficiency was done with a screening battery comprising all of the relevant visual cues, and the patients showed subtle impairments on several of the screening tasks. These problems were, however, insufficient to explain the pronounced recognition problems, because other patients with unilateral brain lesions who do not have recognition deficits are at least as impaired on these sensory tasks as the agnosics.

The conclusion is, therefore, that the visuosensory impairments cannot explain the agnosic problem. These results support the notion of an associative type of prosopagnosia, which can be distinguished from a perceptive type. This is in line with more recent studies in which it is concluded that there are both perceptual and amnestic forms of prosopagnosia. Thus, prosopagnosia is modality- (visual) and stimulus-specific (faces) impairment that may arise in the context of preserved visuoperceptual processing.

III. PROSOPAGNOSIA AND OTHER FACE PROCESSING DEFICITS

Faces form the source for a multitude of inferences. From a perceived face, we are able to determine gender and age and make more subjective judgments regarding attractiveness, etc. We can assess the emotional state of the person (e.g., happy, sad) by analyzing the facial expression, and by observing the movements of the lips and tongue, we gain additional information regarding the verbal message that the speaker is trying to convey. Finally, the face constitutes the principal cue for visual identification of people we know.

Evidence for a dissociation between the recognition of familiar faces and the processing of facial expressions can be traced back to neuropsychological studies in the 1960s. It was observed that some patients with severe impairments of facial identity recognition showed relatively intact ability to recognize facial expressions. Conversely, a group study with patients suffering from a degenerative illness showed that they were impaired at both recognizing facial expressions and recognizing American Presidents. However, the identity and expression recognition impairments did not correlate with each other. The conclusion is that some of these patients must have had intact familiar face recognition but poor facial expression perception. These patients would provide the double dissociation for the previously mentioned studies.

There is also evidence for distinct processing pathways involved in the recognition of facial expressions and the matching of unfamiliar faces. For example, in a 1985 study by Dawn Bowers and colleagues, patients who had left and right hemisphere damage or no neurological disease were assessed using a series of facial affect tests and tasks for unfamiliar face perception. The patients with right hemisphere lesions were significantly impaired on both types of tasks, but the impairments on the affect tests remained significant even when the face perception deficit was statistically partialed out. Several reports subsequently supported the notion of dissociable impairments of facial expression recognition and unfamiliar face

matching after brain injury. A selective deficit in the analysis of facial expressions is sometimes referred to as affective prosopagnosia. Regarding the neuroanatomical substrate of expression analysis, functional imaging studies suggest that the right posterior hemisphere is obviously instrumental in the perceptual processing of facial information, but the amygdala (bilaterally) plays a crucial role in the experience of emotions, especially for fear and anger.

In 1986, Ruth Campbell and colleagues described two Swiss patients. One patient was able to recognize faces but could no longer read lips, and the other showed the opposite pattern. Lip reading is tested using a recognition task in which the patient is shown photographs of the face of an actor making a speech sound, for instance ee or aa. The other method uses what is known as the McGurk illusion. This involves the videotape recording of a face making a speech sound (e.g., da) and the simultaneous sound recording of a different speech sound (e.g., ta). A normal observer confronted with such a stimulus would "hear" a blend of these two speech sounds (e.g., ga). Subjects who can no longer read lips will report the auditory stimulus and not the blend. Apart from this single paper there is little neuropsychological evidence for this dissociation, although there is some convergent evidence from cognitive psychology.

The literature also supports the notion of distinct pathways for the processing of familiar and unfamiliar faces. Prosopagnosia patients may perform normally on tasks of matching unfamiliar faces. Conversely, patients with unfamiliar face matching impairments often are not clinically prosopagnosic. One of the first clear examples of a double dissociation came from a study by Daniel Malone. Case 1 initially was unable to recognize familiar faces, and he was also impaired on the matching of unfamiliar face photographs. Later testing revealed that the familiar face recognition impairment had improved significantly, whereas his unfamiliar face matching problem remained. Case 2 was unable to recognize both relatives and various familiar personalities by their faces alone 6 weeks after an initial testing. There was a significant improvement, however, in his initially impaired unfamiliar face matching performance, which now fell within the normal range. The idea of independence of familiar face recognition from the perception of unfamiliar faces in terms of gender decision is supported by studies with normal subjects.

In short, prosopagnosia is a selective deficit in the recognition of familiar faces that may arise in the context of preserved recognition of other types of information that can be read from faces, such as expressions and speech gestures.

IV. TOWARD A TAXONOMY OF PROSOPAGNOSIA

It is now becoming clear that there are different forms of prosopagnosia that can be distinguished in terms of the underlying functional deficit. The distinction between apperceptive and associative prosopagnosia has already been introduced. Another important form of face recognition deficit could be termed "person identification deficit." The patient M.E. was a right-handed female who, after a vasculitic disorder, suffered from a selective memory deficit. She performed normal to above normal on tasks for the perception of faces (e.g., Benton facial recognition test) and on tasks that required her to choose the familiar face from an array with unfamiliar faces. However, she was very poor at retrieving personal information about the people whose faces she had recognized. Often she would claim that a face looked familiar but that was all she could say about it. These findings provide a strong indication that her face recognition system is unimpaired to the level of familiarity recognition. The dissociation between face familiarity and access to biographical information was confirmed on formal testing.

A related impairment concerns a specific anomia. In 1989, Brenda Flude and colleagues studied a patient with an impairment at the last stage of face recognition, that is, retrieval of the name. Their patient, E.S.T., showed a preserved ability to (a) match unfamiliar faces on identity, (b) distinguish between familiar and unfamiliar faces and names, and (c) access semantic information from faces and written names of familiar people. However, E.S.T. was severely impaired in naming familiar faces. The finding of this selective functional deficit supports the idea that the mechanism dealing with name retrieval (which was severely impaired for E.S.T.) is separable from mechanisms responsible for the sense of familiarity and access to appropriate semantic information (which were both well-preserved for EST). Flude's investigation of E.S.T., then, demonstrates that name retrieval can be impaired when access to identity-specific semantic information is preserved. A more recent study with Alzheimer's patients showed that there were no patients who could name a face without producing any autobiographical information concerning that person. This again supports the proposal that

name retrieval is a separate stage that takes place after access of personal information.

It is concluded that there are several forms of prosopagnosia that can be distinguished on the basis of the functional locus of the deficit. First, higher order perceptual impairments may lead to face recognition problems. In line with Lissauer's suggestion some 100 years ago, there is an amnestic form. Subsequently, patients may be impaired in accessing biographical information about familiar people, and finally there are patients who are unable to retrieve the names of familiar people. In addition, it is useful to point out that prosopagnosia entails, in fact, two impairments: the inability to recognize familiar faces and the inability to learn new faces or relearn old ones. These problems have subsequently been described in isolation. Transient forms can be interpreted as retrograde prosopagnosia, whereas anterograde prosopagnosia refers to those who are no longer able to learn new faces but can recognize faces learned before the onset of the condition.

V. THE ANATOMY OF FACE PERCEPTION

Face processing disorders have been described in a wide range of patient populations. Patients suffering from diffuse brain damage such as dementia or closed head injury have been shown to suffer from severe deficits in face processing. Progressive visual recognition problems, notably for faces, are the prevailing clinical symptom in patients with a degenerative illness that specifically affects the posterior areas of the cortex. Several studies have shown that autistic patients demonstrate problems in the perception and recognition of faces. A number of patients with visual recognition deficits, including prosopagnosia, have been described after carbon monoxide poisoning. Face processing disorders have also been described in patients with neurological illnesses resulting in more localized damage. For instance, temporal and frontal lobectomy may impair the perception of faces and facial expressions. In addition, the famous prosopagnosic case H.J.A., who has been studied extensively by Glyn Humphreys and Jane Riddoch, had suffered a large posterior stroke.

Prosopagnosia is, in most cases, the result of bilateral posterior damage to the cortex. The left and right occipitotemporal junctions have traditionally been identified as the substrate for face recognition. Most patients with prosopagnosia (and all patients who have come to post mortem investigation) had lesions in those areas. In humans, the fusiform and lingual gyri are most often implicated. These observations are somewhat at odds with the primate single-cell recording studies that localize the cells sensitive to face identity much more anteriorly in the upper bank of the superior temporal sulcus. Obviously, these differences could be explained as differences between species, nonetheless it might be prudent to keep this in mind when comparing the human and the primate data on face perception. In this context it is interesting to note that a study found face-specific cells in the prefrontal area of the macaque monkey.

A number of reports have claimed more recently that a unilateral right hemisphere lesion might be sufficient to cause prosopagnosia, but the status of these demonstrations remains somewhat unclear as long as they depend on neurosurgical reports and neuroimaging instead of post mortem findings. It is known from clinical practice that transient or partial prosopagnosia can occur after a unilateral lesion but that full-blown prosopagnosia appears to require bilateral damage.

The upsurge in functional neuroimaging studies has largely served to confirm the existing evidence from neuropsychology. MEG has supported the notion of bilateral processing as well as the importance of the right inferior temporal lobe for familiar face recognition. Work using PET and fMRI scanning have identified a number of areas involved in the perception of familiar faces in the posterior, occipital–temporal areas of the brain, and again the fusiform gyrus—especially on the right side—appears to play a major role.

In 1999, using fMRI, Nancy Kanwisher and colleagues provided further evidence for a specific face processing system, demonstrating that the face area is not especially activated when the subjects are presented with pictures of animals. Perhaps the most interesting result to come out of neuroimaging until now is the that the area involved in face processing is actually adjacent to the area that is involved in object recognition. This raises the possibility that this area processes visual primitives that happen to be important for face recognition. If these observations are replicated and extended, they might well form the basis for a more tractable definition of what is specific about the face area.

The general consensus is that prosopagnosia is caused by bilateral damage to the ventral fusiform gyrus. There are a number of controversial issues, such as the possibility that a unilateral lesion may be sufficient, and whether there is a specific face area or

whether it is just a part of a general visual object processing area. However, the main challenge for future research must be to use the functional subdivisions of prosopagnosia in order to arrive at a more fine-grained localization.

VI. PROSOPAGNOSIA AND KNOWLEDGE WITHOUT AWARENESS

In 1994, Russell Bauer published his seminal paper that fueled the research on face recognition and awareness. He investigated a patient who had become prosopagnosic after a severe closed head injury. First, he asked his patient to select the correct name from five alternatives to match a photograph of a familiar face. All five alternative names were of celebrities and, therefore, familiar to the patient (who had no problem recognizing names). As expected of a prosopagnosic patient, L.F. performed at chance level. However, skin conductance responses recorded during the experiment occurred significantly more often and with higher amplitude to the correct name than to the other four foils. Daniel Tranel and Antonio Damasio have subsequently replicated these surprising findings. They recorded significantly increased autonomic responses when their prosopagnosic patients looked at slides of familiar faces embedded among those of unknown people.

These observations have been corroborated using other psychophysiological techniques. Differential processing of familiar and unfamiliar faces in prosopagnosia has been demonstrated with ERP measures using an odd-ball paradigm in which the patients looks at a long series of faces. Most of the photographs are of completely unfamiliar people, but once in a while the face of a very famous person is embedded in the series. Each time a famous face appears there is a clear increase in the amplitude of the P300 response.

Finally, the recording of eye movements has suggested spared processing of familiar faces in prosopagnosic patients. It has been demonstrated that the way in which normal people look at faces depends on whether they know the person. Unfamiliar faces are scanned in a rather global manner with about an equal amount of attention given to all aspects of the face. However, with familiar faces the emphasis is clearly on the internal part of the face (eyes–nose–mouth region). Although the prosopagnosic patient is unaware of the fact that he is looking is a familiar face, his scanning behavior is as if he is looking at a familiar face. These demonstrations of differential processing of familiar and unfamiliar faces despite the inability to recognize the familiar faces overtly, thus, appear robust.

These data were first interpreted as indicating two separable recognition systems, one for overt and another for covert recognition. The overt system would result in a conscious experience of recognition, whereas the covert system would feed into the limbic system and serve an alerting function. However, there were also some indications that covert recognition might not be restricted to autonomic or physiological measures. Earlier studies had shown that a partially prosopagnosic patient had shown some degree of preserved knowledge of familiar faces of which he did not appear to be aware. These suggestions have been extensively followed up by our research group in a number of studies with the patient P.H., who is completely unable to recognize familiar faces overtly. The extent of P.H.'s recognition problems is well-illustrated by his performance on a forced-choice task where he had to choose the familiar face from an array of two faces. This test procedure is sensitive to small degrees of residual processing as it is not influenced by possible language or memory dysfunction or subject to the common response bias of agnosic patients who respond "I don't know" in standard line-up confrontation tasks. P.H. performed this task at chance level (correct on 51% of the trials), indicating that he has no access to familiarity information from faces.

Next, in seeking to demonstrate covert knowledge, we used experiments that have been shown to be sensitive to knowledge of face familiarity in healthy individuals but that do not require overt identification of the famous faces used as experimental stimuli. Such experiments used the procedures of matching, interference, associative priming, and paired-associate learning. For instance, in the matching experiment, subjects are required to decide whether two simultaneously presented photographs of faces are taken from the same person or two different people. Normal subjects are faster to match photographs of familiar than unfamiliar people, and P.H. showed exactly the same effect, yet he was unable to identify any of the faces used. Covert processing can also be demonstrated in associative priming experiments. Such experiments show the influence of previously presented stimuli on a subsequent response. Subjects have to decide whether the targets (i.e., written names of familiar and unfamiliar people) are familiar. The responses are influenced by the presentation of a primeing stimulus (e.g., a face) shortly before the target appears. If there is a strong association between the prime stimulus (e.g., a photograph of Prince

Charles) and the target (e.g., the name of Princess Diana), the subject responds faster than when the prime is either the face of an unfamiliar person or that of a familiar person who is not closely associated with the target (i.e., the face of Prince Charles followed by the name of George Bush). The patient, P.H., shows this type of priming effect with faces that he does not overtly recognize. Moreover, we were able to compare the extent of the priming effect with that triggered by name primes (which P.H. recognizes without difficulty). The effects are equivalent: overt recognition of name primes makes no additional contribution to the associative priming effect. This suggests that P.H. not only covertly recognizes faces but that his recognition is normal in the amount of associative priming that it produces.

It should be noted that covert recognition effects are not invariably found in agnosias. Some prosopagnosic patients do not show any covert effects at all, and others have exhibited partial covert recognition effects, such as covert recognition effects for only a subset of the people known to the patient.

The observation of covert face recognition, in its different forms, has extended the taxonomy of prosopagnosia. Apart from the difference between apperceptive and associative prosopagnosia, we can now distinguish between prosopagnosia with and without covert recognition. This difference is possibly related to the issue of whether the stored representations of familiar faces are still spared in a prosopagnosic patient. Several authors have commented on the use of mental imagery tests to evaluate the integrity of the stored representations. A number of patients have been described who are able "picture faces in their mind" that they cannot recognize overtly. Obviously testing of such a subjective ability as mental imagery is not easy, but a number of useful procedures have been developed. The method of odd-one-out, in which the patient has to decide which one of three people looks most unlike the other two (e.g., the patient is given the names: Charlie Chaplin, Adolf Hitler, and Bill Clinton) has been used successfully to demonstrate clinical dissociations between impaired recognition and spared mental imagery of familiar faces.

VII. DEVELOPMENTAL PROSOPAGNOSIA

The ability to recognize familiar faces can, thus, be characterized as modular in terms of the ideas put forward by Jerry Fodor. It is a highly specialized function with a well-circumscribed neurological substrate that appears to be hard-wired at birth. Faculties are modular as a consequence of their importance to the individual and, therefore, are designed to mature and develop in an efficient and relatively protected way. This modular, hard-wired nature of face recognition suggests that the variability in capacity in the general population can be attributed largely to biological factors. A genetic basis for language processing is now generally accepted. Developmental face recognition problems have been described in a handful of case studies. By definition, the problem is present from early childhood. In addition, there should be no known neurological history that could explain the recognition problem. There is one case of developmental prosopagnosia that has been followed extensively. This is an intelligent and verbal woman, who experienced very severe difficulties in recognizing familiar faces. Reading and object recognition were preserved, but she encountered problems on most tasks that depend on the use of facial information, such as the visual analysis of expressions and the short-term memory of unfamiliar faces. Her problem is best described as an inability to form an adequate internal representation of faces. As a result, faces have never gained the significance for her that they have for most of us. Instead, she relies heavily on voices for the recognition of familiar people.

An interesting observation, mentioned in some case studies on developmental face recognition deficit, concerns the anecdotal reference to other family members who are supposedly also poor at recognizing faces. One study concerns a family of two parents, three daughters, and one son. Two of the daughters and the father were very poor at recognizing familiar faces. The other family members did not have any problems. Thus, the face recognition problems occurred not only in two family members of the same generation but also in family members of different generations. These observations present clear evidence for a familial factor in the development of face recognition problems.

VIII. CONCLUSIONS

In clinical terms, it has become clear that, although pure prosopagnosia is rare, face recognition impairments are much more common than has been previously suggested. The reasons that these problems often remain undiagnosed are due to the fact that patients do not spontaneously complain either as a result of lack of insight or because the difficulties are

ascribed to a general memory deficit and/or because the assessment of face recognition deficits is often not included in standardized neuropsychological screening. In most cases, face recognition deficits occur in the context of more widespread perceptual problems. The effects on daily living are often underestimated.

Prosopagnosia severely reduced the professional and social possibilities of the patient and in many cases has led to social isolation. Finally, there have been several attempts at developing rehabilitation programs, but until now without much success. Memory training has been successfully applied in patients who can recognize faces but have problems with retrieving the name. However, even patients with intact covert recognition do not appear to benefit from cognitive training.

In terms of understanding the underlying mechanisms of face recognition, the study of prosopagnosic patients has produced a number of intriguing and often counterintuitive results during the past two decades. If the fractionation of face and object recognition remained controversial until quite recently, we have now seen the general acceptance of a specialized face processing system that itself fractionates further into a system responsible for familiar face recognition, expression analysis, face perception skills, such as gender decision and age estimation, and perhaps lip reading. Within the processing route involved in familiar face recognition, separate sequential processing stages have been identified for the processing of the incoming visual image and access to stored representations of faces, autobiographical information, and names. These processing stages are largely automatic and escape conscious introspection as demonstrated by the phenomenon of covert face recognition where these automatic processes continue to operate despite the fact that the output never reaches conscious awareness. Functional imaging techniques have produced new data suggesting that the apparent selectivity of face processing can actually be traced back to the functional organization of the fusiform gyrus, where there may be a continuous representation of form information that has a highly consistent and orderly topographical arrangement. The face area constitutes the part that entails the form detectors that are particularly important for defining faces. The challenge for future research is to refine the functional architecture of face recognition in order to understand the neuroanatomical basis of the different forms of prosopagnosia that can be distinguished.

Psychoactive Drugs

DAVID E. PRESTI
University of California, Berkeley

GLOSSARY

agonist A drug that binds to a neurotransmitter receptor and mimics the action of an endogenous neurotransmitter.

antagonist A drug that binds to a neurotransmitter receptor and has no effect other than to block the action of endogenous neurotransmitters and other receptor agonists.

gamma-aminobutyric acid The major inhibitory neurotransmitter in the human brain.

glutamate An amino acid that functions as the major excitatory neurotransmitter in the human brain.

neurotransmitter A chemical that is released by nerve cells and diffuses extracellularly to bind to receptors on nerve cell membranes, thereby mediating intercellular communication of neural signals.

neurotransmitter receptor Proteins found in nerve cell membranes that specifically bind neurotransmitters, undergo conformational change, and thereby mediate changes in cell membrane electric potential or initiate various intracellular biochemical processes.

psychoactive drug A chemical that in small amounts influences the functioning of the human brain in such a way as to have effects on the psyche or mind.

The human brain is the most complex object in the known universe. Its complexity is apparent in its 100 billion or more neurons interconnected by trillions of synapses. Each synapse is a stage for an intricate molecular drama involving release of chemical neurotransmitters, rapid diffusion of neurotransmitter across the narrow gap separating the presynaptic from the postsynaptic neuron, binding of neurotransmitter to receptor proteins located in the membranes of the postsynaptic and presynaptic neurons, resulting conformational changes of these receptors, and subsequent changes in membrane potential or initiation of various intracellular biochemical processes. The neuronal signaling process is terminated when neurotransmitter is taken back up into the neuron that released it via membrane proteins called reuptake transporters or is otherwise enzymatically degraded.

I. INTRODUCTION

Dozens of different molecules have been identified as neurotransmitters in the human brain. These include glutamate and gamma-aminobutyric acid (GABA), the main excitatory and inhibitory neurotransmitters in

the human brain. Others include serotonin, dopamine, norepinephrine, epinephrine, acetylcholine, histamine, adenosine, glycine, anandamide, and the opioid peptides. Many more neurotransmitter molecules no doubt remain to be discovered. The diversity of chemical neurotransmitters and the numerous different receptor proteins—many different kinds for any one neurotransmitter—are another facet of the vast complexity of the brain.

By psychoactive drug, I mean chemicals that influence the functioning of the human brain in such a way as to have effects on the psyche or mind. It is currently known that psychoactive drugs exert their influence by interacting with the signal transmission process at synapses. There are various ways this can happen. A drug can mimic the effect of a neurotransmitter because sufficient similarity in molecular structure allows it to bind to and activate a receptor in the same way as the natural neurotransmitter. Such a drug is called a receptor agonist. It could also bind to a receptor and block the receptor, preventing its activation by endogenous neurotransmitter. Such a drug is called a receptor antagonist. Some drugs enhance neurotransmitter release or leakage from the presynaptic neuron. Other drugs block release of neurotransmitter from the presynaptic neuron. Still others block reuptake of neurotransmitter from the synapse, interfere with the synthesis or degradation of neurotransmitter, or interact with the chemistry of the brain in ways that have not been elucidated.

Psychoactive drugs include the following chemicals:

- Commonly used nonmedical substances, such as caffeine, alcohol, and nicotine
- Medically used substances, such as morphine and other opioids, amphetamine, and benzodiazepines
- Mind-altering substances that have been excluded from accepted medical use and are declared illegal, such as heroin, marijuana, and psychedelics such as lysergic acid diethylamide (LSD), mescaline, and psilocybin
- Medications used to treat mental-health conditions, such as antidepressants, antipsychotics, and other mood stabilizers

Some of the previously mentioned drugs are frequently used for their pleasure-producing or recreational effects (alcohol, caffeine, etc.), some are used medicinally (antidepressants, antipsychotics, etc.), some are used for both (amphetamine, opioids, benzodiazepines, marijuana, etc.), and some are more prone to fostering problematic relationships such as addiction (nicotine, alcohol, benzodiazepines, etc.).

Historically, psychoactive drugs were all natural products, ingested in the form of plants or fungi or extracts of these organisms. The original meaning of the word "drug" was "dried plant." Beginning in the 1800s, chemists isolated and identified a number of molecules from plants that had psychoactive effects. Morphine, caffeine, nicotine, cocaine, and mescaline were all identified as psychoactive compounds from plants by 19th-century German chemists. In the past century, pharmaceutical chemists synthesized new molecules that have psychoactive effects, some of which have been marketed as drugs for the treatment of various conditions.

In the United States, many psychoactive drugs are classified according to the Controlled Substances Act, a federal law first instituted in 1970 and copied in some form by all of the states. The Controlled Substances Act classifies psychoactive drugs that have been declared to have the potential for abuse (problematic use leading to possible addiction) into five categories or schedules. Schedules II–V are legally available for medical use with appropriate licenses and physicians' prescriptions. Examples are amphetamine, morphine, and the benzodiazepines. Schedule I drugs have been declared categorically illegal and are not available for legal medical use. Examples are marijuana and the psychedelics. Alcohol and nicotine (tobacco), because of the powerful economic interests vested in keeping them easily available, are not regulated by the Controlled Substances Act.

This article only briefly discusses the neurochemical effects of various drugs, but it does contain the essence of what is currently known. As knowledge about the brain increases, we will find that many of the actions of psychoactive drugs are far more complex than is currently understood.

II. SEDATIVE–HYPNOTICS AND RELATED DRUGS

Sedative–hypnotics produce relaxation and often euphoria in low doses, drunkenness and sleep in higher doses, and possible coma and death in overdose. Alcohol (ethyl alcohol or ethanol) is the most widely used sedative–hypnotic. Ethyl alcohol is a natural product produced by yeast via the fermentative metabolism of carbohydrate. Synthetic pharmaceutical sedative–hypnotics include the benzodiazepines [diazepam (Valium), alprazolam (Xanax), lorazopam

(Ativan), temazapam (Restoril), etc.], barbiturates (phenobarbital, secobarbital, amobarbital, etc.), and other substances such as chloral hydrate, meprobamate (Miltown), and methaqualone (Quaalude). Pharmaceutical sedative–hypnotics have been prescribed medically as treatments for anxiety (anxiolytic properties) and as aids to sleep.

General anesthetics are powerful sedative–hypnotics used to induce loss of conscious awareness and insensitivity to pain during surgical procedures. They are often volatile organic compounds inhaled as part of a gas mixture during surgery. Historically, diethyl ether and chloroform were used in this way. Contemporary examples include halogenated compounds such as desflurane, enflurane, halothane, isoflurane, and sevoflurane.

Gamma-hydroxybutyric acid (GHB) is a sedative–hypnotic whose chemical structure is similar to that of the neurotransmitters GABA and glutamate. GHB was recently declared a Schedule I drug in the United States because of its use in recreational settings. Kava kava (*Piper methysticum*, native to South Pacific islands) and valerian (*Valeriana officinalis*) are examples of plants with sedative–hypnotic properties.

Sedative–hypnotics are believed to exert their effect on the brain by interacting with receptors for the neurotransmitter GABA. Their effect at these receptors enhances the action of GABA as an inhibitory neurotransmitter and results in a depression of brain activity. Some (e.g., alcohol) may also have actions at glutamate receptors, reducing the action of glutamate, which is the brain's major excitatory neurotransmitter. In addition, GHB may have direct inhibitory neurotransmitter action in the brain, with its own distinct receptors.

III. CAFFEINE

Caffeine (1,3,7-trimethylxanthine) is by far the most widely used psychoactive drug in the world. It is found in a number of plant sources, the most well-known being coffee (*Coffea arabica*, native to Africa), tea (*Camellia sinensis*, native to China), and cacao (*Theobroma cacao*, native to South and Central America), from which chocolate is made. Other caffeine-containing plants include kola (*Cola acuminata*, native to Africa), guarana (*Paullinia cupana*, native to South America), and yerba mate (*Ilex paraguarienis*, native to South America). Closely related to caffeine are two other botanical methylated xanthines with similar psychoactive effects: theophylline (1,3-dimethylxanthine), found in tea, and theobromine (3,7-dimethylxanthine), from cacao. Caffeine is believed to act by antagonizing (blocking) receptors for the inhibitory neurotransmitter adenosine, thereby producing a stimulating effect on brain activity.

IV. NICOTINE

Nicotine comes from the tobacco plant—*Nicotiana tabacum*, *Nicotiana rustica*, and related species—native to the Americas. It is generally taken into the body by smoking the dried leaves of the tobacco plant. It may also be absorbed through the oral cavity or nasal mucosa if a snuff preparation or chewing tobacco are used. It produces complex effects on the brain that result in relaxation, stimulation, and focused attention. The major known neurochemical effect of nicotine is to bind as an agonist to the nicotinic-type receptor for the neurotransmitter acetylcholine.

V. COCAINE

Cocaine comes from the plant *Erythroxylum coca* and related species, native to South America. Cocaine blocks reuptake transporter proteins for the neurotransmitters dopamine, norepinephrine, and, to a lesser extent, serotonin. In the brain, this results in the activation of circuits that increase alertness and wakefulness, produce euphoria, and decrease appetite. In the peripheral nervous system, cocaine activates the sympathetic branch of the autonomic nervous system, with resultant increased heart rate, blood pressure, pupil size, and bronchial airway size.

VI. AMPHETAMINE AND RELATED MOLECULES

Amphetamine and its close chemical relative methamphetamine are synthetic substances that cause the neurotransmitters dopamine, norepinephrine, and serotonin to leak out of the presynaptic nerve terminal into the synapse. This results in activation of the same brain and peripheral nervous system circuits as with cocaine and substantially similar behavioral effects. There are a number of pharmaceutically manufactured substances that can be considered molecular relatives of amphetamine and that work in similar ways. They have been prescribed as central nervous system (CNS) stimulants for the treatment of narcolepsy, appetite suppressants, and as treatment for attention deficit hyperactivity disorder. Ephedrine (from plants of the

genus *Ephedra*, found worldwide), cathinone (from the plant *Catha edulis*, native to northeast Africa and Yemen), and the synthetic compound phenylpropanolamine are examples of other related molecules with both central and sympathetic nervous system stimulant effects.

VII. OPIOIDS

Opioids (or opiates) are a group of naturally occurring and synthetic chemicals that act on the nervous system in a manner such as opium, the gummy secretion from the unripe seedpod of the opium poppy, *Papaver somniferum*, native to the Middle East and north Africa, now grown throughout the world. Natural opium contains morphine and codeine. In 1803, morphine became the first physiologically active compound to be isolated and identified from a plant. Opioids act on opioid receptors in the brain to reduce the perception of pain (analgesia), suppress cough, constrict pupils, and slow respiration. They may also produce relaxation, euphoria, and a dreamy altered state of consciousness. Medicinally, opioids are invaluable as analgesics and cough suppressants. Acting at opioid receptors in the digestive system, opioids slow intestinal motility and thus are valuable treatments for diarrhea.

A number of opioids either are chemical derivatives of morphine, codeine, or other related molecules in opium or are synthesized from nonopioid precursors. Heroin (diacetylmorphine) is a simple chemical derivative of morphine that allows it to cross the blood–brain barrier into the brain two or three times more efficiently than morphine. Hydromorphone (Dilaudid), oxycodone (Percodan and OxyContin), and hydrocodone (Vicodin) are all derived from opium precursors. Methadone, fentanyl, meperidine (Demerol), and propoxyphene (Darvon) are examples of synthetic opioids.

The endogenous neurotransmitters acting at opioid receptors are a class of small peptide molecules collectively called opioid peptides or endorphins (from "endogenous morphine"). These range in size from the 5-amino acid-long enkephalins to the 31-amino acid-long beta-endorphin.

VIII. CANNABINOIDS

The cannabinoids are a class of chemical substances found in the *Cannabis* plant, the source of marijuana (dried buds and leaves) and hashish (concentrated resinous exudate from the buds and leaves). The primary psychoactive cannabinoid in cannabis is Δ-9-tetrahydrocannibinol, often referred to simply as THC. The cannabis plant is one of the most ancient human cultivars, with medicinal use documented in Chinese medical texts from more than 4000 years ago. Some botanists recognize distinct species of *Cannabis sativa*, *Cannabis indica*, and *Cannabis rudeleris*, whereas others believe that cannabis has been cultivated by humans for so long that no distinct wild-type species remain.

The psychoactive effects of cannabis may include relaxation, sedation, intensification of thoughts and feelings, alterations of perception, and increased appetite. Medicinally, cannabis has been used as an analgesic, an antiinflammatory, a treatment for migraine headache, an antiemetic (to decrease nausea), an anticonvulsant, a muscle relaxant, a treatment for glaucoma, and an appetite stimulant. It was widely used as an accepted pharmaceutical prior to its being declared illegal by the United States government in 1937. Recent years have seen a resurgence of interest in the medicinal properties of cannabis and the discussion and attempted implementation of new laws to allow legal medical research and use to again take place.

For many years, the neurochemical mechanism of action of THC remained obscure. The past decade saw the discovery of specialized receptors responding to THC (cannabinoid receptors). Cannabinoid receptors are widespread in the human brain as well as elsewhere in the body, such as components of the immune and endocrine systems. At least two endogenous compounds have been implicated as neurotransmitters for the cannabinoid system—anandamide and 2-arachidonyl glycerol, both of which are long-chain, polyunsaturated compounds derived from lipids. The function of the cannabinoid neural circuitry remains unknown, although it is likely to be involved in appetite, memory, and the perception of pain.

IX. PSYCHEDELICS OR HALLUCINOGENS

The psychedelics are among the most interesting and ill understood of the psychoactive drugs. They produce a variety of complex effects on the brain and mind, including intensification of thoughts and feelings, alterations of sensory perception, and loosening of psychological defenses. Reported experiences range from euphoria, therapeutic insight, and visions of god, to anxiety and panic. The effects of the psychedelic drugs, more so than with other drugs, may be

significantly influenced by the mental set of the user (expectations, prior experience, mood, etc.) and the physical setting of use (alone, social, therapeutic context with a healer, spiritual ritual, etc.).

In 20th-century medicine, many of these compounds were first called psychotomimetics because it was believed that their effects were like the symptoms of psychosis. This term was eventually discarded in favor of hallucinogen because they may produce alterations of perception that include hallucinations. In 1956, the psychiatrist Humphry Osmond, in correspondence with the author Aldous Huxley, proposed the word "psychedelic" (from the Greek "mind manifesting") to describe the unique effects of these compounds on consciousness. In their plant forms, psychedelics have been used by cultures throughout the world for thousands of years to facilitate spiritual states of consciousness. This has led to the proposal of the word "entheogen" ("generating god within") to emphasize their ritual spiritual use.

Although it has not been discovered as a natural product and its profound psychoactive properties were not known until it was synthesized and tested by Albert Hofmann in 1943, LSD is perhaps the most widely known psychedelic chemical. It is one of the most potent psychoactive compounds known, active in quantities of a few micrograms. Psychedelics identified from plants and fungi include lysergic acid amide from morning glories, psilocybin and psilocin from a variety of mushrooms (many of the genus *Psilocybe*), dimethyltryptamine from dozens of species of plants throughout the world, and mescaline from several species of cacti, one of which is peyote (*Lophophora williamsii*). Numerous chemical relatives of the compounds mentioned previously have been synthesized, tested, and found to have psychedelic effects in humans.

Prior to their being declared illegal in the United States, these compounds were researched and utilized for their psychotherapeutic properties. Research at the time found them to be of value in the treatment of alcoholism and in therapeutic work related to dying in terminally ill patients. There is ample reason to believe that when used with therapeutic intent in carefully controlled settings, they can be of extraordinary value. Such use may also involve some exclusion of individuals having preexisting psychopathology because their powerful effects on the brain and mind may exacerbate preexisting symptoms or tendencies toward psychopathology.

Neurochemically, psychedelics have been found to bind as agonists to various serotonin receptor subtypes, especially type-2 serotonin receptors. Psychedelics also bind to other neurotransmitter receptors, including those for dopamine and norepinephrine. The connection between their neurochemical effects and their profound effects on mental function remains obscure.

X. METHYLENEDIOXYMETHAMPHETAMINE

Methylenedioxymethamphetamine (MDMA), popularly known by the street name "ecstasy," and its close chemical relative methylenedioxyamphetamine (MDA) are often considered together with the psychedelic drugs. Although MDMA does have some of the mind-manifesting characteristics of the psychedelics, its overall properties are distinct enough to warrant a separate categorization. Chemically related to methamphetamine, MDMA produces CNS stimulation, euphoria, and sympathetic nervous system stimulation. The methylenedioxy moiety confers upon the molecule additional psychoactivity that is psychedelic-like, characterized by intensification of thoughts and feelings and enhanced feelings of connection with others. For many individuals, there is a reduction in anxiety and an enhanced ability to verbalize feelings. These qualities led to the use of MDMA as an adjunct to psychotherapy prior to its being declared an illegal Schedule I substance in 1985, an act that followed media attention focusing on its use as a recreational drug in the dance scene. Although illegal, MDMA continues to be used for both its psychotherapeutic and recreational properties by some individuals.

Although MDMA has been found to interact with a number of CNS neurochemical systems, the primary neurochemical effect of MDMA appears to be the release of serotonin and dopamine from nerve terminals into the synapse. Release is not via the usual process of storage vesicle fusion with the cell membrane, as occurs with a nerve impulse, but leakage of neurotransmitter out of the cell via the reuptake transporter.

Animal studies have indicated that MDMA may result in oxidative damage to serotonin nerve terminals. The implications of these findings for human use remain to be determined.

XI. NITROUS OXIDE

Nitrous oxide (N_2O) is a gas (sometimes called laughing gas) widely used for its anesthetic and analgesic properties. It is used by dentists as a sole anesthetic and

is a component of the inhalation anesthesia (together with potent volatile sedative–hypnotic general anesthetics) for major surgeries. In addition, in subanesthetic doses it can produce a powerful psychedelic-like altered state of consciousness. Its various psychoactive properties were documented in 1800 by the British chemist Humphrey Davy, marking the first detailed study of the effects of a defined chemical substance on the human mind. Although it has been found to interact as an antagonist at the NMDA-type of glutamate receptor, the mechanism of its psychoactive effects remains obscure.

XII. DISSOCIATIVE ANESTHETICS

This class of psychoactive drugs includes ketamine and PCP (phenyl cyclohexyl piperidine or phencyclidine). They are synthetic compounds introduced into medicine to produce an anesthetic loss of sensation without depressing respiration and cardiovascular function as do the general anesthetics. Although PCP is no longer used medically, ketamine is used for both human and veterinary surgical procedures. At subanesthetic doses in humans, ketamine produces an altered state of consciousness that has some psychedelic-like characteristics and may be accompanied by a loss of body sensation. The primary neurochemical effect is as an antagonist at the NMDA-type glutamate receptor.

XIII. ANTICHOLINERGICS

These substances act as antagonists at muscarinic-type receptors for the neurotransmitter acetylcholine. Such receptors are found in the brain and in the parasympathetic branch of the autonomic nervous system. Psychoactive effects can range from feelings of disorientation to dream-like alterations of consciousness, powerful hallucinations, and delerium. Effects on the autonomic nervous system produce a cluster of symptoms that include dry mouth, difficulty urinating, constipation, blurry vision, and orthostatic hypotension. Hyoscyamine/atropine and scopolamine are anticholinergics found in a number of species of plants from the family Solanaceae. These include *Atropa belladonna* (deadly nightshade), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Brugmansia*, *Datura*, and *Brunfelsia*.

Atropine, scopolamine, or tincture of belladonna may be used to treat intestinal motility problems such as diarrhea and irritable bowel syndrome. Several synthetic anticholinergic drugs are used as adjunctive treatments for Parkinson's disease. Several of the phenothiazine antipsychotics and tricyclic antidepressants described later have anticholinergic effects in the brain and autonomic nervous system.

XIV. ANTIPSYCHOTICS

In Indian ayurvedic medicine, from ancient times to the present, extracts of the snakeroot plant, *Rauwolfia serpentina*, have been used to treat symptoms of psychosis. In the 20th century, the chemical reserpine was isolated and identified from *R. serpentina* and found to cause decreases in the activity of monoaminergic neurons using the neurotransmitters dopamine, norepinephrine, and serotonin.

The first pharmaceutical antipsychotics were the phenothiazines such as chlorpromazine (Thorazine), introduced in the 1950s. Some nonphenothiazine antipsychotics introduced to the market in the 1960s and 1970s include haloperidol (Haldol) and thiothixene (Navane).

The primary neurochemical effect of these compounds is to block various types of dopamine receptors. This is believed to lead to a reduction of psychotic symptoms and also to the production of various motor side effects, such as parkinsonian-like symptoms and movement dyskinesias.

Recently, several antipsychotic medications have been introduced that have fewer motor side effects, including clozaril (Clozapine), risperidone (Risperdal), olanzepine (Zyprexa), and ziprasidone (Geodon). In addition to being antagonists at dopamine receptors, these drugs are also antagonists at type-2 serotonin receptors. The serotonin receptor antagonism is believed to compensate for some of the dopamine-blocking effects in the motor circuitry of the brain, thereby reducing problematic movement symptoms.

XV. ANTIDEPRESSANTS

Extracts of the plant Saint John's wort, *Hypericum perforatum*, have been used for centuries in Europe for their antidepressant effects. This plant also facilitates wound healing when preparations are used topically. Its healing properties were mentioned in the ancient medical texts of Hippocrates, Pliny, and Galen.

The first modern pharmaceuticals developed and marketed specifically for their antidepressant effects

were the monoamine oxidase inhibitors (MAOIs), discovered in the 1950s. Examples currently on the market are isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate). Via inhibition of the enzyme MAO, these compounds may produce enhanced neural activity in circuits utilizing the neurotransmitters serotonin, norepinephrine, and dopamine.

These were followed in the 1960s by the tricyclic antidepressants (TCAs), such as imipramine (Tofranil), amitriptyline (Elavil), desipramine (Norpramine), nortriptyline (Pamelor), doxepin (Sinequan), and clomipramine (Anafranil). TCAs have been found to inhibit monoamine reuptake transporters, primarily for norepinephrine and serotonin.

Newer generation antidepressants include the serotonin selective reuptake inhibitors, represented by fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), fluvoxamine (Luvox), and citalopram (Celexa), and other compounds such as trazodone (Desyrel), nefazodone (Serzone), bupropion (Wellbutrin and Zyban), venlafaxine (Effexor), and mirtazapine (Remeron). These latter compounds interact in various ways with monoamine neurotransmitter receptors or reuptake transporters.

The prevailing hypothesis regarding antidepressant mechanism is that some sort of change in serotonin and/or norepinephrine synaptic chemistry underlies their clinical action, but exactly what sort of change remains obscure.

XVI. OTHER MOOD STABILIZERS

These compounds are used to treat bipolar or manic–depressive disorder. The most well-known is lithium. The therapeutic effects of lithium in the treatment of manic–depression were discovered in 1949 and lithium has been widely used in psychiatry for more than 40 years. Its mechanism of action remains largely obscure. It is known to influence a variety of different neurotransmitter systems. The most robust neurochemical effect of lithium thus far elucidated is its interference with G-protein-coupled pathways using phosphatidylinositol as an intracellular messenger. Several chemicals, first discovered for their antiseizure properties and used to treat seizure disorders, are also used to stabilize mood in manic–depression disorder. These include carbamazepine (Tegratol), valproic acid (Depakote), and gabapentin (Neurotin). This connection between unstable mood and seizures suggests that there may be so-called kindling processes involved in both, wherein neural pathways become triggered into some sort of chain reaction of overactivity.

XVII. DRUGS AND THE BRAIN

The functioning of the brain depends at least in part on its chemistry and psychoactive drugs work by influencing the chemistry of the brain. This may give rise to short-term behavioral effects, such as relaxation, alertness, euphoria, analgesia, and sleep. Repeated perturbation of the brain's chemistry may bring about changes in the circuitry of the brain that may underlie lasting changes in behavior: improved mood from antidepressants, decreased psychosis from antipsychotics, symptoms of dependence and addiction from a variety of drugs, movement disorders from antipsychotics, and so forth. Changes in the brain's circuitry presumably reflect the strengthening and weakening of synapses through mechanisms such as changes in the number of receptors, changes in the amount of neurotransmitter released, and changes in intracellular biochemical pathways that are activated by membrane receptors. Growth of new dendrites to form new synapses or deterioration of existing synapses may also be involved.

XVIII. WITHDRAWAL, DEPENDENCE, AND ADDICTION

Changes in brain physiology resulting from repeated exposure to psychoactive drugs may result in withdrawal symptoms when use of the drug is decreased or stopped. It is likely that extended use of *any* psychoactive drug will bring about homeostatic changes in brain physiology that will result in symptoms of withdrawal if use of the drug is stopped. In some cases the withdrawal symptoms will be clinically significant, and in some cases they may not be. For example, repeated use of sedative–hypnotics may produce rebound withdrawal symptoms of arousal, anxiety, and insomnia and, in more severe cases, hallucinations, delerium, and seizures. Situations of clinically significant withdrawal are sometimes referred to as marking physical dependence.

Some psychoactive drugs, especially those that produce an experience of reduced anxiety, pleasure, or euphoria, appear to influence neural circuits in the limbic system of the brain. These so-called reward circuits are likely important in the reinforcement of behaviors that are important for survival, such as

eating, sexual activity, and obtaining comfortable shelter. Euphorogenic psychoactive drugs may chemically hijack these circuits and produce anomolously intense stimulation. The resulting homeostatic changes in the circuits might then produce symptoms of withdrawal that include cravings (intense desires) for the drug, dysphoria, anxiety, and a drivenness or compulsiveness directed toward drug use. Clinically significant compulsive drug use is termed addiction.

The reward circuits of the limbic system connect the ventral tegmentum with the nucleus acumbens. The neurotransmitter in these circuits is dopamine. Various drugs known to be euphorogenic and having the potential to produce addiction have been shown to increase the release and activity of dopamine in these circuits. Although different psychoactive drugs (sedatives, stimulants, opioids, etc.) have a variety of different effects on the brain and behavior, it is possible that their actions on the dopaminergic reward circuits may be part of a common neurochemical mechanism underlying addiction.

Whether an individual develops an addictive relationship with a drug is in part dependent on the drug's pharmacology and direct effects on brain neurochemistry. These factors are modulated by genetic proneness for addiction, as well as psychological and sociocultural factors, such as coping strategies for stress and extent of use by others in one's surroundings.

XIX. DRUGS AND THE MIND

I define mind as the collection of mental states, including thoughts, feelings, and perceptions, experienced by the organism. The current working hypothesis in neuroscience is that the mind is associated with the brain, and that neural processes taking place in the brain somehow generate the qualities of mind. I define consciousness as an aspect of mind that involves awareness of these mental states. The neurobiology of mind, of course, is *the* great unsolved problem of neuroscience. We have little clue as to the chemistry and physiology underlying mental states. Drugs that affect consciousness and other qualities of mind can and will be powerful probes to the physiology of mind. To this end, the complex effects of the psychedelics on consciousness may be especially useful probes, but only after our scientific and legal enterprises have risen to embrace the task of such research.

The great scholar William James, whose thinking on the nature of mind was influenced by his self-experiments with nitrous oxide and with cannabis, said a century ago, in words that are every bit as relevant to this day,

> *One conclusion was forced upon my mind at the time, and my impression of its truth has since remained unshaken. It is that our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, while all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different. We may go through life without suspecting their existence; but apply the requisite stimulus, and at a touch they are there in all their completeness, definite types of mentality which probably somewhere have their application and adaptation. No account of the universe in its totality can be final which leaves these other forms of consciousness quite disregarded. How to regard them is the question.…*

GLOSSARY

adrenal glands Situated just above the kidneys, each gland consists of an inner adrenal medulla, which secretes the catecholamines epinephrine, norepinephrine, and dopamine, and an outer adrenal cortex, which synthesizes and secretes steroid hormones.

circadian rhythm Diurnal (daily) cycles of body functions.

gonads Endocrine structures (testes in males, ovaries in females) with dual functions: the production of germ cells (gametogenesis) and the synthesis and secretion of sex hormones.

homeostasis Complement of various physiological arrangements that serve to restore the normal state, once it has been disturbed.

hormones Chemicals (amino acid derivatives or peptides) released by the endocrine glands into the general circulation.

hypothalamus Area composed of distinct collections of neurons involved in the regulation of basic (homeostatic) vital functions and located in the basomedial region of the brain.

negative feedback Deviations from a given normal set point that triggers opposite compensatory changes, which continues until the set point is again reached.

pituitary gland Located below the brain and suspended on a stalk connecting it to the hypothalamus, it is composed of two major regions: the posterior lobe, which resembles neural tissue, and the anterior lobe, which consists of specialized endocrine secretory cells.

portal blood system Circulatory arrangement that begins in a capillary bed and leads not to vessels that carry blood directly toward the heart, but rather to a second capillary bed.

preprohormones Initial gene products in polypeptide hormone synthesis.

pulsatile release The typical pattern of hormone release, generally lasting only a few minutes, which occurs in large pulses or surges several times a day.

steroids Family of hormone molecules derived from cholesterol, including gonadal steroids, glucocorticoids, and mineralocorticoids, which easily cross lipid membranes.

thyroid gland Gland at the base of the neck that helps maintain the level of metabolism at optimal conditions in all body tissues via the synthesis and secretion of thyroid hormones.

Psychoneuroendocrinology is a multidisciplinary field aimed at elucidating endocrine functions ultimately controlled by the brain and, in turn, how the hormonal products of the various organs influence the functioning of the brain, mood, and cognition. The main endocrine functions of the body include development and growth, reproduction, homeostasis, (temperature, fluids, and minerals), and survival (stress). Although endocrine dysfunctions can be linked to organic disorders, many endocrine disorders have their roots in the brain. Together with accumulating evidence indicating direct hormonal effects upon the brain and the realization that psychological status (the mind or psyche) can dramatically impact endocrine functions, the discipline of psychoneuroendocrinology emphasizes the importance of exploring the interrelationships between mind, brain, organs, and hormones. This article is aimed at describing the major constituents of the neuroendocrine systems and how the brain, moods, and cognition regulate and are regulated by hormones.

I. GENERAL PRINCIPLES OF PSYCHONEUROENDOCRINOLOGY

Although the systems controlling different endocrine endpoints are distinct, several parallels can be drawn in

their overall functioning. The action of hormones on the brain also shows similar mechanisms. The following discussion focuses on the similarities and parallels between the various psychoneuroendocrine systems.

A. The Hypothalamus

The human hypothalamus is very small, accounting for approximately 0.003% of the entire brain mass. However, it controls an array of vital functions without which complex organisms simply could not survive. It is perhaps no accident that the hypothalamus is one of the most deeply located cell-containing regions in the brain, residing in the basomedial part of the head and shielded by the rest of the brain (Fig. 1). It was more than 50 years ago that Geoffrey Harris of Oxford University proposed that *neurosecretory* cells of the hypothalamus release substances in the portal blood system, suggesting for the first time a plausible regulatory mechanism in the release of anterior pituitary hormones.

The hypothalamus is often divided into three major areas: an anterior, a middle, and a posterior region. The middle third of the hypothalamus contains the neuroendocrine components that control most of the posterior and anterior lobes of the pituitary gland. The important cell groups of the middle hypothalamus in

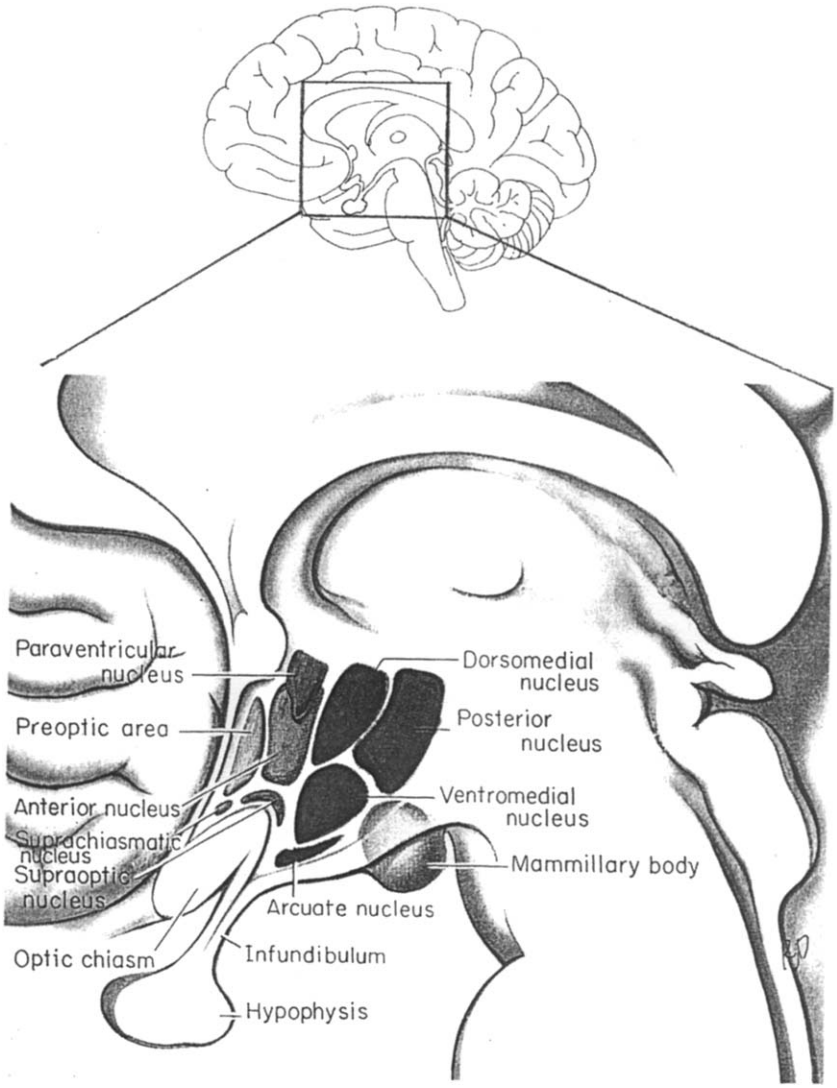

Figure 1 Schematic diagram of a midsagittal section of the human brain showing the location of the hypothalamus and its main subdivisions. Adapted from Carpenter, M. B. (1991). *Core Text of Neuroanatomy*, 4th ed., with permission of Williams & Wilkins.

regard to neuroendocrine control include the paraventricular and arcuate nuclei. The paraventricular nucleus is further broken down into the parvocellular cell group and the magnocellular cell group. In most instances, activity of the parvocellular releasing-factor neurons (also called *hypophysiotropic*) can be linked to the synthesis and secretion of specific pituitary peptides into the general circulation.

B. The Portal Blood System

Unlike the direct projections that exist from the hypothalamus to the *posterior lobe* of the pituitary via axons that join the *internal layer* of the *median eminence* and course through the *infundibular stalk*, the *anterior lobe* of the pituitary does not receive direct axonal projections from the hypothalamus, as shown in Fig. 2. Instead, the connections between the hypothalamus and the anterior lobe are entirely *neurohumoral*. In this process, peptides synthesized in neurons of the middle hypothalamus are carried via their axons to the *external zone* of the median eminence, where they are released into fenestrated capillaries that coalesce to form *portal vessels* that run along the infundibular stalk and terminate in vascular sinuses in the anterior lobe of the pituitary gland.

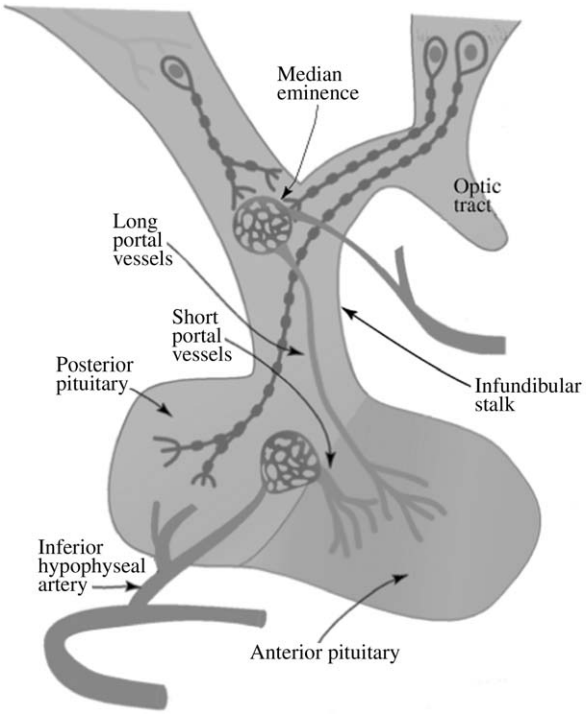

Figure 2 Schematic diagram of the arrangement of the portal blood system connecting the median eminence to the anterior lobe of the pituitary. [From Zigmond *et al.* (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

C. The Pituitary Gland

Referred to as the "master gland," the pituitary gland, also known as the hypophysis, has been recognized for centuries as a vital organ for survival. The pituitary gland lies beneath the brain at the mesodiencephalic junction and is about the size of a garden pea in humans. Although the pituitary gland, and more specifically the anterior lobe of the gland, is responsible for the release of most hormones and tropic peptides acting on tissues and end organs, the anterior lobe is somewhat enslaved by the various tropic factors produced and released by hypophysiotropic neurons and by feedback effects of the released hormones, as shown in Fig. 3.

D. Hormones

Each neuroendocrine system described here releases chemicals (amino acid derivatives, proteins, or peptides), known as hormones, into the general circulation. Once released from their respective glands, most hormones are bound to specialized plasma proteins that help transport them and increase their half-life by protecting them from breakdown. However, most hormones have their highest biological activity in their free forms. Hormones travel throughout the body to act on body tissues wherever their receptors are located (targets). They have access to most body regions, although steroid hormones penetrate the central nervous system through the blood–brain barrier most readily.

E. Tropic Factors

Most of the hypothalamic peptides released into the external zone of the median eminence act upon the anterior lobe of the pituitary gland to *stimulate* the release of other peptides, so that they are known as *tropic factors* (also termed releasing factors). These should not be confused with *trophic factors*, which are generally involved with *growth*. Because many pituitary peptides released into the general circulation likewise stimulate the release of end-organ hormones, they are also termed tropic factors. As an historical aside, the term factor used to be dedicated for suspected tropic chemicals or peptides that had not yet been isolated. Upon isolation, however, these

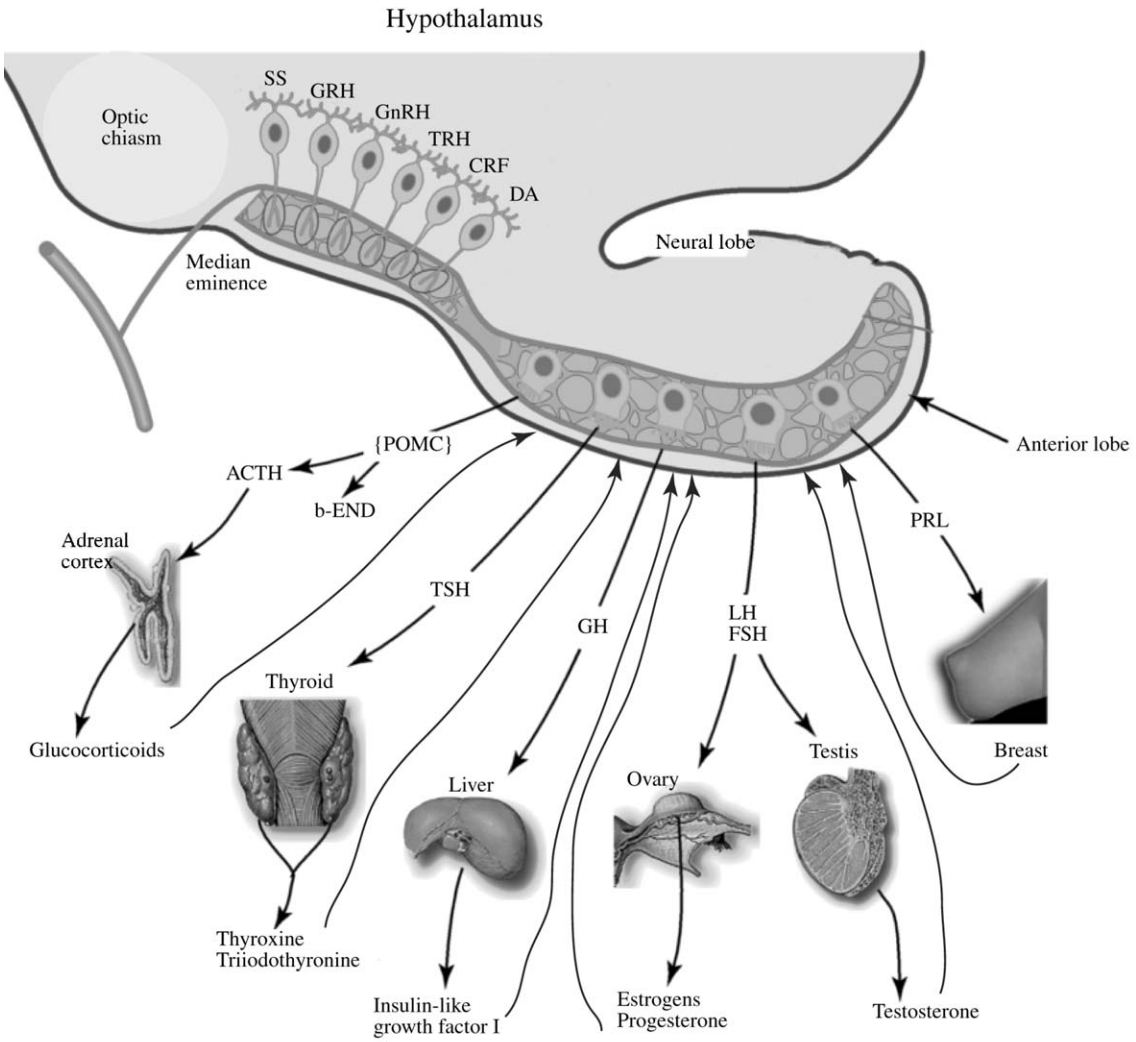

Figure 3 Schematic diagram of the main neuroendocrine systems. See text for abbreviations. [From Zigmond *et al.* (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

tropic factors were renamed hormones. For instance, corticotropin-releasing factor has also been known as corticotropin-releasing hormone (CRH) since its isolation by Wyllie Vale and collaborators in 1981.

F. Negative Feedback

The circulating levels of several hormones in the body are set to optimal points. Deviations from these points are often detrimental to organisms. Thus, the regulation of circulating hormone levels is tightly controlled by several compensatory mechanisms. An important compensatory mechanism works through *negative feedback inhibition*, whereby hormone release acts at several levels, including the pituitary, hypothalamus, and even brain areas that project to the hypothalamus, to reduce its own further release by inhibiting the synthesis and release of the various hypothalamic and pituitary factors. This is a mechanism observed in all neuroendocrine systems. Negative feedback can take place in different time domains, as will be discussed for the hypothalamo–pituitary–adrenocortical axis.

G. Pulsatile Release and Circadian Rhythm

All of the neuroendocrine systems to be discussed show a typical pattern of activity, with hypothalamic factors and their associated pituitary factors released in only a

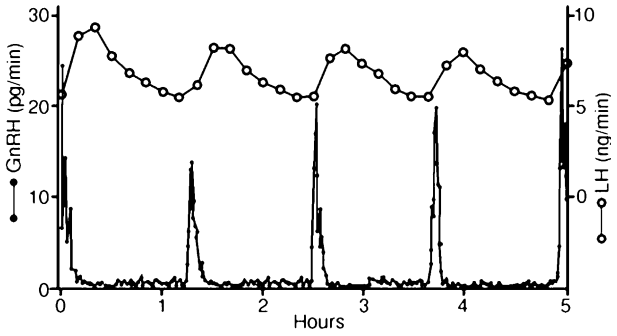

Figure 4 Example of pulsatile release of hypophysiotropic hormone in the hypothalamo–pituitary–gonadal axis. [From Zigmond *et al.* (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

few minutes, which occurs in large pulses or surges several times a day, as is shown in Fig. 4 for the stimulation of luteinizing hormone by gonadotropin-releasing hormone. In most systems, the exact mechanisms resulting in such a pulsatile release are not known, but several factors have been demonstrated to influence it. Intrinsic characteristics of hypophysiotropic neurons as well as the influence of afferent innervation to these neurons are important factors in pulsatile release. The suprachiasmatic nucleus, for example, is an important biological clock shown to drive pulsatile release in some neuroendocrine systems. Feedback inhibition probably plays a role in the pulsatile release of some systems. In addition, meal time, exercise, and sleep time all appear to provide some influence on pulsatile release. Circadian rhythmicity refers to some daily recurring fluctuations in pulsatile release, which is weaker or stronger during some parts of the day.

II. THE HYPOTHALAMO–PITUITARY–ADRENOCORTICAL AXIS

The functions of the hypothalamo–pituitary–adrenocortical (HPA) axis principally include the restoration of homeostasis following internal or external challenge (stress). It also contributes to the normal regulation of energy metabolism throughout the body. The ultimate control of glucocorticoid levels in the bloodstream is intricately regulated positively and negatively by a series of steps initiated at the level of the hypothalamus. Glucocorticoid levels vary significantly over the course of 24 hr, with the highest levels observed upon waking up in the morning. The functioning of the HPA axis thus needs to be understood in the context of both its tonic activation and its responsive phasic tone.

A. Basic Constituents of the Hypothalamo–Pituitary–Adrenocortical Axis

In humans, cortisol is the major glucocorticoid produced and released by the adrenal glands, with corticosterone as a minor component. As will be discussed following a description of the regulation of the HPA axis, dysregulation of glucocorticoid levels is involved in several physical and psychiatric pathologies. Likewise, endogenous psychiatric disorders can also produce abnormal glucocorticoid secretion.

1. The Adrenal Glands and Cortisol

Glucocorticoids, which are part of a larger family of steroid hormones, are synthesized in the zona fasciculata cells of the cortical (external) layer of the adrenal glands. Cortisol, like the gonadal steroids, is synthesized from a series of enzymatic reactions using cholesterol as the precursor. In contrast to several other secretory cells, adrenocortical cells do not store large amounts of readily releasable glucocorticoids. Secretion is, therefore, tightly linked to *de novo* synthesis. The diffusible glucocorticoids, which easily cross lipid membranes, enter the highly vascularized blood supply of the adrenal glands, where 90–95% of glucocorticoids become bound to *corticosteroid-binding globulin* (CBG), also known as *transcortin*, a carrier protein found in plasma. The half-life of cortisol in blood is approximately 60–90 min. Because glucocorticoids are biologically active only in their free form, normally a small fraction of total glucocorticoids is available for bioactivity. However, CBG levels are significantly reduced under some conditions (stress), thus providing one mechanism regulating biologically active glucocorticoids without altering absolute levels.

Secretion and synthesis of glucocorticoids from adrenocortical cells are triggered by the activation of a specific subtype of melanocortin receptor, the adrenocorticotropin hormone (ACTH) receptor, in response to the anterior pituitary hormone ACTH. These receptors are part of the G-protein-coupled, seven-transmembrane-domain receptor superfamily, and, once activated, they increase the production of the second messenger cAMP via the enzyme adenylate cyclase. The adrenal ACTH receptor is positively regulated, that is, it can increase its number of receptors in response to sustained ACTH levels.

2. The Anterior Pituitary Gland and ACTH

The anterior lobe of the pituitary gland is responsible for the synthesis and release of ACTH. ACTH is a

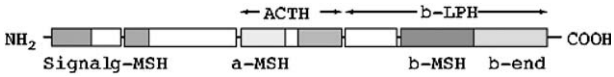

Figure 5 Diagram of one preprohormone, prepro-opiomelanocortin, which is cleaved and processed to give several different products. Abbreviations: ACTH, adrenocorticotropin hormone; end, endorphin; LPH, lipotropin hormone; MSH, melanocyte-stimulating hormone. [From Zigmond *et al.* (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

39-amino-acid peptide secreted by specialized cells known as corticotropes, which account for approximately 10% of the total cell population of the anterior lobe. ACTH itself is derived from a longer peptide precursor, pro-opiomelanocortin (preproPOMC), as shown in Fig. 5. Regulation of the POMC gene has been studied to a great extent, as it was the first mammalian endocrine precursor molecule to be cloned.

3. The Hypothalamus and Corticotropin-Releasing Factors

The secretion of ACTH from corticotropes is signaled by corticotropin-releasing factors from the medial parvocellular region of the paraventricular hypothalamic nucleus. So far, the most potent endogenous factor involved in ACTH secretion is the 41-amino-acid peptide corticotropin-releasing hormone (CRH), which was discovered and sequenced by Wyllie Vale and colleagues some 20 years ago. Parvocellular neurons send their axons to the external zone of the median eminence where, upon activation, CRH is liberated into the portal blood system. Upon destruction of the PVN, several stressors loose the ability to produce ACTH secretion, suggesting that the CRH-containing neurons of the PVN are obligatory for this function. The secretagogue action of CRH has been shown to synergize with additional factors, such as the peptides arginine vasopressin (AVP), oxytocin, and others, some of which are also coexpressed and released from CRH-containing neurons of the medial parvocellular hypothalamic nucleus. Although the cDNA and genes for CRH and AVP peptides have been cloned for some time, it was only relatively recently that the cDNAs encoding the CRH and AVP receptors were cloned. These receptors are also members of the G-protein-coupled, seven-transmembrane-domain superfamily of receptors and are positively coupled either to the production of cyclic adenosine monophosphate (CRH) or to the phosphatidylinositol (AVP) second messenger intracellular pathways. Multiple receptor subtypes have been cloned for each, cut the CRH_1 and V_{1b} subtypes account for the majority of CRH and AVP receptors localized on anterior pituitary corticotropes. Pituitary CRH and AVP receptor peptide levels are rapidly controlled upon continued activation by CRH and AVP, with evidence of up- and down-regulation in response to different manipulations.

B. Control of the HPA Axis

1. Control of Circulating Glucocorticoids

Neurons of the parvocellular hypothalamic area are responsible for the production of corticotropic-releasing factors. CRH and AVP mRNAs and peptides from parvocellular neurons are significantly regulated in response to a variety of experimental manipulations comprising acute and repeated stress. An additional molecule discovered is the corticotropin-releasing hormone-binding protein (CRH-BP), which is found in blood, the pituitary gland, and various brain areas. This protein is localized in neurons and astrocytes, and it binds and inactivates endogenous CRH and other CRH-like peptides, such as the more recently discovered urocortin, providing an additional mechanism to control the levels of CRH reaching the anterior pituitary.

An important level of control over ACTH secretion is exerted by the glucocorticoids themselves. Because the constant exposure of organisms to high levels can produce deleterious effects, including immune suppression, cardiovascular dysfunction, and even death of certain neuronal populations, glucocorticoids exhibit several mechanisms to restrain their own release. It is generally recognized that glucocorticoids provide feedback inhibition at several levels, including the pituitary, paraventricular hypothalamus, and other brain areas such as the hippocampus (discussed in the following section). These inhibitory influences act in several time domains, including fast, intermediate, and slow (genomic) feedback. The genomic and, to some extent, intermediate feedback inhibition is provided by the action of glucocorticoids upon two well-characterized and specific receptors: the mineralocorticoid (MR) or type I receptor and the glucocorticoid (GR) or type II receptor. They are members of a superfamily of cytoplasmic receptors that act as ligand-regulated transacting factors, as depicted in Fig. 6. Upon activation, these receptors translocate to the nucleus where they may interact with other transacting factors to bind to specific recognition elements on the DNA, effecting changes in the transcriptional rates of several genes, including CRH, AVP, and POMC. However, glucocorticoids are also known to produce feedback

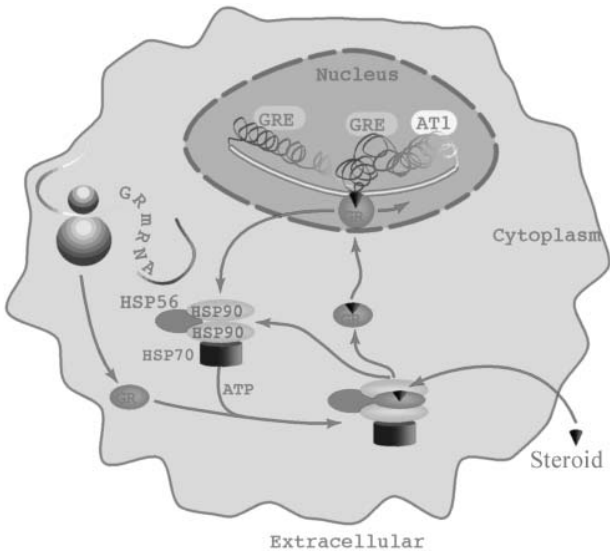

Figure 6 Schematic diagram of glucocorticoid receptor (GR) function. Once translated in the cytoplasm, GR is quickly stabilized by a complex including many heat-shock proteins (HSP). Circulating steroids, including cortisol, easily cross cell membranes to access the cytoplasm from the circulation and bind to GR. Activation of GR by steroid binding induces its separation from the HSP complex and its translocation to the nucleus, where it interacts with DNA (transacting factor) to facilitate or inhibit gene transcription. [From Zigmond *et al*. (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

inhibition that is too rapid to rely on genomic regulation. This glucocorticoid rate-sensitive regulation has not been well-characterized, but it is likely exerted via either nongenomic effects of MR or GR receptor occupancy or via nonclassical glucocorticoid-sensitive receptors.

Hence, the HPA axis provides a cascade of processes exerting positive and negative control at several levels, ultimately participating in the regulation of energy and metabolic activity throughout the body. Even under conditions of homeostasis, glucocorticoid levels display a diurnal rhythm, with higher levels in the morning than in the evening for humans, anticipating increased bodily demands during the day. This rhythm appears to be driven by one of the brain's main biological clocks, the suprachiasmatic nucleus, as well as by the pattern of food intake. Activation of the HPA axis by events that are deemed stressful by organisms occurs in the context of this diurnal regulation and is mediated by several putative brain pathways with direct connections to hypophysiotropic neurons. The following section briefly describes these neuronal circuits, together with their suggested involvement in the regulation of the HPA axis.

2. Brain Circuits Involved in the Regulation of the HPA Axis

Several reviews have described the neuroanatomical afferents to hypothalamic paraventricular neurons that might be involved in the regulation of the HPA axis, as shown in Fig. 7. The available evidence indicates the existence of several distinct afferents that are suggested to regulate the activity of hypothalamic neurons. Some of these circuits likely interact with other hypothalamic–pituitary endocrine systems.

a. Brain Stem and Medullary Afferents Well-known projections to the hypophysiotropic CRH-containing neurons originate from medullary catecholaminergic neurons of the nucleus of the solitary tract (C2) and the ventrolateral (A1, C1) and dorsomedial (C3) medulla. Most of these nuclei are involved in the processing and transmission of visceral or interoceptive information. These catecholamine-containing neurons appear to play a crucial role in activating most types of hypophysiotropic neurons in response to immune activation (e.g., infection, interleukin-1β, and

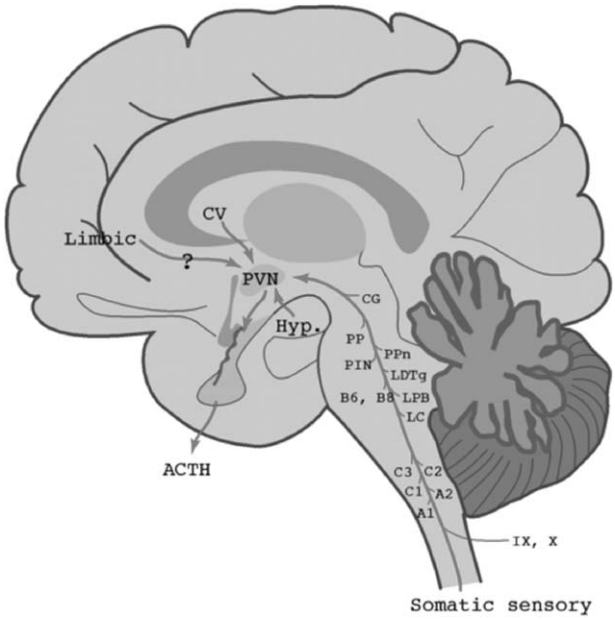

Figure 7 Schematic view of afferent innervation to the paraventricular nucleus (PVN) of the hypothalamus. Abbreviations: A1/2, C1/2/3, LC, catecholamine-containing cell groups of the brain stem; B6/8, serotonin-containing cell groups of the midbrain; CV, circumventricular organs; LPB, lateral parabrachial nucleus; LDTg, PPn, tegmental nuclei; PIN, posterior intralaminar thalamic nucleus; PP, peripeduncular thalamic nucleus; CG, central gray; Hyp, hypothalamic nuclei. [From Zigmond *et al*. (eds). (1999). *Fundamental Neuroscience*. Academic Press, San Diego].

endotoxins) and several types of visceral and somatosensory challenges.

Additional but more limited mesopontine afferents to the hypophysiotropic hypothalamus have been traced from serotonergic cell groups (B7, B8, and B9), some tegmental nuclei (peripeduncular, laterodorsal), the parabrachial nucleus, and some subregions of the central gray. Additional thalamic nuclei, including the peripeduncular nucleus, the posterior intralaminar nucleus, and the intergeniculate leaf, also provide afferents. The proposed function of several of these areas in sensory processing and transmission makes them likely candidates to provide relatively specific sensory information (somatosensory, nociceptive, auditory, and visual) to hypophysiotropic neurons.

b. Circumventricular Afferents Another set of hypophysiotropic afferents, originating from circumventricular organs, includes the subfornical organ, the vascular organ of the lamina terminalis, and the closely related median preoptic nucleus. These nuclei have been implicated in the activation of the HPA axis by blood-borne signals. Such signals include circulating indices of blood volume and ionic concentrations, which also impinge on the magnocellular neurons of the paraventricular and supraoptic nuclei to regulate the release of antidiuretic hormone (vasopressin) and oxytocin involved in water balance and blood pressure.

c. Hypothalamic Afferents An additional important source of afferents to hypophysiotropic neurons originates within the hypothalamus. Indeed, most hypothalamic nuclei contribute afferents to hypophysiotropic neurons with the exception of a few nuclei, namely, the medial and lateral mammillary and supraoptic nuclei. The principal hypothalamic areas providing relatively numerous afferents to the paraventricular nucleus include several preoptic areas, the anterior, lateral, and posterior hypothalamic areas, the dorsomedial and ventromedial nuclei, and the supramammillary nucleus. The suprachiasmatic nucleus, involved in circadian rhythm entrainment, appears to influence the HPA axis via projections to the dorsomedial nucleus. These nuclei are uniquely situated to significantly influence the activity of the neuroendocrine systems. The association of several of these hypothalamic nuclei with basic physiologic functions suggests that they might integrate the sum of all stimuli perceived by an organism at any one moment and then convey this integrated information to hypophysiotropic neurons to keep an optimum level of functioning throughout the neuroendocrine systems, including the HPA axis.

d. Forebrain Afferents Several forebrain areas appear to influence the activity of the HPA axis, including the prefrontal cortex, hippocampus, amygdala, and septum. Surprisingly, none of these areas unambiguously project to hypothalamic paraventricular neurons. Instead, several studies indicate that these areas might regulate the activity of the HPA axis via medial hypothalamic relays or, alternatively, via relays with neurons of the bed nucleus of the stria terminalis, the only additional forebrain structure known to project directly to hypophysiotropic neurons. The preceding forebrain structures are of particular interest because they are all associated with emotionality. Some of these areas might, therefore, be essential in the evaluative process involved in determining or perceiving the stressful character of a situation.

Neuroanatomically, therefore, hypophysiotropic CRH-containing neurons receive a rich set of neural inputs encompassing several categories of stimulus information. In addition, most of these regions, together with the rest of the brain, express one or both glucocorticoid receptors, making the brain an important target for circulating cortisol. The influence of the brain on the activity of the HPA axis, as well as that of cortisol upon brain functioning thus provides a rich set of interactions, the dysregulation of which can have dramatic consequences upon the physical and psychological well-being of individuals.

C. Dysregulation of Circulating Glucocorticoids (Cortisol)

Cushing's syndrome is perhaps the best-known class of diseases involving hypersecretion of glucocorticoids. In the early 1930s, Harvey Cushing described a list of symptoms that was closely associated with pituitary abnormalities. Glucocorticoid hypersecretion can be produced by adrenocortical or pituitary tumors, the latter associated with ACTH hypersecretion. Cases are also known in which increased hypothalamic CRH release produces ACTH hypersecretion. The symptoms of Cushing's disease, characterized by several physical and psychological changes, include thinning of the skin and hair, increased subcutaneous adipose (fat) deposits in the face (moon face), upper back and shoulders (buffalo hump), and abdomen (pendulous abdomen), appearance of reddish purple skin color

from skin stretching, hypertension, and osteoporosis. The psychiatric profile of Cushing's patients includes increased appetite, insomnia, euphoria, anxiety, panic, and unipolar or bipolar disorders. Psychosis (including schizophrenia) is rarely observed in Cushing's patients. Normalization of glucocorticoid levels in these patients greatly improves the physical and mental disorders.

On the other hand, a significant number of individuals seeking help who are diagnosed with major depression present signs of adrenal hypertrophy and increased basal levels (over 24 hr) of circulating cortisol. These endocrine abnormalities can be normalized in a high proportion of patients with a variety of antidepressant treatments (behavioral, pharmacologic, or electroconvulsive therapy), which concurrently improve their psychological status. The dexamethasone suppression test (DST) has been a useful tool to help determine HPA axis dysregulation. Dexamethasone is a glucocorticoid receptor agonist that, when injected intravenously, binds GR receptors at the level of the pituitary corticotropes and perhaps at the level of the hypothalamus and other brain regions and initiates feedback inhibition so that the circulating cortisol levels are suppressed hours after dexamethasone injection. Interestingly, a high proportion of individuals presenting symptoms of endogenous major depression do *not* show the normal suppression of cortisol by dexamethasone; they are said to *escape* the DST effect. Thus, abnormal GR receptor regulation, involved in feedback inhibition, appears to be linked with affective disorders. The most popular mechanisms hypothesized to mediate increased basal cortisol levels and reduced feedback inhibition have implicated an increased drive of central CRH-containing systems and dysregulation of brain serotonergic-containing systems. High levels of circulating cortisol levels have also been linked to neuronal cell death, especially in the hippocampus, a brain region with some of the highest levels of MR and GR receptors that is also thought to play a role in negative feedback of the HPA axis. Cortisol dysregulation thus provides clear example of the interactions between hormones and brain and vice versa.

A reduction in circulating cortisol levels is observed in patients with Addison's disease. This category of diseases includes several pathologies (adrenal autoimmune disease, tuberculosis, and adrenal cancer) that lead to adrenal atrophy and insufficiency. Total adrenal insufficiency is rapidly fatal, but with degenerative diseases, patients develop marked skin pigmentation (melanocyte-stimulating hormone activity of ACTH in blood), hypotension and reduced cardiac size. Even minor stresses can send Addison's patients into fatal shock. Adrenal insufficiency is also correlated with a slower electroencephalogram (EEG of the α rhythm), irritability, apprehension and mild anxiety, inability to concentrate, and increased gustatory and olfactory sensitivity. It is interesting that low circulating cortisol levels produce some of the same affective disorders observed with high circulating cortisol levels, but in milder forms. The mechanisms by which low cortisol levels affect mood and the chemical senses are ill-understood. Learning is also affected by circulating cortisol levels, and evidence of poor memory with either too much or too little cortisol has been documented.

III. THE HYPOTHALAMO–PITUITARY–THYROID AXIS

The hypothalamo–pituitary–thyroid (HPT) axis is the main regulatory system responsible for metabolism in all body tissues throughout life. Metabolism constitutes all biochemical processes that take place at the cellular level and includes functions such as synthesis of protein–lipid–carbohydrate–enzymes, incorporation of nutrients, and breakdown–synthesis of various molecules. Circulating thyroid hormones also stimulate oxygen consumption in most cells of the body. As with the HPA axis, the secretion of thyroid hormones in the bloodstream is intricately regulated at several levels, beginning at the hypothalamus. See Fig. 3 for a summary diagram of the HPT axis. The basic constitutive elements of the HPT axis and thyroid secretion are elaborated first. Central regulation of the HPT axis and dysregulation of thyroid hormones levels are then discussed.

A. Basic Constituents of the HPT Axis

In humans, thyroid hormones, composed mainly of L-thyroxine (denoted as T_4) and triiodothyronine (denoted as T_3), are released by the thyroid gland through a series of steps described next.

1. The Thyroid Gland and the Secretion of Thyroid Hormones

The thyroid gland, located at the base of the neck close to the trachea, synthesizes and stores T_3 and T_4 to large glycoproteins called *thyroglobulins* until they are secreted into the bloodstream. T_3 and T_4 are synthesized from the amino acid tyrosine and involve the incorporation of three (T_3) or four (T_4) iodine atoms,

making it the only molecule in the animal kingdom to contain iodine. Although the only difference between T_3 and T_4 is an additional iodine atom in T_4, this difference provides T_3 with much greater biological activity in all body tissues (3–5 times greater than T_4). In peripheral tissue, T_4 is converted to T_3 by the enzyme 5′-deiodinase type I, whereas T_4 is directly taken up by brain and pituitary cells and transformed into T_3 intracellularly by the type II 5′-deiodinase enzyme. In the bloodstream, thyroid hormones are bound to carrier proteins, including albumin, thyroxine-binding prealbumin (TBPA), and thyroxine-binding globulin (TBG), leaving a very low percentage of free hormones (about 0.2% T_3 and 0.02% T_4). T_4 is carried to the brain across the blood–brain barrier via a specific and saturable carrier molecule, transthyretin (TTR). The half-life of T_4 is approximately 1 week and that of T_3 is slightly shorter.

2. The Anterior Pituitary Gland and TSH

The thyroid-stimulating hormone (TSH), also known as thyrotropin, is responsible for the regulation of thyroid hormone secretion. TSH controls the uptake of iodine by the thyroid gland, regulates the rate of synthesis of thyroid hormones, and controls the storage and release of T_3–T_4 into the bloodstream. As with other neuroendocrine axes, the anterior pituitary is responsible for the production and release of TSH. Thyrotropes, the anterior pituitary cells producing TSH, constitute about 10% of the entire population of the anterior lobe. Through a hypothalamic factor, TSH is released into the bloodstream and eventually reaches the thyroid gland to regulate the synthesis and release of thyroid hormones. TSH release is pulsatile, and in humans the frequency of the pulses varies from 10 to 15 every 24 hr. TSH release also shows a circadian variation, with levels beginning to rise in late afternoon and peaks in the middle of the night (around 4:00 AM). The levels decline until noon and are quiescent until the next rise.

The bloodborne signal from the hypothalamus is mediated by specific membrane receptors on anterior pituitary thyrotropes, the *TRH receptors*. This receptor is a member of the seven-transmembrane, G-protein-coupled receptor superfamily. Binding of TRH to its receptors triggers the activation of the phosphatidylinositol and diacylglycerol second messenger pathways, which eventually leads to increased transcription of the TSHβ gene together with the α gene common to the glycoprotein hormones (TSH, luteinizing hormone, follicle-stimulating hormone, and human chorionic gonadotropin, discussed later in this article) that encode and produce TSH. As with the other glycoprotein hormones, TSH is a heterodimer polypeptide derived from two distinct genes and is heavily glycosylated, which is thought to extend its half-life.

3. The Hypothalamus and Thyrotropin-Releasing Hormone

The hypothalamic factor responsible for the release of TSH is thyrotropin-releasing hormone (TRH). This hormone was the first hypothalamic-releasing hormone isolated and purified from tons of pig and sheep brains in the late 1960s, after many years of hard work, by the research teams of Andrew Schally and Roger Guillemin, for which they would eventually share a Nobel prize. TRH is a small, 3-amino-acid peptide (histidine, proline, and glutamic acid) derived from a larger 242-amino-acid prohormone that contains 6 copies of the TRH sequence. TRH is synthesized in hypothalamic neurons located in the periventricular and parvocellular compartment of the paraventricular nucleus. In the medial parvocellular region, the TRH-containing neurons are observed medial to the CRH-containing neurons. These TRH-containing neurons send their axons to the external zone of the median eminence, where TRH is released into the portal blood circulation bathing the anterior pituitary. Other hypothalamic and extra-hypothalamic regions synthesize TRH, but these neurons do not directly, if at all, control thyroid hormone release.

B. Control of the HPT Axis

1. Control of Circulating Thyroid Hormones

As with the HPA axis and glucocorticoids, the HPT axis exerts rigorous control over thyroid hormone levels. Rising thyroid hormone levels, especially through T_3, act at the level of the pituitary thyrotropes and hypothalamic paraventricular neurons to inhibit further release of TSH and TRH, respectively, in a classic inhibitory feedback mechanism. This action is mediated by thyroid hormone receptors, which are part of a superfamily of cytoplasmic steroid hormone receptors including estrogen, progesterone, androgen, and vitamin D receptors. Several isoforms of the thyroid hormone receptors have been characterized, including Trα1, TRα2, TRβ1, and TRβ2, which act in a manner analogous to the MR and GR receptors as

transacting factors upon genomic response elements. TRα1 and TRβ2 are the most abundant isoforms, found in more than 80% of TRH-producing neurons of the paraventricular nucleus.

2. Brain Circuits Involved in the Regulation of the HPT Axis

Many of the same circuits described in the neural control of the HPA axis also appear to be involved in the control of the HPT axis. The proximity of the medial parvocellular hypophysiotropic neurons containing CRH and TRH can make it difficult, if not impossible, to ascribe distinct sets of afferents to the two endocrine axes. The brain stem catecholaminergic cell groups are known to innervate and play a part in the regulation of the HPT axis. Some of the rostral periventricular TRH-containing neurons also receive a relatively greater input of terminals from the noradrenaline-containing locus ceruleus neurons and from the serotonin-containing neurons of the midbrain raphe nuclei. The thyroid gland is also directly innervated by autonomic fibers (both sympathetic and parasympathetic) that control blood flow and, reportedly, the synthesis of thyroid hormones. These mechanisms can significantly regulate the levels of T_3–T_4 released in the bloodstream. Finally, as is the case with MR and GR receptors, the brain expresses some of the highest levels of the different thyroid hormone receptors. Dysregulation of thyroid hormone secretion can, thus, have dire consequences on physical and psychological status.

C. Dysregulation of Circulating Thyroid Hormones

Consideration of the effects of hypothyroidism or hyperthyroidism can emphasize the importance of normal levels of circulating thyroid hormones. Hypothyroidism is a condition resulting from inadequate thyroid hormone production. If this happens during fetal life, a condition known as *cretinism* develops, in which the afflicted individual remains of short stature, never reaches sexual maturity, and suffers severe mental deficiencies, hearing and speech defects, spastic gait, impaired voluntary motor control, and clonus. This condition can improve if thyroid hormones are provided during the first few months of life.

In adulthood, hypothyroidism is divided into clinical and subclinical types, with clinical hypothyroidism producing several physical and mental conditions. Low thyroid secretion rates produced by reduced thyroid hormone synthesis at the level of the thyroid gland or insufficient dietary iodine can lead to *goiter*, a very apparent enlargement of the thyroid gland produced by sustained TSH stimulation of thyroid growth combined with a lack of adequate thyroid hormone secretion (thus failing to inhibit pituitary TSH secretion). Other symptoms of clinical hypothyroidism include depression, low energy, appetite and sleep changes, poor concentration, memory impairments, apathy, muscle cramps, brittle and thinning hair, husky voice, and elevated levels of cholesterol and triglycerides. The similarity of these symptoms with those of endogenous major depression has prompted clinicians to test thyroid function in order to distinguish between the two conditions. Subclinical hypothyroidism, by definition, does not present the clinical type symptoms, although fatigue, hypothermia, dry skin, memory impairments, and higher scores on ratings of anxiety and depression are reported. The lifetime prevalence of depressive disorders in hypothyroid patients is 56% compared with 20% in euthyroid (high total, but normal free levels of T_4–T_3) individuals. Also, response to tricyclic antidepressant treatment in patients is lower in hypothyroid individuals, but can be improved by cotreatment with thyroid hormones. This may be particularly relevant in women, in whom the incidence of clinical and subclinical hypothyroidism is more than twice that for men, which is also mirrored in the incidence of depressive disorders. A higher incidence of thyroid antibodies is also observed in women, which may be attributed to the higher stimulation of immunologic functions by female gonadal hormones, leading to higher rates of autoimmune diseases. Exactly how hypothyroidism produces affective disorders, particularly major depression and rapid-cycling bipolar disorder, has not been clearly ascertained. Lower thyroid hormone levels have been suggested to reduce β-adrenergic receptor activity and central serotonin activity, effects often associated with endogenous major depression. The higher incidence of both conditions in women might also be linked to the homology and interactions between the estrogen and thyroid receptors, which are known to bind each others' hormones.

The reverse interaction between affective illnesses, particularly major depression, and thyroid hypofunction has also been documented. Patients presenting with major depression often display increased cerebrospinal fluid levels of TRH or a blunting of TSH

secretion in response to TRH challenge, suggesting down-regulation of pituitary TRH receptors in response to chronic high levels of hypothalamic TRH. This also agrees with some reports that depressed patients show blunted circulating plasma levels of TSH at night. There is still scant literature concerning the putative effects of endogenous affective illnesses on the HPT axis, but the preceding preliminary reports clearly indicate the need to better understand this brain–neuroendocrine interaction.

Hyperthyroidism involves conditions in which excess thyroid hormones are secreted. The highest percentage of hyperthyroidism in the United States is caused by Grave's disease, characterized by an autoimmune reaction against the thyroid TSH receptors, which in most cases stimulates the release of excess thyroid hormones. Some of the physical signs of hyperthyroidism include weight loss, palpitations, frequent bowel movements, muscle weakness, thyroid enlargement, and bulging out of the eyes (exophthalmia). Psychiatric symptoms often associated with hyperthyroidism include insomnia, irritability, agitation, general anxiety disorder, major depression, attention deficit disorder, or paranoia. General anxiety is by far the most common psychiatric outcome and generally improves upon the normalization of thyroid hormones. Treatment with antidepressants has also been observed to lower the levels of circulating thyroid hormones.

IV. THE HYPOTHALAMO–PITUITARY GROWTH AXIS

No the hyphen is not missing between pituitary and growth; this is because this endocrine system departs from other neuroendocrine systems by releasing the anterior pituitary growth hormone (GH, also known as somatotropin) directly into the bloodstream to influence body tissues without the intervention of an additional organ (as is also the case with prolactin secretion, discussed later). Growth hormone, as the name implies, is vital for the normal growth and development of humans and most other species, particularly during the perinatal and adolescent periods. However, together with other factors and hormones, including, but not limited to, thyroid hormones, insulin, and dietary nutrients, growth hormone is crucial in the control of carbohydrate metabolism, protein synthesis, body fat, glucose utilization, and other metabolic activity. Without it, abnormal organ, skeletal, and immune functions develop.

A. Basic Constituents of the Hypothalamo–Pituitary Growth Axis

The hypothalamo–pituitary growth axis also departs from other neuroendocrine axes in that two hypothalamic factors mainly regulate growth hormone synthesis and secretion, with one factor demonstrating GH release activity whereas the other inhibits GH secretion.

1. The Anterior Pituitary and Growth Hormone

Growth hormone is released by specialized cells of the anterior pituitary gland called somatotropes. They are located predominantly in the lateral "wings" of the anterior lobe and constitute about 40% of the total anterior pituitary cells (there is a significant gender difference, with women averaging lower percentages than men). In humans, the pituitary gland contains 5–10 mg of somatotropin, a 191-amino-acid peptide derived from a gene located on chromosome 17.

The half-life of GH is relatively short, with an average of approximately 20 min. Upon secretion into the bloodstream, about half of the GH released becomes bound to a protein termed growth-hormone-binding protein (GHBP). GH acts in several different tissues throughout the, body, as discussed earlier, and this action is mediated by specific GH receptors (GH-R) located on the membranes of receptive tissues and organs. Both GH-R and GHBP are derived from the same gene, although alternative splicing of the transcribed mRNAs provides for the two distinct functions of these proteins. Interestingly, to be biologically active, one GH molecule is required to bind sequentially to two GH receptors. This complex then initiates a cascade of events leading to the activation of transcription factors affecting GH-regulated genes. A major effect of GH is to stimulate the production of insulin-like growth factor I (IGF-I), which mediates many of the effects of GH; IGF-I by itself can mimic many effects of GH, although the two molecules are more effective in combination.

GH is secreted by the anterior pituitary upon release of the growth-hormone-releasing hormone (GHRH) signal from the hypothalamus, via the portal blood system, onto GHRH receptors (GHRH-R) of the somatotropes. These receptors are also part of the large family of seven-transmembrane, G-protein-coupled receptors, and they are specifically linked to the stimulatory subtype (G_s) of G-proteins, which activates the cAMP second messenger pathway. Additional evidence also indicates that an as yet

unknown GH-releasing factor from the hypothalamus binds specifically to a different G-protein-coupled receptor, one that is specifically linked to the G_q subtype of G-proteins and appears to synergize, through the inositol triphosphate and diacylglycerol second messenger pathways, with the effects of GHRH-R upon GH secretion. The synthesis of GH in somatotropes is independently controlled by GHRH through a slightly different set of transcription factors associated with cAMP production (cAMP response element binding protein), acting to enhance transcription of the somatotropin gene. Independent regulation of synthesis and release has been shown by the existence of different diseases that are mediated specifically at the level of the pituitary gland upon either GH synthesis or secretion within somatotropes.

The secretion of GH is also negatively regulated by a second hypothalamic factor, somatostatin (SS). Pituitary secretagogues, including somatotropes, contain a variety of SS receptors (at least five different variants with independent genomic origins) that are all linked to the inhibitory G-protein subunit G_i, which inhibits the activation of adenylate cyclase and the production of cAMP. Thus, GH synthesis and secretion are tightly regulated positively and negatively by hypothalamic factors.

2. The Hypothalamus, Growth-Hormone-Releasing Hormone, and Somatostatin

As discussed earlier, the major hypothalamic factor responsible for the synthesis and release of pituitary GH is GHRH. Hypophysiotropic GHRH neurons are located at the base of the brain against the third ventricle in the arcuate nucleus. The human GHRH gene is located on chromosome 20 and gives rise to a preproGHRH precursor of 108 amino acids. Posttranslational processing of proGHRH produces two forms of GHRH: a 44-amino-acid peptide, to which 4 amino acids are found truncated at the C-terminus in some forms. Because the bioactivity of GHRH is restricted to the first 29 amino acids at the N-terminus, this truncation, albeit unique to humans, confers both forms with similar biological activity.

The other hypothalamic factor having a major influence on the control of GH secretion is somatostatin (SS), also known as growth-hormone-release-inhibiting hormone (GHRIH) or somatotrope-release-inhibiting hormone (SRIH). Although SS is found in many cell populations throughout the brain, the important SS-containing neurons in regard to GH release are those in the rostral periventricular region. The human SS gene, located on chromosome 3, encodes a 116-amino-acid preproSS. Posttranslational processing of preproSS in the hypothalamus produces two biologically active forms, SS-28 and SS-14, truncated at the N-terminus. Both forms are released in the external zone of the median eminence and display a short half-life of a few minutes to reach the anterior pituitary somatotropes. A direct inhibitory action of SS upon GHRH-containing arcuate neurons also exists, although the source of this SS input likely is from nuclei other than from the hypophysiotropic SS-containing rostral periventricular region.

B. Control of the Growth Axis

1. Control of Circulating Growth Hormones

As with other neuroendocrine systems, GH and its related product, IGF-I, provide feedback inhibition at both pituitary and hypothalamic levels upon pituitary GH release and upon SS and GHRH synthesis and secretion, respectively. At the level of the pituitary somatotropes, IGF-I is the major inhibitor of GH synthesis and secretion under basal and GHRH-stimulated conditions, with GH displaying little, if any, inhibitory effects. Somatotropes contain IGF-I receptors, which are in a position to respond to both locally produced and circulating IGF-I. Although total IGF-I levels are relatively stable over time, they exist in both free form, which is biologically more active, and in bound form to a plasma protein, IGFBP-3. A number of physiological conditions, such as hyperglycemia, down-regulate IGFBP-3, thus increasing free, biologically active levels of IGF-I, which can then mediate increased inhibition of GH. At the level of the hypothalamus, GHRH- and SS-containing neurons possess both IGF-I and GH receptors, which open these cellular populations to the feedback effects of both molecules. There is limited evidence for IGF-I- and GH-mediated inhibition of GHRH secretion and SS stimulation, which is perhaps linked to the limited crossing of these large peptides across the blood–brain barrier.

Additional neurotransmitter systems are also known to play a role in the secretion of GH, which include, but are probably not limited to, vasoactive intestinal polypeptide (VIP), pituitary adenylate cyclase activating peptide (PACAP), TRH, glucocorticoids, androgens, estrogens, galanin, neuropeptide Y (NPY), interleukins-1 and -2, and the classical neurotransmitters dopamine, noradrenaline, and acetylcholine.

The secretion of GH is also pulsatile, as with most other hormones of the neuroendocrine system. In

humans, there are approximately 12 pulses per 24-hr period, with most of the release (roughly 70%) occurring at night during slow-wave (stages 2–4) sleep. Existing evidence suggests that both GHRH and SS are implicated in the pulsatile release of GH, with GHRH being the dominant regulator in mediating the release of pituitary GH. However, alterations in either GHRH or SS have been shown to block the pulsatile release of GH. In the hypothalamus, GHRH and SS mRNAs also display fluctuating levels, with GHRH and SS mRNA peaks anticipating the GH peaks and troughs by several hours, respectively. There is also a strong sexual disparity in the amplitude of release, with higher levels of estrogen in women contributing to significantly lower GH secretion. Testosterone, which has higher circulating levels in men, has been linked to the higher peak amplitude of GH release in males.

2. Brain Circuits Involved in the Regulation of the HP Growth Axis

Some of the same circuits described previously control the arcuate GHRH-containing neurons as well as the rostral periventricular SS-containing neurons. The brain stem and medullary catecholaminergic cell groups innervate and control the activity of arcuate and periventricular neurons. Other major inputs to the arcuate nucleus originate within the hypothalamus, including the anterior periventricular nucleus, the retrochiasmatic nucleus, the medial parvocellular region, the medial preoptic area, and the ventral premammillary nucleus. The bed nucleus of the stria terminalis also innervates the arcuate nucleus, as is the case for many other hypothalamic subregions. The rostral periventricular region demonstrates a pattern of innervation generally similar to that described for the paraventricular nucleus described earlier, including midbrain, thalamic, hypothalamic, and forebrain afferents. GH and IGF-I receptors are widely distributed throughout the human brain and could mediate some of the effects of circulating growth hormones and their products. However, peripheral GH and IGF-I have limited penetration to the brain due to the blood–brain barrier, and, furthermore, GH and IGF-I are produced in the brain. Thus, direct effects of circulating growth hormones on the brain have been difficult to demonstrate. Similarly, the psychotropic effects of growth hormones have not been well-characterized nor explained. Nevertheless, dysregulation of circulating growth hormones produces marked cognitive and mood alterations.

C. Dysregulation of Circulating Growth Hormones

Physically a very observable effect of growth hormone insufficiency during development is dwarfism (short stature). However, some types of dwarfism result from the insensitivity of tissues to relatively normal circulating GH levels. The psychotropic effects of GH insufficiency in children are not reported to alter intelligence measures, but a higher incidence of attention deficit disorders, anxiety, depressive mood, somatic complaints, impulsivity, distractibility, social adjustment, and attention-seeking are common. The similarity of these psychological effects in idiopathic (not produced by GH dysregulation) short stature vs GH-deficient (GHD) children indicates that environmental and social factors play a role in the development of these traits. Nonetheless, the behavioral, social, and psychological disturbances of GHD children are ameliorated to a greater extent following GH treatment, suggesting a role for circulating GH levels in these disorders. The impact of GH deficiency in adults of normal stature also indicates a higher incidence of affective disorders, lack of energy, and impaired self-control, which are significantly alleviated with GH replacement. Psychosocial dwarfism, a state of short stature sustained by parental abuse, is associated with significantly lower circulating GH levels. Removal of the afflicted children from the abusive environment will often reverse this condition without any other intervention. These examples offer clear instances of the interplay between hormones, psychological status, and the brain.

Just as striking is the effect of excess circulating growth hormones during development, leading to *gigantism* in children and *acromegaly* in adults. These conditions are often associated with pituitary somatotrope adenomas resulting in hypersecretion of growth hormones. Children that grow to be giants have relatively normal features except for their high stature. These children tend to have mood swings, irritability, and lack social skills. They tend to be intellectually normal. The physical and psychological characteristics can be ameliorated with long-acting somatostatin agonists, which reduce circulating GH levels, or with the surgical removal of the adenoma. This growth hormone condition is distinguished from another form of early childhood gigantism known as *cerebral gigantism* or *Sotos syndrome*, which originates from

brain abnormalities and is associated with abnormal EEG, mental retardation, and other physical characteristics, particularly of the facial and cranial bones.

In adults, abnormally high circulating GH levels, also produced by pituitary somatotrope adenomas, present a characteristic pattern of physical changes, including enlarged hands and feet, profuse sweating, protrusion of the lower jaw, overgrowth of facial and cranial bones, hirsutism (increased body hair), osteoarthritic vertebral changes (humpback), headaches, and visual field changes (due to pressure of the pituitary tumor against optic nerves). The psychological symptoms of acromegalic adults include affective disorders (anxiety and major depression), increase in appetite, and loss of drive and libido. These individuals also exhibit normal intelligence and memory functions. Surgical intervention or somatostatin agonists that normalize GH levels ameliorate their physical and psychological symptoms.

V. THE HYPOTHALAMO–PITUITARY–GONADAL AXIS

The hypothalamo–pituitary–gonadal (HPG) axis is responsible for many reproductive functions in humans and other mammals. It plays a pivotal role in the development of mature male and female reproductive organs, secondary sexual traits (breasts, body hair, vocal pitch), and the sexually dimorphic brains allowing appropriate male and female behaviors leading to reproduction, such as courtship and intercourse and probably mate choices and sex preferences. However, many of the stereotypic behaviors attributed to the HPG axis in lower mammals, particularly courtship, mating, and intercourse behaviors, have, for most intents and purposes, been lost in humans. However, sex hormones have been suggested to have some effect on sexual desire, which alternatively has not been investigated to any great extent in animals displaying readily observable stereotypic sexual behaviors. Sexual differentiation is determined very early on during development. The presence of a Y chromosome following fertilization directs the development and maturation of the testes, which begin to produce testosterone early *in utero* and lead to the male phenotype. Without the Y chromosome, the "default" female phenotype emerges. The following section describes the results of this early differentiation and how the various HPG functions are derived.

A. Basic Constituents of the Hypothalamo–Pituitary–Gonad Axis

The HPG consists of a relatively classic neuroendocrine system, in that the various sex hormones are regulated by hypothalamic, pituitary, and end organs (gonads). It is arguably the neuroendocrine system with the most components, with different sex hormones to regulate and track. The different sex hormones, the elements that regulate their secretion, and their effects on various body tissues and reproductive functions are described next.

1. The Gonads and Sex Hormones

The HPG axis is very different between males and females. The sex hormones, also known as the sex steroids or gonadal steroids, consist of *estrogens*, *progesterone*, and the *androgens*, the most well-known of which is *testosterone*. Although all of these hormones are found in both men and women, estrogens and progesterone are observed in much higher levels in women and testosterone in much higher levels in men. The sex steroids are all derived from the same precursor molecule, cholesterol, through a series of aromatic reactions taking place in the gonads (and some in the adrenal cortex and placenta of pregnant women). Most of the sex steroids become bound to plasma proteins [albumin, transcortin, gonadal-binding globulin (GBG), or other proteins] upon release in the bloodstream, leaving approximately 3% of the released pool free. Steroids are relatively small molecules that easily cross lipid membranes. This feature allows sex steroids to act on their respective tissues by interacting with specific receptors (such as the estradiol, progesterone, and androgen receptors) located intracellularly in the cytoplasm of cells, as opposed to binding cell-surface (membrane) receptors. Binding of steroids with their specific cytoplasmic receptors induces a series of reactions that ultimately produces the *translocation* of the steroid–receptor complex (known as a *transacting factor*) from the cytoplasm to the nucleus, where it interacts with specific DNA elements in the promoter region that can increase or decrease the transcription of associated genes.

In females, estrogens and progesterone are synthesized in the ovaries upon stimulation by the anterior pituitary hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH), together known as the gonadotropins. More specifically, FSH produces the growth of follicles within the ovaries (the *follicular*

phase), which produces increasing amounts of estrogens (estradiol mostly). An LH surge produces ovulation, in which a follicle releases an ovum, the former being transformed in the process to the *corpus luteum*. The *luteal* phase is responsible for continued synthesis and release of estrogens as well as increasing amounts of progesterone. The concerted effects of estrogens and progesterone on the uterine endometrium prepare the uterus for possible implantation by a fertilized egg. Estrogens and progesterone are also responsible for the development and maturation of the female secondary sex characteristics, including breast development and the female pattern of fat deposits. The regulation of synthesis and release of estrogens and progesterone needs to be understood more specifically in the cyclical context (ovarian or "menstrual" cycle in women) in which they occur. This will be discussed after all HPG elements have been introduced.

In males, stimulation by pituitary LH chiefly signals the production of testosterone by the interstitial (Leydig) cells of the testes. In conjunction with FSH, testosterone stimulates spermatogenesis in the seminiferous tubules of the testes. Testosterone also plays a role in the control of penile erection and the synthesis and secretion of prostate and seminal vesicle fluids. Testosterone is also responsible for the development of male secondary sex characteristics, which consist of the general male body form and more massive muscle development, male hair distribution, and enlargement of the larynx, leading to deepening of the voice. The relatively low female sex steroid levels in the male circulation also lead to a different pattern of fat deposition in men. Interestingly, testosterone not only acts through androgen receptors but is also converted to a significant degree to estradiol, particularly in the brain and pituitary, where the converted products act on local estrogen receptors.

2. The Anterior Pituitary Gland and Gonadotropins

As discussed earlier, LH and FSH are gonadotropins that are synthesized and released by the *gonadotropes*, constituting less than 10% of the total cells of the anterior lobe. The half-life of human FSH is about 3 hr, whereas that of LH is approximately 60 min. LH and FSH are glycoprotein hormones derived from a common α gene (located on chromosome 6) but two distinct β genes: LHβ, located on chromosome 19, and FSHβ, located on chromosome 11, respectively. Upon signaling mediated by hypothalamic gonadotropin-releasing hormone (GnRH), also known as luteinizing-hormone-releasing hormone (LHRH), cell-surface GnRH receptors (mapped to chromosome 4 in humans), which are parts of the G-protein-coupled receptor family, activate the cAMP second messenger pathway to stimulate the synthesis and release of LH and FSH. A relatively robust correlation has been observed between pulses of GnRH and LH release in the general circulation. However, the concordance between GnRH pulses and FSH release is variable due to the action of additional factors, such as the peptide inhibin, which is produced in the gonads and appears to repress the synthesis and release of FSH.

3. The Hypothalamus and Gonadotropin-Releasing Hormone

The release of gonadotropins is regulated by hypothalamic GnRH-containing neurons. The GnRH-containing neurons are scattered throughout the extent of the hypothalamus, unlike other releasing hormone cell groups. In humans, they are mostly localized to the medial preoptic area near the optic chiasm and to the arcuate nucleus (ventral) hypothalamus near the median eminence, with some additional cells in the lateral hypothalamus and medial septal complex. Approximately 70% of hypothalamic GnRH-containing neurons send their axons to the external zone of the median eminence, where they release GnRH in the hypophyseal portal blood system and target the gonadotropes. GnRH is a relatively small 10-amino-acid peptide that is also derived from a larger preproGnRH product of 92 amino acids. In humans, a single gene codes for hypothalamic preproGnRH located on chromosome 8. Studies have indicated the existence of a second, distinct GnRH gene on chromosome 20 that is expressed in extrahypothalamic areas and peripheral tissues. The function of this extra-hypothalamic-derived GnRH has not been determined.

4. The Anterior Pituitary Gland and Prolactin

Although not part of the HPG axis, prolactin's best-known function is in lactation and, thus, warrants its inclusion with other reproductive hormones. Prolactin, a 198-amino-acid peptide derived from preproprolactin, is released by anterior pituitary lactotropes (also known as mammotropes). Unlike other anterior pituitary tropic hormones, prolactin is under negative control by an inhibitory factor from the hypothalamus, known as prolactin-inhibiting factor (PIF), likely to be dopamine. Thus, upon transection of the pituitary stalk, removal of PIF actions leads to hyper-prolactinemia. Like other pituitary hormones,

pulsatile release is observed with prolactin, with a circadian rhythm displaying greater release during sleep. Both men and women show circulating prolactin levels, with slightly higher levels observed in women. Prolactin acts through specific, multiple forms of its receptors found throughout the reproductive axis of women and men, in addition to the liver, kidneys, adrenals, pancreas, lymphoid tissues, intestines, hypothalamus, and skin.

During pregnancy, circulating levels of prolactin rise significantly but decline rapidly approximately 1 week following childbirth. Suckling then initiates significant bursts of prolactin secretion, which stimulate the synthesis of maternal milk proteins. Pathologically high circulating prolactin levels are associated with gonadal dysfunctions in both women and men, in addition to headaches and visual field disturbances. Hyper-prolactinemia is reportedly the most common form of hypothalamopituitary disorder in humans, which can normally be treated in several ways to restore normal circulating prolactin levels.

B. Control of the HPG Axis

1. Control of Circulating Gonadal Hormones

Control of circulating sex hormones is determined to a large extent by the sex of the individual, and in women it is determined further by the period within the ovarian cycle. As observed with the other neuroendocrine systems, there is a strong component of feedback inhibition provided by the sex steroids at the pituitary and hypothalamic levels. The pulsatile nature of GnRH release could be mediated by the documented extensive connections between the several GnRH neuron populations or by afferent connections. It is clear, however, that the GnRH population of the arcuate nucleus is necessary to derive the pulsatility of GnRH secretion.

In women, it is customary to define the menstrual cycle as beginning on the first day of the menstrual period, which is easily detected by women experiencing vaginal bloody discharges consisting of the endometrial tissue breaking down and being released (sloughing) because fertilization has not taken place. At this point (beginning of the follicular phase), the hypophysiotropic GnRH-containing neurons generate a pulsatile LH release approximately every hour, which is a time at which estrogens are relatively low. As the ovarian follicles grow, they release increasing amounts of estrogens, which feed back at the level of the hypothalamus and reduce the frequency of LH and FSH release to 1 pulse per 90 min. At the same time, the most developed follicle also synthesizes increasing amounts of LH and FSH receptors, thus providing increased gonadotropin sensitivity in the face of decreasing gonadotropin release from the pituitary. The follicle begins to synthesize and secrete large amounts of estradiol, which, through ill-understood mechanisms, produce a *positive feedback* effect at the level of both the pituitary gonadotropes and the GnRH-containing neurons of the hypothalamus, triggering a gonadotropin surge (large amounts of LH and FSH released in the circulation) at approximately midcycle (14 days). This surge is responsible for ovulation and the transformation of the follicle into the corpus luteum. In the luteal phase of the cycle, increasing amounts of progesterone and moderate levels of estrogens are secreted, which feed back upon the pituitary and hypothalamus to reduce the frequency of LH pulses to 1 every 6–12 hr. The rising levels of progesterone and inhibin lead to an inhibition of FSH release as the ovarian cycle progresses. However, at the end of the cycle, with lack of fertilization of the ovum, the corpus luteum degenerates and significantly reduces its release of estrogens and progesterone. Lower levels of sex steroids release FSH from feedback inhibition and allow the cycle to repeat itself.

In men, LH pulse frequency remains relatively constant throughout adulthood, with a frequency of 1 pulse every 2–3 hr. High testosterone levels, however, can significantly inhibit LH release, but FSH release is not altered by testosterone. This inhibition thus occurs at the level of the anterior pituitary gonadotropes. Inhibin, a 3l-amino-acid peptide produced in the testes and ovaries, inhibits the release of FSH in men, which is thought to act mainly at the pituitary level.

Some of the feedback inhibition mediated by estrogens occurs at the level of the anterior pituitary. Estradiol, through interactions with their receptors, reduces the effectiveness of hypothalamic GnRH upon the gonadotropes, thus reducing the "amplitude" of LH pulses but not their frequency. The feedback inhibition mediated by progesterone, on the other hand, is mediated exclusively at the level of the hypothalamus. Hypothalamic feedback inhibition initiated by gonadal steroids is unlikely to be mediated at the level of the hypophysiotropic GnRH-containing neurons because studies have failed to detect gonadal steroid receptors in these neurons. However, many neural systems contacting hypophysiotropic GnRH neurons express these receptors. Thus, the brain circuits providing innervation to hypophysiotropic GnRH-containing neurons appear to be an important

component regulating circulating gonadal steroids. The large number of developmental (fetal life, childhood quiescence, puberty) and environmental factors (daylight, nutrition, stress, exercise) regulating the HPG axis also point to the importance of the circuitry controlling it.

2. Brain Circuits Involved in the Regulation of the HPG Axis

As discussed earlier, the presence of sex steroids, particularly testosterone, around birth is crucial for the development of the male phenotype and, particularly, the brain regions involved in reproduction. These dimorphic sex differences include larger nuclei in the brains of men, including a region of the medial preoptic, suprachiasmatic, and anterior hypothalamic nuclei. Given the multiple origins of GnRH-containing neurons in the medial septal complex and hypothalamus, the neural regulation of GnRH activity thus could be very complex. There are a few well-characterized inputs that may play an important role in reproduction. For instance, the sexually dimorphic preoptic area receives afferents from the medial part of the bed nucleus of the stria terminalis, the ventral part of the lateral septal nucleus, the medial amygdaloid nucleus, and the amygdalohippocampal area. These areas are rich in sex steroid receptors and, in animals, are known to contribute significantly to copulatory behaviors as well as to sexual interest (perhaps desire). The medial preoptic area also receives projections from the sexually dimorphic medial preoptic nucleus, as well as from some medullary catecholaminergic neurons that contain estrogen receptors, which may mediate, in part, the activational effects of catecholamines on GnRH release. Several other neurotransmitter systems appear to directly stimulate or inhibit GnRH release, including serotonin, GABA, substance P, neuropeptide Y, CRH, and opiate peptides.

C. Dysregulation of Circulating Gonadal Hormones

Observed gonadal hormone dysregulation has several etiological causes. In women, menopause provides a natural cause of long-term reduction in circulating estrogens and progesterone, because the ovaries progressively lose their sensitivity to gonadotropins. Surgical removal of the ovaries and various degenerative ovarian diseases also account for reduced circulating sex steroid levels in women. Low levels of circulating sex steroids lead to larger pulsatile releases of LH and FSH. The LH pulses are associated with "hot flashes," a sensation of warmth spreading from the trunk to the face. However, LH is not directly involved in these hot flashes because hypophysectomy does not abolish them; thus, a hypothalamic signal responsible for both the LH surge and the hot flashes appears to be responsible for this condition. Estrogen replacement usually ameliorates the hot flashes and the psychological fluctuations (irritability, depressed mood) associated with menopause.

It is also the case that women have a much higher incidence of depressive disorders than men. Attempts to correlate reproductive hormone status with depression have generally suggested that women are most susceptible to depression at the times in their ovarian cycles when they experience the largest variations in circulating hormones. Thus, women in the perimenopausal period as well as after childbirth (post partum) show increased risks of depressive illnesses, particularly if they have a prior history of depressive mood. In addition, the late luteal phase is associated with the premenstrual syndrome (PMS), a period characterized by increased cramps, bloating, breast tenderness, and headaches physically and by significant moodiness, anger, anxiety, and even depression psychologically in some 30% of cycling women. In carefully controlled studies, no differences between circulating estrogens, progesterone, or LH could differentiate women with or without PMS.

Nevertheless, effective treatment of PMS involves the elimination of ovarian cycling, suggesting, somehow, the involvement of circulating reproductive steroids in this condition. Disturbances in memory retrieval have also been associated with women experiencing PMS. Estrogens have been shown to interact significantly with subtype-specific serotonin receptors (5-HT_{2A}) in some limbic cortices and the nucleus accumbens, areas putatively involved in mood. This may provide the basis for the observation that serotonin-specific re-uptake inhibitors (SSRIs), one of the latest class of antidepressant drugs, may have beneficial effects in menopausal depressed women, particularly in combination with estrogen replacement.

The testes usually continue to respond to gonadotropins throughout life even if it somewhat declines with age; thus, men do not experience menopause. However, the loss of the testes either surgically (orchidectomy) or by diseases almost invariably leads to a decline in sexual desire and impotence. Physically, the lack of circulating testosterone also reduces some

of the secondary male sex characteristics, including muscle loss, reduced body and facial hair, and deposition of fat around the hips. Hot flashes also are experienced by orchidectomized (castrated) men. Testosterone replacement can reverse all of these conditions, just as estrogen replacement reverses the effects of low circulating estrogen levels in women. Although aggressive behavior has been linked with slightly higher circulating testosterone levels in men, the general belief is that these might be reactive effects, not the mediators of aggression as such. The possibility still exists, however, that some violent–aggressive types of behaviors might be correlated with higher circulating testosterone levels. As is the case with the ovaries, there are virtually no known conditions leading to consistently high circulating testosterone levels.

VI. FINAL COMMENTS

It is obvious from the preceding discussion that there are clear psychologic and psychiatric outcomes associated with endocrine imbalances. It is also remarkable that one of the major psychologic outcomes of hormonal dysregulation, be it due to hypo- or hyperfunction, involves mood disorders. Restoration of hormonal balance ameliorates the associated mood disturbances in many instances. Likewise, endogenous psychiatric conditions encompassing affective disorders such as general anxiety and major depression have a significant impact on several hypothalamo–pituitary endocrine systems. Effective treatment of these conditions also normalizes, in most cases, endocrinologic functions. These observations strongly suggest a close association between the brain substrates underlying affect, on the one hand, and the control of endocrine systems, on the other hand. Exactly how dysregulation in one results in disruption of the other remains to be determined. However, their close interactions further suggest that the same brain systems responsible for affect will also be prominently responsible for the control of psychoneuroendocrine functions.

GLOSSARY

cytokines Signal molecules released from immunocytes, supporting cells, or other cell types (e.g., endothelial cells) that can interact with other cells of the immune system or additional targets and alter their intracellular activity.

immunocytes Cells of the immune system.

innervation The distribution of nerve fibers that end in association with a particular structure, region, organ, or cell.

neurohormone A blood-borne signal of endocrine nature that either is derived from the brain directly or is released from the pituitary gland due to neurally derived factors.

neuromodulation Interaction of a neurally derived signal with a target cell that alters the intracellular capabilities of that cell through either genomic mechanisms or intracellular transduction pathways.

neuropeptides Neural signal molecules derived from larger prohormones that consist of 3 to 100 or more amino acids released from nerve endings, cells of neural origin, or cells of immune or endocrine origin.

neurotransmitter A signal molecule released from nerve endings that can interact with specific receptors on target cells and alter either ion channels or second messengers following transduction.

The field of psychoneuroimmunology has demonstrated that the immune system is not an autonomous, exclusively self-regulating system, neither is the brain devoid of influences emanating from immune signaling. Rather, the CNS and the immune system appear to interact with complex signaling and feedback loops for the protection and homeostasis of the whole organism.

I. THE NERVOUS SYSTEM AND THE IMMUNE SYSTEM INTERACT WITH EACH OTHER

A. Historical, Clinical, and Experimental Perspectives

For centuries, an association has been described between "mind" or "emotions" and the course and consequences of disease. Galen proposed an association between "melancholia" in women and breast cancer almost 2000 years ago. Although suspicions of such mind–body interactions often were voiced, the modern era of the scientific understanding of disease and the discovery of micro-organisms as the

cause of infectious diseases led the medical profession away from a more holistic or integrated approach to medicine. Modern mechanistic medicine moved in a reductionistic fashion toward molecular and cellular explanations for disease, an approach that often did not include psychological and psychosocial factors. Thus, medicine in the modern era focused on the "body" without integrating the "mind" and "spirit."

Immunology grew up as a modern discipline with the underlying premise that the immune system is an autonomous and self-regulating system that responds to its own signals and is not subject to perturbation from neural influences, especially those in the realm of the "mind" or "spirit." However, with the advent of parallel integrative research approaches exploring interactions between the nervous system and the immune system during the past two decades, it has become increasingly evident that these two great communication systems are intimately integrated with each other and have constant, ongoing signaling between them. These interactions have a profound functional influence, including altering the onset, progression, and outcome of many disease processes. This field has come to be called "psychoneuroimmunology" (PNI), a name that acknowledges ongoing interactions among behavioral, neural, endocrine, and immunological processes, whose collective communication networks are integrated for the maintenance of homeostasis within the whole organism. An explosion of information in the past decade has revealed wide-ranging links among these systems using molecular signaling via hormones (endocrine), neurotransmitters (neural), and cytokines (immune). Receptors are present on many cells of all three systems for all of these classes of molecules, indicating the capacity for intersystem communication. Studies from the systemic level to the molecular level have provided evidence that these neural–immune channels of communication not only exist but exert a profound influence on the onset and course of disease and even on the life or death of an organism. Although the public and the popular press have embraced this concept as "common sense" and intuitively obvious, scientific and clinical circles have been far more skeptical and initially were downright hostile to the idea that neural–immune influences could be of functional importance. This article will review the evidence that such communication channels exist, do indeed have important consequences for the understanding of signaling within and among the integrated systems, and have functional significance for the practice of medicine.

1. Early Studies Linked Stressors to Increased Susceptibility and Pathological Effects of Viruses in Experimental Animals

In the late 1950s, Rasmussen and colleagues studied the effects of a behavioral stressor, avoidance conditioning, on the susceptibility of mice to a variety of viral infections. This psychological stressor increased the susceptibility of mice to herpes virus, Coxsackie B virus, and vesicular stomatitis virus. In additional work in the 1960s, Rasmussen and colleagues also measured immunological variables as well as disease outcome in stressed mice, a foreshadowing of the more detailed mechanistic studies that were carried out in the late 1980s and 1990s. These same investigators also showed that a stressor in mice could change the course of malignancy from polyoma virus, another forerunner of more recent studies investigating neural–immune signaling and progression and metastases of specific cancers.

George Solomon, a pioneer in the field of PNI in both human and animal studies, in the 1970s, showed that handling during early life could alter subsequent primary and secondary antibody responses to a bacterial antigen, an important component of the sophisticated acquired immune responses. Solomon also showed that the characteristics of the stressor influence the nature and extent of the subsequent alteration in antibody production. These studies implied a link between the central nervous system (CNS) and the cells of the immune system that are engaged in antibody production. Solomon and colleagues also investigated the effects of stressors on animal models of rheumatoid arthritis, graft verus host response, and virally induced tumors, again showing a link between stressors and immunological outcomes. These findings were not appreciated at that time for their almost revolutionary implications for holistic or integrative medicine.

2. Early Clinical Studies Described an Association between Stress and Human Susceptibility to Immune-Mediated Diseases

Solomon and colleagues studied patients with autoimmune disease (rheumatoid arthritis) and found that psychological well-being could provide a protective influence over expression of this disease. Many other correlational studies in the 1970s and 1980s identified psychosocial factors as important influences on the susceptibility to, clinical course of, or recovery from many types of diseases in which the immune system is

involved, including bacterial infections, viral infections, allergic responses, autoimmune diseases, and cancer. However, because these studies were correlational and were not able to specify the precise alterations in signaling or the biological mechanisms by which such influences were exerted, they were not viewed seriously in scientific circles until further cellular and molecular studies were undertaken in the past few years that pointed toward the mechanistic basis for some of these findings. A further complication of studies involving stressors is that subtle variations in the stressor can influence biological processes in a differential fashion; these effects are superimposed on the pathophysiological alterations produced by the disease itself. Also, the demonstration that a stressor alters the outcome of an immune-mediated disease does not pinpoint or even require a direct effect of a neural signal, provoked by the stressor, on cells of the immune system.

3. Experimental Studies Sought Mechanistic Explanations for Neural–Immune Interactions

Both human and experimental animal studies in the 1970s, 1980s, and even earlier indicated that one consequence of psychological stressors was a change in the outcome or susceptibility to a variety of disease processes that involved the immune system. For decades, steroids (glucocorticoids) were used in clinical medicine to reduce inflammation, suppress immune reactivity in patients with autoimmune disease, and suppress rejection responses in transplantation. Therefore, the most convenient explanation for the influence of stressors on immune responses or disease processes was that a glucocorticoid, induced by the stressor, exerted a general suppression of immune responses. This led to some of the first experimental attempts to substantiate that stress-induced alterations in immune responses or immune-mediated diseases are regulated by the hypothalamo–pituitary–adrenal (HPA) stress axis that links the hypothalamus through the pituitary to the secretion of cortisol and other glucocorticoids from the cortex of the adrenal gland. However, studies over the past two decades that have employed adrenalectomy or glucocorticoid blockade to eliminate glucocorticoid secretion and the influence of the HPA have revealed that glucocorticoids are only one of many classes of signal molecules involved in neural–immune communication.

Signaling from the sympathetic subdivision of the autonomic nervous system [sympathetic postganglionic neurons using norepinephrine (noradrenaline) as the main neurotransmitter] also is involved extensively in neural–immune communication. Other neurohormones (e.g., growth hormone, prolactin) and neuropeptides (e.g., substance P, opioid peptides, vasoactive intestinal peptide) also mediate interactions between the nervous and immune systems. Conditioned immunosuppression, stress-induced alterations in splenic lymphocyte function, and the effects of cytokines or related molecules (IL-1 or the HIV protein gp120) are not eliminated by adrenalectomy or glucocorticoid blockade. In animal models of influenza viral infection in C57Bl/6 mice, undertaken by John Sheridan and colleagues, stress-induced exacerbation of the severity of the viral infection involved both the HPA axis and the sympathetic noradrenergic nervous system; only by blocking the excessive stress-induced activation of both of these systems simultaneously was a normal, robust immune response to the viral infection in young mice restored. These two systems are the two great "stress" axes of the body, and they exert a myriad of effects on virtually all organs and tissues of the body. They influence such processes as inflammation, wound repair, natural and acquired immunity, and a host of vascular and cell adhesion events. The rather straightforward demonstration by Sheridan and colleagues of HPA and sympathetic neural involvement in stress-induced alteration of the severity of viral infection in mice has profound implications for both acute and chronic perturbations of these axes and the consequences in humans for the susceptibility and outcome of many disease processes, particularly those mediated by the immune system. The presence of receptors for many neurotransmitters and neurohormones on many sub sets of cells of the immune system suggests that many influences of the nervous system on immune reactivity may be exerted directly by neurohormone and neurotransmitter signaling.

B. Experimental Evidence for Neural–Immune Interactions

1. Immune Responses Can Be Conditioned and Can Alter the Outcome of Immune-Mediated Disease

Behavioral conditioning is a learning paradigm that requires processing of information in the brain and subsequent outflow to peripheral target tissues involved in the conditioned response. Although some early reports of conditioning of immune responses were made by Metalnikov and Chorine in 1926, the

modern era of conditioning of immune responses began with the carefully controlled and analyzed studies by Robert Ader and Nicholas Cohen. They demonstrated that pairing of saccharine as a novel taste stimulus (a conditioned stimulus) with cyclophosphamide (an unconditioned stimulus), an agent that produces nausea and also induces immunosuppression, resulted in both taste aversion and diminished antibody response to a T-dependent antigen, sheep red blood cells, following exposure to saccharine alone. Saccharine by itself in unconditioned animals had no influence on the antibody response. Furthermore, this conditioned immunosuppression still occurred in adrenalectomized animals, eliminating the possibility that it is merely a conditioned corticosteroid stress response.

The initial response to this work by the immunology community was one of disbelief; even if conditioned immunosuppression had occurred, it was argued, the magnitude of change (approximately 30% diminution) was insignificant and had no clinical significance. However, one factor frequently overlooked is that Ader first discovered conditioned immunosuppression in a follow-up investigation seeking to explain why only conditioned animals died in response to saccharine exposure and not members of the other groups; death from pulmonary infections was indeed a significant biological endpoint. Ader and colleagues then hypothesized that, if conditioned immunosuppression had functional consequences, its application to animals with a genetic autoimmune disease (lupus-like NZB $\times$ NZW F1 mice) should prolong their lives compared with unconditioned controls. Such conditioning did prolong their lives through conditioned immunosuppression, and with drug reinforcement to prevent extinction of the conditioned response, Ader and colleagues were able to keep conditioned autoimmune-prone mice alive for a full life span of 27+ months (compared with less than 8 months in unconditioned mice) by using a total dosage of immunosuppressive drug that was considerably less than the dosage required to keep an unconditioned mouse alive. The implications for these findings is that the brain was somehow aware that immunosuppression had occurred following administration of the drug and, in response to the conditioned stimulus alone, was able to generate specific outflow mediators (other than glucocorticoids) that mimicked the initial immunosuppressive effect of the drug and exerted a life-saving influence on the immune system of these genetically autoimmune animals.

Ader and colleagues have shown that pairing of a novel taste stimulus (chocolate milk) as a conditioned stimulus with antigen itself [keyhole limpet hemocyanin (KLH), a T-cell-dependent antigen] as an unconditioned stimulus results in a robust antibody response, in conditioned animals, to a subthreshold dose of antigen that evokes no antibody response in unconditioned animals. This represents the most definitive evidence for direct conditioning of immune responses by the brain.

Numerous studies have shown that many other manifestations of immunity also can be conditioned using classical behavioral approaches, including antibody response to a T-cell-independent antigen, graft versus host response, generation of cytotoxic T lymphocytes following graft rejection, and natural killer (NK) cell activity. NK cell activity in humans can be conditioned by pairing a novel taste stimulus with low-dose epinephrine administration (releases marginated NK cells and possibly splenic NK cells) followed by reexposure to the novel taste stimulus alone, which results in enhanced NK activity in the blood. Such conditioned responses also occur in animal models. These studies suggest that behavioral conditioning can be used to achieve a specific desired immunological activation or suppression in both humans and animals; the brain generates a response using its outflow mediators, neurohormones, and neurotransmitters to produce the conditioned response.

2. Psychosocial Factors in Humans Are Associated with Altered Immune Reactivity

Adverse psychosocial factors or stressful environments have been reported to increase morbidity and mortality to challenges by some tumors or infectious diseases. Because of the central role of the immune system in response to such challenges, it has been assumed that such stressors exert their effect on cells of the immune system itself. This is reinforced by experimental evidence for the suppression of measures of both natural and acquired immunity by stressors. However, the actual demonstration of the mechanistic basis for such interactions has remained somewhat illusive. Not all effects of stressors on the immune system are suppressive, depending on the timing, nature, route, and magnitude of the challenge and many other parameters. Some stresors can exert remarkably different effects on closely related immunologic processes. A major area of missing evidence is a careful characterization of the neurohormonal and neurotransmitter alterations induced by specific stressors, examined in parametric studies that subtly vary conditions of the stressor and look for changes in the

outflow of mediators from the central nervous system (CNS). This characterization needs to be followed by direct correlation with studies using pharmacologic agonists and antagonists of the major neural–immune mediators, followed by evaluation of specific reactivity of specific subsets of cells of the immune system. We also know very little about the influence of the severity, duration, and exact timing of stressors in response to specific immune challenges or reactivity. There may be a considerable difference between an ongoing period of exposure to stress and a poststress interval, particularly in the availability of the CNS-derived mediators and the expression of the appropriate receptors on potential target cells.

a. Depression Early studies of hospitalized drug-free depressed patients found diminished responses of lymphocytes to mitogen-induced proliferation. This led to the popular notion that depression is associated with immunosuppression. However, ambulatory depressed patients did not show such changes, and the literature on studies of depressed individuals is mixed with regard to the presence of absence of various measures of immune dysfunction. One shortcoming of many observations taken from measures of immune parameters such as mitogen-induced proliferation is that such measures provide little predictive value for susceptibility to infection, course or outcome of infections, and reactivity of acquired immune responses toward cell-mediated immunity versus humoral immunity. The predictive value of blood measures is remarkably poor, given the sophisticated state of cellular and molecular immunology in experimental animals. The characteristics of the state of depression (e.g., dexamethasone response, bipolar versus unipolar), the timing and therapeutic intervention of the depression, the age and gender of the patient, and many other variables appear to have some bearing on whether the depressed individual shows altered measures of immunity. In a careful analysis of the literature, Marvin Stein showed that the likelihood of decreased measures of immunity increases with age and severity of depression, particularly in men. Sheldon Cohen, in a detailed meta-analysis of the literature on depression and immunity, concluded that there is an association of diminished immune responses, including NK cell activity (important for antiviral and some antitumor actions), and lymphocyte proliferation.

b. Bereavement Bereavement has been investigated in humans as a potential severe stressor that should reveal stress-induced immunosuppression if such an association occurs. Such studies have shown that men, but not women, who have lost their spouses (conjugal bereavement) demonstrate diminished measures of immune response (mitogen-induced proliferation, NK cell activity). This literature suggests that the quality of social support and the individual perceptions of control over their situations are buffering events to the stress-induced diminution of immune reactivity. Studies of other forms of bereavement, such as parents who lost a son in Israel in the Six-Day War, showed a lack of altered immune measures.

c. Examination Stress in Medical Students Some of the most carefully studied humans with regard to stress-induced alterations in immune reactivity are medical students undergoing blocks of examinations in the basic sciences. Jan Kiecolt-Glaser, Ronald Glaser, and colleagues demonstrated that medical students showed diminution of mitogen-induced proliferative responses, diminished NK cell activity, altered T-cell subset ratios, and increased antibody to specific viral epitopes of Epstein–Barr virus (suggesting activation of this normally latent virus) during the examination periods, with a return toward baseline in the interim examination-free periods and a return to the population baseline during summer vacation. These studies were controlled for sleep, eating habits, caffeine ingestion, and other possible confounding variables and still showed significant alterations. Those students with the poorest measures of immune reactivity showed a significant increase in clinic visits and self-reported symptoms. In some students, the inability of immune reactivity to return to baseline was associated with loneliness and poor social support. Subsequent studies by others showed that examination stress in medical students shifted T helper (Th) cytokine production away from cell-mediated immunity (Th1 cytokines, interleukin 2 and interferon-γ) and toward humoral immunity (Th2 cytokines, interleukins 4 and 10). This shift could result in a diminished capability to respond to viral infections and to clear some pathogens (e.g., influenza) for which cytotoxic T lymphocyte killing of infected cells is necessary.

d. Stress of Caregiving Kiecolt-Glaser and colleagues also have studied caregivers of patients with Alzheimer's disease and other debilitating illnesses. The caregivers demonstrated diminished lymphocyte responses to mitogens, diminished NK cell activity, and altered T-cell subset ratios, suggesting diminished

immune reactivity. However, it also must be remembered that caregiver exposure to potential infectious organisms may be different from that of their age-matched counterparts because of the restrictions inherent in caregiving. Of considerable interest in these studies is that the suppressed immune measures can remain suppressed for several years, even after the death of the individual to whom they gave care. Caregiving may be one of the most severe stressors in humans, particularly in the elderly who already may have age-related diminution of T-cell immunity from which full recovery may be difficult.

e. Other Stressors Other stressors have been studied in humans, again with measures of immune responsiveness taken from peripheral blood samples. This includes women going through a marital separation or divorce and individuals entering a nursing home. These individuals show the same diminution of measures of immune reactivity mentioned earlier. Kiecolt-Glaser and colleagues have shown that even a brief intervention for nursing home patients, such as a 1-hr visit per week from a college student for a semester, can reverse some of these measures. The most compelling findings from all the human stressor studies are the apparent importance of strong and meaningful social support and the patients' perceptions of being in control of their environment and surrounding events as buffers against stress-induced diminution of immune responsiveness.

f. Positive Factors Can Enhance Measures of Immune Responsiveness Many of the studies in humans have looked at severe stressors such as conjugal bereavement, chronic caregiving, marital difficulties, examination stress in medical students, and other apparently negative factors. A more difficult type of study is that of interventions that use "positive emotions" or approaches intended to enhance immune responsiveness. The lay press is replete with claims of programs and regimens that "enhance" immune responsiveness, with little or no supporting evidence that a specific intervention produces benefits. The best data regarding positive interventions are those showing that moderate exercise can enhance NK cell activity, CD4:CD8 ratios, and lymphocyte mitogen responses, lasting for at least 12 hr after the exercise period. Lee Berk and colleagues have studied laughter and exposure to comedic tapes and programs with many similar findings, including enhanced NK cell activity cell-mediated responses. In laughter studies, baseline cortisol and epinephrine levels are suppressed during and many hours after the laughter episode, whereas norepinephrine remains unchanged (unlike exercise, during which norepinephrine levels rise). Individuals watching videos of nature scenery accompanied by a beautiful musical score also show evidence of diminished production of these "stress mediators." Kiecolt-Glaser's demonstration of nursing home interventions with social support from visiting college students also strengthens the notion that positive benefits can be derived from a behavioral intervention. Additional surgical literature on recovery and infections suggests that the hospital environment (e.g., low ambient levels of noise, a window in the room) may play a role in more rapid recovery and a reduced rate of postoperative infections. These types of study are difficult to carry out and control for intervening variables, but they may be able to shed some light on the range of responsiveness of measures of immune reactivity with both positive and negative environmental and psychosocial factors. It also must be borne in mind that measures of immune reactivity from peripheral blood samples can only suggest, and not absolutely predict, a patient's reaction to challenge. Changes in mitogen responses of lymphocytes, T-cell subset ratios, and NK cell activity may reflect temporary changes in cell trafficking and may not be predictive of strengthening or enhancing of the overall ability of the natural or acquired arms of the immune system to mobilize in response to a bacterial infection, viral challenge, or tumor challenge. Indeed, it may be highly undesirable to enhance the immune reactivity of self-reactive clones on lymphocytes or to enhance interferon-γ production in a patient with an autoimmune disease, such as multiple sclerosis.

3. Psychosocial Factors in Humans Can Influence the Outcome of Immune-Mediated Disease Processes

The question of great clinical importance in this field is whether stress-induced or psychosocially influenced measures of immune responsiveness are predictive of, or reflections of, a disease outcome. This has been considered primarily anecdotally or in outcome studies without concomitant investigation of mechanisms and mediators. Cassileth and colleagues reviewed psychosocial factors, obtained from questionnaires, in patients with terminal cancers that were no longer treatable with surgery, radiation, or chemotherapy and found that psychosocial factors had no predictive

value or protective benefit toward death as an endpoint. This study showed that terminally ill cancer patients indeed die regardless of psychosocial variables, a not terribly surprising finding. If psychosocial factors play an important role in such diseases, they are likely to be most evident at the stages of acquisition of, susceptibility to, or progression of these diseases. The initial editorial response to this study was a blanket closing of the lid on behavioral medicine as an important factor in presumed immune-mediated diseases such as some cancers. However, other studies provided more provocative insights into the role of psychosocial factors and disease.

a. Stress and Colds Sheldon Cohen and colleagues investigated the role of life stresses related to an individual's response to challenge with cold viruses. Increasing stress in the previous 6 months was associated with increased infectivity in subjects administered one of several cold viruses. Other factors such as smoking, alcohol consumption, diet, shared housing with infectious people, personality traits, and assessment of personal control and self-esteem did not influence the increased infectivity. In the initial study, only the rate of infections (infectivity) was increased and not the symptomatology of clinical colds, antiviral antibody titers, or white blood cell counts; subsequent studies have suggested that life stressors may also influence the symptomatology of clinical colds. Thus, chronic stress appears to act at the level of infectivity and may have clinical consequences for these viral infections.

b. Counseling and Peer Support and Metastatic Breast Cancer David Spiegel and colleagues reported one of the most remarkable and provocative findings in the field of psychoneuroimmunology. They randomly assigned women with newly diagnosed, disseminated breast cancer into two groups. Each group received state-of-the-art medical care but was assigned to either receive or not receive weekly sessions of counseling and peer support for 1 year, originally to test the hypothesis that such intervention would enhance the quality of life. Not only did counseling and peer support enhance the quality of life for the women who received them, but they extended average life expectancy from 19 to 37 months. This increased longevity could not be explained by severity of medical parameters or other retrospective aspects of assignment into the groups. Unfortunately, no immune measures were monitored in these patients. Some criticism was leveled at this study because the control group had a shorter average survival time than was seen in other studies of breast cancer. Nonetheless, this controlled study did show a remarkable difference in complementary counseling and peer support added to traditional medical care. A working hypothesis is that this intervention enhanced NK cell activity, which in breast cancer patients can influence metastatic spread; it is interesting to note that NK cell activity is among the most responsive immunological measures reacting to stressors and to influences of the stress hormones and neurotransmitters. Observations by Anderson and colleagues at Ohio State University noted that women with breast cancer showed diminished NK cell activity with higher indices of life stressors and more robust NK cell activity with a lesser extent of life stressors. Follow-up studies on Spiegel's initial report, repeating these interventions and including measurements of immune reactivity, currently are under way.

c. Structured Intervention Studies with Malignant Melanoma Fawzy Fawzy and colleagues undertook a structured intervention study in patients with malignant melanoma. Short-term treatment with psychotherapeutic intervention and social support provided clinical benefit to the progression of this cancer. As in the case of breast cancer, the progression of malignant melanoma also is sensitive to NK cell activity. In addition, in many other cancers, even those that are not particularly immunogenic, it appears that robust cell-mediated immunity is associated with better clinical outcomes, and diminished cell-mediated immunity is associated with a rapid downhill course.

4. Stressors in Experimental Animals Can Alter Measures of Immune Responsiveness and the Outcome of Immune-Mediated Diseases

Many studies of stressors applied to experimental animals have been carried out to explore stress-induced alterations in measures of immune responsiveness. Infant squirrel monkeys separated from their mothers show cortisol-independent depressed lymphocyte responses to mitogens and altered measures of complement proteins, IgG levels, and macrophage functions. In studies by Bruce Rabin and colleagues, rats subjected to unavoidable foot shock showed decreased mitogen responses by blood lymphocytes (cortisol-dependent), decreased mitogen responses in splenic lymphocytes (sympathetically driven), and decreased splenic NK cell activity (dependent on opioid peptide activity). Some studies of avoidable

versus unavoidable foot shock have shown that escapability prevents the suppression of splenic NK cell activity seen with inescapable shock. This is consistent with "learned helplessness" studies that suggest that control over aversive stimuli can buffer stress-induced suppression of immune responsiveness. However, the stress and immune studies are very complex and suggest that many characteristics of the nature, severity, duration, and timing of the stressor, many other host characteristics and variables, and the nature of the immune measure or challenge can influence (1) whether there are alterations in immune reactivity, (2) if so, what directionality those alterations will take, and (3) whether there are disease consequences of such alterations.

Stressors, including psychological stressors, can alter disease progression and outcome, as noted earlier in the introductory section. Among the most careful studies of stress influences on disease outcome are those of John Sheridan and colleagues. They showed that restraint stress can suppress T-cell proliferation and cytokine production in response to influenza viral infection in mice, as well as to herpes infection. Reversal of these stress effects can be achieved only with dual blockade of both glucocorticoids (with RU486) and β-adrenergic receptors (with nadolol). Each of these agents, RU486 and nadolol, when given alone, reversed some of the stress-induced alterations in the mice in response to influenza infections, but it took both agents together to reverse all of the major effects of the stressor. Sheridan and colleagues also showed that injection of herpes virus into the tongue in rats resulted in a very high rate of encephalitis in stressed animals, with little or no such encephalitic response seen in unstressed animals with similar injections. These studies suggest that stressors that activate the HPA axis and sympathetic nervous system can alter both immune responsiveness and disease outcome following a challenge.

A study by Zorzet and colleagues investigated the effects of restraint stress on Lewis lung tumors in rats. These tumors can be treated successfully with cytoxan, eliminating the tumors and restoring health to the rats. Restraint stress during treatment with cytoxan (cyclophosphamide) eliminated the ability of the chemotherapy to destroy the Lewis lung tumor, leading to the death of the rats, as was the case in rats with these tumors who received no chemotherapeutic treatment. This provocative study suggests that a stressor may influence the ability of chemotherapy to destroy some cancers, in addition to possible direct effects on tumor proliferation and dissemination.

5. Hormonal and Neurotransmitter Mediators Link the Nervous System with the Immune System through Known Channels of Biological Signaling

Initially, studies reporting that conditioning or psychological stressors could influence immune reactivity or disease outcome were met with considerable skepticism because there were no well-characterized links between the nervous system and the immune system that could provide a mechanistic explanation for signaling to account for these influences. However, increasing numbers of studies, both *in vitro* and *in vivo*, have indicated that neurohormones and neurotransmitters are abundantly available for interaction with cells of the immune system and that these cells possess receptors that are responsive to these neurally derived signal molecules.

a. Classical Pituitary Hormones Profoundly Influence Immune Responsiveness Classical pituitary hormones can influence immune responsiveness both *in vitro* and *in vivo*, as will be discussed in detail later. Hormones shown to exert such effects include adrenal corticotropic hormone (ACTH), β-endorphin, growth hormone, prolactin, thyroid-stimulating hormone, and others. Hormones from the target glands that respond to classical pituitary hormones also can exert influences on lymphoid cells. These hormones include glucocorticoids (cortisol in humans, corticosterone in rats), thyroid hormone, and gonadal steroids. In addition, posterior pituitary hormones (oxytocin, vaopressin) and melatonin from the pineal gland act on some cells of the immune system.

b. Sympathetic Noradrenergic Nerve Fibers and Neuropeptidergic-Containing Nerve Fibers Directly Innervate Parenchymal Zones of All Lymphoid Organs Sympathetic postganglionic noradrenergic (NA) nerve fibers were described several decades ago as innervating vascular smooth muscle and other smooth muscle (e.g., capsular smooth muscle, splenic trabeculae) in lymphoid organs (thymus, spleen, lymph nodes), but they were thought to mainly control blood flow or capsular contraction. David Felten and colleagues found sympathetic NA nerve fibers extending into the parenchyma of primary lymphoid organs (bone marrow, thymus) and secondary lymphoid organs (spleen and lymph nodes), as well as into mucosal-associated lymphoid tissue of the gastrointestinal tract. The NA nerve terminals formed neuroeffector contacts immediately adjacent to T

lymphocytes, macrophages, granulocytes, reticulocytes, and other cell types. These nerve terminals release norepinephrine (NE) adjacent to these target cells that possess β- and α-adrenoceptors. Communication between the nerve terminals and the cells of the immune system include both the close appositions for direct synaptic-like contacts and more widespread diffusion for paracrine-like interactions. Numerous neuropeptidergic nerve fibers also extend into the parenchyma of primary and secondary lymphoid organs and form similar close appositions. These neuropeptide terminals contain neuropeptide Y (colocalized with NE in most sympathetic postganglionic terminals), substance P and calcitonin gene-related peptide (CGRP) (often, but not always, colocalized with each other), vasoactive intestinal peptide (VIP), somatostatin, enkephalin, and others. It appears that these nerve fibers are separate from each other, with the exception of the colocalized neurotransmitters mentioned earlier. We do not yet know the cells of origin for most of these neuropeptide-containing nerve fibers. Such sources include (1) sensory ganglia, (2) autonomic sympathetic ganglia, and (3) enteric neurons whose processes traverse autonomic ganglia.

c. Some Cells of the Immune System Can Produce Neuromediators Nonneural cells, such as thymic nurse cells, can produce neuropeptides, such as oxytocin and vasopressin, that can be released as mediators for interaction with other cells in the thymus. Ed Blalock, Eric Smith, and colleagues found that some macrophages and lymphocytes can be induced to produce classical pituitary hormones such as the proopiomelanocortin (POMC) products ACTH and β-endorphin, thyroid-stimulating hormone, and others. Some viruses can act on receptors that induce the production of a neurohormone. In addition, some releasing factors, such as corticotropin-releasing factor (CRF), can induce the gene for producing POMC, resulting in the production of ACTH in a manner similar to that occurring in the anterior pituitary gland. In addition, some macrophage-like cells can directly produce neurohormones such as CRF itself. Thus, neuropeptides and neurohormones can be produced by neurons or cells of the immune system.

6. Central Nervous System (CNS) Lesions and Intracerebroventricular Infusions Can Alter Immune Responsiveness

Stereotaxic lesions, precisely placed sites of tissue destruction, in specific portions of the CNS induce both structural and functional changes in the immune system, some of which are transient and some long-lasting. Most of the sites in which lesions induce such changes are in the hypothalamus, limbic forebrain, or brain stem structures associated with the hypothalamus and limbic forebrain. For example, lesions in the anterior hypothalamus resulted in thymic involution and a transient decrease in mitogen-stimulated (conA) proliferation of T-cells. Lesions in the lateral septal area resulted in long-lasting decreases in IgG, IgA, and IgM production, whereas lesions in the hippocampus produced elevated IgM and IgG antibody production. However, care must be taken in interpreting these findings. Lesions show only what the remainder of the nervous system can do in the absence of the lesioned structure, not necessarily what the lesioned structure normally did. These lesion studies do provide sites for further probing for a better understanding of neurochemical mechanisms of regulating neuroendocrine and autonomic outflow from the CNS.

A further approach to studying CNS regions that may play a role in modulating immunological reactivity is intracerebroventricular (icv) infusion of immunologic agents influencing neural outflow to the immune system. For example, infusion of interleukin-1β (IL-1β) icv in femtomolar concentrations resulted in diminished splenic immune responses that were abrogated by the administration of ganglionic blocking agents, indicating that the IL-1β activated central circuits that activated outflow of the sympathetic nervous system. Similarly, icv infusion of the HIV envelope protein gp120 resulted in diminished peripheral immune responses and elevated plasma corticosteroid levels, again indicating a central stimulation of outflow neural mediators that can alter immune responses. The sites and receptors by which these infusions interacted with CNS neurons are not yet fully understood.

7. Immunologically Derived Mediators Can Activate Portions of Both the CNS and Peripheral Nervous System (PNS)

a. Cytokine Induction of Fever, Sleep, and Illness Behavior Cytokines, especially the inflammatory cytokines IL-1β, IL-6, and TNF-α, can act directly or indirectly on CNS neurons to induce fever, slow-wave sleep, lethargy, loss of appetite, and other characteristics of illness behavior. Both icv and peripheral intravenous (iv) injection of these cytokines can induce these behaviors, although the icv route requires lower

concentrations. IL-1β is the most studied and most common cytokine thought to mediate such responses. There are several routes by which such actions may occur: (1) IL-1β may enter directly into the cerebrospinal fluid (CSF) by crossing the blood–brain barrier or by crossing at a circumventricular organ such as the organum vasculosum of the lamina terminalis (OVLT); (2) IL-1β may act on cells at the OVLT to release additional mediators such as prostaglandin E2 (PGE2), which in turn activates CNS neurons; (3) IL-1β may activate small-molecule mediators such as nitric oxide (NO) from the vascular endothelium or cells of the CNS, which in turn activate CNS neurons; (4) IL-1β may act on paraneurons associated with the vagus nerve, thus activating afferent pathways to the CNS that induce illness behavior; or (5) IL-1β may activate other sensory neurons or peripheral mediators that in turn signal the CNS. The interleukins IL-1β and IL-2 may act on presynaptic receptors on sympathetic NA nerve terminals to regulate the release of NE directly, thereby contributing to the regulation of neural–immune signaling at a local level.

b. Cytokine Activation of the Hypothalamo–Pituitary–Adrenal (HPA) Axis and the Sympathetic Nervous System In addition to inducing illness behavior, IL-1β and other inflammatory cytokines also activate the HPA axis by elevating the production of CRF, thereby further stimulating ACTH and glucocorticoid production. Central noradrenergic (NA) input to the paraventricular nucleus, deriving mainly from the A1 and A2 cell groups in the medulla, is necessary for the IL-1β- induced elevation of CRF; ablation of this NA pathway in the brain stem (the ventral NA bundle) abrogates the IL-1β-induced CRF elevation. In addition, central IL-1β activates the sympathetic nervous system, also by a CRF-mediated mechanism through the hypothalamus, which in turn interacts with organs of the immune system. These cytokines that can activate the HPA axis and sympathetic nervous system, therefore, act as stressors, activating the same axes that psychological and physical stressors activate. It should be noted that not all immune responses activate these stress axes. Viral infections, inflammatory mediators such as IL-1β and IL-6, and some stimuli such as lipopolysaccharide (LPS) are particularly potent activators. However, immune responses to some antigens do not activate these axes. It is of some concern that viral challenges, bacterial challenges, and inflammatory mediators can activate the HPA and sympathetic stress axes; these are potentially damaging reactions and, if activated in debilitated elderly patients in a setting where nosocomial organisms are abundant, such as a hospital, could have an adverse impact on morbidity and mortality.

c. Cytokine Regulation of CNS Inflammation, Reaction to Injury, and Regeneration and Plasticity Cytokines, especially IL-1β, IL-6, and TNF-α, have been noted to accumulate at the site of central injuries and inflammatory responses. The presence of IL-1β and other inflammatory cytokines also has been noted at an early phase of plaque formation in the brains of patients with Alzheimer's disease. It is not yet known the extent to which these cytokines can enhance or inhibit repair, regenerative responses, and neuronal plasticity. A complicating factor is the presence of IL-1β from blood, IL-1β from invading macrophages, IL-1β from resident microglial cells, endothelial cells, and possibly astrocytes, and the production of IL-1β by neurons themselves. It is likely that a cascade of interactions exists among inflammatory cytokines, other inflammatory mediators, neurotransmitters, acute phase proteins, and other proteins accumulating at inflammatory sites; these many mediators combine to influence the balance between degeneration and cell death on the one hand and regeneration and plasticity on the other.

II. OVERVIEW OF NEURAL COMMUNICATION CHANNELS TO THE IMMUNE SYSTEM

The central nervous system has several routes of communication available for molecular signaling directed toward cells of the immune system. The most conspicuous routes are connections from the CNS through the anterior and posterior pituitary and direct neural connections from the autonomic and sensory components of the peripheral nervous system. In addition, as noted earlier, some cells of the immune system can synthesize and release neural mediators, whereas others can take up such mediators from the local microenvironment.

A. Hypothalamic–Anterior Pituitary–Target Organ Axes

1. Direct Anterior Pituitary Hormone Actions on Immunocytes

Several of the anterior pituitary hormones have direct actions on cells of the immune system, particularly growth hormone (GH), prolactin, adrenocorticotropic

hormone (ACTH), and β-endorphin. The other anterior pituitary hormones have at least some effects on specific subsets of immunocytes. These hormones are released from the anterior pituitary by releasing factors, or inhibited from release by inhibitory factors, produced by neuronal cell groups in the hypothalamus and other CNS regions. The releasing factors and inhibitory factors are secreted from nerve terminals of these cell groups that end on the hypophyseal–portal vessels, a private vascular communication channel linking the hypothalamus with the anterior pituitary gland that is particularly suited for sending very high concentrations of these releasing and inhibitory factors to interact with pituicytes. The neuronal cell groups producing the releasing and inhibitory factors generally are associated with the hypothalamus, limbic system, and brain stem autonomic centers and can be acted upon by appropriate forebrain and brain stem circuits that participate in behavioral control of the periphery.

2. Target Organ Hormone Actions on Immunocytes

The anterior pituitary hormones are released into the peripheral blood, where they can act upon any cells that bear appropriate receptors for them. Whereas some of the anterior pituitary hormones act directly on immunocytes, they also act on their target organs to further release endocrine hormones into the blood. The most important of these hormones that act on cells of the immune system include the glucocorticoids, dehydroepiandrosterone, the gonadal steroids, and thyroid hormones.

B. Posterior Pituitary Hormones

The posterior pituitary hormones oxytocin and vasopressin are synthesized mainly in cell bodies in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus and are released from nerve terminals of those cell groups that end in the posterior pituitary. Oxytocin and vasopressin then are released into the general circulation.

C. Autonomic Outflow to Organs of the Immune System

1. Sympathetic Noradrenergic Connections Are Abundant

Extensive sympathetic neural connections form direct links between the brain and cells of the immune system. The preganglionic sympathetic neurons are found in the intermediolateral cell column of the thoracic and lumbar spinal cord and extend their axons out of the CNS to terminate on ganglion cells in the sympathetic chain and collateral (prevertebral) sympathetic ganglia. These ganglion cells generally use norepinephrine (NE) as their principal neurotransmitter and often have colocalized neuropeptides such as neuropeptide Y (NPY). The postganglionic noradrenergic (NA) nerve fibers extend into primary lymphoid organs (bone marrow, thymus), secondary lymphoid organs (spleen, lymph nodes), mucosal-associated lymphoid tissue (MALT) of the gastrointestinal tract and the airway, and lymphoid cells of the skin. In the bone marrow, thymus, spleen, and lymph nodes, the sympathetic nerve fibers enter the organ with the vasculature, extend along the vascular smooth muscle and other trabecular, capsular, or septal channels, and extend directly into the parenchyma of these lymphoid organs. The sympathetic NA nerve terminals form direct appositions or neuroeffector junctions with lymphocytes, macrophages, granulocytes, reticulocytes, and other cell types of the immune system. These contacts are as close as 6 nm (a gap junction is 2 nm and a classical CNS synapse is 20 nm) and form direct links for the sympathetic modulation of lymphoid cells bearing appropriate adrenoceptors responding to the released neurotransmitter. Some of these contacts have been mapped with anatomical tracing techniques; ablation and stimulation studies have shown that sympathetic contacts play an important role in translating CNS activity into immunomodulating signals. Sympathetic postganglionic fibers from the superior cervical ganglion also innervate the pineal gland and can regulate the synthesis and release of another immunomodulating hormone, melatonin.

2. Parasympathetic Cholinergic Connections Are Sparse or Not Present in Many Organs of the Immune System and Regionally Localized in Some Sites

Initially, it was assumed that sympathetic and parasympathetic nerve fibers constituted a balanced yin–yang interaction with the immune system, providing antagonistic functions similar to those described for the heart. However, with the possible exception of sparse parasympathetic fibers to the thymus, parasympathetic cholinergic nerve fibers have not been found extending into the primary and secondary lymphoid organs. There is no evidence for the

synthesis of choline acetyltransferase or high-affinity choline uptake in these organs. Thus, it appears that the main autonomic innervation derives from the sympathetic nervous system. In some of the MALT areas of the gastrointestinal tract and airway, cells of the immune system might be associated with the cholinergic parasympathetic nerve fibers supplying those systems.

3. Many Neuropeptidergic Nerve Fiber Connections to Lymphoid Organs Appear To Derive from Autonomic Ganglia

Abundant neuropeptide-containing nerve fibers also are present in the bone marrow, thymus, spleen, lymph nodes, and MALT. These fibers include substance P (SP), calcitonin gene-related peptide (CGRP), vasoactive intestinal peptide (VIP), somatostatin, neuropeptide Y (NPY), and others. The full "alphabet" of these neuropeptides has not yet been worked out; very careful studies varying the conditions of immunohistochemical staining must be undertaken to reveal the very fine neuropeptide-containing fibers that are present in lymphoid organs. Similar to the NA sympathetic nerve fibers, the neuropeptide-containing nerve terminals end in direct proximity to lymphocytes, macrophages, and other cells of the immune system. At first, it was assumed that these neuropeptide-containing nerve fibers derived from primary sensory ganglia because, for example, substance P is an important neuropeptide in nociceptive C fibers of the "pain" system. Several tracing studies from primary and secondary lymphoid organs have shown that the retrograde tracers show up principally in sympathetic ganglion cells and not in the primary sensory neurons in dorsal root ganglia or cranial nerve sensory ganglia. For example, the superior cervical ganglion and upper sympathetic chain ganglia supply NA fibers to the thymus. The superior mesenteric–coeliac ganglion supplies NA fibers to the spleen. Ganglia of the appropriate sympathetic plexuses supply the lymph nodes. Whereas some of these labeled cell bodies stained positively for tyrosine hydroxylase (TH), the rate-limiting enzyme for NE synthesis in sympathetic postganglionic neurons, others cell bodies stained positively for neuropeptides. It presently appears that a majority of the neuropeptide-containing nerve fibers derive from sympathetic postanglionic neurons. Until more detailed and careful tracing studies are carried out, it remains possible that a few cells of the primary sensory ganglia, and even enteric neurons whose axons pass through peripheral ganglia, might supply neuropeptide-containing fibers to organs of the immune system.

D. Primary Sensory Mechanisms of Neural–Immune Signaling

1. Primary Sensory Innervation of Lymphoid Organs Appears Sparse

Although only a few tracing studies have identified primary sensory ganglion cells of origin for neuropeptide-containing nerve fibers that distribute into the primary and secondary lymphoid organs, it still is possible that sparse numbers of cell bodies can give rise to abundant arborizations that have widespread functional interactions (e.g., a PNS equivalent of the locus ceruleus' widespread influence in the CNS). We do not yet have enough detailed tracing data to make conclusive statements about the possible role of primary afferents as "sensory" signaling devices for potentially passing immunologic information to the brain. However, it is possible for primary sensory signaling to the CNS to play an important role indirectly, as shown by Robert Danzer, Keith Kelley, Linda Watkins, Steve Maier, and others, who have shown that cytokines such as IL-1β in the periphery can stimulate the release of mediators from paraneurons, which in turn activate vagal afferents. These vagal afferents communicate with the nucleus solitarius and other brain stem nuclei that feed information into the brain stem–hypothalamic–limbic network that is active in neural–immune communication.

2. Substance P Nociceptive Fibers and Inflammatory Responses Link Primary Afferents to the Immune System

Substance P nerve fibers link a wide range of tissues with the dorsal horn of the spinal cord or the descending (spinal) trigeminal nucleus via primary sensory ganglia. These systems often contain colocalized neuropeptides such as CGRP. A remarkable property of these substance P fiber systems is their ability to release their neurotransmitter from both the proximal end (into the CNS site of termination) and the distal end (into the peripheral site of innervation). This has been shown definitively in the joints and gastrointestinal tract and suggests that inflammatory lesions that exacerbate nociceptive systems can release substance P into the site of inflammation; this short loop constitutes a positive feedback link and further

reinforces inflammatory effects, such as extravasation, edema, and attraction of additional pro-inflammatory cells. The extent to which these interactions form channels for the communication of information to the CNS is not known, other than nociception and subsequent perceptions of pain.

E. Neurohormones and Neurotransmitters Are Sometimes Synthesized and Sometimes Taken Up by Cells of the Immune System: Paracrine and Autocrine Signaling

A remarkable finding in the mid-1980s from the laboratories of Ed Blalock and Eric Smith was the discovery that lymphocytes and macrophages can synthesize some neuropeptides previously thought to be present only in CNS-associated systems. For example, New Castle disease virus was able to stimulate the production of mRNA for POMC, resulting in ACTH and β-endorphin synthesis in some lymphocytes. Corticotropin-releasing factor (CRF) also can stimulate POMC mRNA in some cells of the immune system. Subsequent studies have shown that a host of anterior pituitary hormones can be synthesized under certain conditions by cells of the immune system. It is most likely that these hormones, if released, would act in a paracrine fashion rather than an endocrine fashion. Some supporting cells, such as epithelial or nurse cells in the thymus, also can produce neuropeptides such as oxytocin and vasopressin. Work suggests that some cells of the immune system can take up norepinephrine or other neurotransmitters from the microenvironment. The extent to which these locally synthesized neuropeptides, or neurotransmitters that are taken up, can be released and can influence immune reactivity directly as paracrine secretions is not yet known.

F. Some Specific CNS Pathways and Sites Can Regulate Neuroendocrine and Autonomic Outflow to the Immune System: Neural Substrate Linking Behavior and Immune Responsiveness

The consensus from a host of "stressor" studies in humans and experimental animals points to the combined interactions of the HPA axis and the sympathetic nervous system as the two most prominent actors in interpreting CNS activity for peripheral immunomodulating actions. Perhaps this is merely a bias of studies that have been most intensely oriented toward these two conspicuous and important axes, although the most definitive studies, such as those from John Sheridan's laboratory, point to a critically important role for the sympathetic and HPA axes acting in concert. This dual working model focuses attention on the hypothalamic mechanisms that regulate the outflow of the HPA and sympathetic axes. Because central CRF is involved in this process, the paraventricular nucleus of the hypothalamus has been the site of greatest interest. It appears that central noradrenergic pathways (as well as serotonergic and cholinergic pathways) play an important role in regulating CRF in neurons of the PVN. Indeed, it appears that the CRF-elevating action of IL-1β depends on the intactness of the central noradrenergic input to the PVN. Other hypothalamic sites also are involved in regulation of the anterior pituitary and the autonomic nervous system, such as anterior–preoptic and posterior hypothalamic areas. Furthermore, lesion studies suggest that the amygdala, hippocampal formation, septal nuclei, and central autonomic brain stem nuclei can influence the "set point" of immunologic reactivity, probably through connections regulating the hypothalamic regions involved in autonomic and neuroendocrine outflow. Therefore, we now have the appropriate target sites to investigate the specific central pathways and their neurotransmitters in the central regulation of outflow influencing the immune system. We do not yet know the details of which of these specific pathways are involved in stress-related alterations of immune response or behavioral conditioning of immune responses.

III. INFLUENCES OF NEUROENDOCRINE HORMONES ON THE IMMUNE SYSTEM

A. The Hypothalamo–Pituitary–Adrenal (HPA) Axis

1. Pharmacologic Doses of Glucocorticoids Have Long Been Used to Reduce Inflammation, Suppress Both Innate and Acquired Immune Responses, and Suppress Autoimmune Diseases

Early studies showed that corticosteroids can exert profound anti-inflammatory and immunosuppressive effects; these effects generally are brought about by supraphysiological doses of glucocorticoids. These steroids can result in lymphoid involution (the thymus

and secondary lymphoid organs), lymphopenia, decreased antibody formation, prolongation of tolerance, suppression of allograft rejection, inhibition of delayed-type hypersensitivity reactions, inhibition of cytotoxic T lymphocyte activity, reduced production of helper T-cells, and decreased NK cell activity. Glucocorticoids also can inhibit numerous macrophage functions such as cytokine production, phagocytosis, intracellular killing, chemotaxic, antigen presentation, and production of inflammatory mediators. Glucocorticoids can alter the trafficking of specific cells, for example, from blood to bone marrow and away from secondary lymphoid organs. Glucocorticoids also are administered to suppress autoimmune diseases such as lupus erythematosis, rheumatoid arthritis, and others. The actions of glucocorticoids are mediated through soluble cytosolic and nucleus receptors, resulting in the inhibition of transcription and activation of several genes.

2. Physiological Concentrations of Glucorticoids Have an Immunoregulatory Role That Includes Both Inhibition and Enhancement of Some Responses

Whereas a majority of the effects of glucocorticoids appear to be inhibitory in nature, studies of physiological actions of glucocorticoids suggest that they may influence the commitment of T helper lymphocytes toward Th2 cytokine production. Glucocorticoids acting on activated T lymphocytes can result in decreased IL-2 production but increased IL-4 production, suggesting that physiological glucorticoids, under some circumstances, can favor humoral immunity and suppress cell-mediated immunity. In addition, other lymphoid cells may influence the actions of glucocorticoids. Activated macrophages can prevent glucocorticoid-mediated inhibition of T helper cell function. Some *in vitro* studies have shown that glucocorticoids in physiological concentrations can enhance B-cell differentiation.

3. The HPA Axis Represents Only One of Many CNS Outflow Systems That Can Alter Immune Responsiveness When Activated by Stressors

When the phenomena of stress-induced and conditioned immunosuppression were first reported, it was assumed that this reflected a centrally activated HPA axis that led to immunosuppression by glucocorticoids. However, conditioned immunosuppression can occur in adrenalectomized animals, and only some components of stress-induced immunosuppression (conA proliferation of peripheral blood T-cells) but not others (splenic conA proliferation of T-cells, splenic NK cell activity) appear to be glucocorticoid-mediated. Therefore, the sympathetic neural connections, neuropeptide neural connections, and other hormonal interactions, in addition to the HPA axis, must be taken into account to fully catalogue the mediators responsible for behaviorally induced changes in the immune system. It is this author's opinion that the task of defining what changes in hormonal and neural activity occur during specific behavioral conditions is essential to understanding neural–immune interactions and needs vastly greater research efforts.

4. The Reactivity of the HPA Axis May Be an Important Determinant in the Susceptibility of an Organism to Autoimmune Reactivity

Although it has long been known that exogenous glucocorticoids, in pharmacologic doses, can suppress some autoimmune diseases, the possible physiological importance of the HPA axis in autoimmune disease has only more recently come to light from the pioneering work of Esther Sternberg and colleagues. She studied a genetic animal model, the LEW/N rat, that is susceptible to a wide range of autoimmune diseases, including adjuvant-induced arthritis, experimental allergic encephalomyelitis, thyroiditis, and other inflammatory diseases. She found diminished CRF responses in female LEW/N rats and proposed that these animals cannot boost glucocorticoid levels appropriately during a massive challenge such as that encountered in the induction of an autoimmune disease, resulting in excessive proliferation of the clones of cells that should not be proliferating, including autoreactive (anti-self) lymphocytes. She demonstrated that, when glucocorticoids were blocked with RU486 in Fischer 344 rats, a genetic counterpart of the LEW/N rats that are *not* susceptible to autoimmune disease, the Fischer 344 rats became fully susceptible to induced autoimmunity. Thus, the HPA axis may play an important role in signal-to-noise ratio, as proposed more than two decades ago by Hugo Besedovsky, and in the loss of counterregulatory suppression of anti-self clones that can lead to autoimmune disease. However, the sympathetic nerve fibers innervating secondary lymphoid organs also play an important regulatory role in neural–immune

influences on susceptibility to autoimmune diseases, as shown by Dianne Lorton, Denise Bellinger, David Felten, and colleagues, discussed later.

B. Growth Hormone (GH) and Prolactin

1. GH and Prolactin Are Essential for the Competent Development of the Immune System

Deficiencies in growth hormone following hypophysectomy result in diminished cellularity of the bone marrow and thymus and diminished T-cell function, antibody responses, and NK cell activity. These deficiencies can be reversed to a large extent by the administration of GH. Exogenous GH also can enhance peritoneal macrophage superanion production in animals. Prolactin exerts mainly an enhancing effect on immune functions. Inhibition of prolactin secretion from the anterior pituitary results in suppressed antibody production, diminished cell-mediated immune responses, and increased susceptibility to infections such as *Listeria monocytogenes*. These inhibited functions can be reversed by the administration of exogenous prolactin or by the inhibition of dopamine (prolactin inhibitory factor) with antagonists. Stressors that result in the release of prolactin from the anterior pituitary provide a counteracting signal that can dampen many of the immunosuppressive effects of glucocorticoids, but the release of prolactin becomes refractory with repeated application of a stressor. High-affinity receptors for GH have been reported on thymocytes, lymphocytes (resting or activated), and monocytes. Prolactin receptors have been reported on B and T lymphocytes and on macrophages.

2. GH and Prolactin Are Important Regulators of Thymic Function and Can Restore Thymic Cellularity and Responses in Old Animals

Keith Kelley and colleagues studied old rats with involuted thymuses and diminished T-cell mitogen-induced proliferation and IL-2 production. They grafted a tumor cell line that produced both GH and prolactin in these animals and found a restoration of these parameters. Ovine GH itself did not restore thymic cellularity or IL-2 production, but it did enhance T-cell mitogen-induced proliferation. GH administered to normal animals can enhance alloantigen-specific cytotoxic T-cell activity.

C. Opioid Peptides

1. Opioid Peptide Neuronal Systems in the PNS Directly Innervate Lymphoid Organs and in the CNS Influence the Outflow of Other Hormones and Neurotransmitters

ACTH itself exerts actions on cells of the immune system, such as the reduction of mouse spleen cell antibody responses and *in vitro* IFN-γ secretion. ACTH also acts in concert with IL-5 to stimulate late stages of B-cell activation and has been reported to enhance NK cell activity *in vivo* in pigs. Both high- and low-affinity ACTH receptors have been reported on T and B lymphocytes, with greater numbers on B-cells. Additional effects of ACTH are exerted through the stimulation of glucocorticoid production, and some immunocytes can directly synthesize ACTH.

α-MSH (ACTH 1–13) is a potent inhibitor of migration in response to IL-1β or other chemotactic agents, prevents spontaneous neutrophil activation, and counteracts many of the effects of IL-1β both in the periphery and in the CNS.

2. Several Opioid Receptor Subsets Are Present on Cells of the Immune System and Mediate Complex and Diverse Responses to Opioid Peptides

The opioid peptides are low-molecular-weight peptides in three families: the endorphins, the enkephalins, and the dynorphins. They are produced in the pituitary gland, the brain, the adrenal gland, peripheral nerves, and even in cells of the immune system. These hormones are cleaved from prohormones synthesized in the cell body; differential splicing can result in a range of peptide end products, depending upon local influences on the cell. The opioid peptides are a heterogeneous group of agents whose metabolism may result in additional biologically active molecules that have further complex functional roles. Similarly, the opioid receptor expression on cells of the immune system is complex. The best evidence suggests that classical μ and κ receptors are found on mouse spleen cells. A functional role for the opioid peptides is contradictory in some of the literature and not straightforward. For example, β-endorphin exerts opioid-mediated effects of diminishing mouse antibody production and inhibiting human lymphocyte chemotactic factor. β-Endorphin exerts non-opioid-mediated effects of enhancing mouse conA T-cell

proliferation, inhibiting human PHA T-cell proliferation, and blocking PGE1-induced suppression of rat lymphocyte proliferation.

Although α-, β-, and γ-endorphin and met-enkaphalin have identical amino termini, they can exert markedly different biological effects. For example, in one study α-endorphin and met-enkaphalin, but not β- or γ-endorphin, decreased antibody production by mouse spleen cells. Enkephalins may play a role in inflammatory responses through the stimulation of neutrophil superoxide anion production and neutrophil migration.

D. Thyroid and Gonadal Hormonal Axes and Other Hormones

Thyroid-stimulating hormone (TSH) in physiological concentrations enhances both T-dependent and T-independent antibody responses of mouse spleen cells. Thyroidectomy of neonatal or adult rats or hypothyroidism in chickens resulted in diminished lymphoid organ weight, decreased circulating lymphocytes, decreased antibody responses, and decreased T- and B-cell mitogen-induced proliferation. These alterations were restored with the administration of T3 or T4 to the thyroidectomized animals. T3 or T4 in euthyroid animals enhanced antibody responses and mitogen-induced proliferation. Administration of T4 to old mice restored NK cell function, but had no effect in young mice.

Gonadal hormones also exert an effect on the immune system. There is clearly sexual dimorphism in the immune system. Females have higher serum immunoglobulin levels of IgG, IgM, and IgA in several species and show more prolonged and robust antibody responses to both T-dependent and T-independent antigen challenges. Females also are subject to a considerably higher incidence of autoimmune diseases, such as systemic lupus erythematosis, than males. Gonadectomy induces hyperplasia of the thymus and other lymphoid organs in both males and females; 5-α-dihydrotestosterone restored thymic weight in males, and prior thymectomy prevented hyperplasia in other lymphoid organs. Manipulation of testosterone or estrogen can alter the progression or onset of autoimmune disease in experimental animal models. Estrogen induces extrathymic T-cell differentiation. Estrogen also enhanced polyclonal Ig, antigen-specific proliferation, and autoantibody production. Testosterone inhibited polyclonal Ig production.

IV. NERVE FIBER CONNECTIONS WITH THE IMMUNE SYSTEM

A. Sympathetic Noradrenergic Innervation of Lymphoid Organs

1. Primary Lymphoid Organs: Bone Marrow and Thymus

a. Noradrenergic Nerve Fibers Distribute into the Parenchyma and along the Vasculature NA postganglionic sympathetic nerve fibers enter the bone marrow with the nutrient arteries, arborize along the vasculature, and distribute among the stem cells between the sinuses. These nerve fibers form close appositions with cells in the parenchyma. In the thymus, NA nerve fibers, derived mainly from neurons in the superior cervical ganglion, enter with the vasculature, distribute along the capsule and in subcapsular and septal regions, and also arborize within the thymic cortex. Some NA nerve fibers also are found in the medulla, but a majority of the sympathetic NA innervation is confined to the cortex. Both bone marrow stem cells and thymocytes possess functional β-adrenoceptors. In these primary lymphoid organs, NA nerve terminals appear to release NE into the microenvironment, where it acts in a paracrine fashion. The significance of close appositions of nerve terminals with parenchymal cells is not yet clear.

b. Norepinephrine Modulates Stem Cell Proliferation, Differentiation, Trafficking, and Adhesion In the bone marrow, NA denervation (chemical sympathectomy) resulted in an increase in the number of peripheral blood leukocytes after syngeneic bone marrow transfer. Prazocin, an α-adrenergic antagonist, mimicked this effect. In a study by David Wu, David Felten, and colleagues using a 3-dimensional bone marrow culture system built on a microsphere scaffolding, the β-agonist isoproterenol was found to enhance hemopoiesis up to 3-fold during 5 days of culture. Isoproterenol stimulated granulopoiesis as effectively as granulocyte colony stimulating factor (G-CSF) and synergized the effects of G-CSF Thus, α- and β-adrenoceptors may exert differential effects on stem cell populations. In the thymus, NE from the sympathetic nerves inhibits thymocyte proliferation and enhances the expression of markers indicating differention. NA denervation in mice results in enhanced thymocyte proliferation, but only in older animals in which the thymus has involuted.

2. Secondary Lymphoid Organs: Lymph Nodes, Spleen and MALT

a. Noradrenergic Nerve Fibers Are Compartmentalized to T-Cell Zones and Macrophage Zones and Do Not Directly Innervate B-Cell Zones Sympathetic NA nerve fibers enter the spleen with the splenic artery, distribute with the capsular–trabecular system, arborize extensively along the central artery of the white pulp, and also branch extensively within the parenchyma of the white pulp. NA nerve fibers that innervate the parenchyma of the white pulp are the first to appear in development; they are present in the parenchyma before smooth muscle cells are present along the vasculature and nerve fibers are present along the vascular compartment. In the parenchyma, the NA fibers distribute among T lymphocytes [both T helper–inducer cells (CD4) and T cytotoxic–suppressor cells (CD8)] in the periarteriolar lymphatic sheath, along the macrophages of the marginal sinus, and within the marginal zone. NA nerve fibers distribute along the outside edge of the B-cell follicles, but do not directly contact B lymphocytes in adults, although B-cells have high numbers of β-adrenoceptors on their surfaces. Electron microscopic studies have shown direct appositions between NA nerve terminals and lymphocytes, macrophages, granulocytes, and reticuloendothelial cells. Extensive evidence indicates that NE is released from these terminals and is available for interaction with cells of the immune system that bear adrenoceptors on their surfaces.

Lymph nodes also are innervated by postganglionic NA nerve fibers. These fibers enter the nodes along the hilar vasculature and along the capsular surface, extend through the medullary cords, and arborize extensively among the T-cell compartments (among both CD4 and CD8 cells) and macrophage compartments, but not the B lymphocyte compartments. However, NE released from the nerve terminals probably has access to B-cells through diffusion. Perhaps the very close apposition (as close as 6 nm) between NA nerve terminals and T lymphocytes or macrophages serves a role to allow cytokines, secreted by these lymphoid cells, to regulate NE release from those terminals. Both IL-1β and IL-2 have been reported to stimulate the release of NE directly from nerve terminals in the spleen.

In gut-associated lymphoid tissue, NA nerve fibers enter with the vasculature, travel along the smooth muscle layers, extend inward through the T lymphocyte zones, and arborize among the lamina propria, adjacent to the immunoglobulin-secreting plasma cells, but they avoid the follicles.

b. Norepinephrine Modulates Innate and Acquired Immune Responses, Including Both Humoral and Cell-Mediated Immunity and Influences Trafficking and Cell Adhesion The role of NE in the regulation of immune responses is complex. β-Adrenoceptors have been identified on many subsets of T and B lymphocytes and macrophages in humans, rats, and mice. α-Adrenoceptors have been reported on activated mouse macrophages and on human and guinea pig T lymphocytes. Infusion of epinephrine or NE into the blood increases both circulating lymphocytes and NK cells transiently and may account for such transient elevations with exercise. There appear to be both α- and β-mediated catecholamine effects on cell migration. NE generally appears to inhibit effector cell functions in cells already activated to this stage (e.g., antibody-secreting plasma cells and cytotoxic T lymphocytes), particularly at peripheral sites where they are recruited (e.g., in the lung in an influenza infection). However, in the early phases of an immune response, NE and other catecholamines can enhance both antibody and cytotoxic T-cell responses. Denervation of NA nerve fibers from the spleen and lymph nodes results in diminished cell-mediated immune responses, has a variable effect on humoral immunity (depending on the predominant T-cell orientation), and exacerbates the severity of induced autoimmunity in autoimmune-prone strains of rodents. Thus, the presence of NE early in an immune response may enhance immune responsiveness, whereas its presence at the effector cell stage may inhibit the ability of the effector cells to act. Also, the collective result of NE influences on the multiple interacting cells in a specific immune response may be complex to interpret. In the inductive phase of an immune response, NE may favor Th1 cytokine production by T helper cells, promoting cell-mediated immunity, consistent with evidence for β-adrenoceptors on Th1 but not Th2 cells. Several studies have suggested that catecholamines may inhibit NK cell activity.

3. Peripheral Sites of Inflammation and Immune Reactivity

a. Noradrenergic Nerve Fibers Are Present at Many Sites Where Inflammatory Responses Occur (e.g., Joints) NA sympathetic nerve fibers are present in many peripheral sites where inflammatory responses

may take place, including joints, the gut, and the skin. These fibers distribute with vascular smooth muscle and other smooth muscle compartments and also innervate secretory glands and metabolic regions such as brown fat and liver.

b. Norepinephrine Can Directly Mediate Inflammatory Responses That Occur at Target Organs of the Inflammation At sites of inflamed joints in rheumatoid arthritis, blockade of NE or ablation of NA nerves resulted in a reduction in inflammation, as did blockade of substance P or destruction of the substance-P-containing nerve fibers; these fibers are nociceptive fibers mediating sensations interpreted by the brain as pain. However, selective destruction of NA innervation of draining lymph nodes prior to immunization in the induction of adjuvant-induced arthritis in LEW/N rats led to a severe exacerbation in the severity, and an earlier onset, of arthritis. This suggests that NA fibers to a joint may play a proinflammatory role, whereas NA innervation to the draining lymph node may dampen the vigor of autoimmune reactivity or processing.

B. Neuropeptide Innervation and Influences on Inflammation and Immune Reactivity

1. A Wide Range of Neuropeptide-Containing Nerve Fibers Innervate Both Primary and Secondary Lymphoid Organs

a. Neuropeptide Y (NPY) Is Often Colocalized with Norepinephrine in Sympathetic Postganglionic Nerve Fibers Although NPY receptors have been reported on some subsets of lymphoid cells, we do not yet have a clear understanding of the role of NPY in immunomodulation. It appears that NPY is extensively colocalized with NE in sympathetic nerve terminals, although some NPY-positive nerve fibers are found that do not colocalize norepinephrine. NPY also is present abundantly in platelets in the spleen. Irwin and colleagues have found that NPY measurement in peripheral blood is a more dependable estimate of sympathetic activity than NE measurement.

b. Substance P (SP) and Calcitonin-G-Related Peptide (CGRP) Are Often Colocalized in Separate Nonnoradrenergic Nerve Fibers, but Can Occur Individually in Nerve Fibers in Lymphoid Organs and Skin Substance P nerve fibers are found in spleen, lymph nodes, thymus, and bone marrow. They distribute with the vasculature and in the parenchyma and appear to be completely separate from the sympathetic NA nerve fibers. CGRP nerve fibers show a distribution similar to that of SP fibers; CGRP is usually, but not exclusively, colocalized with SP. In some sites, such as the skin, CGRP nerve fibers innervate a specific type of antigen-presenting cell, the Langerhans cells, which are markedly inhibited by this neuropeptide. Receptors for SP on lymphocytes have been cloned, and SP receptors have been identified on a human B-cell line, human T-cells, and mouse T- and B-cells. The substance P receptors (and other receptors for tachykinins) differ on nerve cells and lymphocytes; there is greater overlap and cross-talk between substance P and substance K receptors on lymphocytes than on neural tissue.

Functionally, it is clear that SP is a potent regulator of inflammatory responses. SP is proinflammatory, can induce extravasation and edema, can attract additional inflammatory cells to a site, and can stimulate other inflammatory mediators, such as IL-1β, tumor necrosis factor-α, and IL-6, from unstimulated peripheral blood monocytes. SP in a joint can exacerbate rheumatoid arthritis, whereas ablation of SP nerves or blockade of SP can have an anti-inflammatory effect. SP exerts a strong enhancing effect on a wide range of immune responses, including increased polyclonal IgA and IgM production by lymphocytes in Peyer's patch and mesenteric lymph nodes, increased T-cell proliferation and IL-2 production, increased antibody responses *in vivo*, and increased proliferation of unstimulated lymphocytes. SP nerve fibers in draining lymph nodes also contribute to the severity of adjuvant-induced arthritis in LEW/N rats. Many of these enhancing effects can be countered by somatostatin, but somatostatin nerve fibers have not yet been identified or mapped carefully in many sites where SP–CGRP nerve fibers reside. A report noted a marked inhibitory effect of CGRP on antigen-presentation functions of Langerhans cells in the skin.

c. Vasoactive Intestinal Peptide (VIP) Is Present in Nerves in Lymphoid Organs and Particularly Influences T-cell Trafficking and Function VIP-containing nerve fibers have been identified in Peyer's patch, thymus, chicken bursa of Fabricus, and spleen. VIP receptors have been identified on murine T-cells and human peripheral blood lymphocytes. VIP can inhibit T-cell proliferation. In a series of elegant studies by Cliff Ottaway, the expression of VIP receptors on T-cells was shown to enhance their migration to

gut-associated lymphoid tissue and mesenteric lymph nodes, whereas their down-regulation resulted in the failure of T-cells to traffic to these gut-related sites.

d. Many Other Neuropeptide Systems (Opioid Peptides, Cholecystokinin, Neurotensin, Corticotropin-Releasing Factor, Somatostatin) Are Present in Lymphoid Organs, but Their Functions Remain Unknown Neuropeptide-containing fibers that contain opioid peptides such as β-endorphin, cholecystokinin, neurotensin, CRF, or somatostatin have been identified in primary and secondary lymphoid organs with immunohistochemical staining. Although there are some published data suggesting that these neuropeptides may be able to modulate aspects of immune reactivity directly, the actual role of these compounds is not well-understood and the extensive criteria for neurotransmission have not been worked out. Perhaps the best studied of these neuropeptides is CRF, which exerts an enhancing effect on T-cell functions and acquired immune responses. Denise Bellinger, David Felten, and colleagues have identified CRF-containing nerve fibers in primary and secondary lymphoid organs in rodents; the intensity of CRF staining is enhanced by the prior presence of IL-2, suggesting that a cytokine may up-regulate a neuropeptide that, in turn, can be released and act on the target cells of the immune system.

e. The Cells of Origin for Many Neuropeptide Fibers Are Not Known For some SP–CGRP neurons and the sympathetic NE–NPY neurons, the cells of origin have been mapped by tracing studies. However, we do not yet know the site of origin for the cell bodies giving rise to the majority of neuropeptide innervation of lymphoid organs.

C. Presence of Adrenoceptors, Neuropeptide Receptors, and Hormone Receptors on Cells of the Immune System

1. α- and β-Adrenoceptors Are Present on Many Subsets of Lymphoid Cells

As noted previously, T-cells, B-cells, and monocytes–macrophages possess mainly β-adrenoceptors, but also some α-adrenoceptors, as shown by receptor-binding studies. Pharmacological studies with adrenergic agonists and antagonists suggest abundant functional roles for both subsets. It appears that these receptors have differential distribution, with higher numbers of β-adrenoceptors on B-cells compared with T-cells and on CD8 T-cells compared with CD4 T-cells. β-Adrenoceptors are expressed on Th1 but not Th2 helper T-cells and on pre-IgM cells but not pre-IgG cells.

2. Neuropeptide Receptors Are Present on Selected Subsets of Lymphocytes, Macrophages–Monocytes, and Other Lymphoid Cells

The identification of receptors for neuropeptides on various populations of cells of the immune system does not entirely clarify the role of those receptors. We do not yet know whether only a selected subset of such cells contains a high number of receptors, or whether some broader populations contain a lesser number of receptors. More sophisticated cell-sorting approaches will be needed to clarify this issue, an approach only now being used for some α-adrenoceptors.

3. Most Lymphoid Cells Possess Receptors for a Wide Variety of Neurohormones and Target Organ Hormones under Anterior Pituitary Influence

These receptors allow such anterior pituitary hormones as GH, prolactin, and ACTH to act directly on cells of the immune system and to stimulate the release of other hormones from target organs, such as thyroid hormone, gonadal hormones, and glucocorticoids. These hormones derived from target endocrine organs also can act through appropriate cognate receptors also found on or inside of cells of the immune system.

4. The Neurotransmitter and Neurohormone Receptors on Lymphoid Cells Transduce Signaling through Classical Second Messenger Systems and Exert Both Genomic and Nongenomic Effects on Their Target Cells

In detailed studies of receptor–ligand interactions of neurotransmitter and neurohormone actions, a classical second messenger system usually has been identified. These second messenger systems are typical for the receptor (e.g., cAMP response for the β-adrenoceptor in lymphocytes), activate the appropriate protein kinases or other signaling pathways, and provide a classical cascade system for the exertion of genomic and nongenomic effects. In some populations of lymphoid cells, hormone response elements have been identified in the nucleus, providing a further

opportunity for the hormonal regulation of gene expression.

D. Receptors for Neurotransmitters and Hormones Usually Interact in Multiples and Can Exert Synergistic and Nonlinear Interactive Effects with Each Other and with Cytokine Receptors

Lymphoid cells possess receptors for cytokines, neurohormones, and neurotransmitters. These sytems appear to act nonlinearly with each other. For example, β-endorphin and somatostatin can enhance IL-2-stimulated, lymphokine-activated killing (LAK cell activity), but they have no effect alone without IL-2. Occupancy of the β-adrenoceptor during anti-CD3 activation of the T-cell receptor on human T lymphocytes synergizes the production of cAMP intracellularly, but not other intracellular signals generated by activation of the T-cell receptor. Isoproterenol can synergize the effects of G-CSF on bone marrow cell proliferation in a 3-dimensional culture system. It also is possible that colocalized neurotransmitters, such as NE and NPY, may exert synergistic effects with each other on cells of the immune system, as they do on certain vascular beds.

V. IMMUNE SYSTEM COMMUNICATION WITH THE NERVOUS SYSTEM

A. Hypothalamic and Other CNS Alterations Follow Immune Activation

1. Altered Neuronal Electrical Activity

Hugo Besedovsky and others showed that, during the time of peak antibody production in an immune response, increased electrical activity was detectable in several sites of the hypothalamus, including the anterior region, the PVN, and the dorsomedial region. It was assumed that this increased activity reflected either the actions of cytokines on hypothalamic neurons or some indirect signal from the periphery activated by the immune response.

2. Altered Monoamine Release and Turnover

Sonia Carlson and colleagues showed that, during an immune response, NE levels decreased in the PVN, presumably reflecting increased NE turnover. Adrian Dunn subsequently showed that IL-1β, administered either peripherally or centrally, can provoke a wide range of changes in the turnover of NE and serotonin at numerous central sites, including an increase in turnover of NE in the PVN. Work from several laboratories has shown that the release of NE onto CRF neurons of the PVN is necessary for IL-1β to exert its CRF-elevating effect that is involved in activating the HPA and sympathetic axes.

3. Altered HPA Activation

Besedovsky and others have shown that an immune response to an antigenic challenge with sheep red blood cells, administration of lipopolysaccharide (LPS), and the immune response to a range of viruses can result in an elevation of peripheral glucocorticoids in both the early and late phases of immune response to these challenges. The elevation of glucorticoids occurs through the elevation of both CRF and ACTH. However, not all antigen challenges resulted in such elevations of glucocorticoids. It is not yet known what characteristics of an immune challenge can provoke activation of the HPA axis.

4. Altered CNS Cytokine Production

Glial cells (astrocytes and microglia) and some neurons themselves possess the capacity to synthesize IL-1β, and perhaps TNF-α and IL-6. Inflammation in the brain, rejection of an allograft, or even the neurodegenerative process producing placques and tangles in Alzheimer's disease can result in the production and secretion of cytokines such as IL-1β in the brain. Some investigators, such as Carlos Solomon-Plata, have provided evidence that peripheral stimulation of the brain with IL-1β can directly or indirectly lead to the central production of IL-1β, presumably by glial cells.

B. Many Cytokines Can Influence the Nervous System

1. CNS Influences of IL-1β, IL-2, TNF-α, IFN-γ, IFN-β, and Other Cytokines

A wide range of inflammatory cytokines, especially IL-1β, have been shown to exert numerous central effects. IL-1β can induce slow-wave sleep, produce a fever through the alteration of thermoregulatory set points, induce lethargy and reduced locomotor activity, reduce appetite and sex drive, and change electrical

activity and neurotransmitter turnover in the brain. In studies aimed at enhancing lymphokine-activated killing of cancer cells, the administration of IL-2 in chemotherapeutic regimens produced toxic CNS effects, including some of the characteristics listed earlier, as well as depression and altered affective behavior. IFN-γ was administered to patients with multiple sclerosis in an attempt to ameliorate exacerbations, but it was found to actually increase the frequency of demyelinating attacks. Current therapy now uses IFN-β, which inhibits T-cell activity and diminishes exacerbations of multiple sclerosis.

2. PNS Influences of IL-1β and IL-2

In the peripheral nervous system, both IL-1β and IL-2 appear to provoke the release of NE from sympathetic nerve terminals. This may be a mechanism by which the immune system can regulate the availability of a neural signal molecule by cytokine action on receptors that are present on the presynaptic nerve endings. IL-2 also appears to up-regulate the production of CRF in peripheral neurons that innervate secondary lymphoid organs.

C. Lymphoid Cells and Cytokines Have Many Routes of Access and Many Mechanisms of Immune Communication with the Nervous System

1. Immune Trafficking and Cellular Presence in the Brain

William Hickey and colleagues have shown that activated T lymphocytes can traffic through the brain and have at least a 24-hr window of activity during which they may provoke reactivity by other cell types. These T lymphocytes can release cytokines such as IFN-γ, which in some experimental settings can provoke glial cells to become antigen-presenting cells; such a process could remove the partial ''immune privilege'' of the brain in which a therapeutic graft was present.

2. Production of Cytokines by Neurons and Glia

Chris Breder and Cliff Saper reported the presence of IL-1β in neurons in the hypothalamus. A report by Schultzberg and colleagues described IL-1β colocalized with NE in peripheral sympathetic nerve fibers. Numerous studies have identified IL-1β production by microglia *in vivo* in the CNS. Cytokines also can be produced by astrocytes, especially *in vitro*; the extent to which this process occurs *in vivo* is not known.

3. Peripheral Cytokine Access through the Blood–Brain Barrier

Cytokines initially were assumed to be unable to cross the blood–brain barrier because they are large molecules and do not readily equilibrate between the blood and the CSF. However, William Banks and colleagues have reported a crossing of the inflammatory cytokines, IL-1 (α and β), IL-6, and TNF-α. Sundar and Weiss have used intracerebroventricular administration of IL-1β to activate central pathways and have reported effects from the administration of femtomolar concentrations. This concentration certainly is a conceivable concentration of IL-1β to cross into the CNS from the peripheral blood.

4. Cytokine Actions at the Circumventricular Organs (e.g., OVLT)

Cytokines also may act on cells of the circumventricular organs. The most studied of these systems is the OVLT. IL-1β appears to activate PGE2 secretion by cells of the OVLT, thereby providing direct access into the CNS by this secondary signal. The status of cytokines acting at other circumventricular organs is not as clear.

5. Cytokine Actions on the Pituitary and Target Endocrine Organs

Some cytokines, particularly the inflammatory cytokines, may have direct action on some of the supporting folliculostellate cells in the pituitary, thereby providing a stimulus for potential influence over the release of neurohormones at this level. This action is in addition to the actions on releasing and inhibitory factors that activate hormones of the anterior pituitary through the brain.

6. Cytokine Actions on Peripheral Nerves: Modulation of Autonomic Output, Vagal Input, and Somatosensory Input

As noted previously, cytokines may act directly to release NE from sympathetic nerve terminals, may act on paraneuronal cells to stimulate vagal input into the CNS, and may activate some sensory fibers such as the SP nociceptive axons, providing numerous routes for cytokine signaling to the CNS.

D. Regulatory Loops Link the Immune and Nervous Systems

The influences of neurotransmitters and neurohormones on cells of the immune system and, conversely, the influence of cytokines on the CNS do not occur in isolation and are part of feedback circuits that assure appropriate interactions with proper activation, as well as cessation of potent signals. In this manner, the study of neural–immune interactions parallels the work on feedback circuits that characterized the founding of the field of neuroendocrinology a few decades earlier. The following two examples are the major substantiations of this linked circuitry: (1) Cytokines modulate the activity of the HPA axis and sympathetic nervous system outflow through actions impinging on the PVN of the hypothalamus; and (2) glucocorticoids and catecholamines that are produced by the activation of the HPA axis and the sympathetic nervous system, respectively, modulate cytokine production and immunological reactivity.

VI. CLINICAL IMPLICATIONS OF NEURAL–IMMUNE SIGNALING IN BOTH DIRECTIONS

A. Neural Mediators Can Influence Immunologic Reactivity and Response to Viral and Bacterial Infections and Other Pathogens

1. Both Behavioral and Pharmacologic Interventions Can Alter Neural Mediators Involved in Such Interactions

It now is clear that the CNS can influence immune responses, as shown by stressor studies, conditioning studies, human studies correlating behavior and changes in immune responses, and lesion studies in experimental animals. Many neurohormonal and neurotransmitter systems have been identified that can serve as links between the CNS and the immune system, and cytokine feedback to the CNS has been abundantly demonstrated. The two main choices for approaches that could manipulate this interactive circuitry for clinical benefit are behavioral or pharmacological. Use of behavioral interventions can activate the CNS pathways (presumably from cortical and limbic forebrain input) that regulate outflow to the immune system. Pharmacological interventions with agonists or antagonists to neurotransmitters or neurohormones or with other drugs that influence the availability and binding of these mediators could alter one or more of the mediators used by the CNS to interact with cells of the immune system.

2. Neural Mediators Can Influence Susceptibility to, Progression of, and Outcome of Such Infections

Studies by Sheridan and colleagues have shown that both behavioral and pharmacological interventions can change the susceptibility to infection by herpes simplex virus or influenza virus, as well as the subsequent course of the disease. Stressors such as restraint or differential housing paradigms can result in greater susceptibility to infection. Such increased susceptibility can only be reversed by blocking both glucocorticoids and β-adrenoceptors simultaneously; these blockades differentially affect specific immune functions that combine to restore homeostasis.

3. Neural Mediators Can Influence the Latency and Reactivation of Some Viruses

In vitro studies have shown that some latent viruses can be reactivated by the direct application of glucocorticoids. Stressors can activate some herpes viruses, such as herpes zoster. The extent to which glucocorticoids and other mediators of CNS stress responses exert influence on the progression of HIV is not yet known.

B. Neural–Immune Signaling Can Influence Autoimmune Diseases

1. Some Autoimmune Diseases Directly Affect the Nervous System

a. Multiple Sclerosis (CNS) Multiple sclerosis is a remitting and exacerbating demyelinating disease of the CNS. It is characterized by multiple white matter demyelinating lesions over both time and space. A T-cell-mediated attack on oligodendroglia characterize this condition, and β-interferon or other immunosuppressive therapies now characterize clinical approaches to this disease.

b. Guillain–Barre Syndrome (PNS) Guillain–Barre syndrome is an autoimmune attack on the peripheral myelin, frequently following a few weeks after an infectious process such as an upper respiratory infection (possible autoimmunity by molecular mimicry). There is a rapid progression of distal to proximal

weakness, sometimes accompanied by epicritic somatosensory loss (vibratory sensation, position sense, fine discriminative touch) as the disease progresses. This condition can progress all the way to respiratory failure and dependency on respiratory assistance. The reversal of this disease requires remyelination over the course of several months; some residual effects are sometimes found, and slowing of conduction velocity will be present after remyelination.

c. Myasthenia Gravis (Neuromuscular Junction) Myasthenia gravis (MG) is characterized by the production of antibodies against the nicotinic neuromuscular cholinergic receptors, resulting in easy fatiguability of muscles affected by this disease.

2. Neuromediators Can Influence the Onset, Progression, and Severity of Some Autoimmune Diseases (e.g., Lupus, Rheumatoid Arthritis, Autoimmune Demyelination)

Esther Sternberg and colleagues have suggested that glucocorticoids and the HPA axis play a critically important role in modulating the onset, progression, or severity of autoimmunity in susceptible hosts. Barry Arnason, Eva Chelmicka-Schorr, and colleagues have hypothesized that sympathetic ablation or diminished activity can exacerbate the severity of multiple sclerosis in humans or experimental allergic encephalomyelitis in LEW/N rats. This hypothesis has been supported by data from David Felten and colleagues in LEW/N rats with adjuvant-induced arthritis. In genetically susceptible mice with autoimmune disease (e.g., MRL lpr/lpr mice), there is a deficiency in the sympathetic innervation of secondary lymphoid organs, as there is in several other autoimmune-prone mouse strains, suggesting that the loss of sympathetic innervation of secondary lymphoid organs may be a factor contributing to the development of autoimmunity. Further work from Jon Levine, David Felten, and others has suggested that substance P fibers, both in the joints and in the draining lymph nodes, may modulate the severity and progression of autoimmune rheumatoid arthritis.

C. Neural–Immune Interactions Can Influence Responses and Progression of Some Specific Tumors

Work by Shamgar Ben-Eliyhu and colleagues has shown that a stressor can result in more extensive metastatic spread of mammary tumors compared with unstressed controls and that this is mediated through NK cell activity. They have studied NK cell responses in detail and provide the best evidence that NK cell activity exerts potent antitumor effects on some cancers such as breast cancer. It is tempting to extend this hypothesis to the increased survival of breast cancer patients in the study by Spiegel and colleagues, where peer support and psychotherapy as an adjunct to appropriate treatment doubled the survival. It is not yet known whether this was immune-mediated and, if so, whether it was through NK cell ctivity. Studies by S. ThyagaRajan, David Felten, and colleagues have shown that the use of low doses of deprenyl (selegiline), a monoamine oxidase B inhibitor, can inhibit the growth and spread of carcinogenically induced mammary tumors and can suppress the spontaneous appearance of mammary tumors in old age in susceptible strains. It is possible that this agent, acting on both central neural circuits and the peripheral sympathetic nervous system, can exert a protective effect against mammary tumors through neural actions.

D. Immunosenescence May in Part Reflect Neural Dysfunction

1. An Age-Related Severe Loss of Sympathetic Noradrenergic Innervation from Spleen and Lymph Nodes Is Accompanied by Diminished T-Cell Functions, Especially Cell-Mediated Responses

Denise Bellinger and colleagues have reported that secondary lymphoid organs (spleen, lymph nodes) show an age-related loss of NA nerve fibers, accompanied by diminished cell-mediated immunity. This same functional decline is found in young animals following sympathectomy of the secondary lymphoid organs. Restoration of innervation to the spleen in old rats, via treatment with deprenyl as a stimulator of growth factors, resulted in reinnervation of the secondary lymphoid organs by sympathetic noradrenergic nerve fibers and partial restoration of T-cell functions, suggesting that altered neural relationships with cells of the immune system may contribute to immunosenescent changes.

2. Thymic Involution and Loss of T-cell Responsiveness with Age Can Be Restored by GH and Prolactin Administration

The ability of GH and prolactin to restore thymic cellularity and some T-cell functions suggests that age-related neuroendocrine changes may contribute to

immunosenescence. Use of hormonal and/or neurotransmitter pharmacological interventions may be useful for the restoration of T-cell function in aging.

3. An Altered Microenvironment in Both Primary and Secondary Lymphoid Organs May Contribute to Age-Related Deterioration of Some Aspects of Innate and Acquired Immunity

At least some critical aspects of an altered microenvironment in primary and secondary lymphoid organs may be due to changes in neurohormone and neurotransmitter availability and interactions. In addition, lymphoid cells may alter their responses to neural signals (e.g., diminished intracellular generation of cAMP from β-adrenoceptor activation of lymphocytes in aging, despite the increase in actual numbers of β-adrenoceptors on the surface of aging T lymphocytes). The possibility that neuromediators may be involved in such alterations suggests new therapeutic approaches using neuropharmacological and behavioral means of altering immune reactivity.

E. Cytokine Signaling to the CNS Can Provoke a Host of Reactive Responses Related to Illness and Stress

Many major changes in brain function can be evoked by the action of cytokines, including (1) fever, sleep, and illness behavior; (2) activation of stress axes (HPA axis, sympathetics); (3) affective, cognitive, and behavioral changes; and (4) direct immune cell invasion of and interactions in the CNS. The role that cytokines play in altering CNS function in helps part to explain ''illness behavior'' and suggests interactions between health status and CNS functions that may be particularly devastating in the elderly, where hippocampal function may be compromised and CNS perfusion may be diminished.

VII. A FINAL REEVALUATION OF THE AUTONOMY OF INDIVIDUAL SYSTEMS: NEW OPPORTUNITIES FOR A MOLECULAR AND CELLULAR UNDERSTANDING OF MULTISYSTEM INTERACTIONS IN THE WHOLE PATIENT

The field of psychoneuroimmunology has demonstrated that the immune system is not an autonomous, exclusively self-regulating system, neither is the brain devoid of influences emanating from immune signaling. Rather, the CNS and the immune system appear to interact with complex signaling and feedback loops for the protection and homeostasis of the whole organism. Although we how have wonderful opportunities to use molecular and cellular (and, hence, reductionistic) approaches to study neurohormonal and neurotransmitter signaling of cells of the immune system and cytokine signaling of neurons and glia, ultimately we must return to the host, the whole organism. The individual is a complex product of cognition, emotion, and other CNS functions that cannot be studied with full understanding *in vitro* or in isolation. Yet, a holistic approach is extremely challenging in a research setting, particularly where complex variables must be controlled. However, we may have an unprecedented opportunity for a better understanding of behavioral influences on neurohormonal and neurotransmitter responses in the periphery and ultimately may be able to synthesize a more complete understanding of the complexities of biological signaling among the cytokines, neurohormones, and neurotransmitters. We finally are on the threshold of a biologically sound and mechanistically understandable merging of body, mind, and spirit.

Psychophysiology

DAVID LYKKEN
University of Minnesota

GLOSSARY

alpha rhythm EEG or brain waves in the frequency range from 8 to 12 Hz, found in most human subjects during a state of relaxed wakefulness.

electrocardiogram (ECG) The electrical signal generated by the heart muscle, which can be recorded between two electrodes on the body surface. The principal components are the P wave, produced by atrial contraction, the QRS complex, produced by contraction of the ventricle, and the T wave, representing repolarization of the muscle.

electroencephalogram (EEG) The electrical signal recorded from the scalp and reflecting the synchronous activity of masses of cortical neurons in the region under the active electrode.

electromyogram (EMG) The electrical signal recorded from the body surface that is produced by the synchronous contraction of a muscle mass.

emergenic trait A characteristic that is determined by independently segregating genes that combine configurally rather than additively. Monozygotic twins are similar with respect to emergenic traits, whereas siblings or parent–child pairs are not.

event-related potential (ERP) An EEG signal representing aspects of the brain's response to discrete stimuli. Normally hidden by on-going EEG activity, ERPs can be visualized by summing 0.5 sec segments of EEG following repeated presentations of the stimulus so that the background activity averages out.

functional magnetic resonance imaging (fMRI) A noninvasive technique for identifying currently activated brain regions by their increased blood flow.

guilty knowledge test (GKT) A method of forensic interrogation that involves recording autonomic or ERP activity elicited by the alternatives in a series of multiple-choice questions presented orally or visually; the purpose is to determine whether the subject responds differently to the correct alternatives, thus revealing that he or she recognizes which alternatives are correct.

monozygotic (MZ) Twins that result from the early splitting of a fertilized ovum and who share an identical genome or DNA blueprint.

plethysmograph A device for recording changes in the volume of a part of the body.

polygraph An instrument for recording several different electrical signals by pens writing in parallel on a moving paper chart.

preception The modulation of the sensory impact of a stimulus, the nature and timing of which can be accurately predicted. Thus, a painful electric shock produces less impact, indicated by an attenuated psychophysiological response, when its time of occurrence can be accurately predicted (''negative'' preception).

skin conductance level (SCL) The average level of electrical conductance of the palmar skin, a quantity that varies monotonically with CNS arousal.

skin conductance response (SCR) A wavelike increase in SCL elicited by stimuli, external or internal. The amplitude of the SCR varies with the subjective impact of the stimulus.

tachycardia Rapid heart rate.

two-flash threshold (TFT) The shortest interval (e.g., 50 msec) between two brief flashes of light that allows the subject to detect the paired flashes as different (e.g., as a flicker) from a single flash.

volar Palm of the hand or sole of the foot.

Psychophysiology is the study of mental or emotional processes as revealed through involuntary physiological reactions that can be monitored noninvasively from an intact subject. The independent variables usually will be psychological. A human subject may be asked a question, given a problem to solve, put under emotional stress, instructed to perform some task, or to attend to a series of simple stimuli, and so on. The dependent variables will be physiological changes that can be recorded peripherally either as electrical signals

(e.g., brain waves, muscle potentials, the electrocardiogram), as pressure, volume, or temperature changes (e.g., blood pressure, skin temperature), or as reflexive movements (e.g., eye blinks, breathing movements). Rarely, the psychophysiologist might use biochemical changes in urine, blood, or sweat as dependent variables.

Research in *physiological psychology* usually reverses this sequence of stimulus and response. There the independent variables are normally physiological (e.g., electrical or chemical stimulation of brain centers), whereas the dependent variables are commonly psychological (e.g., behavior observations or subjective report.) One exception includes the neuroimaging techniques, especially fMRI, which are being used increasingly for the purpose of identifying brain regions involved in specific forms of neurocognitive processing or emotional experience. One anticipates that these techniques will one day be used to identify the cognitive events or emotional experiences that were elicited by some stimulus and, thus, become tools of psychophysiology.

Psychophysiology must be distinguished also from the field of *psychosomatic medicine*, because workers in both areas share an interest in many of the same physiological manifestations of mental and emotional events. For the psychophysiologist, the physiological reaction is a medium that carries a message about events occurring in the mind or brain. The fact that fear can produce peripheral vasoconstriction and a rapid heartbeat is a concern to the student of psychosomatic medicine, who is interested in these physical reactions in their own right. It is the fact that cold hands and tachycardia *betoken* fear that is of interest to the psychophysiologist.

Psychophysiology is not one of the substantive disciplines within psychology, such as psychopathology or cognitive or social psychology, but rather it is a technology that might be (and has been) employed in all of these disciplines. In this respect, psychophysiology is to psychology as, say, microscopy is to physiology. The psychophysiologist's formal training may be in psychology, physiology, medicine, or engineering. Because many of the phenomena studied are electrical in nature and the instrumentation is electronic, a psychophysiologist must understand at least the rudiments of electrical theory. Many psychophysiologists function adequately with minimal training in anatomy and physiology. A typical psychophysiologist will devote part of his or her professional career to improving methods of measurement or inventing new ones and the rest of the time in applying this technology to some substantive problem in psychology, psychiatry, or even such diverse fields as criminology or political science. The principal scientific journals in this field are *Psychophysiology*, the journal of the Society for Psychophysiological Research, and the *International Journal of Psychophysiology*, the journal of the International Organization of Psychophysiology.

I. PSYCHOPHYSIOLOGICAL MEASUREMENT

The immediate object of psychophysiological measurement is to generate an electrical signal that faithfully mimics the manner in which the physiological phenomenon being measured varies over time. Once the phenomenon has been represented as an electrical signal, it can easily be amplified or filtered, visualized as a tracing on a polygraph chart or on a computer monitor, and recorded digitally for later playback or analysis. Some psychophysiological phenomena, such as the electroencephalogram (EEG), the electromyogram (EMG), and the electrocardiogram (ECG), are already electrical signals generated in the body, and their measurement requires only a pair of electrodes appropriately placed to pick up the biological voltage and connected to the input of an amplifier that will boost this voltage until it is strong enough to be recorded in some way. The most versatile method of recording is as a digitized computer file, but many psychophysiology laboratories also make a permanent visual record of the signal using an electrically driven pen that moves up and down with changes in the signal, writing on a paper chart that moves laterally. A *polygraph* consists of several pen motors arranged side by side, each driven by a separate amplifier, so that several separate signals can be recorded on the same time base on one chart. A polygraph with, say, four amplifiers and pen motors is said to have four *channels*.

It is important to note that a single channel can contain numerous variables. For example, the ECG channel provides a complex analog record of the electrical events associated with the cardiac cycle. There are many separate variables that can be quantified from this record: the height of the P, R, and T waves, the time periods between them, the time between successive R waves, which is the reciprocal of heart rate, and so on.

A. Electrodes

Electrodes used in psychophysiology are junctions where the flow of electric current changes from ionic, in

the skin and other tissues, to electronic, in the wires of the external circuitry. Such an interface is subject to electrochemical processes that can produce polarization. A polarized electrode acts like a high-pass filter that discriminates against slow or low-frequency changes. Relatively nonpolarizing electrodes are available, typically made of silver coated with silver chloride. An electrode paste or electrolyte is applied between the skin surface and the electrode; the properties of this conductive paste are also important for successful recording.

B. Transducers

Phenomena such as pressure or temperature changes can be converted into electrical signals by means of an appropriate transducer. A thermister, for example, is a device whose electrical resistance varies reliably with temperature. By passing a weak electric current through a thermister probe and amplifying the voltage developed across it, one can produce a signal that accurately represents changes in temperature. A strain gauge, similarly, changes in resistance as it is flexed and therefore can act as the "sense organ" of a pressure transducer or a device for measuring, for example, breathing movements.

Some psychophysiological phenomena that do not produce signal voltages directly may involve changes in the electrical properties of tissue that can be measured by passing an external sensing current through the tissue. The electrical conductance of the palmer skin is one example. The standard technique for measuring the skin conductance response (SCR) involves applying a constant 0.5 V between two nonpolarizing electrodes attached to the palmar skin surface and measuring the small direct-current flow (less than 10 μA per cm^2 of electrode area) through the tissues. A number of physiological phenomena, including blood flow, heart action, muscle contraction, and respiration, produce changes in the electrical impedance of the associated tissue that can be measured by passing a weak, high-frequency (e.g., 50 kHz) sensing current through the body. These impedance techniques are used infrequently but have considerable promise for specialized applications.

C. Noise

The modern world is literally full of electrical "noise," electromagnetic emanations from television transmitters, electric motors, passing autos, fluorescent lights, and so forth, which the human body picks up as an antenna does. Bioelectric signals originating in the body, similarly, become noise when they are not the signal one wants to measure but appear nonetheless in one's recordings. Where once it was necessary to study weak signals such as the EEG in awkward and expensive shielded rooms, using ranks of storage batteries to provide power untainted by the AC mains, modern amplifiers make this task much simpler. The noise-rejecting capabilities of these amplifiers will be realized, however, only if one (and only one) low-resistance electrode connects the subject to earth or electrical ground.

Noise of biological origin, as when eye movements affect the EEG or when the ECG shows up unwanted in the electrodermal channel, requires special solutions. Sometimes reorientation of the electrodes will suffice. If the noise consists mainly of frequencies outside the bandwidth of the desired signal, a bandpass filter may provide the solution. A third approach is to measure the noise directly in a separate channel and then subtract it from the signal channel by electronic inversion and summation.

D. Safety

Unpleasant or even dangerous electric shocks are always a potential hazard in the vicinity of apparatus connected to the AC power mains. These same shocks can easily be fatal if the recipient happens to be well-grounded. Because subjects in psychophysiological research are almost always well-grounded, it is necessary to take sensible precautions. The voltage with respect to ground of every electrode, wire, or other conductive surface with which the subject might come into contact should be measured, and a variety of other safety measures are available.

E. Computers

Most psychophysiology laboratories now employ small computers for on-line control of experiments and immediate analysis of data and also for more complex subsequent analyses. Laboratory interface systems are available that make it possible to turn things on and off under computer control, to generate stimuli, to time events, and also to provide to the computer data, command signals, and other information from the laboratory. The computer can present pictorial or alphanumeric information to the subject by means of a monitor display and also a variety of

auditory stimuli including spoken words such as "right," "wrong," and "good," which have been digitally recorded and stored in the computer's memory. Psychophysiologists of the past have required a working knowledge of electrical principles, physiology, and statistics and a more than rudimentary understanding of psychology; competent psychophysiologists of the present require a working knowledge of the computer as well.

II. ANALYSIS OF THE DATA

A. Components of the Response

The variance of a sample of scores on some psychophysiological variable, ω, can be partitioned thus:

$$\sigma_\omega^2 = \sigma_\psi^2 + \sigma_\phi^2 + \sigma_\varepsilon^2 \quad (1)$$

where σ_ψ^2 is the variance due to individual differences in the underlying psychological variable of interest, σ_ϕ^2 is the orthogonal component of variance due to physiological differences, and σ_ε^2 represents measurement error. If skin conductance level (SCL), represented by ω, is being measured, for example, ψ might be central nervous system (CNS) arousal or "energy mobilization," ϕ would reflect individual differences in the density and activity of volar sweat glands (which largely determine skin conductance), and ε would increase with variations in cleaning the skin surface, positioning of the electrodes, the area of skin contacting the electrolyte, and so on.

Underlying most psychophysiological measurements is the implicit assumption that ω is a monotonically increasing function—and, it is hoped, a simple linear function—of the underlying variable of interest, ψ, as in

$$\omega = a + b\psi + \varepsilon. \quad (2)$$

By using SCL again as the example, the parameter a would represent this subject's minimum SCL when sudomotor activity is zero, whereas b would be determined by the reactivity of the entire electrodermal system, that is, the increase in conductivity produced by a unit increase in ψ. Very similar assumptions are implicit in most psychological measurements. The problem is that the parameters a and b also vary, often within the same individual from time to time and certainly from one individual to another. This is the variation represented by σ_ϕ^2 in Eq. (1). The job of the psychophysiologist is, first, to ensure that the physiological variable chosen (ω) *is* linearly related to ψ, at least approximately, and then to try to minimize both the measurement error σ_ε^2 and also σ_ϕ^2, the variance due to physiological variability, within subjects or between subjects, which also must be regarded as error variance in this context.

B. The Linearity Assumption

Consider an experiment in which the subject is intensely stressed at the outset and then is allowed to relax and go to sleep, while skin potential level (SPL) is continuously monitored. The SPL will be fairly low under intense stress, then will rise to a maximum while the subject is, say, listening to an interesting story, and then will fall again to a minimum when the subject goes to sleep. These individual curves show us that SPL has an inverted U-shaped relationship to CNS arousal and is therefore a poor index of that variable. Skin conductance level (SCL) and also its reciprocal, skin resistance level (SRL), both normally vary monotonically with CNS arousal, and it appears that the relationship of SCL to arousal is more nearly linear than that of SRL.

Suppose that, in the same experiment, we also measure electrodermal responses: SCRs from one hand and resistance changes or SRRs from the other. Because resistance is the reciprocal of conductance, and the responses are being elicited over widely varying levels of tonic SCL and SRL, the SCRs will be poorly correlated with the corresponding SRRs. Thus, SCR and SRR cannot be equivalent indicants of the same psychological process, for example, of the psychological impact of the stimulus. Which of the two should be used? There is both theoretical and empirical support for the view that conductance is more simply related to central events than is resistance.

These examples illustrate that it is important to investigate the form of the relationship between ω and ψ, that this requires experimental manipulation of ψ (remembering, as we have seen, that the parameters of the function also will vary among subjects), and that the investigation will be illuminated by whatever one knows about the physiological substrate of the variable studied.

C. Minimization of Extraneous Variance

Minimization of variance resulting from error of measurement is largely a matter of competent and

consistent technique; the details will depend on the variable being measured. To minimize variance due to extraneous physiological differences requires a statistical correction for individual differences in the range over which the measured quantity can vary in that subject at that time. The basic idea is to express each individual's score as a fraction of the range over which that person's scores can vary, thus:

$$\text{score}_{RC} = \frac{\text{score}_{raw} - \text{min}}{\text{max}}$$

In the case of SCL, for example, min would be the subject's minimum SCL obtained when relaxed or asleep. The estimate of max might be obtained from that subject's maximum SCL shown under high stress (having the subject blow up a small balloon until it bursts has been found to elicit good estimates of SCL_{max}.) In the case of phasic changes such as the SCR, min or the minimum value is always zero. Phasic response values can therefore be range-corrected merely by dividing by an estimate of that subject's maximum response amplitude.

D. Correction for Unsystematic Variation

Most psychological trait or response variables show intraindividual variability when the measurements are repeated, especially over long intervals (e.g., months or years). Although part of this variation can be attributed to measurement error, some of it reflects variability of the relevant response system or the state of the organism (e.g., mood, fatigue) due to recent events or due to variations in the context of measurement. Thus, for example, whereas MZ twins may show within-pair correlations of, say, 0.50 with respect to certain personality traits, the *between-twin cross-time* correlations over a period of months or years may be almost as high as the *within-twin cross-time* or retest correlation. Such results indicate that the stable component of the trait has a much higher heritability than does a measurement made on a single occasion. These findings suggest that relationships between single-occasion measurements of psychophysiological variables are likely also to underestimate the true or stable correlations of those variables. That being so, the additional cost of retesting the same subjects on different occasions is likely to pay benefits in terms of stronger and more revealing measures of association.

E. Within-Subject versus Between-Subject Correlations

Many psychophysiological studies that are intended to discover within-subject relationships between variables actually employ a between-subject design. Consider, for example, the question of whether a measure of autonomic arousal, such as SCL, is related to measures of cortical arousal, such as reaction time (RT) or the two-flash threshold (TFT). Suppose that, for each of N subjects, one measures the mean SCL during the brief time required to estimate the TFT and then plots these pairs of values over the N subjects. This plot will represent the true within-subject relationship *only* if the within-subject curves all have similar shapes and parameters. This appears to be true for normal subjects because the between-subject correlation of SCL with TFT is strongly negative. For unmedicated schizophrenic subjects, however, the between-subject relationship is negligible. It may be, however, that for schizophrenics TFT decreases linearly with increasing SCL, as it does for normals, but that the individual curves have widely varying slopes. That could yield a negligible between-subject correlation but with very different theoretical implications than if the within-subject plots also showed little correlation.

III. THE CHANNELS OF PSYCHOPHYSIOLOGY

A number of organ systems provide the psychophysiologist with a variety of (clouded) windows through which to observe mental events. This section reviews the most widely studied of these systems.

A. The Cardiovascular System

People have been drawing inferences about each other's mental and emotional processes from cardiovascular changes since the dawn of history because some changes—blushing and blanching of the skin, pounding of the heart, cold hands, and the like—can be detected without instrumental assistance. The important channels are the ECG, arterial pressure, finger pulse pressure, and perhaps digital temperature. The ECG is a sequence of electrical signals generated by the busy heart muscle and radiated throughout the body. The psychophysiological variable most

commonly derived from the ECG channel is heart rate, the reciprocal of the time interval between successive R waves produced by ventricular contractions. The ECG is often fed into a device called a cardiotachometer, which electronically measures this interval, converts it to rate, and outputs a signal proportional to instantaneous heart rate.

In the intact subject, blood pressure can be measured only intermittently by auscultation. A pressure cuff on the upper arm is inflated until the brachial artery is sufficiently compressed to occlude the flow of blood. With a stethoscope over the artery distal to the cuff, the pressure is gradually released until the first Korotkoff sounds are heard. These sounds are caused by the spurting of blood through the arterial occlusion during the peak of the pressure cycle, just after ventricular contraction. The first sounds mark the peak or *systolic* blood pressure. As pressure is relaxed further, the sounds wax and wane until a point is reached at which blood flow continues even at the minimum of the pressure cycle; this is the *diastolic* pressure.

Electronic detectors are now available to replace the ears of the skilled clinician and can measure blood pressure reliably, although their absolute accuracy may be off by several millimeters of mercury. Automatic systems for intermittently inflating and deflating the cuff have been used with some success, but the process is cumbersome and both distracting and uncomfortable to the subject. A possibility currently being explored is that blood pressure may be reliably related to pulse transit time, that is, the time required between the initiation of the pressure pulse when the ventricles contract and the arrival of that pulse at, say, the finger. Peripheral blood flow can be detected either by a pressure transducer (a plethysmograph) on a finger or by means of a photoplethysmograph, a device in which a light is directed into the skin at an angle and the reflections are detected by a photoelectric cell. The reflectance varies as blood surges in and out of the vascular bed of the dermis, yielding a signal that varies with the digital pressure pulse.

One must always remember that the heart has more important things to do than to whisper secrets to the psychophysiologist, and it is under strong homeostatic control. Heart rate and blood pressure tend to obey the law of initial values, which states that the change in either variable produced by a stimulus will be inversely correlated with the prestimulus level of that variable. A pressor stimulus will cause a smaller increase in the rate of an already racing heart than in one beating slowly and calmly.

B. The Electrodermal System

Compared with subdermal tissues, the skin has a relatively high resistance to the passage of electric current. In the latter part of the nineteenth century, it was discovered that the resistance of the thick skin of the palms and soles was extraordinarily reactive to psychological stimulation. It is known that the sweat glands in these volar regions subserve a special function; instead of helping with thermoregulation, they moisten grasping surfaces in preparation for action. Dry palmar skin is both slippery and more subject to abrasion. Neural circuits arising in the activating systems of the midbrain control volar sweating, which increases tonically with CNS arousal and which also shows wavelike, phasic increases in response to any stimulus important enough to produce an orienting response. In part because the sweat gland tubules provide a low-resistance pathway through the epidermis, the electrical resistance of the skin varies with sweat gland activity. Because, in fact, resistance varies inversely with sweating, current practice is to measure skin conductance, the reciprocal of resistance.

Skin conductance level (SCL) is lowest in a drowsy or somnolent subject, rises sharply with awakening, and rises still further during mental effort or emotional storm. Superimposed upon these tidal changes of SCL are the wavelike, phasic skin conductance responses (SCRs) to discrete stimuli. After a latency of perhaps 1.5 sec, conductance rises rather quickly to a peak and then returns more or less rapidly to the prestimulus level. Both the latency period and the size and shape of the SCR are affected by hand temperature; if the hand is cold, SCRs are sluggish and diminished in amplitude. The SCR amplitude seems to vary with the psychological impact of the eliciting stimulus; other things being equal, strong stimuli produce larger SCRs than weak ones, but an unexpected or especially significant weak stimulus will produce a larger SCR than an expected but meaningless strong stimulus.

Probably as a result of inward pumping of sodium ions from secreted sweat, the skin surface tends to be 10–80 mV negative with respect to the underlying tissues. Also a result of sweat gland activity, this endogenous skin potential provides a channel of information that is to some extent parallel with the skin conductance channel, but there are nonlinearities that complicate interpretation. The skin potential response (SPR) may be an increase in negativity, an increase followed by a decrease, or a monophasic wave of decreased negativity, depending on the strength of the stimulus and the prestimulus SPL. For these

reasons, the modern tendency is to employ the skin conductance channel in preference to skin potential.

Because the SCR varies with the psychological impact of the eliciting stimulus, it has been used to assess individual differences in *preception*, the ability to reduce the impact of a predictable noxious stimulus. Because it requires stimulus predictability, such negative preception can be regarded as supplementary to habituation, which requires less predictability but more repetitions of the to-be-attenuated stimulus before it takes effect.

C. Electromyography (EMG)

An electrode on the skin over any muscle mass, referenced against an electrode in some quiescent region such as an earlobe or over the shin, will pick up a high-frequency (100–500 Hz) signal produced by the repeated firing of hundreds or thousands of muscle fibers. This signal can be electronically integrated to yield a simpler curve representing average muscle tension. Except perhaps in deep or Stage 4 sleep, the striate muscles maintain a degree of tonus even at rest, with individual fibers firing asynchronously at a low rate. In a ''tense'' individual, this resting tonus may be quite high, either generally or in specific muscle groups. Surface electromyography provides a means of monitoring such subactive muscle tension. One common application is in relaxation training, in which some easily interpretable indicant of current muscle tension is fed back to guide the subject's efforts to achieve voluntary control.

An important research application of electromyography is the detection and recording of facial expressions having emotional significance. For example, small electrodes positioned above the eyebrow, over the corrugator supercilli muscle, will record frowning, whereas placements on the cheek, over the zygomaticus major muscle, will record smiling.

D. Eye Movements

The eyes, those portals through which the brain receives so much of its information about the external world, are also ''windows of the soul'' through which one obtains glimpses of the workings of that brain. Eye movements and the direction of gaze can be monitored by electrooculography (EOG). The eye is like a little battery with the cornea about 1 mV positive with respect to the back of the retina. If electrodes are positioned adjacent to the outer canthus of each eye, then when both eyes are turned to the right, for instance, the electrode on that side becomes electropositive to the one on the left. Another pair of electrodes above and below one eye will record vertical eye movements and also eye blinks (because the eyeball rotates upward with each blink). The sensitivity of the EOG is illustrated by the fact that, when subjects track a target moving sinusoidally from side to side of a computer screen, the EOG recorded on the polygraph will usually be a nearly perfect sine wave. If the target is then driven by a triangular waveform, the EOG record will reproduce this change.

The EOG has been used to study the saccadic eye movements employed in reading or in searching a visual display. It has also been used in the study of nystagmus and the smooth following movements with which the eyes track a moving target. A defect in smooth tracking performance has been shown to be characteristic of many schizophrenic patients. This deficit appears to result from some central defect in the processing of visual information. Because it appears in schizophrenics in remission as well as in many first-degree relatives of these patients, it is now believed that visual smooth-following dysfunction may prove to be a marker for the genetic predisposition associated with at least one subtype of that illness.

E. The Pupillary Response

The size of the pupil, which can vary from about 2 to 8 mm in diameter, is regulated by the autonomic nervous system so as to tend to hold constant the intensity of light admitted to the retina. However, the pupil is also reactive to psychological stimulation with small (< 1 mm), but regular changes (usually dilations) that follow a stimulus with latencies on the order of 0.2 sec. Of the various techniques that have been used for measuring these pupillary responses, the most sophisticated involves a TV monitoring system using infrared illumination and automatic measurement of the image of the pupil, which yields an output signal proportional to pupil size that can be recorded on the polygraph or in the computer. An accumulation of evidence indicates that the pupillary response measures the proportion of total cognitive processing capacity that has been invested in the analysis of the eliciting stimulus. For this reason, larger responses will be elicited by more complex stimuli or more difficult problems, by more interesting or more important stimuli, and also by those near-threshold stimuli that

are detected (and thus require processing) as compared with those that escape detection. Earlier theories that pupil size varies with the attractiveness of stimuli are subsumed by the processing hypothesis; it is likely that more attractive stimuli tend to be subjected to more intensive processing. Pupillary responses to relatively simple mental tasks are larger for less intelligent subjects, suggesting that the less efficient brain must deploy a greater proportion of its resources to solve a given problem.

F. The Eye Blink

The eye blink is a component of the reflexive startle response. The startle elicited by a sudden-onset auditory stimulus is related to the subject's prestimulus emotional state. For example, a subject viewing a disturbing scene produces a stronger blink response than when viewing a neutral scene, whereas, if the scene is pleasant and engaging, the blink response is attenuated. However, within the first few hundred milliseconds after a picture is presented, there is a general inhibition of the blink reflex to acoustic probes. This inhibition reflects the attenuation of new sensory input in order to ensure adequate processing of the prior stimulus.

This paradigm has been used to demonstrate that, unlike normal subjects, primary psychopaths react to frightening scenes as they react to pleasant, interesting scenes, by showing reduced startle responses in both conditions. Similarly, if the acoustic probes are presented while subjects are anticipating a painful electric shock rather than while viewing slides, psychopaths show less startle potentiation than do nonpsychopaths.

G. Electroencephalography (EEG)

Whereas the EEG might appear to provide the most direct "window" of all through which to observe mental events, the electroencephalographer has been likened to a spy, prowling outside the concrete walls of a great factory complex, trying to infer from the din of noises reaching the outside what is going on within. The electrical activity of the brain is far more complex than that in the most elaborate manufactured computer; only a minute part of this information is available at the brain's surface and still less at the scalp. Because an electrode on the scalp integrates electrical activity over a considerable area of cortex, a reasonably comprehensive record of the total EEG can be obtained from about 20 electrodes distributed systematically over the head. A set of standard placements has been defined, called the International Ten–Twenty System. The complete montage will be used by clinicians looking for EEG evidence of tumors or epileptiform activity, whereas the researcher more commonly uses only one or a few EEG channels.

The most common use of the spontaneous EEG is in sleep research where, with additional channels recording lateral eye movements and muscle tension, it is possible to identify, with considerable reliability, the stages of sleep. Computer programs are available for doing a fast Fourier transform of a segment of EEG from, say, a relaxed waking subject, thus producing a spectrum or graph of the frequency content of the EEG, most of it contained in the band from 0 to 20 Hz. An individual's EEG spectrum is relatively distinctive and also stable, as long as it is obtained under similar conditions each time. The spectra of "identical" or monozygotic twins tend to be as similar as that of one person measured on two occasions. Fraternal or dizygotic twins, on the other hand, show negligible similarity with respect to spectral parameters. Thus, it appears that the features of the resting spectrum, the relative amounts of alpha, beta, or theta activity, the midfrequency of the alpha rhythm, and so on, though strongly determined by genetic factors, are emergenic traits that are not commonly passed from parent to offspring. Whereas it seems reasonable to expect that these parameters ought to have interesting psychological correlates, as yet none have been reliably demonstrated.

H. Event-Related Cortical Potentials (ERPs)

Virtually any stimulus sensed by the subject will produce an effect upon the EEG; indeed, much of the apparently spontaneous EEG may be simply the composite effect of the flux of stimulation, external and internal, that continuously bombards the sensorium. To detect the effect of all but the most intense stimuli, against the background of EEG activity, requires repeated presentations of the stimulus so that the immediate poststimulus segments of the EEG record can be averaged together. If 100, 0.5-sec EEG segments are randomly selected and then averaged, the mean will tend toward a straight line. But the 0.5-sec segments that follow 100 presentations of, say, an auditory click will each contain the ERP elicited by that click, a relatively complex train of waves that is

time-locked to the stimulus. The averaging process minimizes the random background activity and reveals the features that are consistent in each sample.

The earlier components of the ERP seem to represent earlier stages of cerebral processing. Evidence suggests the possibility of a relationship between the speed (latency) of these components and some basic dimension of intelligence. Later components, especially a positive wave about 300 msec poststimulus, seem to reflect the completion of a process of stimulus identification or classification. The actual latency of this wave varies with reaction time, and its amplitude varies with the information content of the stimulus; unexpected, important, or possibly memorable stimuli produce larger P300 components. The amplitude of the P300 wave also decreases as part of the aging process.

Other types of ERP that have received research attention include *contingent negative variation* (CNN) and *mismatch negativity* (MMN). In studies of reaction time, where a warning signal precedes the imperative stimulus (the "Go!" signal) by one or a few seconds, the EEG signal measured at the top of the head moves in a negative direction, and the magnitude of this CNN is related to the degree of attentional focus and, thus, to the speed or accuracy of the response. MMN is a negative ERP seen most strongly in frontal areas, which is elicited by a deviant stimulus presented infrequently in a train of repeated standard stimuli.

The study of the psychological correlates of components of the ERP and the use of these data in formulating and testing models of the way in which the brain processes information constitute one of the most active and promising areas of current psychophysiological research.

IV. APPLIED PSYCHOPHYSIOLOGY

A. Biofeedback

Psychophysiological techniques are sometimes used for purposes of relaxation training. Skin conductance or heart rate can be measured and converted to a visual or auditory signal that is fed back to the subject. The subject uses this signal during relaxation training in order to monitor success. Because the alpha rhythm of the EEG occurs during relaxed wakefulness but gives way to higher frequencies when the subject is aroused or anxious, a feedback signal that is proportional to the average amplitude of this activity is sometimes used for the same purpose. Lower frequency (1–5 Hz) EEG waves, as well as sporadic spiky waves called *sleep spindles*, indicate incipient sleep onset. An EEG monitoring system that feeds back an alarm signal in response to such activity has been proposed for use as an accident prevention tool by long-distance truck drivers or persons subject to attacks of sleep apnea.

B. Polygraphic Detection of Deception

The most extensive and socially important use (or misuse) of psychophysiology is the polygraph or "lie detector" test. Since the early twentieth century, primarily in the United States, police and various federal agencies increasingly have employed polygraphs to monitor blood pressure changes, breathing movements, and palmar skin resistance during the questioning of criminal suspects or job applicants. The federal employee Polygraph Protection Act of 1988 prohibits requesting or requiring job applicants or employees to submit to polygraph testing in most areas of the private sector. Ironically, however, this practice continues to be used by federal police and security agencies and by the military. On evolutionary grounds, it would be unlikely that our species would have acquired by natural selection some involuntary response that we show when, and only when, we attempt to deceive. No such specific lie response has ever been demonstrated.

Most people, however, will tend to show some perturbation in their breathing, blood pressure, and/or in the sweating of their palms after falsely answering an accusatory question. The problem is that most people will also evince similar autonomic disturbance even when answering truthfully. Beginning in the 1950s, polygraph examiners began interspersing their accusatory or *relevant* questions with what were called "probable lie control" questions. These questions refer in a vague and general way to probable misdeeds in the examinee's past, e.g., "Have you ever told a lie to someone in authority?" The examiner induces the subject to deny each such question by implying that admitting such past misdeeds might lead to his or her being diagnosed as deceptive in respect to the relevant questions. In fact, however, it is assumed that a subject who can answer the relevant questions truthfully will be less disturbed by them than by the probable lie questions. A subject who shows stronger polygraph disturbance after the relevant than after the probable lie questions is classified as deceptive.

The test format just described is known as the Control Question Test or CQT, but it will be apparent

that the probable lie questions used in such tests are not controls in the scientific sense of that term. If Jones is accused of crime X and has reason to believe that he may be prosecuted, even convicted of crime X, then—whether Jones is innocent or guilty—it is not reasonable to suppose that a question of the form, "Prior to last year, did you ever tell a lie to someone in authority" can be expected to have stimulus value equal to the relevant questions of the form, "Did you commit crime X?" Therefore, it is to be expected that many innocent persons will display stronger polygraphic reactions to the relevant than to the "control" questions and become false-positive errors. This, in fact, is what the few validity studies of the CQT indicate, studies done of actual criminal suspects in real life circumstances.

Unfortunately, however, no wholly satisfactory study of lie test validity has ever been accomplished. Existing studies have used polygraph-induced confessions as their criterion of ground truth. One pragmatic virtue of the polygraph test is that guilty suspects, when told that the "impartial, scientific instrument has revealed" that they were lying, often confess their guilt. Validity studies have used other polygraphers to blindly score such confession-verified charts in order to estimate the sensitivity or true-positive validity of the CQT. However, even if we assume all such polygraph-induced confessions to be valid (although it is known that some innocent suspects, feeling that all hope is lost, will make false confessions), the charts thus rescored are not representative of all charts produced by guilty suspects. Some guilty suspects "fail" the test, are interrogated, but do not confess. Moreover, some guilty suspects will "pass" the test, therefore will not be interrogated, and will not confess.

Some polygraph-induced confessions will clear other suspects in the same crime. However, it almost always happens that the only innocent suspects thus cleared will be suspects tested before the guilty suspect, who then confesses. This is because, if the first-tested innocent suspect had failed his test, then it is most unlikely that the second and guilty suspect would ever have been tested, the examiner having assumed that the first test solved the crime. This means that charts of innocent suspects, cleared by another's confession, are almost always charts that examiners will classify as truthful. Therefore, as is true for the confession-verified deceptive charts, blind rescoring of confession-verified truthful charts will necessarily overestimate the validity of the CQT.

The only acceptable scientific assessment of CQT validity would require that all possible criminal suspects be given polygraph tests (e.g., by the FBI) and then the charts left unscored until the case had been definitively cleared on the basis of extra-polygraphic evidence. Then the relevant charts could be blindly scored and the results compared against ground truth thus determined independently of the polygraph results. No such proper study has ever been done of any method of polygraphic interrogation.

The CQT requires that the examiner be able to ask "control" questions, which the suspects will answer deceptively, and also that the examiner can persuade the suspect that he or she is in real jeopardy if it is concluded that he or she is answering these "control" questions deceptively. Because both of these assumptions are implausible, a different question format is being increasingly substituted for the CQT. This is the Directed-Lie Test or DLT. In this method, the "control" questions are similar to those used in the CQT, but they are presented differently. The examiner says, for example, "You must have told a lie sometime in your life, haven't you?" When the suspect admits to this, the examiner continues: "Well, I am going to ask you that question during this test and I want you to answer it 'No.' Then you and I will both know that your answer is not true, and I will be able to see from your polygraph chart what your response looks like when you lie." The DLT is scored in the same way as the CQT.

Thus, the DLT assumes that an innocent person will be more disturbed by a question about some minor misdeed that, on instruction, he or she answers deceptively, than by an accusatory question about some real crime of which he or she is suspected, which is answered truthfully. No good evidence of the validity of the DLT has ever been published in a refereed scientific journal, but the assumptions of the technique seem so implausible that one wonders why the FBI, the NSA, the Secret Service, and other government agencies continue to rely upon it.

Another problem with any form of lie detector test, in addition to the high rate of false-positive errors that result, is the fact that any guilty suspect who understands the simple principles on which these tests are based can easily employ countermeasures designed to beat the test. If one can recognize the "control" questions, then one need only to self-stimulate after answering such questions—by tightening one's toes or one's anal sphincter or by biting one's tongue—so as to augment one's polygraph reactions selectively to these questions. The examiner cannot detect such countermeasures and, if one is successful in augmenting the responses to the "control" questions so that

they average larger than one's responses to the relevant questions, then one will pass the test.

Polygraph tests such as the DLT are now used extensively by U.S. government agencies in order to screen job applicants and to periodically screen employees in sensitive positions, such as the scientists working in the weapons laboratories at Lawrence Livermore, Sandia, and Los Alamos. Due to the assumptions of these tests, as outlined earlier, one would expect that such screening would produce a very high proportion of false-positive errors. Because of this, it is a fact that many innocent and patriotic young applicants for positions with the FBI or other agencies have been turned away, their career aspirations smashed. However, when these methods are used to periodically screen employees in the nation's weapons laboratories, or military personnel involved in the nuclear missile system, it would obviously be unacceptable to "fail" 30–40% of them. Therefore, government examiners have wisely (but covertly) modified their scoring protocols in order to avoid this result. Instead of failing everyone who is more disturbed by the relevant than by the "control" questions, these periodic screening tests are scored by requiring a *much* stronger response to the relevant than to the "control" questions. *How much* stronger has never been made public. However, in as much as there is no acceptable scientific evidence that the probability of guilt increases monotonically with the difference between the amplitudes of the responses to the two types of question, there is no reason to suppose that this higher cutting score actually increases lie test validity.

C. Detecting Guilty Knowledge

The Guilty Knowledge Test or GKT is a method of polygraphic interrogation that attempts to determine whether the suspect possesses knowledge (e.g., of a crime scene or of military secrets) that he or she should not possess if innocent (e.g., of the crime or of espionage). Facts that an innocent person should not recognize are presented, verbally or pictorially, together with several alternative "facts" chosen to appear equally plausible to an innocent person in the form of a multiple-choice question. For example, "Where in the house did the murderer leave the body of the victim? Was it on the porch? In the kitchen? In a bedroom? In the basement? In the living room? In a hallway?" The GKT assumes that a suspect who possesses guilty knowledge will recognize the correct alternative and therefore will respond more strongly to it than to the others. If each GKT question contains five scoreable alternatives (the first alternative is always incorrect and left unscored), then the probability that an innocent suspect will chance to "hit" on a single question equals 0.2. However, the probability that an innocent suspect will chance to hit on each of 10 questions is 0.2^{10} or 1 in 10 million. Well-constructed GKTs have been shown to have high validity in experiments involving mock crimes and are currently used by police agencies in Israel and Japan, but not in the United States.

Reading Disorders, Developmental

VIRGINIA A. MANN
University of California, Irvine

GLOSSARY

decoding The act of converting a written word into its spoken counterpart.

dyslexia A specific learning disability of neurological origin that hinders the ability to learn to read fluently and accurately. It affects approximately 4% of the population and does not imply low intelligence or poor educational potential. It is also independent of race and social background.

morphophonological orthography An orthography such as English or French that preserves both the phonemes and morphemes of spoken words.

orthography A symbol system used to transcribe or represent a spoken language. Logographies (i.e., Chinese and Japanese Kanji) use symbols to represent morphemes, syllabaries (i.e., Hebrew and Japanese Kana) use symbols to represent syllables, and alphabets (i.e., English and Spanish) use symbols to represent phonemes.

phoneme The minimal segment of sound that distinguishes two words or syllables (e.g., "cat" and "cap" differ in their third phoneme). Phonemes are the units of language represented by the letters of an alphabet.

phoneme awareness Sensitivity to the phoneme-sized units in spoken words, measured as the ability to analyze (e.g., do "cap" and "tap" start with the same sound?) or manipulate (e.g., say "cat" without the first sound) words in terms of the phonemes they contain.

syntax The grammar of language; the system of rules by which words are combined and moved to form phrases and sentences.

working memory A temporary memory system in which material is held for a short time and analyzed. Different working memory systems exist for different types of information and they use different types of codes. The working memory for language uses a phonological code that represents words in terms of the syllables and phonemes they contain.

I. INTRODUCTION: THE LINK BETWEEN READING PROBLEMS AND LANGUAGE PROBLEMS

What makes a poor reader a poor reader? Why do some children fail to learn to read when others succeed and even excel? Although learning to read is a task that most children accomplish relatively early in their education, it poses a specific difficulty for approximately 4% children who may be labeled as "dyslexic" or "reading disabled." The syndrome of dyslexia is now widely recognized as a specific learning disability of neurological origin that does not imply low intelligence or poor educational potential and which is independent of race and social background.

Research during the past few decades has increasingly identified the neurological and behavioral factors that are responsible for difficulties in learning to read. Psychologists, educators, and neurologists have all, in one way or another, tried to identify the basis of early reading difficulty, and their efforts have been guided implicitly, if not explicitly, by some basic assumptions about skilled reading and its demands on perceptual and cognitive abilities. Those researchers who have

succeeded were able to do so because they had a framework in which to interpret their results as well as a meticulous methodology that allowed them to separate spurious observations from replicable generalities. In recent years, the most successful approaches to the problem of early reading disability have been guided by the assumption that reading is first and foremost a language skill. Thus, a primary goal of this article is to review both the theoretical underpinnings and the empirical research that show how reading is tied to the integrity of language skills.

II. PRIOR ACCOUNTS OF POOR READING

A time-honored means of discovering the problems that underlie reading disorders is to compare children who differ in reading skill. This approach has a long history with many false turns, and has only recently converged on the link between reading and language problems. This section reviews a sample of the most influential accounts as a preface to current research.

Learning to read is a specific example of a complex learning task that correlates about 0.6 with IQ. However, a low IQ cannot be the sole basis of reading problems since there are children who have low reading ability but average intelligence, just as there are children of low intelligence who are nonetheless able to read. Children who possess a seemingly adequate IQ (typically 90 or higher) but nonetheless encounter reading problems are said to have a specific reading difficulty. Their actual reading ability lags between 1 and 2 years behind that which is predicted on the basis of their age, IQ, and social standing. For these children, something other than general intelligence must be the primary ''cause'' of many instances of poor reading.

In attempting to discover the cause of early reading problems, many early theories were biased by a popular assumption that influenced psychologists and educators alike. It was commonly believed that reading is first and foremost a complex visual skill that demands differentiation and recognition of visual stimuli. Owing to this view, models of skilled reading have often been biased toward clarification of how readers see and recognize the various letter and word shapes, causing many studies of the cause of poor reading to conclude that early reading difficulty is due to some problem in the visual domain. Recently, however, visual theories of reading disability have become less popular because it seems that, at best, only a few of the children who are poor readers actually suffer from perceptual malfunctions that somehow prevent recognition, differentiation, or memory of visual forms. In short, many visual perceptual skills cannot very reliably distinguish children who differ in reading ability, so visual problems may not underlie most reading problems. The only exception involves recent evidence that poor readers tend to have impaired contrast sensitivity to transient (i.e., flickering) low-luminance visual stimuli. Although the existence of the impairment is increasingly clear, its causative role in reading disability is not. The flickering conditions of low-illumination under which dyslexic individuals ''see'' less well are not characteristic of printed text read under normal conditions. It can thus be argued that this particular visual impairment may be a concomitant factor in reading problems but not necessarily a causal one.

Additionally, two other pieces of evidence show just how unfair it is to attribute the majority of early reading difficulties to visual deficits. First, 5- and 6-year-old children identified as having deficient visual perception and/or visuomotor coordination skills show no more instances of reading difficulty at age 8 and 9 than do matched controls who possess no such deficits. Second, although it is true that most young children tend to confuse spatially reversible letters such as ''b,'' ''d,'' ''p,'' and ''g'' until they are 7 or 8 years old, letter and sequence reversals actually account for only a small proportion of the reading errors that are made by children in this age range. Even children who have been formally diagnosed as dyslexic make relatively few letter and sequence reversal errors, as shown by I. Liberman and D. Shankweiler.

Theories that place primary emphasis on ''cross-modal'' integration have also been popular at one time or another. One particular misconception posited that reading involved translating visual information into auditory information, and that dysfunctions of this cross-modal match served as the source of reading problems. However, when investigators carefully examined the behavior of skilled readers, they realized that the translation of stimuli did not proceed directly from the visual to auditory domain. Instead, visual information was first translated into an abstract linguistic code. Further studies made it clear that poor readers tended to make inefficient use of an abstract linguistic code in a variety of circumstances, including cross-modal integration. Consequently, researchers noted that visual-auditory integration problems were often coupled with auditory–auditory problems and, in some cases, visual-visual ones as well. Thus, the poor readers' problems with visual–auditory integration

have come to be viewed as one of the many consequences of a more general linguistic coding problem that impairs short-term or "working" memory and negatively affects integration both within and between different sensory modalities.

Other theories have suffered from similar attempts to explain observations about poor readers in terms that are somehow too general. For example, certain theories were preoccupied with the fact that reading involves remembering an ordered sequence of letters in a word, words in a sentence, etc. Hence, it was suggested that poor sequential order memory or poor short-term memory (STM), in general, might be a cause of poor reading. Other observations about the specific pattern of deficits that are characteristic of poor readers prompt a need for refinements in the methodology/logical foundation on which STM theories of dyslexia are based. For example, good and poor readers do not differ on all tasks that require temporary memory for items or their order. Likewise, good and poor beginning readers are equivalent, for example, in their ability to remember faces or visual stimuli that cannot readily be assigned verbal labels. Only when the to-be-remembered stimuli can be linguistically coded do children who are poor readers consistently fail to perform as well as good readers.

Various other general or visual accounts of reading disability have been offered in the literature. These tend to be inadequate because they fail to explain why poor readers often do as well as good readers on nonlinguistic tasks, but lag behind good readers in performance on many linguistic tasks. For the sake of brevity, such general accounts will not be discussed here. Instead, I turn to the more positive task of reviewing evidence that links language and reading problems. I begin with a justification of why a language-based approach to reading is the most appropriate approach to take.

III. WHY SPOKEN LANGUAGE IS CRITICAL TO READERS

Two insights underscore the role of language problems in poor reading. One stems from the fact that writing systems function as written language by transcribing the units of spoken language. Another concerns the active role of language skills in skilled reading. We often think of reading as a visual skill, but it is so much more. For readers to successfully perceive, recognize, remember, and interpret various letters and the words, sentences, etc. that they form, readers must first map their written language onto their spoken language. Spoken language comes first in both the history of the individual and the history of our species; furthermore, spoken language is far more universal and far more natural than written languages. The latter constitute a human invention. Thus, it should come as no surprise that written language makes use of some of the very same language skills that allow us to be speakers and hearers of our language.

A. How Writing Systems Represent Language

Writing systems (or orthographies) are symbol systems by which we are able to write spoken language. They "write" language by representing or "transcribing" the units of spoken language. Since most of the readers of this article will be interested in children who are having problems with an alphabetic writing system (English being a case in point), I focus on alphabets and on the English alphabet in particular. All writing systems represent units of a spoken language, but there are differences between writing systems and even between alphabets that turn on which type of linguistic units are being represented. Ideographies, such as American Indian petroglyphs or the universal set of road signs that a driver encounters in a daily commute, represent language at the level of ideas, and logographies such as the Chinese writing system and Japanese Kanji represent units called morphemes. Syllabaries such as Hebrew and Japanese Kana represent syllables. Alphabets represent units called phonemes. Each of the different types of writing systems makes different demands on the beginning reader because of the differences in the type of the unit they transcribe.

It is important that the would-be reader of a writing system have some appreciation of the existence of whatever units that writing system happens to transcribe. Otherwise, it will be difficult to understand how written words relate to their spoken language counterparts. Since alphabets represent phonemes, someone who wishes to learn how an alphabet functions should be sensitive to the fact that spoken language can be broken down into phonemes, the minimal units of sound that are referred to as consonants and vowels. Section VI presents evidence that this sensitivity, referred to as phoneme awareness, is a very important trait of successful beginning readers. It is also a major problem for many young children and for poor readers, in particular.

More precisely, the English alphabet is a less than perfect one. It does not provide the consistent

one-to-one mapping of letter to phonemes that one finds in Spanish or German, for example. Rather, it provides a ''deeper,'' more abstract level of representation that goes beyond phonemes and sounds to the morphemes and meanings of words. As such, it has been referred to as a morphophonological transcription because it combines the transcription of morphemes and phonemes. Morphophonological transcription corresponds not so much to the consonants and vowels that speakers and hearers think they pronounce and perceive as much as it does to the way theoretical linguistics assumes that words are abstractly represented in the ideal speaker–hearer's mental dictionary or lexicon. According to this view of the mental lexicon, words are represented in terms of the basic units of meaning that we refer to as morphemes as well as in terms of phonemes. When they produce or perceive language, speakers and hearers convert the morphophonological representations of the words in their lexicon to less abstract, phonetic representations by using an ordered series of phonological rules that alter, insert, or delete phonemes.

If a writing system correctly represents words in a deep manner that approximates the mental lexicon, it will sometimes fail to represent the phonetic representations with which we are most familiar. Witness the spellings of words in pairs such as ''*atom*'' vs ''*atomic*,'' ''*heal*'' vs ''*health*,'' and ''*relate*'' vs ''*relation*.'' In each of these pairs of words, the similar spelling of the base and derived form captures the relatedness of their meanings. However, the similar spelling comes at the cost of having a letter or letter sequence represent different phonemes in different words. Preservation of common roots and of common word ancestries is one of the reasons why the English vowel system is so complicated and one of the reasons why English uses nearly 120 spelling patterns for 40 phonemes. It is also the source of the notorious evil triplets, ''*to*''–''*two*''–''*too*'' and ''*their*''–''*there*''–''*they're*.'' The different spellings of these homonyms reflect their different meanings, the common pronunciation is what makes their usage so difficult. The important point to be remembered is that the English alphabet represents phonemes and morphemes and there is a certain trade-off between the two types of representation.

Why should English use a writing system that transcribes both phonemes and morphemes? One general benefit of systems that transcribe phonemes is that they are economical. The transcription of phonemes greatly reduces the number of individual characters that a child must learn to recognize and reproduce. Consider the ease of learning the 26 letters used in the English alphabet as opposed to learning the 2000–3000 characters needed to read a newspaper written in the Chinese logography. Aside from being economical, phoneme transcription is highly productive. It allows for a highly rule-governed relationship between written and spoken words. Knowledge of the rules that relate written words and spoken words rests on the rules that relate letter sequences to their pronunciation. This allows the reader to read not only highly familiar words but also less familiar ones such as ''skiff'' and even nonsense words such as ''ifts'' or ''polypluckable'' that are lawfully constructed. A skilled reader of the Chinese logography must have memorized thousands of distinct characters, and even then may encounter difficulty in reading a new word. On the other hand, skilled readers of English need know only a limited set of phoneme to grapheme correspondences and the phonological rules of their spoken language in order to decode most words (and any phonologically plausible nonwords such as ''bliggle'').

There is also a benefit to the English morphophonological system as opposed to the more transparent alphabetic systems used in Spanish and German. By transcribing a ''deep,'' relatively abstract level of phonological structure where units of meaning are represented, the English writing system helps convey cues to meaning as well as to sound. If one recognizes ''heal'' in ''health,'' ''atom'' in ''atomic,'' or ''relate'' in ''relation,'' this can facilitate the recovery of those words' meanings. Another advantage to the transcription of morphemes is that it can avoid the need to create different spelling patterns for people who speak with different accents. Were English to use a more shallow alphabet, speakers from Boston would spell ''cot'' and ''cart'' the same way, speakers from the South would spell ''pen'' and ''pin'' the same, and speakers from Brooklyn would spell ''oil'' and ''earl'' the same—imagine all the inconveniences this could cause. A final advantage of the English alphabet is that its morphophonological spelling can disambiguate homonyms. Indeed, the key to disentangling ''there,'' ''their,'' and ''they're'' depends on their respective meanings and the context in which they occur in both spoken and written language.

This is not to imply that there is anything inherently undesirable about reading a syllabary or a pure logography. Ultimately, the utility of a given orthography rests on the nature of the spoken language it transcribes. For example, a logography is appropriate for Chinese because it allows people to read the same

text even though they cannot understand each other's speech. Likewise, for Japanese, the Kana syllabaries are quite well suited to the approximately 100 syllables in the Japanese language. English, however, has a less profound dialectical variation than Chinese, and the English language employs more than 1000 syllables. Hence, an alphabet is appropriate, and it would be less efficient and even a disservice to present the English writing system otherwise. However, this will require that a child who is learning to read possess two things: language processing skills and phonological sophistication.

B. Phoneme Awareness: A Requirement of Alphabetic Systems

Consider that almost all normal children "know" spoken English when they start to read. If reading is a language skill, why is it that not every speaker of English automatically becomes a successful beginning reader? The answer to this question is that knowing spoken English is a necessary but not sufficient requirement for skilled reading. Would-be readers must go one step further than merely being a speaker/hearer of their language: They must be able to consciously analyze and manipulate the units that their writing system represents. For readers of an alphabet, this means that they must be aware of phonemes. Phoneme awareness, as first discussed by Mattingly and later developed by many others, is not something that we use in the normal activities of speaking and hearing. We use it in certain secondary language activities such as appreciating verse (i.e., alliteration), making jokes (i.e., "Where do you leave your dog? In a barking lot"), and talking in secret languages (i.e., pig Latin). Such activities require that we consciously compare and manipulate the consonants and vowels that comprise spoken words.

One problem with the term phoneme awareness is that it is often used interchangeably with several other terms, *phonemic awareness*, *phonological awareness*, *metalinguistic awareness*, and *linguistic awareness*. By using the term phoneme awareness (or phonemic awareness) we confine the issue to sensitivity about phonemes. Phonological awareness could also include sensitivity to syllables, morphemes, and the phonological rules that operate on them; linguistic awareness and metalinguistic awareness would further include sensitivity to syntax (i.e., grammar), semantics (i.e., meaning), and their rules. To date, awareness of phonemes has been most often studied and deficient phoneme awareness is a major factor in reading disorders.

C. Language Skills That Skilled Readers Use

Considerations about the way in which the English alphabet transcribes language offer one form of deductive evidence about the importance of spoken language skills to reading. A second source of evidence comes from studies of skilled readers. These studies show a clear involvement of certain spoken language processes in the skilled reading of words, sentences, and paragraphs. Furthermore, these studies have shown that reading is quite parasitic on spoken language processes and have inspired subsequent investigations that contrast good and poor beginning readers.

The question of whether or not written words must be recoded into some type of silent speech has been a topic in much of the research on the psychology of skilled reading. It has especially preoccupied those who study the processes that facilitate word recognition, (a.k.a. lexical access or word perception). In some circumstances, successful word recognition may not require silent speech. Some words may be directly perceived as visual units instead of being decoded into a string of phonemes. However, there is also clear evidence implicating at least some speech code involvement in word perception, making many psychologists favor models in which both phonetic and visual access occur in parallel. Some believe that access via the speech code or phonetic route may be most heavily used in the case of less frequent words and unfamiliar ones, and that the visual or whole word route is most important for very familiar words and words with irregular spelling patterns. Still others regard the phonetic route as playing an early, dominant role in all lexical access.

Regardless of how a word is recognized, its subsequent processing will involve the use of speech or phonological coding. It may not be necessary to recode print into a speech code in the process of gaining access to the mental lexicon. Lexical access could occur in terms of morphemes or syllables. At some level, however, phonological recoding clearly must occur; otherwise, reading phrases, sentences, and paragraphs would not be possible. This is because, from the point of word perception onward, the involvement of speech processes in reading is most clear. First, there is considerable evidence that temporary or working memory for written material involves recoding the

material into some kind of silent speech or phonological representation. This type of representation is used whether the task requires temporary memory for isolated letters, printed nonsense syllables, or printed words. In all these cases, both the nature of the errors that subjects make in recalling such material and the experimental manipulations that help or hinder their memory performance have indicated that a phonological representation is being used. That is, subjects are remembering the items in terms of the consonants, vowels, and syllables that form the name of each item rather than the visual shape of the letters, the shape of the words, etc. Furthermore, subjects appear to rely on phonological representation when they are required to comprehend sentences written in either alphabetic or logographic orthographies. This is one reason why we may observe such significantly high correlations between reading and listening comprehension across a variety of languages and orthographies, including English, Japanese, and Chinese.

Thus, it is apparent that regardless of the way in which the reader recognizes each word, the processes involved in reading sentences and paragraphs place certain obvious demands on temporary memory, and temporary memory for language appears to make use of phonological representation in short-term memory. In Section V, it will be shown that problems with the use of phonological representation in working memory are often found among poor beginning readers.

IV. TWO TYPES OF LANGUAGE SKILLS THAT ARE ESSENTIAL TO BEGINNING READERS

What skills does a child need in order to learn to read well? Obviously, would-be readers need to possess the visual skills that allow them to differentiate and remember various letter shapes, but this is not a very prevalent source of difficulty. The deficits that tend to trouble disabled readers are classified into two areas of language skill: language processing and phoneme awareness. Readers also need language processing skills in order to be able to perceive and recognize their teacher's spoken words and sentences as well as to combine written words into phrases, sentences, and paragraphs, as discussed in Section III. They need to possess phoneme awareness if they are to make any real sense of the way in which the alphabet works.

In principle, beginning readers should possess language processing skills at four different levels. First, they need the speech perception skills that make it possible to distinguish the words of their vocabulary so that they can hear the difference between "cat" and "hat," for example. They also need vocabulary skills to understand what words mean and morphological skills to understand how words are built from roots, suffixes, and prefixes (although they need not necessarily possess fully mature morphophonological representations in their lexicons since the experience of reading, in and of itself, serves to stimulate and further development). Beginning readers should also have an adequate working memory for language since this is not only critical to skilled readers but also supports retention of sufficient words to understand the sentences and instructions that their teacher is saying. Finally, they should be able to recover the syntactic and semantic structure of phrases and sentences (although their mastery of these aspects of language, like their mastery of phonology, may be facilitated by the experience of reading).

Language processing skills, however, are only one aspect of the language skills needed by would-be readers of English. As noted in Section III, successful readers need to be sensitive to phonemes; otherwise, the alphabet will make no sense as a transcription of spoken English. The achievement of phoneme awareness proves an initial obstacle for most young children and an enduring one for those who become disabled readers.

Why should this be the case? One reason is that phonemes are quite abstract units of language, more so than either words or syllables. As noted by Alvin Liberman and colleagues at Haskins Laboratories, humans reflexively and unconsciously perceive phonemes when listening to the speech stream because they possess a neurophysiology uniquely and elegantly adapted to that purpose. However, phonemes cannot be mechanically separated like beads on a string. Most of them cannot be produced in isolation as can syllables and words. This was a groundbreaking discovery of the speech research team at Haskins Laboratories, headed by A. Liberman and Cooper. There are some very interesting indications that infants may distinguish phonemes and preschool-aged children most certainly employ phonological representation when holding linguistic material in short-term memory. However, these are automatic, tacit aspects of language processing ability. The child who tacitly knows his or her language well enough to hear that "*cat*" and "*hat*" are different words may perceive and remember phonemes while being blissfully unaware of the fact that it is the initial phoneme that differs in "*cat*" and "*hat*." Young children can be as unaware of

phonemes as you and I are unaware of the rods and cones that allow us to see.

The problem with using written language is that the tacit perception and remembering of phonemes must become an explicit ability to analyze and manipulate. Successful beginning readers must know not only the difference between words such as "*cat*" and "*hat*," but also how to hold these words in memory. They must also possess the awareness of phonemes that allows them to appreciate the fact that "*cat*" and "*hat*" differ in one phoneme, namely the first, and share a final phoneme that is the initial one in "*top*." Otherwise, the alphabet will remain a mystery to them, and its virtues will be unrealized.

V. DEFICIENT LANGUAGE PROCESSING AS A CAUSATIVE FACTOR

Section II mentioned several studies that demonstrate how good and poor readers differ in their performance on certain linguistic tasks but not in their performance on comparably demanding nonlinguistic ones. That evidence receives further support from a consideration of the frequency of reading difficulties in children with various sorts of handicaps. Children deficient in visual–perceptual and/or visual–motor skills do not encounter reading difficulty any more frequently than matched controls, but speech- and language-retarded children encounter reading problems at least six times more often than do controls. Deaf individuals may have the greatest difficulties of all. However, we can ask whether there is a more fine-grained analysis of the language problems found among poor readers. Are some areas of language skill more problematic than others? Considered broadly, the language disabilities that tend to be found among poor beginning readers can be classified into two categories of language processing and phoneme awareness. Next, I examine the evidence within each area.

Without spoken English, there would be nothing for the English orthography to transcribe; the well-known difficulties of prelingually deaf readers attest to the importance of spoken language skills for successful reading. However, deaf children are not the only ones for whom deficient language abilities are a cause of reading problems. As discussed later, many of the hearing children who are poor readers also suffer from spoken language problems. Although their problems are considerably subtler than those of the deaf, they are no less critical.

Since the mid-1970s, there has been considerable activity in the psychology of early reading problems, and many studies have uncovered some link between difficulties in learning to read and difficulties with some aspect of spoken language processing. This connection is clearly established beyond question, not only in English but also in Swedish, Hebrew, and Chinese. In the case of English, there have also been considerable attempts to more precisely specify the nature of the language problems that typify poor beginning readers. These attempts can be organized in terms of the four levels of language processing that were identified in Section IV as being important to beginning reading: speech perception, vocabulary skills, linguistic short-term memory, and syntax and semantics.

A. Speech Perception

The possibility that some aspect of speech perception might be a special problem for poor readers has come from a variety of sources. At least a subgroup of poor readers may have phonological categories that are more prone to disruption during perception in noise or gating conditions that present parts of words. For example, Brady and colleagues report that poor readers are less able to identify spoken words under a "noisy" listening condition. They also present evidence that this lack of ability is not simply a hearing problem: The poor readers had audiometry scores in the normal ranges and were just as capable as good readers when the stimuli were environmental sounds instead of speech sounds. Their problem was limited to the perception of speech.

Other studies have investigated the categorical perception of synthetic speech stimuli by good and poor beginning readers. These studies report that categorical perception is evident in both groups of subjects, but a subgroup of poor readers either fail to meet the level of intercategory discrimination predicted on the basis of their identification responses or fail to give as consistent a pattern of identification responses. These findings have also been interpreted as reflecting deficient speech perception processes on the part of poor readers. Some debate surrounds the possibility that the speech perception difficulties of poor readers may be explained by a more general problem with the perception of rapidly changing auditory events. Whatever the basis of the impairment, the point is that when listening conditions are noisy or otherwise degraded, at least some poor readers do not perceive speech as well as do good readers.

B. Vocabulary Skills

There are several indications that reading ability is related to vocabulary skills, depending on how reading ability is measured and on what type of vocabulary skill is at issue. Recognition vocabulary tests require the child to point to a picture that illustrates a word. These sometimes relate to early reading ability, especially if measured in terms of comprehension. Naming or productive vocabulary tests require the child to produce the word that a picture illustrates and these are more clearly linked to both decoding and comprehension. Tests of continuous naming (sometimes called rapid automatized naming) require children to name a series of repeating objects, letters, or colors. These tests have demonstrated that children who are poor readers take longer to name the series than do good readers.

A causal link between naming problems and reading problems is indicated by the discovery that performance on naming tests can predict future reading ability. Problems with rapid letter recognition and with naming also play a more prolonged role in the reading of severely impaired readers. Since letter naming predicts future reading ability more consistently than current reading ability predicts future letter naming ability, it is likely that something above and beyond a lack of educational or home literacy experience is preventing reading impaired children from naming the letter names as fast as other children can. That "something" may entail problems with productive vocabulary skills.

Another pertinent piece of evidence about the vocabulary problems of poor readers is that children who perform poorly on a decoding test are particularly prone to difficulties in producing low-frequency and polysyllabic names. Such children may possess less phonologically complete lexical representations than good readers. However, because speech rate may not reliably predict naming problems, researchers such as Wolf and Bowers have come to regard difficulties with naming speed as reflections of some deficiencies in the precision and timing of rapid processes.

C. Working Memory

The observation that poor readers perform worse than good readers on a variety of short-term memory tests has given rise to one of the more fruitful lines of research in the field. It has often been noted that poor readers tend to perform worse on the digit span test and are deficient in their ability to recall ordered strings of letters, nonsense syllables, or words, whether the stimuli are presented by ear or by eye. Additionally, poor readers may not recall the words of spoken sentences as accurately as do good readers. Evidence that these differences are not merely a consequence of differences in reading ability comes from longitudinal studies that have shown that problems with working memory can precede the attainment of reading ability and may actually serve to presage future reading problems.

To explain this pattern of results, researchers employed the aforementioned investigations into short-term memory (namely the research that indicated that linguistic materials such as letters and words are held in short-term memory through use of phonological representation, see Section III). Observations about the errors that poor readers make and the conditions under which they succeed or fail have led to the postulation that poor readers—and children who are likely to become poor readers—are for some reason less able to use phoneme and syllable structure as a means of holding material in short-term memory. They do not avoid phonological representation altogether. They merely use it less proficiently, a problem that may persist even into adulthood.

D. Syntax and Semantics

Do poor readers have a problem with the syntax (the grammar) and the semantics (the meaning) of language in addition to their problems with speech perception, vocabulary, and the use of phonological structure in short-term memory? The observation that poor readers cannot repeat sentences as well as good readers has prompted some obvious questions regarding these two higher level language skills and their involvement in reading problems. However, researchers have found no conclusive evidence supporting the notion that syntactic and semantic problems arise as a direct consequence of reading disability. Although there is an accumulating body of evidence that good and poor readers differ in the ability to both repeat and comprehend spoken sentences, these problems seem to reflect difficulties with using phonological coding in working memory rather than a form of agrammatism. As discussed by Shankweiler and colleagues, it appears that poor readers are no less sensitive to syntactic structure than good readers, but they fail to understand because they cannot hold an adequate representation of the sentence in short-term memory.

Another higher level language task that proves problematic for poor readers is the cloze task, in which subjects must supply a missing word. My colleagues and I have found that when we ask children to choose among derivational forms that complete a sentence, as in "He was blinded by the…: bright, brighten, brightly, brightness," poor readers perform worse than normal readers. Moreover, this is true whether they are reading the sentences or hearing them aloud, and whether the word that fills in the blank is a real word or an appropriately derived nonsense word such as "froodness." Here, the poor readers' difficulty in distinguishing among noun-, verb-, adverb-, and adjective-forming suffixes may be attributed to a problem with derivational morphology rather than a syntactic problem. Given the discussion in Section III regarding the transcription of morphemes by English orthography, the fact that reading problems are linked to problems with morphology should come as no surprise. What we find particularly striking in our own research is the fact that morphological skills in both written and spoken language relate to both the comprehension and decoding of written language.

Although it is clear that poor readers do have sentence comprehension problems, there is little reason to think that their difficulties reflect a problem with the syntax of language. Problems with working memory morphology seem a more likely source of the difficulty. Moreover, such syntactic differences that have been evident among good and poor readers are relatively subtle, with poor readers performing only as well as children younger than the good readers. These syntactic problems could be either the cause of reading difficulty or a consequence of different amounts of reading experience. Regarding the question of semantic impairments among poor readers, there is no reason to presume any real deviance exists. If anything, poor readers place greater reliance on semantic context and semantic representation than do good readers, perhaps to compensate for their other language deficits.

VI. DEFICIENT PHONEME AWARENESS AS A CAUSATIVE FACTOR

Inadequacies in phonetic perception, naming ability, and working memory for language are only part of the story behind reading failure. As noted in Section III, successful readers of the alphabet must go beyond these tacit language processing abilities to achieve an explicit awareness of phonemes. Here, I discuss studies concerned with the pertinence of phonological sophistication to success in learning to read an alphabetic orthography.

A. Evidence from the Analysis of Reading Errors

The errors that a person makes can be informative about the difficulties that produce those errors, and oral reading errors are a particularly important source of evidence about the cause of reading problems. I. Liberman and colleagues' consideration of these errors has shown that a lack of phoneme awareness is responsible for making beginning reading difficult for all young children, including dyslexic ones. Such errors do not tend to involve visual confusions and letter or sequence reversals to any appreciable degree. Instead, they reflect a problem with recovering and integrating the phonological information that letter sequences convey. Hence, children often tend to correctly pronounce the first letter in a word but experience increasing difficulty with subsequent letters and exhibit a particular problem with vowels as opposed to consonants. These decoding problems stem from a problem with understanding how the spoken word is transcribed by a string of letters representing the sequence of phonemes that form the word. In other words, they stem from deficient phoneme awareness.

B. Evidence from Tasks That Measure Awareness Directly

Most of the studies linking reading ability to phoneme awareness have concerned tasks that measure awareness directly. These tasks require children to play language games that manipulate the phonemes within a word in one way or another: counting them, deleting them, choosing words that contain the same phoneme, etc. The use of these tasks has revealed that phoneme awareness develops later than phonetic perception and the use of phonological representation, and it remains a chronic problem for those individuals who are poor readers. Research has shown that the awareness of phonemes and syllables develops considerably between the ages of 4 and 7. However, a child's phoneme awareness undergoes a slower and less natural development than the awareness of syllables. Both types of awareness markedly improve at just the age when children are learning to read, but phoneme awareness is more critically dependent on instruction in an alphabetic orthography.

Numerous experiments involving widely diverse subjects, school systems, and measurement devices have shown a strong positive correlation between a lack of awareness about phonemes and current problems in learning to read. There is also evidence that lack of awareness about syllables and such subsyllabic units as phonemes, onsets, and rhymes is associated with reading disability. Finally, studies of kindergarten children provide evidence that problems with phoneme segmentation, onset-rhyme segmentation, and syllable segmentation can all presage future reading difficulty. For example, we found that 85% of a population of kindergarten children who went on to become good readers in the first grade correctly counted the number of syllables in spoken words, whereas only 17% of the future poor readers could do so. Stanovich and colleagues found that a kindergarten battery of tests that assessed phoneme awareness accounted for 66% of the variance in children's first-grade reading ability.

C. Morpheme Awareness: Another Problem for Poor Readers

Although deficient phoneme awareness is the most reliable attribute of disabled reading in the early elementary grades, deficient morpheme awareness begins to play an increasingly important role as children reach the later grades. Several researchers have shown that disabled readers in later grades have problems with the morphological aspects of both written and spoken language. The difficulties of the disabled readers are seen in spelling errors, in performance on cloze tasks, and in vocabulary exercises such as defining a word or giving its derivational forms. The difficulties are linked to poor phoneme awareness and poor vocabulary, but we have found that, after the third grade, they play a role of their own when phoneme awareness and vocabulary are controlled. The link between morphological abilities and reading ability should come as no surprise given the morphophonological nature of the English alphabet (see Section III).

VII. EXPLANATIONS OF THE LANGUAGE PROBLEM: NEUROLOGICAL AND EXPERIENTIAL

Both theoretical and practical matters are at stake when we ask why poor readers are lacking in certain language skills. Much of the available literature on the causes of language processing problems is centered on what can be referred to as neurological causes. These involve factors that are somehow intrinsic to the child, owing to his or her brain structure. Problems with phoneme awareness have also been explained in these terms, but it has been more common to attribute problems in this area to an insufficient exposure to instruction in the use of an alphabetic writing system.

A. Neurological Accounts

Why should a neurological account be considered as a cause of reading disorder? Perhaps the strongest reason is that reading disability appears to have a genetic basis. It consistently runs in certain families and has been linked to certain autosomal-recessive chromosomal abnormalities. In these families, the nonaffected members of the family tend to show a higher incidence of language and speech problems. It has a higher concordance rate in identical twins.

Five neuropsychological theories are representative of the types of constitutional explanations currently favored. They are offered as a representative but by no means exhaustive summary of the literature in this area and need not be taken as mutually exclusive. In fact, current trends in research lean toward an emphasis on structural and functional abnormalities in the left cerebral hemisphere. This corresponds well with the language disabilities described previously.

Orton offered one of the first neuropsychological accounts in his theory of strephosymbolia. In this theory, mirror reversals (which Orton erroneously thought to be the predominant symptom of reading disability) were attributed to insufficiently developed cerebral dominance. This insufficiency further manifests itself, according to Orton, in such abnormalities of lateral preference as mixed dominance. Wealthy in its own heuristic value, Orton's theory inspired considerable research as well as criticism. On the one hand, it has been falsified by findings that reading difficulty is not associated with any particular pattern of handedness, eyedness, or footedness. It has also motivated a number of studies of cerebral lateralization for language processing among good and poor readers, though with mixed results. Some such studies have provided evidence that poor readers show a reversal of the normal anatomical asymmetries between the left and right hemispheres, in conjunction with a lower verbal IQ. Others have reported that poor readers may show a lack of cerebral dominance for language processing. To date, research has yielded only a weak association between abnormal

lateralization and poor reading since not all individuals who display abnormal cerebral lateralization are poor readers. It must also be recognized that several other studies have failed to find that good and poor readers differ in the extent or direction of the lateralization for language processing.

The data are not particularly supportive of Orton's theory about incomplete cerebral dominance as an explanation of reading difficulty. However, Orton may still have been correct in the spirit, if not the letter, of his explanation. If we accept the left hemisphere to be the mediator of language processing (in the majority of individuals), and if we accept that language processes are deficient among poor readers, then certainly we may suppose that some anatomical or neurochemical abnormality of the left hemisphere is involved in early reading difficulty. This is the position taken by three contemporary researchers: Geschwind and Galaburda in their theory of cerebral lateralization; Pugh and colleagues in their emphasis on the integrity of posterior left hemisphere circuits; and Temple and colleagues, who focus on myelination and functional integrity within the left hemisphere's temporoparietal regions. Geschwind and Galaburda attempted to explain developmental dyslexia as a consequence of slowed development of the left hemisphere, owing early exposure to testosterone. They point to the greater instance of reading problems in males and evidence from a variety of sources, including autopsies of the brains of several adult dyslexics and population studies that indicate a certain profile of disabilities (language problems), abilities (spatial skills), and other traits (left handedness and allergies) that distinguish the population of dyslexics from the general population. However, some evidence, challenges this theory. There are claims that the ratio of male to female dyslexics is actually quite close to 1:1 and claims that handedness, immune disorders, and dyslexia are not always correlated.

An emphasis on the integrity of the left hemisphere is shared by recent functional magnetic regonance imaging and DTI (diffusion tensor imaging) studies of dyslexic individuals. Based on findings of reduced activation and reduced functional connectivity during reading tasks, Pugh and colleagues in the Yale–Haskins reading group suggest that fluent word reading is related to the integrity of the dorsal (temporal parietal) circuit and the ventral (occipital–temporal) circuit of the left hemisphere. As a compensatory consequence, disabled readers demonstrate heightened reliance on left inferior frontal and right hemisphere posterior regions. The initial cause of the disabled readers' problems is said to lie in a disruption of the integrity of the temporoparietal system, although its genetic or teratogenic basis remains unspecified. As a consequence of this disruption, phonological and lexical semantic features of words are not well organized and integrated. This slows the acquisition of rule-based analyses of the relations between orthography, phonology, morphology, and meaning and hinders basic decoding and word analysis. As a consequence, fluent word identification by the left occipitotemporal region suffers and other areas (left frontal and right posterior circuits) take over inappropriately.

Temple and colleagues have a related but slightly different perspective. One observation concerned the use of diffusion tensor imaging to study the integrity of white matter in dyslexic individuals. This relatively new technique, which measures the diffusion of water molecules, suggests that dyslexic adults show evidence of decreased myelination within anterior-posterior circuits of the left hemisphere, and that the extent of decrease correlates with measures of decoding ability. Thus, there seems to be impairment in the strength of communication between cortical areas. These researchers have also documented that dyslexic children show a disruption in the left temporoparietal response to letter rhyming and matching tasks, consistent with the observations of Pugh and colleagues. They have also shown that intensive training may help reduce this disruption.

A fifth neuropsychological account that has received attention in the literature owes to Tallal, who regards the phonological difficulties of poor readers as a symptom of an underlying auditory temporal processing deficit. It has been suggested that an inability to recognize the very short-duration sounds of speech is at the root of some poor readers' phonological difficulties. Originally an account of the perceptual deficits of dysphasic children, Tallal's account states that the left hemisphere is specialized for the rapid auditory temporal processing that is essential to speech processing and that the phonological deficits seen among some dysphasic children and some dyslexic children are due to left hemisphere-based deficits in auditory temporal processing. Her theory draws on several forms of results, predominantly on studies of dysphasic children but also on some research involving aphasic adults and reading impaired children. She and her colleagues have shown that some spoken language impaired children show deficits in performance on (1) discrimination and temporal order judgments of long versus short stimuli separated by long versus short

intervals and (2) in performance in identifying synthetic speech in which the relevant cues involve rapid changes in acoustic spectra. They have developed training programs that give experience with enhanced speech and have shown that these improve the language skills of some language learning impaired children.

The rapid temporal processing approach is controversial. On the one hand, it seems consistent with evidence that dyslexics have a defect in the magnocellular system (see Section II) responsible for temporal contrast sensitivity and temporal order resolution in visual stimuli as well as auditory ones. On the other-hand, it finds a strong and compelling critic in the research of Studdert-Kennedy and Mody, who point out that the errors that Tallal ascribes to poor temporal judgment reflect problems with rapidly identifying similar stimuli (i.e., naming problems) rather than problems with temporal order per se. They also note that certain findings about the processing of nonspeech stimuli fail to support the contention that the left hemisphere is specialized for rapid temporal processing as opposed to language processing. Perhaps most compelling is their result involving a group of impaired readers in the second grade who were selected on the basis of having made many errors in Tallal's tonal order judgment task. The children who showed problems with tonal order judgment were impaired, but only when the stimuli were highly similar pairs of syllables. Moreover, although the children had problems with discriminating similar speech sounds (i.e. "*ba*" and "*da*") their problems did not extend to nonspeech analogs of the rapidly changing parts of the difficult syllables, nor did they extend to another speech task that involved brief transitional cues. Thus, Mody and Studdert-Kennedy conclude that poor readers' problems with speech perception and their diminished ability to access speech codes have nothing to do with auditory temporal processing, in general, so much as with phonological skills. The problems appear to be domain specific and phonological rather than general and auditory.

B. Experiential Accounts

Both genetic and environmental influences can factor into reading difficulties. On the one hand, there are clearly heritable aspects of reading disability. Disruptions of neurological integrity seem to prevail in the left hemispheres of reading disabled individuals. However, poor reading and low verbal intelligence also tend to be associated with low socioeconomic status (SES) and large family size. By the time they are in kindergarten, children in lower SES families tend to have weaker spoken language skills and weaker phonological awareness skills, both of which place them at risk for reading problems in the future. Experience is no doubt important to the child's development of the language processing skills involved in speech perception, vocabulary, etc., but the role of the experiential environment in poor readers' problems with speech perception is only beginning to receive attention and remains a topic for future research. However, there is a wealth of evidence about the role of the environment—specifically the educational environment—in the development of phoneme awareness.

Phoneme awareness is a cognitive skill of sorts and, as such, must surely demand the attainment of a certain degree of intellectual maturity. However, phoneme awareness undergoes a spurt when children begin formal instruction in learning to read. For example, American children undergo the spurt earlier than German ones due to the fact that they receive literacy instruction in kindergarten, whereas literacy instruction in Germany is delayed until the first grade. Likewise, illiterate adults are unable to manipulate the phonetic structure of spoken words. It seems that awareness of phonemes is enhanced by (and perhaps dependent on) reading instruction methods that direct the child's attention to the phonetic structure of words. However, inadequate experience alone cannot globally account for some children's failure to achieve phoneme awareness. This is aptly shown by Bryant and colleagues' finding that among a group of 6-year-old skilled readers and 10-year-old disabled readers who were matched for reading ability, the disabled readers performed significantly worse on a phoneme awareness task, even though they would be expected to have had even more reading instruction than the younger children. Here, it could be argued that some constitutional factor limited the disabled readers' ability to profit from instruction and thus limited their attainment of phonological sophistication. This problem with achieving phoneme awareness is a primary trait of individuals who are familial dyslexics. It may relate to a more basic problem with using phonological representations as discussed by Elbro and colleagues, for example.

VIII. SUMMARY AND CONCLUDING REMARKS

The International Dyslexia Association defines dyslexia as a neurologically based, often familial disorder

that interferes with the acquisition of language. It varies in degrees of severity but manifests itself in difficulties with receptive and expressive language, including phonological processing, reading, writing, spelling, handwriting, and sometimes arithmetic. Dyslexia is not the result of a lack of motivation, sensory impairment, inadequate instructional, or environmental opportunities, but it may occur together with these conditions. Although dyslexia persists through life, individuals with dyslexia frequently respond successfully to timely and appropriate intervention.

This article attempted to give substance to this definition by proceeding from a consideration of the importance of certain language skills to reading, to a survey of evidence that links problems with these language skills to early reading disability, and to a consideration of some plausible origins of these problems. By way of a conclusion, some generalizations are now offered.

A. Conceptualization of the Problem

The literature on the relation between language processing skills and reading problems indicates that poor readers—and children who are likely to become poor readers—tend to have problems with phoneme awareness and also with three aspects of language processing skill: speech perception under difficult listening conditions; vocabulary, especially when it is measured in terms of naming ability; and using a phonological representation in linguistic short-term memory. They also possess less well-integrated neural structures in the left hemisphere. There is a logical interrelation between the behavioral difficulties of poor readers because they all involve phonological processes that concern the sound pattern of language. Hence, we may speculate that the cause of many instances of reading disability involves a certain dysfunction within the phonological system—a phonological core deficit.

This article focused primarily on the language problems of reading disabled children in general, and there has been no attempt to differentiate between dyslexic children and so-called garden variety poor readers. Recent reviews have seriously discredited the use of a discrepancy between IQ and reading ability as a definitive characteristic that sets dyslexic children and their difficulties apart from other poor readers and their difficulties. From the perspective of current research, the two groups of children seem to form a continuous distribution. Both have problems with the language skills reviewed in Sections V and VI, and the phonological core deficit seems just as characteristic of dyslexic children as of garden variety poor readers. To date, the only language measure that distinguishes the two groups of children is receptive vocabulary, which may account for the lack of consensus about the role of receptive vocabulary problems in reading, as discussed in Section V. All other differences between the groups seem to involve real-world knowledge and strategic abilities: Generally, dyslexic children possess superior skills in these nonlinguistic areas, hence the discrepancy between their IQ and their reading ability, whereas the garden variety poor readers may show a developmental delay in these skills as well as in their phonological ones.

Future research can help us to better approximate a more accurate description of the phonological core deficit and its role in the reading problems of different groups of children. For example, it may help us contrast children within each group, informing us as to whether there are subtypes in terms of different problems or different clusters of problems. In this regard it is interesting to note Pennington and colleagues' observation that the language problems of adults from dyslexic families tend to be restricted to phoneme awareness, whereas those of individuals from nondyslexic families demonstrate problems with linguistic short-term memory as well as problems with phoneme awareness. In the future, researchers will surely attempt to determine whether this distinction applies to the population of young children who have reading problems as well as it applies to that of adult disabled readers.

Future researchers may also draw a closer link between the neurological problems currently being identified and the language deficiencies of poor readers. The strongest consensus of current neuropsychological research is that the reading problems of disabled readers are somehow linked to the integrity of structures and systems in the left cerebral hemisphere. Current hypotheses range from considerations of the integrity of systems, especially the left posterior systems, to considerations of the connections among systems, especially anterior and posterior systems. Linking these to behavioral deficits and effective remediation are important goals as well.

B. Practical Applications and Implications for Future Research

One of the practical benefits of the research described in this article is its potential for suggesting ways of

predicting and remediating early reading difficulty. One obvious benefit concerns screening devices for identifying children at risk for early reading problems. Such phonological processing skills as the ability to rapidly access the names of objects and the ability to make effective use of phonological representation in short-term memory have already proven effective kindergarten predictors of first-grade reading success. It is the task of future research to consider other tests of speech perception and tests of sentence comprehension that place special demands on short-term memory for language. It is also important for future studies to address the very practical matter of how to administer such tests to groups of children. To date, the studies that have successfully predicted future reading problems have tediously involved two or more sessions of individual testing—hardly practical for large-scale use in public school systems.

The research surveyed in this article may also be of interest to those who are concerned with the remediation of reading problems. As we begin to identify the linguistic problems associated with specific reading difficulty, and to refine their causes, we should also be able to develop more effective procedures for their remediation.

Certainly the brightest prospects for remediation are offered by research that has shown that various types of training can facilitate phoneme awareness. The best favor we can do for all children is to promote their phoneme awareness so that we may let them in on the secrets of the alphabetic principle as early as possible. Some very interesting and very practical advice on how to facilitate phoneme awareness is currently available from researchers such as Liberman, Blachman, Torgesen, and Bradley and colleagues. There exist a variety of word games, nursery rhymes, and other prereading activities that can help nurture a child's awareness of the way in which words break down into phonemes. Such activities will undoubtedly pave the way for phonics-oriented methods of instruction obviously favored by current research and so obviously in keeping with this article's focus on the importance of phoneme awareness in early reading.

Receptive Field

RAJESH P. N. RAO
University of Washington

GLOSSARY

classical receptive field The region of sensory space that activates a given neuron.

color-opponent receptive field A type of center-surround receptive field characterizing a cell that increases its response when light of a particular wavelength (e.g., red) is turned on in the center, and decreases its response when light of a different wavelength (e.g., green) is turned on in the surrounding region.

Hebbian learning An algorithm for modifying the connection between two neurons in proportion to the correlations between the activity of the input neuron and the output neuron.

nonclassical receptive field The region of sensory space surrounding the classical receptive field of a neuron that allows stimuli placed within it to modulate the responses of the neuron to stimuli placed within the classical receptive field.

"on"-center, "off"-surround receptive field A type of receptive field characterizing a cell that responds best to a circular stimulus being turned on in the center of the cell's activating region and an annular stimulus being turned off in the surrounding region.

oriented receptive field A receptive field whose structure is oriented in at least two of its stimulus dimensions, for example, x and y spatial coordinates, space and time, or frequency and time. Cells with oriented receptive fields enable detection of features such as oriented edges, motion in a particular direction, or auditory features exhibiting increasing or decreasing frequencies.

spectrotemporal receptive field Receptive field of an auditory neuron that depicts the response of the neuron as a function of sound frequency and time.

The receptive field of a neuron is traditionally defined as the region of sensory space whose stimulation influences the response of the neuron. Recent definitions also include the specific properties of the stimulus that generate a strong response in addition to the region of sensory space causing the response. By mapping the receptive field of a neuron, one obtains crucial insights into the role that the neuron plays in transforming sensory information into perceptually useful quantities. This article reviews methods for mapping receptive fields, the types of receptive fields found in visual, auditory, somatosensory, olfactory, and gustatory neurons, modulation of these classical receptive field responses by stimulation of surrounding regions and by attention, plasticity of receptive fields, and computational models for receptive field development.

I. MAPPING RECEPTIVE FIELDS

A. Traditional Mapping Techniques

The notion of receptive fields was first explored systematically in the visual system by Hartline, Kuffler, Barlow, and Hubel and Wiesel in the 1940s, 1950s, and 1960s. To determine the receptive field of a sensory neuron, one probes the responsiveness of the neuron by presenting the animal with specific stimuli. For example, to determine the receptive field of a retinal ganglion cell in an anesthetized cat, the eyes of the cat are focused on a screen and spots of light are projected for brief durations at different spatial locations on the

screen. The responses of the retinal cell are recorded using a microelectrode. Spots flashed within a restricted location on the screen may increase or decrease the firing rate of the cell. The receptive field can thus be mapped by determining all areas on the screen that influence the firing rate of the cell either by increasing it or by decreasing it. Figure 1 illustrates this mapping procedure for retinal ganglion cells.

B. Mapping by Reverse Correlation

Recent methods for receptive field mapping are based on using white noise stimuli and reverse correlation analysis (borrowed from linear systems theory) to determine receptive field properties of a neuron in both space and time. For example, to map receptive fields in primary visual cortex, the stimuli used consist of sequences of small bright or dark bars whose orientation matches the preferred orientation of the recorded neuron. The bars are flashed one after another at random locations on a uniformly gray screen. The contrast of each bar (bright or dark) is chosen randomly and a given randomized sequence contains bright and dark bars presented once at each discrete screen location. The spike train of the neuron is recorded for each randomized sequence of bar stimuli. For each spike, the stimuli that occurred a brief period of time (typically a few hundred milliseconds) before that spike are summed, adding 1 or -1 at location (X, Y) and time T if the stimulus at time T before the spike contained a bright or dark bar at location (X, Y). This process is repeated for 20–40 random stimulus sequences and the resulting summated stimulus is divided by the total number of spikes to obtain the average spatiotemporal stimulus profile that causes the given neuron to spike. This spatiotemporal average is known as the space–time receptive field of the neuron. The value at (X, Y, T) in the space–time receptive field map represents the contribution made to the generation of a spike by a stimulus presented T milliseconds ago at spatial position (X, Y). Reverse correlation analysis thus allows one to determine the size, shape, and dynamics of a neuron's receptive field in a quantitative fashion, assuming that the relationship between the input stimulus and the response of the neuron is linear. Figure 2 depicts the process of reverse correlation for a neuron in cat visual cortex.

II. VISUAL RECEPTIVE FIELDS

A. Retina

Visual information reaching the eye is first processed by the circuitry of the retina. The output of the retina is conveyed to the lateral geniculate nucleus by the axons

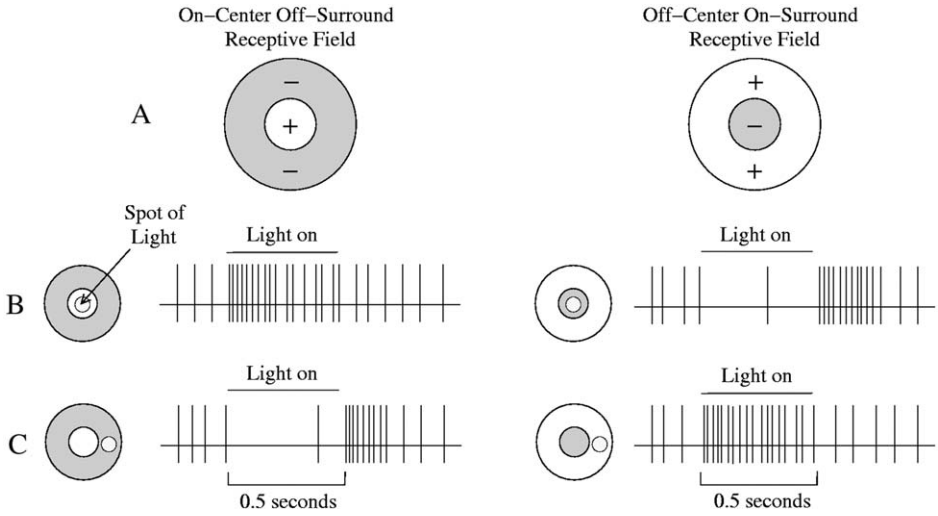

Figure 1 Mapping a receptive field. (A) An "on"-center "off"-surround receptive field (left) and an "off"-center "on"-surround receptive field (right) in the retina. These receptive fields are mapped by determining all areas on the screen that influence the firing rate of the cell either by increasing it or by decreasing it. Spots flashed within a restricted location on the retina increase or decrease the firing rate depending on the location of the spot. (B) "On"-center refers to an increase in the firing rate when a spot of light is turned on in the center (left). "Off"-center refers to a decrease in the rate when the spot is turned on in the center (right). Note that in the latter case, the firing rate also increases when the spot is turned off. (C) "Off"- and "on"-surround refer respectively to a decrease or increase in the rate when a spot of light is turned on in the region surrounding the center of the receptive field (after Nicholls *et al.*, 1992).

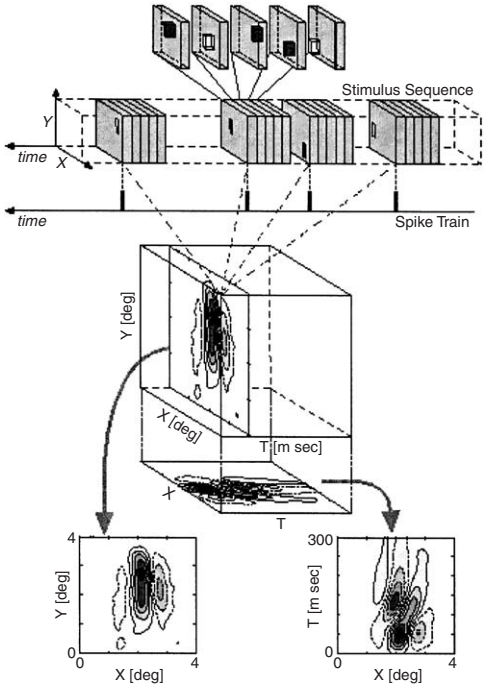

Figure 2 Using reverse correlation to map receptive fields. The top of the figure represents a segment of a randomized stimulus sequence that can be thought of as a time series of two-dimensional spatial patterns, as shown by a collection of square "slabs" stacked from right to left. These slabs are shown separately at the top in an exploded view for five consecutive stimuli. Each slab represents a single stimulus presentation containing a bar stimulus that is either bright or dark and flashed on an otherwise uniformly gray screen somewhere within the square region. Some of these stimuli fall on excitatory regions of the receptive field and spikes are elicited. A spike train is depicted below the stimulus sequence. For each spike generated, we look back in time (rightward in the figure, shaded cube) for stimuli that are likely to have elicited the spike, starting at the instant of spike occurrence. The stimuli in the shaded cubes are summed for all spikes generated in a stimulus sequence, counting each bright bar stimulus as 1, each dark bar as -1, and the background as 0. This produces the average stimulus profile (after division by the number of cubes added) that elicits a spike. The average profile is depicted within a cube shown in the center. An element within this cube at (X, Y, T) represents the contribution that a stimulus makes to the generation of a spike, i.e., a stimulus presented T milliseconds ago at spatial position (X, Y) contributes to spike generation by the amount indicated by the value at (X, Y, T) in the averaged cube. A cross section at a given T is a spatial map of the receptive field at that instant, as shown at the bottom left. A cross section along the Y dimension gives the space–time $(X–T)$ receptive field, as depicted by the inset at the bottom right (reproduced with permission from Ohzawa *et al.*, 1996, Encoding of binocular disparity by simple cells in the cat's visual cortex. *J. Neurophysiol.* **75,** 1779–1805).

of ganglion cells, which form the optic nerve. The receptive fields of ganglion cells provide insight into the type of processing and transformations occurring in the retina. The typical receptive field of a ganglion cell is a circular area on the retina, consisting of a central region and an annular surrounding region. Some cells respond best when a bright spot of light is shone in the center of the receptive field surrounded by darkness: These cells are known as "on"-center cells. Shining light in the annular surround region of these cells decreases their response. Other cells decrease their activity or stop firing when light is shone in the central area but fire vigorously when the light is turned off: These cells are known as "off"-center cells. "Off"-center cells typically have "on"-surrounds (i.e., they increase their response when light is turned on in the annular surrounding region of their receptive field) (Fig. 1). Both types of cells do not respond at all or respond weakly to uniform illumination covering both the center and the surround, as expected from their antagonistic receptive field structure. In addition, the size of the receptive fields increases as one progresses from the center of the retina (fovea or area centralis) to the periphery. In the primate, the two major classes of ganglion cells are P cells and M cells. P cells are sensitive to color and have "color-opponent" receptive fields: They receive antagonistic center-surround input from the long-, middle- and short-wavelength-sensitive (L, M, and S) cones in the retina. For example, red–green P cells (or equivalently, red-on green-off cells) are excited by red (or L-wavelength) light shining in the center of the receptive field and inhibited by green (or M-wavelength) light in the surround. Blue–yellow cells are excited by blue light in the center and inhibited by yellow light (which is the sum of inputs from L- and M-wavelength cones) in the surround. In contrast to P cells, M cells have a larger receptive field and are insensitive to color but highly sensitive to low contrasts. They receive mixed L, M, and S cone inputs to both the center and surround of their receptive fields. Figure 3 illustrates the center-surround color-opponent receptive fields of P and M retinal ganglion cells.

B. Lateral Geniculate Nucleus

The receptive fields of neurons in the lateral geniculate nucleus (LGN) in the thalamus, which receives the outputs of retinal ganglion cells via the optic nerve, are in many ways similar to retinal receptive fields. They have "on"-center, "off"-surround-type and "off"-center, "on"-surround-type concentric receptive fields, but compared to ganglion cells, the inhibitory interaction between the center and the surround is more finely

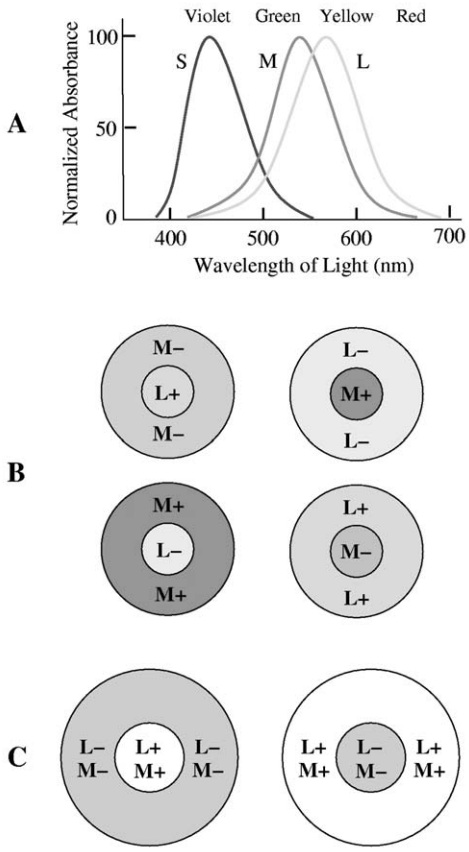

Figure 3 Color-opponent receptive fields. (A) Absorption spectra of long, middle, and short wavelength-sensitive cones (L, M, and S) in the human retina. (B) Center-surround color-opponent receptive fields of "red–green" parvocellular ganglion cells in the retina (projecting to the parvocellular layers of the LGN). Turning on long-wavelength (red) light in the receptive field center excites L "on"-center cells (L+) but inhibits M "off"-center cells (M−). Four possible combinations of L or M and "on"- or "off"-center-surround receptive fields are shown. (C) Center-surround receptive fields of magnocellular retinal ganglion cells. The receptive fields are not color sensitive, receive both L and M inputs, and are either "on"-center (L+M+) or "off"-center (L−M−) (after Zigmond *et al.*, 1999).

matched, resulting in much weaker responses to uniform illumination. In the primate, cells in the parvocellular layers (found dorsally in the LGN) receive inputs from retinal P cells and exhibit color-opponent receptive fields, whereas cells in the ventral magnocellular layers receive inputs from M cells and are not selective for color. In addition, unlike retinal ganglion cells, the responses of LGN neurons can be influenced by feedback from the visual cortex. For example, some LGN neurons are sensitive to the length of a moving bar, responding more weakly for longer bars than shorter bars, a property known as end inhibition or endstopping. Inactivating cortical feedback may disinhibit these neurons, causing them to lose their sensitivity to bar length. The influence of cortical feedback on LGN receptive fields is still unclear due to incomplete knowledge about the precise nature of cortical feedback and its interactions with inhibitory interneurons in the LGN.

C. Primary Visual Cortex

Axons from the LGN terminate in the primary visual cortex (V1 in primates and area 17 in the cat). Although cells in layer 4C of the cortex, where most of the geniculate fibers terminate, possess concentric center-surround receptive fields, the vast majority of neurons in other cortical layers exhibit receptive field properties that are much richer than those of their retinal and geniculate counterparts. Most of these neurons respond best not to spots of light but to elongated bars or edges that are flashed or moved in a particular direction. In addition, receptive field sizes in V1 can reach up to 8° or more, compared to a maximum size of 2 or 3° in the LGN, suggesting that these neurons spatially integrate the outputs of their antecedent LGN neurons, yielding receptive fields that are combinations of LGN receptive fields. Unlike LGN cells, many cells in V1 have binocular receptive fields (i.e., they are driven by stimuli presented to both eyes).

1. Simple Cells

Two major classes of cortical neurons were identified by Hubel and Wiesel in their seminal studies of the visual cortex. One class of cells, known as simple cells, possess receptive fields consisting of elongated "on" and "off" subregions oriented at a particular angle and localized to a small region of visual space. For example, a simple cell with a receptive field consisting of a vertically oriented elongated central "on" region flanked by two elongated "off" regions (Fig. 4A, left) responds best to a vertical bar of light that entirely fills the central "on" region. Figure 4B illustrates the responses of this neuron to bars at different orientations. Figure 4A also shows other simple cell receptive fields selective for dark bars or edges in images. Binocularly driven simple cells fuse information from both eyes and act as "disparity detectors," with selectivity for near, far, or zero disparity depending on whether they respond most to stimuli nearer than, farther than, or on the plane of fixation. They typically have receptive fields with the same preferred

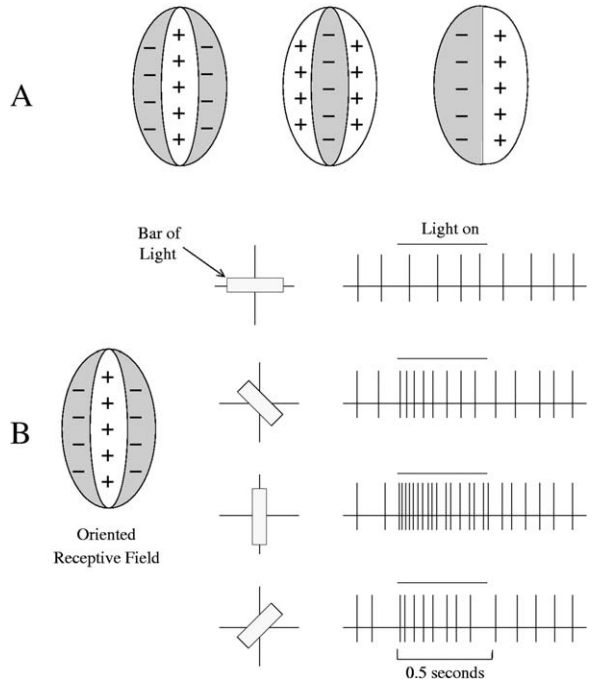

Figure 4 Oriented receptive fields. (A) Examples of oriented receptive fields of three simple cells selective for (from left to right) a bright vertical bar in the center, a dark vertical bar in the center, and a bright edge turned on in the right half of the receptive field. Although these receptive fields are all at a single orientation (vertical), a wide range of orientations are found in the cortex for each type of receptive field (as illustrated in Fig. 15). (B) (Left) A receptive field with an elongated "on" area (+) surrounded by two antagonistic "off" areas (−). A cell with such a receptive field responds best to a vertically oriented bar of light turned on in the center of its receptive field, other orientations producing little or no response (see examples on the right).

orientation in both eyes. Receptive field locations may be identical or differ in the two eyes. In the latter case, disparity may be detected due to a phase shift in the receptive field structure. Presenting optimally oriented stimuli simultaneously within the receptive fields of both eyes typically yields a much larger response than stimulating each eye alone, indicating a nonlinear facilitatory interaction between the two eyes (Fig. 5). Simple cells are generally found in layers 4 and 6 of primary visual cortex.

2. Complex Cells

A second major class of neurons, found primarily in layers 2, 3, and 5 of primary visual cortex, differ from simple cells in that they respond to both bright and dark bars (or edges) and are insensitive to their position within the receptive field. These cells are known as complex cells. The receptive fields of complex cells cannot be separated into distinct "on" and "off" subregions as in the case of simple cells but can be conceptualized as consisting of many subregions integrating both "on"- and "off"-type responses; this prompted Hubel and Wiesel to propose that complex cell receptive fields were constructed by combining several antecedent simple cell receptive fields (Fig. 6). Most complex cells have binocular receptive fields that are nearly identical for dark and bright stimuli. Due to their invariance to stimulus

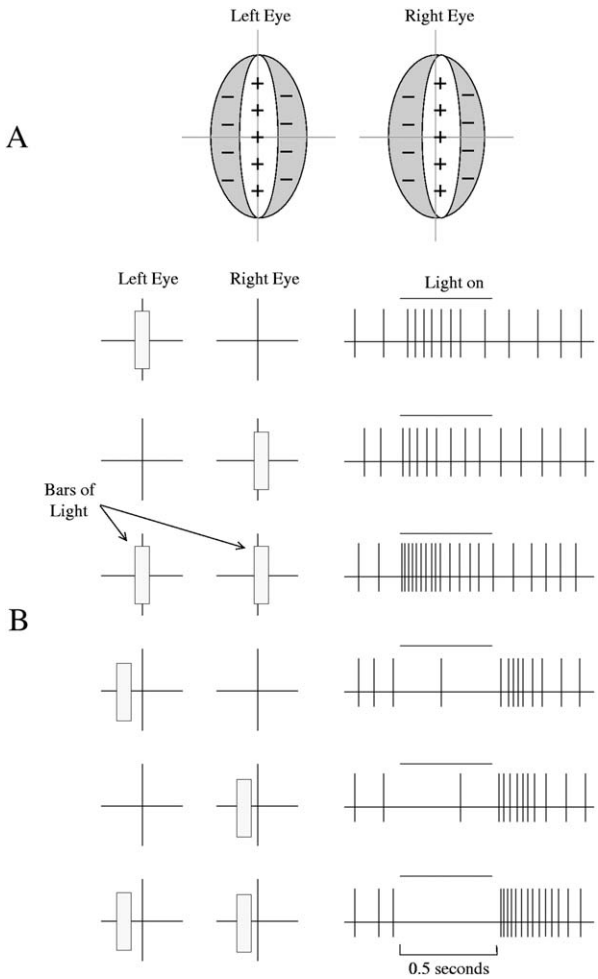

Figure 5 Binocular receptive fields. (A) Receptive fields of a cortical cell for the left and right eye. The receptive field for the right eye is shifted slightly to the right relative to the receptive field for the left eye. (B) Simultaneous presentation of bright bars in the "on" region of the receptive fields produces a much larger response from the cell (see third row) than presentation of the stimulus to either eye alone (first two rows). A similar nonlinear interaction is observed in the "off" responses of the cell when a bright bar is flashed in the left "off" region of the receptive fields. Such binocular receptive fields contribute to depth perception.

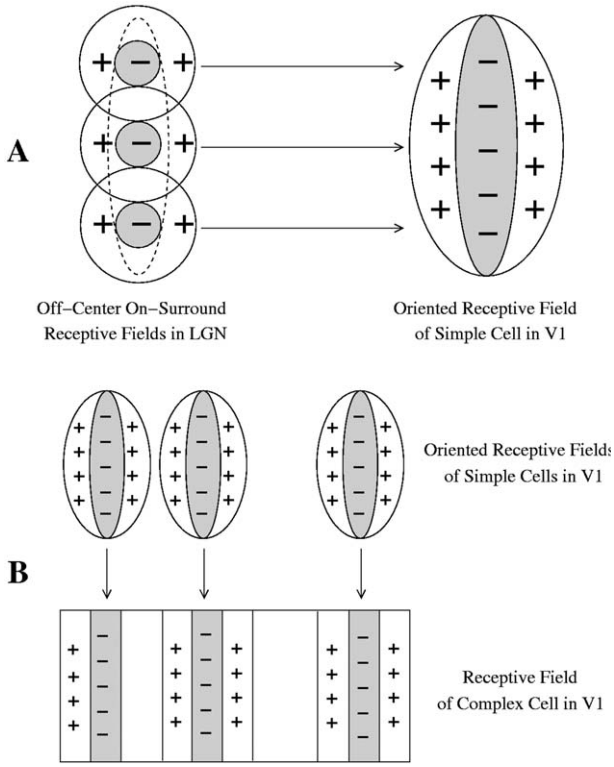

Figure 6 Model of simple and complex cell receptive fields. The figure depicts the hierarchical model proposed by Hubel and Wiesel for the construction of simple and complex cell receptive fields from center-surround LGN receptive fields. (A) A simple cell receptive field is synthesized from converging inputs from LGN cells whose center-surround receptive fields are displaced along the preferred orientation of the simple cell. (B) The receptive field of a complex cell is constructed from converging inputs from many simple cells that respond best to vertically oriented bars at different spatial positions. This allows the complex cell to respond to vertical edges anywhere within its receptive field.

position, they are thought to play an important role in computing stimulus depth.

3. Endstopped Cells

Some simple and complex cells respond optimally to stimuli of a particular size (e.g., a bar of a particular length); their response is reduced or even eliminated when the stimulus size is further increased beyond the optimal length. Such cells are known as endstopped cells because the optimal stimulus is an oriented bar or edge that "stops" at a particular place beyond the receptive field of the cell. In other words, there exists an "off" region just beyond the top and/or bottom ends of the receptive fields of these neurons that tends to inhibit the firing of the neuron. Figure 7 illustrates the response properties of an endstopped neuron in primary visual cortex. Note that endstopping or end inhibition is also found in the LGN (see Section II.B) as well as higher cortical areas and can be regarded as a type of nonclassical receptive field effect (see Section IV.A).

4. Double-Opponent Color Coding Cells

An important class of color-sensitive cells found in V1 but not in the retina or the LGN is that of double-opponent cells. These cells have concentric center-surround receptive fields with red–green or blue–yellow opponency, but unlike color-opponent cells in the LGN, these cells exhibit antagonistic responses in the center and surround for both colors. For example, in the case of a red–green "on"-center "off"-surround double-opponent receptive field, a red spot in the center excites the cell, and a red spot in the surround reduces its response; a green spot in the surround excites the cell but green in the center reduces the cell's response. Double-opponent receptive fields may play a crucial role in mediating color constancy, the phenomenon that allows us to perceive the color of objects despite large variations in ambient lighting conditions. Figure 8 illustrates the receptive field and responses of a red–green double-opponent cell.

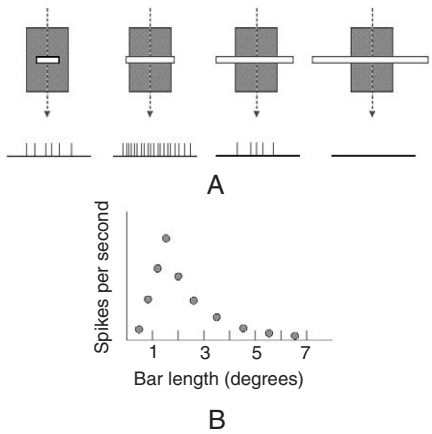

Figure 7 Endstopping. (A) The responses of an endstopped neuron to vertically moving bright bars of increasing length. The classical receptive field of the neuron is shown as a shaded rectangle. As the length of the bar is increased, the response of the neuron first increases and then decreases to zero. The peak response occurs when the size of the bar matches the width of the classical receptive field (second column). (B) The average response of the neuron (in spikes/second) plotted as a function of bar length (in degrees of visual angle).

D. Space–Time Receptive Fields of LGN and V1 Neurons

We have thus far focused on the spatial structure of visual receptive fields, as determined by flashing spots of lights or bars at different retinal locations. Recent techniques such as reverse correlation (see Section I.B) allow receptive field structure to be mapped in both space and time. Reverse correlation studies have revealed that the spatial structure of visual receptive fields may change over time. For example, an "on"-center "off"-surround-type receptive field in the LGN may gradually transform into an "off"-center "on"-surround-type receptive field over time. The evolution of such a receptive field is depicted in Fig. 9 as a space–time plot. Similarly, neurons in V1 may switch their "on" and "off" subregions over time. Some of these V1 receptive fields can be modeled by multiplying an oriented spatial receptive field by a temporal sinusoidal function with an initial positive lobe and a later negative lobe (Fig. 10). Such receptive fields are called separable. Many space–time receptive fields in V1, however, are inseparable (i.e., they cannot be expressed as a product of a spatial function and a temporal function). Such receptive fields generally have an orientation not only in space but also in time, as shown in Fig. 11. This orientation in time is due to a gradual shift in the phase of the oriented "on"–"off" subregions of the spatial receptive field over time: the spatial receptive field "moves" in a particular direction for a brief duration of time. The faster the shift, the greater the slope of orientation and the greater the velocity preferred by the cell. The direction of shift matches the preferred direction of motion of the cell. The space–time receptive field of a simple cell thus accurately predicts the orientation, direction of motion, and the preferred velocity of stimuli that best activate the cell. Space–time receptive fields of complex cells obtained through reverse correlation are limited in their usefulness due to the nonlinear summation inherent in these cells. Second-order methods involving the interaction of multiple stimuli presented at different positions and times are currently being explored to understand their receptive field properties.

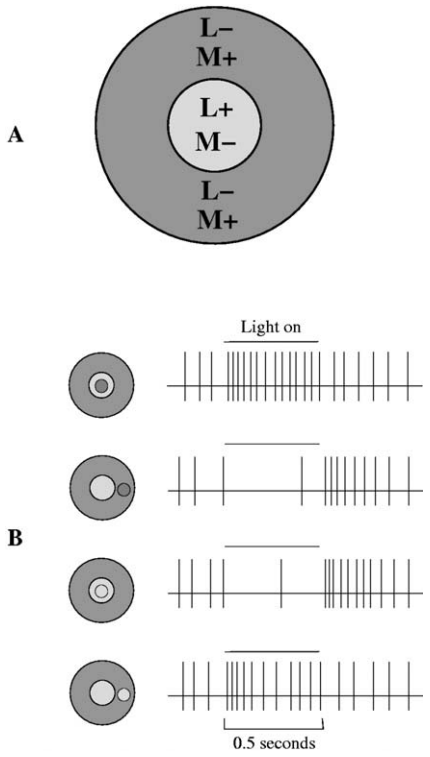

Figure 8 Double-opponent receptive fields. First discovered in the goldfish retina and later in the primate visual cortex, double-opponent receptive fields consist of concentric center-surround fields with L–M (red–green) or S–(L + M) (blue–yellow) antagonism. However, unlike color-opponent receptive fields in the retina (Fig. 3), each color produces antagonistic effects both in the center and in the surround. (A) An L–M (red–green) double-opponent receptive field. (B) Shining red light in the center of the receptive field produces an "on" response (first panel), whereas shining red light in the surround produces an "off" response (second panel). Green light in the center causes an "off" response (third panel), whereas in the surround it causes an "on" response (fourth panel). Double-opponent cells are believed to play a major role in color constancy, the phenomenon by which we perceive objects to be of the same color regardless of background illumination.

E. Higher Visual Cortical Areas

Based on anatomical considerations, visual cortical areas can be classified into a rough hierarchy with a coarse dichotomy between a dorsal visual processing pathway, involving areas V1, V2, MT, MST, and areas in the parietal cortex, and a ventral processing stream, involving areas V1–V4 and areas in the inferotemporal (IT) cortex. The receptive field properties of V1 neurons were discussed previously. V2 neurons share many of the receptive field properties of V1 neurons, including orientation selectivity and endstopping, but integrate information over a larger portion of the visual field. In addition, many V2 neurons respond to complex visual stimuli such as wedges, concentric circles (Fig. 12), or illusory contours of appropriate orientation, the latter being an example of contextual influences from stimuli lying beyond the classical

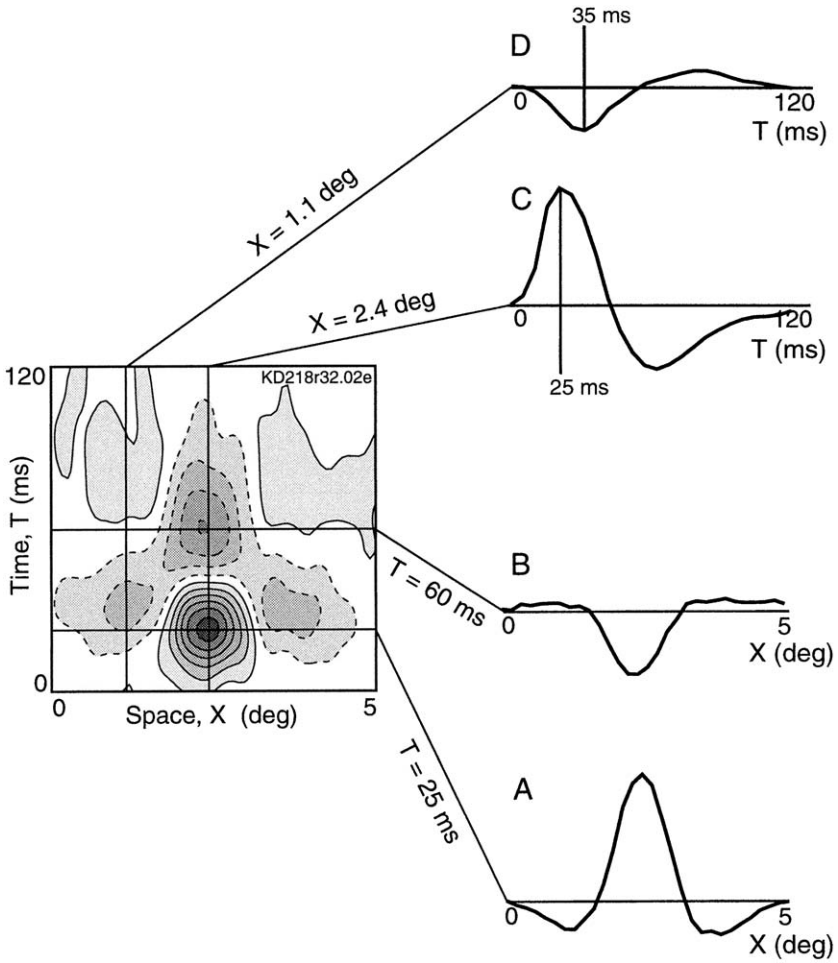

Figure 9 LGN space–time receptive field. The X–T contour plot on the left depicts the space–time receptive field of an LGN neuron: areas enclosed by solid contours correspond to bright-excitatory regions (bright bars at the these locations excite the neuron), whereas areas enclosed by dashed contours correspond to dark-excitatory regions (dark bars at these locations excite the neuron). It can be seen that the receptive field of this neuron transforms over time from an on-center, off-surround-type spatial receptive field (profile shown in A for $T = 25$ msec) to an off-center, on-surround-type spatial receptive field (shown in B for $T = 60$ msec). (C and D) Evolution of two different spatial values in the receptive field ($X = 1.1$ and 2.4°) over time (reproduced with permission from Cai *et al.*, 1997, Spatiotemporal receptive field organization in the lateral geniculate nucleus of cats and kittens. *J. Neurophysiol.* **78,** 1045–1061).

receptive field of the neuron (see Section IV.A). Comparably little is known about the receptive field properties of V3 neurons, except that they are selective for stimulus orientation and direction of motion, with a receptive field size even larger than those of V2 neurons. On the other hand, much is known about the properties of MT neurons. Most of these neurons are highly selective for stimulus velocity, with preferred speeds ranging from 2 to 256°/sec compared to a range of 1 to 32°/sec in V1. MT neurons are relatively insensitive to stimulus form (as defined by luminance, texture, color, or relative motion), but many are selective for binocular disparity, suggesting a role for these neurons in detecting motion in depth. An interesting receptive field property found in MT but not V1 is selectivity for pattern motion (as opposed to component motion): MT neurons respond to the direction of motion of the plaid pattern resulting from superimposing a pair of sinusoidal gratings moving in two different directions, whereas V1 neurons do not. Neurons in area MST are selective for more complex patterns of motion, such as rotations, dilations, and translations, within a receptive field that is larger than those of MT neurons. Most are disparity selective but largely insensitive to form and color.

Neurons in V4 are known to be selective for color as well as shape of stimuli. Many V4 neurons remain selective for length and width of bar stimuli over a

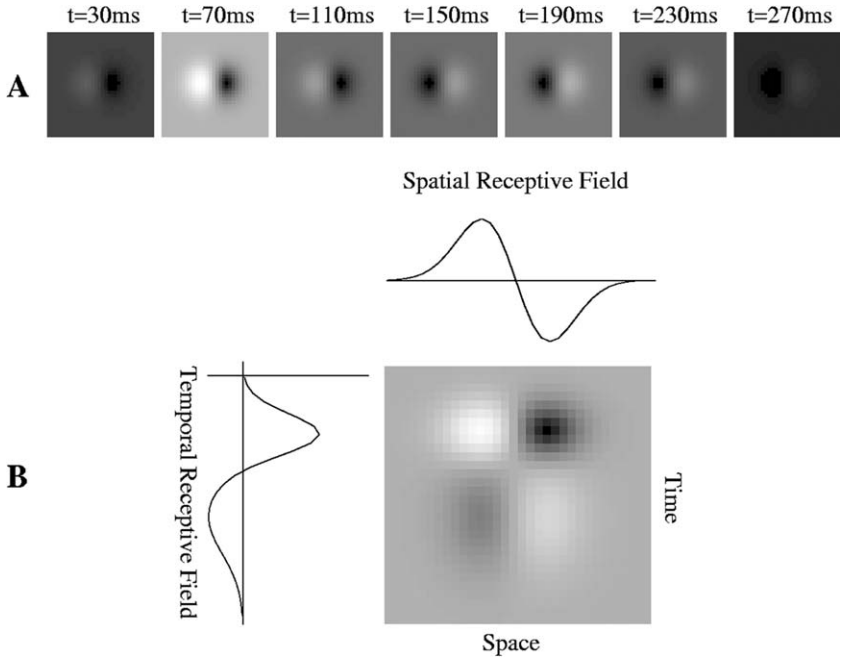

Figure 10 Separable space–time receptive fields. (A) An oriented spatial receptive field that reverses the polarity of its on and off regions (bright and dark regions) over time. The evolution of the receptive field is shown as a series of snapshots in increments of 40 msec. (B) The space–time evolution of the receptive field in A can be captured in a space–time plot obtained by integrating along the axis of orientation (vertical in this case) for each moment in time. As shown in the figure, the space–time plot for this receptive field can be characterized as the product of a spatial receptive field profile (top) and a temporal receptive field profile (left). Receptive fields with such space–time plots are said to be "separable." Some simple cells in primary visual cortex possess such separable space–time receptive fields.

much larger receptive field than do V2 or V3 neurons. Some V4 neurons prefer more complex shapes, such as conjunctions of edges or bars, star-like patterns, and concentric regions of contrast (Fig. 12). Neurons in areas TEO and TE of IT cortex have large receptive fields (20° in width or more) that often span both contralateral and ipsilateral visual fields. They show a selectivity for a range of complicated 2-dimensional and 3-dimensional shapes, from stars and concentric circles to hands and faces (Fig. 12). In addition, responses of IT neurons are often invariant to the position, size, and orientation of their preferred stimulus shapes. Finally, some neurons in IT cortex respond not to the stimulus but to its memory. Some of these neurons reduce their response gradually as the stimulus is repeatedly presented, whereas others continue to fire after the stimulus has been removed, essentially holding a memory trace of the stimulus.

F. Summary of Visual Receptive Field Properties

As one progresses from lower visual processing centers, such as the retina and LGN, to higher cortical areas, one witnesses a gradual increase in receptive field size (Fig. 13). Simultaneously, there is an increase in both response invariance and selectivity for higher order stimulus features: while complex cells in V1 respond to oriented edges or bars and remain invariant over a spatial extent of a degree or two, cells in IT maintain their response selectivity for complex stimuli such as faces across several tens of degrees of visual space. In addition, as one progresses along the visual hierarchy, one begins to encounter cells that store information regarding the recency and familiarity of a stimulus rather than responding to the stimulus per se.

III. RECEPTIVE FIELDS IN OTHER SENSORY MODALITIES

The study of receptive fields in sensory modalities other than vision is still in its infancy. Here, I briefly review some of the known properties of somatosensory, auditory, gustatory, and olfactory receptive fields, with an emphasis on the similarities in receptive field structure across modalities.

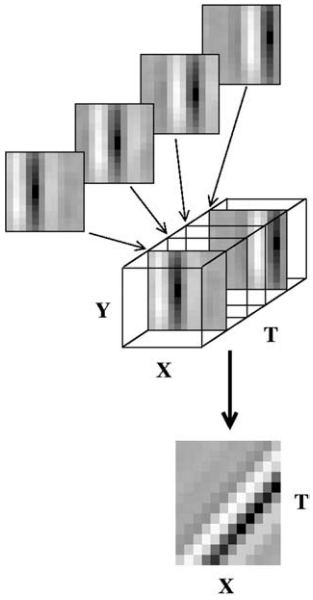

Figure 11 Inseparable space–time receptive fields. The X–Y–T cube depicts the space–time receptive field of a direction-selective cell that responds best to a dark bar moving rightwards. Four spatial cross sections of this cube are shown at the top for four different time values (time values increase from front to back). The bright regions in the receptive field represent spatial locations where a bright bar elicits a response from the cell, whereas the dark regions denote locations where a dark bar causes a response. The degree of brightness indicates the magnitude of responses. An X–T plot is obtained by integrating the three-dimensional cube along the Y axis, which is normalized to be parallel to the preferred orientation of the cell. The gradual shift in the spatial receptive field (in this case, to the right) as a function of time is responsible for the rightward slope in the space–time receptive field (X–T plot) and for the direction selectivity of the neuron. Note that unlike the receptive field in Fig. 10, the receptive field of this simple cell is space–time inseparable: its X–T plot cannot be approximated as the product of a spatial and a temporal receptive field profile (after DeAngelis *et al.*, 1993).

A. Somatosensory Receptive Fields

Somatosensory receptive fields are defined in terms of areas of skin within which a mechanical stimulus such as a touch causes a neural response. The receptive fields of afferent fibers carrying information from mechanoreceptors in the skin are primarily excitatory and only a few millimeters in diameter, with size and location determined by the receptor. Such receptive fields are analogous to the receptive fields of photoreceptors in the retina.

In the primate primary somatosensory cortex (S1), there are antagonastic center-surround receptive fields: the somatosensory neuron produces a robust response when a particular area of skin is touched but the neuron is inhibited when any part of the surrounding area is touched (Fig. 14). This is reminiscent of the center-surround organization of receptive fields in the retina and LGN. Some cells in somatosensory cortex are direction-selective (i.e., they respond only to movement of touch in a particular direction on the skin). Such cells have an inseparable oriented space–time receptive field, analogous to the receptive fields of direction-selective cells in visual cortex.

B. Auditory Receptive Fields

The receptive fields of neurons in the early auditory pathway have traditionally been studied using tone bursts at particular sound frequencies. These studies reveal that early auditory neurons, such as the type I neurons that transmit information from the inner hair cells in cochlea, show sharp tuning for particular characteristic frequencies: The response diminishes

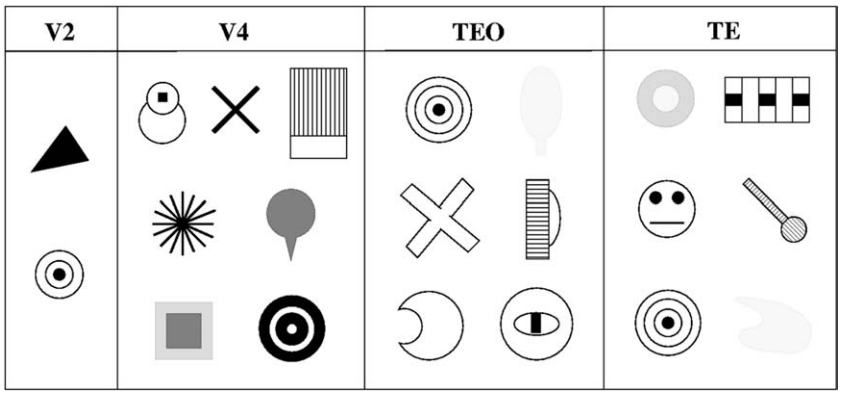

Figure 12 Receptive fields in higher visual areas. The figure shows some of the complex object features that elicit the best responses from different neurons in the higher visual cortical areas V2, V4, TEO, and TE (after Zigmond *et al.*, 1999).

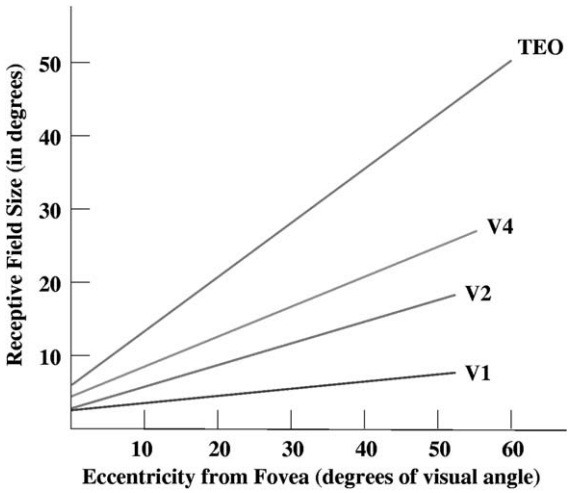

Figure 13 Receptive field sizes in different visual cortical areas. The graph plots receptive field size, defined as the square root of receptive field area, as a function of receptive field eccentricity for four different visual areas. The lines are based on linear regression from individual data points, replotted from Zigmond *et al.*, 1999. Two trends are apparent: (i) There is a linear increase in receptive field size with eccentricity for each area and (ii) receptive field sizes in higher visual areas (TEO, V4, and V2) are consistently larger than receptive field sizes in corresponding lower areas (V4, V2, and V1, respectively), reflecting the anatomical convergence of information from many neurons in a lower area onto a single higher area neuron.

rapidly for frequencies that are not close to the characteristic frequency. Other neurons, such as those in the cochlear nucleus, exhibit center-surround-type receptive fields when their responses are mapped as a function of sound pressure level and frequency. As one proceeds to higher auditory centers, the range of frequencies that characterize the receptive field becomes narrower. Many neurons in the auditory cortex do not respond to pure tones but do respond to changes in frequency in a particular direction (up or down) and at a particular rate. The spectrotemporal receptive fields of these neurons are oriented when plotted as a function of frequency and time; they are thus analogous to the oriented space–time receptive fields of direction-selective neurons in the visual and somatosensory cortex.

C. Olfactory and Gustatory Receptive Fields

Researchers have only recently begun to explore the structure of olfactory and gustatory receptive fields at different levels of processing. Much of the past research focused on elucidating the mechanisms by which taste receptors on the tongue and epithelia in the mouth and odor receptors in the epithelia of the nasal cavity convert chemical substances into neural signals. Most neurons in the early stages of processing have been found to be broadly tuned to a range of stimuli (e.g., salty, bitter, or sweet taste qualities) and are also modulated by intensity. Some also respond to tactile and thermal stimuli. However, it has been suggested that some olfactory receptive fields are analogous to retinal center-surround receptive fields: Mitral cells in the olfactory bulb exhibit excitatory responses to certain chemical compounds in a homologous series of compounds and inhibitory responses to neighboring compounds that flank the excitatory compounds in the series. The presence of antagonistic center-surround receptive fields in the olfactory system suggests that higher level receptive fields, such as those of neurons in the olfactory cortex, may possess an oriented structure

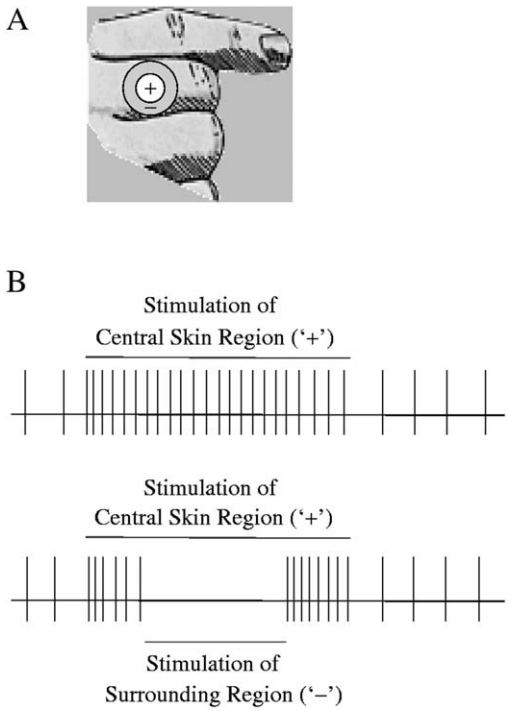

Figure 14 Somatosensory center-surround receptive field. (A) An example of a center-surround antagonistic receptive field of a neuron in the somatosensory cortex. The receptive field is located on the right hand and consists of an excitatory central region (+) surrounded by an annular inhibitory region (−). (B) The spike trains produced by a cell with such a receptive field for two cases: (i) stimulation of the skin in the central receptive field region (top) and (ii) stimulation of the skin in the central region together with stimulation in the surrounding region for a brief period of time (bottom). These spike trains illustrate the center-surround antagonism characterizing the cell's receptive field.

analogous to visual and auditory cortical receptive fields. However, the orientation would be in the space of chemical concentration and time, implying a sensitivity toward increasing or decreasing amounts of particular chemical compounds at a particular rate.

IV. NONCLASSICAL RECEPTIVE FIELDS AND ATTENTIONAL MODULATION

A. Nonclassical Receptive Field Effects and Contextual Modulation

The responses of many neurons can be modulated by presenting stimuli in the region surrounding the receptive field of the neuron. For example, a visual cortical neuron that responds to a moving bar or an oriented grating within its receptive field may no longer respond when the bar extends into the surrounding region or when the surrounding region contains a grating oriented in the same direction as the central grating. The region of space surrounding the "classical" receptive field that modulates the responses of the neuron to the central stimulus is known as the neuron's nonclassical or extraclassical receptive field. The modulatory effect is sometimes referred to as contextual modulation.

B. Attentional Modulation

The receptive fields of certain cortical neurons are also modulated by attention. For example, some neurons in areas V2 and V4 of the monkey visual cortex that respond vigorously to a bar stimulus in their classical receptive field reduce their response when a second stimulus is placed inside the receptive field. If, however, the monkey is trained to attend to the bar stimulus, the introduction of a second stimulus does not reduce the response. The neuron responds as if its receptive field has shrunk to include just the bar stimulus, ignoring the distracting second stimulus. Similar attentional effects have also been observed in imaging studies involving human visual cortex.

V. RECEPTIVE FIELD PLASTICITY

In addition to short-term modulation of receptive fields due to context and attention, the receptive fields of many neurons are labile and may be subject to long-lasting modifications in their structure. Some neurons exhibit a "critical period" during which exposure to stimuli from the external world causes changes in their receptive fields. For example, in kittens that are raised in a visual environment containing only vertical stripes, there is a predominance of visual cortical neurons with vertically oriented receptive fields. Similarly, although the receptive fields of many neurons in kitten visual cortex are directionally selective before eye opening, these receptive field lose their directionality when the animal is placed in a strobe environment, in which flashes occur a frequencies less than 10 Hz.

Receptive field plasticity has also been observed in adult animals. For example, in monkeys, if the skin from two adjacent fingers is surgically joined so that the two fingers now behave as one functional unit, the receptive fields of neurons in the somatosensory cortex that initially coded for just one of the fingers now extend across both fingers. If the fingers are then separated and used individually again, the receptive fields reorganize and start coding for the individual fingers. Similarly, in monkeys that have lost a limb, the receptive fields that were initially selective for stimuli on the lost limb may reorganize and start coding for other parts of the body. This reorganization of receptive fields after changes in the pattern of inputs is thought to occur through "Hebbian" adaptation of horizontal connections between cortical neurons. Hebbian mechanisms play an important role in models of receptive field development.

VI. COMPUTATIONAL MODELS OF RECEPTIVE FIELDS

Computational models of receptive fields can be divided into two categories: models that seek to explain receptive field properties based on known anatomical connectivity and physiological data, and models of the development of receptive fields based on, for instance, the statistics of natural images or sounds. An example of a model of the first type is Hubel and Wiesel's hierarchical model of the receptive fields of simple and complex cells in primary visual cortex (Fig. 6). In this model, the oriented receptive field of a simple cell is assumed to be constructed by aligning the center-surround receptive fields of a set of antecedent LGN cells in the proper orientation. In other words, the receptive fields of simple cells are assumed to be determined by pooling the outputs of LGN cells. The

receptive fields of complex cells are in turn determined by pooling the outputs of a set of simple cells with receptive fields of similar orientation. Such a "feedforward" model has received some support in both anatomical and physiological studies. However, other studies support a competing model based on local feedback connections between neurons, which amplify weak biases in the feedforward inputs. Clarifying the role of feedforward and feedback connections in determining cortical receptive field properties remains an active area of current research. A second class of models ask not *how* receptive fields are constructed but *why* they exhibit the properties that they do. These models seeks to explain the receptive field properties of sensory neurons in terms of the statistics of natural sensory signals. For example, the antagonistic center-surround receptive fields in the retina can be explained in terms of predictive coding theory: since natural images are not random but contain statistical regularities such as correlations over space and time, the value of an image pixel can usually be predicted quite accurately using a weighted average of the surrounding pixels. Thus, the output of a retinal ganglion cell, as determined by its center-surround receptive field, encodes the difference between the actual pixel values in the center and the predictions of these pixel values based on surrounding pixel values. Such a strategy minimizes redundancy and enhances dynamic range. It can also be interpreted in terms of the statistical operations of whitening and smoothing of input signals based on the frequency spectra of natural images. A similar explanation applies to color-opponent receptive fields and the center-surround receptive fields in the LGN.

Cortical receptive fields appear to be the result of a more sophisticated predictive coding strategy, which takes into account properties such as orientation, disparity, and direction of motion of objects. Models of cortical receptive field development have typically invoked Hebbian learning mechanisms that are based on correlations between inputs and outputs of neurons. Computer simulations of these models show how oriented receptive fields may develop from initially random receptive fields. Recent simulations using collections of natural images have shown that oriented receptive fields very similar to those measured in cortical neurons develop as a consequence of learning rules that maximize the statistical independence between outputs of cortical neurons (Fig. 15). Divisive normalization of neural activity based on the responses of neighboring neurons has also been suggested as an additional mechanism for achieving independence. Other models have shown that nonclassical receptive field effects may be a consequence of predictive coding in abstract parameter spaces such as orientation rather than the raw image space as in the case of the retina. The implementation of such models using lateral and/or corticocortical feedback connections remains a subject of current research.

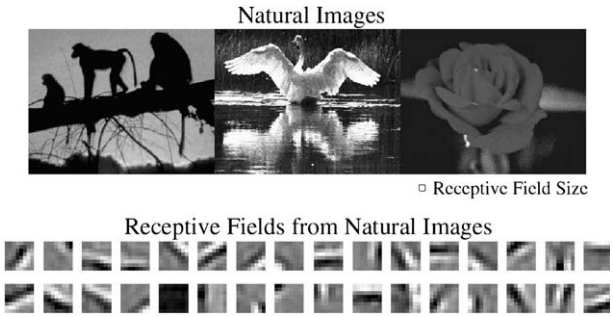

Figure 15 Oriented receptive fields from natural images. (Top) Three of the natural images used in training an artificial neural network whose goal is to reconstruct patches of these natural images using a linear combination of a given set of receptive fields. An additional constraint that the responses of model neurons be as statistically independent as possible helps to minimize the redundancy in the outputs of the neurons. Starting from a random set of receptive fields, the network learns a set of receptive fields that simultaneously optimize the goals of information preservation (reconstruction) and statistical independence for a large set of randomly extracted natural image patches. The relative size of the patches and receptive fields (8×8 pixels) is shown below the natural images as a square box labeled "Receptive Field Size." (Bottom) The receptive fields learned by the network after exposure to several thousand natural image patches. Bright pixels denote "on" regions of the receptive field, whereas dark pixels represent "off" regions. These receptive fields, which are both localized and oriented, resemble those of simple cells in primary visual cortex, as first noted by Olshausen and Field (1996). Results from such simulations support the hypothesis that receptive fields in sensory systems are often a consequence of efficient coding strategies applied to natural signals.

VII. CONCLUSIONS

The receptive field of a neuron provides a succinct characterization of the properties of the sensory world that the neuron is most selective for. Neurophysiologists have characterized a wide range of receptive fields in visual, auditory, somatosensory, and other sensory modalities. Many of these receptive fields are plastic and can be modulated by contextual information and attention. Receptive fields across different sensory

modalities share many similarities in their structure, such as center-surround opponent organization (Fig. 16) and orientation along their defining axes (such as space and time). These similarities in organizational principles are thought to reflect a set of common goals related to the efficient coding of natural sensory signals. Computational models of efficient coding based on the ideas of redundancy reduction, statistical independence, and predictive coding have provided new functional interpretations of classical and non-classical receptive field properties.

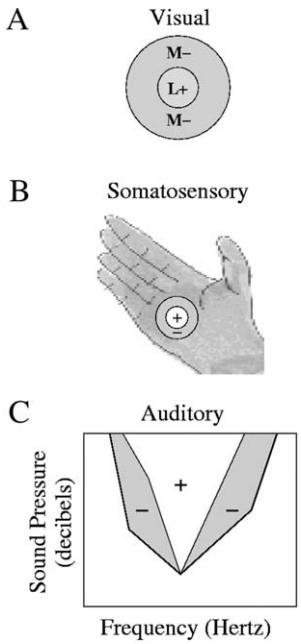

Figure 16 Similarities in receptive fields across sensory modalities. (A) Color-opponent center-surround receptive field in the retina. (B) Center-surround receptive field of a somatosensory neuron with an "on" response for skin stimulation in a circular region on the palm and an "off" response for stimulation in the annular surrounding region. (C) Center-surround receptive field of an auditory neuron in the cochlear nucleus. The center-surround antagonistic mechanism operates within the 2D space defined by sound pressure level, or loudness, and the frequency of the sound (a tone). The neuron is excited (+) by tones of a characteristic frequency (near the center of the frequency axis) but is inhibited (−) by surrounding frequencies.

GLOSSARY

betrayal trauma theory A theory that predicts that the degree to which a negative event represents a betrayal by a trusted, needed other will influence the way in which that event is processed and remembered.

dissociation A psychological state involving alterations in one's sense of reality and one's identity, hypothesized to influence the storage and accessibility of event memories.

encoding specificity The tendency for a prior experience to come to mind when one encounter cues in the environment that correspond to the conditions in which the experience was originally encoded.

false memory A memory for an event that did not occur.

forgot it all along effect The claim that various biases sometimes cause individuals to overestimate the degree to which they had previously forgotten an experience.

memory persistence The degree to which a memory has remained available over time.

metaconsciousness One's explicit appraisal of his or her own's phenomenological experience. Variations in metaconsciousness of abuse experiences have been hypothesized to contribute recovered memories.

prospective trauma studies A research methodology in which participants are identified on the basis of their known history of trauma and are then contacted in order to determine their subsequent memory for the trauma.

psychogenic amnesia The report of profoundly forgetting experiences hypothesized to be due to psychological rather than physiological factors.

recovered memory The recollection of a memory that is perceived to have been unavailable for some period of time.

repression A defense mechanism hypothesized to keep unwanted information out of an individual's awareness.

Recently, there has been disagreement in the public, legal, and academic communities regarding if, how, and why people forget and later recover memories of traumatic life events. This article addresses the specific situation of remembering experiences of childhood sexual abuse, one of the most controversial types of trauma.

I. INTRODUCTION

There are many experiences in life that we expect to forget: a name, a birthday, perhaps even a trip we once

took. Typically, however, we expect to remember our most significant life experiences: one's wedding day, the birth of a child, or the death of a parent. Although very significant life events are generally remembered (albeit often far from perfectly) there is at least one type of situation in which people sometimes report forgetting seemingly unforgettable experiences. Specifically, for centuries, people have reported forgetting, and later recovering, memories for traumatic events. For almost as long it seems people have been discussing if, how, and why this phenomenon actually occurs. By the end of the 1900s, this discussion appeared in the popular and academic press as a heated and polarized debate, focused primarily on memory for childhood sexual abuse. On one extreme, it was argued that not only can significant events be forgotten and later recovered but also such recovered memories are intact and accurate. On the other extreme, it was argued that a developing community of hysteria, based on the assumption that almost any adult difficulties were due to forgotten childhood trauma, could convince otherwise normal adults that they were abused as children. All involved in the discussion emphasized the emotional significance of such claims and the importance in furthering our understanding of how trauma can affect memory. Fortunately, much of the fervor seems to have quieted, and what remains are a number of interesting and important scientific questions on the nature of human memory.

This article attempts to give the reader an overall picture of the issues surrounding recovered memories in which individuals report having remembered long-forgotten experiences of trauma. Although this article uses the standard term "recovered memory," we note that some have expressed concerns that this term makes undue assumptions. In particular, it implies that a memory had been entirely "lost," and that the memory that was ultimately recovered is the same as that which was lost. As will be noted, there are many cases in which individuals appear to sincerely believe they have discovered long-lost memories of trauma, even though the accuracy of the memories and/or the degree to which the memories had been entirely lost are unclear. Jonathan Schooler suggested that the term "discovered memory" may be more appropriate because it maintains agnosticity regarding both whether the memory was truly forgotten and the degree to which the memory corresponds to an experience that really occurred. At the same time, however, it respects the integrity of the individual's experience of having made a profound memory discovery. Clearly, the field would be well served by a careful consideration of the most appropriate term for this contentious construct. Here, we use the standard term recovered memory in deference to the fact that it is currently the most commonly used term in this context.

We begin by briefly summarizing the proposed social situation in which the current debate arose. Then, we present a sample of published research that has attempted to document the forgetting and recovery of memories for childhood sexual abuse. This is followed by a discussion of possible mechanisms for recovered memories, including ones proposed to be specific to traumatic events and others that are more standard mechanisms for remembering and forgetting. Finally, we discuss issues of accuracy in recovered memories.

II. SOCIOHISTORICAL CONTEXT

The idea that memories of painful events can be selectively forgotten and later recovered has been around at least since the late 19th century, when it was discussed in association with hysteria by Charcot, Janet, and Freud. This concept of repression experienced renaissance periods after each World War, when numerous soldiers reported experiencing an inability to remember and later recovery of parts or all of traumatic combat experiences, then considered a symptom of combat neuroses. Although the topic of war neuroses was periodically addressed and forgotten, it does not appear that the question of whether or not war experiences could be forgotten or recovered was particularly controversial. Furthermore, since it was well-known that the men had been in horrible combat situations, there was little need to doubt their reports of exactly what occurred. When the diagnosis of posttraumatic stress disorder (PTSD) first entered the third *Diagnostic and Statistical Manual of the American Psychological Association*, it included psychogenic amnesia as a symptom of the disorder.

In the 1980s and beyond, individuals began making claims regarding the forgetting and discovery of memories for a topic that was controversial—sexual abuse. The feminist movement of the 1960 and 1970s increased awareness of the prevalence of physical and sexual abuse in the lives of women and children. Furthermore, it was noted that the response to such trauma was similar to the response of the combat veterans to war; the women were displaying the same symptoms of PTSD as the men. Both of these claims in and of themselves were debated. First, it has been

argued that the prevalence of sexual abuse—variously defined—is actually very low. Second, it has been argued that many childhood sexual abuse experiences may not actually be traumatic. Needless to say, determining the precise incidence of sexual abuse and the concomitant trauma that is experienced at the time are complicated issues. Nevertheless, there is a large body of evidence indicating sexual abuse does occur with alarming regularity, and that many experiencers of such abuse find it extremely upsetting.

The major issue in the current controversy surrounds memory. In the 1980s and 1990s, the notion that traumatic events could be forgotten and later accurately recovered received a great deal of public support and attention. Along with this movement came several ideas that would cause the greatest amount of controversy. First, some groups asserted that an individual might have been abused even if he or she did not remember the abuse. Possessing symptoms from a broad list of possible consequences of trauma was proposed to be enough to assume that abuse did occur. Second, therapeutic techniques arose with the prime goal of recovering "repressed" memories. Free association, dream interpretation, hypnosis, and sodium amyatal, among other techniques, were used to uncover memories for abuse. Perhaps most critically, a number of individuals were encouraged to bring criminal or civil law suits against their perpetrators based on their recovered memories. Furthermore, numerous states passed special statutes of limitations for cases in which the plaintiffs purport to have only recently remembered the crime. These ideas were soon heavily contested. The inability of researchers to find unique and consistent symptoms of a history of trauma argued against making assumptions that an individual was abused based on his or her current psychological profile. In addition, concern was raised in research, practitioner, and legal communities that the strong influence of therapist beliefs, especially in combination with highly suggestive and aggressive techniques such as hypnosis, could lead to the creation of false beliefs and memories about childhood trauma. The acceptance of recovered memories as legal testimony further increased the emphasis on the accuracy of such memories.

Interestingly, the shift in public interest was reflected in popular media. In an analysis of the content of four popular magazines—*Time*, *Newsweek*, *US News and World Report*, and *People*—sociologist Katherine Becker documented this change. According to Becker, in 1991, 80% of articles on childhood sexual abuse cases weighted toward the survivors, with their memories and therapeutic histories virtually unquestioned. By 1994, 80% of the articles focused on false accusations of abuse and supposedly false memories. A major influence in this shift of media attention was credited to an organization named the False Memory Syndrome Foundation, a support group for parents who claimed to be falsely accused of abusing their children. The foundation, whose board members include many eminent scientists and scholars, argued that there was little evidence that extensive traumatic events could be forgotten and later recovered. Moreover, individuals expressed concern that the social and therapeutic climate was causing an epidemic of false recovered memories.

For a number of years, the controversy was often treated as a black-and-white issue of whether recovered memories should be considered real or false. However, in recent years a more nuanced perspective has emerged in which most researchers and practitioners seem willing to accept that both false memories and authentic recovered memories do in fact occur. The distinct questions of the degree to which a traumatic memory is available over time and the degree to which that memory is accurate are beginning to be disentangled in human memory research. Within the topic of memory availability, the distinction between claims that events can be forgotten and claims that the memory for such events can be recovered has also been noted. Disagreements still exist, particularly with respect to estimation of the relative frequency of authentic and false recovered memories and the precise therapy practices that are or are not appropriate. Nevertheless, a spirit of moderation has emerged in which individuals from alternative perspectives have begun to work collectively to assess the current evidence and identify promising areas for future research.

III. EMPIRICAL RESEARCH ON RECOVERED MEMORIES

Numerous methodologies have been employed to study forgotten and recovered memories. Here, we present a brief sampling of the different studies. We begin with interview studies on patient populations and survey studies, discussing the advantages and disadvantages of these methods. We then discuss several prospective and case studies that have attempted to address some of the difficulties found in the earlier research.

A. Studies on Patient Populations

In one of the earliest empirical studies on forgetting of sexual abuse, Judith Herman and Emily Schatzow interviewed women in group psychotherapy for incest. In this sample, 38% reported that they had never experienced amnesia for the abuse, 36% reported experiencing moderate memory deficits, and 26% reported severe memory deficits. Relatedly, Elizabeth Loftus and colleagues interviewed a number of substance abuse patients, most of whom had experienced sexual abuse. Although most of those women reported always remembering the abuse, 12% reported consistently remembering only part of the abuse and 19% said they forgot abuse for period of time only later to have the memory return. However, results from this study must be taken with caution due to the effect of drug abuse on memory. In an additional study, Steven Gold and colleagues surveyed individuals entering therapy for sexual abuse. Approximately one-third reported that they "always contained a fairly complete memory of all or most episodes of abuse" and an additional 16% "remembered at least one episode of abuse in its entirety, but not all of them." About 14% reported having only a partial memory or flashes of recollection for some aspects of the event only. Ten percent "had a vague sense or suspicion but no definite memory" and almost another one-third "completely blocked out any recollection of the abuse."

B. Survey Studies

In an often-cited study, John Briere and Jon Conte surveyed hundreds of individuals in outpatient therapy, all of whom reported a history of child sexual abuse (CSA). One critical question on this survey asked "During the period of time between when the first forced sexual experience happened and your 18th birthday, was there ever a time when you could not remember the forced sexual experience?" Almost 60% of the respondents answered yes to this question. Similarly, Shirley Feldman-Summers and Kenneth Pope published the results of a randomized national survey of psychologists. Of the respondents who reported experiencing CSA, approximately 40% reported forgetting some or all of the abuse for a period of time. Non-sexual abuse was also reported to be forgotten. Interestingly, about half of these respondents said their abuse memories were triggered by therapy. Half reported having corroboration.

C. Methodological Issues in Patient and Survey Studies

These studies demonstrate that some people do indeed believe that they experienced abuse as children and subsequently had partial or no memory for the abuse. Furthermore, although there were a few cases of people still reporting difficulty in remembering abuse experiences, most believed they later recovered the previously inaccessible memories. Once again emphasizing the complexity of memory, awareness ranged from vague suspicions to "flashes of recollection" and full knowledge. The patient studies have the advantage of being more in-depth than standard survey studies, although surveys allow for the collection of vast amounts of data.

Although compelling, there are problems with these studies on therapist or patient populations. First, one might be concerned with surveying beliefs about memory in any individual who has been exposed to therapeutic notions of forgetting and recovery, as may happen in any therapy session. Only the study by Gold and colleagues attempted to account for this by conducting the memory interview at the intake interview. However, even they did not indicate which of their participants had received prior therapy. None of the studies can rule out the possibility that therapist or patients' beliefs about memory and trauma have tainted patients' recollection of their past memory. In fact, all retrospective studies suffer from reliance on the biased and difficult task of estimating past states of knowledge, especially in response to one or two nondetailed questions. Imagine trying to estimate if there was ever a period of time in which you had forgotten your sixth birthday party. There was probably a long period of time during which you did not think of the party, but it is very difficult to answer the question, "Could you have remembered if you tried?"

In addition, critics of these studies have raised the issue of corroboration for the abuse. Sexual abuse in particular is one of the most difficult crimes to find objective evidence for, and it is obvious that perpetrators have a great deal of motivation to lie and not confess their guilt. Additionally, one could argue that attempts to seek out corroboration in the therapeutic setting are bad for an atmosphere of trust in the patient. However, in scientific research one wants corroboration. Although Herman and Schatzow reported that three-fourths of the women were able to find independent corroboration, the authors relied on the patient reports of that evidence. Similar to the requirement of corroboration for the abuse, it is

difficult to give evidence that the memory was actually inaccessible had the individual tried to remember the event. Indeed, the study by Gold and colleagues reported their clinical observation that many individual's beliefs about their memories can change over the course of therapy (though this was in the context of an observation that most came to believe they had less complete memories than before). As discussed later, it is possible for individuals to believe they forgot something during a period of time in which they demonstrated awareness of that event.

D. Prospective Studies

Studies employing prospective methodologies have attempted to address the issue of corroboration by identifying individuals with documented abuse experiences and following them to later test their memory for the event. For example, Linda Williams published a study of 129 women whose childhood abuse experiences were documented due to required treatment at a hospital emergency room. In an interview conducted on average 17 years after hospitalization, the women were asked in detail about their abuse histories. Thirty-eight percent of the participants did not recall or did not report the abuse. Importantly, these women were no less likely to disclose personal information than the women who did report the specific abuse experience, suggesting this finding was not just due to an unwillingness to report the event. Williams also ruled out the possibility that all of the nonreporters were simply too young at the time the abuse occurred to remember it, and that the nonreporters likely represented original false reports. In addition to the group that seemed to have forgotten the abuse experience, approximately 10% of the participants reported recovered memory experiences. Based on an analysis of the hospital records, the women who reported recovery experiences had no more inaccuracies in their accounts than the women who reported continuous availability of the memory.

This type of study has the benefit of corroboration for the abuse. Furthermore, the interviews conducted in the Williams study and others like it allow for more in-depth questioning about the person and his or her experiences. Some have criticized the Williams study because it did not specifically ask about the abuse experience in question, thus why participants did not report the abuse experience cannot be definitively argued. In this study, the possibility cannot be ruled out that some individuals either felt disinclined to report the abuse or conflated the target incident with some other incident that they did recall. However, as described previously, the author made great efforts to rule out this possibility. Another limitation to prospective memory studies is that the evidence that they provide for forgetting only applies to those memories that *were not recalled* at the time of the interview. Since the recovered memories identified in these studies *were recalled* during the interview, these studies do not speak to the degree to which recovered memories are ever fully forgotten. Indeed, as discussed later, case study analyses have provided evidence that individuals may sometimes overestimate the degree that they had previously forgotten memories that they describe as recovered. A final limitation of all of the approaches outlined previously is that they aggregate data across cases, possibly obscuring potentially critical details of individual cases that may provide important clues about the nature of the phenomenon. Case study analyses help to fill this critical gap.

E. Case Studies

Another approach for investigating recovered memories is to engage in detailed retrospective analysis of the various elements of individual cases. For example, Jonathan Schooler and collaborators interviewed a number of individuals who reported having discovered previously forgotten memories of abuse. In one case, JR reported that following viewing a movie involving sexual abuse, he suddenly remembered incidents of being molested by a priest on camping trips when he was an adolescent. In another case, DJ reported that following a dinner with a neighbor whom she had not seen in many years, she suddenly recalled that this individual molested her numerous times between the ages of 5 and 7. In each of seven cases collected thus far, the investigators sought independent corroboration of the abuse, usually by contacting other individuals who the victim indicated had prior knowledge of either the abuse or the abusive tendencies of the alleged perpetrator. For example, in JR's case another individual indicated that the priest had attempted to molest him also, and in DJ's case, her mother reported that the alleged perpetrator had confessed. In each of these cases, independent evidence of the abuse was found. Moreover, in each case the individual reported a strong belief that there was a period of time in which he or she did not remember the abuse experience. The individuals also provided numerous details regarding their "memory discovery experiences," which were typically

described as involving shock, surprise, and a sudden unfolding of events. On the basis of the details extracted from these cases, Schooler proposed a number of possible mechanisms that may help to explain what he terms "discovered memories" of trauma.

In addition to Schooler's case studies, at least two other case studies have recently been published. Interestingly, both of these cases are prospective in nature. David Corwin and Erna Olafson published an incredibly detailed case history (including interview transcripts) of a young girl referred to Corwin for a court-appointed evaluation of allegations of physical and sexual abuse against the mother. At the age of 6, this girl made consistent allegations of abuse against her mother. At the age of 17, she requested to see the videotape of herself because she claimed she could not remember what had actually happened to her. During a subsequent interview between Corwin and the girl, she seemed to have a recovery experience, in which the allegations of abuse suddenly, and with great emotion, came back to her. Interestingly, although some of her memory corresponded to what was on record, she seemed to "remember" other information for which there was no evidence and no previous claims.

Sunita Duggal and Alan Stroufe also published a prospective study on a young girl in Minnesota who reported being abused by her father at age 4. Although the father always denied the abuse and the police were not able to obtain enough evidence to press charges, the girl was believed by her therapist, mother, and caseworker. The girl displayed memory for the abuse during all yearly research interviews conducted through the third grade. However, during annual interviews at ages 16 and 17, in structured interviews she denied experiencing sexual abuse in response to general "negative event" questions and questions specifically about sexual abuse. At age 18, she reported recovering her memory for the abuse.

In each of these cases there are compelling reasons to believe that the individual's memory recovery experiences corresponded to actual abuse events because at least some independent corroboration was obtained. However, the toughest critics may point out that corroboration does not absolutely guarantee that the events took place. Even in the prospective cases, there is no definitive evidence of the abuse. Furthermore, there is no way to prove forgetting occurred. Interestingly, in two of Schooler's case studies, participants judgments about their forgetting were contradicted by close others. In both cases, ex-husbands reported that they had been told about the event; however, the disclosure was remarkably devoid of affect. Although it is possible that the husbands are the ones who are wrong, the individuals could have made errors in the degree to which they forgot the event or the period of time during which the forgetting occurred. Collectively, the reports and the corroborative evidence suggest the strong likelihood that recovered memories really can occur and can correspond to actual events.

F. Summary of Research Documenting Discovered Memories

Despite the methodological difficulties involved in documenting recovered memory experiences, there seems to be at least reasonable agreement that individuals can have sincere recovery experiences corresponding to actual abuse that was perceived to have been entirely forgotten. Although the precise degree of forgetting in these cases may be unclear, the fact that individuals regularly perceive themselves to have forgotten the abuse indicates that at a minimum the memory was less accessible (i.e., less likely to come to mind) prior to the recovery, relative to after the recovery. In other words, even the most conservative assessment of the evidence indicates that traumatic memories can fluctuate in their persistence, with periods of time in which the memories are relatively less accessible. It is therefore appropriate to consider the various mechanisms that might in principle influence the accessibility of traumatic memories. In addition, given that estimations of forgetting are often retrospective, it is also important to consider the factors that might influence the judgment of past accessibility.

In reviewing variables that might contribute to the actual and perceived reduction in the accessibility of memories, it is important to emphasize that much research is still needed in these areas before definitive conclusions regarding the relative contribution of various mechanisms will be possible. Nevertheless, it is useful to outline the various mechanisms that current evidence suggests might be involved.

IV. THEORIES AND MECHANISMS OF RECOVERED MEMORIES

A. Mechanisms Specific to Emotional Events

1. Psychodynamic Theories of Repression

Freudian notions of repression argue that painful or threatening material can be selectively, though

effortfully, kept out of conscious awareness. According to Freud, the memory or impulse still exists as a disconnected idea that can affect the person despite lack of conscious awareness. Importantly, the material can later return to conscious awareness. In this view, repression is a protective device. Forgetting occurs to ease pain. Whether Freud considered repression to be an intentional or unintentional occurrence is still a matter of debate since Freud was inconsistent in his writings. Similarly, how this selective awareness occurs is also unknown. Regardless, the notion of repression remains well-known by the layperson and is popular within many mental health communities.

In 1990, David Holmes published an article titled "The Evidence for Repression: An Examination of Sixty Years of Research." Although he noted the observation that Freud was often ambiguous and inconsistent about the exact definition of repression, Holmes decided to investigate experimental evidence for the "conventional use" of the concept. According to Holmes, this conventional definition contains three necessary elements: (i) the selective forgetting of painful information, (ii) it must be involuntary, and (iii) the information can be recovered under the right conditions. His review addressed several different experimental approaches to finding a mechanism for this definition of repression. These areas included the differential recall of pleasant and unpleasant memories, differential recall of completed and incompleted tasks, changes in recall associated with the introduction and elimination of stress, individual differences in repressive tendencies, and perceptual defense. Based on the results of his literature review and some resulting investigations, Holmes concluded that there is no laboratory evidence of a mechanism for Freudian repression.

Holmes' article has been frequently cited as evidence that recovered memories cannot occur. However, it is important to point out that his work investigates mechanisms for repression, not the phenomenon of memory inaccessibility. Furthermore, since the publication of Holmes' studies there have been a number of laboratory studies that offer evidence of repression-like mechanisms. Several studies have investigated the memory performance of individuals who are classified as "repressors"—people who report low anxiety and simultaneously report using various defensive strategies (such as trying not to think about things that bother them). In a study by Penelope Davis it was found that repressors recall fewer negative childhood memories than do nonrepressors. In a related study by Lynn Myers and colleagues, it was found that when instructed, repressors were better than nonrepressors at forgetting negative words that they had recently read. Of course, findings such as these do not necessarily demonstrate that individuals can massively repress severely emotional experiences, but no laboratory experiment could ethically be expected to demonstrate such repression.

Currently, the following conclusions regarding evidence for repression are probably warranted. First, the question of whether or not individuals can forget extensive incidents of trauma is independent of whether the specific mechanism of repression contributes to such forgetting. Second, although laboratory evidence has been difficult to obtain, there have been a number of studies that can be interpreted as supporting the notion that defensive strategies may lead to the forgetting of some negative material. Finally, regardless of one's opinions on the laboratory evidence for repression, its applicability to the forgetting reported in recovered memories is limited because traumatic experiences are ultimately much more emotional, and the alleged forgetting is reportedly much more extensive, than anything that can be expected to be produced in the laboratory.

2. Dissociation during Traumas

Similar to the notion of repression, theories on traumatic dissociation propose that some individuals may psychologically separate themselves from overwhelming negative experiences. Pierre Janet first identified the phenomenon in the late 1800s and proposed that the intense emotion aroused during trauma could interfere with the assimilation and integration of perceptions, thoughts, and experiences. Current understanding of the phenomenon argues that there are three components to an acute dissociative response: derealization (alteration in one's perceptions), depersonalization (alteration in one's sense of self and connection to one's own body), and memory disturbances. Further research has identified a persistent, dissociative personality trait that seems to lie on a continuum throughout all members of the population. In addition to having a joint component of derealization and depersonalization and a memory disturbance component, this concept includes a measure of absorption, the ability to become "lost" in one's thoughts or activities.

The concept of dissociation is central to current research and psychiatric theorizing about trauma. Acute dissociative responses have been identified in survivors of overwhelming traumas such as combat,

sexual abuse, accidents, natural disasters, and fires. Furthermore, it has been argued that immediate dissociative responses to trauma predict poorer psychological recovery. Additionally, trait dissociative tendencies seem to be higher in individuals with a traumatic history. How acute dissociative responses and trait dissociation are related is unclear. Researchers have distinguished between normal and pathological dissociation in the trait variable, arguing that the absorption factor does not seem to be related to pathological dissociation. Thus, it may be that a preexisting dissociative tendency can lead to an acute dissociative response to trauma, which in turn increases one's dissociative tendencies. Of primary interest to the current discussion is how an acute dissociative response or dissociative tendencies may affect memory.

One possibility is that an acute dissociated state leads to poor encoding of a traumatic event. In this situation, trauma memories could be fragmentary or missing but could not be completely recovered. The second possibility is that the dissociated state is functionally distinct from the normal state of mind, leading to state-dependent effects in which dissociated material cannot be retrieved until one once again enters the dissociated state of mind. Experimental research has demonstrated that memory can improve if one is in the same mood or physical location at the time he or she tries to recall something as he or she was at the time he or she learned the information. Thus, material learned while dissociated may be difficult to remember when one is in a normal state of mind but more easily retrieved when one returns to the dissociated state. In a study using highly hypnotizable undergraduates, Heidi Sivers and Gordon Bower gave participants a series of items to learn while in either a hypnotically induced ''dissociated'' or ''normal'' state. They then asked the participants to later recall the items, again while in a dissociated or normal state. Although they had hypothesized that state-dependent memory would be found, instead they found what appeared to be very poor recall of the learn-dissociated items regardless of retrieval state. This suggests that dissociation was indeed negatively affecting the original encoding of the material learned.

Jennifer Freyd and colleagues relatedly found that dissociative trait can affect attention and memory. Using a measure called the Dissociative Experiences Scale (DES), they identified members of the general population who were either high or low on dissociative tendencies. They discovered that highly dissociative individuals are worse at filtering out irrelevant material in tasks that require attending to a select portion of incoming information. However, these same people are better at tasks that require attending to more than one thing at a time. In a different task, high and low DES individuals were asked to learn portions of a list containing neutral and trauma-relevant words. If asked to simply recall everything, there were no differences between the two groups. However, when their attention was divided at learning by an additional task, high DES participants recalled fewer trauma-related and more neutral words than did low DES participants. In both learning conditions, high DES participants recognized fewer trauma-related and more neutral words than did low DES participants. These findings suggest that dissociation may be adaptive in keeping threatening information from awareness in certain circumstances. In particular, attentional context may be a central factor in understanding when dissociative tendencies are most likely to help people keep threatening information from awareness. Thus, the lack of integration of experiences, memories, and thoughts creates an environment that requires constant divided attention and encourages cognitive strategies for functioning efficiently in such environments.

Our understanding of state and trait dissociation is thus still growing. For now, it remains a concept based primarily on clinical observation and self-report, lacking a known cause or mechanism. This had led many research psychologists to view the concept and its attendant hypotheses skeptically. Although much more research is needed before we fully understand what dissociation is, at a minimum measures that purportedly measure dissociation have proven to be a useful tool for predicting both the response to trauma and performance on a number of standard cognitive tasks. This is currently an area being heavily researched, and it is hoped that our understanding of the concept and its relation to trauma and memory will continue to grow.

3. Brain Theories on ''Processing''

There now exists a reasonable amount of evidence to support the idea that emotional information is processed and remembered through partially different pathways than nonemotional memories. Highly arousing situations may increase the involvement of an area of the brain called the amygdala. Interestingly, Joseph LeDoux has discovered evidence that there are two primary information pathways involved with the amygdala. One pathway is fast, has only generic

information, and does not involve interaction with the areas of the brain involved in the higher processing systems of thinking, reasoning, and consciousness (the cortex). A second, slower and more refined pathway sends input to the amygdala through the sensory cortex. LeDoux suggests that the fear reaction system involves parallel transmission to the amygdala from these two pathways. The subcortical pathway provides a crude image of the external world, whereas a more detailed, accurate, and perhaps conscious representation comes from the cortex. Interestingly, a third input system comes from the sensory-independent hippocampus. The hippocampus is the area of the brain argued to be primarily responsible for normal long-term memory. This hippocampal pathway seems to be involved in the integration of individual stimuli (sights, sounds, and sensations) during learning in order to create a broader context. The hippocampus also seems to play a role in integration at retrieval.

There is evidence that extreme and continuous stress damages the hippocampus. For example, monkeys who died due to extremely stressful living conditions showed damage to subregions of the hippocampus. Relatedly, many different research labs have found decreases in hippocampal volume in Vietnam War veterans with PTSD compared to noncombat control subjects. Based on this research, it is possible that the fear-conditioning pathways may correspond in some way to claims made regarding traumatic memory. The first two pathways are sensory specific, with one occurring completely without cortical involvement, suggesting it may be possible to process some fear-related information with little or no conscious awareness. The second pathway involves some areas of higher processing. Thus, it is possible that the sensory-dependent memories (memories that do not arise unless one is exposed to a specific, sensory cue) are related to representations held within this second system. Because this system is responsible for stimuli discrimination, it may have important ramifications for cue sensitivity. Processing in these cortical areas would allow the individual to be consciously aware of sensory information during the experience. However, extreme terror and fear would interfere primarily with the third pathway projecting to the hippocampus, perhaps the area responsible for integrating those representations into a complex whole. This would result in the isolated sensory recollection posited by some models of traumatic memory. Although these suggestions are highly speculative, there is currently a great deal of research in investigating the neural correlates of traumatic forgetting and memory recovery.

4. Betrayal Trauma Theory

Betrayal trauma is a theory proposed by Jennifer Freyd that addresses both the how and why issues of forgetting of traumatic experiences. In this theory, she argues that amnesia for childhood abuse exists, not for the reduction of suffering but because not knowing about abuse by a caregiver is often necessary for survival. From a logical analysis of developmental and cognitive research, she argues that a cognitive information blockage under certain conditions, such as sexual abuse by a parent, can be expected. This is the "why" portion of the argument that childhood abuse is forgotten.

Betrayal trauma theory proposes a two-dimensional model of trauma. One dimension addresses terror, the emotional state required in the definition of traumatic response. This dimension corresponds to threats to life—things that actually can cause one bodily harm and often do. Another dimension is that of betrayal and threats to social relationships. In this case, the event involves a treacherous act by someone depended on for survival. Some traumas are high on both these dimensions; for example, sadistic abuse by a caregiver, the Holocaust, some combat experiences, and many childhood sexual abuse situations. These events are both terrorizing and involve a betrayal of a relationship. Although the fear dimension is important for some of the anxiety responses found in PTSD, amnesia is especially likely to occur for the events that are high in betrayal.

Betrayal trauma theory leads to specific predictions about the factors that will make amnesia most probable. One notable factor is the individual who is perpetrating the abuse. According to this theory, childhood sexual abuse is more likely to be forgotten if it is perpetrated by a parent or other trusted caregiver. If a child processes the betrayal in the normal way, he or she will be motivated to stop interacting with the betrayer. Essentially, the child needs to ignore the betrayal in order to preserve the attachment. Thus, for a child who is dependent on a caregiver, the trauma of abuse, by the very nature of it, demands that information about the abuse be blocked from mental mechanisms that control attachment and attachment behavior. How is a child to manage this on a long-term and sometimes nearly daily basis? How is the child to succeed at maintaining this necessary relationship when a natural response is to withdraw from the source of the pain? Betrayal trauma theory proposes that the child blocks the pain of the abuse and betrayal by isolating knowledge of the abuse/betrayal

from awareness and memory. There are various avenues for achieving this isolation, one being conscious memories without affect and another being the isolation of knowledge of the event from awareness.

Freyd relies on numerous concepts from cognitive psychology to support the "how" argument of betrayal blindness. She points to mental mechanisms for processing information in parallel, selective attention, sharability of information, and the time course of complex information processing to support the fact that knowledge can be isolated by interrupting the extended processing of complex events. Furthermore, she mentions research on inhibition and recovery of well-formed memories. In summary, there are multiple ways for the abused child to disrupt knowledge integration and awareness of the abuse while facilitating the important and crucial relationship. Furthermore, there are multiple ways for the adult survivor of childhood abuse to recover these memories, and these will depend in part on how the memories were isolated in the first place. At the same time, this cognitive plausibility does not negate the potential for false memories to occur. Indeed, the cognitive mechanisms that support knowledge isolation and recovery may be in part the same mechanisms that may support memory errors.

To support the notion that amnesia will be more likely the more dependent the victim is on the perpetrator, Freyd reanalyzed three sets of extant data, including those described in the Feldman-Summers and Pope and Williams papers articles discussed previously. This investigation indicated that amnesia rates are higher for parental or incestuous abuse than for nonparental or nonincestuous abuse. Furthermore, she and her students collected survey data questioning individuals' memory for a wide array of specific situations of physical, emotional, and sexual abuse in childhood. The preliminary results support the prediction that the greater the victim's dependence on the perpetrator, the less persistent are memories of abuse. Together, these data sets suggest that social dependence may play an important role in memory for traumatic events.

Although the betrayal trauma theory has considerable potential, current evidence in support of it is largely preliminary and exclusively correlational in nature. Although a relationship has tentatively been observed between reported memory persistence and the relationship of the victim to the alleged pertpetrator, it does not necessarily follow that the cause of this relationship is betrayal trauma processes. In principle, a variety of other potential factors could account for these correlations, including age at the time of the event, differences in the interpretations of abuse associated with caretaker vs stranger abuse, differences in the likelihood of talking about the two types of abuse, and/or differences in the likelihood that the memories of the two types of abuse may be fabricated. Freyd and colleagues are currently measuring some of these potentially confounding variables and will be able to evaluate statistically the contribution of these covarying factors in predicting memory impairment. Preliminary analyses indicate that one factor, age at the time of the event, does not account for memory persistence over time. Some issues will require specialized populations. For instance, to evaluate the possibility that there is a difference in the likelihood that memories of types of abuse are fabricated, it will be necessary to use a prospective methodology with documented abuse samples. In correlational research there is always the possibility of unmeasured confounds; because we cannot ethically vary many of the factors of interest related to real abuse, the best we can currently do is to systematically evaluate the contribution of covarying factors that we identify as possibly accounting for differences in rates of reported forgetting.

None of the theories discussed here—repression, dissociation, or betrayal trauma—are exclusive of many standard memory mechanisms that can affect whether any type of information is encoded, stored, or recalled over time. In fact, betrayal trauma theory incorporates many of them. In the next section, we review a number of more standard memory mechanisms that have been proposed to play a role in traumatic amnesia.

B. Well-Established, or Non-Trauma-Specific, Memory Mechanisms

Although many accounts of recovered memory have focused on processes that may be unique to trauma, other approaches have emphasized the various general memory/forgetting mechanisms that could be involved. There are several well-documented general memory mechanisms that seem readily applicable to the current discussion. Here, we review the mechanisms we believe are most relevant.

1. Simple Forgetting

Many observers have noted that we routinely forget all sorts of experiences in life. In one survey, Don Read

found that a significant proportion of people reported recovering memories for all sorts of significant but nontraumatic life experiences. Thus, in many cases the forgetting of childhood abuse may simply reflect the passage of time and the fact that we simply cannot constantly remember the plethora of experiences from our past.

2. Directed/Intentional Forgetting

In many cases individuals may try to forget their unpleasant abuse experiences. In fact, there is a large body of laboratory research indicating that people can intentionally forget information when they try. In numerous word-list learning paradigms it has been repeatedly demonstrated that individuals can intentionally forget something. In a typical experiment, participants are given an initial list of words and then told to forget that list and focus on remembering a new list of words. They are then surprised with a memory test for all of the items, including items presented on the first list. The results demonstrate that memory for items on the first list is worse in individuals who were instructed to forget the list than in individuals who were told to remember both lists. Thus, individuals can intentionally forget information.

Many have interpreted these results as due to selective rehearsal. It could be that the first list is simply rehearsed less in the "forget" than the "remember" condition. Relating this to forgotten memories of childhood sexual abuse, a lifetime of avoiding the thought of the abuse or keeping the abuse secret would lead to poor memory due to a lack of rehearsal. Additional directed forgetting studies have attempted to equate intentional rehearsal or use incidental memory and have still found poorer memory for the first list. Furthermore, if nonrecalled forget and remember items are later re-presented for learning, evidence for a "release from inhibition" is found in that original forget items are recalled better than original remember items. This line of cognitive research has been used as support for the notion that information can be intentionally inhibited from conscious awareness and later recovered.

3. Interference Theories of Memory

Countless examples of word-list learning experiments have demonstrated that if two related pieces of information are learned, practice of one piece of information can interfere with the ability to remember the other piece of information. This can take the form of prospective interference, in which past information interferes with the ability to retrieve new information. One example of this phenomenon is having difficulty remembering a friend's married name because her maiden name keeps popping to mind. Alternatively, retrospective interference can occur, in which the learning of new information interferes with the ability to recall old information; the new married name gets in the way of recalling the friend's maiden name. In either case, recall of one set of information "interferes" with the ability to recall the other. When considering traumatic experiences, imagine the child who's favorite uncle sexually abused him on one occasion and takes him to a ball game on another. The child may rehearse the uncle–ball game association repeatedly while never rehearsing the uncle–abuse experience due to pressure not to disclose, threats or denial from the uncle, or numerous other reasons. According to standard interference theories of memory, the strengthening of the uncle–ball game association would actually decrease the ability to recall the uncle–abuse situation.

4. Change in Understanding/Reinterpretation

It is frequently proposed that an individual who experiences CSA may not fully understand the event at the time it originally occurs. Knowing when an unfamiliar type of touch is acceptable instead of abusive, for example, may require understanding of social norms and the intentions of the individual doing the touching—a difficult task for an adult, let alone a young child. It has been demonstrated that individuals have very poor memory for information for which they do not have a "schema" or knowledge system. For example, in one research study, participants who read an ambiguous passage had very poor memory for the content of the passage unless a title presented ahead of time indicated what the story was about. In this laboratory study, it was found that if the title was presented after the story, memory was even worse than if no title was provided. Thus, if a person has no way to label, understand, or describe an experience, memory for that experience may suffer.

Even if an event is learned and understood in one manner, a later reinterpretation of the event as "abusive" may cause one to feel like the event is being recalled for the first time. Furthermore, changes in the interpretation of an event may activate previously inaccessible information. Again turning to psychological research studies, it was demonstrated that individuals who were told to read a description of a house from the perspective of a robber remembered

different information than did individuals who read the same description from the perspective of a home buyer. Interestingly, when told afterwards to take on the other role, participants recovered previously unremembered information in line with the new perspective. Therefore, an individual who interprets an event in a different way could actually retrieve additional information related to the new interpretation.

5. Encoding Specificity/State Dependency

As mentioned previously, an additional relevant mechanism is found in encoding specificity or state dependency theories. Encoding specificity theory states that the probability of retrieving a memory is maximized when retrieval conditions correspond to the encoding conditions. Similarly, state dependency argues that memory improves if one is in the same state of mind at the time of recall as when he or she originally learned the information. For example, psychologists Baddeley and Godden had scuba divers learn two lists of words, one while under water and one while on dry land. On a subsequent memory test, it was discovered that individuals recalling information while on dry land remembered more words from the list learned in the same physical location. Likewise, individuals recalling under-water recalled more under-water-learned words. Similar results have been found in studies comparing happiness to sadness and drunkenness to sobriety, among other mind states. Strikingly, when considering the case examples given in support of recovered memories, in all the cases collected by Schooler and the Corwin case there was notable correspondence between the original abuse situation and the situation in which the memory was ultimately recalled. Furthermore, it is possible that the proposed knowledge isolation, or the fragmentary nature of traumatic memory, could make such memories even more dependent on highly specific cues, thus making the events irretrievable except in very limited circumstances.

C. Speculative, Non-Trauma-Specific Memory Mechanisms

In addition to the previously mentioned well-established, non-trauma-specific memory mechanisms, there are more speculative memory mechanisms that may play an important role in recovered memories. Although these mechanisms remain to be definitively established, they are largely consistent with extant evidence and are worthy candidates as possible accounts for at least some recovered memories.

1. The ''Forgot It All Along'' Effect

In several of his cases, Schooler found that the individuals underestimated their prior knowledge about the event as evidenced by the fact that others reported they had talked about the abuse during the time that they thought they were being amnesic. Schooler likens this to a similar bias in individual's estimates of past knowledge, the ''knew it all along'' effect. The premise of the knew it all along effect is that a person who is told something new comes to believe that he or she knew it all along. This happens because the current knowledge state is used to infer the earlier knowledge state. Although there has been little research to date on cases of underestimations of prior knowledge, it seems reasonable to suppose that if one can use one's current knowledge state to overestimate prior knowledge, one may also use it to underestimate prior knowledge. In the context of an emotional onrush associated with thinking about memories of abuse, individuals may assume that they had no previous knowledge about their abuse. They may reason, ''If I'm this shocked and surprised now, then I must have previously completely forgotten about the experience.'' In short, individuals may misattribute the emotional onrush associated with thinking about the event to the emotional onrush of discovering the memory. Future research is needed to determine whether and, if so, to what degree this intriguing mechanism, which is consistent with apparent mischaracterizations of forgetting in several of Schooler's cases, applies more generally to recovered memory cases.

2. Precipitous Forgetting of Nocturnal Experiences

Recently, Schooler proposed that there may be something ''special'' about nocturnal experiences that could lead them to be forgotten almost immediately after occurring. Although characterizations of forgetting as precipitous are certainly not ubiquitous, it has been reported. One possible explanation is that various physiological processes that contribute to dream forgetting may also contribute to the forgetting of nocturnal abuse. Individuals often, indeed usually, forget dreams, even traumatic and disturbing ones. Schooler argues there are a number of striking

parallels between dream forgetting and allegations of forgetting of sexual abuse. First, sexual abuse, like dreams, often occurs at night while the individual is in bed. Second, like dreams, sexual abuse experiences are often bizarre, occur in isolation, and may be difficult to reconcile with preexisting schemata and other events. In fact, descriptions of dissociated experiences often include the statement "it was as if I was dreaming." These parallels between dreams and nocturnal abuse may both contribute to the forgetting of such abuse and to the dismissal of such recollections as being merely "bad dreams," especially in children, who have lesser ability to distinguish between reality and fantasy. In support of this notion, laboratory studies have demonstrated increased forgetting for materials presented immediately prior to sleep onset and immediately after awakening. However, there is no direct empirical evidence that such memories can later be recovered.

3. Metaconsciousness

Recently, Schooler proposed a theory of metaconsciousness that assumes that experiential awareness (i.e., the contents of phenomenological experience) can be distinct from metaconsciousness (i.e., one's explicit understanding of his or her phenomenological experience). In this context, recovered memories involve changes in individuals' metaconsciousness of the abuse. In some cases, they may involve the gaining of a different metaconsciousness of the meaning of an experience, which may become confused with the discovery of the memory. The result of such confusion would be the sometimes erroneous belief that the memory is just now being accessed for the first time (similar to the notion of reinterpretation discussed earlier). In other cases, the memory discovery may involve regaining a prior metaconsciousness that was avoided for some time. In still other cases it may involve the gaining of a previously nonexistent metaconsciousness of the experience. A variety of factors ranging from the very straightforward (e.g., age, lack of discussion, and stress) to the more esoteric (e.g., dissociation and nocturnal cognitive processing) may prevent incidents of abuse from being initially encoded with metaconsciousness. Such nonreflected memories, particularly when they are aschematic and disjunctive with other experiences, may continue to elude metaconsciousness until a specific contextual retrieval cue is encountered. Once recalled in the light of metaconsciousness, individuals may understand what happened to them, and this discovery may fundamentally change their view of their personal histories. Again, research is needed to establish the role that changes in metaconsciousness of abuse may have in contributing to recovered memories.

D. Conclusions Regarding Theories and Mechanisms of Recovered Memories

Currently, understanding of the mechanisms behind recovered memory experience has resulted in many advances, but there is much to uncover. It seems likely that no one cognitive process will be able to explain all forgetting and recovery of awareness for traumatic events. Indeed, a range of devices, from standard memory mechanisms to processes unique to trauma, should come into play, influenced by the nature of the trauma, the situation in which it occurs, and the immediate and subsequent reaction of the survivors and their social network. Thus, scientific research and discussion on the topic of recovered memories must reflect this complexity and not attempt to reduce the answer of whether traumatic experiences can be forgotten or if they can be accurately recovered to a simple "yes" or "no."

Memory in general is a reconstructive process. We use our current knowledge and understanding to recreate our knowledge of the past. Thus, all memory has the potential for inaccuracy. For centuries, the reliability of our knowledge of the past has been discussed. Of particular relevance to the current discussion is how emotion influences memory. We know that emotion influences the persistence or availability of events over time. Within the range of everyday events, we tend to remember emotionally arousing events more than the mundane. For extraordinary events, extreme emotion is claimed to make an experience impossible to forget (as seen in traumatic flashbacks of PTSD) or difficult to remember (as discussed in this article). What is currently unclear is the degree to which emotion influences the probability of inaccuracies in memory.

V. ISSUES OF ACCURACY AND INACCURACY IN RECOVERED MEMORIES

Although there are good reasons to believe that many recovered memories of abuse correspond to actual events, there are also compelling reasons to be concerned that some recovered memories may be false. A variety of lines of research raise the specter of false recovered memories.

A. Research Supporting False Memories

First, individuals can remember, sometimes in excruciating detail, memories of events that are extraordinarily unlikely to have occurred. For example, Michael Persinger found that individuals can recover memories of alien abductions in a manner that at least superficially resembles that associated with some recovered memories of sexual abuse.

Second, under certain experimental conditions, subjects can be induced to recall "memories" of disturbing events that never happened. For example, Ira Hyman and colleagues planted, in a sizeable minority of participants, a variety of mildly upsetting and somewhat bizarre memories, such as spilling punch on a bride's parents at a wedding.

Third, a variety of psychotherapeutic techniques such as visualization repeated retrieval attempts, dream interpretation, and hypnosis can increase individual's beliefs that unlikely events actually occurred. For example, Mary Anne Garry and colleagues found that visualization techniques increased many peoples' beliefs that they might have experienced events (such as putting a hand through a window) that they previously reported were very unlikely to have happened.

Fourth, these techniques correspond, with disturbing closeness, to those argued to be used by a sizeable minority of clinicians in their aggressive efforts to recover memories of abuse. For example, in a national survey of licensed practitioners, Mellisa Polusny and Victoria Follete found that more than 25% of therapists reported using guided imagery, dream interpretation, bibliotherapy regarding sexual abuse, referral to sexual abuse survivors' group, and free association of childhood memories as memory retrieval techniques with clients who had no specific memory of childhood sexual abuse.

Finally, many individuals with recovered memories conclude that their memories are false. For example, a review by Joseph de Rivera reported that more than 300 people have retracted charges of sexual abuse based on memories recovered in psychotherapy.

B. Discussion of False Memory Research

The previously mentioned findings raise the real concern that individuals may, as a consequence of aggressive memory therapy techniques and other social pressures, develop recovered memories for events that never happened. However, just as some cautions are appropriate in interpreting the evidence in support of authentic recovered memories, so too some caveats are in order in interpreting the evidence for false memories.

A central potential limitation of the evidence for false memories is that for ethical reasons it is simply not feasible to attempt to induce false memories that are as emotionally disturbing as sexual abuse. Thus, some have raised the question of whether research on the more benign false memories that have been produced in the lab (such as being lost in a mall or spilling punch on someone in a wedding) would generalize to falsely recalling being abused by one's parents. Although the issue of generalization is important, it should be pointed out that real-world recollections of highly unlikely events, such as past life, prenatal, and UFO-associated traumas, suggest that false memories of even highly disturbing experiences are possible.

Furthermore, it has been argued that false memory research investigating the creation of memory errors, including those that have been characterized as involving the creation of false memories, has not been focused on the phenomenology of recovered memories per se. In other words, it has not fully addressed the experience of the individual at the time of recollection. Thus, is it unclear if the false memory is experienced as recovered from a previously inaccessible state or as a continuous memory. On the basis of such observations, it has been suggested that false memory research may only be applied to the question of memory accuracy when individuals believe they have always remembered something. However, in some laboratory studies, such as that of Ira Hyman mentioned previously, participants typically denied the suggested experiences when first asked about them. Only after engaging in extensive visualization did some subjects come to remember the suggested events. This process of nonrecall followed by considerable effort and eventual recall is in fact akin to recovered memories. Therefore, although this is an area of dispute, it seems clear that false memories of both continuous and recovered memories can occur and are important topics for further investigation.

Another concern regarding false memory studies involves the degree to which the ideas that individuals generate are best described as false memories. Many studies that have been characterized as involving the creation of false memories have not actually caused individuals to specifically recall events that never occurred but rather have caused them to believe that such events might have occurred. For example, as

noted previously, when individuals are encouraged to imagine various unlikely events, they subsequently estimate that such events are more likely to have occurred. However, in research on the topic, individuals did not actually report remembering these events. This and other studies of its type might be better characterized as involving false beliefs about memory rather than false memories per se. Although false beliefs about memory are clearly relevant to this discussion, future research is needed to determined whether a false belief can transform into a full-fledged false recollection.

Critics have also noted that in much of the false memory research there is no way to be certain that the allegedly false events did not actually take place. For example, in one very influential false memory study by Elizabeth Loftus and Jacqueline Pickerel, college student participants came to remember being lost in a mall, even though a parent had indicated that such an experience had not occurred. Given how common it is to be lost in a mall (probably many readers have had this experience), these findings could be interpreted as cases in which the parents forgot the critical incident. Indeed, little research has specifically examined whether parents' memories are necessarily any more accurate than their adult children's. Research that increases the estimated probability that highly unlikely events occurred beyond what can be reasonably expected (e.g., 25% of students remembering spilling punch on a bride at a wedding) provides more conclusive evidence that memories can be planted for specific events that never occurred. Nevertheless, in these cases it seems quite plausible that individuals' false memories might incorporate details from related events that did occur (spilling a drink at some other social occasion). In more naturalistic cases it is similarly possible that individuals who report UFO traumas with sexual elements experienced and forgotten more mundane sexual abuse. Research is needed to investigate the relationship between actual experiences and the probability of accepting a false event as having occurred.

Relatedly, some have suggested that in order for individuals to develop false memories they must have some sort of "schema" or "knowledge structure" through which to create the false information. For example, Kathy Pezdek and colleagues were unable to plant false memories for experiences that individuals had little knowledge about (e.g., receiving a rectal enema) or that they perceived as being highly implausible (e.g., Jewish students receiving communion). Importantly, however, one of the central components of many therapy practices, self-help groups, talk shows, and books is that they provide individuals with a clearer picture of abuse scenarios and persuade them that such scenarios might in fact apply to them. The resulting increased knowledge and plausibility of the abuse scenarios may be just what it takes for the abuse suggestion to take hold.

Ultimately, our understanding of the recovered memory phenomenon will require us to develop a broader appreciation of the various ways in which individuals can acquire false beliefs about their personal memories. We need to continue to investigate the various conditions that can lead individuals to accept false memories as being true. At the same time, we also need to understand the likely (though less often considered) factors that may cause individuals to reject true memories as being false, as for example might occur following the application of pressure from an authority figure insisting that an event never occurred (such as a perpetrator denying abuse). In addition, we need to attend to the various mechanisms that may lead individuals to generate false beliefs about the degree to which a memory had or had not persisted over the years.

VI. CONCLUSIONS

In the new millennium, we can be hopeful that the old polemics regarding whether recovered memories are false or authentic will increasingly be replaced by a more nuanced understanding of the issue. It will be understood that recovered memories may vary in their degree of accuracy, ranging from largely accurate to entirely false, with many gradations of gray in between. Moreover, the issue of accuracy in recovered memories will be carefully separated from consideration of the degree to which they are forgotten. Careful analyses of the variables that may lead individuals to perceive themselves to have recovered long-lost memories of trauma seem likely to identify a plethora of important mechanisms, some trauma specific and others general to all memories, and some known for years and others only recently conjectured. Such advances will help to reveal the important insights into the human mind that can be gained by exploring this unequivocally remarkable phenomenon. It is hoped that these insights will help and perhaps even provide some consolation to the untold numbers whose personal tragedies serve as the inspiration for this research.

Reinforcement, Reward, and Punishment

DANIEL T. CERUTTI
Duke University

GLOSSARY

contingency A conditional "if–then" relation between events such as responses and reinforcers.

discrimination Differential responding to stimuli that results when the stimuli signal the presence of a reinforcement contingency.

operant Behavior that is modified by its consequences, as in reinforcement and punishment.

punishment A reduction in the frequency of a behavior that results from its consequences. In positive punishment, behavior produces aversive stimuli such as illness; in negative punishment, behavior causes the loss of appetitive stimuli such as food. Punishment refers to both a procedure and a process—one in which the consequences are punishers.

reinforcement As in punishment, reinforcement refers to both a procedure and a behavioral process. The procedure involves providing reinforcers for responses; the process is the increase in the frequency of the behavior that results from the procedure. The consequences arranged in a reinforcement contingency are called reinforcers or rewards. In positive reinforcement, behavior produces appetitive stimuli such as food; in negative reinforcement, behavior eliminates or prevents aversive stimuli such as predators.

schedule Programs defining the necessary conditions for responses to produce consequences. Schedules arrange consequences as a function of time, number of responses, or both; they can be signaled by discriminative stimuli, and they can deliver appetitive or aversive stimuli.

Behavior interacts with the environment in a few important ways. Frequently, the environment supplies a stimulus that elicits a response; alternatively, the environment directs behavior by providing consequences for a response. The concepts of reinforcement and punishment deal with the effects of the latter; responses can be made more likely when they produce certain kinds of consequences and less likely when they produce other kinds. Sensitivity to the consequences of one's own behavior is among the most significant evolutionary innovations—a sort of ontogenetic natural selection to local aspects of ecology—extending the process of adaptation throughout the life of the individual.

Reinforcement and punishment entail both an environmental operation, arranging a consequence for a response, and a behavioral process, the effect on the frequency of the response. Like the reflex, the concepts are descriptive rather than explanatory—to observe an instance of reinforcement or punishment is not to explain it. However, the tautology implied in the definitions is easily refuted by findings showing that changes in the operation are always followed by related changes in the process.

Despite their apparent simplicity, processes of reinforcement and punishment are affected in complex ways by numerous variables and are capable of producing exquisitely coordinated behavior. The effect of a particular reinforcer depends on prior reinforcers, other sources of reinforcement, and many

other variables. Nor does reinforcement influence only the simplest varieties of behavior. Basic research on reinforcement is concerned with problems ranging from timing behavior in animals to concept learning in humans.

The challenge for the psychology of learning has been to understand the dynamic mechanisms of reward, the functions relating changes in the availability of reinforcers to changes in behavior. Knowledge of these functions will be essential to discover the physiological basis underlying the reinforcement process. Meanwhile, the pragmatic concerns of clinical psychologists and educators have benefited greatly from applications of basic findings helping them to develop effective behavior management programs for education, industry, and individuals with behavior problems.

I. HISTORY

The earliest concepts of reinforcement originated within experimental neurobiology and philosophy, but psychological investigation is largely responsible for unraveling its complexity.

In the middle of the 18th century, spinal reflex arcs had been isolated and used to support one-half of the Cartesian distinction between reflexive behavior and a spiritual mind. However, the latter half, Rene Descarte's assumption of native mental knowledge, was more difficult to endorse. Empiricist philosophers such as Locke proposed that complex knowledge could be explained by the accumulated experience of associated ideas. In the mid-19th century, Alexander Bain conceived the first modern idea of reinforcement by extending empiricism to action. He proposed that in addition to reflexes, organisms spontaneously emitted random, nonpurposive movements. When one of these actions produced pleasurable consequences, it would be repeated because of the association of a "muscle sense" with pleasure. This early conception of habit, behavior acquired by experience, gained acceptance in the late 19th century amidst the rising tide of Darwinism. Importantly, it provided a viable alternative to the creationist spirit implicit in Descarte's assumption that rational knowledge preceded complex action.

Approximately 40 years later, Edward Thorndike provided the first experimental demonstration that behavior could be affected by its consequences. One of his cat "puzzle boxes" is shown in Fig. 1. The top of Fig. 1 shows that the latency to escape from the box was long at first but gradually shortened. He called the behavior "trial-and-error learning" and formulated the law of effect, stating that pleasurable consequences "stamped in" responses and annoying consequences "stamped out" responses. Shortly thereafter, Pavlov's research on conditioned reflexes showed how reflexes could be conditioned to previously neutral stimuli. Thorndike and Pavlov had provided strategic concepts and tools for the new independent field of experimental psychology.

Pavlov's work initially overshadowed that of Thorndike because of arguments that Thorndike's finding could be explained by conditioned reflexes. However, in the 1930s, B. F. Skinner promoted the currently held view that Thorndike and Pavlov had discovered different processes. Skinner went on to design a highly successful experimental chamber to study reinforcement with rats and a cumulative recorder to record behavior in time (Fig. 2). His simplest design involved fitting a box with a lever, a food dispenser, and a light to signal the availability of food. He used his box to conduct numerous critical experiments on reinforcement, including several influential studies of discrimination learning and reinforcement schedules. Unlike puzzle boxes and mazes that studied learning in a trial-by-trial format, where the experimenter determined when a subject was placed in the apparatus, Skinner's automated apparatus permitted analysis of "free-operant behavior," where the animal could respond without an experimenter's intervention. Free-operant procedures are ideally suited to reveal the real-time dynamic interaction between behavior and environment, such as how quickly an organism adapts to changes in the availability of food. Skinner disdained statistical research designs comparing average performances of groups of animals and promoted single-subject designs in which very few subjects, exposed repeatedly to different levels of an independent variable, serve as their own controls. The latter approach seeks to reveal sources of variations in an individual's behavior rather than to deal with them simply as average performances subject to "error variance."

Researchers and theorists have since broadened the relevance of reinforcement to economics, language, problem solving, and other varieties of complex behavior. These advances have occurred simultaneously with the recognition that the effects of reinforcement are constrained by biological endowment: Ultimately, the organism constrains both the responses that are available to be modified by consequences and how they can be modified. Now the

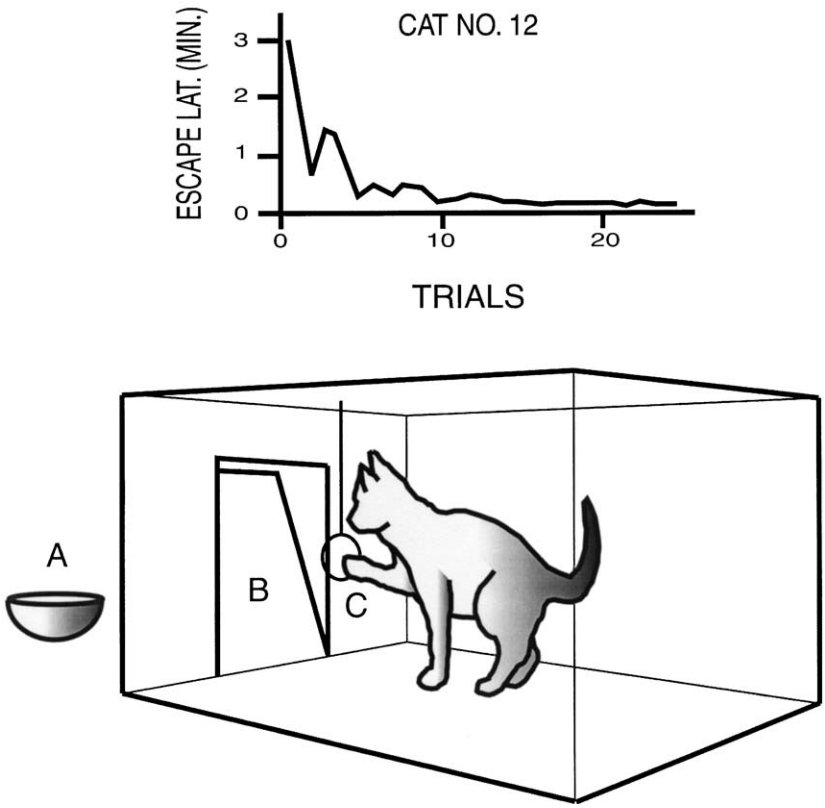

Figure 1 Thorndike's 1898 puzzle box. (A) Food placed outside of the box could be reached through a door (B) by pulling a loop (C) (Top) Time to escape as a function of trials.

challenge is to understand this interaction between the organism and its environment.

II. OPERANTS, REFLEXES, AND CONTINGENCIES

The reinforcement process can be illustrated by contrast with the reflex. In a reflex, a stimulus elicits a response and the response is said to be elicited. As shown in Fig. 3, reinforcement reverses the role between stimuli and responses an emitted behavioral response produces a reinforcing stimulus and the response is said to be operant. Operant and reflex responses are frequently linked by the same eliciting stimuli. For example, foods that elicit ingestion reflexes can vary in their form and distribution; these variations in foods can reinforce novel forms of operant handling and search trajectories. The effects of reinforcers and punishers do not require conscious deliberation, as illustrated by the nightly unconscious restraint of our movements that keep us from falling out of our beds.

Operants and reflexes are defined empirically by computing the conditional probabilities between stimuli and responses. In a reflex, response probability must be higher given a stimulus than given no stimulus. In an operant, response probability must be higher when responses produce reinforcers than when responses have no consequences or when reinforcers are delivered independently of responses.

A. Contiguity and Contingency

Reinforcers are most effective if they are contiguous with responses and less effective if they are delayed (Fig. 4). In animals, delays of just a few seconds are very detrimental. Even in the case of immediate reinforcement, however, reinforcers may not affect responding. There must also be a positive contingency, where the probability of a reinforcer is greater following a response. For example, rats will stop pressing a lever if the probability of reinforcement is the same with and without reinforcement, even if response-produced reinforcers are contiguous with

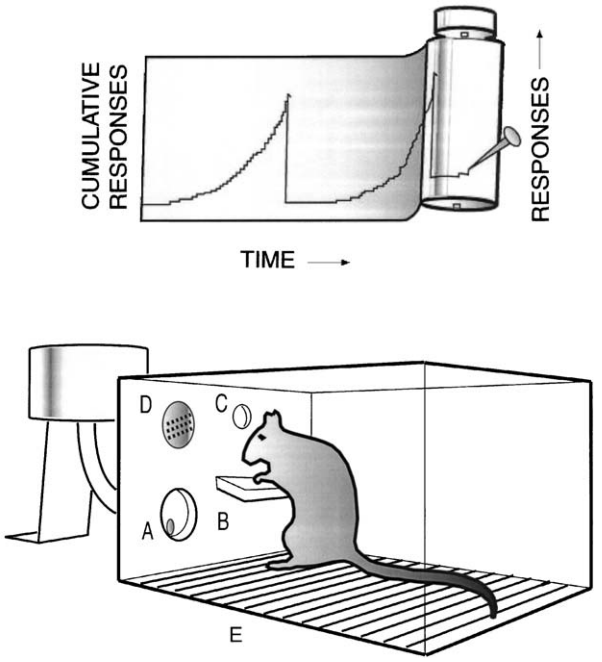

Figure 2 Skinner's 1938 electromechanical rat chamber. (A) Food is produced by pressing on a lever. (B) Stimuli signaling the availability of food or other events can be presented via a light (C) or a speaker (D). (E) The metal grid floor can be used to present electrical shock. (Top) A cumulative record: A clock motor feeds paper past a pen that increases with responses.

responses. Reinforcers that are delivered independently of responses diminish the effect of contiguous reinforcers, reducing their effect. Negative contingencies, sometimes called differential reinforcement of other behavior, are an effective way to reduce problem behavior in applied settings.

Responding can be maintained by slightly delayed reinforcers but only if there is a positive contingency.

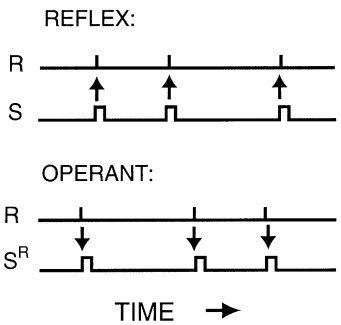

Figure 3 Causal relations between stimuli and responses in reflex and operant behavior. Arrows indicate dependencies between behavior and environment.

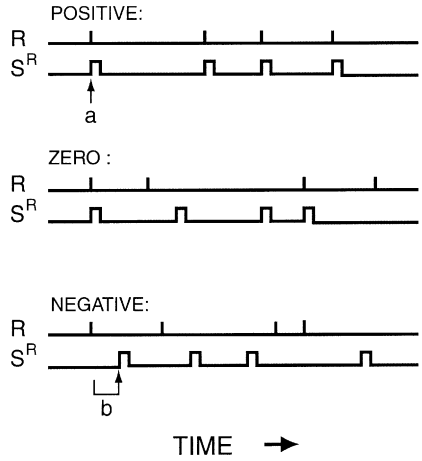

Figure 4 Contiguity and contingency in operant behavior. Contiguity is shown at a, when a response (R) is immediately followed by a reinforcer (S^R); a delay between a response and reinforcer is shown at b. Contingency is defined by (i) the probability of a reinforcer given a response and (ii) the probability of a reinforcer given no response. In a positive contingency, $1 > 2$; in a zero contingency, $1 = 2$; and in a negative contingency, $1 < 2$.

The detrimental effect of delay is dramatically reduced if the delay between responses and reinforcers is signaled by a stimulus that bridges the gap between a response and its delayed consequence. In the absence of signals, delayed reinforcers maintain more responding with variable delays than with fixed delays.

B. Extinction

Operant responses can be reduced in frequency by extinction (i) by terminating the reinforcement contingency or (ii) by delivering reinforcers independently of responses. Extinction procedures do not eliminate operants; rather, they produce additional learning that the operant contingency is broken. This can be seen in the rapid recovery of an operant when a reinforcement contingency is reinstated after extinction.

C. Conditioned Reinforcement

Reinforcers can be produced by procedures that generate conditioned reflexes, which are learned reflexes that result from a contingency between neutral stimuli and elicitors. In a conditioned reflex, a neutral stimulus becomes a conditioned stimulus and the response it elicits is a conditioned response. For example, if a light is paired with food, the light will elicit salivation as a conditioned stimulus but it can

also serve as a conditioned reinforcer. The effects of conditioned reinforcers change when the association between the conditioned stimulus and the reinforcer is changed.

D. Relativity of Reinforcement

Early theories of reinforcement argued that reinforcers served to reduce drives. Although some behavior could be explained by these motivation accounts, much behavior is not driven by need reduction. Many activities, such as play, seem to be maintained independently of their immediate consequences; moreover, a child might be induced to eat dinner in order to be able to play. Observations such as this led David Premack to suggest that if might be easier to understand the reinforcement process if reinforcers were identified by activities rather than stimuli. He proposed that relative time spent in different activities could be used to predict their value as reinforcers. For example, if a person spent more time in activity A than in activity B, the rate of B could be increased by reinforcing B with opportunities to do A. Figure 5 presents data from a human in a long-term observational study. During baseline conditions, this subject read more often than worked on art. When reading was restricted, and the opportunity to read was made contingent on art, the amount of time devoted to art increased. In control conditions in which reading was restricted without a contingency, the rate of art increased, but not to the levels seen with the contingency. The control demonstrated that the increase in artwork activity could not be explained only in terms of the restriction procedure; the increase required a contingency.

The fact that some infrequent activities such as sex can still be very reinforcing led to a modification of Premack's theory proposing that organisms work to maintain a balance between activities. This theory predicts that any activity can serve as a reinforcer if it is restricted: The individual will work to restore the balance. In the previous example, restricting the time available for B would cause B to be reinforced by A. This prediction has been experimentally supported.

III. VARIATION AND SELECTION

Reflexes are innate, stereotyped mechanisms selected by invariant phylogenic contingencies on survival. They serve prey capture, feeding, defense, escape, reproductive behavior, and care of offspring. In contrast, emitted responses contribute adaptive variations in behavior that assist in dealing with unpredictable features of the environment: locating food sources, nesting sites, mates, and other valuable resources.

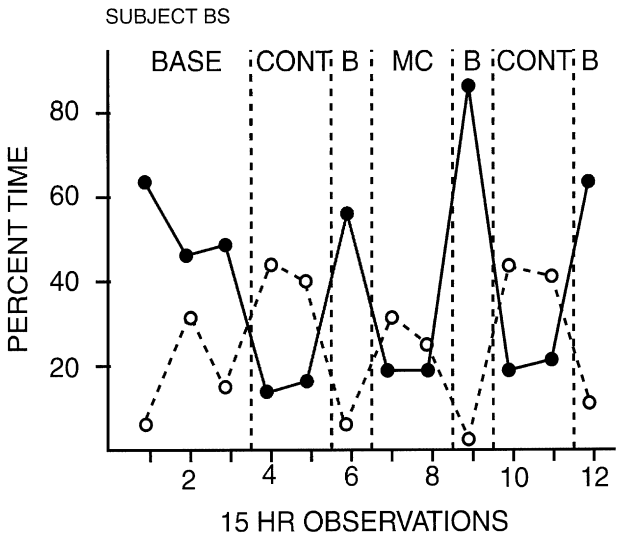

Figure 5 Premack contingencies. Open circles indicate time devoted to an instrumental response (artwork); solid circles indicate time devoted to a contingent response (reading). Vertical dashed lines indicate condition changes: baseline observations when activities were not restricted (BASE and B), contingency conditions when reading was restricted and access to reading depended on doing artwork (CONT), and matched control conditions in which reading was restricted (MC) (data from Bernstein and Ebbesen, 1978, Reinforcement and substitution in humans: A multiple response analysis. *J. Exp. Anal. Behav.* **30,** 243–253).

The selection of behavioral variations by reinforcement is illustrated in Fig. 6. In this puzzle box experiment, movements of a pole opened the box door. Camera records of the cats' behavior showed that a single response, emitted early in test trials, came to dominate. The response form differed between cats, suggesting that reinforcers were selecting random variations. Later experiments revealed that the escape responses these cats emitted, such as nuzzling the pole and rubbing the pole with their backside, were social responses elicited by the experimenters. The finding illustrates two important points about reinforcement. First the behavior a reinforcement contingency captures is constrained by the range of response variation provided by the organism in a particular situation. Second operant responses can have features that are reinforced but that are not essential to the contingency; for example, a rat might learn to operate a lever by pressing it with two paws even though one might suffice.

Reinforcement contingencies serve to narrow the range of variability in emitted behavior by selecting its most successful forms, making them more frequent and thereby displacing less effective forms. Juvenile hawks and wolves, for example, show adjustments in hunting strategies as a result of their effectiveness. The differential reinforcement of some responses to the exclusion of others is called shaping. In a dramatic example, invisibly small thumb twitches in college students were trained with a shaping procedure by connecting subjects to recording instruments and telling them that by relaxing they could earn money. When a particular thumb-twitch amplitude was emitted points were added on a counter in front of the subject, indicating money. The procedure quickly increased frequency of the target response. In debriefing it was found that students were never aware of how they produced money, experimentally demonstrating learning without awareness in humans.

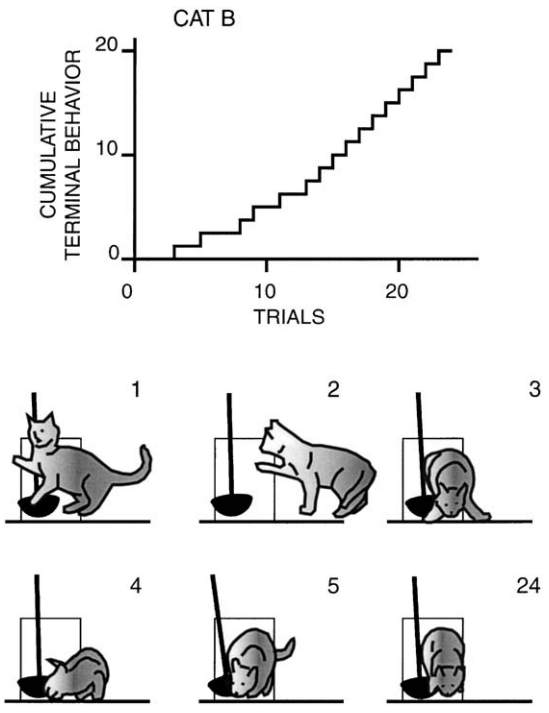

Figure 6 The stop-action principle of reinforcement. The cat's task involved escaping from a puzzle box by moving a pole. The cat's escape responses for trials 1–5 and 24 are shown below an inset showing the cumulative occurrences of the terminal response (pushing the pole with its hindquarters) (adapted from Guthrie and Horton, 1946, *Cats in a puzzle box*. Rinehart & Company. Copyright Edwin R. Guthrie and George P. Horton).

Shaping is closely analogous to natural selection, where different responses are analogous to phenotypic variations. Shaping illustrates the importance of variation in emitted behavior. Without variation, changes in reinforcement contingencies could not select new forms of behavior. This points out the trade-off in the variability reducing effects of reinforcement since less variation means diminished adaptability to future changes in contingencies. However, reinforcement never reduces variations in behavior entirely. For example, variability returns to emitted behavior in extinction, a potentially adaptive reaction to dwindling resources. Also, several studies have shown that variability in behavior can serve as the basis for reinforcement, as in the reinforcement of creative behavior (e.g., each reinforcer is contingent on the emission of a novel pattern of behavior).

A. Superstition in Animals

Skinner arranged response-independent food for a pigeon at 13-sec intervals and found that it developed stereotypical patterns of behavior. He called the behavior "superstition," arguing it was adventitiously reinforced by the accidental contiguous pairing of a response with a reinforcer and suggested that some human superstition could be explained in the same way. An important implication of the experiment was that contiguity was the necessary and sufficient condition for reinforcement. However, experiments have since shown that the behavior Skinner observed is not a simple reinforcement effect but instead complexly determined by the food and the experimental chamber. The behavior of a typical pigeon in such a

procedure is shown in Fig. 7: Some types of behavior reliably occur early in the interval (interim behavior) and other types occur later (terminal behavior). Also unlike the reinforced behavior shown in Fig. 6, the patterns are nearly identical in different pigeons. Evidence suggests that some responses such as pecking the wall are conditioned reflexes; others seem to be food-elicited foraging responses. The conclusion from this and other studies is that nonhuman animals are very sensitive to the difference between response-produced and response-independent reinforcers.

IV. ELICITING EFFECTS OF REINFORCERS AND PUNISHERS

The eliciting effects of reinforcers can reduce variability in behavior by restricting the range of responses available for reinforcement. The most dramatic examples arising from the animal-training literature have been misnamed "misbehavior." An example is illustrated in Fig. 8. The operant contingency involved reinforcing putting coins in a bank. Shortly after learning to do this, the raccoon began to misbehave, rubbing the coins together for long periods of time. However, the rubbing is actually a raccoon species-typical food washing behavior elicited by food. As a result of earning food by depositing coins, the coins became a conditioned stimulus for food and elicited washing.

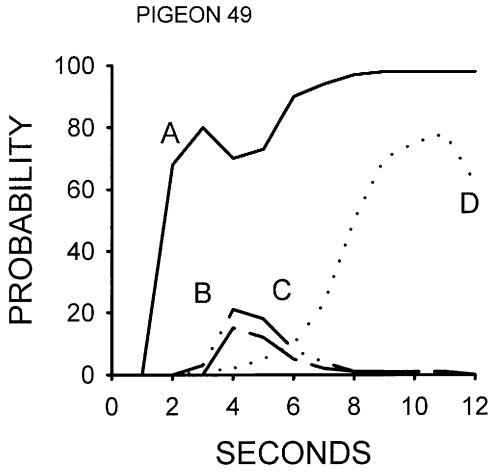

Figure 7 Probabilities of pigeon 49's behavior in successive seconds under a fixed-time 12-sec schedule. The letters indicate behaviors: A, facing the feeder wall; B, pecking the floor; C, quarter turns, and D, pecking at the feeder wall (data from Staddon and Simmelhag, 1971, The "superstition" experiment: A reexamination of its implications for the principles of adaptive behavior. *Psych. Rev.* **78,** 3–43).

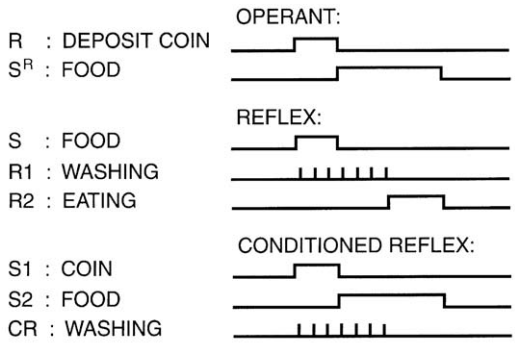

Figure 8 "Misbehavior" in the raccoon. The operant contingency reinforced depositing money in the bank. However, the additional contingency between coins and food resulted in the coins becoming conditioned elicitors of washing, interfering with the operant performance.

Many instances of punishment reduce the frequency of behavior in a similar manner: An emitted response produces a painful stimulus that elicits defensive behavior such as escape and avoidance. The result is that "punishment" reduces the target behavior but not just by being a consequence of behavior. As a rule, reinforcers are most effective when the responses they elicit are identical to or compatible with a reinforced response and punishers are most effective when the responses they elicit are incompatible with the punished response.

Conditioned aversive stimuli, stimuli that are paired with pain-eliciting stimuli, can suppress operant behavior. They can do so by being made contingent on operant responses or by their mere presence because they elicit defensive behavior that is incompatible with the operant. Figure 9 illustrates the interaction between conditioned-aversive stimuli and food-reinforced responding. As the tone + shock trials proceed, less operant responding is seen during the

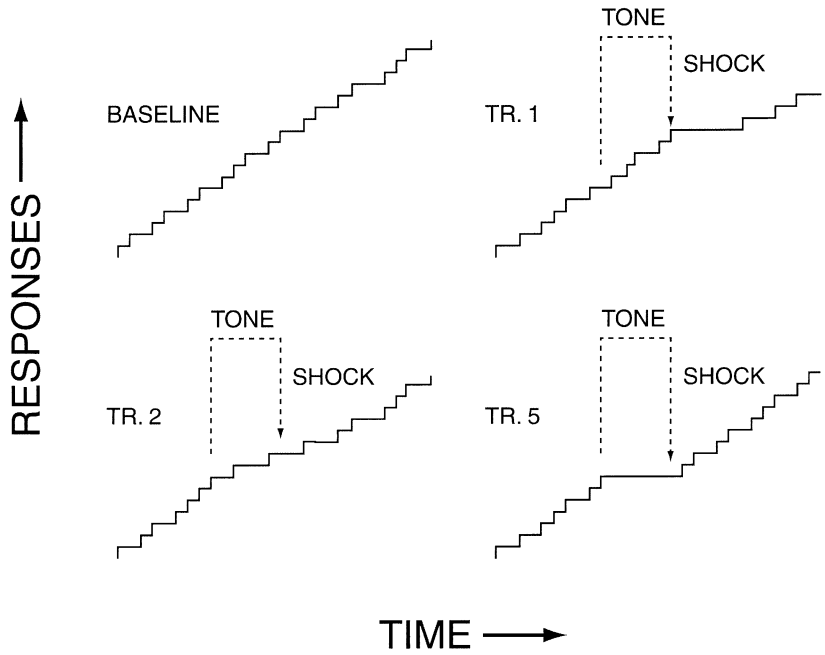

Figure 9 The development of a conditioned-aversive response as indicated by disruption of ongoing operant behavior.

tone. The amount of suppression generated by a conditioned-aversive stimulus depends greatly on the level of deprivation maintaining the operant behavior —a very hungry rat will show less suppression of food-reinforced lever pressing than a less hungry rat.

V. PUNISHMENT

Punishment contingencies are in opposition to reinforcement; they reduce the frequency of responses. Many of the variables that determine the effects of reinforcement similarly affect punishment. These variables are the following: (i) Immediate punishers are more effective than delayed punishers, (ii) strong punishers are more effective than weak punishers, and (iii) punishers are most effective that are presented only for target responses and not at other times.

The concept of punishment includes two operations: positive punishment, in which behavior produces aversive events such as hitting, and negative punishment, in which behavior causes the loss of a currently available appetitive stimulus such as food. However, these need not imply the same behavioral process even though they are both called punishment. For example, the former operation involves the presentation of eliciting stimuli with responses that habituate over repeated presentations, making punishers less effective over time.

Positive punishment has two effects that account for the reduction in behavior: (i) elicitation of species-typical escape or defensive behavior and (ii) the effect of the punishment contingency. These can be distinguished by comparing the effects of response-independent with response-contingent punishment. For example, a rat's lever pressing for food will be reduced by simply presenting occasional response-independent shocks, but it will be reduced more if shocks are contingent on lever presses. This finding shows that not all the effects of punishment are due to the elicitation of escape or defensive behavior; some are due to the punishment contingency.

Punishment can be seen as the opposite of reinforcement, but if differs from reinforcement in another important way. Punishment operations are always superimposed on a baseline of existing responding, usually maintained by reinforcement. In the laboratory, for example, punishment is usually studied on responses maintained by food. The result is that the effect of a given punishment is determined largely by the target response's level of motivation.

In extinction from punishment, responses recover to previous levels. Although the effects of punishment can be long-lasting, there are only a few experimental

examples in which a punishment eliminates responding permanently.

VI. SCHEDULES OF REINFORCEMENT

The same reinforcer can have very different effects on behavior depending on the reinforcement schedule that arranges it. Very few naturally occurring reinforcement contingencies arrange reinforcement for every response. Instead, the rule is partial reinforcement, in which responses are reinforced on the basis of time, number of responses, or some combination of time and responses. Figure 10 shows typical patterns of behavior on four simple schedules—the where, when, and how much of operant behavior is determined by schedules. These patterns and their dynamics are the subject of much quantitative modeling in search of a simple set of principles that will generate the gamut of schedule-typical performances. An adequate model must encompass complex behavior such as choice, self-control, and the temporal patterning of behavior.

Skinner pioneered the study of schedules, documented many of their effects, and developed a highly successful graphical form to display changes in behavior over time, the cumulative record. The discovery of the orderly and distinctive patterns of behavior on different schedules of reinforcement led Skinner to argue that rate of responding is the primary datum of the science of behavior. However, attention to the molar property of rate has had the unfortunate effect of obscuring investigation of the moment-to-moment molecular dynamics of behavior.

A. Interval versus Ratio Contingencies

In an interval schedule, a reinforcer is produced by the first response after the passage of a specified interval of time. In a ratio schedule, a reinforcer is produced after the emission of a specified number of responses. Time or response requirements can either be fixed or variable around some mean value (of time or responses). Figure 11 shows typical data from a pigeon responding on variable interval (VI) and variable ratio (VR) schedules. When rate of reinforcement in interval and ratio schedules is equated, organisms respond at higher rates on ratio schedules (although the difference is

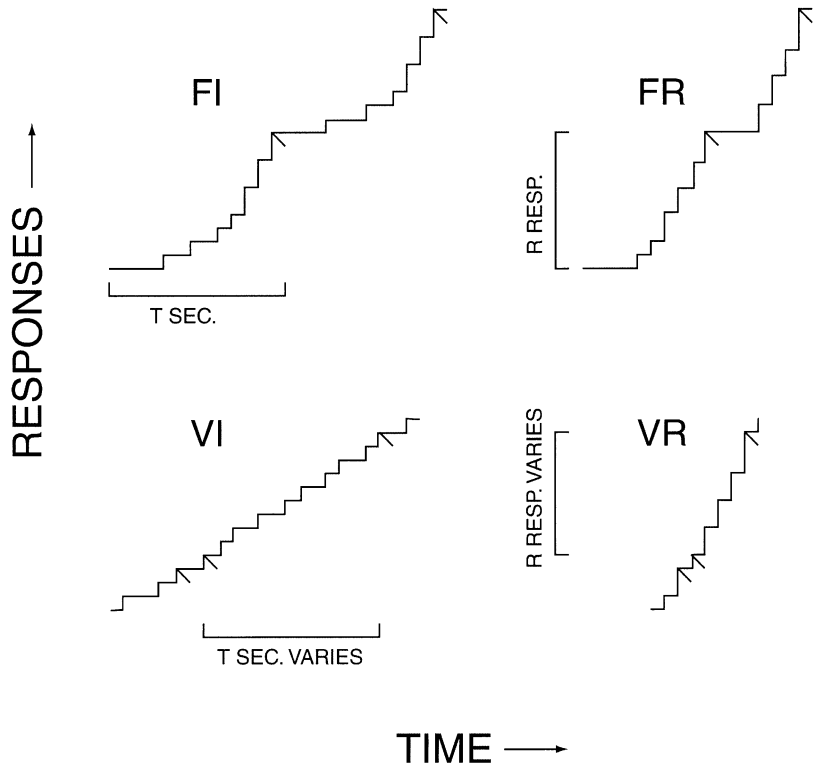

Figure 10 Schedule-typical response patterns on four simple schedules: fixed interval (FI), fixed ratio (FR), variable interval (VI), and variable ratio (VR). Ratio schedules produce higher rates of responding than interval schedules at a given rate of reinforcement, and fixed schedules show more pausing after reinforcement than variable schedules.

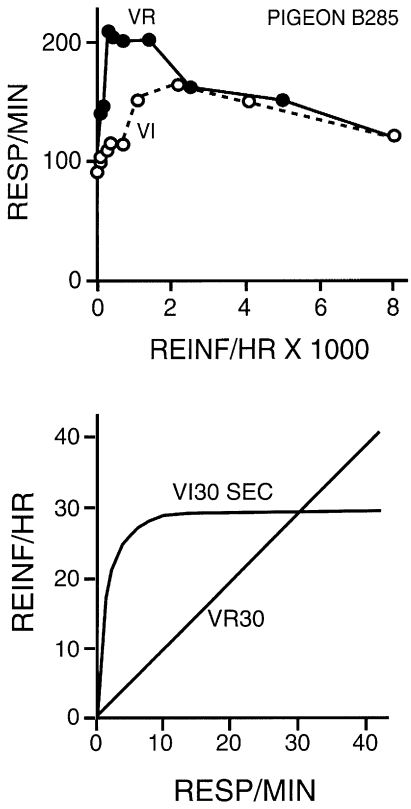

Figure 11 Interval and ratio schedule feedback contingencies. (Top) Response rates of a pigeon on variable interval (VI) and variable ratio (VR) schedules as a function of reinforcement rate.

small at very high rates of reinforcement). The reason is illustrated by the feedback functions in the bottom of Fig. 11: Rate of reinforcement in ratio schedules increases directly as a function of response rate but not in interval schedules. Fixed interval (FI) and fixed ratio (FR) schedules show similar rate functions.

Ratio and interval schedules produce distinctive declines of responding in extinction. In interval schedules, responding declines gradually; in ratio schedules, responding alternates between periods of high rates and no responding.

B. Waiting: The Timing of Operant Behavior

Organisms show characteristic pausing before responding, or waiting, after earning a reinforcer. Figure 12 shows pause distributions for simple interval and ratio schedules. Pausing is greatest on FI and FR schedules and minimal on variable interval VI and VR schedules. In VI and VR schedules, wait times are heavily influenced by the shortest interreinforcement intervals or ratios in a schedule: Organisms wait somewhat less than the shortest interfood interval.

Figure 13 shows characteristics of waiting on FI schedules in a typical pigeon, patterns that are seen in a broad variety of species, including monkeys, fish, and humans. The top plot in Fig. 13 shows that in an FI, wait time is reliably a fixed proportion of the FI value. Proportional timing is sometimes complemented by scalar variability in wait times, where variance in waiting is a constant proportion of interval value. The bottom plot in Fig. 13 shows that variability in this pigeon's wait time increases with FI duration. The proportional and scalar properties of waiting are so ubiquitous that they have led to several timing models.

Waiting is obligatory: Organisms will pause after earning a reinforcer even when doing so reduces the immediacy and overall rate of reinforcement. This is illustrated in experiments with response-initiated delay (RID) schedules. The contingency is shown in the bottom of Fig. 14: After a reinforcer, a response initiates a delay of T seconds that ends in reinforcement. Instead of responding immediately after reinforcement (an optimal strategy), pigeons treat the RID like an FI with a duration equal to the wait plus T. Moreover, waiting on the current trial is a function of the preceding trial, a linear-waiting rule. A linear-waiting rule has been demonstrated by adding an adjusting feature to the RID such that the value of T depends on the duration of the preceding interfood interval, i.e.,

$$T(N+1) = \alpha(t(N) + T(N)) \qquad (1)$$

where t is the time until the first peck (i.e., pause or wait time), α is a proportionality constant, and N is the time between food deliveries. If the animal behaves in such a way that pause in interval $N+1$ is simply proportional to the preceding interreinforcement time, this process is unstable: t should decrease to 0 if α is less than 1, but increase without limit if α is greater than 1. The top of Fig. 14 shows data that illustrate this instability.

C. Differential Reinforcement of Rate

Reinforcement can be arranged to follow a pause followed by a response, an interresponse time (IRT). If the IRT must be less than a maximum value, response rate is increased; if the IRT must be greater than a minimum value, response rate is decreased. Differential reinforcement of IRTs has been proposed to

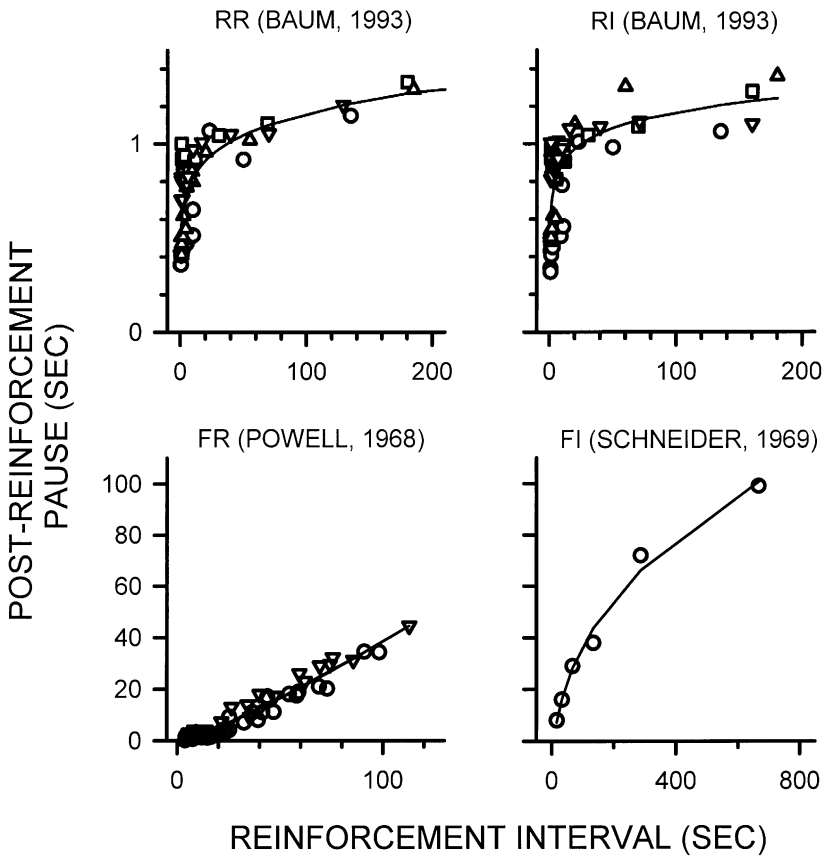

Figure 12 Pause distributions on the four basic schedules. FI data points are means; other plots show individual organisms. [Data from: Baum, W. M. (1993). Performance on ratio and interval schedules of reinforcement: Data and theory. *J. Exper. Anal. Behav.* **59,** 245–264; Powell, R. W. (1968). The effect of small sequential changes in fixed-ratio size upon the post-reinforcement pause. *J. Exp. Anal. Behav.* **11,** 589–593; Schneider, B. (1969). A two-state analysis of fixed-interval responding in the pigeon. *J. Exp. Anal. Behav.* **12,** 677–687].

explain rate differences in interval and ratio schedule behavior since the probability of reinforcement in interval schedules is greater for responses following long IRTs, and ratio schedules reinforce short IRTs. However, behavior produced by IRT schedules is unlike that seen under interval and ratio schedules. For example, it is difficult to differentially reinforce wait times longer than about 20 sec, even though waiting on FI schedules can extend to many minutes. This is because the proportional aspect of timing, pausing for a proportion of a reinforcement interval, preempts the wait time required for reinforcement.

D. Behavior Chains, Sequences, and Multiple Schedules

Much complex behavior, such as building a house, is made up of elementary tasks that must be executed in a fixed order to obtain a reinforcer. This is the essence of a behavior chain: One contingency is made a consequence of another until a terminal reinforcer is procured, and each contingency is signaled by a unique stimulus. The bottom diagram in Fig. 15 shows a three-link chain—cumulative records from tandem and chain schedules made up of three FI 60-sec schedules. Original accounts of how behavior in early elements of a chain was maintained appealed to conditioned reinforcement. However, the data shown at the top of Fig. 14 clearly show that response rates in the early links of the tandem schedule (a chain in which the links are not signaled by distinctive stimuli) are higher than in a chain schedule. Although conditioned reinforcement effects are well documented, they do not seem to apply to behavior chains. A completely satisfactory explanation has not yet been obtained, but there is a similarity between chain and RID schedules that can explain a large part of the effect: Any tendency of the

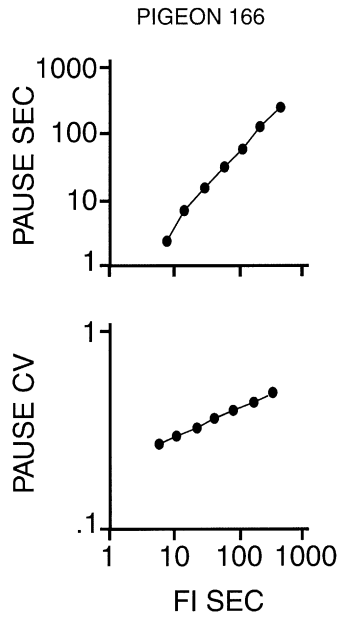

Figure 13 Properties of pausing on FI schedules. (Top) Pausing. (Bottom The coefficient of variation (standard deviation of wait times divided by their mean: CV). Data are on log–log coordinates

animal to wait in the first link of a chain in proportion to the delay to the terminal reinforcer would produce behavior like that seen in Fig. 15.

E. Multiple Schedules

The rate of responding on a schedule is affected by the existence of alternating schedules. This is seen in multiple schedules in which a schedule identified by stimulus A alternates with another schedule identified by stimulus B. For example, if a multiple VI–VI schedule is changed to a multiple VI–extinction, the rate in the unchanged VI will increase. This effect is called behavioral contrast. Several variables appear to contribute to contrast; one important reason is simply that the rate of one operant is suppressed by the availability of alternative sources of reinforcement for other operants.

F. Choice

Reinforcements can occur simultaneously for different responses. In concurrent schedules, choices between alternatives are a function of the types of competing schedules. Studies of choice have found that the behavior is complexly determined and not just a simple function of competing rates or magnitudes of reinforcement.

Humans and other organisms faced with two VI schedules will choose in proportion to the relative rates of reinforcement they provide. Figure 16 presents data from an experiment with pigeons in which the

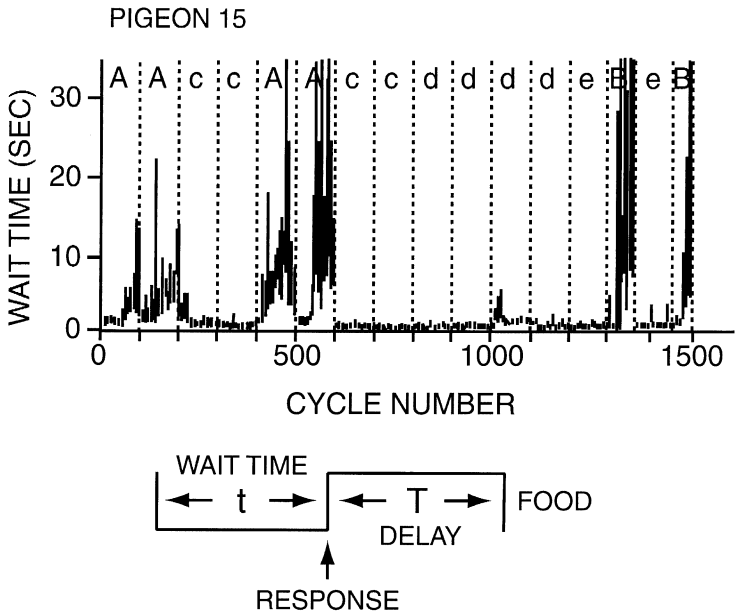

Figure 14 Dynamics of waiting on RID schedules. Vertical dashed lines show sessions during different values of the gain parameter α: A = 7, B = 4, c = 0.5, and d = 0.25 (data from Wynn and Staddon, 1988, Typical delay determines waiting time on periodic schedules: Static and dynamic tests. *J. Exp. Anal. Behav.* **50,** 197–210).

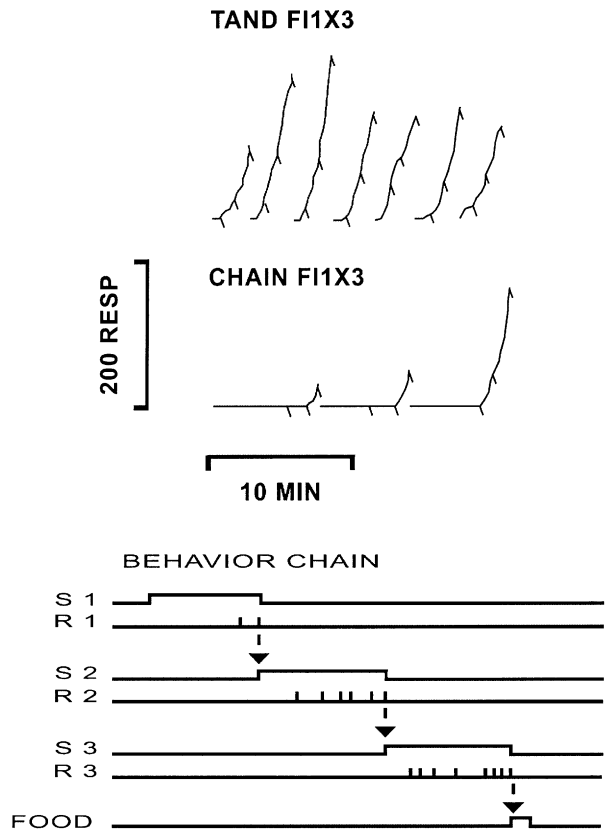

Figure 15 Chain and tandem schedules. In both schedules, reinforcement is obtained after completing a succession of three FI 60-sec schedules. In the chain, the stimuli identifying each FI (S1–S3) are distinctive; in the tandem, they are identical. (Top) Cumulative records from one pigeon (downward pips of the response pen indicate the last response in each FI; the response pen was reset after the third link of each schedule) (data from Kelleher and Fry, 1962, Stimulus functions in chained fixed-interval schedules. *J. Exp. Anal. Behav.* **5,** 167–173).

proportion of reinforcement available on left and right VI schedules was varied over sessions. Data points along the diagonal of the figure indicate that the pigeons' choices tracked reinforcement; for example, they selected the alternative producing 20% of the total reinforcers about 20% of the time. Richard Herrnstein formalized this observation in the matching principle, the first quantitative formulation of choice:

$$\frac{R_L}{(R_L + R_R)} = \frac{r_L}{(r_L + r_R)} \qquad (2)$$

where R_L and R_R are response rates on left and right alternatives and r_L and r_R are reinforcement rates on left and right alternatives. The matching principle has been demonstrated in a variety of species, tasks, and circumstances, including in conversation between a speaker and two listeners who reinforced verbalizations at different rates.

Matching assumes that behavior is controlled by the molar properties of rate of reinforcement. Molecular models, attempting to account for choice in terms of the moment-to-moment tracking of reinforcement probabilities for different alternatives, have not been supported by experimental tests. However, the effects of reinforcers can be seen at the molecular level. In simple FI schedules, for example, shortening a single interval will produce a shorter waiting time in the next interval (i.e., linear waiting). Models that predict such dynamic properties of behavior have only just appeared and have not yet been applied to choice behavior.

G. Choice and Conditioned Reinforcement

Despite questions about whether stimuli in behavior chains are conditioned reinforcers, many experiments have studied choice in concurrent chain schedules. The procedure is illustrated in Fig. 17. In a typical concurrent chain schedule with pigeons, two white response disks are presented. Pecking on each disk is reinforced according to a VI schedule, the same for each key. This is the first link of a two-link chain. When the schedule on a key "times out," the next peck causes a change in both keys: For example the pecked key changes to red (the second link on the left), and the

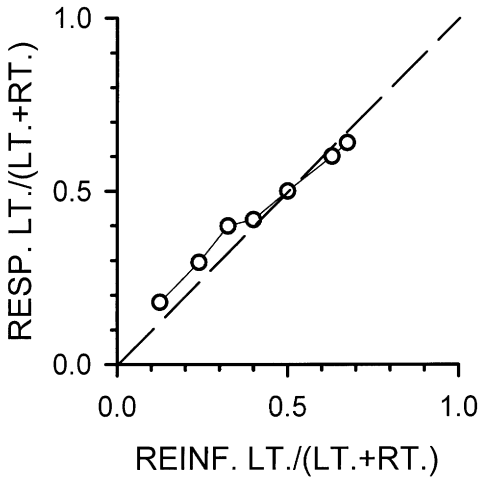

Figure 16 Choice on concurrent VI–VI schedules (data from Catania, 1962, Concurrent performances: Reinforcement interaction and response independence. *J. Exp. Anal. Behav.* **6,** 253–263).

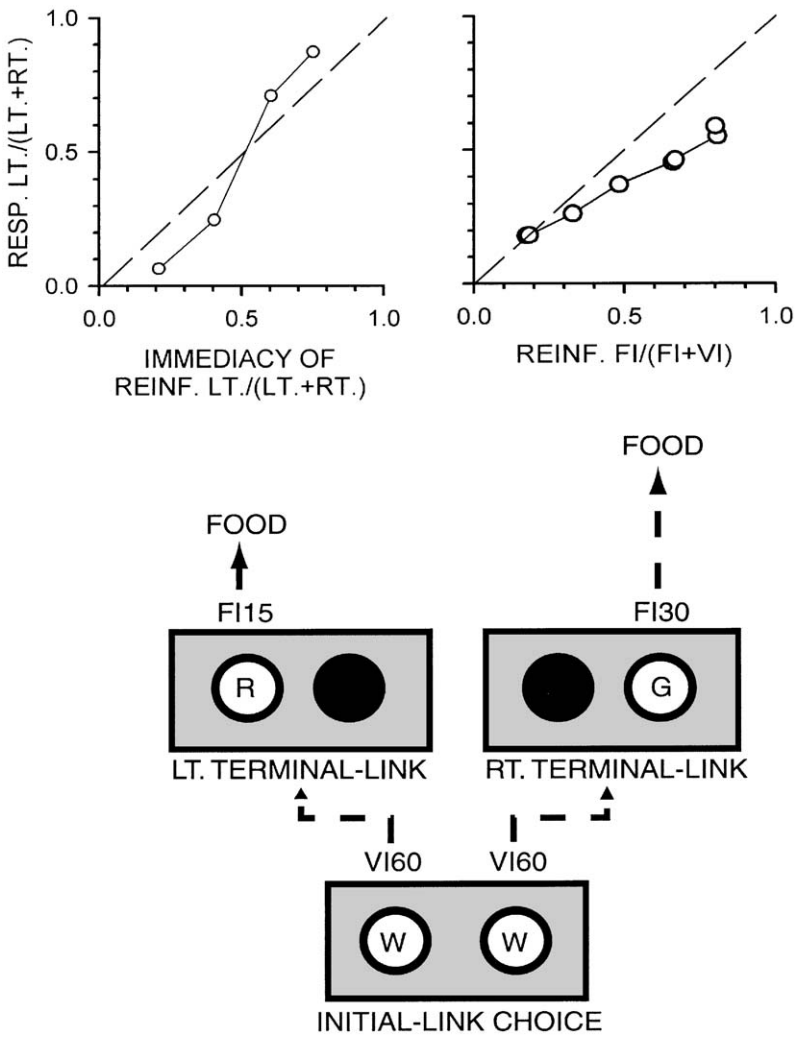

Figure 17 Concurrent chains schedule. (Top) Data from pigeons with FI schedules in second links on the left (data from Killeen, 1970, Preference for fixed-interval schedules of reinforcement. *J. Exp. Anal. Behav.* **14,** 127–131) and with VI and FI second links on the right (data from Trevett *et al.*, 1972, Performance in concurrent interval schedules. *J. Exp. Anal. Behav.* **17,** 369–374).

other is blacked out. In the presence of the red key, food reinforcement is delivered according to another schedule, (e.g., FI, VI, VR, or FR). A similar sequence operates for the other second-link stimulus (green, on the right).

The usual dependent measure in these experiments is steady-state relative response rate, $x_L/(x_L+x_R)$, in the first link. Typical independent measures in the second links are absolute and relative reinforcement rates (R_{1L} and R_{1R}) and the associated average delays to reinforcement ($1/R_{1L}$ and $1/R_{1R}$). In the second links, in addition to absolute reinforcement rates, studies have varied the number of links with or without distinctive stimuli, size, and delay (VI or FI value) of food reinforcement. The following are reliable results from these experiments:

1. First-link preference tends to indifference as the absolute value of the first-link VI is increased: The longer the delay to the second link, The more indifferent the animal is to which link is chosen.
2. A single FI second link is preferred to an equal-rate two-link FI chain.
3. A short FI second link is preferred over a long FI second link more than predicted by the matching principle.
4. A VI second link is preferred to an equal-reinforcement-rate FI.

One of the important generalizations that can be made from these findings is that organisms value immediate reinforcers more than delayed reinforcers more than predicted by rate of reinforcement, even in the case in which the immediate reinforcers are infrequent (3 and 4). Several quantitative theories have been proposed to account for these and other results from concurrent chain schedules.

Delay-reduction theory (DRI) proposes that the value of a conditioned reinforcer, $V(S_i)$, is directly related to the difference to delay to reinforcement signaled by the current stimulus and the succeeding stimulus (i.e., to the first derivative of expected reinforcement rate). In its simplest form, DRT is $V(S_1) = k(t_1 - t_2)$, where t_1 is average time to reinforcement in the first stimulus, t_2 is average time to reinforcement in the succeeding stimulus, and k is a constant. Preference (relative response rate) is determined by relative V values:

$$\frac{x_{L1}}{x_{L1} + x_{R1}} = \frac{\Delta_L}{\Delta_L + \Delta_R} \tag{3}$$

where Δ_L is $d_{L1} - d_{L2}$, the delay reduction on the left, and similarly for Δ_R. A later version of DRT, modified to incorporate reinforcement rate, describes a number of experimental findings in the concurrent chains literature but it has difficulty if the initial links are not VI schedules and difficulty with terminal links made up of complex schedules, such as two-link chains or multiple schedules. DRT can account for properties 1 and 2 but has difficulty with 3 and 4.

Incentive models of conditioned reinforcers share the assumption of a nonlinear relation between stimulus value and reinforcement rate. For a simple two-link concurrent chain, incentive theory (IT) reduces to the relation

$$x_{L1} = \frac{1}{d_{L1} + d_{L2}} \left(e^{-qt_{L2}} + \frac{1}{d_{L2}} \right), \tag{4}$$

and similarly for the other choice. This equation, with decay (q) and a bias variable as free parameters, could fit data from concurrent chain experiments with two-link second links (which pose problems for DRT) as well as a number of other studies.

Melioration theory differs from DRT and IT in that it makes predictions directly about the value of a stimulus (i.e., without concern about the overall rate of reinforcement). Melioration theory assumes that conditioned stimulus value is a function of the value and rate of the primary reinforcer identified with the stimulus, and that there is a hyperbolic growth function relating rate to value. This model can make similar predictions to DRT but fails to handle complex second-link concurrent chains (e.g., a behavior chain).

None of these theories account for all the data on concurrent chains. Recently, researchers have turned to economic models of choice. These models treat responses per reinforcer as cost and incorporate factors such as elasticity and demand in their predictions. Economic models work well with simple procedures involving cost and demand, but organisms deviate substantially from predictions of performance on complex schedules. Moreover, economic models have demonstrated that animals do not make optimal choices (or, as suggested by RID schedules, show optimal behavior).

The most successful quantitative accounts of reinforcement, such as variants of the matching law, involve molar averages of behavior and consequences. This has led to speculation that reinforcement mechanisms operate on molar principles. Despite the success of these models, molecular effects of reinforcement are abundantly obvious. Recent models of reinforcement suggest that there are two processes that determine the effect of a reinforcer, one "slow" and one "fast." The slow process accumulates the effect of reinforcers over long periods of time, reducing fast changes in behavior that occur when contingencies change.

VII. DISCRIMINATION AND EXTINCTION

In early experiments on the law of effect, Thorndike recognized that the effect of reinforcers was to strengthen behavior in a particular situation. In formal terms, this is the three-term contingency relation of discriminative stimulus (S^d), response, and consequence. The discrimination procedure arranges for responses to have consequences in the presence of an S^d and not at other times; the S^d is said to occasion responses. Discrimination learning underlies much behavior said to involve cognition, including important aspects of concept learning, verbal behavior and problem solving.

A. Generalization, Concepts, and the Quantal Nature of Discrimination

Once responses are reinforced in the presence of a stimulus, generalized responding will be occasioned by

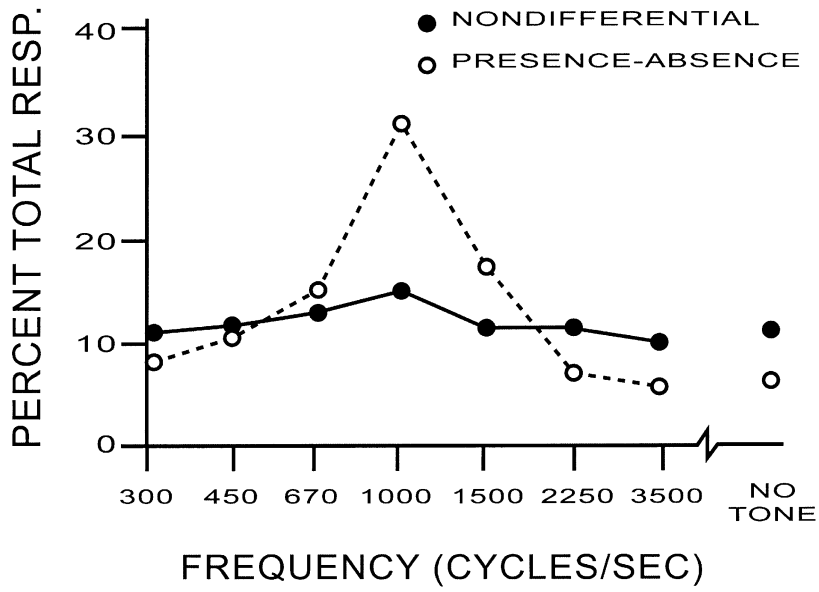

Figure 18 Generalization gradients from pigeons after nondifferential training with a 1000-Hz tone and presence–absence training with and without the tone (data from Jenkins and Harrison, 1960, Effect of discrimination training on stimulus generalization. *J. Exper. Psych.* **59,** 321–334).

similar stimuli without additional reinforcement. With tone and color S^d, generalization shows a peak around the S^d that is called a generalization gradient: The probability of responding decreases as a function of the difference with the training stimulus. Figure 18 shows that discriminative stimulus control is tighter (the gradient is peaked) following training in which reinforcement in the presence of the S^d was alternated with periods of extinction without the S^d (presence–absence training) in comparison to training without extinction periods (nondifferential training).

Figure 19 shows the effect of training with an S^d and extinction stimulus that lie on the same stimulus dimension of light (wavelength). In this case, the postdiscrimination gradient is steeper and the peak is displaced away from the training frequency. A satisfactory explanation for the shift has not been determined but it is possible that the extinction stimulus produces an inhibitory gradient that subtracts from the excitatory generalization gradient.

Discriminative stimuli can be very complex. Natural concepts, such as trees, water, and flowers, can form the basis of discriminations. In a concept, perceptually similar stimuli occasion a response such as saying "tree, "water," or "flower." Concepts are trained by reinforcing a response in the presence of concept exemplars and extinguishing the response in the presence of other stimuli. Demonstrating a concept requires testing with novel stimuli and finding generalization to untrained examples of the concept but not to other stimuli. Research investigating the basis of concept learning in animals has found that some concepts such as cars require training with several examples, but others, such as an oak leaf, can be learned after a single exemplar. The findings suggest that some concepts involve learning about correlation of stimulus features and other concepts contain a single perceptually distinct feature.

Generalization is an adaptive process since discriminative stimuli in the natural environment are likely to vary from instance to instance. However, if discriminative stimuli vary, reinforcement ensures that responses do not. This has been demonstrated in tasks in which both responses and stimuli are continuous. In one study, pigeons were trained to peck at one end of a 25-cm strip when the strip was brightly illuminated and to peck at the other end when it was dimly illuminated. In tests with intermediate levels of illumination, the pigeons pecked only at the end points where responses had previously been reinforced. Moreover, the end they pecked depended on the similarity of the test stimulus to the training stimulus. This property of behavior is seen in naming. For example, a child who has learned the concepts of "dog" and "horse" will not say "dorse" in the presence of a llama (assuming that a llama has intermediate dimensions); instead, the child

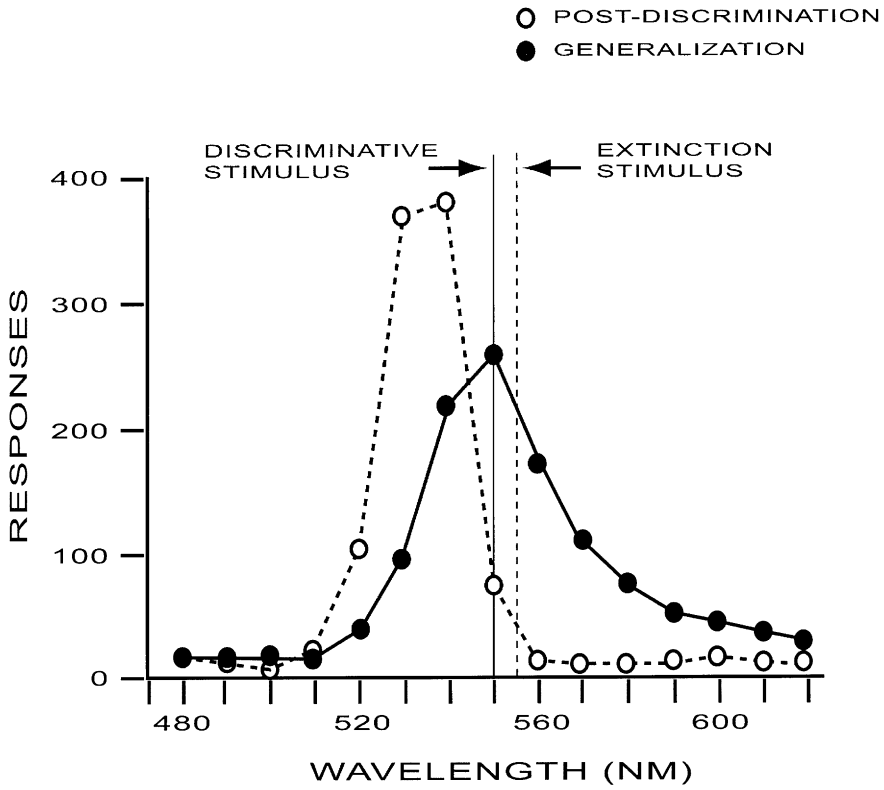

Figure 19 Postdiscrimination and discrimination gradients in pigeons for wavelength of light (data from Hanson, 1959, Effects of discrimination training on stimulus generalization. *J. Exper. Psych.* **59,** 246–253).

will emit one or the other of the previously learned responses. The invariance of discriminated responses has been called the quantal nature of discrimination to emphasize the fact that response forms remain discrete.

B. Learning Set and Learning by Exclusion

Discrimination learning can be generalized. The point is illustrated by experiments with monkeys on learning set. In the typical procedure, a monkey is presented with two objects; under one is a piece of food. When it learns the discrimination, two new objects are presented, and so on. Learning proceeds more rapidly after each problem until it learns new discriminations in a single trial. Learning set has also been demonstrated in other species and with other tasks.

Learning set is evident in a word-learning discrimination called learning by exclusion. In typical experiments employing nonverbal humans with mental retardation, subjects are first taught names for several foods. Then a new food is placed among foods with known names. Without any further training or prompts, subjects are asked to point to the new food that is given a never before heard name. Experienced subjects correctly select the novel food on the first test, and in subsequent tests with that food and new foods they demonstrate retention of the new name. These experiments show that after learning several names, individuals learn the contingency that exists between new names and new objects.

C. Conditional Discrimination

Reinforcement can be made contingent on conditional relationships between stimuli. Figure 20 shows a pigeon in an identity matching task in which stimuli are matched on the basis of similarity: In the example, selecting the "square" comparison is conditional on the square sample. Conditional discrimination is the basis of symbolic behavior. For example, in the presence of a red triangle, we say "red" when prompted with "color?" and "triangle" when prompted with "shape?"

It is in this domain of conditional discriminations that clear differences between humans and other

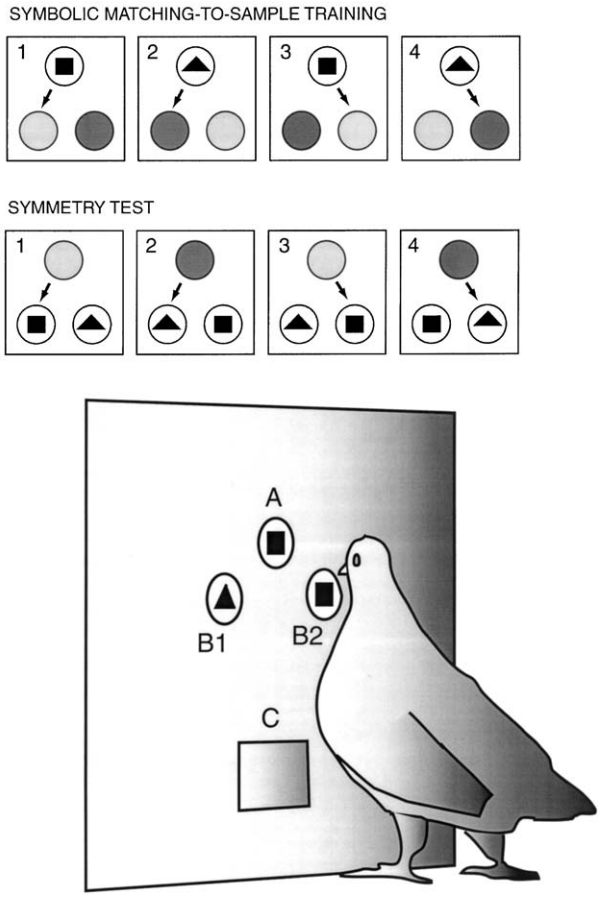

Figure 20 Matching-to-sample procedure. The pigeon is shown matching the comparison stimulus, B2, to the sample stimulus, A, on the basis of identity. (Top) Symbolic matching training trials between sample shapes and comparison hues and a symmetry test in which the hues are samples and the shapes are comparisons. Arrows indicate correct selections.

species arise. Animals and humans can learn conditional discriminations, such as "same" and "different," as well as symbolic matching between arbitrarily related stimuli, such as words and their referents. However, only humans can demonstrate some kinds of emergent conditional discriminations. For example, once humans learn the symbolic stimulus relation, "if stimulus A then B", they can respond correctly to a symmetry test, "if B then A", without further training (the simplest training and test relations necessary to evaluate symmetry are shown at the top of Fig. 20). The variables that explain symmetry are not yet understood; the ability may be a uniquely human accomplishment or emerge from experience with language. Interestingly, both humans and other species show transitivity: training the relations, "if A then B" and "if B then C"; finally, test "if A then C."

D. Recombination of Discriminations

Novel behavior results when discriminative stimuli controlling different responses or response dimensions are combined in novel ways. Recombinant generalization underlies some instances of problem solving, instruction following, and productivity in language. Figure 21 illustrates an example taken from the literature on language training for children with mental retardation. In this study, the child was first taught to push the 12 objects when given the instructions "push the glass," "push the scissors," and so on for the remaining nouns. Then, the next verb, "drop," was taught in the same way. As more verbs were taught, the child soon generalized new verbs to the objects after training with only one noun. Recombination processes have been demonstrated in a variety of species and in other contexts, including productivity and problem solving (e.g., cases in which a solution requires testing different combinations of elements).

E. Fading, Attention, and Blocking

Difficult discriminations, such as subtle differences between hues, can be established by initiating training with very different stimuli and progressively making them more similar. This procedure, called fading, is analogous to shaping. Fading can establish a difficult discrimination in fewer trials than is possible by prolonged training with the more subtle target stimuli.

When discriminative stimuli contain multiple dimensions, such as shape and color, organisms may show attention to one dimension and ignore the others. Selective attention is common in nonhuman animals and is more common in humans with mental retardation. For example, a child with autism may fail to recognize a teacher who just got a haircut, indicating that the child identified the teacher by her hair. Some attention effects in children are due to language exposure. For example, 3-year-old children who learn the name of a novel object show attention to its shape, not other attributes such as color or texture. This shape bias (or shape generalization) results because of the prevalence of object names in early language training and not because of a perceptual bias.

Attention to a stimulus can also be blocked by an established S^d. For example, after training a discrimination to a green circle, further training with the green circle plus a white cross will result in no learning to the white cross. Blocking is easily shown in nonhuman animals but difficult to demonstrate in humans.

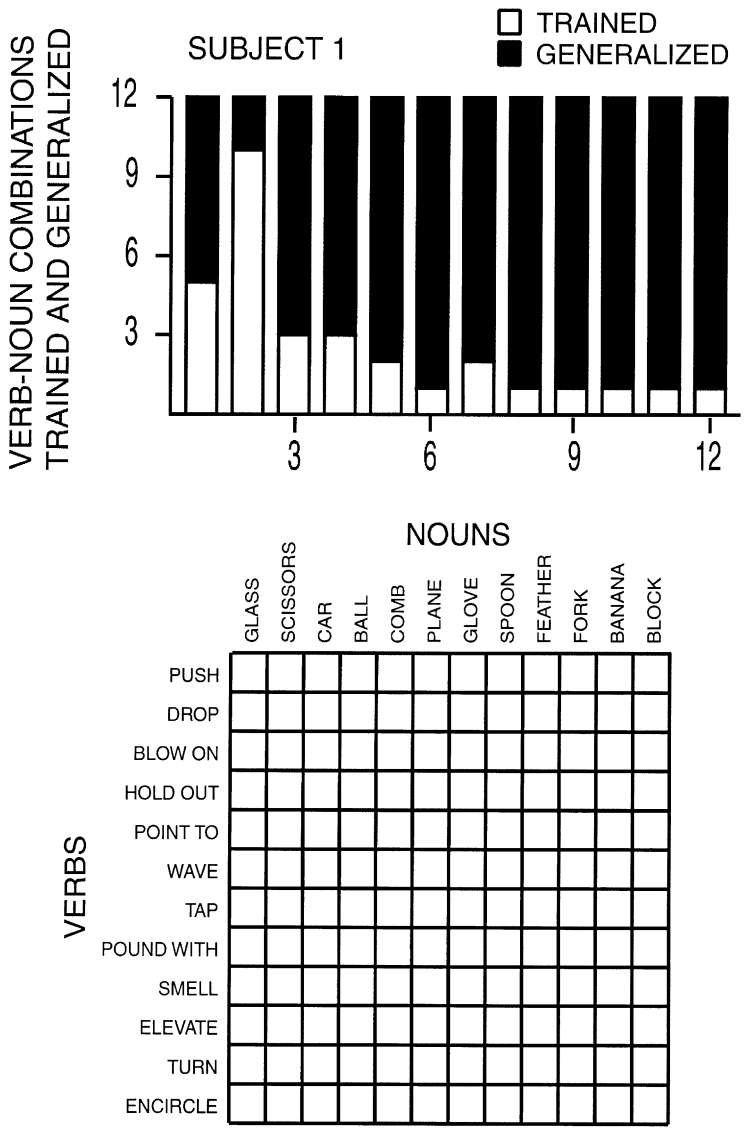

Figure 21 A factorial discrimination contingency. The noun–verb matrix shows the combinations that were arranged for training and testing the receptive skills of two children with mental retardation. A verb was first tested with 12 nouns, and if the child failed to follow the verb–noun instruction he received training. (Top) Learning for one of the children. As the child learned more verbs, his performance reached the point where learning a new verb with only one noun was sufficient to produce generalized compliance with the remaining nouns (data from Striefel *et al.*, 1976, Establishing generalized instruction-following skills in retarded children. *J. Exper. Child. Psych.* **22,** 247–260).

F. Preparedness and Latent Learning

Some three-term contingencies are more readily established than others for reasons that have to do with the species' ecological niche. For example, rats are biologically prepared to learn the spatial locations of food sources and to avoid previously depleted food locations. Similarly, experiments with food-storing birds have found that they selectively attend to the spatial locations of food sites and not their nonspatial aspects such as colors. Preparedness in spatial learning is also evident in latent learning, in which rats have been found to learn mazes in the absence of food reinforcement. Latent learning and related experiments show that rats are prepared to learn the spatial relations between cues and paths. Humans show analogous behavior by remembering the locations of stimulus objects without reinforcement, sometimes called automatic processing.

G. Extinction, Spontaneous Recovery, and Contingency Discrimination

Operant responding declines once a reinforcement contingency is discontinued. However, several findings show that operants are not erased by extinction. For example, after being removed from a situation in which an operant has undergone extinction, a return to the situation will produce a burst of responding called spontaneous recovery. Also, even if a response is completely extinguished, a single reinforcer will reestablish even a complex performance rapidly.

Spontaneous recovery and other findings suggest that extinction is not a distinct learning process but, rather, extinction procedures actually result in discrimination learning. Several lines of evidence support this interpretation of extinction. For example, extinction is more rapid if it is arranged in different conditions than those existing during reinforcement. If instead conditions during extinction are the same as those during reinforcement, responding decreases more rapidly with successive extinction conditions, showing a discrimination of the presence versus the absence of the contingency.

VIII. NEGATIVE REINFORCEMENT: AVOIDANCE AND ESCAPE

Responses can be reinforced by the production of appetitive stimuli or by the removal of aversive stimuli. Negative reinforcement operations include avoidance, in which responses prevent the occurrence of aversive stimuli, and escape in which responses terminate an existing aversive stimulus. Responses reinforced by escape are subject to effects of contiguity as in positive reinforcement; for example, escape is maintained best by immediate removal of aversive stimuli and less well maintained with delayed removal. Avoidance, however, is maintained in the absence of contiguity (responses prevent reinforcement) and has therefore attracted far more attention.

A. Theories of Avoidance

Avoidance can be maintained when responses remove an immediately present conditioned aversive (warning) stimulus. This is called two-factor avoidance because it invokes both operant and respondent conditioning; this reduces avoidance to a variant of escape—the conditioned stimulus elicits fear from which the organism escapes (and thus invokes contiguous reinforcement). However, experiments show that avoidance can be maintained in the absence of conditioned aversive stimuli and experienced organisms do not show fear to conditioned aversive stimuli in avoidance procedures. Figure 22 diagrams a free-operant avoidance procedure in which responses occurring before a fixed time serve to postpone a shock. Without a warning stimulus, rats in this procedure responded with equal probability throughout the interval; with the addition of a warning stimulus toward the end of the stimulus, the rats were more likely to wait for the stimulus and then respond. This and other similar findings run counter to predictions of two-factor theories since subjects waited for the warning stimulus to respond rather than preventing it from occurring.

As in the case of positive reinforcement, avoidance is sensitive to contingency effects. For example, responding is maintained when the probability of an aversive stimulus is lowered following a response but not if the probability of the stimulus is the same regardless of whether responses occur. Avoidance and punishment are closely linked because organisms will learn to avoid situations in which responses are punished.

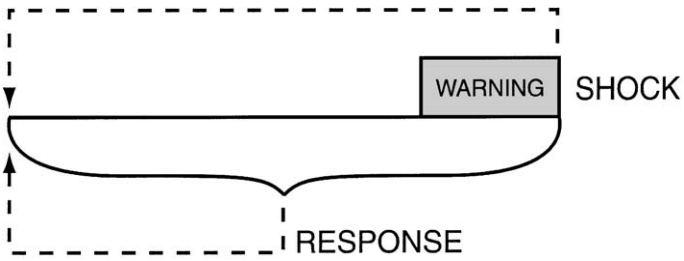

Figure 22 Stimulus function in negative reinforcement.

B. Learned Helplessness

Prior exposure to unpredictable noncontingent aversive stimuli can retard or prevent learning of avoidance responding. Learned helplessness theory holds that organisms can learn about the absence of a contingency, and this retards learning about the presence of a contingency. Some theories of functional depression in humans hold that people who experience many aversive, uncontrolled life events will show learned helplessness.

IX. LANGUAGE AND CULTURE

The social environment is rich in reinforcement contingencies. It provides models to imitate, opportunities to cooperate, and the possibility to exchange reinforcers. Instructional control by verbal discriminative stimuli vastly extends the power of individuals. For the speaker, instructions instantly generate target behavior in the listener; for the listener, instructions generate complex adaptive behavior that might have taken a culture centuries to perfect.

A. Verbal Behavior

Reinforcement theories of language have been proposed from the outset. Skinner outlined the most complete program based entirely on his concept of the discriminated operant. His account distinguished between the behavior of speakers and listeners, parsing their interactions in terms of discriminative stimuli, responses, and social reinforcers. Skinner identified contingencies operating in processes analogous to naming, requesting, and the grammatical processes such as assertion. The account was initially severely criticized by linguists but it continues to be influential and to provoke research. At the heart of the controversy was the question first raised in the opposing views of Descartes and Locke: Is language a unique accomplishment of humans or is it the result of social contingencies of reinforcement?

Early experiments with children were concerned with simple problems such as showing that reinforcement could increase the rate of target vocalizations. Later research turned to the problem of training language in individuals with developmental disabilities. These studies were motivated by both practical and scientific concerns. For example, studies with typical children showed that correspondence between things said and things done, as in ''telling the truth,'' had to be established by differential reinforcement. Another important finding from language programs for children with mental retardation was the importance of noun–verb recombinant generalization training to establish generalized instruction-following repertoires (Fig. 21).

However, these experiments did not answer the important question about reinforcement and language. Some researchers turned to nonhuman primates for a solution. Early efforts to teach chimpanzees (Pan troglodytes) vocal speech failed because their vocal process only allows them to emit a few vowels. Researchers then turned to training sign language in juvenile chimps, but with limited success. Chimps easily learned to sign object names but tended to imitate their trainers and showed little evidence of grammar. In contrast, chimps and bonobos (Pan paniscus) raised from birth in language-rich environments have shown comprehension of simple spoken English grammar. The interpretation of these experiments continues to be controversial, but the apes have demonstrated rudimentary language competencies such as symbolic behavior, grammar, comprehension, and verbal exchanges between themselves.

Reinforcement is also apparent in the language learning of typical children. Early developmental studies with children appeared to show that language developed without parental feedback. However, recent reanalysis of these data show that parents' verbal interactions included large amounts of modeling and differential approval and correction. These findings do not imply that reinforcement processes are sufficient to explain human language but, rather, that social reinforcement plays a role in language development.

B. Generalized Imitation

Almost as important as language is imitation of a model. In fact, the two frequently occur together, such as in ''Watch how I do it.'' Infants show some elicited imitation of facial expressions at birth, but research shows that a generalized repertoire of imitation of skeletal motions, such as that in dance, must be established by reinforcing many instances of imitation.

C. Human Schedule Behavior and Superstition

Infants show schedule performances very much like those seen in other species. However, laboratory studies with human adults show a variety of response

patterns, many of which suggest insensitivity to schedule contingencies. Some of these patterns can be traced to discriminative control by instructions. For example, human subjects earning money by pressing a button according to a FI schedule will respond at very high rates if they are told that the schedule is a FR; they will wait out the entire interval before making a response if they are told it is a FI schedule. Neither pattern is seen in nonhuman organisms: Their behavior is under discriminative control of the instructions and not under direct control of the FI contingencies. Many experiments have shown this effect—the insulation from contingency control by instructional control: Even simply telling humans to press a button to earn money will make them insensitive to reinforcement schedules. Ironically, the very strength of language, its instructional function, interferes with control by the nonsocial environment.

Enduring superstitions have never been documented in other species, but they are extremely common in humans. Laboratory studies of humans suggest that instructions are not sufficient to produce insensitivity; the instructions must be combined with ambiguous tasks. For example, in one study, subjects were told that they could press a button to prevent a computer's speaker from beeping. In reality, the computer presented beeps independently of subjects' button pressing; presses had no consequences. However, subjects who were presented with randomly timed beeps diligently followed the instructions to press and even erroneously reported having prevented the beeps, whereas subjects presented with fixed timed beeps quickly stopped following the instruction to press and correctly identified the inaccuracy of the instruction. Control experiments showed that the superstition did not depend on fortuitous contingencies but on the interaction between instruction and environmental ambiguity. The finding is consistent with the human tendency to show superstitious behavior in the face of unpredictable illnesses, births, weather, sports, and the like. The mechanism is unclear; however, the findings that the superstitions were maintained in the absence of a reinforcement contingency do show that the environment exerts strong discriminative control over instruction following in humans.

X. THE PHYSIOLOGY OF REINFORCEMENT

All attempts to match physiology to behavior have been based on the assumption that the description of behavior will guide the discovery of neurological mechanisms. In the case of reinforcement, the principle of selective neural strengthening has dominated neurological theories since the time of Bain and Thorndike.

Converging evidence suggests that the brain reinforcement system, the selective strengthening process, is mediated by the neuromodulator dopamine. Reinforcers such as food and addictive drugs cause the release of dopamine, and animals will work to obtain electrical brain stimulation of the medial forebrain bundle, the main ascending path for dopamine. These pathways project to various brain regions, including the motor association areas that contain both sensory inputs and connections to motor systems. The effect of dopamine may be to selectively sensitize those glutaminergic processes between sensory and motor neurons that are active at the time of reinforcement. Once the synaptic efficacy of the postsynaptic neuron has been increased in this manner, the neuron will be more likely to respond to glutamate whether or not dopamine is present. Support for this theory is provided by the fact that drugs that block glutamate receptors also interfere with long-term memory in many learning tasks.

The amygdala is implicated in conditioned reflexes involving aversive stimuli, but its role in operant performances involving aversive control has not been determined. Much more is known about the role of the hippocampus in learning. Damage to the hippocampus in rats interferes with memory of the most recently visited locations in a maze but not with memory of the areas in the maze that contain food day after day. This is approximately analogous to the effect in humans with hippocampus lesions, who cannot remember the flow of daily events but can remember that chairs are to sit in, beds are to sleep in, and so on. It is also consistent with behavioral models of reinforcement schedule effects showing that learning must be characterized by both fast (short-term) and slow (long-term) processes.

XI. APPLICATIONS

Knowledge of reinforcement and punishment has guided the evolution of a vast behavior modification industry. The concept of conditioned reinforcement gave rise to token economies used in schools and correctional institutions, shaping suggested the development of programmed instruction now implemented with computers, the matching principle has been applied to the reduction of maladaptive behavior in individuals with mental retardation without the need for punishment, various principles have been applied to

problems of treatment adherence in drug dependency programs, and so on. Among the most innovative and successful applications to date has been the introduction of the Premack principle to language instruction programs for children with autism. These children typically do not develop language without intense training efforts. Previously, training them involved sitting them at a desk, presenting them with objects to name, and reinforcing their efforts with food. The latest and most successful programs for these children employ a method called incidental teaching. The children are placed in a room containing many objects, such as toys, tools, and sandboxes. When a child shows interest in an object, the teacher uses access to the object as a reinforcer for talking. The method guarantees that the teacher is always working with the momentarily most potent reinforcer. The results are rapid and show far greater generalization to new situations than previously reported. Our understanding of the reinforcement mechanisms makes such simple yet sophisticated approaches to complex problems possible.

Respiration

HOMAYOUN KAZEMI and DOUGLAS C. JOHNSON
Harvard Medical School and Massachusetts General Hospital

GLOSSARY

aortic and carotid bodies Chemoreceptors at the arch of aorta and bifurcation of carotid artery and sensors of PO_2, PCO_2, and pH of arterial blood.

minute ventilation Volume of air inhaled or exhaled per minute.

nucleus tractus solitarius A nucleus in the midbrain in which afferent impulses from aortic and carotid bodies terminate.

respiratory drive Central neural output to drive muscles of respiration.

ventral medullary surface Area near the ventral surface of the medulla that is critical in central chemical drive of ventilation.

Respiration, as considered here, is an automatic function in which the level of ventilation, minute ventilation (volume of air per minute inhaled or exhaled) is set to meet the metabolic needs of the whole body in order to provide adequate quantities of oxygen for metabolism (O_2 consumption) and remove the primary by-product of metabolism, carbon dioxide (CO_2 output). Respiratory control mechanisms that regulate this essential function match respiration to metabolic needs through a complex and diverse system of receptors and feedback loops under control of the brain. In the brain impulses arising from different sites and receptors are integrated and a final coordinated command is issued through the respiratory centers in the medulla to the motoneurons of nerves of respiratory muscles, primarily the phrenic nerves to the diaphragm, nerves of intercostal muscles, and nerves of the muscles of the upper airway. However, there is reflex modulation of this central command by stimuli arising from the respiratory apparatus, which also affect the central output. In this article, we review the current knowledge about the stimuli to respiration, the receptors and mechanisms and sites within the central nervous system (CNS) that control respiration, acid–base and ionic composition of fluids bathing the brain that affect respiration, and neurotransmitters involved centrally in respiratory drive.

I. RESPIRATORY CENTERS AND RESPIRATORY CONTROL

Since one of the primary functions of the lungs is gas exchange and maintenance of acid–base homeostasis, the respiratory control system is exquisitely responsive to changes in O_2 tension (PO_2), CO_2 tension (PCO_2), and hydrogen ion concentration ($[H^+]$) in the blood. The respiratory receptors must initiate rapid responses to transient changes in internal and external environments of the subject and adapt to sustained changes as occurs during exercise, sleep, residing at high altitude, or illnesses that affect not only the lungs and the respiratory system but also the whole body.

Receptors for this elaborate control system vary in structure and function and include mechanical and irritant receptors in the lung and airways, receptors in respiratory muscles, and chemoreceptors in the carotid body and aortic body (peripheral chemoreceptors) and, most important, in the brain stem (central chemoreceptors). Receptors send signals to the brain

respiratory centers based on changes in their chemical or physical environment or their metabolism. The centers in the brain integrate these impulses and produce appropriate neuronal responses that then set the level of ventilation. There is great variation in the types of stimuli and the response they elicit. Since ventilation is essential to life, considerable redundancy exists in the system. In addition to these receptors and their feedback loops, ventilation is also under volitional control. Namely, one can voluntarily increase the level of ventilation (hyperventilation) or reduce ventilation to an extreme (breathold). This implies cerebral cortical control of ventilation, but clearly it has finite limits. The known factors that control ventilation broadly speaking can be divided into two categories: chemical factors and neural factors. Chemical factors are stimuli that arise from changes in PO_2, PCO_2, and pH in the arterial blood and are most critical in respiratory control. Neural factors are neural stimuli that arise from the lungs, pleura, muscles of respiration, pulmonary vessels, joints, and other structures. Figure 1 depicts the known mechanisms of respiratory control, various receptors, and coordination of the respiratory command from the medulla to the muscles of respiration. For this system to work properly the respiratory centers within the

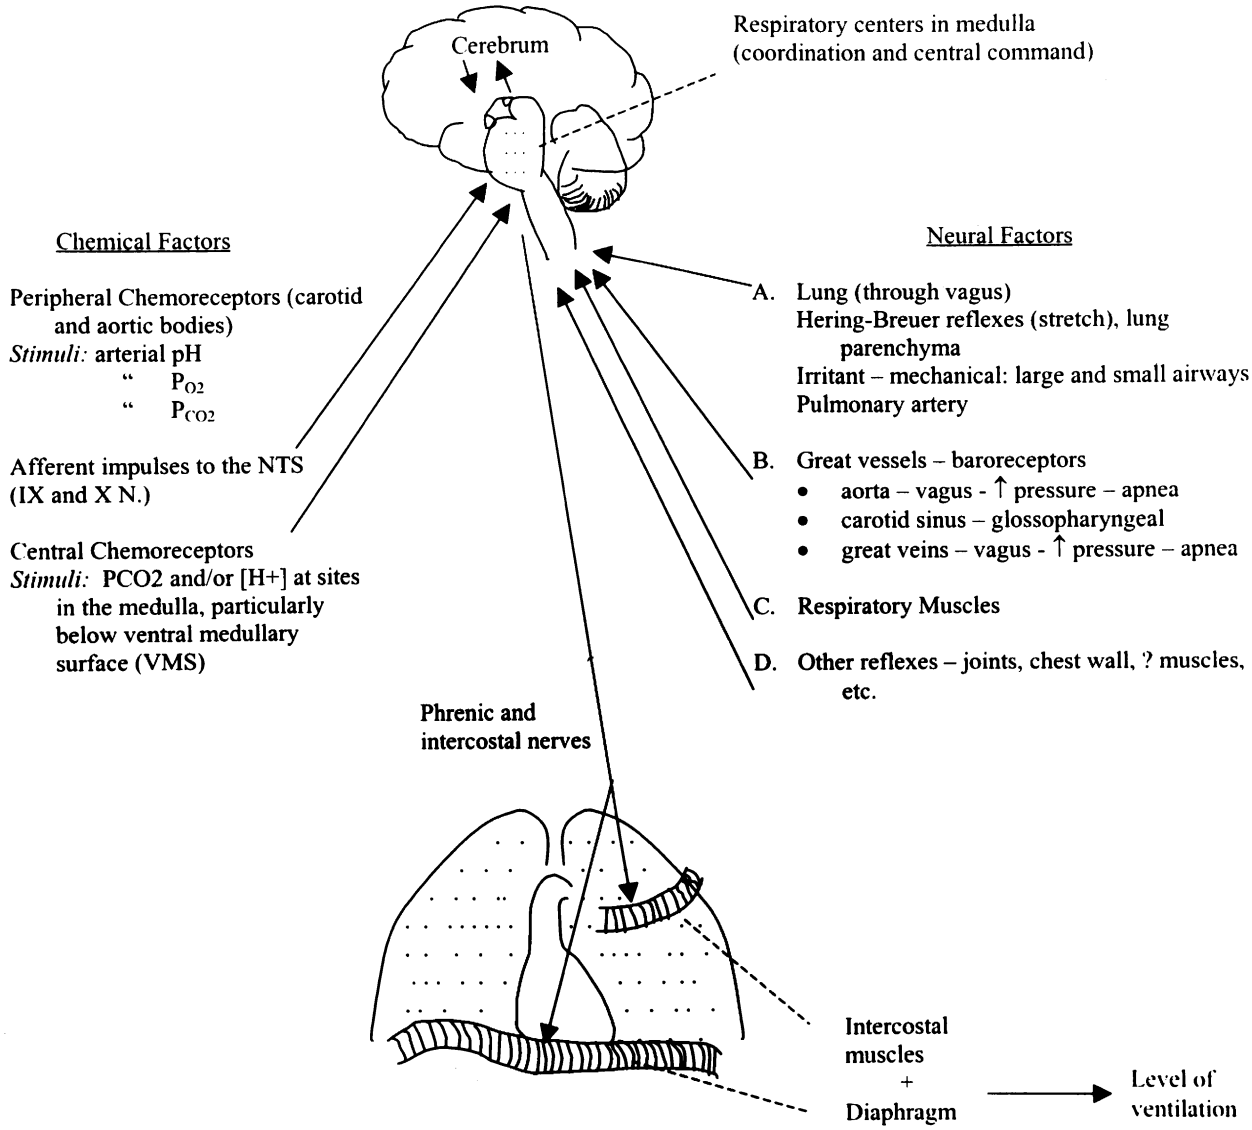

Figure 1 Schematic presentation of both chemical and neural mechanisms in control of ventilation.

brain need to receive the stimuli, integrate them, and send appropriate impulses to inspiratory and expiratory neurons; proper transmission of the impulses from the brain to the respiratory muscles must occur; and there must be a properly functioning lung and thoracic cage capable of responding to the action of respiratory muscles.

A. Chemical Factors

Chemical control of ventilation is the primary control mechanism. Classically, chemical factors influencing ventilation are O_2, CO_2, and pH. Chemoreceptors sensing changes in these variables reside in the carotid body and, to a lesser extent, the aortic body. Carotid and aortic bodies are called peripheral chemoreceptors. Changes in $[H^+]$ and CO_2 in the brain extracellular fluid are sensed by a group of chemoreceptors that are present at several sites in the medulla but predominantly very close to the ventral medullary surface (VMS). These sites are the central chemoreceptors.

1. Peripheral Chemoreceptors

The carotid and aortic bodies are the peripheral chemoreceptors. Carotid body chemoreceptors are located at bifurcation of common carotid arteries and the aortic body chemoreceptors between the arch of the aorta and pulmonary artery. Both sets of chemoreceptors are distinct and separate from baroreceptors that also reside in these bodies. Afferent impulses from aortic chemoreceptors reach the medulla via the vagus nerve, and those from the carotid chemoreceptors reach the medulla via the nerve of Hering to the IX cranial nerve, the glossopharyngeal. In respiratory control carotid chemoreceptors are much more significant that aortic chemoreceptors, particularly in the adult human. Carotid body stimulation increases ventilation several folds. Decreases in arterial PO_2 or increases in arterial PCO_2 increase carotid body firing, as does an increase in $[H^+]$ (i.e., a decrease in pH). Because of its high rate of blood flow in relation to its mass and metabolism, carotid chemoreceptors closely monitor and respond to changes in the arterial blood gases and pH. Five different cell types have been identified in the carotid body, but type I cells, or glomus cells, are thought to possess chemoreceptor function. The exact mechanism of signal transduction in the chemoreceptor cells is not established, and evidence indicates that dopamine and possibly acetylcholine are involved. The afferent impulses from the carotid body reach the caudal part of the nucleus tractus solitarius, where the excitatory amino acid neurotransmitter glutamate is released, increasing ventilation.

Whether hypoxia, hypercapnia, or acidosis stimulate the peripheral chemoreceptors through identical mechanisms is not clear. Evidence suggests that signal transduction by hypoxia may be different from that by hypercapnia. The peripheral chemoreceptors are the primary oxygen sensors in the body and ventilation increases significantly in man when arterial PO_2 decreases to values below 60 Torr. A decrease in arterial pH is associated with an increase in ventilation because of stimulation of peripheral chemoreceptors. The increase in ventilation is relatively modest as arterial pH decreases from 7.40 to 7.25, but once pH decreases below 7.20 there is a brisk and significant increase in ventilation.

Peripheral chemoreceptors also respond to changes in arterial PCO_2, where an increase in PCO_2 stimulates the chemoreceptors and ventilation increases. However, peripheral chemoreceptors have a modest role in CO_2 homeostasis. Peripheral chemodenervation in man causes a modest increase in resting arterial PCO_2 of about 5 Torr. The CO_2 effect is predominantly central by stimulating the central chemoreceptors that reside in the medulla.

2. Central Chemoreceptors

It is well established that central chemical control of ventilation is at the apex of hierarchy of respiratory drive, and that the acid–base status of extracellular fluid (ECF) of the brain bathing the "chemosensitive areas" near the VMS is key in central ventilatory drive. Studies in unanesthetized goats have shown that perfusion of the brain ECF in the medullary region with acid solutions increases ventilation, and that with alkaline solutions depresses ventilation. In unanesthetized animals, other investigators have shown that ventilation can be described as a single function of $[H^+]$ of brain interstitial fluid (ISF) over a large change in $[H^+]$. Changes in PCO_2 instantly affect brain pH and thus ventilation changes to correct the pH. When there is central acidosis, ventilation is stimulated, PCO_2 decreases, and central pH returns toward normal. The reverse occurs when there is central alkalosis. In many physiological situations, acid–base status of the arterial blood mirrors that in the brain ECF, particularly in the steady state.

The exact location of the medullary chemosensitive areas has been studied extensively. By direct application of minute quantities of acid to the VMS, three chemosensitive areas have been identified: the caudal, intermediate, and rostral areas. There are no distinct anatomical landmarks at these sites, but receptors responsive to changes in $[H^+]$ reside approximately 200 μm below the medullary surface in close proximity to brain ISF. Microinjection techniques using acid solutions, CO_2, and acetazolamide in animals have demonstrated several other sites in addition to the areas below the VMS that are involved in respiratory control and chemosensing. The exact mechanism of neuronal stimulation by CO_2 and/or H^+ is unknown. Evidence from several sources has shown that the neurotransmitter acetylcholine is essential in chemoreception centrally in the response to changes in CO_2 and/or H^+. In particular, increases in $[H^+]$ lessen the activity of the enzyme acetylcholinesterase, which degrades acetylcholine; thus, in the presence of central acidosis acetylcholine degradation is slowed, allowing the excitatory neurotransmitter to increase its duration and intensity of action.

In man a number of clinical disorders whose hallmark is diminished ventilatory response to CO_2 (reduced CO_2 sensitivity) have been associated with neuropathological findings in the respiratory-related nuclei in the midbrain, indicating diminished cholinergic activity. These studies have been performed almost entirely in infants and children since lack of CO_2 response increases the risks of hypoventilation, leading to death. In sudden infant death syndrome, there is hypoplasia of arcuate nucleus and diminished expression of acetylcholine receptors, and identical findings have been reported in the brain of children dying from congenital central hypoventilation syndrome (CCHS). Family studies of CCHS have revealed an associated increase in CCHS, suggesting a genetic link, probably related to abnormal development of the cholinergic system. Many patients with CCHS have aganglionic colon (Hirschprung's disease) and a mutation in the *ret* protooncogene.

ret gene encodes for a receptor tyrosine kinase that transduces signals for cell growth and is essential in neural crest development. Since cholinergic pathways are essential for CO_2/H^+ sensitivity, homozygotic *ret* mutant mice show essentially no CO_2 sensitivity and die within 48 hr of birth, indicating the importance of the *ret* gene in autonomic nervous system development, particularly the cholinergic system and the CO_2/H^+ axis in the central chemical control of respiration. Further molecular biology and genetic data in man should help decipher the molecular basis of respiratory drive in the brain.

3. Neural Factors

Neural factors are important in respiratory control but secondary to chemical factors. They become prominent in certain disease states or in special circumstances. Many of the neural stimuli are transmitted to the brain through the vagus nerve.

a. Hering–Breuer (Stretch) Reflexes These reflexes arise from the lung parenchyma. There are two primary reflexes: the inhibitoinspiratory reflex and the excitoexpiratory reflex. Afferent stimuli travel through the vagus. When lung is inflated, the inhibitoinspiratory reflex is stimulated and inspiration is terminated. When lung volume is reduced, excitoexpiratory reflex is stimulated, inspiration is initiated, and respiratory frequency is increased. The excitoexpiratory reflex is stimulated not only when lung volume is reduced but also by pulmonary congestion and inflammatory processes in the lung parenchyma—all leading to an increase in respiratory frequency.

b. Irritant and Mechanical Reflexes Receptors are located near the mucosal surface in the tracheobronchial tree and their stimulation by inflammation or irritant gases such as cigarette smoke leads to cough or forceful expiration as well as the sensation of dyspnea.

c. Pulmonary Vessels and Great Vessels Congestion and distention of pulmonary vessels lead to increased ventilation, mostly an increase in respiratory frequency. An increase in transmural pressure of the aorta and carotid sinus can cause a reduction in ventilation or apnea. These reflexes become important in respiratory control primarily in disease states.

d. Respiratory Muscles Muscles of respiration possess a stretch reflex similar to that in all striated muscles. This reflex through the gamma fibers interacts with alpha fibers coming from the anterior motoneurons in the spinal cord. Thus, there is interaction between local muscle reflexes through the gamma efferent system and impulses arriving from higher centers through the alpha system to set the level of muscle contraction and thereby ventilation.

e. Other Reflexes Impulses arising from systemic muscle groups, joints, and possibly other visceral organs can influence the level of ventilation, but their

roles and mechanisms of action are not well understood, as is the case with hyperventilation associated with exercise.

II. CENTRAL FLUIDS AND RESPIRATION

The brain and spinal cord are bathed in the cerebrospinal fluid (CSF). Ionic composition and acid–base balance of CSF play an important role in the central control of respiration, and "acidity" of this fluid has been thought to be a major stimulus to ventilation since Haldane and Priestly's suggestion in 1905 that CO_2 drove ventilation by making brain "acid."

A. CSF Formation

CSF is a protein-free fluid secreted in the CNS by the choroid plexus and brain tissue. The choroid plexus is responsible for two-thirds of the fluids secreted. A number of factors are responsible for the differences in electrolyte composition and acid–base values in cerebral fluids compared to those in plasma, including the brain–blood barrier, the nature of brain blood vessels, and the mechanisms of CSF formation. The choroid plexus is important in CSF composition since it is a major source of CSF production. The choroid plexus is composed of microvilli and a core containing capillaries and fenestrated endothelial cells with loose connective tissue in between. The cells of the choroid plexus are also endowed with a number of ionic pumps and transport systems. Furthermore, cells of the choroid plexus also contain abundant quantities of carbonic anhydrase, which catalyzes the CO_2 hydration reaction. Carbonic anhydrase catalyzes the reaction $CO_2 + H_2OHCO_3^- + H^+$. In the CNS, glia cells and the choroid plexus contain carbonic anhydrase in high concentrations. The carbonic anhydrase inhibitor acetazolamide, when given intraventricularly or intravenously, reduces CSF formation.

B. CSF Ionic Composition and Acid–Base Balance

There are differences in the ionic composition, pH, and PCO_2 between CSF and plasma. These differences are maintained by active regulation of cerebral fluid composition. CSF is secreted as an ultrafiltrate of the plasma and has Na^+ and Cl^- concentrations similar to those of plasma. The cisternal CSF, however, has a $[Cl^-]$ that is about 10–15 mEq higher than that of the nascent CSF and a $[HCO_3^-]$ that is 10–15 mEq lower than that of the nascent CSF. The mean CSF PCO_2 is about 4–11 mmHg higher than arterial PCO_2, and this gradient is relatively well maintained in respiratory acidosis and alkalosis in the steady state.

Regulation of CNS $[H^+]$ results from changes brought about by the independent variables of PCO_2 and the strong ion difference (SID). SID, which is the difference between cations and anions in the cerebral fluids, determines the $[HCO_3^-]$ since these fluids contain little protein. Of the various strongly dissociated ions, chloride is the most significant in the regulation of CSF acid–base status. Na^+ concentration in the CSF is kept constant in a variety of conditions, probably because of its role as an "osmoregulator." The other cations are also well regulated and kept constant despite major alterations in their plasma concentration. Chloride, whose concentration varies considerably in CSF in acid–base distress, becomes the variable ion in determining SID in cerebral fluids. In metabolic and respiratory acid–base disorders there is a reciprocal relationship between CSF $[Cl^-]$ and $[HCO_3^-]$. Ionic regulation of cerebral fluids is a dynamic process that includes movement of ions to and from blood as well as to and from brain.

In systemic acid–base disorders there are also changes in CSF $[H^+]$ and $[HCO_3^-]$; however, for any given change in plasma $[H^+]$ and $[HCO_3^-]$ there is less of a change in CSF $[H^+]$ and $[HCO_3^-]$. The change in CSF $[HCO_3^-]$ is about 30–40% of the change in plasma $[HCO_3^-]$ in metabolic acidosis and alkalosis and 65–95% in respiratory acidosis and alkalosis in the steady state. With respiratory acidosis, the increase in arterial PCO_2 is rapidly reflected in brain and CSF PCO_2 because CO_2 is freely diffusible across membranes. CSF pH becomes acidic during hypercapnia, and there is then compensation with a variable increase in CSF $[HCO_3^-]$ and decrease in CSF $[Cl^-]$. In high-altitude acclimatization, CSF pH becomes alkaline during the first few hours; by 24 hr, CSF pH becomes less alkaline but changes little thereafter.

The acid–base status of the brain ECF and CSF plays a significant role in determining the ventilatory output for a given PCO_2. At constant temperature, ventilation depends on brain interstitial fluid pH. However, as temperature varies, ventilation no longer tracks pH but the level of α-imidazole or the fractional dissociation of the imidazole moiety of histidine. This results in a decrease of 0.010 pH U/°C and thus helps maintain protein charge states and enzymatic functions constant as temperature and pH change.

In addition to PCO_2, the pH of brain ECF also depends on CSF electrolyte composition, which varies within hours of arterial acid–base changes. Respiratory or metabolic acidosis or alkalosis lead to changes in brain CSF composition that help keep brain ECF pH within a narrow range. Chronic respiratory acidosis leads to a higher CSF [HCO_3^-] and lower CSF [Cl^-], which lowers the central drive of ventilation. With a decrease in PCO_2 in respiratory alkalosis, such as occurs with the respiratory acclimatization to high altitude, CSF pH becomes alkaline and during the first 24 hr it returns toward normal. Regulation of brain ECF electrolyte composition is a complex process and involves a number of cells that are metabolically active, including the glia cells, the cells of the choroid fluxes, and cells at the blood–brain barrier.

III. NEUROTRANSMITTERS AND RESPIRATION

Neuronal firing in the midbrain is essential in the central drive of ventilation. The importance of O_2, CO_2, and H^+ in respiratory control was previously discussed. However, a number of neurotransmitters and neuromodulators centrally regulate neuronal firing and thus the respiratory drive. Changes in O_2 and CO_2 affect brain metabolism; as a consequence, the concentrations of certain amino acid neurotransmitters are changed, which affects the level of ventilation. Broadly speaking, amino acid neurotransmitters and acetylcholine are fast-acting neurotransmitters; their effect on neuronal firing is instantaneous. A diverse group of other substances, such as adenosine, substance P, dopamine, progesterone, and thyroid hormone, also affect ventilation, but their time constants are much slower minutes to hours and they are thus termed neuromodulators.

Among amino acid neurotransmitters involved in respiration are the excitatory amino acids, glutamate and aspartate, and inhibitory amino acids, GABA, glycine, and taurine. The effect of neurotransmitters centrally on ventilatory drive parallels their effects on neuronal function. Excitatory neurotransmitters stimulate ventilation and inhibitory neurotransmitters depress ventilation. Of particular significance is the fact that receptors for many of these neurotransmitters and neuromodulators have been identified in the brain in respiratory-related nuclei, especially in the midbrain. Studies in animals have shown that both GABA and glutamate are operative in setting the resting level of ventilation. Inhibiting GABA increases the resting ventilation, whereas inhibiting glutamate markedly reduces resting ventilation.

Both oxygen and CO_2 affect the concentration of amino acid neurotransmitters in the brain. During hypercapnia, brain free amino acids and acetylcholine concentrations change. Acetylcholine, GABA, and glutamine levels increase, whereas glutamate and aspartate levels decrease. These changes affect neuronal firing and the resulting ventilation is the product of this interaction. The role of acetylcholine in the CO_2/H^+ drive of ventilation was discussed previously. In hypoxia, amino acid neurotransmitters are of particular significance in setting the level of ventilation. Their role in acute hypoxia ventilatory response has been studied extensively, whereas their role in ventilatory adaptation to chronic hypoxia is less clear.

Hypoxia stimulates the peripheral chemoreceptors, and in adult humans primarily the carotid body, whose afferent impulses terminate in the caudal part of the nucleus tractus solitarius and cause the release of the excitatory amino acid glutamate. Brain hypoxia at the same site causes the release of the inhibitory amino acid neurotransmitter GABA. Release of GABA in the brain during hypoxia is due to conversion of glutamate to GABA by the enzymatic action of glutamic acid decarboxylase (GAD): glutamic acid $\xrightarrow[\text{GAD}]{}$ GABA + CO_2. GAD is one of the primary anaerobic enzymes in the brain and it continues to function during hypoxia, allowing for a significant increase in the brain's GABA content. Thus, during acute hypoxia the initial hyperventilatory response in the first 2–5 min is due to the excitatory effects of glutamate; subsequently, with the increase in GABA there is a decrease in ventilation. The level of ventilation at any point in time during acute hypoxia is determined by the interaction between the opposing effects of these amino acids. In addition, there are also increases in aspartate, which stimulates ventilation, and an initial decrease and subsequent increase in taurine, which is a respiratory depressant and thus has a variable effect based on whether it is increasing or decreasing.

Glutamate and GABA centrally also affect cardiac output, systemic blood pressure, oxygen consumption, and CO_2 output in a manner similar to their effects on ventilation. Therefore, these two amino acids in the brain are important in coordinating ventilation, cardiac function, and metabolic demands and maintaining overall homeostasis in the body.

IV. DISORDERS OF CENTRAL RESPIRATORY CONTROL

A. Abnormal Patterns of Breathing

There are cells in the brain stem, mainly in the medulla, that act as central pattern generators, helping set the breathing frequency, inspiratory time, and expiratory time. Abnormal patterns of breathing can occur with certain brain stem lesions. Ataxic or grossly irregular breathing can occur with medullary lesions. Apneustic breathing, characterized by prolonged expiratory pauses, can occur with pontine lesions.

B. Depressed CO_2 Ventilatory Response

The central ventilatory drive can be assessed by studying the change in ventilation with increasing levels of PCO_2. In normal individuals, the slope of the CO_2 ventilatory response is approximately 2 or 3 liters/mm increase in PCO_2 (i.e., ventilation increases by 2 or 3 liters/min for every millimeter increase in PCO_2. However, about 15% of adults have a diminished response to CO_2, with the slope being approximately 1 liter/mm PCO_2. These individuals are likely to develop CO_2 retention when additional problems occur, such as obesity, obstructive lung disease, or status asthmaticus. Many normal family members of patients with CO_2 retention also have a depressed ventilatory response to CO_2, again indicating a possible genetic basis for the depressed CO_2 ventilatory response. One beneficial effect of depressed CO_2 ventilatory response is seen in endurance athletes, many of whom have a CO_2 ventilatory slope of approximately 1 liter/mm PCO_2. The reasons for this are not clear, but it is probably due to a combination of genetic factors and training.

Depressed ventilatory response to CO_2 can also occur with elevation of serum and brain ECF bicarbonate, as in metabolic alkalosis or chronic CO_2 retention, because an increase in PCO_2 causes a reduced increase in hydrogen ion concentration with the increased bicarbonate concentration.

C. Ondine's Curse

The term Ondine's curse refers to patients with alveolar hypoventilation due to impaired autonomic control of ventilation. Classically, they "forget to breathe" when they fall asleep but maintain relatively normal blood gases while awake. Ondine's curse is usually due to CCHS, but it can be caused by surgery-induced incisions into the second cervical segment to relieve intractable pain.

D. Congenital Central Hypoventilation Syndrome

CCHS is associated with a nearly absent respiratory response to hypoxia and hypercapnia, mildly elevated arterial PCO_2 during wakefulness and markedly elevated PCO_2 during non-rapid eye movement (REM) sleep, and no respiratory discomfort during CO_2 inhalation. CCHS often occurs in association with Hirshsprung's disease, which is characterized by abnormalities of the cholinergic system in the gastrointestinal tract. This supports the view that the cholinergic system is crucial for central chemical drive, as discussed previously.

E. Cheyne–Stokes Respiration

Cheyne–Stokes respiration is a form of periodic breathing in which apnea is followed by gradually increasing breaths and then gradually decreasing breaths to the next apneic period. Patients with neurologic cause for Cheyne–Stokes respiration generally show increased respiratory sensitivity to CO_2, likely related to depressed cortical inhibition. Cheyne–Stokes respiration is also present in some patients with congestive heart failure.

F. Myxedema

Hypoventilation can occur in patients with hypothyroidism (myxedema). This appears to be due in part to both a depressed drive to breathe centrally and respiratory muscle weakness.

G. Sleep and Respiration

Sleep has profound effects on respiration and is mentioned briefly here. Breathing disorders during sleep are relatively common and include obstructive sleep apnea, hypopneas, hypoventilation, Cheyne–Stokes respiration, and central apneas. The central drive to breathe (CO_2 response) decreases during sleep, more so during REM than non-REM sleep. Muscle tone also decreases during sleep, promoting a tendency

for the upper airway to collapse and develop obstructive hypopneas or apneas.

GLOSSARY

amacrine cells Neurons whose processes are confined to the inner plexiform layer.

bipolar cells Output neurons of the outer plexiform layer that carry information to the inner plexiform layer.

fovea Specialized retinal region of highest visual resolution, containing only cones.

ganglion cells Third-order neurons in retina whose axons form the optic nerve and carry visual information from the eye to the rest of the brain.

horizontal cells Neurons whose cell bodies lie along the distal margin of the outer nuclear layer and that extend processes mainly in the outer plexiform layer.

interplexiform cells Neurons whose cell bodies reside in the proximal part of the inner nuclear layer and that extend processes in both plexiform layers.

plexiform layers Regions consisting principally of neuronal processes, where synaptic interactions take place.

receptive field Area of retina that when illuminated influences the activity of a cell.

visual pigments Light-sensitive molecules in photoreceptors consisting of 11-*cis*-retinal (vitamin A aldehyde) and protein (opsin).

The retina is a thin (~0.25-mm) layer of neural tissue that lines the back of the eye. It is a true part of the brain displaced into the eye during development. In addition to the light-sensitive photoreceptor cells, the retina contains five basic classes of neurons and one principal type of glial cell, the Müller cell. The neurons are organized into three cellular (nuclear) layers, which are separated by two synaptic (plexiform) layers. Virtually all the junctions (synapses) between the retinal neurons are made in the two synaptic layers, and all visual information passes across at least two synapses, one in the outer plexiform layer and another in the inner plexiform layer, before it leaves the eye.

I. INTRODUCTION

Processing of visual information occurs in both plexiform layers of the retina. The outer plexiform layer separates visual information into "on" and "off" channels and carries out a *spatial*-type analysis on the visual input. The output neurons of this layer, the "on" and "off-" bipolar cells, demonstrate a center-surround antagonistic receptor field organization. The inner plexiform layer is concerned more with the *temporal* aspects of light stimuli. Many cells receiving input in this layer respond with transient responses and respond better to moving stimuli than to static spots of light. The output neurons of this layer, the ganglion cells, tend to reflect the processing of information in either the outer plexiform layer (i.e., the cells respond in a sustained fashion to appropriately positioned stimuli) or the inner plexiform layer (i.e., the cells respond better to moving stimuli than to static ones).

Figure 1 shows a light micrograph of a piece of human retina. The photoreceptors are located furthest from the front of the eye, at the top of the micrograph.

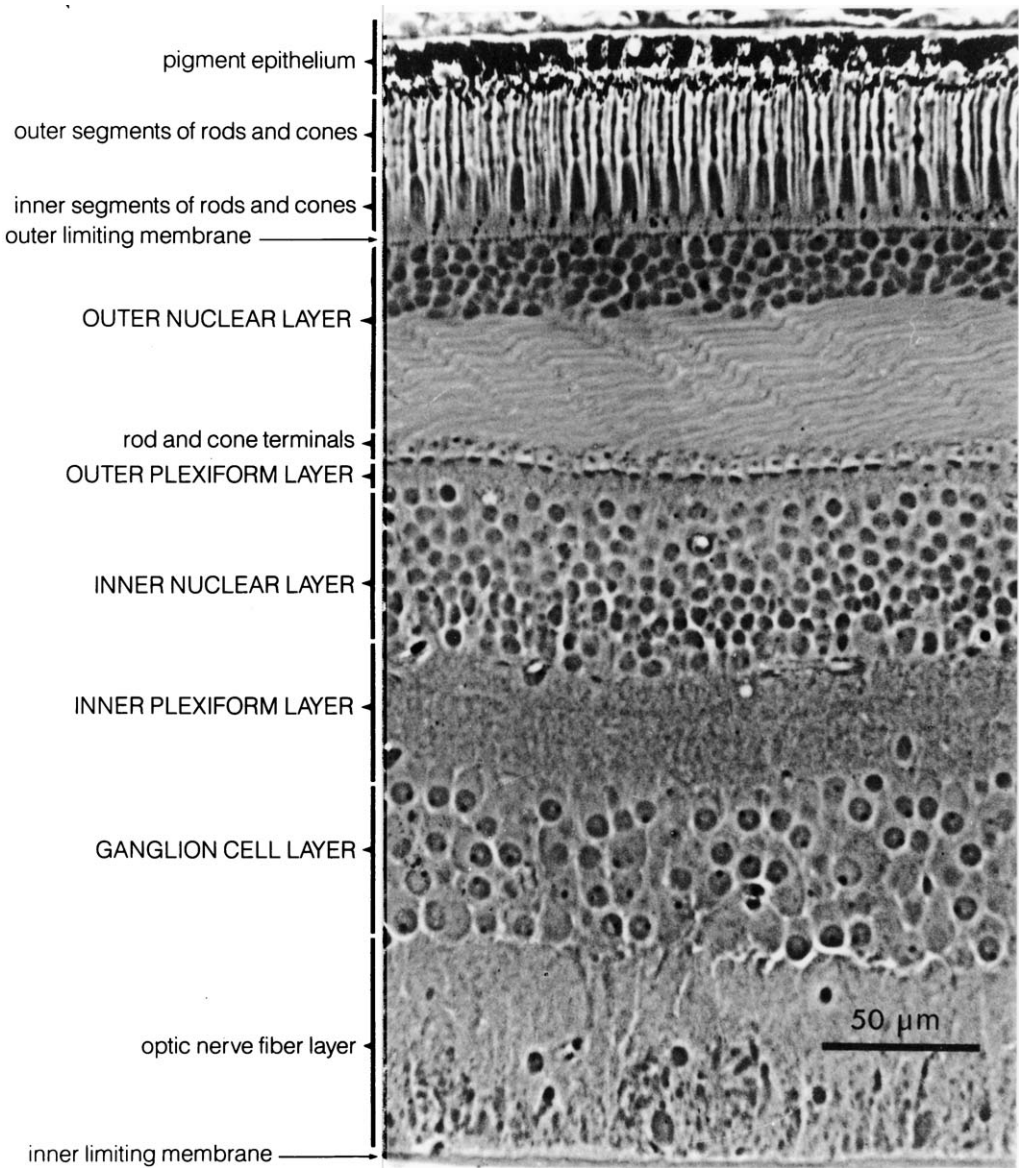

Figure 1 Vertical section through the human retina. Micrograph shows an area approximately 1.25 mm from the center of the fovea. In the foveal region of the retina, the inner layers of the retina are pushed aside so that light can impinge more directly on receptors. Thus, around the fovea and for some distance away (as shown here), receptor terminals are displaced laterally from the rest of the photoreceptor cells.

Light entering the eye passes through the transparent retina and is captured by the pigment-containing outer segments of the photoreceptors. (Overlying the photoreceptors is the pigment epithelium, which serves to absorb stray light and to prevent backscatter of light into the retina.) The cell bodies of the photoreceptors are located in the outer nuclear layer, whereas the cell bodies of three of the basic classes of retinal neurons—horizontal, bipolar, and amacrine cells—are in the inner nuclear layer. The cell bodies of the ganglion cells make up the most proximal cellular layer. The outer and inner plexiform layers are interspersed, respectively, between the outer and inner nuclear layers and the inner nuclear and ganglion cell layers.

In many primates, including humans, a small region of the retina is specialized for high-acuity vision. It is called the fovea and is centrally located (i.e., on the

visual axis of the eye). The layers of the retina below the photoreceptor inner and outer segments are displaced from the fovea so that light can impinge directly on the photoreceptors. Only cones are present in this area, and the foveal cones are the thinnest and longest photoreceptors in the retina. The rod-free area is about 0.3 mm in diameter and contains approximately 35,000 cones. No blood vessels are found in the fovea, and there are few, if any, blue-light absorbing cones in the center of the fovea. These specializations serve to improve the visual resolution of the fovea.

II. PHOTORECEPTORS

The human retina contains two types of photoreceptors, rods and cones, differentiated on the basis of their outer segment shape (see Fig. 1). This criterion is not always reliable; for example, the outer segments of the cones found in the fovea show no significant taper (i.e., they are rod shaped). Rods mediate dim-light vision, whereas cones function in bright light and are responsible for color vision.

A. Visual Pigments

Light sensitivity of the photoreceptors results from the presence of visual pigment molecules contained within their outer segments. One rod pigment, called rhodopsin, and three cone pigments are in the human retina. Rhodopsin absorbs light maximally in the blue-green region of the spectrum ($\sim$500 nm), whereas the human cone visual pigments absorb maximally in the blue ($\sim$430 nm), green ($\sim$530 nm), and red-yellow ($\sim$560 nm) regions of the spectrum. The cone pigments are segregated into separate classes of cones; thus, blue-, green-, and red-yellow-sensitive cones are in the human retina. In the human eye, there are more red and green cones than blue cones and, as noted previously, blue cones are extremely rare in the high-acuity foveal region of the retina.

The genes encoding for rhodopsin and the cone pigments have been identified and isolated in humans and in a number of other species. The red- and green-sensitive pigment genes in humans are on the X chromosome (i.e., they are sex-linked), whereas the genes for the blue-sensitive pigment and rhodopsin are on autosomes. The red- and green-sensitive visual segments are highly homologous ($\sim$95%), whereas there is approximately 40% homology between the red and green pigments and the blue pigment and approximately the same homology between all the cone pigments and rhodopsin. Studies of the color vision pigment genes in red- and green-blind individuals have shown that color blindness is caused by a loss or alteration of one or another of the genes. Red-blind individuals (protanopes) have an altered gene for the red-sensitive pigment, whereas green-blind individuals (deuteranopes) have an altered green-sensitive pigment gene or are lacking the gene altogether. Blue-blind individuals (tritanopes) likewise are missing or have an altered blue visual pigment. When the gene for the red or green pigment is altered, usually no red- or green-sensitive cone cells develop in the retina. Sometimes, red- or green-sensitive cones form, but the pigment within the cell, and therefore color vision, is abnormal (a condition termed anomalous trichromacy).

The visual pigment molecules are concentrated to a high degree in the outer segments of the photoreceptors. The outer segments contain numerous transverse membranous discs (Fig. 2), and virtually all the visual pigment molecules are contained within the disc membranes. A typical outer segment may have as many as 2000 transverse discs and may contain 10^9 visual pigment molecules.

1. Visual Pigment Chemistry

All visual pigments have a similar chemistry. They consist of two components: retinal (vitamin A aldehyde), termed a chromophore, which is bound to a protein called opsin. Different visual pigments have different opsins, and this accounts for the variations in their color sensitivity. The light sensitivity of the visual pigments is due to the retinal chromophore. When a visual pigment molecule absorbs a quantum of light, several molecular transformations occur, first in the chromophore and then in the protein (opsin) part of the molecule. These transformations lead to the excitation of the photoreceptor cell and also to the separation of the retinal chromophore from opsin. This latter process is called bleaching because it results in the loss of color of the visual pigment molecules and their ability to absorb visible light.

Retinal can exist in different shapes (i.e., several *cis–trans* isomers of the molecule are possible). All visual pigments require one particular isomer, the 11-*cis*, for their synthesis, and this form of the chromophore combines spontaneously with opsin to form visual pigment. When a visual pigment molecule absorbs a

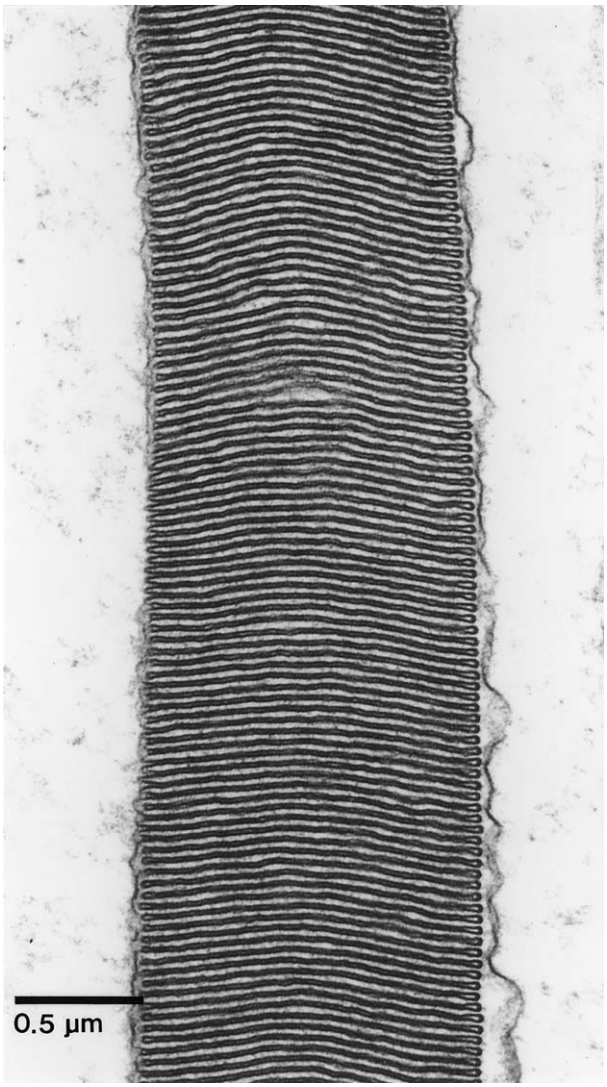

Figure 2 Electron micrograph of a portion of a cone outer segment. Contained within the structure are numerous transverse membranous discs. The visual pigment molecules and associated proteins that lead to excitation of the photoreceptors are contained within or in association with the disc membranes.

quantum of light, the first transformation is the isomerization of the chromophore from the 11-*cis* to the all-*trans* form. Indeed, the only action of light in the visual process is to change the shape of the chromophore. The chromophore shape change initiates a series of conformational changes in the opsin, and this leads to excitation of the photoreceptor cell and release of the chromophore from opsin.

A series of intermediates have been identified between the absorption of light by visual pigment molecules and the release of the chromophore from opsin. One of the intermediates, metarhodopsin II, is responsible for excitation of the photoreceptor cells (i.e., it is the photoactive intermediate). Figure 3 shows a simplified scheme of the visual cycle for the rod visual pigment rhodopsin.

The retinal chromophore of rhodopsin derives from vitamin A, and it represents a slightly oxidized (aldehyde) form of the vitamin. During the operation of the visual cycle, some retinal is lost and must be replaced from body stores of the vitamin. In vitamin A deficiency, this replenishment fails. A full complement of visual pigment can no longer be synthesized in the photoreceptors, and light sensitivity of the rods and cones is decreased. The loss of light sensitivity is more obvious in the dark; hence, the condition is known as night blindness. Refeeding of vitamin A to a vitamin A-deficient animal or patient usually restores visual sensitivity.

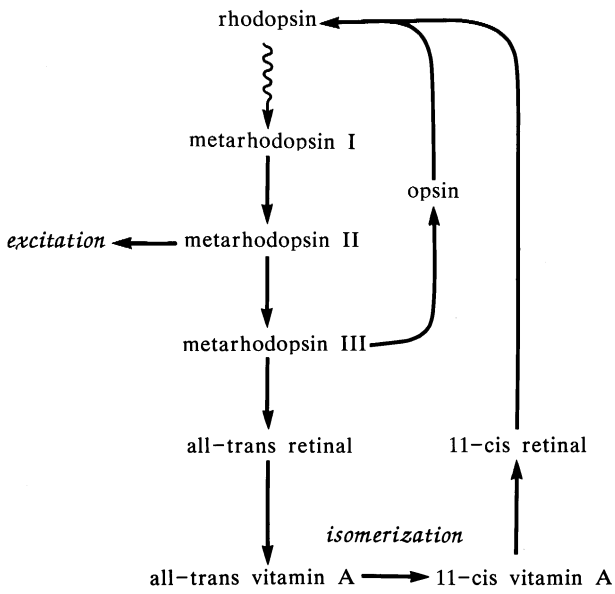

Figure 3 Scheme of the sequence of events that occur following the absorption of a quantum of light by the rod visual pigment, rhodopsin. Light initiates the conversion of rhodopsin to retinal and opsin through a series of metarhodopsin intermediates. Metarhodopsin II is the active intermediate leading to excitation of the photoreceptor cell. Eventually, the chromophore of rhodopsin, retinal, separates from the protein opsin and is reduced to vitamin A (retinol). For the resynthesis of rhodopsin, the shape of vitamin A must be changed (isomerized) from the all-*trans* to the 11-*cis* form, and this isomerization takes place in the pigment epithelium overlying the receptors (see Fig. 1). Vitamin A is replenished in the eye from the blood.

B. Photoreceptor Responses

Excitation of visual pigment molecules leads ultimately to a change of potential across the membrane surrounding the photoreceptor cell. Membrane potential controls the release of neurotransmitter from synapses, and in this way light influences the exchange of information between photoreceptors and second-order neurons in the retina.

All vertebrate photoreceptors hyperpolarize in response to light (i.e., the membrane potential becomes more negative), for the following reason: In darkness, the membrane of the outer segment is permeable (leaky) to Na^+. Because Na^+ levels are higher outside the cell than inside, positive Na^+ ions enter the cell in darkness, causing the cell to be partially depolarized (i.e., the membrane potential is more positive than is typically the case for neurons at rest). Light decreases the conductance of the outer segment membrane to Na^+, thereby decreasing the flow of positive ions into the cell and causing the cell to become more negative (i.e., to hyperpolarize).

The conductance of the outer segment membrane to Na^+ is controlled by a second messenger molecule, cyclic GMP, which maintains channels in the membrane in an open state. In the light, levels of cyclic GMP decrease because an enzyme (phosphodiesterase), which breaks down cyclic GMP, is activated, and this causes the channels in the outer segment membrane to close. Phosphodiesterase, in turn, is activated by a protein called transducin (a G protein), and transducin is activated by metarhodopsin II, the photoactive visual pigment intermediate. The cascade between the visual pigment molecule and the Na^+ channel in the outer segment membrane is shown in Fig. 4.

The cascade between the light activation of visual pigment molecules and the closing of Na^+ channels in the outer segment membrane is important for amplification of the signal. That is, one photoactive visual pigment molecule can interact with many transducin molecules (as many as 500), and one phosphodiesterase molecule can break down about 2000 cyclic GMP molecules per second. The cascade of reactions between photon absorption and cyclic GMP inactivation can result in an amplification of about 10^6.

The channels in the outer segment membrane controlled by cyclic GMP also allow some Ca^{2+} to enter the photoreceptor cell, and Ca^{2+} plays an important regulatory role in the phototransduction process. For example, Ca^{2+} entering the cell inhibits an enzyme, guanylate cyclase, which synthesizes cyclic GMP. Thus, in the dark, cyclic GMP synthesis is relatively low. In the light, when the channels in the outer segment membrane are closed, Ca^{2+} entry into the cell decreases and intracellular Ca^{2+} levels decline. This results in an increased synthesis of cyclic GMP, which serves to counter the effect of light lowering cyclic GMP levels. Thus, in continuous light, the photoreceptor response recovers partially to dark levels, enabling the photoreceptor to continue to respond even in bright light. This process is termed adaptation and photoreceptor light and dark adaptation play an important role in the ability of the visual system to respond over a wide range of ambient illumination. Ca^{2+} appears to mediate many aspects of photoreceptor light and dark adaptation.

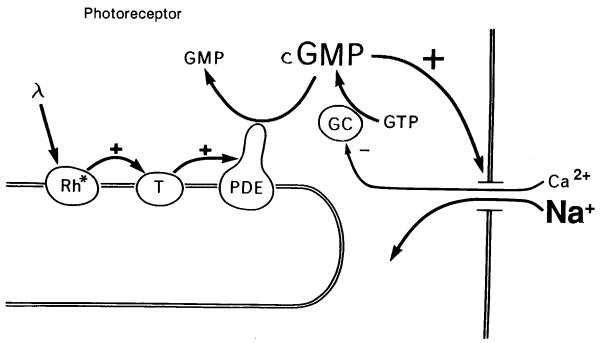

Figure 4 Summary diagram of interactions occurring in the rod outer segment during phototransduction. Light-activated rhodopsin (Rh*) activates a G protein transducin (T), which in turn activates the enzyme phosphodiesterase (PDE). These interactions occur in the disc membrane. Activation of PDE leads to breakdown of cyclic GMP (cGMP) to an inactive product (GMP). Cyclic GMP maintains channels in the outer segment membrane in an open configuration, thereby allowing both Na^+ and Ca^{2+} to enter the cell in the dark. With a decrease in cGMP levels in the light, channels in the outer segment membrane close. The resulting decrease in Na^+ levels causes the cell to hyperpolarize. Decrease of Ca^{2+} levels enhances guanylate cyclase (GC) activity, an action that counters the effects of light and increases GMP levels in the outer segment.

III. CELLULAR AND SYNAPTIC ORGANIZATION

A. Cellular Organization

Most of what is known about the classes of retinal cells in all vertebrates has come from light microscopic studies of retinas processed by the silver-staining method of Golgi. This technique enables investigators

to see the extent and distribution of the processes of the cells within the retina, to classify the cells, and to construct schemes of the cellular organization of the retina such as that shown in Fig. 5 for the primate retina. Although there are just five major classes of neurons in the retina, there are many morphological subtypes in each major cell class, and even today the total number of morphological subtypes is not known. It is clear that some cell subtypes are much more common than others, and the focus here is on the major subtypes of cells in the mammalian and primate retinas.

In the outer plexiform layer, two cell classes—horizontal and bipolar cells—receive input from the photoreceptors. The bipolar cells are the output neurons for the outer plexiform layer; all information passes from outer to inner plexiform layers via these neurons. Horizontal cells, however, extend processes widely in the outer plexiform layer, but their processes are confined to this layer. Their role is to mediate lateral interactions within this first synaptic zone.

Bipolar cell terminals provide the input to the inner plexiform layer, and two cell classes—amacrine and ganglion cells—are ultimately activated. Amacrine cells, like horizontal cells in the outer plexiform layer, spread processes widely in the inner plexiform layer, but their processes are usually confined to this layer. Ganglion cells are the output neurons for the retina; their axons run along the margin of the retina, collect at the optic disc to form the optic nerve, and carry all visual information to higher visual centers.

1. Outer Plexiform Layer Neurons: Horizontal and Bipolar Cells

Most mammalian retinas contain two basic subtypes of horizontal cells; a cell with a short axon that runs approximately 400 μm before ending in a prominent terminal expansion and an axonless cell. The axonless cell has not been seen in the primate retina; rather, the second horizontal cell type in primates has a short axon, although its synaptic connections are like those of the axonless cell—they are all cone.

Horizontal cells of the cat have been studied in detail, and Fig. 6 shows examples observed by looking down on a flat mount of the whole retina. Electron

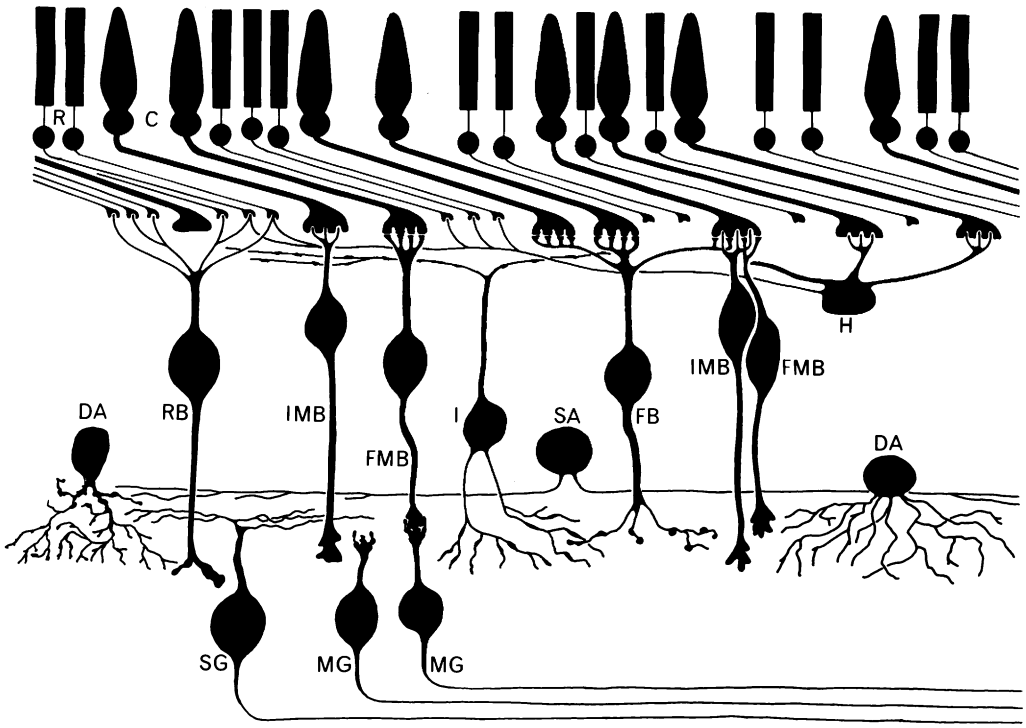

Figure 5 Major cell types found in primate retina as viewed in vertical sections of Golgi-stained retinas. See text for description of cells. R, rods; C, cones; RB, rod bipolar cells; IMB; invaginating midget bipolar cell; FMB, flat midget bipolar cells; FB, flat bipolar cell; H, horizontal cell; I, interplexiform cell; DA, diffuse amacrine cell; SA, stratified amacrine cell; MG, midget ganglion cell; SG, stratified ganglion cell.

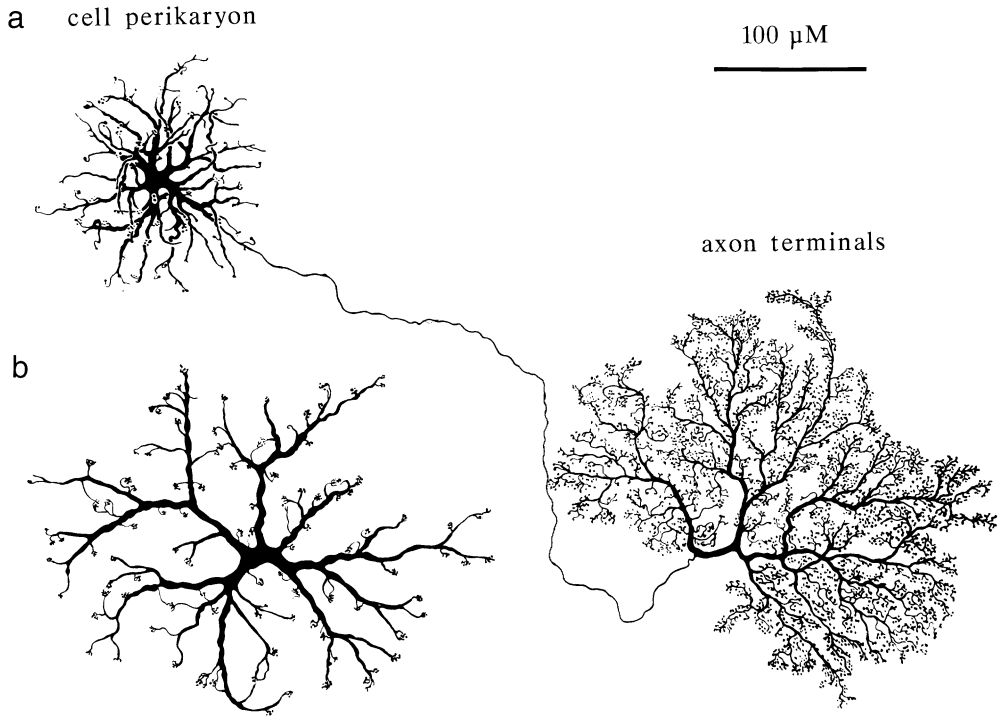

Figure 6 Drawings of Golgi-stained horizontal cells from the cat, viewed by looking down on a flat mount of retina. There are two types of horizontal cells in cat retina: an axonless cell (b) and a cell with a short axon (a).

microscopy has shown that the processes of the axonless cell (Fig. 6b) and the proximal dendritic processes of the short axon cell (Fig. 6a) connect exclusively with cone synaptic terminals, whereas the axon terminal processes of the short axon cell end exclusively in the rod terminals. Why the input to the short axon cells is organized this way is not clear; an appealing suggestion is that this allows for segregation of rod and cone responses in different regions of the cells. In fish, for example, there are separate rod and cone horizontal cells.

In primates, up to 11 subtypes of bipolar cells have been distinguished: One type is exclusively connected to rods and the rest are connected to cones. The rod-related bipolar cells extend their dendrites into the rod synaptic terminals, and their axon terminals end deep in the inner plexiform layer. The rod bipolars contact between 15 and 50 rod terminals depending on eccentricity. More peripherally located rod bipolar cells contact more rods.

Two of the cone-related bipolar cell types contact only a single cone terminal. These cells, called midget bipolar cells, make different kinds of synaptic contacts with the cone terminals: invaginating and flat contacts (see Section III.B). Their axon terminals end at different levels within the inner plexiform layer, and they appear to be related to the generation of either "on" or "off" responses to light in the retina. Every cone terminal in the primate retina probably makes connections with both kinds of midget bipolar cells (see Fig. 5). In addition to the cone midget bipolar cells, there are also bipolar cells that contact several cones, probably as many as six or seven. They are called diffuse flat bipolar or diffuse invaginating bipolars based on the type of connection they make with the photoreceptors (see Section III.B).

2. Inner Plexiform Layer Neurons: Amacrine, Interplexiform, and Ganglion Cells

Most amacrine cells have no axonal processes; all their processes look similar. Some amacrine cells do show two sets of processes emerging from the cell body. The thinner of the two has a wider extent and has been termed an axon. Many such processes (up to 40) can emerge from a single cell body and it is not known

whether they have axon-like properties (i.e., conduct action potentials). Amacrine cells are diverse in terms of the extent and distribution of their processes, and it is possible to describe a large number of amacrine cell subtypes in most species (up to 30–40). Investigators typically classify amacrine cells into two major types: diffuse and stratified amacrine cells. Diffuse amacrine cells extend their processes throughout the thickness of the inner plexiform layer, whereas the stratified cells extend their processes on one or a few levels in the layer. This simple classification scheme can be expanded to include narrow- and wide-field diffuse or stratified amacrine cells, depending on how far their processes extend, and mono-, bi-, or multistratified cells, depending on whether their processes are confined to one, two, or several levels in the inner plexiform layers, respectively.

A cell termed the interplexiform cell deserves special mention. Some investigators classify these cells as a separate class of retinal neuron, but others believe they are a subtype of amacrine cell. Their perikarya (cell bodies) sit among the amacrine cells, but unlike typical amacrine cells they send processes to both plexiform layers. Input to these cells is in the inner plexiform layer, whereas most of their output is in the outer plexiform layer. Hence, they appear to be mainly a centrifugal type of neuron, carrying information from inner to outer plexiform layers.

Ganglion cells, like amacrine cells, are also diverse in their morphology. In most vertebrate retinas as many as 20 morphological subtypes can be distinguished. They are mainly stratified cells. In primates, particularly in the central region of the retina, ganglion cells are observed with limited dendritic fields. These cells, termed midget ganglion cells, receive input from one midget bipolar cell. The dendrites of these midget ganglion cells ramify in either the upper or the lower parts of the inner plexiform layer so that they receive input from one or the other of the two midget bipolar cells described earlier. This implies that one cone in the central (foveal) part of primate retina can send two separate messages to the rest of the brain via two midget ganglion cells. One cell is believed to signal increases in illumination of the cone (i.e., it is an ''on'' cell); the other signal decreases in cone illumination (i.e., it is an ''off'' cell).

The other major ganglion cell subtype in the primate retina is called the parasol ganglion cell. It receives most of its bipolar cell input from diffuse bipolar cells, extends its processes in either the ''on'' or ''off'' laminae of the inner plexiform layer, and is physiologically either an ''on'' or ''off'' cell.

3. Retinal Processing of Visual Information: Ganglion Cell Responses and Receptive Field Organization

As noted earlier, ganglion cells signal brightness and darkness information to the rest of the brain, but they also communicate much more. Indeed, two basic kinds of processing appear to be occurring in the retina: one carried out mainly in the outer plexiform layer and the other in the inner plexiform layer. Ganglion cells convey information to the rest of the brain that reflects these two stages of processing.

Ganglion cells typically respond to illumination of a restricted but relatively large region of the retina. This region is called the receptive field of the cell and is typically about 1 mm in diameter. The most common ganglion cell in the mammalian retinas shows evidence of spatial processing of visual information in its responses. Ganglion cells of this type are often called contrast-sensitive cells, and they are subdivided into two mirror-image classes: ''on''-center, ''off''-surround cells and ''off''-center, ''on''-surround cells. Each has a receptive field that is organized into two concentric zones that are antagonistic to each other (Fig. 7a).

''On''-center cells respond to an increase in the illumination of the receptive field center with a sustained burst of nerve impulses, whereas illumination of the surround inhibits the firing of nerve impulses by the cell for as long as the light is on. ''Off''-center cells respond in the opposite way: Illumination of the receptive field center inhibits the cell, whereas surround illumination provides a sustained excitation of the cell. In both cases the center and surround zones are antagonistic; if center and surround areas are simultaneously illuminated, the cell responds only with a weak response that usually reflects the central response. These ganglion cells mainly reflect the processing that occurs in the outer plexiform layer of the retina. In cat these ganglion cells are termed X cells; in primate, they are called P cells.

Other types of ganglion cells respond with more transient responses to retinal illumination, regardless of the position of the illuminating spot in the receptive field, and they reflect more responses of inner plexiform layer neurons. These cells typically respond with more vigorous responses to moving stimuli than to static spots of light. The receptive fields of some of these cells are organized into antagonistic center and surround regions, like the sustained contrast-sensitivity cells described previously. The transient ganglion cells with a center-surround organization are termed Y

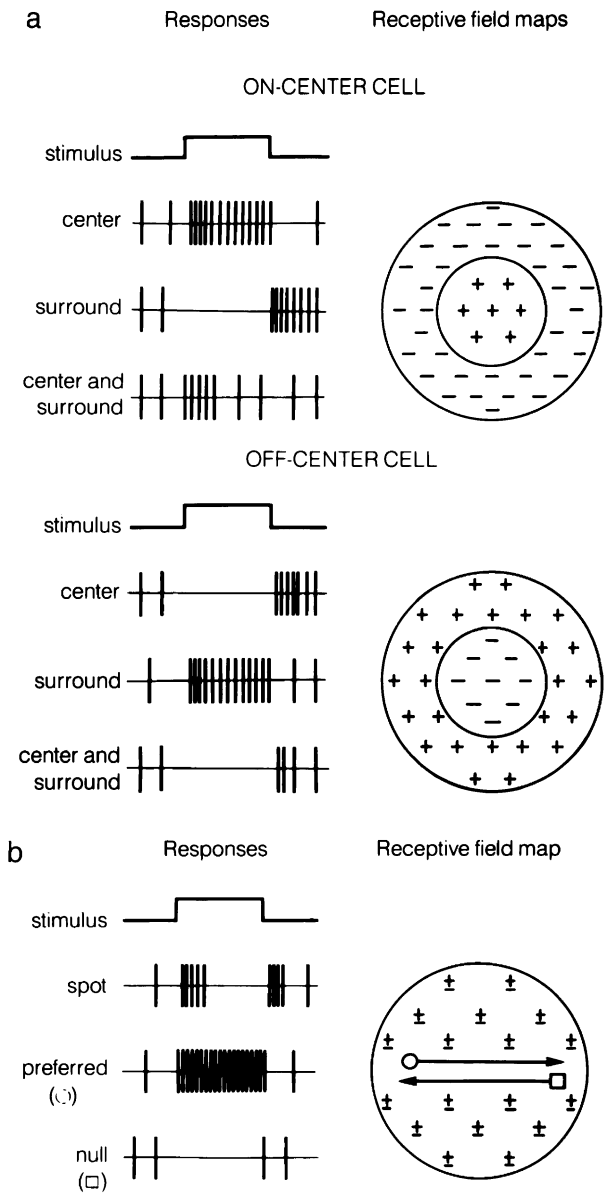

Figure 7 (a) Idealized responses and receptive field maps for on-center (top) and off-center (bottom) contrast-sensitive ganglion cells. Drawings on the left represent hypothetical responses to a spot of light presented in the center of the receptive field, in the surround of the receptor field, or in both center and surround regions of the receptive field. +, an increase in firing rate of the cell (i.e., excitation); –, a decrease in firing rate (i.e., inhibition). (b) Idealized responses and a receptive field map for a direction-sensitive ganglion cell. Such cells respond with a burst of impulses at both onset and termination of a spot of light presented anywhere in the cell's receptive field. This response is indicated by ± symbols all over the map. Movement of a spot of light through the receptive field in the preferred direction (○) elicits firing from the cell that lasts for as long as the spot is within the field. Movement of a spot of light in the opposite (null) direction (□) causes inhibition of the cell's maintained activity for as long as the spot is within the receptive field.

cells in cat and M cells in primate. Other ganglion cells give short on–off bursts of impulses to spots of light positioned anywhere in the receptive field. Some of the latter cells (particularly in nonprimate species) show direction-selective properties (Fig. 7b). Movement of a light spot in one direction vigorously excites the cell, whereas movement in the opposite direction inhibits the cell.

As noted earlier, midget ganglion cells receive input from a single midget bipolar cell, which in turn receives input from a single cone. The center of the receptive field corresponds to this direct pathway and is therefore cone specific. The antagonistic surround response, however, reflects mainly horizontal cell activity, and the horizontal cells receive input from many cones. Therefore, the center of the receptive field, is very small and has a spectral sensitivity different from that of the surround. Such ganglion cells are termed color-opponent cells and are thought to be involved in the early stages in color vision processing.

B. Synaptic Organization

Two types of chemical synaptic contacts are observed in both plexiform layers. One of these is similar in morphology to known chemical synapses seen throughout the brain, and it is termed a conventional synapse. It is characterized by an aggregation of synaptic vesicles in the presynaptic terminal clustered close to the membrane. In the retina, conventional synapses are made by horizontal, amacrine, and interplexiform cells. The other type of synapse is characterized by an electron-dense ribbon or bar in the presynaptic process and is called a ribbon synapse. The ribbon is thought to act like a conveyer belt, directing and allowing a large number of synaptic vesicles to discharge their contents into the synaptic cleft at the base of the ribbon (Fig. 8). Photoreceptor and bipolar cells make ribbon synapses in the retina. Electrical (gap) junctions are also observed in both plexiform layers of the retina, and they are believed to mediate direct electrical interactions between certain retinal neurons.

Figure 8a shows a drawing of a bipolar cell ribbon synapse and an amacrine cell conventional synapse in the inner plexiform layer. Typically, there are two postsynaptic processes at the ribbon synapses of bipolar cells, whereas at conventional synapses only one postsynaptic process is found. In this drawing, the amacrine cell synapse is made back onto the bipolar

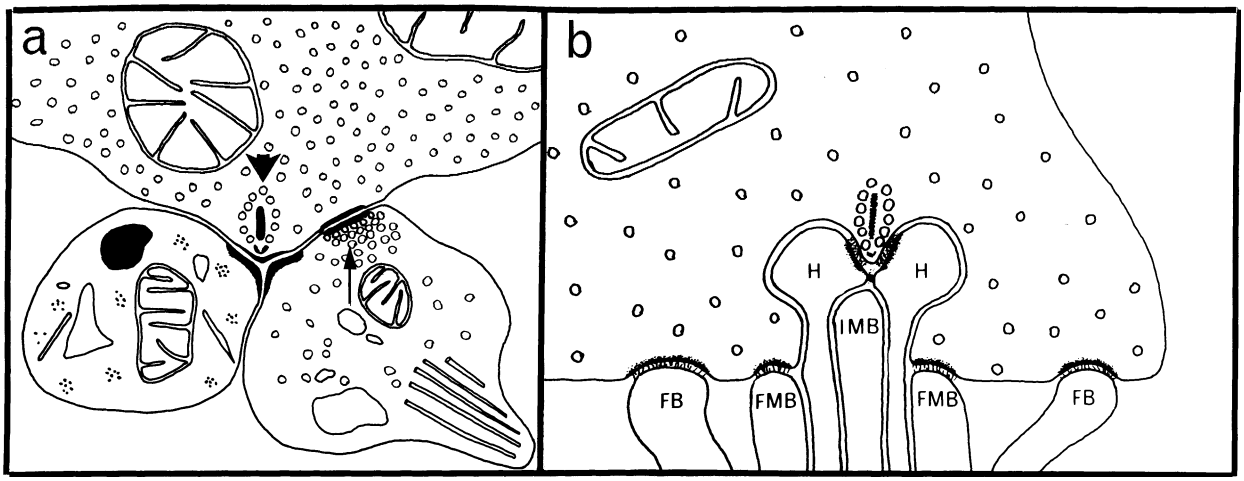

Figure 8 (a) Schematic drawing of a bipolar cell ribbon synapse (arrow) back onto the bipolar cell terminal. One postsynaptic process at the ribbon synapse is an amacrine cell process (right) and the other is a ganglion cell dendrite (left), a typical arrangement at cone bipolar cell terminals in primate. (b) Schematic drawing of synapses made by cone terminals in primates. See text for details. H, horizontal cell process; FB, flat bipolar cell dendrite; FMB, flat midget bipolar cell dendrite; IMB, invaginating bipolar cell dendrite.

terminal that is making a synapse on it. Thus, a reciprocal or feedback synaptic arrangement is suggested, which is commonly seen between bipolar cell terminals and amacrine cell processes. Amacrine cell synapses are also made on the processes and cell bodies of ganglion, interplexiform, and other amacrine cells.

Photoreceptor cell synapses are particularly complex, and a summary drawing of a part of a cone synaptic terminal is shown in Fig. 8b. The synaptic ribbons are found above invaginations of the basal surface of the terminal. Processes from horizontal cells and invaginating midget and invaginating diffuse bipolar cells penetrate into the terminal invaginations. Horizontal cell processes lie lateral to the synaptic ribbons, whereas the dendrites of the invaginating bipolar cells are centrally positioned. In addition to the ribbon synapse, the cone photoreceptor terminals make a second, unusual synaptic contact with the flat bipolar cells, which is called a flat or basal junction. No ribbon or vesicle cluster is associated with this junction, but some specializations of the membranes on both sides of the synapse are seen. The flat midget bipolar processes are typically found immediately adjacent to the invaginating midget bipolar processes, whereas the processes of the other flat bipolar cells are positioned away from the invaginations. Rod photoreceptor terminals do not make basal junctions; all rod bipolar dendrites penetrate into invaginations of the rod terminal.

Figure 9 is a simplified summary diagram of the synaptic organization of the primate retina. Each cone in the primate retina makes connections with two midget bipolar cells—one that makes invaginating-type junctions and a second that makes flat junctions (Fig. 9, left). In the central region of the primate retina, these two bipolar cell types synapse on separate midget ganglion cells. In the periphery of the primate retina, midget bipolar cells synapse on ganglion cells that receive input from a few to many midget bipolar terminals.

All cone terminals in primates also make synapses with diffuse cone bipolar cells and the proximal (dendritic) processes of horizontal cells. The axonal processes of the horizontal cells usually extend to the rod terminals. Synapses made by the horizontal cells have been observed on bipolar cells in many species but very rarely back onto the photoreceptor terminals. (However, there is good physiological evidence for feedback from horizontal cells into photoreceptors in many species.) Another interesting feature of the cone photoreceptor terminals is that they make junctions with each other and with adjacent rod terminals. Evidence in many species, including primates, suggests that these junctions are small electrical synapses.

Rod bipolar terminals in the mammalian retina do not contact ganglion cells directly (Fig. 9, right). Rather, amacrine cell processes are always postsynaptic at the ribbon synapses of the rod bipolar terminals. One of these makes a feedback synapse onto the terminal, whereas the other belongs to a special subtype of amacrine cell called the All cell, which makes both gap junctional (electrical) and

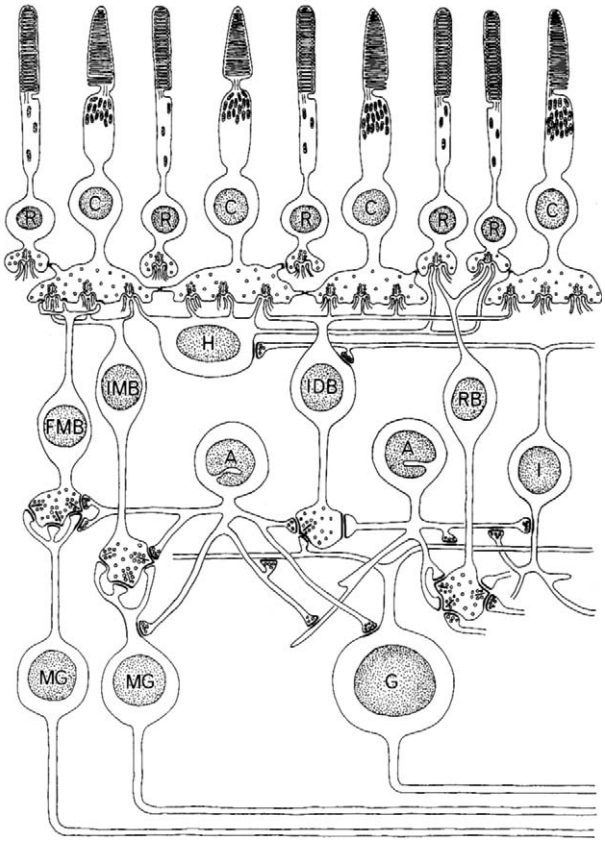

Figure 9 Summary diagram of the synaptic organization of the primate retina. See text for details. conventional (chemical) synapses with cone bipolar terminals. These cone bipolar terminals then contact the ganglion cells. Thus, rod information in the mammalian retina usually passes through an amacrine cell before it is transmitted to the ganglion cells via the cone bipolar cells. Why this is so is not clear: It has been suggested that the amacrine cell serves to amplify and quicken the rod signal.

Finally, interplexiform cells receive their input from amacrine cells, and they make some synapses in the inner plexiform layer on amacrine and ganglion cell processes. Most of their synapses, however, are made in the outer plexiform layer on bipolar and horizontal cells.

It should be noted that Fig. 9 is highly simplified. It is unlikely that any one amacrine cell makes the variety of contacts shown for either of the amacrine cells drawn in the figure.

IV. NEURONAL RESPONSES

In many nonmammalian species, intracellular recordings can be made routinely from most of the retinal cells. In mammalian retinas, intracellular recordings are more difficult to make, and relatively few have been reported from the primate retina. The following discussion is based mainly on recordings from nonmammalian species, but the recordings made so far from mammalian retinal neurons are similar.

The distal retinal neurons—receptors, horizontal cells, and bipolar cells—respond to light with sustained, graded membrane potential changes (Fig. 10). Unlike most neurons found elsewhere in the brain, they do not generally generate action potentials. This may be the case because these neurons have relatively short processes, and they do not need to transmit information over long distances; in other words, passive spread of potential along the cell membrane is sufficient to transmit information from one end of the cell to the other. The distal retinal cells may also function with graded potentials because such potentials are capable of discriminating a wider range of signals than can all-or-none events (i.e., action potentials).

Another unusual feature of the distal retinal neurons is that most respond to light with hyperpolarizing potentials; during illumination, the cell's membrane potential becomes more negative. Elsewhere in the nervous system, hyperpolarizing potentials are usually associated with inhibition because they prevent neurons from generating action potentials. In the distal retina, the neurons do not generate action potentials; thus, hyperpolarizing potentials can reflect excitation, and the photoreceptors are a good example.

A. Photoreceptors

Both rod and cone photoreceptors only hyperpolarize in response to illumination, but rods are more sensitive to light than are cones by about 25 times in the primate and other species. The reasons photoreceptors hyperpolarize in response to light and why in darkness the membrane potential of the cell is partially depolarized were discussed earlier. A typical resting value for the membrane potential of photoreceptors in the dark is

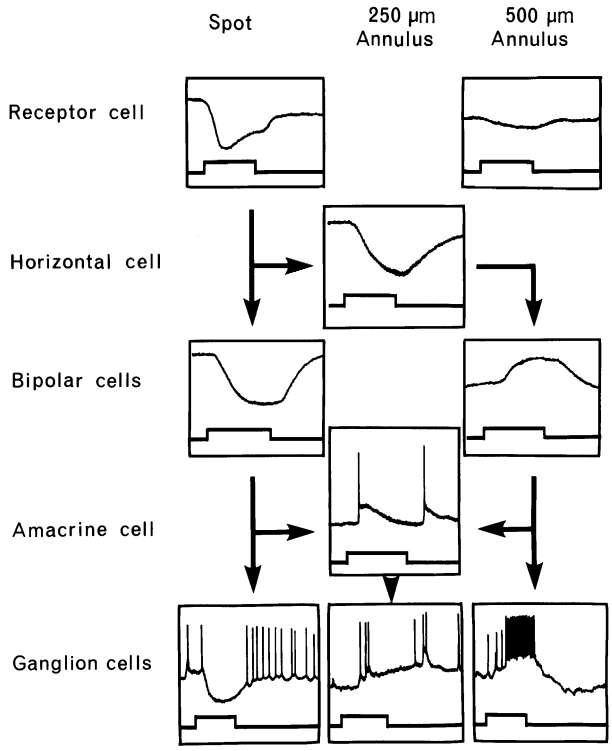

Figure 10 Intracellular responses from receptor, horizontal, bipolar, amacrine, and ganglion cells of mudpuppy retina. Distal retinal neurons (receptor, horizontal, and bipolar cells) respond to illumination with sustained graded potentials; proximal retinal neurons show both sustained and transient potentials and action potentials. Receptor, bipolar, and ganglion cells respond differently to center (spot) and surround (annular) illumination. Horizontal and amacrine cells usually respond similarly to spot and annular illumination; here, responses to a small annulus (250 μm) are shown that stimulate both the center and surround of the receptive field. The bipolar cell illustrated is a center-hyperpolarizing cell, the amacrine cell shown is a transient amacrine cell, and the ganglion cell is an off-center cell. Arrows indicate in a general way how the responses are synaptically generated (but see Fig. 11).

−30 mV, and in response to bright illumination the membrane potential is −60 mV, a typical resting potential for most neurons at rest. Thus, in the distal retina, photoreceptors and other neurons behave as though darkness is the stimulus and light turns them off (i.e., it hyperpolarizes them). It is not known why the system works is this way.

As noted earlier, there are electrical synapses between photoreceptors, but their role is not well understood. They may relate to the functioning of the photoreceptors or as a pathway for information flow. For example, they may provide an alternative pathway for rod signals to reach the cone bipolar cells. On the other hand, it has been proposed that electrical coupling between photoreceptors can reduce membrane noise and thus improve signal detection and also that it may increase the amplification of signals transmitted from the photoreceptors at their synapses. Whatever the functions of the electrical coupling between photoreceptors, it does increase the receptive field size of the cell. That is, the receptors respond to illumination over a wider area of the retina than that of a single receptor. Nevertheless, photoreceptors typically have the smallest receptive fields of any of the retinal neurons (Fig. 10).

B. Horizontal Cells

Horizontal cells, like photoreceptors, have relatively low resting membrane potentials in the dark (−30 mV), and often they only hyperpolarize in response to light (see Fig. 10). Some horizontal cells respond with small depolarizing responses to certain wavelengths of light and with hyperpolarizing responses to other wavelengths. These cells appear to be involved in color processing and are termed chromaticity cells. Horizontal cells that only hyperpolarize to illumination are called luminosity cells.

The receptive fields of horizontal cells are characteristically large, often several millimeters in diameter. Thus, the receptive field size usually exceeds the dendritic spread of the cells. Horizontal cells typically make extensive electrical junctions with each other, and the large receptive fields of these cells can be explained on the basis of the extensive electrical coupling between horizontal cells.

C. Bipolar Cells

Bipolar cells, like receptors and horizontal cells, respond to light with sustained graded potentials (see Fig. 10). In the mammalian retina, all rod bipolar cells depolarize to light. However, these are two physiological types of cone bipolar cells: those that depolarize in response to central spot illumination and those that hyperpolarize to such stimuli. Furthermore, the cone bipolar cell receptive field is organized into antagonistic zones such that illumination of the surround antagonizes the response to spot illumination. Thus, cone bipolar cells show a center-surround receptive field organization. "On" (center-depolarizing) and "off" (center hyperpolarizing) bipolar cells have been

found in all species so far examined, both mammalian and nonmammalian.

D. Amacrine Cells

In most retinas two basic types of amacrine cell responses are observed: transient and sustained. Transient amacrine cells usually give "on" and "off" depolarizing responses to illumination presented anywhere in their receptive field (see Fig. 10), but there are also transient amacrine cells that respond only at the "on" or "off" of illumination. Transient amacrine cells typically generate action potentials, and these potentials are observed on the transient "on" and "off" depolarizations. Usually only one to three action potentials are observed on the transient depolarization; thus, it has been proposed that the action potentials may serve as a local amplifying mechanism for the amacrine cell potentials rather than as the signal transmitted along the cell, as is the case for many neurons.

Sustained amacrine cell responses often resemble horizontal cell responses. They may be either hyperpolarizing or depolarizing in polarity, and the amplitudes of the two response types are comparable. Usually, sustained amacrine cells, like transient amacrine cells, give similar responses to spot illumination anywhere in their receptive field. There are also amacrine cells whose responses are a mix of transient and sustained potentials.

E. Interplexiform Cells

Only a few recordings from interplexiform cells have been reported, and they have all been from the retinas of nonmammalian species. In some cases the potentials are sustained with transient components. In other words, they are like amacrine cell responses.

F. Ganglion Cells

The receptive field properties of ganglion cells were discussed earlier, and it was pointed out that two basic types of ganglion cell responses are recorded in most retinas: sustained and transient responses. Intracellular recordings reveal the underlying potentials that give rise to these two response types. For example, Fig. 10 illustrates a sustained "off"-center, "on"-surround ganglion cell. With central spot illumination (Fig. 10, left), a sustained hyperpolarizing potential was evoked in the cell, and the cell was inhibited from discharging action potentials for the duration of the stimulus. With annular illumination (Fig. 10, right), a sustained depolarizing potential was produced, which elicited a steady discharge of action potentials from the cell for the duration of the stimulus.

Figure 10 also illustrates an "on"–"off" transient ganglion cell response (center response). With small annular illumination, the cell responded with transient depolarizing potentials at the onset and offset of the light. Each depolarization evoked a short burst of action potentials, but the durations of both the depolarizing potentials and action potential discharge were always shorter than that of the light stimulus. Such cells give similar responses to illumination anywhere in the receptive field.

G. Functional Organization of the Retina

Figure 11 shows in a simplified way how the potentials shown in Fig. 10 and the receptive fields of the retinal neurons may be produced by the synaptic interaction occurring within the retina. The figure correlates the basic connections of the retinal cells with intracellular responses recorded from an amphibian (mudpuppy) with a spot of light, small annulus, or large annulus.

As noted earlier, receptors have small receptive fields. They respond well to spots of light centered over the receptor but poorly to surrounding annuli (i.e., to light that does not directly strike the cell). The anatomy of the retina indicates that bipolar and horizontal cells are both activated by the receptors and Fig. 11 shows that both cell types respond with sustained graded potentials that resemble in waveform the photoreceptor response. Figure 11 also shows that the horizontal cells interact with bipolar cells and that this interaction is opposite in terms of receptor sign from the receptor–bipolar interaction. In Fig. 11 the receptor causes the bipolar cell to hyperpolarize, whereas the horizontal cell causes the bipolar cell to depolarize. Horizontal cells have a much larger lateral extent than do bipolar cells; thus, a center-surround receptive field organization is observed in the bipolar cell response. The center response of the bipolar cell (Fig. 11, left) is mediated by direct receptor–bipolar cell interactions, whereas the surround response (Fig. 11, right) reflects input to the bipolar cell via the horizontal cells.

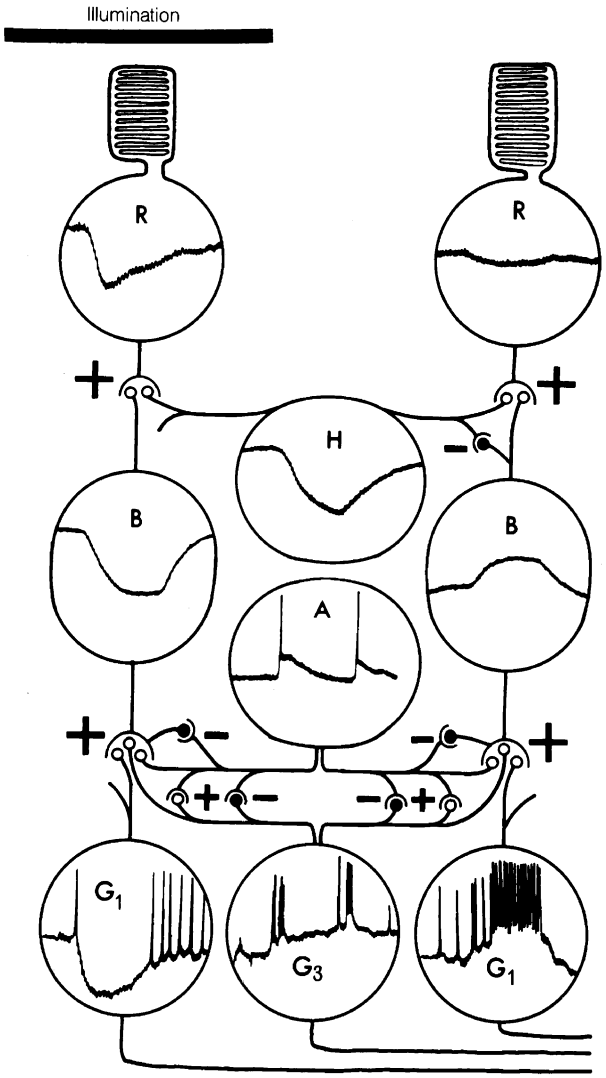

Figure 11 Summary diagram correlating the synaptic organization of the vertebrate retina with some of the intracellularly recorded responses from the mudpuppy retina. This figure shows how the receptive field organization of the hyperpolarizing bipolar cells, "off"-center ganglion cells, and "on"-"off" ganglion cells is established. The responses occurring in the various neurons upon illumination (bar) of the left receptor are indicated. The hyperpolarizing bipolar cells and "off"-center ganglion cells (G_1) respond to direct central illumination (left) by hyperpolarizing and to indirect (surround) illumination (right) by depolarizing. Note that the switch from hyperpolarizing to depolarizing potentials along the surround illumination pathway occurs at the horizontal–bipolar cell junction. The "on"-"off" ganglion cell (G_3) receives strong inhibitory input from amacrine cells; the figure indicates that these cells receive their excitatory input from both amacrine and bipolar cells. Inhibitory feedback synapses from amacrine cells onto the bipolar terminals are also indicated. R, receptors; H, horizontal cell; B, bipolar cells; A, amacrine cells; G, ganglion cells; + with open circles, excitatory synapses; − with filled circles inhibitory synapses.

How horizontal cells mediate the surround response in bipolar cells is not well understood. In most species, feedback from horizontal cells to cone photoreceptor cells has been observed, and it has been proposed that the surround antagonism is generated in this way. Feedforward inhibition of horizontal cells onto bipolar cells has also been seen in some species, and no feedback inhibition has been observed on rod photoreceptor cells. Thus, the surround response of the bipolar cells probably results mainly from feedback interactions, but feedforward interactions may contribute as well. Furthermore, the mechanism underlying the feedback or feedforward interaction is unclear. It may represent classic chemical synaptic inhibition or complex electrical interactions between the cells in the outer plexiform layer.

As noted earlier, two types of synapses made by the cone terminals have been observed: invaginating and flat junctions. It appears that in many cases (but not always) the flat synapses result in the center-hyperpolarizing responses in bipolar cells, whereas the invaginating junctions result in the center-depolarizing bipolar cell responses.

The bipolar cell terminals carry the visual signal from the outer to inner plexiform layers. Depolarizing or "on" bipolar cell terminals are found in the inner half of the plexiform layer, whereas hyperpolarizing bipolar cell terminals are in the outer half of the layer. Thus, there is a division of the inner plexiform layer into "on" and "off" laminae or strata. "On" responses of amacrine and ganglion cells are generated in the lower part of the layer, whereas "off"-responses are generated in the upper part. Thus, "on"-center ganglion cells have their processes in the lower or "on"-strata of the inner plexiform layer, "off"-center cells in the upper or "off" layer, and "on"–"off" ganglion cells spread processes in both halves of the layer. In addition to the "on" and "off" laminae, there is evidence for as many as 10–12 sublaminae in the inner plexiform layer. The cells contributing processes to these sublaminae have distinct properties with regard to such things as rod or cone dominance, response waveform, and excitatory and inhibitory input. Each sublamina thus appears to process visual information somewhat differently.

The responses of the two basic types of ganglion cells found in the mudpuppy (and other retinas) appear to relate to the responses of the input neurons to the ganglion cells. The sustained "on"- or "off"-center ganglion cells (G_1 cells in Fig. 11) appear to receive much of their synaptic input directly from the bipolar cells; their responses resemble those of the "on"- or

"off"-bipolar cells, and their receptive fields thus primarily reflect the processing that occurs in the outer plexiform layer. The "on"–"off" transient ganglion cells, on the other hand, resemble in their properties the transient amacrine cells, and they appear to receive more of their input from amacrine cells (G_3 cell in Fig. 11). These cells reflect more the processing that occurs in the inner plexiform layer. As noted earlier, the transient ganglion cells respond better to moving than to static stimuli, and some of these cells show complex receptive field properties such as direction selectivity. Substantial anatomical evidence shows that complex ganglion cell receptive field properties, such as motion and direction sensitivity, are mediated in the inner plexiform layer, predominately as a result of interactions between amacrine and ganglion cells. That is, in those species that have many motion- and direction-selective cells, there are more amacrine cell synapses per unit area of the inner plexiform layer than there are in species that have relatively few motion- and direction-selective ganglion cells.

In addition to the two basic types of ganglion cells described here, many ganglion cells have a mix of transient amacrine and bipolar cell characteristics. The Y-type ganglion cell of the cat and M-type primate ganglion cell are examples. They show a center-surround receptive organization like the bipolar cells, but their responses to both center and surround stimulation are quite transient and they are sensitive to moving stimuli. These cells appear to receive more of a mix of bipolar and amacrine cell synaptic input than the more sustained "on"-center or "off"-center ganglion cells of the cat and primates, the X and P cells.

In primates the P cells correspond to the midget ganglion cells, whereas the M cells are parasol cells. The designation P and M cells derives from the layers of the lateral geniculate nucleus (LGN) to which these cells project; P cells go to the parvocellular layers and M cells to the magnocellular layers of the LGN.

V. PHARMACOLOGY

The retina, like other regions of the brain, contains a large number of neuroactive substances. Currently, the following substances are believed to be released from retinal neurons during retinal activity:

- Amino Acids
  - γ-Aminobutyric acid (GABA)
  - L-Glutamate
  - Glycine
- Amines
  - Acetylcholine
  - Dopamine
  - Serotonin
- Peptides
  - Cholecystokinin
  - Enkephalin
  - Glucagon
  - Neurotensin
  - Neuropeptide Y
  - Somatostatin
  - Substance P
  - Vasoactive intestinal peptide
- Unconventional modulators
  - Nitric oxide
  - Retinoic acid
  - Zinc

Also, like in other brain regions, these substances may be classified into two general categories, neurotransmitters and neuromodulators, based on their mode of action. Relatively few substances appear to serve as neurotransmitters in the retina. L-Glutamate and acetylcholine mediate fast excitatory pathways in the retina, whereas GABA and glycine mediate fast inhibitory pathways. The bulk of the neuroactive substances released from retinal neurons appear to be neuromodulatory in nature, although little is known about the action or role of most of these substances, especially the peptides.

A. Amino Acids

Both photoreceptors and bipolar cells employ L-glutamate as their transmitter. L-Glutamate depolarizes both horizontal cells and "off"-center (hyperpolarizing) bipolar cells, whereas it hyperpolarizes the "on"-center (depolarizing) bipolar cells. Neurotransmitter is released when neurons are depolarized, and because photoreceptors are maintained in a depolarized state in the dark they release L-glutamate in the dark. When illuminated, photoreceptors hyperpolarize, and transmitter release is decreased. Thus, the light responses of the horizontal and bipolar cells reflect the withdrawal of transmitter from the cell. Horizontal cells are depolarized in the dark because of a dark release of L-glutamate from the photoreceptors; their light response is a hyperpolarization, reflecting the decrease in transmitter release from the photoreceptors in light. The same explanation holds for the off-center bipolar cells. These cells are depolarized in the

dark; they hyperpolarize in light as transmitter release from the photoreceptor decreases. The ''on''-center cell, however, is hyperpolarized in the dark, and it depolarizes in the light in response to the decreased release of L-glutamate from the photoreceptor.

Although the same substance, L-glutamate, mediates the photoreceptor input to horizontal cells and both types of bipolar cells, the receptor proteins with which the glutamate interacts differ in the three types of cells. ''Off''-bipolar and horizontal cells possess ionotropic glutamate receptor channels, whereas many ''on'' bipolar cells have metabotropic glutamate receptor proteins. Thus, it is possible to block the responses of one or another of the three cells with pharmacological agents while leaving the responses of the other cells intact. One substance, 2-amino-4-phosphonobutyric acid (APB), blocks specifically the metabotropic receptors of the ''on''-center bipolar cells, and this results in the loss of ''on'' activity throughout the visual system in many species. Monkeys treated with APB are unable to distinguish increases of illumination, although they can discriminate decreases of retinal illumination.

The amino acids GABA and glycine serve as the main inhibitory neurotransmitter agents in both the inner and outer plexiform layers. Many horizontal cells contain GABA, and approximately 80% of the amacrine cells in many retinas contain either GABA or glycine, equally divided. Both GABA and glycine powerfully inhibit ganglion cells by opening channels in the cell membrane that cause hyperpolarization of the cell and inhibition of action potential generation. GABA and glycine act on many retinal neurons, mediating specific inhibitory effects. For example, by blocking the effects of GABA in a retina with pharmacological agents, direction-sensitive ganglion cells lose their directional selectivity. Such cells then respond to spots of light moving in any direction across the retina. Therefore, it is believed, that direction sensitivity is mediated by GABAergic amacrine cells in the inner plexiform layer.

B. Amines and Peptides

Most amines and neuropeptides appear to function as neuromodulatory agents in the retina, although little is known about the function of most of these agents, particularly the neuropeptides. The exception is acetylcholine, which functions in the retina as an excitatory neurotransmitter in the inner plexiform layer. Acetylcholine is found in a specific type of amacrine cell, the starburst cell, and half of these cells spread processes in the ''on'' region of the inner plexiform layer and respond with transient depolarizing responses at the onset of illumination. The other half extend processes in the ''off'' region of the inner plexiform layer and respond with transient depolarizing responses at the offset of illumination. The cell bodies of the on acetylcholine-containing amacrine cells are found among the ganglion cells, whereas the cell bodies of the ''off'' acetylcholine-containing amacrines are in the inner nuclear layer. The acetylcholine-releasing amacrine cells are believed to provide excitatory input to the transient ''on''–''off'' ganglion cells, especially those that are direction selective. They also provide input to the parasol (M-type) ganglion cells in the primate and may play an important role in the development of the retina. Interestingly, the starburst amacrine cells also contain GABA, and both acetylcholine and GABA are released by this neuron. The significance of a neuron releasing simultaneously an excitatory and inhibitory neurotransmitter is not understood.

The other amines, dopamine and serotonin, and the neuropeptides have also been localized principally to amacrine cells. For the most part, these cells are relatively scarce, accounting for no more than a few percent of the total number of amacrine cells. These cells usually spread their processes widely in the inner plexiform layer; thus, they are capable of exerting wide modulatory effects. It is also the case that coexistence of neuroactive substances occurs in many amacrine cells. It has been reported that two peptides can coexist in the same amacrine cell, that a peptide and a monoamine coexist, or that a peptide or monoamine and an inhibitory amino acid (usually GABA) are in the same cell. Some evidence has been provided that three or even more agents may be colocalized in the same neuron. Currently, the significance of the colocalization of two or more neuroactive agents in a single retinal neuron is not understood, although an obvious hypothesis is that it permits multiple effects to be exerted on postsynaptic neurons.

1. Interplexiform Cells and Dopamine

Much of what we know about the action of neuromodulators in the retina has come from the study of dopamine in cold-blooded vertebrate retinas, especially fish and amphibian retinas. In the teleost, dopamine is present in interplexiform cells and so these studies have also shed light on the role of these cells in retinal

function. A brief summary of the findings is presented as a model for the action of neuromodulators in the retina.

In teleosts, the synaptic output of the interplexiform cells is mainly on the cone-related horizontal cells. Two effects of dopamine on these cells have been observed; a loss of light responsiveness (i.e., light responses are reduced in amplitude after dopamine application to the retina) and a decrease in electrical coupling between horizontal cells. Dopamine does not exert these effects by acting directly on horizontal cell membrane channels; rather, it interacts with a membrane receptor protein linked to the enzyme adenylate cyclase that catalyzes the formation of cyclic AMP (Fig. 12). A specific kinase (PKA) activated by cyclic AMP in horizontal cells phosphorylates both the glutamate channels (i.e., the channels activated by the photoreceptors transmitter) and the gap junctional channels. The phosphorylation of these channels serves to alter their properties. In the case of the gap junctional channels, phosphorylation mainly decreases the time that the channels remain open, thereby decreasing the flow of current that passes across the junction. Phosphorylation of the glutamate channels modifies the frequency of opening of the channels, which again modulates ion flow across the membrane.

The action of dopamine on teleost horizontal cells is therefore not to initiate activity but to modulate chemical synapses made onto the cell and the electrical synapses made between horizontal cells. Similar effects of dopamine on chemical and electrical synapses have been seen in a variety of animals, including turtles, toads, tiger salamanders, and rabbits. Dopamine modulates gap junctions between horizontal cells in turtle, between rod–cone photoreceptors in the toad, and between amacrine cells in rabbit. In tiger salamander, dopamine modulates glutamatergic chemical synapses onto bipolar cells, whereas in the toad, *Xenopus*, dopamine alters the rod–cone balance of input to the horizontal cells presumably through a similar mechanism. Dopamine modulation of GABAergic synapses in the retina has also been reported. Dopamine also has a variety of other actions in the retina, including the control of retinomotor movements of the photoreceptors in fish and the regulation of Ca^{2+} currents in turtle ganglion cells.

One major effect of dopamine in the teleost retina is to decrease the effectiveness of the horizontal cells in mediating lateral inhibitory effects in the outer plexiform layer. Decreasing light responsiveness of the cell and shrinking its receptive field size are effective ways of lessening its influence. As noted earlier, horizontal cells form the antagonistic surround response of bipolar cells, and thus a decrease in bipolar cell surround response is observed after dopamine application to the retina.

What might be the significance of the modulation of lateral inhibition and surround antagonism by

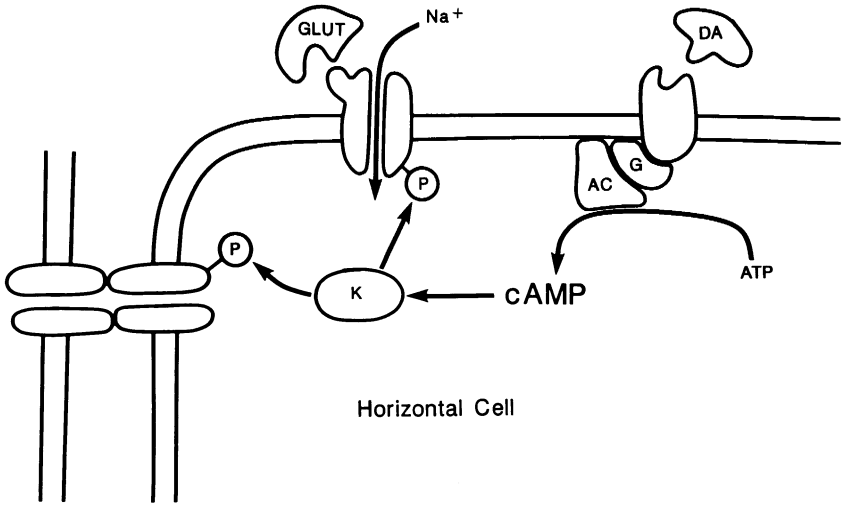

Figure 12 Summary scheme showing how dopamine (DA), acting via cyclic AMP, may influence responsiveness of horizontal cells to L-glutamate (the photoreceptor transmitter) and electrical coupling between horizontal cells. DA interacts with receptors that are linked to the enzyme adenylate cyclase (AC) via a G protein. Activation of AC results in conversion of ATP to cyclic AMP. Cyclic AMP interacts with a kinase (K) that phosphorylates (P) glutamate (Glut) channels or the gap junction channels.

dopamine and the interplexiform cells in the retina? It has long been known that after prolonged periods of time in the dark the antagonistic surround responses of ganglion cells are reduced in strength or even eliminated. An obvious speculation is that interplexiform cells and dopamine play such a role and regulate the strength of lateral inhibition and center-surround antagonism in the retina is a function of adaptive state. In fish, there is evidence supporting this view. After periods of prolonged darkness, horizontal cell receptive field size and light responsiveness are substantially decreased.

C. Unconventional Modulators

Three unusual substances have been shown to modulate retinal neurons, and they appear to play roles as neuromodulators, especially in the outer retina. Nitric oxide (NO) is a gas that has the interesting property of being able to diffuse from cell to cell. NO activates the enzyme guanylate cyclase, which produces the second messenger cyclic GMP. Cyclic GMP, in turn, activates the kinase PKG. NO, through PKG, has similar effects as dopamine on horizontal cell coupling, but it does so via a different mechanism. Whereas dopamine reduces coupling mainly by decreasing gap junction channel open time, NO reduces coupling by reducing channel opening frequency, suggesting that PKC interacts with a different site on the gap junctional channel than does PKA. NO, like dopamine, also modulates glutamate receptors on horizontal cells, but its effects are complicated. It decreases the affinity of the receptors for glutamate, but it increases the maximal current that can pass through the glutamate receptors on horizontal cells.

The enzymes that produce NO are found in many cells throughout the retina, including several types of amacrine cells; thus, it is believed that NO exerts a variety of effects in the retina in addition to those shown on horizontal cells.

Retinoic acid (vitamin A acid) is usually considered to be a morphogen, playing an important role in the development of many tissues including the retina. For example, retinoic acid is important for ventral retinal development and it is also involved in photoreceptor maturation. Retinoic acid is known to regulate a number of genes, which it does by interacting with specific retinoic acid receptors known as RARs or RXRs. On horizontal cells, retinoic acid, like dopamine and NO, uncouples horizontal cells. It appears to act directly on the gap junctional channels and not via second messengers or kinases. Retinoic acid levels in the retina are modified by light, suggesting that retinoic acid is a third substance involved in the regulation of horizontal cell gap junctions. Whether retinoic acid plays other neuromodulatory roles in the retina is unknown.

Finally, zinc, a trace metal, has been shown to be colocalized with glutamate in the photoreceptor synaptic terminals, and it is thought to be released with glutamate from the photoreceptor terminals. Zinc has been found to modulate both glutamate and GABA receptors in the retina. In both cases, zinc decreases the membrane current flows elicited by glutamate or GABA. Again, it is possible that zinc plays a role at other glutamatergic and GABAergic synapses in the retina.

VI. CONCLUSIONS

The retina is a relatively well-understood part of the central nervous system, but its complexity is overwhelming. Although we have long recognized that it consists of five major classes of neurons, it is now apparent that each class of neuron consists of many cell subtypes, perhaps as many as 30–40 in the case of amacrine cells. Furthermore, although we can classify the responses of most retinal neurons as ''on'' cells, ''off'' cells, or ''on''–''off'' cells, and as giving principally sustained or transient responses, it is now recognized that a variety of subtle image representations are sent to the brain via the optic nerve and that this variety reflects complex synaptic excitatory and inhibitory synaptic interactions occurring among various neuronal subtypes at different levels of the retina, particularly in different laminae in the inner plexiform layer. Finally, although relatively few substances appear to serve as the principal excitatory and inhibitory neurotransmitters in the retina, a much larger number of neuromodulatory substances are known to exist in the retina, including several unconventional substances that have been shown to have significant effects on the retinal cells. Thus, the responses of individual retinal neurons reflect not only the direct excitatory and inhibitory synaptic interactions between neurons but also an extensive modulation of these synaptic interactions by multiple substances acting in different ways on the neurons and their channels.

In this article, I presented a broad introduction to the retina and how it functions. I hinted at the complexity of interactions occurring in the retina,

but I hardly did them justice. An example is the multiplicity of channels and receptor proteins that any one neurotransmitter or neuromodulator can activate, such as the three types of GABA receptors—$GABA_A$, $GABA_B$, and $GABA_C$—thought to be key in shaping the responses of inner retinal neurons.

GLOSSARY

contour integration The process of grouping of edge fragments into an extended contour.

distractor Items that are presented together with the target in a search task that share some but not all of the features of the target.

outliers Observations that are significantly different from the majority of the observations.

pop-out The degree to which a target can be detected in brief presentations.

preattentive Operations that are rapidly accomplished without apparent conscious effort.

visual search Psychophysical task of finding a target embedded in an array of distractors.

Salience refers to the perceptual prominence of an object relative to its background. The word "salience" derives from roots connoting an assault or sally, in this case upon the senses, and it implies a quality of leaping or springing forth from the stimulus. The salience of a visual target is determined by the degree to which the features of the target differ from those of the surroundings. However, it is not completely understood which "features" of the stimulus are relevant for the visual system. Measurement of salience requires a quantitative scale for assessing differences in features, sometimes across several dimensions. A red circle in a field of green squares is nominally salient, but is it more or less salient than a fast-moving dot among slow-moving dots? From an ecological perspective, animals must be rapid and reliable at detecting certain types of targets—an object directed at one's head is salient regardless of its texture. Essential targets—food, predators—must induce rapidly discriminable patterns of neural activation. An understanding of salience thus provides a glimpse into how the brain prioritizes the world. The salience of a target can be evaluated by preattentive processes, or operations that are carried out rapidly without apparent conscious effort, and is often measured by "pop-out," the degree to which the target can be detected in brief presentations. However, salience is also closely related to attentional processes; for example, search targets can be found more easily if subjects are provided with instructions relevant to the task. The mechanisms by which salience is generated in the nervous system thus involve the integration of both bottom-up and top-down influences.

I. SALIENCE, POP-OUT, AND VISUAL SEARCH

Although salience is a property of stimuli in all sensory modalities, previous studies have focused primarily on

vision. Salience is often measured by using a two-interval, forced-choice paradigm. Two stimuli are briefly presented in succession, separated by a short interval; one stimulus contains the target, and the other contains a generically similar stimulus, but lacking a target. Over multiple trials with different stimuli, the results of these trials generate a psychometric function in which the accuracy of detecting the target is plotted versus changes in stimulus parameters (e.g., contrast, size, spacing). The detection accuracy reflects the salience of the target. Brief presentations (<100 msec) restrict visual processing to preattentive vision, and targets detectable in such conditions are said to "pop out."

Alternatively, the salience of a target can be measured by recording the time required to detect the target in a visual search task. In general, the time required to detect a target increases with the number of distractor elements. However, the slope of this function—reaction time (RT) versus number of distractors—depends upon the salience of the target relative to that of the distractors. Highly salient targets pop out and can be found effectively instantly, regardless of the number of distractors. When the target has less salience, detection requires a serial, attention-based scan of putative target locations.

Interestingly, in many cases, there is an asymmetry in salience when the roles of target and distractors are exchanged. For example (as shown in Fig. 1), a long line is salient when placed amid shorter lines, but a short line is less salient among longer lines. A tilted line is salient among vertical lines, but a vertical line pops out to a lesser degree from a field of tilted lines. A circle with a gap pops out from a field of closed circles, but less so the converse. On the basis of dozens of such examples, Anne Treisman concluded that salience resembles a signal detection problem and must depend upon a signal-to-noise ratio. The degree to which the distractor elements activate the relevant feature detectors defines the noise level. If the relevant neural feature detectors are strongly activated by the distractor elements, then a target that less strongly activates the neural detectors will be below the noise level. The less strongly distractors activate the neural detectors in comparison to the target, the more salient the target will appear.

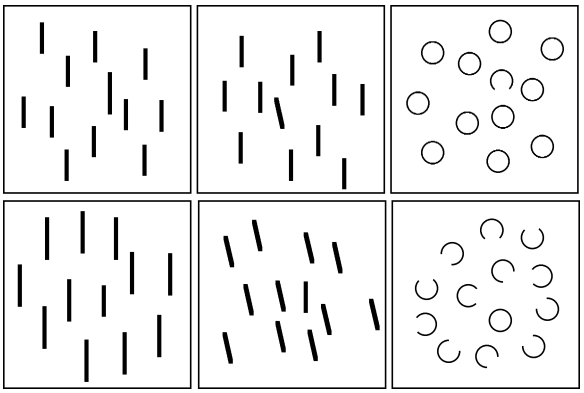

Figure 1 Asymmetries in salience. Left column: A long line is salient when placed amid shorter lines (top), but a short line is less salient among longer lines (bottom). Middle column: A tilted line is salient among vertical lines (top), but a vertical line is less salient among tilted lines (bottom). Right column: A circle with a gap is salient among closed circles (top), but a closed circle is less salient among circles with a gap (bottom). Adapted from Treisman and Gormican (1988).

Treisman used this approach to attempt to identify what features (e.g., closure, line intersections) are actually employed by the early visual system and to substantiate her Feature Integration theory of visual function. According to this theory, visual features are extracted in multiple parallel maps, but the *locations* of these features are independently coded in separate maps. Attention is posited to be necessary to bind features with their spatial location. Thus, visual search can operate in a scanning mode, where attention is serially directed to each element, or search can involve attending to larger areas containing several elements and measuring the total amount of feature activation within each area. If the wider area contains the target and several distractors, then the amount of feature activation differs from that measured in areas of the image containing only distractors. Treisman's point is that signal-to-noise constraints make it easier to detect a large target signal on top of small distractor signals than to detect a small target signal mixed in with a number of large distractor signals. Search asymmetries would then follow from Weber's law: the minimal detectable increase in signal energy over the noise level is proportional to the noise level.

Search asymmetries provide clues to the feature detectors used by the visual system because the signal-to-noise ratio will depend on which particular feature detectors are used. However, we have to be careful about making the distinction between features of a stimulus and the postulated feature detectors in the visual system. Because the visual system has multiple feature maps, target activation may be above the noise level in some maps, but below the noise level in other maps.

As an example, it has been found psychophysically that a field of L's surrounded by a field of $+$'s is nearly twice as salient as a field of $+$'s embedded in a field of

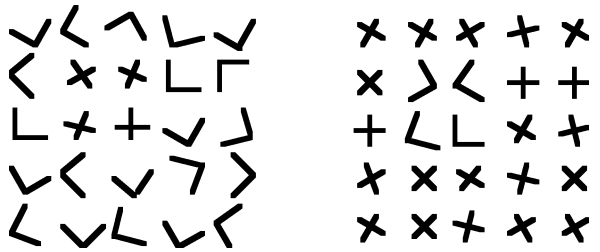

Figure 2 Asymmetry in texture pop-out. A field of L's within a larger field of +'s (shown on right) is more salient than the converse (shown on left).

L's (see Fig. 2). These texture elements are similar: both contain horizontal and vertical segments; the L contains two line endings and a single corner junction, whereas the + contains four line ends, four corner junctions, and a line intersection. According to Bela Julesz, these elements differ in the number and kind of "textons" and should be discriminable—as indeed they are. However, Treisman argued that the pop-out is due to global aspects of the elements, namely, despite the fact that they are composed of identical lines, the L's appear bigger than the +'s. Treisman carried out trials using portions of the elements (e.g., just one quadrant of the +) and found that none of these component elements pop out. In fact, she concluded that no features based on line arrangement (angles, intersections, etc.) are detected preattentively.

Interestingly, Jitendra Malik and Pietro Perona measured the response to these two texture elements by using an array of spatial filters at different spatial frequencies and orientations, resembling those in the visual pathway. The filters included circularly symmetric on- and off-center filters (corresponding to the receptive fields of retinal ganglion cells or cells in the lateral geniculate nucleus) and oriented difference-of-offset Gaussian (DOOG) filters (corresponding to the receptive fields of striate cortical simple cells). They found that most filters showed differential responses to the two elements; however, the maximum difference in response arose from the circularly symmetric filters, which responded more vigorously to the +'s. Similar results were reported by Edward Adelson and James Bergen. Note that these reported responses are the spatially averaged responses of a bank of non-interconnected filters centered at different positions with respect to the stimulus. If one considers the response of individual oriented DOOG or Gabor-type filters within a cortical network, then the L might evoke a greater peak response than the + because there is less cross-orientation inhibition. Thus, multiple neural dimensions appear to conflict regarding which stimulus is more salient. The question is whether we can identify the rules by which the visual system integrates this information.

II. SALIENT TARGETS AS STATISTICAL OUTLIERS

In our initial definition of salience, we observed that an object has salience only in comparison to a population of other objects. A 6′7″ tall basketball player stands out in his college class but is less salient on an NBA team. Weber's law implies that the degree of salience depends upon the distribution of feature properties. In some sense then, salience determination is similar to testing for outliers in a statistical distribution. The distribution of feature values over the distractor population provides a basis for determining whether the feature values of the target are statistical outliers. Ruth Rosenholtz has elegantly formulated this idea in terms of a statistical parametric test for outliers. Given a one-dimensional normal (Gaussian) distribution, a target is an outlier if its feature value lies several standard deviations away from the mean. To determine an outlier in multiple feature dimensions, Rosenholtz developed the use of the Mahalanobis distance between the target and the mean of the distractor distribution.[1]

Rosenholtz's approach is powerful because the Mahalanobis distance can provide a *quantitative* measure of salience and target discriminability. With a few additional assumptions, it can be extended to allow comparisons across feature dimensions. For example, how does the salience of a red target among yellow distractors compare to the salience of a 45° line among vertical lines? The use of a parametric test is not meant to imply that the underlying feature distributions must be Gaussian or are known *a priori* by the visual system. Rather, Rosenholtz suggests that a parametric test is simply an efficient means of rapidly determining whether a point is an outlier. This efficiency might come into play in brief stimulus

[1] Δ is defined as $\Delta^2 = (\mathbf{v}-\mu)^{\mathrm{T}}\Sigma^{-1}(\mathbf{v}-\mu)$, where $\mathbf{v}$ is a vector containing the feature values for the target in each dimension, and μ is the mean and Σ the covariance of these feature values across the population. In one dimension, the covariance matrix Σ reduces to the standard deviation, and so Δ measures the distance in terms of standard deviations between the target's feature values and the mean of these values across the population. T signifies the transpose.

presentations (<100 msec) in which the preattentive visual system may only have time to determine general properties of the object population, such as its mean and covariance.

Rosenholtz has used the Mahalanobis metric to explain asymmetries in search difficulty reported in experiments involving target and distractor motion. For example, the Mahalanobis metric correctly predicts that it is rather easy to detect a single moving target in a field of stationary distractors, but that it is more difficult to detect a stationary target in a field of moving distractors. Similarly, search for a fast target among slow distractors is more efficient than search for a slow target among fast distractors. Treisman's explanation based on Weber's law can qualitatively account for these findings, but the Mahalanobis metric quantifies the difference in difficulty. For example, in the search for fast versus slow elements, the stimuli consist of objects oscillating back and forth horizontally, with the target and distractors differing only in speed. A small amount of noise is added to the velocity profile of each object. As shown in Fig. 3 the distribution of velocities is thus centered on two values for each class: v_t and $-v_t$ for the target versus v_d and $-v_d$ for the distractors. When the target is fast and the distractors are slow, $v_t > v_d$, the target velocity lays outside the 1σ covariance ellipse (one standard deviation from the mean) of the velocities of the distractors. However, when the target is slow compared to the distractors, its velocity is within 1σ of the mean of the distractor distribution. The Mahalanobis measure clearly shows that only in the former case is the target an outlier compared to the distractor distribution.

Rosenholtz demonstrates that this approach can account for all of the well-known cases of asymmetries in motion search. She argues that the method holds as well for salience in the color dimension. In one dimension the Mahalanobis metric is similar to the Weber law approach. But when targets and distractors differ in multiple dimensions, intuition is less clear. For example, Rosenholtz considers the case in which targets and distractors can move with varying speeds in different directions. Psychophysics shows that it is easy to find a moving target among distractors with varying speeds if the distractors all move in the same direction as the target. But it is difficult if the distractors have both varying speeds and varying directions. On the other hand, if the distractors move in different directions, it is equally difficult to spot the target if the distractors all have the same speed or each has different speeds. The Mahalanobis model predicts the observed result in all cases.

III. FEATURAL AND CONFIGURAL SALIENCE

Treisman's Feature Integration theory was originally developed to explain a set of findings using stimuli in which target and distractors differ only in the *conjunction* of features. For example, the target might be a horizontal blue line within a field of horizontal green

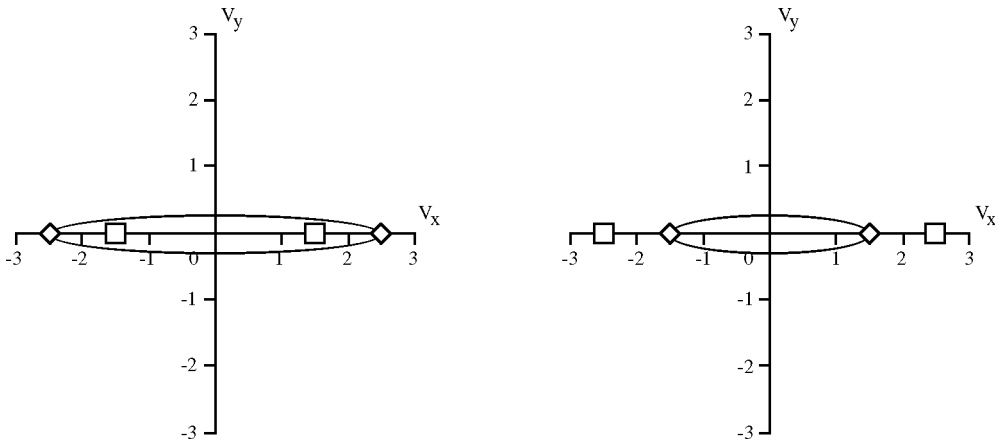

Figure 3 Search asymmetry and the Mahalanobis measure. The two graphs plot the x and y component vectors of the target (plotted with squares) and the distractors (plotted with diamonds). The ellipse delimits one standard deviation from the mean of the distractor velocities. The graph on the left illustrates search for a slow target among fast distractors, and the Mahalanobis measure correctly predicts a difficult search task. The graph on the right illustrates the search for a fast target among slow distractors, and the Mahalanobis measure again correctly predicts an easier search task. Adapted from Rosenholtz (1999).

lines and vertical blue lines. Such tasks are difficult; they generate reaction time plots whose slopes increase sharply with increasing number of distractors. On the basis of such tasks, Jeremy Wolfe has proposed models for attention-based search that incorporate more sophisticated grouping and segmenting mechanisms than the simple pooling used by Treisman. In the preceding example, all horizontal lines could be grouped and segmented from lines of other orientations. Similarly, all blue lines could be grouped and a selected search could be directed within these maps, making target detection more efficient.

Theories of attention have focused on binding features across dimensions (orientation, color, line endings, etc); however, binding also occurs across spatial locations. As Gaetano Kanizsa and others have shown, preattentive vision carries out an array of grouping and segmentation processes that organize the scene. In Fig. 4, we perceive alternating horizontal rows of open and closed circles. Despite the myriad other possible ways these elements could be grouped, we cannot consciously desist from organizing the elements into groups on the basis of similarity and proximity. This illustrates the central problem of Gestalt psychology: what object characteristics determine figure versus ground. The Gestaltists identified several characteristics that cause elements to be grouped together: similarity, proximity, good continuation, closure, symmetry, and common motion. Elements that share these characteristics tend to be grouped together, segmented from other elements, and tend to be perceived as more salient because the difference between figure and ground *is* salience. Camouflage attempts to manipulate these Gestalt characteristics so that the parts of the object are bound to the background rather than with each other thus decreasing object salience and pop-out.

Thus, in some stimulus domains, objects are salient based on the *relations* between stimulus elements

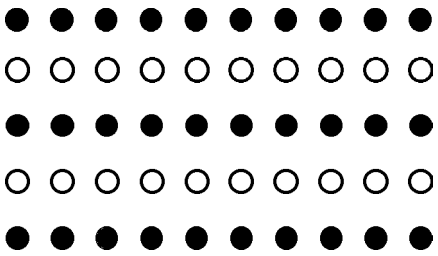

Figure 4 Perceptual grouping. The predominant percept is to group the array of dots into alternating rows of black and white dots. According to the Gestalt psychologists, this is an example of grouping using the similarity cue.

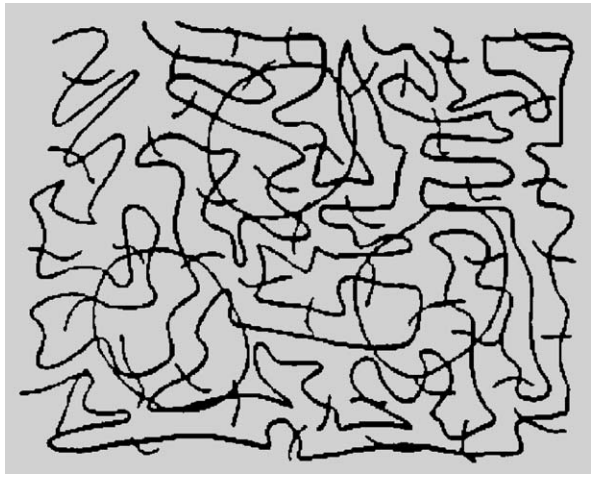

Figure 5 Salient contours. The three circular contours pop out despite the fact that there is nothing locally salient about any part of the contour as compared to the contours that make up the background. From Ullman and Sha'ashua (1988).

rather than on the features themselves. The prime example of this configural salience is contour detection and the issue of which contours in an image are most salient. Contour detection also offers the most intensively examined paradigm for understanding the link between neural and psychophysical mechanisms.

IV. CONTOUR SALIENCE

The study of contour salience was established by the work of Shimon Ullman and his colleagues in the late 1980s. Ullman was the first to articulate the global or configural nature of contour salience. Fig. 5 from Ullman's original paper, shows an image consisting of various contours that are roughly equal in contrast, spatial frequency, and orientation. Why do the three circular contours pop out? The Gestaltists would argue that the circles are most salient because they have greater continuity (longer extents with less abrupt changes in curvature) and because they are closed. Ullman attempted to quantify this Gestalt explanation by developing a simple but rigorous model, consistent with known cortical mechanisms but also computationally efficient and analyzable, that could be tested on a variety of images to evaluate its performance relative to human psychophysics.

Ullman proposed that the salience of a contour is due to three main characteristics: overall length, degree of continuity, number and size of any gaps. He proposed a weighting function to combine these contour features into an overall salience measure.

The salience measure increases monotonically with length of contour, decreases monotonically with total squared curvature of contour, and decreases with amount of fragmentation. Salience is measured iteratively at each pixel in an image, and a salience map is constructed—an image where the intensity of each pixel corresponds to the salience score of the most salient curve emanating from that pixel. Once computation of the salience map stabilizes, the most salient contours are then picked out by tracing the contours starting from the most salient points.

As shown in Fig. 6, the contours judged most salient by the algorithm correspond, at least qualitatively, with intuitive perceptual judgment. In this case, the most salient contours in an image of an automobile are produced by the wheels, the roof, the hood, etc. The fact that one can identify the object shows that, like in a caricature, these contours contain key information about object identity. The network is capable of filling in gaps and completing curves in the presence of noise. By using this measure of salience, the network is also capable of carrying out perceptual grouping. Under attentional scrutiny, we might wish such an algorithm to provide additional contour information, for example, to allow us to recognize the make and model of the car. Ullman's algorithm ranks all contours in the image, and thus attention could determine the threshold for including additional contours in further processing.

The computational power of the Ullman salience network arises from its instantiation as a relaxation algorithm: it recasts the search for the globally most salient contour into an optimization problem over local connections. The resulting algorithm is extremely efficient. Whereas the number of contours grows exponentially with image size, the time for the algorithm to find the most salient contour only grows quadratically with image size.

In a subsequent study, Tao Alter and Ronen Basri identified two critical elements of the Ullman algorithm that underlie its efficiency: (1) extensibility—the property that the most salient curve of length N contains, as subcurves, the most salient curves of lengths $N-i$ (where $N>i>0$) pixels, and (2) geometric convergence—the choice of exponential fall-off in the effects of distant portions of the curve, which limits the range of interactions particularly on closed curves.

However, Alter and Basri found that these two properties that underlie the efficiency of the algorithm also give rise to certain shortcomings. For example, the salience measure is not completely scale-invariant. For short contours, the algorithm ranks straight lines as more salient than circles, whereas for long contours circles are ranked more salient. This is because, according to the algorithm, the salience of a line grows linearly with length, whereas the salience of a circle grows quadratically with the length of its perimeter. Thus, there is a trade-off for contours above a certain size. A second problem uncovered by Alter and Basri is that the algorithm occasionally ranks a particular contour segment as the most salient, even if it does not lie on what the algorithm ranks as the most salient contour. For example, if the end of a straight line touches a circle such that the line is tangent to the circle, the line will be ranked as more salient than the circle, even if the line is quite short and on its own would be ranked far less salient. This is because there is no mechanism for segmenting contours into separate objects; thus, osculating contours (those that intersect and whose tangents agree at that point) can appropriate salience from the other curve.

Alter and Basri also point out difficulties that arise with gaps in the contour and with discretization errors. For example, the algorithm ranks a circle with one large gap as more salient than a similar circle with several smaller gaps (where the total gap size is the

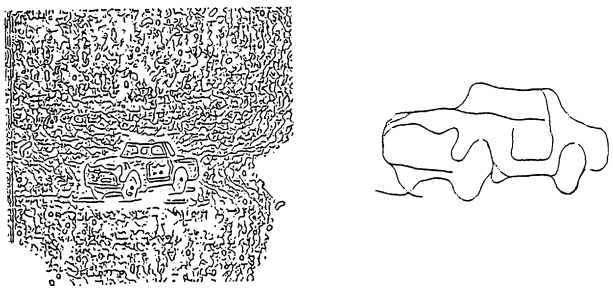

Figure 6 Result of the saliency algorithm. The figure on the left shows the input image to Ullman's saliency network. The figure on the right shows the most salient contours traced out from the points on the saliency map that have the highest values. From Ullman and Sha'ashua (1988).

same in both cases). Psychophysical studies indicate that humans perceive the opposite ranking to hold. Finally, in some cases simple aliasing in a contour, due to sampling on a x–y grid can cause an aliased straight line to be ranked less salient than an actual corner of a polyhedron.

These technical shortfalls in the algorithm arise from the simplifications adopted for computational efficiency. They do not detract from the central point that a network based on local interactions can account for global contextual effects. However, by illuminating the detailed and idiosyncratic nature of human perceptual salience, these studies suggest that the cortex employs additional mechanisms.

Can the statistical outlier idea be used to improve things? In the spirit of Ullman's approach, we might characterize a contour in terms of several dimensions: length, gap size, total curvature, etc. The target contour can be compared to all possible distractor contours in the image or, more efficiently, to the distribution predicted from knowledge of how the distractors are generated (e.g., random orientations). One would then expect that the Mahalanobis distance between a target contour and the overall distribution would correlate with the perceptual salience of the contour.

There are several impediments to developing such a measure for contour salience. Gestalt psychology provides hints as to the dimensions along which contour salience should be evaluated, but the exact measures are not known. Ullman's choices (length, curvature, etc.) are reasonable and correlate to an impressive degree with perceptual judgments. However, as Alter and Basri have shown, the correspondence is not perfect. In addition, because the dimensions are diverse in nature, e.g., length versus deviation from constant curvature, they must be normalized in order to generate a covariance matrix Σ. Finally, and most critically, the contours in such images must be actively generated by the subject through a process of perceptual grouping. Unlike the moving dots of Rosenholtz's motion stimuli, here both the target and the distractors must first be generated before their salience can be evaluated. Yet, at the same time, the salience of the contour appears to affect the grouping process.

The path out of this paradox is not totally clear, but significant insight is available by examining what is known of the psychophysics and underlying neurophysiology relating to contour detection. The quest of all of these analyses, theoretical and experimental, after all is to understand the *neural mechanisms* that mediate perceptual salience. The goal is to appreciate how the cortical machinery could carry out a process akin to distinguishing statistical distributions.

A. Psychophysical Studies of Contour Salience

Because the salience of a target depends upon context, psychophysical studies of salience have employed stimuli in which the structure of the background elements can be carefully controlled. In 1993, David Field, Anthony Hayes, and Robert Hess introduced a stimulus in which a contour is formed by a number of discontinuous, oriented elements (Gabor functions) embedded in a field of randomly oriented elements (see Fig. 8). A two-alternative, forced-choice procedure was used in which one stimulus contained a contour embedded in the random background, whereas the other stimulus contained only randomly oriented elements. Detection threshold was set at 75% accuracy for choosing which image contained the contour (presentation order was randomized). Field and colleagues found that contour salience, as measured by the detection threshold, depends on the relative position and orientation of the contour elements (all elements had the same, relatively high, contrast). The effect was scale-invariant, i.e., when the separation between all of the elements was reduced, the dependency on relative position and orientation remained unchanged.

Because each Gabor function optimally stimulates a local set of orientation columns in cortex, Field and colleagues argued that their results reflect the wiring of an underlying cortical "association field." Each cell must receive long-distance cortical connections from other cells tuned to a specific range of orientations depending upon the relative positions of the two cells. The shape of the association field closely resembles cortical connection patterns proposed in earlier computational studies of Stephen Grossberg and colleagues (see Fig. 7). In their models of boundary completion, as occurs in illusory contours and real images, Grossberg proposed a similar, bipolar-shaped connection structure.

The Gestalt law of good continuation is vague regarding what makes a particular contour better or worse. An elegant solution was put forward in 1989 by Steven Zucker and colleagues—cocircularity. Given a contour element of orientation θ_1 at position (x_1, y_1), then the optimum orientation of a contour element at position (x_2, y_2) is determined by the unique circle

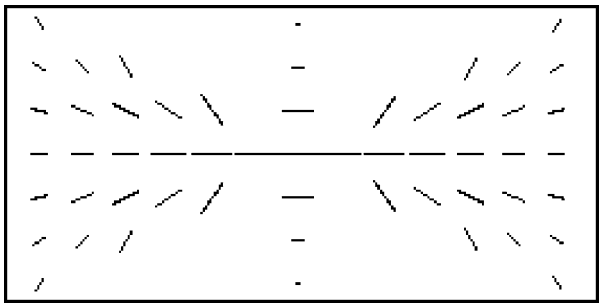

Figure 7 Presumed cortical connection pattern. Illustration of the cocircular connection pattern put forward by Zucker and colleagues. The length of the line segment indicates the strength of the connection, and the orientation of the line segment indicates the preferred orientation at each spatial location. The connection pattern is consistent with the association field suggested by Field and colleagues, as well as the bipolar connection structure proposed by Grossberg and colleagues.

passing through both points whose tangent at (x_1, y_1) has orientation θ_1 (see Fig. 7). Note that cocircularity allows the curvature to change along the course of the contour and that a straight line is cocircular (with curvature = 0). The association field conforms, at least qualitatively, to cocircularity. Moreover, cocircularity provides a metric for evaluating salience by associating a defined penalty as a function of the deviation from cocircularity.

Contour salience has also been shown to depend on the ratio of the distance between contour elements versus the distance between distractor elements. Thus, elements can be spaced over a wide range of absolute distances, and the perceptual salience remains invariant as long as the normalized distance ($d_{\text{contour}}/d_{\text{distractor}}$) remains fixed. This finding suggests the presence of a cortical normalization mechanism, akin to that controlling contrast invariance.

By using stimuli similar to those of Field and colleagues, Ilona Kovács and Bela Julesz studied another cue affecting contour salience: the Gestalt property of closure. They first established the maximum interelement spacing at which open contours and closed contours were just detectable (75% accuracy in two-interval trials). They found that the threshold spacing for closed contours was approximately twice that for open contours. Next, they plotted psychometric functions for detection accuracy versus number of elements on the contour. Starting with four elements spaced at the threshold for open contours, Δ_{Open}, and four elements spaced at the threshold for closed contours, Δ_{Closed}, additional elements were appended to both types of contours at their respective threshold separations. The surprising finding was that, whereas the psychometric curve for the open contours monotonically increased with increasing number of contour elements, the psychometric curve for the closed contours remained at chance (50% accuracy in a two-alternative choice) until the final (twelfth) element was added, at which point accuracy nonlinearly jumped to threshold (75% accuracy; see Fig. 8). Note that the "closed" contours were not closed until composed of all twelve elements, so that before the last element was added the contours were open and were effectively spaced at twice the threshold distance for open contours. Thus, it might not be too surprising that these contours were not detectable. What was unexpected, however, was the sudden jump in salience that arose with closure. We will consider possible mechanisms for this phenomenon later.

One caveat to these findings comes from more recent work by Jochen Braun. Braun has argued that the methods used to generate the Field-type stimuli introduce a small, but significant difference in the distribution of distances between elements on the contour versus the distribution of distances between distractor elements. This implies that the local context around a contour element differs from that around a distractor element, and thus their activation may differ simply on the basis of proximity cues. Braun has developed a statistical method for generating contour displays that controls contour–background element densities. By using these stimuli, Braun finds only a small effect of closure (6–14%) on contour salience. In addition, Braun suggests that the stimuli of Kovács and Julesz confound closed versus open contours with differences in eccentricity (open contours extended further) and a difference in element number. He reports a large nonlinear increase in salience as the number of contour elements increases in the range of 10–12. Thus, the change in the number of elements may have contributed to the change in salience, in addition to the difference between closed and open contours.

Braun also determined the stimulus offset asynchrony (SOA) (time between stimulus presentation and a subsequent masking stimulus) to detect stimuli with elements spaced at various distances. For very salient stimuli, the SOA was approximately 100 msec, suggesting that the visual system only needs 100 msec to detect the contour. However, as the contours became less salient and approached perceptual threshold, the SOA increased nonlinearly, with a value of 250 msec near threshold. Braun suggests that this timing

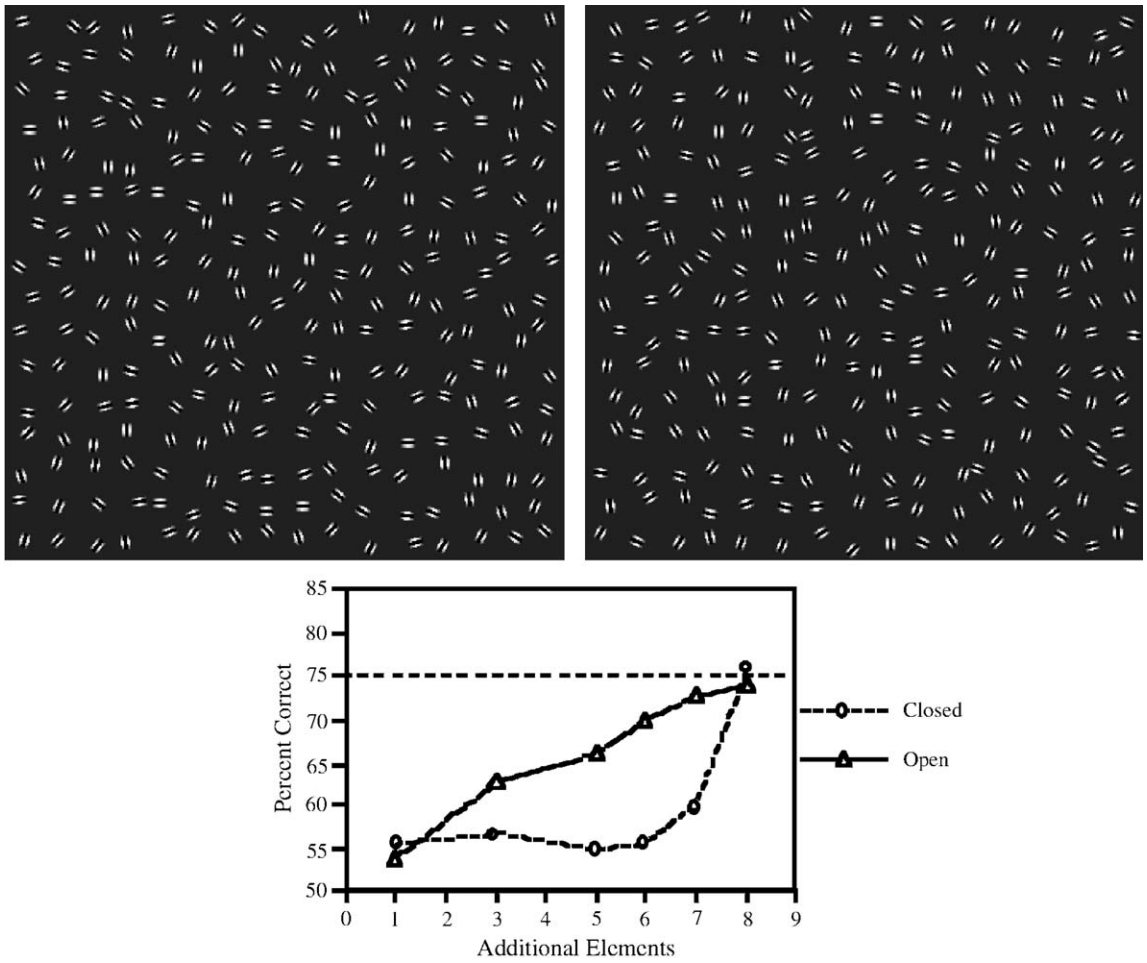

Figure 8 Psychophysical effect of closure. The figures on the top show examples of a stimulus with an open contour (left) and one with a closed contour (right), embedded in an array of randomly oriented elements. The bottom graph, adapted from Kovács and Julesz (1993), shows the performance of subjects as a function of the number of elements on the contour. The points plotted with triangles show that the salience of the contour with elements spaced at Δ_{Open} increased monotonically with each additional element. The points plotted with circles show that the salience of the contour with elements spaced at Δ_{Closed} did not increase with each additional element until the last element was added and the contour was closed.

information places a constraint on computational models of salience. He makes the argument that, if information must be transmitted sequentially between neurons responding to the elements, then in order for the elements at the ends of an eight-element open contour to transmit information to each other, 250 msec represents approximately 30 msec per iteration. Perhaps not coincidentally, cells spiking with this interspike interval would produce strong energy in the γ frequency range (roughly 30–80 Hz). We will return to the possible significance of this frequency range later.

B. Anatomical and Physiological Basis of Salience

These observations bear on the most important question: What is the neural representation of salience? Most attempts to answer this question have targeted the first visual cortical area, also known as primary visual cortex, where segmentation and grouping are also hypothesized to take place. Two aspects of this question have been addressed: How do neurons representing different parts of visual space interact with each other? What is the form of this interaction?

These two aspects are analogous to the physical wiring used to connect telecommunication devices and the transmission code (e.g., Morse code, digital encoding) used to relay the information over those wires.

The neurons in the primary visual cortex are organized topographically, with each neuron representing a part of visual space. Integration of a set of discontinuous oriented elements into a contour requires communication between spatially segregated sets of cortical cells. Charles Gilbert has proposed that this communication may be mediated, in part, by horizontal connections between pyramidal cells in superficial layers of primary visual cortex. These long-distance connections can travel several millimeters in cortex, corresponding to receptive field locations up to 6° apart (1° of visual space is approximately equivalent to the area spanned by the thumbnail when held at arm's length). Work by David Fitzpatrick and colleagues has shown that these connections are spatially organized, connecting cells whose receptive fields and orientation preferences are collinear. These connections are remarkably reminiscent of the Gestalt law of good continuation, the cocircular connectivity rule, as well as the association field, and these cortical connections may well underlie many of the feature relationships that are perceptually salient.[2]

The function of these connections has also been studied by the Gilbert group. By recording from awake monkeys, Gilbert and colleagues examined the response of cells in the superficial layers to sets of oriented bars placed in various configurations inside and outside the receptive field and compared the neuronal firing rates to perceptual responses. In agreement with their own psychophysical studies, as well as those of Field and colleagues, they found that cell responses diminish as the alignment of the oriented bars deviates from collinearity or cocircularity and also with increases in separation between the bars. The interaction between cells can be facilitatory or suppressive, depending upon the cells' relative positions and orientations.

Gilbert, together with Mitesh Kapadia and Gerald Westheimer, has also mapped the spatial structure of the facilitatory/suppressive regions using an ingenious technique based on the tilt illusion. The tilt illusion refers to an illusory perceptual tilt of a vertically oriented bar placed between two flanking bars oriented at a different orientation. The vertical target appears to tilt either toward (attractive) or away from (repulsive) the flanking bars. Attractive or repulsive tilts are observed as the flankers are placed at different spatial locations and orientations with respect to the target. Gilbert and colleagues found a beautiful correspondence between the direction of the tilt illusion and the presence of facilitation and suppression, effectively demonstrating the basis of the tilt illusion. Figure 9 shows the spatial structure of these facilitatory and inhibitory sites as derived from physiological recordings in the primary cortex of alert monkeys. Again, the agreement with the cocircular connection pattern is remarkable.

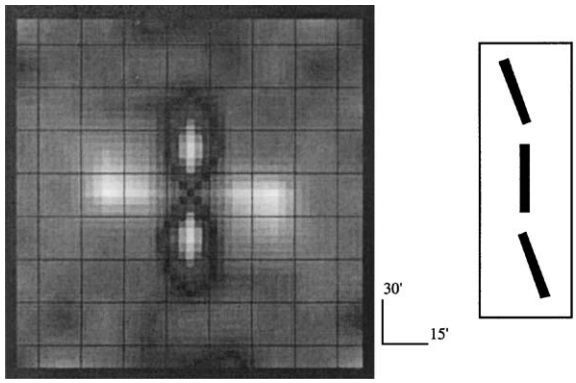

Figure 9 Map of contextual effects surrounding a neuron in primary visual cortex. The two vertical blobs in the middle indicate positions around the neuron where the introduction of a bar produced facilitation, whereas the regions in white surrounding the two vertical blobs indicate positions around the neuron where the introduction of a bar produced suppression. The scale bar indicates that the vertical grid points are separated by 30′ (0.5′), whereas the horizontal grid points are separated by 15′. The inset shows an example of a tilt illusion stimulus used in the studies. From Kapadia *et al.* (2000). Reprinted with permission from The American Physiological Society.

The studies described earlier suggest that primary visual cortical neurons show elevated firing rates when they are stimulated with aligned stimuli, but it is not clear whether this elevated firing rate is used to represent salience. The firing rate of a neuron is well-correlated with a number of different stimulus parameters, including the contrast, orientation, and spatial frequency of the stimulus. How would a neuron receiving input from these primary visual cortical neurons distinguish between elevated firing rates that

[2]It should be noted that extensive horizontal connections are also found in infragranular layers and in many extrastriate visual areas, as well as in higher cortical areas including prefrontal cortex. In fact, loss of horizontal connections in layer III is a common finding in the prefrontal cortex of schizophrenic brains, suggesting perhaps a more general role for such connectivity in cortical integration.

represent higher salience and elevated firing rates that represent, for instance, contrast? It has been shown that the performance of subjects in a contour detection task is not affected when the Gabor elements that make up the contour as well as those that are distractors have different contrasts. In this case, there would be neurons stimulated by high-contrast distractors that have higher firing rates than some of the neurons stimulated by elements on the contour. The salience representation would be confused in this situation.

One alternative is that, because contrast, orientation, and spatial frequency are represented using population codes, it might be possible to represent salience using a subpopulation of cells without perturbing the other representations. Another possibility that has been suggested is that the initial phase of the response of a neuron (less than 80 msec after the stimulus is presented to the retina) could represent local stimulus parameters like contrast, orientation, and spatial frequency, whereas the delayed response phase (80–150 msec) could represent global stimulus properties like salience. In fact, a number of research groups have shown that elevations in the firing rate during the delayed response phase appear to be correlated to global properties such as figure–ground segmentation and contour tracing. These effects have mostly been attributed to feedback from higher cortical areas, but it is certainly plausible that the horizontal connections might provide a similar effect. However, the effect is relatively small, and it is not clear that the cells could encode different levels of salience within such a small range in firing rates.

Separate evidence suggests that salience may be encoded in a different dimension of the neural response. Since the late 1970s, a number of groups have postulated that the timing of a neuron's response might be used to represent global properties. The idea was first postulated to be a solution to the puzzle that, although brain areas are highly specialized with different cortical areas responding to color, motion, shape, and location, our percept is perfectly unified. In addition, we have little difficulty paying attention to several objects with different properties. That meant that neurons in different areas of the brain not only have to be able to signify that they belong together as an object but they also have to be able to signify that they are distinct from the neurons representing other objects. This puzzle has often been referred to as the binding problem. The proposed solution postulated that, if groups of neurons representing the same object fired together, or in synchrony, and were distinct, or desynchronized, from other groups of neurons representing other objects, that would allow the brain to keep track of multiple objects with multiple stimulus properties. There has since been a large body of experimental evidence in many different brain areas and in many different animal species that supports this hypothesis, although it remains hotly debated in neuroscience. Interestingly, most of the experimental evidence has been correlated with increased energy in the γ frequency range.

A similar idea has been proposed to account for the representation of salience. For instance, we have proposed that the salience of a contour is represented by the degree of synchrony among the responding neurons. Our modeling studies have shown an interesting parallel between changes in synchrony and the changes in salience observed in a number of psychophysical studies. Of special interest is the ability of the models to account for the difference in the changes in salience between open and closed contours described earlier.

We modeled the neurons that were stimulated by Gabor elements as oscillators that were coupled in the cocircular connection pattern shown in Fig. 7 via the horizontal connections found in the superficial layers of primary visual cortex. (Cells exhibiting oscillatory or periodic firing have been observed in a number of physiological experiments and are thought to be closely linked to synchrony.) In our model, salience was measured using the amount of synchronized activity. It has been shown, both in simulation and analytically, that, whereas a chain of strongly coupled oscillators will reliably synchronize, a chain of weakly coupled oscillators will not approach synchrony. However, if the ends of the same chain are coupled together, the oscillators will reliably synchronize. Weak and strong coupling corresponds to connections only between nearest neighbors or connections between next nearest neighbors as well.

Our simulation results led us to propose the following account of the closure effect (also shown in Fig. 10): when the contour elements were separated by Δ_{Open}, the horizontal connections were strong enough to cause the neurons stimulated by the contour elements to synchronize. As a result, each additional element adds to the synchronized activity and, thus, the salience of the contour. When the contour elements were separated at Δ_{Closed}, the reduced strength of the horizontal connections was no longer effective in synchronizing the neurons stimulated by the contour, and as such there was no increase in synchronized

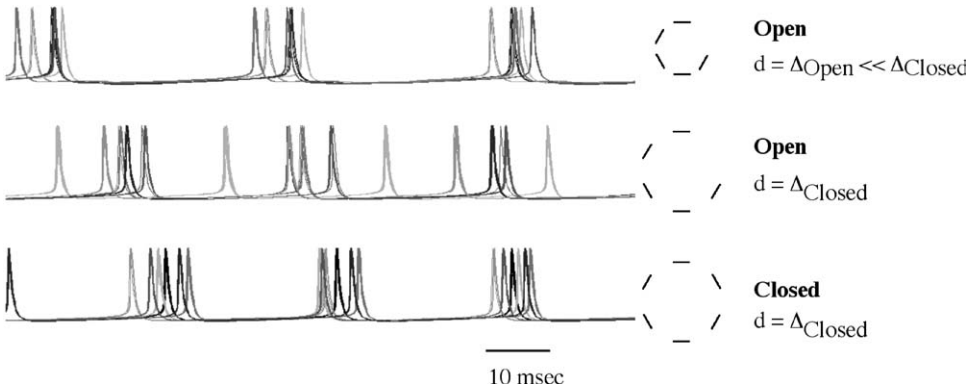

Figure 10 Simulation results illustrating the closure experiment. The different gray level traces represent the membrane potentials of groups of pyramidal cells in an orientation column stimulated by the different Gabor elements that make up the contour. Neighboring groups are connected via horizontal connections, and these connections decrease in strength as the separation, *d*, between the elements increases. The set of traces plotted at the top illustrates that, at the separation Δ_{Open}, the cells are synchronized, as they fire within 10 msec of each other. As a result, each additional element adds to the synchronized activity of the population and, thus, to the salience of the contour. The traces plotted in the middle show that, at the separation Δ_{Closed}, the cells are not synchronized, and as such each additional element does not add to the amount of synchronized activity. However, when the last element is added, which changes the contour from an open contour to a closed contour, the traces at the bottom show that the cells are again synchronized. This then leads to an increase in the synchronized activity and, thus, the salience of the contour.

activity with each additional element. However, when the last element was added, the topology of the connections between the neurons changed from an open chain to a closed chain, and this allowed the neurons to synchronize and, thus, led to an increase in the salience of the contour.

The use of synchrony to represent salient contours provides a way for contours in close proximity to be represented distinctly from one another. It also avoids the problem of confusing representations of salience with other feature dimensions. However, although we have been able to reproduce this effect using a wide variety of oscillator models, the time needed for synchrony to emerge in the models is substantially higher than the 100- to 250-msec time window estimated from the psychophysical studies discussed earlier. This suggests that, if the brain uses synchronized oscillations to represent salience, the oscillations may be of a very different nature from the oscillators that we have used in our models.

Although there is indirect evidence for the different hypotheses, the question of how the brain represents salience is still very much an open question. There are a number of plausible hypotheses, but the definitive experiments have yet to be done. The results of these experiments not only will provide insights into the representation of salience in the brain but also will shed light on an even more fundamental issue, the form of the codes used by the brain to process and transmit information.

V. THE ONTOGENY OF SALIENCE

Evolutionary biologists distinguish between proximate and ultimate causation of phenotypic properties. The properties of salience thus must have both proximal (physiological) and ultimate (evolutionary) components. Cortical interactions provide the proximal mechanisms underlying salience, but what determines the ultimate cause?

One idea proposed in the literature is that Gestalt properties such as continuity and cocircularity abound in natural images, and particularly in the types of objects of adaptive interest. Charles Gilbert and colleagues analyzed the statistics of a set of natural images (pictures of farmland, woods, etc.) and determined the probabilities of contour elements lying at various relative orientations as a function of their relative position in the images. They found that cocircularity was the most probable relationship, and there was a high degree of cocircular contours in the images analyzed. In a related study, William Geisler and colleagues identified all contours in a set of natural images and found that the statistically most likely relations between contour elements were described well by an association-field-like structure. Thus, collinear and cocircular arrangements are most common.

These and similar studies suggest that the visual system has evolved to detect and amplify the presence of continuous contours in the environment, perhaps

because of their association with the boundaries of objects of interest. Salience emerges from the resonance of naturally occurring continuity with the cortical mechanisms evolved based on these stimuli. In addition to the sun and the moon, biological organisms tend to be distinguished by continuous contours.

An additional consideration, however, arises from the active nature of vision. Babies have an intrinsic fascination with high-contrast salient edges—shadows, corners, etc. Most parents have had the experience of watching an infant focus back and forth along a shadow edge on the wall or stare, somewhat disturbingly, at the edge of one's face. Perhaps certain innate preferences are built into the nervous system for high-contrast edges. High contrast induces higher signal-to-noise ratios in the firing rates across a cortical region, and the system may try to maximize this type of stimulation through eye and head movements. What may be relevant then is not the statistics of natural images *on their own*, but rather the statistics of foveated regions of these images. Hebbian mechanisms underlying connection formation might also be sensitive to neuromodulatory inputs that reflect the innate degree of arousal by images, so that a high-contrast edge or a mother's face may induce more plasticity. In addition, moving stimuli evoke more activity than static images and the statistics of spatiotemporal imagery show higher degrees of continuity, so that these properties might also have an influence on the development of cortical connections.

Eye movements might induce much greater coactivation of collinearly or cocircularly arrayed cells than static stimuli, and the series of fixations might activate cells in a temporal pattern as required for synaptic plasticity. Thus, an innate preference for one type of salience, high-contrast edges or smooth motion, might drive cortical development, and the resulting network connectivity might then respond to other types of salient stimuli. In amblyopia, where the retinal images are discordant, cortical connectivity develops in a disorganized manner, and subjects display higher thresholds for detecting salient contours. The ability to influence the spatial and temporal pattern of stimulation, through active vision, may continue through life and may underlie our aesthetic appreciation for certain images over others.

VI. CONCLUSIONS

An object appears salient based on its features relative to those in the surroundings. As the Gestalt psychologists discovered, certain features and configurations of features are naturally more salient, and more recent work indicates that these correspond to intrinsic selectivities and connectivities in visual cortex, respectively. It is possible to quantify the salience of a target using psychophysical paradigms, and salience should correspond to the degree to which the target is a statistical outlier from the distractor distribution.

Despite these conclusions, the neural representation of salience remains an open question. A link between salience and synchronization would be theoretically satisfying, but the definitive experiments have yet to be done. The rapidity of perception, however, does put a possibly unattainable time constraint on any synchronization process.

We have concentrated on perceptual salience in the context of striate visual cortex; however, it is clear that many brain regions play a role in controlling salience. One of the primary effects of a lesion in extrastriate visual area V4, for example, is an inability to notice less salient objects in the presence of more salient objects. The hippocampus also has been proposed to restructure the representation of neocortical information to reflect its salience to the animal. Sustained activity in prefrontal cortex in delay-period working memory tasks has been shown to be robust against distractor inputs, and thus attractor-type behavior in prefrontal circuits maintains goal-directed behavior in the face of less salient competing drives. It appears that many, if not all, higher brain areas face similar problems of integrating bottom-up, top-down, and horizontal inputs and of regulating which among many competing parallel processes should receive priority. Many of these brain regions make use of similar anatomical architectures, including specific long-distance connections. Salience may be the perceptual manifestation of this process of integration and gating.

Schizophrenia

LISA T. EYLER ZORRILLA and DILIP V. JESTE
University of California, San Diego and VA San Diego Healthcare System

GLOSSARY

atypical antipsychotics A newer class of antipsychotic medications available since 1988 that act at both 5-HT_2 and D_2 receptors and carry a lower risk of motor side effects, e.g., clozapine.

conventional, or typical, antipsychotics A class of antipsychotic medications available since 1952 with a high affinity for D_2 dopamine receptors that carry a high risk for either motor side effects (with high-potency agents such as haloperidol) or sedation and anticholinergic side effects (with low-potency agents such as chlorpromazine).

dementia praecox Kraepelin's term for a psychotic disorder, eventually known as schizophrenia, characterized by progressive functional decline beginning in adolescence or early adulthood.

diathesis–stress model An etiologic theory in which environmental events interact with an underlying vulnerability (usually genetic) to produce a disorder.

executive functions Cognitive functions involving higher order processing such as abstraction, planning, problem solving, and initiation.

hypofrontality A state characterized by less blood flow or metabolism in the frontal lobes relative to posterior brain regions or a state of lower activity in the frontal cortex relative to healthy individuals.

negative symptoms Symptoms, including poverty of emotions, speech, and intention relative to healthy individuals, seen in patients with schizophrenia.

neurodegenerative disorder A disorder characterized by progressive deterioration of brain systems from a healthy baseline state, often marked by the presence of gliosis.

neurodevelopmental disorder A disorder caused by abnormal development of specific neural structures.

paranoid A common subtype of schizophrenia characterized by delusions, especially of persecution, a preponderance of auditory hallucinations, and few negative or disorganized symptoms.

positive symptoms Symptoms present in patients with schizophrenia and absent from healthy individuals, including delusions, hallucinations, and disorganized thought and behavior.

tardive dyskinesia A disorder characterized by abnormal, involuntary hyperkinetic movements that can develop in patients on long-term neuroleptic treatment.

Schizophrenia is a psychopathological disorder characterized by symptoms of delusions, hallucinations, disorganized thought and behavior, and poverty of emotion, speech, and intention. Features associated with the disorder include abnormalities of neurotransmitter systems, brain structure, neurophysiology, and cognition. Although the etiology of the disorder is not yet understood, genetic and perinatal predisposition appears to play a critical role. Treatment for the disorder involves pharmacological and psychosocial interventions.

I. INTRODUCTION

A. History

Schizophrenia is likely an ancient disorder. Despite many obstacles to identifying the disorder in historical records (e.g., lack of detailed descriptions and clear terminology, a tendency to ignore psychiatric diseases or consider them in the domain of religion), early accounts seem to contain descriptions of schizophrenia-like disorders. It was not until the nineteenth century, however, that schizophrenia as we know it

today was first defined. French physician Benedict Morel described *demence precose* in 1857, and Emil Kraepelin later formalized the diagnosis of *dementia praecox*, which was characterized by a progressive downward course with symptoms such as hallucinations, delusions, thought disorder, catatonia, blunted affect, and lack of insight. The term "schizophrenia" was coined in 1911 by Bleuler, who brought psychological theory to bear on the disorder and also broadened the concept to include thought-disordered individuals with progressive decline in functioning without evidence of delusions and hallucinations. Until the 1960s, there was a great deal of confusion regarding the diagnosis of schizophrenia due to conflicts between these two conceptualizations and evidence that some individuals with characteristic symptoms did not decline progressively. Eventually, awareness of substantial differences in rates of diagnosis of schizophrenia between the United States and other countries stimulated efforts to operationalize the criteria for the disorder. This led to development of many diagnostic schemes, which, though more structured, still differed considerably from one another. The two most widely used classification systems today are the Diagnostic and Statistical Manual of Mental Disorders, 4th ed. (DSM-IV) and the International Classification of Diseases, 10th ed. (ICD-10).

B. Symptoms

Diagnosis of schizophrenia is based on a constellation of signs and symptoms; there is no laboratory test that can definitively indicate the presence of the disorder. The DSM-IV criteria for schizophrenia include presence of certain characteristic symptoms for longer than 6 months and evidence of impairment in social or occupational functioning. In the ICD-10, symptoms must persist for only 1 month and functional consequences are not specified. Symptoms of schizophrenia can be broadly classified into "positive" (i.e., present in patients and absent from healthy individuals) and "negative" (i.e., reflecting a deficiency of normal psychological functions in patients). Positive symptoms include hallucinations, delusions, disorganized or catatonic behavior, and some forms of thought disorder. Hallucinations are most frequently auditory and may be voices of people talking to one another or commenting on the patient's behavior. Visual, tactile, olfactory, and gustatory hallucinations can be present but are less common. Delusions include paranoid ideation (i.e., the belief that others intend to harm the patient), delusions of reference (i.e., the belief that others are talking about the patient or that the television is communicating directly with the patient), somatic or grandiose delusions, and delusions of mind control, thought insertion or withdrawal, or thought broadcasting. Disorganized behavior includes silliness and unpredictability and may be reflected in disheveled or inappropriate dress and poor hygiene. Catatonia, including stupor, rigidity, negativism, posturing, and excitement, may also be observed but is much less common now than historically. Thought disorder is a disruption of the form of thought that is primarily evident in speech characterized by loosening of associations, disorganization, wandering or off-topic discourse, and use of idiosyncratic terms (i.e., neologisms). Although traditionally grouped with the positive symptoms, factor analytic studies of schizophrenic symptoms have often found that disorganized thought and behavior load on a separate factor from hallucinations and delusions. Negative symptoms form yet a third cluster, including flat affect, poverty of speech (i.e., alogia), and lack of will (i.e., avolition), and they are significant contributors to deficits in everyday functioning. Finally, although not part of most classification systems, cognitive deficits are now generally accepted to be characteristic symptoms that also seem to have a large impact on a patient's daily life.

Symptoms similar to those seen in schizophrenia are present in many other disorders. In schizoaffective disorder, symptoms of an affective disorder are present at the same time as active-phase psychotic symptoms and the mood component is substantial in duration, but hallucinations and delusions also must be present for at least 2 weeks in the absence of mood symptoms. Psychotic symptoms also can be found in primary mood disorders, brief psychotic disorder, delusional disorder, and substance abuse and dependence. There is considerable debate about the degree of overlap in the etiology of these potentially related disorders.

C. Subtypes

In response to the heterogeneity of symptoms, treatment response, and functional outcome in schizophrenia, a number of subclassifications of the disorder have been proposed. Subtypes based on symptom profiles include predominantly positive vs predominantly negative, as well as subtypes specified by the DSM-IV and ICD-10, some of which date back to Kraepelin and Bleuler's original formulations. These include

simple, hebephrenic, catatonic, paranoid, disorganized, undifferentiated, and residual. The symptom profiles associated with each of these subtypes are listed in Table I. Accumulating evidence suggests that symptom subtypes generally are not stable throughout the course of illness, thus reducing their usefulness for determining prognosis or etiology. In response, there has been a move away from symptom categorization toward a dimensional approach in more recent years. In addition, subtyping schemes that rely on distinctions regarding age of onset (e.g., early onset vs typical onset vs late onset), course [e.g., Kraepelinian (progressive) vs non-Kraepelinian (stable); reactive vs endogenous], or presence vs absence of associated features (e.g., family history positive vs negative; with or without cerebral ventricular enlargment) have become more prominent.

D. Onset, Course, and Prevalence

The typical age at onset of schizophrenia is in late adolescence or the early 20s for males, with a somewhat later age at onset for females. Although onset may be acute, often development of the disorder is preceded by a prodromal phase of illness that includes gradual development of symptoms such as social withdrawal, loss of interest in activities, deterioration in grooming, and unusual behavior. Personality disturbances including paranoid or schizotypal (e.g., unusual perceptions, thinking, and behavior) traits are common premorbidly.

Rarely, florid symptoms of schizophrenia manifest for the first time in childhood or late adulthood. Childhood-onset schizophrenia (i.e., onset before age 12) is qualitatively similar to adult-onset schizophrenia in symptoms, developmental precursors, and associated features. Prognosis, however, is generally worse, and evidence suggests that childhood-onset patients show prolonged deterioration in intellectual function and progressive ventricular enlargement. Schizophrenia can also manifest for the first time after age 45. Although precise estimates are lacking, approximately 15% of all the patients with schizophrenia may have onset after age 45. The prevalence of late-onset schizophrenia is difficult to determine due to poor sampling of older adults in epidemiologic studies and past criteria prohibiting the diagnosis of schizophrenia with onset in late adulthood. Research suggests that, whereas late-onset schizophrenia shares core features with earlier-onset schizophrenia, differences exist that raise the possibility of differing disease-modifying factors. Table II presents a comparison of features of childhood-, late-, and typical-onset schizophrenia.

There is considerable variation in the course of schizophrenia. After an initial acute stage during which the risk for suicide is quite high, a small proportion of patients suffer a declining course similar to that described by Kraepelin, a majority evidence a stable or fluctuating course, and a smaller percentage appear to remit to a clinically significant degree (Fig. 1). Several factors appear to influence prognosis and course in schizophrenia. Features associated with

Table I
Symptom Profiles Associated with Subtypes of Schizophrenia

Subtype	Symptom profile	Classification system
Catatonic	One or more of the following: stupor or mutism, excitement, posturing, negativism, rigidity, waxy flexibility, automatic imitation of sounds or gestures (i.e., echolalia, echopraxia).	DSM-IV[a] and ICD-10[b]
Disorganized	All of the following are prominent: disorganized speech, disorganized behavior, flat or inappropriate affect. Criteria for catatonic type are not met.	DSM-IV
Hebephrenic	Disturbances of affect, volition, and thought disorder are prominent. Hallucinations and delusions are not prominent. Onset between ages 15 and 25 years.	ICD-10
Paranoid	Preoccupation with one or more delusions or frequent auditory hallucinations. Disorganization, catatonia, and flat affect are not prominent.	DSM-IV and ICD-10
Residual	Absence of prominent hallucinations, delusions, disorganization, or catatonia, in the context of continuing negative symptoms or attenuated positive symptoms.	DSM-IV and ICD-10
Simple	Slowly progressive development of negative symptoms without a history of positive symptoms.	ICD-10
Undifferentiated	Symptom profile does not fit any of the other subtypes.	DSM-IV and ICD-10

[b]International Classification of Diseases, 10th ed.

Table II
Childhood- and Late-Onset Schizophrenia: Similarities with and Differences from Typical-Onset Schizophrenia

Similarities	Differences
Childhood Onset	
Symptom profile	More chronic course and poorer outcome
Deficits in attentional processing	Continued declines in intellectual functioning 2–3 years after onset
Decreased total brain volume, increased volume of lateral ventricles, decreased thalamic volume	Larger effect sizes for decreases in total brain and thalamus volume and progressive longitudinal changes
Qualitative response to antipsychotics, including posttreatment homovanillic acid levels	
Premorbid developmental delays and neurologic signs	
Eye-tracking abnormalities	
Metabolic hypofrontality in adolescents	
Late-Onset	
Degree of psychopathology	Preponderance of women
Severity of positive symptoms	Less severe negative symptoms
Family history	Mostly paranoid subtype
Qualitative response to antipsychotics	Lower daily antipsychotic doses
Early childhood maladjustment	Better early adulthood psychosocial functioning
Overall pattern of cognitive deficits	Milder impairments in learning, retrieval, and abstraction–cognitive flexibility
Disrupted quality of well-being	Less disturbance of semantic network
Degree of nonspecific structural brain abnormalities (ventricular enlargement, white matter hyperintensities)	Larger thalamus (?)
Minor physical anomalies	Unique electrophysiological findings (e.g., normal P300 amplitude, longer latency of N400 congruity effect)
Constitutional (uncorrected) sensory impairment	
Increased mortality	

poorer outcome include hebephrenic or simple subtype, early and insidious onset, delayed neuroleptic treatment, more negative symptoms, greater cognitive deficits, and poor premorbid adjustment.

The prevalence of schizophrenia is approximately 1%. Because of the morbidity associated with the disorder, however, it is the most expensive psychiatric disorder. The total economic burden of schizophrenia is estimated to be $40–60 billion, including both direct (approximately $30 billion) and indirect (approximately $20 billion) costs.

II. SCHIZOPHRENIA AND THE BRAIN

Despite a tradition of using psychological theories to explain the psychopathology of schizophrenia that began with Bleuler and Freud, most contemporary research into the etiology of the disorder has focused on the role of brain abnormalities. Deficits at all levels of analysis, from the synaptic cleft to cognitive performance, have been associated with schizophrenia. Unfortunately, none of these abnormalities has yet proven sensitive or specific enough to implicate a clear etiopathology of schizophrenia.

A. Neurotransmitter Abnormalities

1. Dopamine

One of the most researched biochemical theories of schizophrenia is the "dopamine hypothesis," which posits that the disorder results from dopamine (DA) overactivity in the brain. This theory was developed in response to evidence that the administration of DA agonists induced psychotic symptoms and research showing that neuroleptic drugs with efficacy in the treatment of schizophrenia were those that effectively

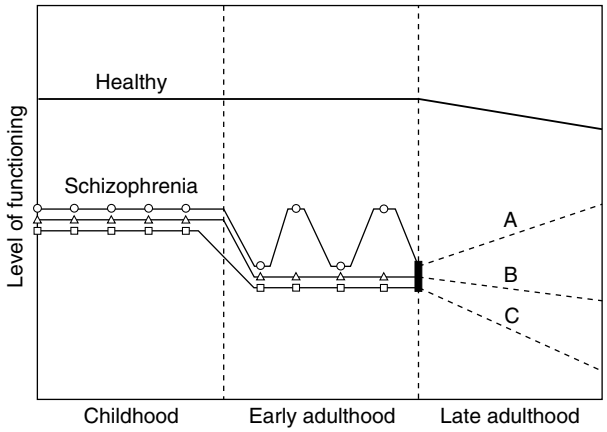

Figure 1 Possible functional courses of schizophrenia in childhood, early adulthood, and late adulthood, compared to healthy individuals. Healthy individuals (black line) show good functioning in childhood and early adulthood with mild declines in late adulthood. In childhood, patients with schizophrenia may have mild functional deficits (○, △, □) compared to healthy individuals, and some patients (□) may begin to show prodromal signs of schizophrenia. Onset of the disorder typically occurs in adolescence or early adulthood and may be acute (△, ○) or more gradual (□). Course can be stable (□, △) or fluctuating (○). In late adulthood, most patients remain relatively stable with only mild age-related declines (B), whereas a smaller proportion may show clinically significant remission (A) or continued degeneration as proposed by Kraepelin (C).

blocked DA receptors in the brain. Further work, however, failed to support an increase in DA turnover as indexed by levels of the metabolites homovanillic acid (HVA) and 3,4-dihydroxyphenylacetic acid (DOPAC), and studies of DA levels in post mortem brains were equivocal. Instead, the evidence suggests that DA overactivity may be the result of increased receptor sensitivity, as post mortem studies have consistently demonstrated increased numbers of and binding to D_2 receptors in the brains of patients. Unfortunately, interpretation of post mortem studies is complicated by the long history of neuroleptic exposure in most patients. Whereas neuroimaging using radioactive DA receptor ligands holds great promise for overcoming this difficulty, the results so far have been conflicting. Some studies of neuroleptic-naive patients have shown the up-regulation of receptors, whereas others do not find differences. The myriad receptor subtypes for DA further complicates the investigation of the role of this neurotransmitter. In addition, studies have suggested that positive symptoms may be related to hyperdopaminergia, whereas negative symptoms are related to hypodopaminergia in different areas of the brain. Clearly, more research is needed to specify the details of the dopamine hypothesis and to explore the usefulness of this theory for understanding the neurochemistry of schizophrenia.

2. Serotonin

Partly in response to the shortcomings of the dopamine hypothesis, studies have revived an interest in the role of serotonin (5-HT) in schizophrenia that began with the observation of the hallucinogenic properties of structurally similar lysergic acid diethylamide (LSD). Alterations in 5-HT receptors have been found in limbic and prefrontal cortices, and atypical antipsychotics with an affinity for 5-HT_2 receptors have been reported to improve negative symptoms of schizophrenia. Work has emphasized the importance of interactions between 5-HT and DA, because studies of 5-HT metabolite levels have been equivocal and selective 5-HT_2 antagonists do not ameliorate positive symptoms.

3. Glutamate

The excitatory amino acid glutamate, which is the primary transmitter of pyramidal neurons, may also play a role in the neurochemistry of schizophrenia. Although direct examination of glutamate levels has yielded conflicting results, studies of the *N*-methyl-D-aspartate (NMDA) receptor have proved more fruitful. Generally, it has been shown that NMDA receptor levels and binding are reduced in medial temporal lobe structures and increased in orbital frontal cortex. These findings are consistent with etiologic theories of early developmental insults to the medial temporal lobe and failure of proper neuronal pruning in the frontal lobe. Also, early lesions of glutamate receptors in rats produce behavioral changes only after puberty, which models the usual onset of schizophrenia. Finally, glutamate and DA interactions in the striatum, with subsequent influence on the activity of the thalamus, have been proposed to underlie the defective sensory filtering seen in patients with the disorder.

4. Others

Investigations of the role of other neurochemicals, such as norepinephrine (NE), monoamine oxidase (MAO), γ-aminobutyric acid (GABA), and acetylcholine (ACh), have provided mixed results. Early studies that demonstrated a reduction in dopamine-β-hydroxylase, a marker for NE neurons, have not been replicated. Similarly, some studies have found

alterations in the distribution of NE receptor subtypes in limbic regions, whereas others failed to show a difference between patients and controls. Platelet levels of MAO, which inactivates DA, NE, and 5-HT in the brain, have been proposed to mark genetic vulnerability to schizophrenia because reduced activity was found in discordant twins. Other studies have not supported an MAO abnormality, however, and research has suggested that MAO levels are influenced by neuroleptic exposure. In addition, cigarette smoking, which is widespread among patients with schizophrenia, has been found to reduce MAO levels, which may also account for the apparent heritability of this putative marker. Finally, MAO activity in brain tissue has been shown not to be deficient. The interactions between GABA and DA in the striatum and limbic system led to an interest in this inhibitory amino acid. Studies of glutamate decarboxylase, a marker of GABA activity, have not found abnormalities in patients with schizophrenia, however. Results of receptor-binding studies have been equivocal as well, and GABA agonists do not appear to have any therapeutic efficacy. Finally, a possible role for ACh deficiency in schizophrenia has been examined. ACh agonists do not seem to have efficacy in the treatment of positive and negative symptoms, and investigations of brain receptor levels have yielded conflicting results. An association between cigarette smoking and schizophrenia, however, suggests a possible role for nicotinic ACh receptors. Ongoing work is centered on the importance of ACh in the cognitive deficits of schizophrenia.

B. Structural Abnormalities

1. Macroscopic

Studies of the volume of brain structures using post mortem samples as well as *in vivo* neuroimaging techniques have found differences between patients and controls in both generalized and specific features. The most consistent finding has been that patients with schizophrenia show lateral and third ventricle enlargement (Fig. 2), although the magnitude of these changes is small and there is considerable overlap between the patient and control distributions. In addition, schizophrenia has been associated with overall loss of cortical gray matter, decreased volume of the temporal lobe, especially in medial temporal structures, and more modest decrements in frontal lobe volume. In addition to these alterations, growing evidence suggests that normal brain asymmetries are disrupted in schizophrenia, with somewhat greater pathology on the left side. Volumetric abnormalities do not appear to be restricted to one subgroup of patients, and they are present in first-episode, unmedicated patients. In addition, individuals at high risk for developing schizophrenia (e.g., children of patients with schizophrenia) show similar structural brain abnormalities. The course of macroscopic abnormalities in patients is controversial: for some, values remain stable over time, whereas others show a deteriorating course.

2. Microscopic

A great deal of neuropathological research in schizophrenia has addressed the question of whether there is evidence of gliosis in the brains of patients. The weight of the evidence suggests that there is no significant gliosis, thus lending support to a neurodevelopmental, rather than neurodegenerative, etiopathology of schizophrenia. Studies also have examined the incidence of Alzheimer's-like pathology and found that, even among elderly schizophrenia patients with severe dementia, no such pathology is evident. Further support for a neurodevelopmental view of schizophrenia comes from cytoarchitectural studies. Decreased neuronal size in the hippocampus and frontal lobes has been found, although neuronal density studies have been equivocal. Synaptic density, as reflected by synaptic protein levels, is reduced in the hippocampus, frontal and cingulate cortex, and thalamus of patients with schizophrenia. Despite continuing controversy and some failures to replicate, the literature also supports some degree of abnormality of the structure of the entorhinal cortex, disarray of hippocampal pyramidal neurons, and deeper distribution of subplate neurons in the white matter of the frontal and temporal cortices. Finally, magnetic resonance spectroscopy (MRS) studies have demonstrated abnormalities in cell membrane phospholipids in the frontal lobes and decreases in *N*-acetylaspartate, a putative marker of neurons, in the temporal lobe.

C. Neurophysiological Abnormalities

1. Metabolism and Blood Flow

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) have been used extensively to study differences between patients with schizophrenia and healthy

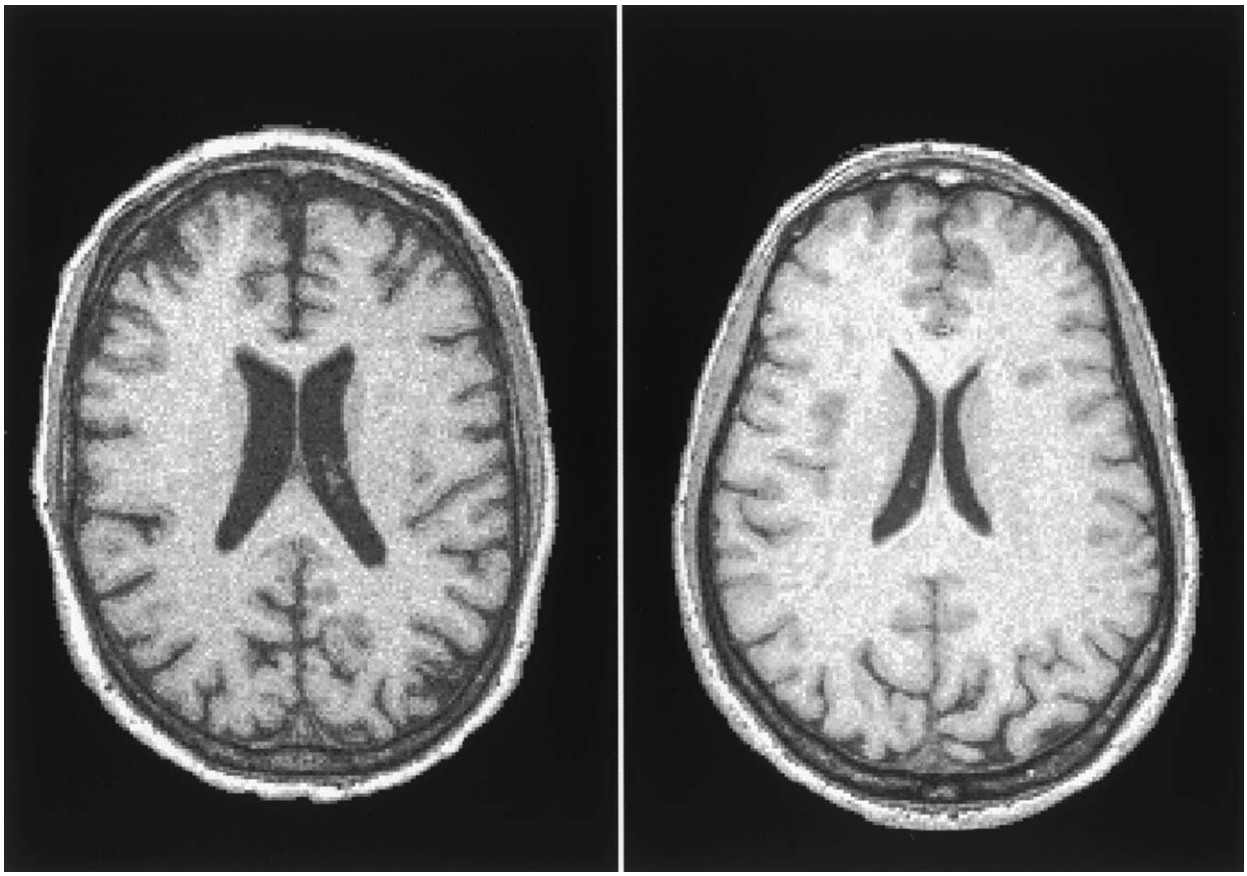

Figure 2 Magnetic resonance images of the brain at the level of the lateral ventricles in a patient with schizophrenia (left) and a healthy comparison subject. Both subjects were 57 years old at the time of the scan. Notice the greater size of the ventricles as well as more prominent sulci in the patient's image.

individuals in both brain metabolism and regional cerebral blood flow (rCBF). Resting metabolism, as measured by the uptake of radioactively labeled fluorodeoxyglucose (FDG), has been found to be lower in the frontal lobes than in the occipital lobes in many studies. This contrasts with healthy individuals, who generally demonstrate higher frontal metabolism at rest. The term "hypofrontality" has been used to describe both the frontal–occipital imbalance seen in patients and the relative deficiency compared to healthy individuals in frontal activity. Hypofrontality has also been observed in many, but not all, studies of rCBF during rest, and the degree of abnormality appears to be related to the severity of negative symptoms. Metabolic reductions in the striatum of unmedicated patients have been demonstrated repeatedly, and left greater than right temporal lobe metabolism in the context of overall lower temporal metabolism is a common finding. More recent studies using PET, SPECT, or the newer functional magnetic resonance imaging (fMRI) have tended to examine rCBF of patients during cognitive tasks. Although complicated by performance differences between patients and controls, possible effects of structural abnormalities, and the impact of neuroleptic medication, these functional neuroimaging studies have consistently demonstrated reduced blood flow to frontal regions during cognitive challenge. Abnormalities of blood flow and metabolism appear to be stable, but the few published twin studies suggest that they are state rather than trait deficits. Because hypofrontality has been observed consistently in affective disorders as well, the specificity of blood flow and metabolism deficits for understanding the etiopathology of schizophrenia remains to be seen.

2. Electrophysiology

Another approach to understanding the role of the brain in schizophrenia has been to study evoked

response potentials (ERPs) measured on the scalp using an electroencephalograph (EEG). By far, most research has focused on the positive-going electrical impulse that occurs in healthy individuals approximately 300 msec following an unusual target stimulus. The P300 (or P3) component is reduced in amplitude in patients with schizophrenia, even those who have never been medicated, and the reduction is often greatest over the left temporal lobe. Whereas P300 abnormalities are found in other psychopathological conditions, the lateralized findings appear to be more specific to schizophrenia. Evidence from depth recordings, lesion studies, fMRI investigations, and new methods of determining ERP localization has pointed to the superior temporal gyrus and inferior parietal lobe as primary sources of the P300 component. Other ERP research has focused on the P50 response. Patients with schizophrenia fail to show a suppression of the P50 response that occurs in healthy individuals when two auditory stimuli follow each other in rapid succession. This effect appears to be trait-related, as it is also reliably observed in the patients' nonpsychotic biological relatives. Several negative-going ERPs also have been investigated. Patients show abnormalities in the N100 evoked response to auditory stimuli, in the mismatch negativity seen approximately 200 msec following an unusual or novel stimulus presented in the background, and in the N400 component elicited in response to semantic incongruity. Further research is needed to determine the sensitivity and specificity of these less-studied ERPs.

D. Behavioral and Cognitive Abnormalities

1. Startle Response

The startle reflex is a cluster of defensive responses to a sudden, intense stimulus. In healthy individuals, the magnitude of startle diminishes with each stimulus presentation. Patients with schizophrenia, however, show reductions in the normal habituation to startle. In addition, they do not exhibit prepulse inhibition (PPI). PPI refers to the normal suppression of the startle response by the introduction of a weaker prestimulus and is thought to reflect behavioral gating processes that are hard-wired in the mammalian brain. Individuals with schizotypal personality traits show similar deficits. Deficits in PPI are not specific to schizophrenia, however, as they have been found in other disorders with putative abnormalities in the cortico–striato–pallido–pontine circuitry thought to be involved in the startle response. Because the startle response is seen in all mammals, this behavioral abnormality has proved useful for the development of some animal models of schizophrenia.

2. Oculomotor

Many studies have demonstrated that patients with schizophrenia show abnormalities in smooth-pursuit (SP) voluntary eye movements required to follow a moving target. Although the source of some continuing debate, these deficits appear to result from low-pursuit gain (the ratio of eye velocity to target velocity) with a concomitant increase in the number of corrective saccades. SP deficits do not appear to be affected by neuroleptic medication and are present in nonpsychotic biological relatives of patients. Impairments of SP eye movements are also found in other psychopathological disorders, though further detailed analysis of the nature of the deficits may reveal a more specific marker of schizophrenia. In contrast, abnormalities in the performance of an antisaccade task appear to be relatively specific to patients with schizophrenia and their relatives. This inability to inhibit a reflexive saccade to a location while making a voluntary saccade to an opposite location is thought to reflect functional deficits of the frontal lobe.

3. Cognition

Patients with schizophrenia suffer from cognitive deficits that are stable across changes in clinical status. Thus, studies of neuropsychological abnormalities are thought to provide information about the brain systems involved in schizophrenia. Several areas of particular impairment exist above and beyond the oft-observed deficits in global intellectual functioning. Patients consistently perform poorly on tasks of sustained and selective attention. Deficits on the same tasks are found in individuals at risk for developing schizophrenia (i.e., patients' biological relatives). Learning and memory are impaired too, and deficits in these abilities are also apparent in patients' first-degree relatives. Acquisition of new information and free recall of verbal and visual information are both impaired. In contrast, patients are not likely to forget information rapidly once it is learned, and procedural learning appears to be relatively intact. Working memory, or the on-line manipulation or maintenance of information in a short-term store, has been shown to be abnormal. These results point to a disruption of frontal lobe mechanisms known from animal studies to be involved in working memory tasks. Further

evidence for the role of frontal dysfunction in schizophrenia comes from studies of executive functions. Patients perform more poorly than healthy individuals on tasks that assess planning, strategy, set shifting, and abstraction, such as the Wisconsin Card Sorting Test and the Tower of London test. Neuroimaging studies have suggested that failure on these tasks is related to underactivation of the frontal lobes. The weight of the evidence from longitudinal studies and family studies supports the idea that cognitive deficits in schizophrenia are stable, trait-related features of the disorder. Research also suggests that these abnormalities are related to functional deficits such as quality of life, independence, and work status. Unfortunately, most current treatments do not significantly impact cognitive deficits in patients with schizophrenia.

III. THEORIES OF ETIOLOGY

A. Genetics

Schizophrenia has a strong familial component. Siblings and parents of patients have an 8–10% chance of developing the disorder and offspring have a 12–15% risk, compared to a 1% risk in the general population. Evidence from twin and adoption studies suggests that a portion of the familiality of the disorder is genetic. Specifically, monozygotic (MZ) twins have a 40–60% concordance rate, whereas dizygotic (DZ) twins have a 12–15% concordance. In addition, the offspring of schizophrenic mothers who are adopted away have a higher risk of schizophrenia than those from nonschizophrenic mothers.

Despite strong support for the role of genes in the disorder, the search for a particular gene related to schizophrenia has been disappointingly unfruitful. Linkage analyses have revealed several candidate markers that have not been confirmed in subsequent studies. The most studied have been the long arm of chromosome 22, chromosome 6p, and genes for various dopamine receptors.There are several methodological issues that complicate the search for a ''schizophrenia gene.'' First, there is great heterogeneity of symptom presentation among those diagnosed with schizophrenia. It is quite possible that different symptom profiles are related to abnormalities in different sets of genes. Thus, by combining all subtypes into one category, potentially relevant genes may be missed. Relatedly, the boundaries of schizophrenia are not well-defined. Results of linkage analyses are likely to be strongly influenced by how broadly the schizophrenia spectrum is defined. Thirdly, schizophrenia is not likely to be caused by just one gene. Multiple genes, interacting with one another, are the appropriate targets for genetic research in this disorder. Finally, although genes clearly play some role in the etiology of schizophrenia, results from twin and adoption studies also point to the importance of environmental factors. For instance, the concordance rate for MZ twins is only half of that expected in a purely genetic disorder, and adoption studies have found that characteristics of the adoptive parents contributed substantially to the risk of developing schizophrenia. Thus, even if genes related to schizophrenia are discovered, they are unlikely to explain fully the etiology of the disorder.

B. Environment

Early theories regarding environmental risk factors for schizophrenia focused solely on the role of parenting styles (especially, ''schizophrenogenic'' mothering). These theories were eventually supplanted, however, by hypotheses centering on biological precursors. Most current research has focused on influences in the perinatal period of development. There are three main reasons for this emphasis. First, as reviewed earlier, the nature of the brain abnormalities in schizophrenia suggests neurodevelopmental aberrations instead of neurodegenerative processes. Second, patients with schizophrenia have an increased prevalence of minor physical anomalies and neurological soft signs, pointing to a gestational origin. Third, birth-cohort and high-risk studies that followed subjects into the risk period for development of symptoms have consistently demonstrated that patients with schizophrenia show deficits long before the onset of the disorder. By using techniques such as the retrospective review of home movies and records as well as prospective studies, it has been shown that individuals who later develop schizophrenia demonstrate at an early age motor and psychomotor abnormalities, cerebral ventricular enlargement, neurological soft signs, cognitive deficits including lower IQ and attentional dysfunction, and social and emotional disturbances at school.

Exploration of perinatal environmental influences on the development of schizophrenia has centered on two main candidates: obstetric complications and viruses. History of obstetric complications (OCs) is more common in patients with schizophrenia than in healthy individuals. Specifically, prematurity, low birth weight, and complications involving trauma or

oxygen deprivation are frequently found. Because the medial temporal lobe is known to be particularly sensitive to hypoxia, the prevalence of OCs among patients provides a potential origin of the neurodevelopmental deficits seen in this region. A viral origin of schizophrenia has also been proposed. Support for this hypothesis comes from epidemiological studies showing an increased rate of schizophrenia among the offspring of women who were in the second trimester of pregnancy during an influenza epidemic. In addition, it has been argued that the increased risk of schizophrenia found among those born in the winter, in urban areas, and during times of famine supports a viral etiology. Finally, adult patients with schizophrenia show a wide variety of immunologic abnormalities, although the specificity of these deficits is not determined. Despite these pieces of circumstantial evidence, no virus has been identified that explains most cases of schizophrenia.

C. Interactive

Due to the complexity of schizophrenia, it is unlikely that genes or environmental factors alone cause the disorder. Rather, some interaction of these factors probably leads to the heterogeneity of symptom profiles, course, and outcome. The diathesis–stress theory posits that environmental factors combine with an underlying genetic vulnerability to produce schizophrenia. In support of this theory, research suggests that the offspring of mothers with schizophrenia who also suffer delivery complications are the most likely to develop schizophrenia later in life. In addition, early separation from caregivers increases the risk of schizophrenia only among those individuals with a family history of the disorder. Finally, studies have suggested that individuals at genetic risk for the disorder who receive poor parenting are more likely to develop schizophrenia. Thus, environmental risks at many stages of development appear to interact with genetic factors to promote the genesis of schizophrenia.

D. Developmental

A complete understanding of the etiopathology of schizophrenia must include an explanation of the age at onset of characteristic symptoms. As reviewed earlier, most known risk factors have their effects perinatally. In addition, subtle abnormalities of functioning are evident in childhood and adolescence in those individuals who are eventually diagnosed with schizophrenia. The pathognomonic signs and symptoms of schizophrenia, however, do not usually arise until late adolescence or early adulthood and typically erupt rather forcefully in the form of a "first break." In addition, in some individuals onset is earlier (childhood onset), and in others, especially women, onset is later in life (late onset). One class of theories that attempts to explain these facts hypothesizes that perinatal events (either genetic, environmental, or an interaction) create a brain vulnerability that only becomes apparent after normal developmental changes occur near the age at onset. In search of support for these hypotheses, the role of developmental hormones in the onset of schizophrenia has been investigated. In childhood-onset schizophrenia, the onset of puberty is related to the onset of the disorder, though only in girls. In addition, the preponderance of women among late-onset patients with schizophrenia has led to the suggestion that female reproductive hormones, such as estrogen, may be protective factors against onset of the disorder. It is posited that the decrease in estrogen levels during menopause promotes the onset of schizophrenia. Related theories suggest that the nature of the congenital abnormality is a *disruption* of normal developmental changes, such as a delayed expression of abnormal genes or failure of normal synaptic pruning that should occur around the second decade of life. Finally, other theories emphasize an accumulation of adverse events that eventually reach a threshold, leading to onset of the disorder. At this time, no definitive evidence has been found that favors any of these theories over others.

IV. TREATMENT

Until the etiology of schizophrenia is well-understood, curative treatment may not be possible. Current palliative treatments of schizophrenia include both pharmacological and psychosocial approaches and are most effective for positive symptoms. More research on interventions aimed at the improvement of negative symptoms, cognitive deficits, and functional status is needed.

A. Pharmacological

Since the 1950s, when chlorpromazine was first shown to be effective for the treatment of patients with schizophrenia, antipsychotic medications have been used to treat the psychotic symptoms of the disorder

Table III
Selected Antipsychotic Agents Used in the Treatment of Schizophrenia

Drug	Possible mechanism of action	Clinical benefits	Important side effects
Conventional:			
Chlorpromazine	D_2[a] blockade (low potency)	Positive symptoms, calming effect	Autonomic, sedation, EPS,[b] TD[c]
Haloperidol	D_2 blockade (high potency)	Positive symptoms, calming effect	EPS, TD, NMS[d]
Atypical:			
Clozapine	Selective blockade of mesolimbic neurons via D_2[e] occupancy and/or combination of lower D_2 blockade with 5-HT_{2A}[f] antagonism	Positive symptoms, negative symptoms, improved cognition and functioning	Agranulocytosis, sedation, anticholinergic, orthostatic hypotension
Risperidone	Antagonism of D_2, 5-HT_{2A}, α_1[g], and α_2[h]	Positive symptoms, negative symptoms, improved cognition (especially working memory) and functioning	Somnolence, orthostatic hypotension, EPS, hyperprolactinemia
Olanzapine	Greater 5-HT_{2A} than D_2 antagonism, affinity for D_3[i], D_4, 5-HT_3[j], 5-HT_6[k], H_1[l], α_1, and M_{1-5}[m]	Positive symptoms, negative symptoms, improved cognition (especially verbal fluency) and functioning	Sedation, orthostatic hypotension, weight gain
Quetiapine	High 5-HT_{2A} relative to D_2 and D_1[n] antagonism	β positive symptoms, β negative symptoms	Sedation, orthostatic hypotension, increased risk of cataracts (?)

[a]Dopamine subtype 2 receptor.
[b]Extrapyramidal symptoms.
[c]Tardive dyskinesia.
[d]Neuroleptic malignant syndrome.
[e]Dopamine subtype 4 receptor.
[f]Serotonin subtype 2A receptor.
[g]Noradrenaline subtype α_1 receptor.
[h]Noradrenaline subtype α_2 receptor.
[i]Dopamine subtype 3 receptor.
[j]Serotonin subtype 3 receptor.
[k]Serotonin subtype 6 receptor.
[l]Histamine subtype 1 receptor.
[m]Acetylcholine muscarinic subtype 1–5 receptors.
[n]Dopamine subtype 1 receptor.

and to prevent relapse. Conventional or typical neuroleptics, including the low-potency agent chlorpromazine and high-potency drug haloperidol, repeatedly have demonstrated efficacy compared to placebo, especially in the treatment of positive symptoms such as hallucinations, delusions, thought disorder, and bizarre behavior. In addition, these compounds have been shown to prevent relapse: a majority of untreated patients relapse, whereas only about 20% of treated patients do so over a 1-year period. Efficacy appears to be related to the affinity of these compounds for the D_2 dopamine receptor (see Table III), although the onset of antipsychotic effect is generally slower (5–10 days) than the time course of receptor blockade (hours). Unfortunately, this same affinity results in a high risk of motor side effects, such as extrapyramidal symptoms (EPSs) and potentially persistent tardive dyskinesia (TD). EPSs include akathisia (i.e., restlessness), dystonia, tremor, and rigidity and are generally treated with anticholinergic agents, such as benztropine. TD is a movement disorder characterized by abnormal, choreiform movements of the mouth, face, limbs, or trunk, which can develop after chronic neuroleptic exposure. The benefits and risks involved in long-term treatment with typical neuroleptics complicate decisions regarding the optimal duration of treatment and whether discontinuation is recommended. In addition to these issues, conventional neuroleptics do not seem to reduce the chronicity of the disorder, do not ameliorate negative symptoms, and have little impact on cognitive deficits.

In contrast, the newer atypical antipsychotics, such as clozapine, risperidone, olanzapine, and quetiapine, reduce the intensity of positive symptoms, carry a

lower risk for EPSs and TD, and seem to demonstrate better efficacy in treatment of negative symptoms. The atypicality of these medications appears to stem from their affinity for non-D_2 receptors, such as the D_1 and D_4 dopamine receptors and 5-HT_2 serotonin receptors (see Table III). Claims that newer atypical medications also improve cognitive deficits and everyday functioning require further investigation. In addition to antipsychotic medications, other psychotropic agents are sometimes employed in the treatment of schizophrenia. Mood stabilizers such as lithium and antiseizure medications, antidepressants, and anxiolytic agents have all been used. None of these compounds has proved superior to neuroleptics in the management of psychosis, but their use as adjunctive agents, especially in patients with schizoaffective disorders, has been supported.

B. Psychosocial

Whereas antipsychotic medication is the first line of treatment for individuals with schizophrenia, several observations point to the important role that psychosocial and rehabilitative interventions can play. First, as noted earlier, medication treatment does not improve all types of symptoms and often does not result in improvements in functional status, such as returning to work or decreasing level of care. In addition, medication compliance among patients with schizophrenia is often poor. Because medications can only be effective if they are actually taken by the patient, improving adherence is one of the targets for psychosocial intervention. Finally, studies suggest that relapse among medicated patients is more likely following stressful life events. Thus, interventions aimed at coping with such situations may reduce relapse rates.

Some psychosocial interventions have targeted symptom reduction. Behavioral and cognitive–behavioral techniques aimed at reducing hallucinations, delusional beliefs, and bizarre behavior generally show efficacy, but many of these interventions have failed to generalize outside the treatment setting. Other interventions have focused on improving problem solving, social skills, independent living skills (including medication management), coping skills, and cognitive deficits. In general, studies have shown that these treatments decrease symptoms and relapse rates and improve the everyday functioning of patients with schizophrenia. Further research is necessary, however, to identify the necessary features of these treatments and to determine whether all, or only specific, patients benefit.

Semantic Memory

MURRAY GROSSMAN and PHYLLIS L. KOENIG
University of Pennsylvania

GLOSSARY

aphasia Acquired disturbance of language that can include difficulty with semantic memory. Aphasia can be seen in the setting of a stroke or a neurodegenerative condition such as Alzheimer's disease. Transcortical sensory aphasia, for example, is a language disturbance that includes fluent speech that is often empty of content, associated with poor comprehension of language.

category-specific An impairment in meaning for a particular domain of knowledge, such as animals or tools, with minimal impairment of other semantic domains.

functional magnetic resonance imaging (fMRI) A technique used to study brain activation during cognitive challenges, such as understanding word meaning.

semantic memory The long-term representation of meaningful information and the processes we use to make this information available for a multitude of cognitive tasks.

Semantic memory is the long-term representation of meaningful information and the processes we use to make this information available for a multitude of cognitive tasks. Unlike episodic memory, we cannot necessarily recall the specific experiences associated with the acquisition of information represented in semantic memory. Semantic memory allows us to recognize a fork as a tined implement used for transferring food (without having to recall how we learned what a fork is) and to know that an apple is a sweet, red fruit with a pitted core that grows on trees in moderate climates (apart from our memory of the last time we ate one). The goal of current research efforts at several laboratories has been to establish the cognitive and neural bases for the representation of semantic knowledge and to define the set of cognitive processes and neural structures that support semantic memory in communication and thought. This article will summarize several advances in the area of semantic memory. We focus on results that have contributed to our understanding of the neural substrate for semantic knowledge and associated processes. It is important to recognize that these studies have been motivated by one of several theories of semantic memory, that theories of semantic memory play a crucial role in helping us interpret the results of studies investigating neural mechanisms associated with semantic memory, and that the results of such neural-based investigations in turn help constrain the nature of the cognitive models we develop for understanding semantic memory.

I. SEMANTIC MEMORY: A BRIEF OVERVIEW

In brief, semantic memory involves at least two key elements. First, there is the representation of semantic knowledge. This includes facts about the perceptual features (e.g., shape, color) and functional features (e.g., intended use of an implement, inherent activity of a beast of burden) associated with objects. We consider other facts beyond object recognition as well, such as the origins and biological properties of natural kinds such as ANIMALS (we use capitals to denote concepts) and FOODS and the range of perceptual variability displayed by manufactured artifacts such as TOOL and WEAPON, while still retaining the

essence of the object's meaning. Some of these features are relatively necessary components of a concept (e.g., apples grow on trees), whereas others are characteristically associated with a concept even if they are not necessary (e.g., many apples are red). Whereas we consider knowledge in semantic memory generally to be modality-neutral, allowing it to be represented visually, auditorially, or in any other fashion, there are certainly constraints on the manner in which some types of information can be represented. For example, semantic knowledge extends to nonobject concepts that are best represented propositionally, such as JUSTICE, or that depend on analog representations such as a visual image (e.g., RED). Semantic memory also includes actions, manners of thought, and emotions that are quite plastic in their manifestations and often entail relational information.

The mere existence of semantic knowledge is not sufficient to guarantee its effective use. The second key element of semantic memory involves the processes required to implement the contribution of semantic knowledge in our thoughts and actions. For example, we must be able to organize this vast array of knowledge for it to be used in a rapid and coherent fashion during thought and communication. Some of the properties of the concepts represented in semantic memory may cluster themselves in a categorical manner that groups like features and objects, but such "autoassociation" does not explain how the massive volume of our meaningful experiences coheres into concepts. Specific processes used for categorizing objects may help organize the immense amount of information about our meaningful experiences. One such process is thought to be "rule-based" and involves an analysis of a test object for the necessary and sufficient features of a concept; a second categorization process is based on "similarity" and involves a comparison of a test object with a prototype or with remembered instances of a concept. Moreover, we must be able to access and retrieve semantic knowledge, and this conceptual information must then be represented in a material-specific symbol system, such as writing or speech, for the purpose of communication. We also put semantic knowledge to many uses beyond an encyclopedic collection of facts for concept identification. For example, we make inferences about our world that are not readily apparent from the superficial appearance and function of an object, and we often acquire new knowledge on the basis of its relationship to established knowledge.

We are faced with the problem of mapping a semantic memory system such as this onto the brain, a 3-lb gelatinous mass composed of billions of neurons and a greater number of support cells. Broadly speaking, there are at least two approaches to the neural bases for semantic memory. First, there is a distributed account, in which the information in semantic memory is represented in a diffuse fashion throughout the superficial cortical gray matter of the brain. Several biochemical and microanatomic changes have been described during learning in simple organisms like aplysia that result in greater connective strength among neurons. Complex knowledge in semantic memory may be represented in the massively interconnected nature of neural elements bearing these microscopic changes. During learning, for example, we can imagine a specific network of connections between nodes representing particular features of a concept being facilitated by these microscopic changes. This allows the neural network to settle into a solution that represents the specific knowledge of a concept. From this perspective, a category—a collection of similar concepts such as FRUIT—may be a family of similar network solutions. The fact that a stable solution to a concept has been achieved is equivalent to the process of retrieving a concept. This hypothesis about the neural basis for semantic memory has been difficult to test directly, but researchers have attempted to simulate this distributed approach with computers using neural nets: computer simulations of cognitive functions that involve large arrays of interconnected nodes. These simulations are acknowledged by their developers to represent only a pale metaphor for the truly massive complexity of the central nervous system, but they represent an important start. Additional support for this approach comes from neuroimaging studies that fail to find distinct activation patterns for specific categories of knowledge.

A second approach to the neural basis for semantic memory hypothesizes the localized representation of semantic knowledge and semantic processes in specific parts of the brain. For example, the specific features of a concept in semantic memory may constrain the anatomic distribution of this concept in the brain because its representation must be processed by a particular modality (e.g., the visual representation of color concepts). Imaging tools such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are available for directly studying the neural substrate of cognitive processes involved in semantic memory *in vivo*. These techniques allow us to image the gross spatial and topographic distribution of the brain working to solve a cognitive challenge, but these tools give us little insight into the

microscopic workings of human neural tissue when it is considering the meaning of an object. We have learned about the temporal characteristics of thought from cognitive event-related potential (ERP) studies. This technique uses powerful electrical detectors at the surface of the skull—and even directly on the cortical surface during the course of neurosurgery—to examine the spatial and temporal distribution of the electrical potentials generated by neurons during cognitive activity. The great achievement of high-resolution temporal information about semantic memory unfortunately comes at the cost of poorer spatial resolution. Studies of subhuman species have monitored neuronal activity directly with implanted electrodes, but comparable electrical studies in humans (as a prelude to the surgical management of intractable epilepsy) generally involve relatively primitive extracellular monitoring under highly restricted circumstances. New techniques such as magnetoencephalography and evoked-potential studies performed in the bore of a magnet during fMRI offer the potential of excellent temporal resolution with improved spatial resolution.

In other words, we are only at the very beginnings of our exploration of the neural basis for semantic memory, quite analogous to the European voyagers of the fifteenth century. These explorers hypothesized a vast world beyond their shores, and they forged ahead in the face of frequent false steps, poor tools, and misleading theories. Despite this grim picture, we are beginning to understand the gross lay of the land, as outlined in this article.

II. SEMANTIC KNOWLEDGE IN BRAIN-DAMAGED POPULATIONS WITH SEMANTIC MEMORY IMPAIRMENT

A. Investigations of Clinical Patient Groups

Much of the early work devoted to investigating semantic memory from a neural perspective focused on groups of patients with aphasia or a language disturbance following a stroke or other discrete cerebral injury. One subgroup of fluent aphasics—transcortical sensory aphasics—is said to be particularly impaired on tasks requiring semantic memory, such as word definition and picture naming. Their spontaneous speech typically is empty, with difficulty retrieving content words (e.g., the names of objects and actions), and is circumlocutory, with vague descriptions of the intended target word. These aphasics also substitute verbal or semantic paraphasias for many of the content words that they produce [e.g., for the intended target *egg* (we use italics to indicate a stimulus), they might produce "chicken" or "milk"], yet their utterances often appear to be grammatically intact. Evidence that this is not a deficit restricted to speech comes from the observation of similar difficulties in writing. Moreover, errors are found on comprehension measures that do not require expression, including word–picture matching, synonym judgments, and other tasks that require knowledge of word meaning. On the basis of these observations of oral and written difficulty with word meaning in comprehension and expression, researchers have concluded that patients with a transcortical sensory aphasia have a central deficit in semantic memory.

Whereas it is possible that these patients are impaired at some level associated with the concept underlying a word, an alternative account is that fluent aphasics have a language disturbance that is material-specific, that is, an impairment restricted to the language domain. This would be consistent with models of semantic memory that partition acquired knowledge into different, material-specific segments, including concepts that are said to be most amenable to representation in a propositional format (e.g., language-based semantic memory) and concepts with analog features that can be represented best as an image (e.g., visual-based semantic memory). Support for this material-specific model of semantic memory comes from observations of patients with a visual agnosia who appear to have a material-specific deficit for the meaning of visual material. Visual agnosics thus have profound difficulty understanding line-drawings of objects. These patients nevertheless have relatively intact elementary visual perceptual functioning that allows them to identify the location of a small dot on a page and even to specify its color. Visual agnosics often are able to recognize, copy, and match simple regular geometric shapes such as a square or a circle. A subgroup of visual agnosics—visual associative agnosics—are even capable of copying a complex line-drawing quite accurately, although this is accomplished in a slavish, line-by-line fashion that includes the unintended imperfections of the model. The material-specific nature of the deficit is emphasized by the fact that visual agnosics are relatively intact in their comprehension of objects presented linguistically and in other nonvisual modalities such as by hearing or feeling. Observations such as these suggest that all concepts represented in semantic memory are not compromised following focal cerebral injury, although

there may be selective difficulty understanding concepts that are particularly dependent on a specific type of material.

Transcortical sensory aphasics and visual agnosics may have material-specific difficulty understanding some representations of concepts, but other groups of patients are said to have difficulty with meaning that appears to be material-neutral in nature. Many of these patients have a dementia, that is, a progressive neurodegenerative disease that increasingly interferes with cognitive functioning over time. For example, Progressive Fluent Aphasia or Semantic Dementia is a neurodegenerative condition that results in fluent spontaneous speech with empty content but well-formed grammatical features that resembles transcortical sensory aphasia in many ways. Additional examination of these patients demonstrates profound difficulty on tasks such as picture–word matching, word sorting, picture sorting, and definition generation. They are limited on verbal and nonverbal measures assessing lexical and picture associations (e.g., Pyramid and Palm Trees Test, in which the subject decides which of two available choices, such as a *palm tree* and a *pine tree*, goes best with a target stimulus, such as a pyramid), and their coherence judgments of pictures composed of elements from two different objects (e.g., the head of a cow on the body of a monkey) also is compromised. Whereas these patients are relatively impaired in their knowledge of information at a basic object level (e.g., semantic knowledge associated with COW characteristics), their appreciation of superordinate category knowledge appears to be relatively preserved (e.g., knowledge that a cow is a kind of ANIMAL).

Similarly, some patients with Alzheimer's disease are thought to have semantic memory difficulty that transcends material and modality. As with transcortical sensory aphasia and Semantic Dementia, Alzheimer's disease results in fluent, grammatically well-formed speech that is empty and contains few content words. These patients also have difficulty on tasks that require semantic memory, such as matching pairs of words and pairs of pictures, judgments of anomalous pictures, category membership judgments for words and pictures, definition generation, and knowledge of object attributes.

Group studies such as these are immensely valuable because they demonstrate a consistent pattern of difficulty across a large number of similar patients, a process of generalization that adds confidence to our observations. However, there are several problems associated with investigations of semantic memory in a clinical group. One practical limitation is that it is difficult to test all members of a large group of subjects on an extensive series of measures. More importantly, there can be considerable variability within the population of patients bearing a similar diagnosis. Within Alzheimer's disease, assessments of individual patient profiles reveal an apparent semantic memory impairment for words as well as pictures in only about 50% of these patients. Different patterns of results thus can emerge in a group assessment, depending on the specific subgroup of patients constituting the cohort under study. For example, some investigators find greater semantic memory difficulty in Alzheimer's disease (AD) as a function of their impairment with the specific perceptual characteristics associated with a particular subset of words and objects, whereas other researchers AD associate the semantic memory impairment with a limited appreciation of the functional features associated with concepts. Our understanding of semantic memory through these group studies thus can be complemented by careful case studies of informative patients with discrete deficits, as will be discussed later.

B. The Neural Basis for Semantic Memory Impairment in Clinical Patient Groups

Observations of groups of similar patients with difficulty understanding and expressing meaningful material provide important confirmation that semantic memory can be compromised following central nervous system disease. But what is the neural basis for semantic memory? Although we can speculate about the architecture of a model of semantic memory—whether we are more accurate to use an information processing model or a parallel distributed processing model, for example—the accuracy of our models can be significantly enhanced by direct investigations of the neural basis for semantic memory. Moreover, information about the neural basis for semantic memory can help constrain the nature of a cognitive model of semantic memory. This two-way interaction is a keystone of cognitive neuroscience.

The process of studying brain–behavior relationships in semantic memory has been significantly advanced by the advent of modern neuroimaging techniques. Rather than waiting for a patient to die, as was the case until relatively recently in the history of neuroscience, we can immediately observe the locus of cerebral insult with any of several modern

neuroimaging techniques. For example, injury to the posterior superior temporal and inferior parietal regions of the left hemisphere appears to play a crucial role in the difficulties of patients with a transcortical sensory aphasia. Imaging studies of patients with visual agnosia emphasize bilateral dysfunction of visual association cortex in the context of the relative preservation of primary visual cortex and posterior superior temporal regions of the left hemisphere. Studies such as these suggest that there may be distinct neural substrates associated with representing concepts propositionally and visually.

Group assessments also have been performed that directly correlate a semantic memory deficit with a focus of neurological dysfunction. In a study of Alzheimer's disease, for example, patients were asked to judge the membership of words and pictures in a category: When given a picture of an apple or the word "apple," for example, patients decided whether the test item was a FRUIT. Judgment accuracy correlates with regional cerebral activity in the superior temporal and inferior parietal regions of the left hemisphere, and Alzheimer's disease patients with significant difficulty making these judgments have significantly less activity in this area than patients who are successful at making these judgments. This corresponds to the distribution of increased cerebral activity of healthy subjects during some functional neuroimaging studies of category membership judgments. Imaging studies also associate Semantic Dementia with disease in portions of the left temporal lobe. For example, analyses of the distribution of structural changes on MRI demonstrate significant atrophy in the anterior portions of the left temporal lobe in these patients, whereas functional neuroimaging with PET during the performance of an association task (Pyramids and Palm Trees Test) shows reduced activity in the posterior inferior portion of the left temporal lobe. This corresponds to the locus of cortical recruitment in healthy subjects while performing this association task. The investigators conclude that a disconnection within the left temporal lobe contributes importantly to the breakdown of semantic memory in patients with Semantic Dementia. Findings such as these appear to underline the contribution of various regions within the left temporal lobe to semantic memory. However, these studies leave open the question of exactly what role these brain areas play in semantic memory. Is it the facts represented in semantic memory that are degraded by disease, or is it the processes making use of these facts that are compromised? We address this issue later.

It is convenient to assess information processing models of semantic memory in stroke patients because the focal cerebral insult caused by a stroke may interfere with a particular component of semantic memory such as a specific process or a specific kind of semantic knowledge. A distributed approach to modeling semantic memory has been proposed as well, but this kind of theory is difficult to test in patients suffering from focal neurologic injury. Investigators thus study dementing patients from the perspective that their illness causes diffuse damage to the distributed network underlying semantic memory. According to this approach, the semantic memory deficit in Alzheimer's disease is due to nonfocal damage that loosens axonal projection patterns and degrades the synaptic densities of interneuronal connections in a massively complex neural network. As the disease progresses, the neurodegenerative process results in greater semantic memory difficulty due to continuous degradation of the neural network supporting semantic memory. However, evidence supports the claim that many patients with a dementia have a focal neurodegenerative disease that disproportionately compromises the functioning of specific cortical regions.

Yet another source of information is available for assessing the neural basis for semantic memory—a highly focal technique whose results surprisingly support the distributed approach to semantic memory. Specifically, many patients requiring surgical treatment for pharmacoresistant epilepsy have direct electrocortical stimulation obtained during the intraoperative evaluation prior to the removal of neural tissue. This allows the neurosurgeon to map out "eloquent" cortical regions and avoid damage to the patient's language system. These stimulation studies suggest that components of language systems are widely distributed throughout the frontal and temporoparietal cortices of the left hemisphere. For example, electrocortical stimulation in a wide area of the left hemisphere—including frontal, temporal, and parietal regions—disrupts naming. To be sure, the patients examined during these studies have sustained significant brain injury, leading to the need for a surgical cure for their intractable epilepsy. This can have a significant impact on the representation of language in the brain. These findings nevertheless contrast with the localization studies described earlier and emphasize the possibility that the neural basis for word meaning that is associated with naming is distributed in a relatively undifferentiated fashion throughout a large area of the left hemisphere.

C. Category-Specific Semantic Memory Impairment: Selective Deficit for Natural Kinds or Manufactured Artifacts

Recent findings in groups of patients with apparent semantic memory difficulty discussed earlier raise important questions about the nature of semantic memory and its neural representation. One model of semantic memory proposes that specific types of visual and linguistic semantic knowledge can be selectively compromised. The limits of this compartmentalized approach to semantic memory are tested with detailed case studies of patients who have highly selective semantic memory impairments. In particular, semantic memory deficits are detailed that are putatively category-specific because they are associated with relative difficulty in only one domain of knowledge. These observations prompt widespread excitement and controversy because of their potentially important contribution to a theory of semantic memory and the neural representation of the semantic memory system.

Whereas observations of selective difficulty understanding specific categories of information have been noted for many decades, Warrington and her colleagues published several case studies that provide the path-breaking impetus for our renewed interest in this focal approach to the neural representation of knowledge in semantic memory. These patients have relative difficulty on tasks requiring knowledge of natural kinds such as ANIMALS, VEGETABLES, and PLANTS, although performance on comparable tasks involving manufactured artifacts such as TOOLS, VEHICLES, and WEAPONS is relatively preserved. For example, these patients provide impoverished definitions of living things (e.g., *daffodil*: ''plant;'' *duck*: ''an animal'') compared to their definitions of manufactured artifacts (e.g., *compass*: ''tool for telling the direction you are going;'' *umbrella*: ''object used to protect you from water that comes''). The patients of Warrington and Shallice, as well as additional patients described since this seminal report, also have greater difficulty on measures of word–picture matching, picture naming, naming to definition, attribute judgment, and category naming fluency (e.g., ''name as many different ANIMALS as you can in 1 minute'') for stimuli involving natural kinds, compared to manufactured artifacts.

The basis for this intriguing deficit is the subject of intense investigation, and several questions have since arisen regarding the reliability of these findings. For example, one objection is that the stimuli used to test notions about natural kinds and manufactured artifacts are not carefully matched for frequency, familiarity, visual complexity, and other ''nuisance'' variables that can potentially affect performance. For example, a case of herpes encephalitis has been reported in which the patient demonstrates a clear category-specific deficit for living things compared to manufactured artifacts. When the lists representing each category are matched for frequency, the category-specific advantage for living things remains. However, when the stimulus lists are jointly matched for frequency, familiarity, and visual complexity, the category-specific advantage disappears. To be sure other cases are reported in which the category-specific effect remains despite matching lists of stimuli jointly for frequency, familiarity, and visual complexity. Attention to details such as this nevertheless helps underline the variety of subtle individual differences that exist across the cases said to have a category-specific semantic memory impairment.

Another more substantive issue related to case-by-case variability is the precise nature of the categories that are compromised. We often think of terms such as ''living things'' and ''natural kinds'' to be coreferential, for example, but there appear to be subtle and potentially important differences in the scope of the deficit across individual patients with a category-specific impairment. A relatively large number of patients thus have a category-specific deficit for natural kinds that includes both categories of ANIMALS and FOODS. Other patients may be impaired for the category of FOODS but not ANIMALS, or for ANIMALS but not FOODS. Similar controversies arise regarding the status of artifact categories such as MUSICAL INSTRUMENTS and BODY PARTS. This kind of variability makes it difficult to identify a theoretically coherent account that is explanatory across the spectrum of individuals with a category-specific deficit for natural kinds.

Despite these case-by-case differences, some theorists relate category-specific impairments to the model of semantic memory that differentiates between visual semantics and propositional semantics mentioned earlier. From this perspective, conceptual knowledge is organized in the brain according to the sensory (visual, auditory, kinesthetic, etc.) and motor modalities that contribute features to the concept. This model holds that the same neural elements responsible for perceiving an object's attributes are also partially responsible for their long-term neural representation. The various properties of an object are said to be distributed across these sensory–motor

representational domains, and the conceptual representation of an object is an "autoassociated" collection of its attributes. Warrington and Shallice thus argue that the concepts underlying natural kinds hold in common their dependence on visual properties, for example, whereas the concepts associated with manufactured artifacts are more dependent on functional properties. From this perspective, the visual sensory attributes of natural kinds are crucial for identifying and distinguishing between items such as strawberries and raspberries or between zebras and horses, although these pairs of items are not readily distinguished in terms of their functional attributes. On the other hand, a screwdriver and an ice pick look very similar visually, just as a minibus and a van closely resemble each other, but these pairs of items are said to be readily distinguished on the basis of their functional characteristics.

This theory of semantic memory receives some support from computational models. For example, one simulation represents semantic knowledge in separate but interconnected networks of visual and functional attributes, and the ratio of visual to functional properties in living things is set to be much greater than in nonliving things. The ratios are derived from subjects who inspect dictionaries for the relative numbers of visual and functional attributes associated with living things and nonliving things. When Farah and McClelland simulate a brain lesion by damaging the visual components of their model, the resulting pattern of performance resembles that seen for a category-specific impairment for living things. Conversely, when they lesion the functional components of their model, a category-specific impairment for nonliving things emerges. Caramazza and Shelton as well as other investigators have objected that the instructions for culling information from dictionaries does not reasonably ascertain the frequency of the nonsensory properties of objects. When Caramazza and Shelton replicate the Farah and McClelland experiment by rephrasing the instructions for identifying functional attributes to include all nonsensory properties, they find a ratio of sensory to nonsensory properties that approaches 1:1 and is essentially identical for living things and nonliving things.

This sensory–motor model for semantic memory is put to the test in patients with a category-specific impairment. For example, knowledge of natural kinds and manufactured artifacts in patients with a category-specific impairment can be probed for visual attributes and functional attributes. Evidence to support the sensory–functional model would come from the finding that patients with a category-specific impairment for natural kinds have relatively impoverished knowledge of the visual attributes of these objects compared to their functional knowledge of the same objects. Indeed, a patient with a category-specific impairment for living things is described with disproportionate difficulty identifying the visual feature that distinguishes between two objects. However, these investigators use animal stimuli that are less familiar than their artifacts. Another reported case of category-specific impairment for natural kinds has much more difficulty with visual than with functional properties of natural kinds, and these are more difficult than both visual and functional properties of artifacts. However, this pattern of difficulty is evident only when the patient is probed verbally: The patient is considerably less impaired when asked to evaluate the visual properties of visually presented objects. For example, the patient has difficulty deciding verbally whether an elephant is orange-colored or gray-colored, but he or she is virtually error-free when asked to judge the coherence of pictures of an orange-colored elephant and a gray-colored elephant. Yet other investigators object that patients with a category-specific impairment for natural kinds have equal levels of difficulty with visual and functional probes of natural kinds and are equally superior in their responses to probes of visual and functional properties of manufactured artifacts.

Another concern about the category-specific impairment for natural kinds is that natural kinds are somehow more difficult or less familiar than manufactured artifacts. However, Warrington and others describe patients with the inverse pattern of impairment, namely, greater difficulty with manufactured artifacts compared to natural kinds. As with category-specific difficulty for natural kinds, patients with selective difficulty for manufactured artifacts are less than consistent from case to case: One case has difficulty predominantly with small manipulable objects, whereas another patient has difficulty with artifacts of any sort (e.g., TOOLS, VEHICLES) as well as BODY PARTS.

Difficulty with manufactured artifacts is attributed to an impairment in appreciating the functional properties of objects that are thought to be so crucial to the semantic feature representation of these objects. However, studies focusing on the functional properties associated with manufactured artifacts are difficult to interpret, possibly because functional attributes have a much more complicated mental organization than perceptual attributes. For example, there appear to be

functional attributes that are common only to natural kinds (e.g., BREATHES, EATS) or manufactured artifacts (e.g., STAPLING, CARVING), there are additional functional features that help distinguish among natural kinds (e.g., EXTRACTS OXYGEN FROM WATER or FROM AIR) or among manufactured artifacts (e.g., CUTS BY SAWING or CHOPPING), and there are distinct action schemata for expressing a function.

Some evidence to support dissociations among these elements of function is seen in patients with impaired semantic memory. For example, patients with difficulty appreciating fine-grained functional features that distinguish among natural kinds nevertheless are able to appreciate functional features common to all natural kinds. In another study, a double dissociation is found between knowledge of functional attributes in a Semantic Dementia patient and errors of object selection and usage on a naturalistic action test in a patient with impaired executive function.

Given the many concerns about the sensory–motor account for category-specific impairments, several alternative models have been forwarded to account for semantic memory deficits in patients with a category-specific deficit. One approach suggests that category-specific deficits cannot be reduced to sensory and functional limitations, but that categories of knowledge themselves are directly compromised. Patient E.W. has a category-specific impairment for natural kinds that narrowly affects the category of ANIMALS. Her difficulty spans naming, visual and auditory recognition, and visual and functional statements about animals. On the basis of these observations as well as those of other investigators, a domain-specific basis for the organization of conceptual knowledge in the brain is proposed. In this view, the categories of ANIMALS, FRUITS AND VEGETABLES, and ARTIFACTS can be damaged independently of each other due to an evolutionary adaptation of dissociable neural circuits dedicated to responding selectively to instances of these domains.

In contrast to this sensory–motor approach based largely on an information processing model, an alternative theory focuses on the distributed nature of the characteristics contributing to semantic knowledge. According to this model, there is a high intercorrelation among features of natural kinds, allowing collateral support from other features and similar objects even if there is some degradation of natural kind knowledge. For example, many fruits are round, and this is highly correlated with other features of fruits such as color, size, and taste. Even if the round shape feature of an orange is destroyed, the semantic memory system can "infer" on the basis of the high intercorrelations among fruit features that oranges are round. By comparison, knowledge of each manufactured artifact is said to be relatively more dependent on a unique feature that does not have much collateral support, and destruction of the neural representation of this feature will consequently lead to reduced knowledge of this object. Following the destruction of the blade feature of a saw, for example, the semantic memory system cannot easily infer from other manufactured artifacts that a saw must have a blade for cutting because this feature is relatively unique to saws.

This distributed model can be assessed in patients with Alzheimer's disease. Mildly demented patients are found to have greater impairment for manufactured artifacts than for natural kinds. The investigators argue that random destruction of neural elements representing specific manufactured artifact features results in a decline in knowledge of these objects, but an equal burden of disease with randomly destroyed natural kind features has less of an effect on natural kind knowledge. The authors attribute this finding to the higher intercorrelation among natural kind features that allows collateral support from other natural kinds. By comparison, more severely demented patients have more difficulty with natural kinds than manufactured artifacts. The investigators attribute this to the progressive level of damage sustained by the brain that is sufficient to interfere with the feature system of natural kinds. This hypothesis is implemented in a connectionist model that emphasizes the distributed nature of correlated features in natural kind and manufactured artifact categories.

D. Neural Basis for Category-Specific Semantic Memory

What can we learn about category-specific impairments from direct studies of the brains of these patients? Can such studies discriminate between the localized, information processing approach and the distributed, nonlocalized approach that are proposed to account for these intriguing deficits? By focusing on differences in the statistical distribution of features associated with natural kinds compared to manufactured artifacts, some investigators demonstrate distinct patterns of relative impairment in cross-sectional studies and in a limited longitudinal study of Alzheimer's disease. This disease condition is examined because the investigators claim that these patients have

diffuse, nonfocal disease. In essence, these researchers assert that the disturbed connectivity pattern among categories of objects—rather than the anatomic locus of disease—defines the nature of category-specific representation of semantic information in the brain and explains the deficit in Alzheimer's disease.

A major difficulty for this approach is that Alzheimer's disease appears to have a specific anatomic distribution of disease. Thus, other assessments of the category-specific deficit in Alzheimer's disease directly challenge the distributed account of higher intercorrelation of features among natural kinds compared to manufactured artifacts. These investigators find the same pattern of cognitive impairment described by Gonnerman *et al.*: greater difficulty with artifacts in mildly impaired patients, but greater difficulty with natural kinds in moderately impaired patients. However, they attribute the distinct impairment patterns to the specific anatomic distribution of neuronal dysfunction seen at different stages of Alzheimer's disease.

An alternative hypothesis proposes that category-specific difficulty is attributable to a specific, structural locus of disease. Patients with category-specific difficulty for natural kinds often sustain damage to inferior temporal lobe structures. A common cause of disease in this location is herpes simplex encephalitis, although other patients with a category-specific impairment for natural kinds suffer from a neurodegenerative condition or head trauma involving this brain area. By comparison, most patients with a category-specific deficit for manufactured artifacts have larger lesions such as a stroke affecting lateral aspects of the left hemisphere in the distribution of the middle cerebral artery.

Whereas this approach to localizing a category-specific impairment is highly appealing because of its direct, one-to-one mapping of a category onto a neural substrate, several shortcomings are associated with this approach. The most important of these is the difficulty in establishing the precise locus and extent of disease, particularly when disease quantification is ascertained only with a structural imaging study. For example, diseases causing structural lesions such as a stroke often are indiscriminant in the extent of damage to gray matter, and there may be insult extending into functionally unrelated cortical regions that are interfering in a "nuisance" fashion with some aspect of task performance. Further, damage to the underlying white matter may interrupt projections that have little to do with the cortical area of concern, resulting in a remote functional defect that confounds the localizing value of the lesion.

More recently, functional neuroimaging studies of healthy adults have significantly aided our analysis of the neural basis for category-specific semantic knowledge. Functional neuroimaging studies have the distinct advantage that regional recruitment of the brain in response to a cognitive challenge can be studied in a healthy, neurologically intact individual. Perhaps the most elegant study involves the examination of patients with lexical retrieval difficulty who have focal insult involving the left temporal lobe, compared with the assessment of healthy adults exposed to natural kinds and manufactured artifacts while regional cerebral blood flow is monitored with PET. These investigators define the damaged neural substrate common to a series of patients with selective difficulty naming manufactured artifacts—the ventral midtemporal region of the left hemisphere—and the brain region compromised in patients with a category-specific deficit naming natural kinds—the posterolateral midtemporal region of the left hemisphere. In their PET study challenging healthy subjects with natural kinds and manufactured artifacts, these investigators observe a distinct distribution of activation associated with each category that corresponds to each of the damaged areas responsible for a category-specific deficit. The involvement of visual association cortices in these category-specific phenomena is interpreted to support the sensory–functional account for the representation of knowledge in the brain.

Additional support for the sensory–motor model comes from a PET study that monitors regional cerebral activity while subjects judge whether pairs of line-drawings are different exemplars of the same kind of object or are two different objects. These investigators find that subjects recruit bilateral inferior temporal regions when animals are presented, but they activate a left hemisphere network including left dorsolateral prefrontal cortex when artifacts are presented. Another PET study directly investigates the pattern of regional cerebral recruitment associated with sensory and functional characteristics. These investigators find recruitment of left ventral temporal regions during naming of a color associated with a word or a picture representing an object, but they observe activation of left frontal and temporal–parietal areas during naming of an action associated with a word or a picture of an object. In sum, observations of brain-damaged patients with a category-specific impairment and functional neuroimaging studies of healthy adults challenged with specific categories of knowledge provide some support for the hypothesis that the neural representation of semantic

information is organized in a fashion that is sensitive to the cortical region processing the features critical to the mental representation of a specific category. It remains to be determined whether the neural representation of information within these regions is distributed or topographically localized.

E. Other Forms of Category-Specific Difficulty: Action Verbs, Proper Nouns, and Abstract Nouns

Many investigators argue that the category-specific difficulties evident in studies of natural kinds and manufactured artifacts provide important insights into the neural representation of knowledge. However, these hopes must be tempered by the fact that this theory of category-specific knowledge is based on concrete objects such as natural kinds and manufactured artifacts, which represent only one kind of knowledge, and categories such as these have relatively unique sensory and functional properties that may not generalize to other domains of knowledge. This note of caution is emphasized by the fact that we use terms with concrete reference relatively rarely in our day-to-day conversations: our speech consists of words like "word" and "example," for example, much more often than "apple" and "screwdriver."

A handful of studies has begun to test the hypothesis that category-specific difficulties can be found in other domains of knowledge. Consider actions, a domain of knowledge that is associated with a different major word class—verbs—and has different kinds of perceptual and functional features. Verbs are not static, visuoperceptual entities, for example, but instead are dynamic, relational concepts with highly malleable visual perceptual manifestations that have an important motor-related component. Some evidence has emerged that patients with disease in motor-related cortices, such as in frontotemporal forms of degeneration, are relatively impaired with action verbs compared to concrete nouns. Observations such as this raise the possibility that domains of knowledge labeled by verbs also have a distinct, category-specific neural representation and potentially provide important evidence that the sensory–motor model of category-specific knowledge is not simply a special case relevant to specific kinds of objects or parts of speech.

However, there are several confounds that must be addressed before this line of thinking receives unequivocal support. For example, verbs have a rich family of associated grammatical features (e.g., whether the verb takes a direct or indirect object), and it may be these grammatical attributes that determine in part the neural representation of verbs. In this context, a considerable body of work demonstrates that the left prefrontal regions of the brain play a special role in grammatical aspects of comprehension. Another issue has to do with the stimuli that the patients are asked to name. For the most part, static line-drawings are used to illustrate the verbs, and it may be that the relative difficulty inferring an action from such a representation plays a role in the verb-specific impairment of these patients. Indeed, there appear to be brain regions in the posterolateral temporal–occipital area that are specialized for the perception of motion that may play an important role in action verb knowledge. In comparison to generation of a color term associated with pictures and words denoting object stimuli, generation of an associated action term results in the recruitment of posterolateral temporal–occipital cortices. Another issue has to do with the sheer amount of information represented in a verb compared to a noun. The coordination of processes underlying verb use may depend in part on working memory resources that are supported by prefrontal cortices. In separate subgroups of patients with a frontotemporal form of dementia, for example, a dual-task study of word–picture matching with verbs and nouns finds that patients with a nonfluent form of progressive aphasia have greater difficulty with verbs than nouns regardless of the condition during which verb comprehension is assessed. However, frontotemporal dementia patients with executive difficulty but no aphasia have difficulty with verbs depending on the simultaneous performance of a resource-demanding secondary task.

Some evidence has accumulated to indicate that frontal brain regions contribute specifically to action verb comprehension. In a study assessing regional cerebral activity during subjects' judgments of words from various verb categories, motion verbs recruit left inferior frontal as well as right striatal regions in comparison to judgments of cognition verbs (e.g., mental state verbs like "discuss"), whereas the reverse contrast shows recruitment of left posterolateral temporal regions. Both verb categories also recruited right ventral temporal, bilateral temporal–occipital, and striatal regions. A direct contrast of motion verbs and cognition verbs demonstrated specific activation of inferior frontal regions for motion verbs.

Another category with its own neural representation may be proper nouns. These words have a concrete referent—the person, geographic location, or object that each proper noun names—and thus resemble common nouns such as natural kinds. However,

proper nouns differ from common nouns such as natural kinds because of the arbitrary relationship that exists among the set of features associated with the referent. Several cases are reported with selective proper noun impairment. These patients are not able to produce the names of famous individuals in response to a picture or to verbal description, even though they are able to use the same phonologic shape accurately to name a picture or a description of a common object. The reverse pattern is reported as well, that is, greater difficulty with common nouns than proper nouns. This suggests that proper nouns are not simply more difficult to name and understand than common nouns, but that proper nouns may represent a distinct category of knowledge.

The neural representation of proper nouns is quite controversial. Damasio and his colleagues describe seven patients who have selective difficulty in naming with proper nouns. These subjects have disease that affects the left temporal pole. These investigators also find that healthy individuals recruit anterior portions of the left temporal lobe when naming with proper nouns. However, a summary of the lesion localization of patients with proper name difficulty reveals widespread insult in many areas of the left hemisphere. Whereas the neural representation for proper nouns remains unclear, all of these investigators interpret their results in the context of an information processing model that localizes proper nouns to some specific brain region.

A stronger challenge to the sensory–motor model comes from studies of the neural basis for abstract words. These words have few sensory–motor features and thus are difficult to link to a specific brain region concerned with processing visual perceptual or motor–kinesthetic information. Nevertheless, the concepts underlying abstract words are readily understood due to their propositional content. Perhaps the most intriguing evidence concerning the psychological reality of abstract concepts comes from the demonstration of the ''reversal of the concreteness effect'' in patients with Semantic Dementia. Whereas we typically understand concrete nouns more rapidly and accurately than abstract nouns, these patients are more rapid and accurate at understanding and naming abstract nouns.

The neural basis for abstract nouns has been investigated with functional neuroimaging studies as well. One study examines the distribution of neural activation associated with the passive presentation of abstract nouns or concrete nouns, using as a baseline an ''anticipation'' condition that involves the presentation of instructions without the actual presentation of stimuli during imaging. This study reports activation in left middle temporal, left inferior frontal, and left occipital cortices in association with abstract nouns. However, a similar pattern of activation in left middle temporal, left inferior frontal, and left middle and inferior occipital regions is seen during passive presentation of concrete nouns. Another fMRI study reports left posterolateral temporal and left prefrontal activation during abstract noun stimuli as well as IMPLEMENTS. On the basis of observations such as this, the sensory–motor approach to category-specific knowledge does not appear to account fully for the neural representation of semantic memory because similar brain regions are recruited for concrete and abstract nouns, despite minimal sensory and motor attributes associated with the latter. One possibility is that these brain regions are activated to make decisions about any type of word, regardless of its content, rather than because the neural representation of knowledge represented in specific categories is represented in this portion of neocortex. In sum, some evidence supports the claim that category-specific knowledge is topographically distributed in the brain, depending on the nature of the category. However, important questions remain to be resolved before this model can be fully endorsed.

III. PROCESSING COMPONENTS OF SEMANTIC MEMORY

The studies reviewed previously provide considerable evidence to support the claim that some form of category-based organization of long-term semantic knowledge is honored by the brain, although the precise basis for the category-specific form of neural organization remains to be established. Is this determined by the sensory–motor features that must be recruited in association with a concept? Is the category-based organization due to some genetically determined predisposition that grants specific categories a special status? Or is there some other variable remaining to be uncovered that will encompass abstract concepts as well as the categories of knowledge with sensory–motor features that have been so well-studied? Regardless of the ultimate outcome of this debate, concerns about the representation of categories of knowledge in the brain rarely address a crucial issue in our understanding of semantic memory, namely, how these concepts are *processed*. For example, it may be that the distinct status of natural

kinds is determined only in part by the neural representation of knowledge of the visual properties of these objects, but natural kinds additionally may be related to the visual–perceptual processing of a concept that is recognized by its visual attributes or to some other aspect of processing these concepts.

Some investigators suggest that patients with Alzheimer's disease do not have an impairment in the neural representation of semantic knowledge. Instead, Alzheimer's patients may have difficulty accessing long-term semantic knowledge that is otherwise relatively intact. This assertion is based on the results of priming studies. In this work, a semantically related priming word facilitates performance on a lexical decision task or a timed reading task when the priming word immediately precedes the target word, but this facilitation does not occur when the preceding word is unrelated to the target word. For example, the speed at which we initiate our oral reading of the word "doctor" is more rapid when preceded by the semantically related priming word "nurse" than by the semantically unrelated foil "purse." This phenomenon is equally robust in some studies of patients with Alzheimer's disease, suggesting that their semantic knowledge is fundamentally preserved. This line of investigation leads to the conclusion that the semantic deficit in Alzheimer's disease is due to an impairment in the effortful processes needed to access and retrieve information from semantic memory.

Whereas this phenomenon is reported in several studies of patients with Alzheimer's disease, support for this approach is far from universal. For example, some investigators demonstrate hyperpriming in Alzheimer's disease, that is, word recognition in a priming paradigm that is even more rapid than in control subjects. Moreover, the specific items with which Alzheimer's disease patients have the greatest hyperpriming are the items that the same Alzheimer's patients have the greatest difficulty understanding in nonpriming studies. It is hypothesized that there may be "pruning" of semantic relationships in an associative network, thus leading to very fast priming in the setting of sparse semantic associative knowledge that may otherwise "distract" patients from the associative link.

An alternative account has been forwarded. This considers the nature of the semantic relationship being tested in priming studies. The high associative strength between prime–target pairs of words often used in priming studies is not necessarily semantic in nature, but may be due to a high frequency of lexical co-occurrence that is not necessarily semantic. For example, "cottage" and "cheese" are words that co-occur frequently but have no true semantic relationship that binds them together. Compare these pairs with words that have a low frequency of co-occurrence but a high degree of semantic relatedness, such as members of the same superordinate semantic category like "rooster" and "canary." A priming study examines pairs of words that co-occur at a high frequency but have a low index of semantic associativity and word pairs that are semantically related by virtue of their membership in a common superordinate category but rarely co-occur. The findings demonstrate that Alzheimer's disease patients prime for word pairs that co-occur at a high frequency, but not for semantically related word pairs.

Functional neuroimaging studies can examine the neural basis for retrieving semantic knowledge. This work demonstrates that inferior frontal as well as temporal regions of the left hemisphere are recruited during tasks assessing the retrieval of semantic knowledge. Thompson-Schill and her co-workers attempt to establish the role of this inferior frontal recruitment by varying the selection demands across three semantic tasks. They observe changes in inferior frontal recruitment as a function of task demands, associating inferior frontal recruitment with the retrieval process involved in semantic memory.

There is another, more fundamental way in which a processing impairment can interfere with the comprehension of word meaning. If information about concepts is distributed in the brain, then there must be some way in which this information is synthesized into a coherent whole that can be useful to us in our communication with others and in our internal mental musings. Allport and others allude to this issue when they discuss the "autoassociation" between elements of an object that are distributed across many modality-specific segments of conceptual knowledge. However, the nature of this autoassociative process remains to be defined, and no independent evidence supports the claim that autoassociation in fact is the mechanism by which elements of a concept are synthesized into a coherent whole representing an object. Studies of categorization in fact propose at least two distinct ways in which we organize semantic information into coherent categories. One process for organizing distributed information about semantic memory is said to be *rule-based* in nature. According to this approach, there are specific attributes that are generally necessary and sufficient for identifying an instance of a category, and an object must have these attributes in order to be a member of the target category. This is an analytic,

effort-demanding process that requires us to hold in mind a list of attributes that are selected to be necessary features of a concept and to verify the presence of each and every one of these attributes in a test object while nonnecessary features are inhibited. A second process for organizing semantic knowledge is said to be *similarity-based* in nature. According to this approach, a global comparison based largely on perceptual features is made between a test object and an ideal instance (or remembered instances) of the category. If the similarity between the test object and the ideal instance is close enough, then the test object is said to be a member of the category.

One study attempts to test the integrity of categorization processes such as these by asking patients to judge the category membership of familiar objects taken from well-defined or nominal categories such as FEMALE and MALE, or from categories with poorly defined or fuzzy boundaries such as VEGETABLE and FRUIT. A subgroup of Alzheimer's disease patients has a significant impairment in deciding the category membership of test items from fuzzy categories. Among these patients with a deficit pattern said to be typical of a semantic memory impairment, there is no deficit in category decisions about items taken from well-defined categories. Similarity-based categorization and rule-based categorization thus are equally effective at supporting decisions about well-defined categories, but similarity-based categorization can be misleading and unreliable for decisions about fuzzy categories. Therefore, we appear to be relatively dependent on rule-based categorization for poorly defined categories. These findings thus are thought to be most consistent with the hypothesis that AD patients have a rule-based categorization impairment that selectively limits their judgments of objects taken from categories with fuzzy boundaries.

A neuroimaging study assessed the neural representation of similarity-based and rule-based processes. These investigators taught subjects about categories of artificial animals using one of two strategies: memorizing instances of each category (i.e., similarity-based categorization) or using a set of rules for determining category membership (i.e., rule-based categorization). Subjects subsequently were scanned while they attempted to generalize their knowledge to a new set of these artificial animals. The results revealed a different distribution of neural activation depending on the process used initially to learn category membership. The subjects asked to memorize the instances of each category recruited visual association cortices, consistent with the hypothesis that these subjects are making perceptually based similarity judgments between a test object and a remembered instance. The subjects using a rule-based approach also activated some frontal regions, consistent with the contribution of executive processes to rule-based categorization decisions. These findings suggest that the categorization processes implicated in organizing knowledge for the purpose of understanding concepts are honored by the brain and appear to be supported by dissociable neural systems.

IV. SUMMARY

Where have we come by the end of this brief review? It should be apparent that more questions remain to be answered than have been addressed at this early stage of investigation. The barest of outlines nevertheless is beginning to emerge from the haze to indicate that the semantic memory system has a store of knowledge that sorts meaningful experiences in a systematic fashion and that several kinds of processes are available to make use of this information. This body of work begins to demonstrate the way in which cognitive investigations of semantic memory can constrain our interpretation of neurologically based investigations, and direct assessments of the neural basis for semantic memory can help develop a model of the way in which the brain supports our representation and use of concepts. We can be hopeful, moreover, that new, *in vivo* techniques are continuing to emerge that will help us assess the neural basis of semantic memory during life with increasing detail.

We believe that the data discussed earlier are consistent with a model of semantic memory in which information is represented in a distributed network. Each concept contains information describing at least perceptual and functional features that are stored in modality-specific, sensory–motor association cortices, as well as propositional knowledge possibly in language-related brain regions. This massive network of information is organized with the aid of at least two processes: rule-based categorization implemented in part in frontal heteromodal association cortex that uses working memory to process the necessary features defining a concept, and similarity-based categorization implemented in part in posterior heteromodal association cortex that evaluates the graded resemblance between a stimulus and an ideal (or remembered) representative of the concept. Concepts are retrieved so that they can be represented by a phonological, orthographic, or visual structural description that is

processed in the appropriate modality-specific association regions.

Sensory Deprivation

JOSEF P. RAUSCHECKER
Georgetown University Medical Center

GLOSSARY

amblyopia Reduced vision not correctable by glasses (thus of central origin), which can be caused by various forms of visual deprivation at an early age.

cerebral cortex Outer sheet of the mammalian brain consisting of several dozen functionally specialized areas, each consisting of vertical columns with various functional properties as well as six horizontal layers with connections to other cortical areas, to the thalamus, and to other subcortical nuclei.

compensatory plasticity Improved performance of a sensory system in response to sensory deprivation in another; one system compensating for the loss of function in the other.

deafferentation Severing of afferents to a particular region of the central nervous system.

enucleation Surgical removal of an eye.

Hebbian synapses Synaptic connections that are strengthened as a function of coincident activation in pre- and postsynaptic neurons.

monocular–binocular deprivation Visual deprivation in one or both eyes.

representational plasticity Shrinkage or expansion of brain maps as a result of sensory deprivation or training.

sensitive period Time period of postnatal development during which a brain region or perceptual function is particularly sensitive to the effects of sensory deprivation (analogous to "critical period:" the time period of postnatal development during which exposure to adequate stimuli is particularly critical for normal development).

sensorineural hearing loss Hearing loss due to the destruction of hair cells in the inner ear, often associated with aging.

synaptic competition Competition between synapses for space at their common target neurons, which is controlled by activity in the respective pathways, with active synapses winning over silent ones.

tinnitus Ringing or buzzing in one or both ears, presumably of central origin, but usually initiated by peripheral damage.

Sensory deprivation studies consider the role that sensory experience plays in the development, reorganization, and plasticity of the brain and behavior by withholding or restricting that experience. This article will review animal studies in higher vertebrates in which sensory deprivation is brought about experimentally as well as some studies in congenitally blind or deaf humans. Most of this work assesses the effects of deprivation with either neurophysiological–anatomical or neuroimaging techniques, both within the same sensory system and across systems. The overarching role that neuronal activity plays in the modification of individual synapses and distributed representations is discussed.

I. INTRODUCTION

The question of whether nature or nurture determines our sensory and perceptual abilities is as old as human culture and goes back to Plato and Aristotle. An Egyptian pharaoh purportedly separated identical twins at birth in order to study the nature–nurture question, and Kaspar Hauser became a household name in the eighteenth century when he was found after having been deprived of language from birth. Whereas the role of nature is usually subsumed under the terms "innate" or "genetic," nurture has many different connotations. The most common one implies a role of sensory experience or the active use of an

individual's sensory systems. Withholding of that experience by sensory deprivation thus directly tests the influence of the nurture component on sensory development. The answer to the question of how important nurture is for brain development is likely to influence our thinking about the importance of education and environmental enrichment in the upbringing of our children. These issues therefore are often politically loaded, and results of research on these topics are hotly debated to this day.

Before modern neurobiological techniques became available, an assessment of the effects of sensory experience or deprivation was restricted to the behavioral level. To measure the effects of sensory experience on the brain, the first anatomical studies on visually deprived animals were performed in the nineteenth century. When Hubel and Wiesel and their contemporaries took up the theme of sensory deprivation in the last third of the twentieth century, electrophysiological single-unit recording, supplemented with more refined neuroanatomy, became the method of choice. Most recently, biochemical and molecular biological techniques have been applied to these questions as well.

At the single-neuron level, the effects of sensory deprivation can be observed by changes in sensory input pathways and their central representations. For example, temporary loss of pattern vision early in life can lead to permanently reduced vision because of neural changes in the brain's representations of vision. In normal animals, neurons are highly selective for certain properties of sensory stimuli, depending on the brain region in which these neurons are found. Neurons in the visual cortex, for instance, are "tuned" to the orientation of visual bars or gratings; neurons in the primary auditory cortex are tuned to tones of particular frequencies. Rearing of kittens in a striped environment or with strong cylindrical lenses that blur vision in all orientations but one leads to a distortion in the number of visual cortical neurons tuned to particular orientations. Thus, deprivation within a parameter domain, such as orientation selectivity, leads to changes of tuning within that domain. An altered performance of the neural system leads to corresponding changes in behavioral performance.

One of the major effects of sensory deprivation on brain circuitry is a loss of neural connections. Neural circuitry in newborn animals is overdefined and is pruned during development in a use-dependent manner. Sensory experience plays an important role in this selection process by feeding highly specific neural activity into the system. By contrast, sensory deprivation reduces this activity and therefore renders the brain circuitry less selective. Sensory experience is also sometimes capable of inducing the growth of new connections ("sprouting"), and sensory deprivation prevents this from happening. Whether one looks upon the role of sensory experience as maintaining neural selectivity that is otherwise lost or as actively instructing specificity depends on one's perspective. The amount of selectivity found at birth ("innately") varies across species and brain regions. Therefore, one may look at the effects of sensory deprivation as supporting both nativist and empiricist views of brain development.

Whereas sensory deprivation often has a detrimental effect on circuitry within the deprived modality, cross-modal effects have also been reported in which other, nondeprived modalities can actually improve their performance, so as if to "compensate" or substitute for the loss of the other modality. The existence of such "compensatory plasticity" or "sensory substitution" has been much debated over the years but now seems well-established. Experimental work presently focuses on the mechanisms governing such compensatory changes that can obviously be highly beneficial to the individual. It appears that the same synaptic mechanisms may be invoked cross-modally that govern adaptive changes within a single modality. The activity-dependent modification of synaptic connections originally proposed by D. O. Hebb in 1949 for learning-related changes in brain connections seems also to be the underlying mechanism for cross-modal effects.

II. VISUAL DEPRIVATION

A. Animal Studies

One of the ingenious ideas of Wiesel and Hubel in their studies of visual deprivation was the use of a reversible technique that permitted later testing of the deprivation effects on the visual system through the very end organ through which the animals had been deprived. By sewing the eyelids of young kittens or monkeys together before the time of natural eye opening, input to the visual system was prevented, but the optics of the eyes and their sensory receptor surface remained unharmed. With most deprivation studies in other sensory modalities (e.g., auditory or somatosensory, see later discussion), irreversible deafferentation of the sensory pathways is the only practical way to investigate the effects of sensory deprivation.

1. Effects on Retina and Lateral Geniculate

Whereas early studies of visual deprivation denied any effect on the physiology of the retina or lateral geniculate nucleus (LGN), later scrutiny found some subtle changes. Anatomically, changes in cell size are found in the layers of the LGN after monocular deprivation, with cells in the nondeprived layers being larger than those in the deprived layers. However, these changes were shown to be retrograde changes resulting from binocular competition at the cortical level. This was demonstrated first by the fact that cells in the monocular segments of the deprived layers, which do not have to compete with cells from the other eye, were of normal size. In a second series of experiments, an artificial monocular segment was created in the LGN by making a defined lesion in one retina with a laser (thus removing binocular competition specifically for this retinal location). In these cases, a shrinkage in cell size in the deprived laminae of the LGN was observed only in those sections that had an intact binocular representation and not in those areas that corresponded to a part of the visual field not represented in the other eye. Thus, it is the binocular competition of these projections at the cortical level that leads to retrograde changes in LGN cell size, not the direct effect of visual deprivation.

2. Effects on Visual Cortex

a. Monocular and Binocular Deprivation Extensive effects of visual deprivation during a critical period of visual development have been demonstrated on the primary visual cortex (V1, A17, striate cortex) of kittens or infant monkeys. Experimentally, visual deprivation can be achieved by occlusion with opaque contact lenses or by lid suture, which completely abolishes patterned visual input and drastically reduces the luminance on the deprived retina.

Although profound effects on neural response selectivity were reported after binocular deprivation (see later discussion), very robust consequences for the binocularity of cortical neurons are found by withholding normal visual input to only one eye (monocular deprivation). After just a few hours of monocular deprivation at the height of the critical period (in kittens around 1 month of age), many neurons in the primary visual cortex showed reduced excitability when tested through the previously deprived and then reopened eye. After progressively longer deprivation periods, the effects become more and more pronounced until, with about 1 week of monocular deprivation, virtually all cortical neurons (which normally receive binocular input) are driven only through the experienced eye. This means that, as a result of monocular deprivation, the input from the deprived eye to the cortical neurons becomes disconnected. These effects are reversible when, during a restricted sensitive period, the deprived eye is reopened and, at the same time, the experienced eye is closed. Simple reopening of the originally deprived eye is usually ineffective, which is interesting from a mechanistic point of view (“competition,” see earlier discussion), but also has practical consequences for the treatment of amblyopia in human infants (see later discussion).

The anatomical correlates of monocular deprivation are equally striking. Cells in the striate cortex of rhesus monkeys are organized into a band- or stripelike pattern of ocular dominance columns that are normally of equal width for either eye. Monkeys with long-term lid suture in one eye are found to have ocular dominance columns that strongly favor the nondeprived eye by expanding its representation at the expense of the deprived eye and show only small islands of input from the latter.

Shutting of both eyelids (binocular deprivation) during visual development does not create an ocular input asymmetry to the cortex, and the effects of binocular deprivation therefore cannot be measured by determining a shift in ocular dominance. However, its effects on other physiological response properties of visual cortical neurons are similarly dramatic: general responsiveness to visual stimuli drops (i.e., excitability thresholds rise) and the tuning of neurons for pattern-selective properties, such as orientation and direction selectivity, suffers drastically. Effects similar to binocular lid suture can be found with rearing kittens in total darkness.

Monocular and binocular deprivation meanwhile have become the most robust paradigms for the testing of changes in neural connectivity of the brain. Monocular deprivation is a standard bioassay for the synaptic mechanisms of cortical plasticity. Pharmacological and biochemical procedures for the development of new drugs are using the synaptic changes during monocular deprivation as their main testing ground, and the primary species for testing these effects are now rodents.

b. Pattern-Selective Deprivation The manipulations described so far have been rather crude. Closing of an eye lid or rearing in darkness deprives an animal of total pattern vision. Vision comprises many aspects such

as color, motion, contrast, spatial frequency, and depth. Experimental designs to withhold some specific aspect of normal visual experience while leaving the others more or less intact have originated from an understanding about the parameter domains within which cortical neurons are "tuned." These include orientation and motion-direction selectivity. The assumption behind such "selective-rearing" (or "selective-deprivation") studies was that neural networks encoding each selective property require experience in that particular domain to either establish or confirm their selectivity.

i. Orientation-Selective Deprivation: The earliest attempts to influence the development of orientation selectivity were made in the early 1970s and continued for more than a decade. Various techniques were used with the aim of rearing kittens with visual input restricted to only a narrow range of orientations. One group reared their kittens in striped drums, similar to what had been used earlier in behavioral studies of sensorimotor development. Another group used goggles that had contours of one orientation carved onto their semitranslucent occluders. A third group used cylindrical lenses, which blur vision in all orientations except for one narrow sector, and this sector remains constant relative to retinal coordinates regardless of head motion. The main outcome of all of these studies was that more cortical neurons were found with preferences for orientations that the animals had experienced. Thus, it seems that orientation tuning in visual cortical neurons requires sensory experience to maintain or fully develop that selectivity.

ii. Direction-Selective Deprivation: Selective deprivation of direction-selective mechanisms in the visual cortex has been performed in two ways: (1) Rearing of kittens in an environment without visual motion by using stroboscopic light. This procedure dramatically increases the number of neurons without direction selectivity. (2) Striped drums that move in only one direction have been used successfully to bias the distribution of direction-selective neurons in the visual cortex of kittens.

iii. Deprivation of Depth Vision: Various methods have been used to interfere with the normal means of binocular interaction in the visual cortex. Cutting of an eye muscle leads to strabismus or squint, i.e., a divergence or convergence of the visual axes. If strabismus is induced in young kittens or monkeys, the result is a reduction in binocularity of cortical neurons. This is caused by a loss of the normal binocular facilitation that occurs when the eye axes are aligned. Similar effects are found when kittens are reared with alternating occlusion of the two eyes.

Rearing of kittens in artificial environments that are moving toward or away from the animals causes visual association areas involved in the processing of optic flow to develop abnormally. Few other attempts have been made to deprive higher visual areas of their normal visual input, but the expectation is that adequate stimulation is required for normal development or maintenance of visual functions and that cortical areas with different specializations may possess different critical periods.

3. Cross-Modal Effects of Visual Deprivation

Behavioral observations of visually deprived animals demonstrate that they are highly adept at a variety of behaviors, including the localization of objects. Uninformed observers could not infer the blindness of these animals. This suggests that other sensory systems compensate for the loss of vision. In neural terms, the increased usage of these other systems (relative to sighted animals) may lead to an enlarged and refined representation of these senses in the brain of visually deprived (blind) animals.

a. Auditory Compensation for Visual Deprivation

i. Behavioral Evidence: Auditory spatial testing after visual deprivation has been performed in two nonhuman mammalian species: cats and ferrets. Ferrets are particularly useful because their brains are highly immature at birth. Both sets of data demonstrate increased auditory spatial acuity (i.e., decreased sound localization error) in early blind animals, binocularly lid-sutured from birth. The most pronounced effects were found in lateral and rear positions of azimuth, where the differences to sighted controls were highly significant.

ii. Neural Changes: Neurophysiologically, the most extensive studies on cross-modal effects of visual deprivation have been performed in cats and monkeys. Changes have been observed in the superior colliculus (SC) and in the parietal and occipital cortices. Overall, an increased number of auditory neurons compared to normal controls was found in visually deprived animals. In the SC, a higher incidence of auditory neurons was found in intermediate and deep layers, but what appeared to be new auditory neurons were also occasionally found in the superficial layers, where normally only visual cells are present. In the cortex of visually deprived monkeys, cross-modal changes were found primarily in association regions (area 7 in parietal cortex and areas 18 and 19 in occipital cortex).

In cats binocularly deprived from birth, visual responses of area AEV in the fundus of the anterior ectosylvian sulcus (AES) (the probable homolog of parietal area 7) virtually disappeared. Neurons in this region, however, did not become unresponsive, but were replaced by neurons with brisk responses to auditory and tactile stimuli. Apparently, auditory and somatosensory areas within the AES had expanded at the expense of formerly visual territory.

The response properties of the expanded auditory ectosylvian area (AEA) and those of neighboring auditory fields in the AES region were homogeneous. Auditory spatial tuning (the tuning for the location of a sound source in free field) was significantly sharper in the whole AES region when compared to sighted controls. Visually deprived cats had close to 90% spatially tuned cells (with a spatial tuning ratio of better than 2 : 1 between best and worst location). In addition, neurons with spatial tuning ratios of 10 : 1 or better were more abundant in blind cats. The increased number of auditory cortical neurons, together with their sharpened spatial filtering characteristics, is likely to improve the sampling density of auditory space and provide the neural basis for the improved spatial abilities of early blind cats and ferrets.

b. Tactile Compensation for Visual Deprivation - Cross-modal changes also occur in the somatosensory system of visually deprived cats and rodents. Visually deprived cats grow longer and thicker facial vibrissae. The same is true for mice and rats in which both eyes were removed (binocularly enucleated) at birth. Binocularly enucleated mice also show an expansion of the whisker barrels, the neural representation of the vibrissae in the primary somatosensory cortex. Barrels corresponding to whiskers in lateral positions show the most significant expansion, and whiskers in these same positions show the greatest hypertrophy, thus increasing the lateral range of the vibrissae as a tactile "organ." Increased usage and stimulation of the whiskers seem to be the common cause of both processes, but different signals may be responsible on the two levels.

Whereas the representation of nonvisual modalities in the cortex expands, the total visual cortex of rhesus monkeys after binocular enucleation is reduced in size and contains smaller cell bodies. Taken together, these findings suggest that cross-modal compensatory plasticity is guided by the same principles of activity-dependent synaptic competition as unimodal forms of neural plasticity, where active representations expand at the expense of inactive ones.

B. Human Studies

1. Visual Deprivation and Amblyopia

Visual deprivation in humans due to congenital cataract, if not corrected early in life, has the same devastating consequences as deprivation due to lid suture in cats and monkeys: adequate stimulation is withheld from cortical neurons and will inevitably lead to the same negative effects on neural selectivity. At the behavioral level, the neural deprivation effects can be recognized by reduced visual acuity that is uncorrectable through optical means (even if the cataract is removed or bypassed with laser optics). This deficit is characterized by the term "deprivation amblyopia" (amblyopia = weak vision).

Congenital cataracts that can cause deprivation amblyopia, previously not uncommon due to eye infections and oxygen toxicity for premature babies in incubators, have become quite rare in the Western world because of increased monitoring and even more rarely remain uncorrected due to improved surgery techniques. There are other forms of visual deprivation, however, that still pose a threat to normal vision and whose neural bases are less well-understood. Anisometropic amblyopia, which is caused by unequal refractive power in the two lenses, is related to deprivation amblyopia, because the unfocused image generated by one eye reduces the responses of cortical neurons in ways similar to those of diffuse light.

The most common form of amblyopia, strabismic amblyopia, is caused by a deviation of one eye axis from its regular position and a subsequent mismatch of the two retinal images at their corresponding cortical locations. The missing binocular facilitation also leads to reduced firing of cortical neurons and a resulting disconnection of visual inputs from their target neurons. Furthermore, a desynchronization of the inputs from the two eyes results in the loss of stereopsis and reduced visual acuity in the amblyopic eye.

2. Compensatory Plasticity in Blind Humans

As in visually deprived animals, blind humans have been reported to compensate for their loss of vision by increased use of their remaining senses and by correspondingly improved capacities in these senses. In the following, evidence in favor of these observations will be reviewed.

a. Auditory Compensation for Early Blindness *i. Behavioral Evidence*: Early studies of compensatory

plasticity in blind humans yielded controversial results. Some studies found evidence for an improvement in nonvisual functions after early blindness, whereas others found just the opposite: a deterioration in hearing compared to sighted controls. Several factors contributed to the confusion in the field: inhomogeneous patient populations with diverse etiology and unknown neurological status [partly due to the unavailability of objective tests such as magnetic resonance imaging (MRI)], different ages of onset and duration of blindness, and small numbers of patients combined with possible experimenter bias.

Studies with large patient populations have been undertaken that tested subjects with similar histories under stringent conditions. None of these studies found a disadvantage for the blind in their sound localization abilities, and most showed them to be superior. Most interestingly, another study found patients with partial vision to be the worst of all three groups (fully sighted, completely blind, and partially sighted) at localizing sounds. The same study provided valuable hints as to the neural basis for the improvement in spatial tuning in the blind: the biggest improvement was found when monaural spectral cues had to be used for sound localization. Other studies found the greatest improvements in sound localization in blind humans for lateral and rear positions of azimuth, precisely as had been demonstrated in visually deprived cats.

ii. Auditory Neuroimaging Studies in Blind Humans: Modern imaging techniques permit the mapping of neural activity during auditory stimulation in blind and sighted subjects directly in the human brain. Studies using event-related potentials (ERP) have demonstrated that the extent of cortical activation by changes in the frequency, intensity, and location of a sound is expanded in blind people, and the center of gravity of cortical activation is shifted posteriorly toward occipital areas. Comparison of patients blind from birth with those who became blind later in life reveals that a posteriorly directed expansion is also found in late blind patients, although it is smaller in extent than the shift found in the early blind. This expansion in late-blind adults implies at least partial cross-modal plasticity in the adult human, which is consistent with the behavioral and neurophysiological findings in visually deprived cats described earlier.

Investigations with positron emission tomography (PET) comparing congenitally blind and sighted subjects showed massive activation of the occipital cortex in the blind during a sound localization task in virtual auditory space. The sounds were presented via headphones, and the spatial cues were simulated using standardized head-related transfer functions, which present monaural spectral as well as binaural cues. Other PET studies have shown that the occipital cortex in blind subjects has metabolic rates that are as high as during visual stimulation in sighted controls. This is compatible with the notion that the occipital cortex in the blind is not idle but is recruited for functions other than vision.

Localization of sounds in virtual auditory space by sighted subjects leads to the activation of specific foci in the inferior parietal lobule (IPL) and in the frontal cortices, with a bias toward the right hemisphere as measured by PET. The same foci light up in blind subjects but are vastly expanded toward parieto-occipital (area 7) and occipital locations (areas 18 and 19), which normally are not active during sound localization, and the right-hemisphere bias is even more pronounced. The areas of expansion are probably homologous, in part, to higher visual areas shown to be newly activated by auditory or somatosensory stimuli in visually deprived cats and monkeys (see previous discussion).

In neuroimaging studies, regional activation alone, expressed as increased activity relative to a control state, does not necessarily indicate functional involvement. Interregional correlation analysis between activated brain regions provides additional information regarding the function of the right occipital cortex during auditory localization in the blind. By using the right IPL as a reference region, correlation analysis reveals a functional network of connections involving inferior and posterior parietal and occipital areas of the right hemisphere. Comparison of blind and sighted subjects revealed significantly greater interregional correlations in the blind between the right IPL and the right parieto-occipital (areas 7–19), right peristriate (BA 18), and right superior temporal cortices (area 22). This suggests that auditory signals from the temporal areas reach the occipital (formerly visual) cortex via parietal and parieto-occipital areas. Whether this involves the formation of new or the strengthening of existing connections remains to be elucidated. The animal work from binocularly deprived cats would suggest that the original cross-modal expansion happens in a competitive fashion in parietal cortex and that the back-projections from parietal to occipital cortex already carry an enhanced auditory signal.

b. Human Studies of Tactile Compensation Interest in the question of whether blind humans develop

enhanced tactile capacities has been great at least since the days of Louis Braille, mainly because of the practical implications of such potential improvements. Early behavioral studies in the tactile domain have been as controversial as those described earlier for the auditory domain. It is very difficult to control for practice effects, because very few sighted individuals would devote as much time and effort to working with Braille script. Thus, even those studies that demonstrated an improvement in spatial acuity in blind Braille readers often attributed the improvement to training effects, i.e., greater opportunity to practice Braille reading.

PET studies have begun to shine some light on whether blind people have improved tactile capacities at least in neurobiological terms. The activation of occipital areas by tactile Braille reading has been demonstrated to be higher in blind Braille readers than in normally sighted people trained to read Braille. Transcranial magnetic stimulation (TMS) of the occipital cortex disrupts the ability to recognize Braille characters. Even a case of "Braille alexia" has been reported, in which a blind subject became unable to decipher Braille after a stroke in the occipital cortex. The tactile consequences of focal damage to the visual cortex demonstrate unequivocally that the expanded region of cortex actually participates in the processing of tactile information in blind people. It appears that somatosensory regions normally participating in this task have expanded into formerly visual territory. How these newly invading somatosensory and auditory inputs coexist in occipital cortex and share this territory remains to be elucidated.

A more philosophical problem concerns the question of how blind individuals "see" their world. Does the activation of occipital cortex by auditory and somatosensory stimuli cause a "visualization" of the world? Similarly, does this activation evoke an "image" in the blind that can somehow be compared to vision because it is mediated by a brain region that was designed to process visual information? Or does the altered input change the function of these areas so fundamentally that they, in essence, turn into an extension of auditory or somatosensory cortex and provide sensations equivalent to those generated by these areas? In other words, is the perceptual and cognitive function determined by the recipient structure or by its inputs? The visual cortex in blind individuals certainly participates in auditory and somatosensory perception, but the studies reviewed here do not provide a final answer about the qualities of the experience.

C. Synthesis of Human and Animal Data: Mechanisms and Loci

Whereas many similarities between the animal and human responses to deprivation exist, as described earlier, one major difference stands out: an expansion of the auditory-responsive cortex in visually deprived cats and monkeys was reported only for higher association areas. By contrast, ERP and neuroimaging studies of blind humans additionally demonstrate a vast expansion of auditory activation into the occipital cortex, corresponding to primary and secondary visual areas. The explanation for this seeming discrepancy may be quite simple, however. Auditory responses were never tested in the primary occipital areas of blind cats and monkeys, because it seemed unlikely that auditory input could expand so far into normally visual territory. Cross-modal expansion was thought to be limited to neighboring areas that already had multimodal overlap and where competition could occur between overlapping input from different modalities. In light of the PET data, a possible reexamination of this view appears to be warranted. The invasion of new areas with minimal functional input from the auditory modality would at first imply a different mechanism from cross-modal competition. On the other hand, multimodal overlap may exist even in occipital cortex, especially during early postnatal stages when occipital areas still receive input from auditory cortex, as has been reported in newborn kittens. Such transitory input may be stabilized in blind animals and humans. Another, perhaps very likely, possibility is that nonvisual activation of the occipital cortex simply reflects the changes in the modality of the feedback projection from multimodal association cortex, in particular parietal cortex, where the initial modifications have taken place on the basis of cross-modal competition.

III. AUDITORY DEPRIVATION

A. General Remarks

Compared to the vast number of experimental studies performed in the visual system, sensory deprivation of the auditory system has received much less attention. This is surprising because a lack of normal auditory experience in early childhood is known to have profound and permanent effects on hearing. Most importantly, normal speech can only be acquired with auditory feedback. Likewise, sound localization

depends to a large extent on experience and can be modified by it. The extraordinary precision with which this system operates can only be accomplished with tuning mechanisms that recalibrate the system continually, especially during the growth phase of the head and outer ears.

At subcortical levels, there have been relatively few experimental studies of auditory deprivation, learning, and plasticity, but even less work has been performed on deprivation effects in the auditory cortex. To be sure, auditory deprivation cannot be accomplished as easily nor as fully as visual deprivation. Plugging an external ear canal can, at best, achieve an attenuation of sound by 20–30 dB. Rearing in controlled or restricted auditory environments is difficult, although some studies have shown that altered activity patterns during development can indeed reduce the frequency tuning of central auditory neurons. Most other methods for creating auditory deprivation, such as partial deafening with antibiotics or loud sound exposure, exert their effects by destroying the sensory receptor cells in the inner ear. However, the receptors need to be intact if the influence of deprivation on the central auditory system is to be tested. This is different from deprivation of the visual system by lid suture, which leaves the sensory end organ intact.

B. Effects of Auditory Deprivation on Speech and Language

As stated earlier, the literature does not provide such an abundance of examples of experimentally induced auditory deprivation studies in animals as it does for visual deprivation. However, there are plenty of examples of ''natural deprivation'' in humans in which modified or incomplete experience with the natural auditory environment leads to permanent deficits in hearing and, consequently, in speech. Because of their practical importance, we will deal with these studies first.

1. Specific Language Impairments and the Influence of Early Phonetic Environment

Congenital deafness or severe hearing impairment in early childhood leads to irreversible deficits in the perception and production of speech. Even transient elevations in hearing thresholds, such as during otitis media, if frequently recurring, may lead to permanent deficits. Although genetic influences may play a role as well, specific language impairments have been attributed to deprivation in the domain of rapid transients in the acoustic speech signal, which are important carriers of information. Language-impaired children often have severe perceptual deficits for brief tones when they are masked by noise. The fact that auditory feedback is essential for the development of normal vocal production is also suggested by studies of the song system in birds. Deafening at an early age leads to permanent deficits.

The phonetic environment in which a child is reared during early language acquisition undoubtedly has a profound influence on what he or she can or cannot perceive later in life. As such, this selective experience can also be seen as selective deprivation. Indeed, the inability of many speakers of Asian languages, in particular Japanese, to recognize distinct sounds for ''r'' or ''l'' is probably due to the absence of the distinguishing features in their early auditory environment. Once acquired through early exposure, such a predisposition can only be reversed through intensive training. Infants in different countries (Sweden, Russia, and the United States) initially do not show a preference for phonemes unique to their own language. By about 6 months of age, however, they suddenly develop this bias. Language-specific preferences for prosodic cues, which are necessary for the segmentation of the speech stream into perceptual units, also develop between 6 and 9 months of age.

Specific experience during a critical period of early postnatal development also seems to be necessary for the development of better-than-average musical skills. Early musical training in children is closely related to the development of absolute pitch and a concomitant expansion of auditory cortex. The conclusion is not far-fetched, therefore, that lack of such training (or partial deprivation) leads to an impoverished or less than fully developed auditory cortex. Experience-dependent plasticity for the perception of harmonic sounds is greatest before the age of 8 or 9, which coincides with the critical period for development of absolute pitch. This is in striking parallel with findings on phonological development, which also demonstrate that foreign accents in a second language invariably develop if the latter is acquired after the age of 8.

C. Cross-Modal Effects in Deaf Subjects

Processes analogous to auditory and tactile compensation for sensory deprivation in the blind can be demonstrated in congenitally deaf subjects. It can be shown with event-related potentials (ERP), as well as with neuroimaging techniques, that the brains of deaf

subjects are reorganized profoundly. Visual motion areas in the right parietal cortex thought to be involved in the initial decoding of visual motion in American Sign Language (ASL) are expanded. At the same time, "auditory" areas in the superior temporal (ST) cortex also become activated by sign language, but not by the presentation of English words as in hearing subjects. However, areas responsible for the processing of language-specific contents in the anterior ST and inferior frontal (Broca's) regions develop normally, even though they must be fed through a different input system. Hearing children of deaf parents, whose first language is ASL but who also develop normal English skills, do not show the same deprivation effects. Neurobiologically speaking, the mechanisms responsible for cross-modal reorganization during visual or auditory deprivation must be very similar. As has been argued earlier, the neural mechanisms are even likely to be the same for reorganization within and across modalities.

D. Effects of Auditory Deprivation on Sound Localization

Localization of sounds by the brain requires either the evaluation of binaural cues (intensity or time differences between the two ears that depend on the angle from which the sound comes) or monaural spectral cues (that are created by the filter characteristics of the head and pinnae). Some of these cues are already extracted at the brain stem level and are carried on into higher areas of the auditory cortex, where they create neurons with pronounced spatial tuning and possibly specialized representations for the perception of auditory space. As the complete deprivation of sound is close to impossible, most studies have sought to perform a selective deprivation of certain parameters to determine their influence on the development of binaural or spectral cues.

Ligation of one ear canal in rats leads to latency increases in neurons in the inferior colliculus (IC). After an ear had been deprived of sound from 10 days after birth, response latencies of high-frequency (but not low-frequency) units in the contralateral IC were 2–3 times higher than normal. This result is intriguing because high-frequency units in the IC are thought to participate in the coding of interaural intensity differences (IIDs), one of the major binaural cues for the coding of auditory space. Ears sound-deprived later in life were also associated with changes in latencies at the IC, but these were much less than in those deprived from birth, which hints at the existence of a critical period. Latencies of gross potentials at the auditory nerve were not affected by early deprivation, indicating a central origin for the latency changes.

Some of the most interesting experiments on the plasticity of sound localization have been performed in barn owls, which show exceptional precision in this domain. Plugging of one ear causes a change in the IID, which is one of the main binaural cues to sound source azimuth. Ear plugging leads to systematic behavioral sound localization errors, which can be predicted from the experimental change in the IID. The map of auditory space in the superior colliculus, which is considered the neural basis for sound localization behavior in owls, is systematically distorted in the direction of the changed IID. More specifically, implantation of an acoustic filtering device that alters both the timing and the level of sound reaching one eardrum in a frequency-dependent fashion induces frequency-specific adjustments in the auditory spatial tuning of collicular neurons. These results demonstrate that the response properties of higher-order auditory neurons in the optic tectum of the barn owl can be adjusted during development to reflect the influence of frequency-specific features of the binaural localization cues experienced by the individual. Most of the effects are reversible during a critical period, similar to that for the effects of monocular deprivation in the visual cortex.

The importance of auditory experience for the development of sound localization in humans is underscored by the observation that familiarity with a sound's spectrum makes it easier to localize the sound in elevation, and filtering of a sound in specific ways can bias its perceived elevation. This is due to the fact that elevations are encoded by notches in the frequency spectrum created by the head and pinnae. These notches seem to become associated with certain elevations by learning-induced mechanisms. The comparison with a stored sound template works best if the sound is familiar. If the spectrum is not known, the brain seems to work under the assumption of a flat frequency distribution, which leads to larger errors.

E. Central Effects of Peripheral Lesions

Small lesions in the cochlea of the inner ear (in a restricted region of the frequency axis that is represented along the basilar membrane) lead to a missing frequency representation in the contralateral auditory cortex. Input from neighboring frequencies expands

into the vacated cortical region that would normally process the frequencies from the lesioned part of the cochlea. A similar frequency expansion is not observed in the brain stem, which indicates that the reorganization occurs more centrally, perhaps as central as the auditory cortex itself.

The same mechanisms may lead to tinnitus, a sensation of ringing or buzzing in one or both ears, after sensorineural hearing loss due to aging or loud noise exposure. A particular frequency representation, deafferented by a peripheral lesion, is taken over by input from neighboring frequencies, which leads to an overabundance of activity from these frequency ranges. Human brain mapping studies using magnetoencephalography (MEG) and PET provide evidence that such cortical reorganization and the resulting frequency shift do indeed occur in tinnitus patients. Support for a central origin of tinnitus also comes from the fact that tinnitus persists in patients with acoustic neuroma even after transection of the auditory nerve. Furthermore, studies using 2-deoxyglucose autoradiography in gerbils treated with salicylate (which is known to generate tinnitus) demonstrate reduced activity in the inferior colliculus, but increased activation in portions of the auditory cortex.

Very similar reorganization of central representations after small peripheral lesions is found in the visual system. Laser lesions of the retina in animal studies lead to filling in of the resulting scotoma; neglect of the blind spot of the eye is the perceptual counterpart in human perception. Both phenomena can be considered to be analogous to tinnitus.

Reorganization of the auditory cortex after changes in peripheral activity is also observed, in a more positive fashion, after chronic auditory stimulation of a particular frequency region in owl monkeys. This leads to an expansion of the corresponding frequency representation in the auditory cortex and an enhanced discriminability of the corresponding frequencies. These findings underscore the idea that cortical representations are dynamic, continually shaped by sensory experience and deprivation, and that these dynamic map changes form the basis for experience-dependent behavioral effects, in both a positive and a negative sense.

IV. SOMATOSENSORY DEPRIVATION

The conclusions drawn in the preceding section on map changes in auditory plasticity apply in analogous ways to the effects of somatosensory experience and deprivation on the organization and reorganization of the somatosensory cortex. Partial denervation in monkeys by transection of peripheral nerves or at the level of the dorsal roots in the spinal cord leads to shrinkage in the corresponding cortical field representations and expansion of neighboring points, whereas increased peripheral stimulation causes the expansion of the corresponding representations. Just as in the auditory system, most work on somatosensory deprivation has been done on the effects of peripheral deafferentation. It is just as difficult to deprive the somatosensory system of its natural stimulation as it is to selectively deprive the auditory system, in contrast to the visual system in which this can be done so effectively.

One of the few classic examples in which somatosensory deprivation can be accomplished without deafferentation or neural injury is the clipping of whiskers in rodents. The effects of this procedure on the "barrel cortex," the representation of the whiskers in the somatosensory cortex, are noticeable but not as profound as after eradicating one of the whiskers altogether. The latter leads to a complete disappearance of the corresponding barrel, whereas clipping leads only to an attenuation or partial shrinkage of the barrel.

There are, however, several studies on the role of specific sensory experience that demonstrate the importance of peripheral stimulation for normal somatosensory development. Repetitive, long-term stimulation of a specific finger in monkeys leads to an expansion of that finger's representation in the somatosensory cortex. In syndactyly, a condition in which several fingers are pathologically joined at birth, receptive fields (RFs), as determined with MEG in humans, stretch across all of these fingers. When the fingers are surgically separated, the cortical MEG activation also begins to divide into separate zones. Experiments in monkeys in which several fingers were surgically joined together by suture have the opposite effect: RFs in the somatosensory cortex, which are normally well-separated into distinct finger representations, become larger and stretch across fingers. Once the fingers are separated, the RFs separate again as well. Coselection of coincident inputs according to Hebb's rule again is the principle after which the cortex becomes reorganized.

Whereas the results of these studies show that reorganization takes place largely at the cortical level (as in the visual and auditory systems), other experiments suggest that somatosensory subcortical structures, including the thalamus and spinal cord, can also be reorganized in response to deafferentation or

deactivation. Whether this occurs under cortical control is currently an active area of research. It will be interesting to determine whether a real difference exists between the somatosensory and the visual–auditory systems in that respect.

Cross-modal compensatory plasticity as described earlier for congenitally blind or deaf individuals, who show an improved representation of their other senses, is more difficult to discern with somatosensory deprivation because it is never complete. However, a rare form of severe pan-sensory neuropathy leads to an almost complete absence of proprioceptive input to the cerebral cortex. Imaging studies have shown that this somatosensory deprivation is partially compensated by increased visual activation in the parietal cortex.

V. CONCLUSIONS

Sensory deprivation studies in all three major modalities (visual, auditory, and somatosensory) demonstrate the importance of sensory experience for normal brain development. The activity-dependent reorganization of the brain (and in particular the cerebral cortex) follows rules postulated by Hebb for associative learning. In their most general form, these rules state that synaptic connections are strengthened in which the pre- and postsynaptic neurons are active together. Many modifications of these rules have been explored, in both theoretical models as well as experimental studies: Coactivtation is sometimes defined as a "firing together" of the neurons (as envisioned by Hebb) or merely as a joint rise in membrane potential. In addition to a strengthening of synapses by temporally coincident activation (long-term potentiation), a weakening of synapses by anti-correlation is now also generally accepted ("anti-Hebb," long-term depression). Both rules together also incorporate the important concept of synaptic competition, mentioned variously throughout this review, in which connections are strengthened (and maps expand) at the expense of others. Cross-modal compensation by the nondeprived senses is also a natural consequence of deprivation in one sensory modality, which is governed by the same rules for synaptic modification.

Sex Differences in the Human Brain

LAURA S. ALLEN and ROGER A. GORSKI
University of California, Los Angeles

GLOSSARY

critical period In terms of sexual differentiation, this is the period during perinatal life that levels of gonadal hormones impose permanent modifications on the structure and functional potential of the brain. It varies from species to species and between structures and functions.

interstitial nuclei of the anterior hypothalamus-3 (INAH-3) A cell group in the human brain that is about 2–3 times larger in males than in females or homosexual males. It is a possible homolog to the SDN-POA in the rat brain.

sexual differentiation The process by which structures and functions of the body and brain become different, largely as a result of circulating gonadal hormones.

sexually dimorphic A structure or function that is, on the average, different between males and females.

sexually dimorphic nucleus of the preoptic area (SDN-POA) A nucleus in the preoptic area of the rat that is about 5 times larger in males than in females; its size is determined by levels of gonadal hormones during perinatal life. This nucleus has served as the most studied model for the process of sexual differentiation.

Every school child knows that there is a difference between boys and girls and between men and women. What remains novel to many adults—to those in the general public as well as to many *biological* scientists—is that there are measurable sex differences in the human brain as well, in terms of both structure and function. Some of these differences have been well-established, whereas many more recent findings have not been consistently replicated or even replicated at all. Some of these studies, after publication in the popular press, have been used to form or support political and religious viewpoints. More importantly, however, they contribute significantly to our fundamental biological understanding of human development, educational issues, disease, variations in human sexuality, and the process of aging. Studies in laboratory animals have led to concepts about the biology of sex differences in the human brain. Clearly, it is not sociocultural factors in the rat cage that determine sex differences in maze performance and sexual behavior. However, in humans, the separation of biological factors, sociocultural influences, and the interaction of nature and nurture are more difficult to dissect, because we cannot experimentally manipulate the human being and because one's environment without question modifies certain sex differences in human behavior. Research findings of sex differences in the human brain demand replication. Even in studies of laboratory animals, subtle, even unrecognized differences in technical approach, subject selection, inherent biological variations, experimental design, and interpretation of the results may produce data that cannot be replicated or are contradictory to other findings. With research involving human beings this problem is increased by orders of magnitude. The format of this article necessitates statements without detailed citations. The generalizations in this review reflect the research

results that appear most predominantly and/or that are consistent with the prevailing concepts. The field of sex differences in the human brain should be further researched in part because many classic and very important studies are awaiting replication for the first time.

I. SEXUAL DIFFERENTIATION OF THE MAMMALIAN BODY

In the late 1940s, scientists began to understand the mechanism by which male and female mammals become different, or "sexually differentiate." In a landmark experiment, caesarian-like operations were performed early in the pregnancy of rabbits to expose their fetuses. The abdomens of the fetuses were then opened to remove their gonads, which had not yet differentiated into either ovaries or testes. The incisions in the fetuses and mothers were carefully stitched back together, and the pregnancies continued. After birth, all of the gonadectomized infants, whether genetic males or females, developed as normal-appearing females. Without the testes, even the internal sex organs of both the males and females were feminine. It was concluded that male development depends on male sex hormones called androgens, which are primarily secreted by the testes. Without androgens, regardless of genetic sex, the body develops in a feminine direction. Subsequently, pregnant female rabbits were injected with a drug called cyproterone acetate, which prevents the influence of the androgens on sexual development. Although the testes continue to manufacture androgens, this drug blocks testosterone's entrance into cells, thereby preventing its masculinizing influence. As expected, all of the infants born—even the genetic males—looked like females.

Scientists turned to the cattle industry to ask the opposite question: If a lack of testosterone results in the feminine development of genetic males, does the presence of testosterone result in the masculine development of genetic females? Usually cows have one calf per pregnancy, but on occasion twins or triplets are born. If the calves are both brothers or both sisters, they can grow up to be normal bulls and cows. But if the siblings are of opposite sex, the female is frequently masculinized by the androgens secreted by her brother *in utero*. These cows are known as *freemartins*. Although they are sexually normal on the outside, on the inside their ovaries, fallopian tubes, and uterus are usually stunted, and they may have internal male sex organs such as an epididymis and seminiferous tubules. Thus, these females exposed to testosterone were masculinized. Do these principles of sexual differentiation apply to humans as well?

II. SEXUAL DIFFERENTIATION OF THE HUMAN BODY

The sexual differentiation of the human body remarkably resembles that of the rabbit, cattle, and other mammals in that it is the level of androgens during a critical period of early development that determines the genital phenotype. Until the 8th week of fetal life, the female and male fetus look identical. Each fetus has all of the anatomical structures to become either male or female. On the inside of their bodies they have an identical gonad, which will become either an ovary or a testis. There are two pairs of ducts: *Müllerian ducts*, which form the female's internal reproductive organs (the fallopian tubes, uterus, cervix, and upper vagina), and the *Wolffian ducts*, which can form the male's internal reproductive organs (the epididymis, vas deferens, ejaculatory duct, and seminal vesicles). Normally, only one pair of these ducts actually develops; the other disappears. On the outside of their bodies the genitals appear identical. At about 8 weeks, however, sexual differentiation of the body begins. If the fetus is genetically male, then a gene on the Y chromosome called the sex-determining region of the Y chromosome (SRY) causes the undifferentiated gonads to become the testes. The testes begin to produce two hormones required for masculine development: Müllerian-duct-inhibiting hormone (MIH), a polypeptide that prevents the development of the Müllerian ducts, and the androgens, primarily testosterone, which promote the development of the Wolffian ducts. Testosterone is converted by the enzyme 5α-reductase to dihydrotestosterone (DHT) to masculinize the external genitalia, including the penis and scrotum. A baby boy is born. However, if there is no Y chromosome and no SRY, the gonad automatically becomes an ovary, and the fallopian tubes, uterus, vagina, and labia form. The baby is born a girl. Without testosterone, regardless of genetic sex, the fetus develops in the feminine direction. Metaphorically, the body is inherently female.

A. Variations in Sexual Differentiation of the Body

Although we cannot experimentally manipulate the sexual differentiation of human beings, we can turn to

individuals who, for medical reasons, have had altered hormone levels during development, such as those with genetic variations that result in either high or low levels of androgen action. Three commonly studied conditions include the androgen insensitivity syndrome, 5α-reductase deficiency, and congenital adrenal hyperplasia.

1. Androgen Insensitivity Syndrome (AIS)

This is a genetic variation whereby receptors for testosterone do not function. Because SRY is present, the gonads become testes. The testes secrete MIH, preventing the development of the Müllerian ducts. At puberty, the testes produce increasing amounts of testosterone, some of which is aromatized to estrogen, resulting in feminine breast development. In this case, the genetic male develops into a normal-appearing psychosexual female.

2. 5α-Reductase Deficiency

This genetic variation involves a deficiency in the enzyme 5α-reductase that converts testosterone into DHT, the hormone largely responsible for masculinizing the external genitalia. With a deficiency in DHT, the external genitalia appear feminine and the urethra may open into a vagina-like urogenital sinus. Because MIH is produced, the Müllerian ducts involute and the Wolffian ducts develop normally. At birth these children are often identified as girls; however, at puberty, rising levels of testosterone masculinize the body, including the external genitalia.

3. Congenital Adrenal Hyperplasia (CAH)

In contrast to AIS and 5α-reductase deficiency, which impair the masculinity of males, CAH results in exposure to high levels of androgens, thus masculinizing females. This rare genetic disease involves one or more defects in the enzyme system of the adrenal glands necessary for the synthesis of cortisol. Cortisol normally provides negative feedback to the hypothalamo–hypophyseal axis. However, with reduced cortisol and, thus, reduced negative feedback, there is excess secretion of adrenocorticotropic hormone, stimulating the adrenal cortex to increase steroidogenesis and resulting in the excessive formation of adrenal androgens both before and after birth.

Like other female fetuses, those with CAH exhibit normal development of the Müllerian ducts with regression of the Wolffian system. However, their clitoris may be so masculinized that it appears to be a penis, and they are sometimes mistakenly identified at birth as boys. Their external appearance is usually corrected surgically, and both boys and girls with this syndrome are given life-long medication to control their condition.

III. SEXUAL DIFFERENTIATION OF THE BRAIN OF NONHUMAN MAMMALS

Because the reproductive organs that are required for bisexual reproduction are sexually dimorphic, it is logical that the brain, *which controls the behavior and hormonal regulation of bisexual reproduction*, also exhibits sex differences. In fact, a similar process of sexual differentiation that occurs in the body and reproductive organs in animals including humans has been well-established to occur in the *brains* of many animals, including amphibians, birds, and mammals. With respect to mammals, high levels of sex hormones —whether secreted by the testes or administered by a scientist—result in masculine brain development; low levels of androgens result in sexually dimorphic brain functions and structures that remain feminine.

A. Gonadal Hormones Influence the Brains of Nonhuman Mammals

Rats are the most studied species in terms of sexual differentiation of the brain. The principles that have been observed in rats often apply to other species and have stimulated studies in other animals, including human beings. The most studied functions controlled by the brain that differ between males and females are reproductive physiology and sexual behavior.

In terms of reproductive physiology, the female rat has a 4-day ovarian cycle. At first, the ovaries secrete increasing amounts of estrogen that result in an abrupt surge of leutinizing hormone-releasing hormone from the brain, causing the release of leutinizing hormone from the pituitary, which in turn triggers ovulation. This process is termed *positive feedback*. Positive feedback is not present in the normal adult male rat, even when given injections of estrogen; testosterone early in life has permanently prevented positive feedback in response to estrogen. Similarly, males and females exhibit differences in partner preference and sexual behavior. In rats, basic sexual behavior involves mounting and penile intromission by the male and an arching of the back, termed lordosis, in the female.

1. Historical Perspective

In the late 1930s and early 1940s, a series of experiments was performed in newborn rats: in males the testes were removed and replaced with transplanted ovaries; in females the ovaries were removed and replaced with testes; and in some pups, additional gonads were added so that they had both ovaries and testes. When these rats became adults, the males with ovaries and no testes displayed the female ability to produce corpora lutea, whereas those with both ovaries and testes failed to form any corpora lutea. Among the females with intact ovaries and transplanted testes, many failed to either show estrous cycles or form corpora lutea. From these results it was deduced that, regardless of genetic sex, if testosterone was present during a critical period, then in adulthood the *pituitary* would produce secretions in the noncyclic male mode, and if testicular androgens were *absent* during early life, then in adulthood the pituitary would be cyclic and feminine in nature.

However, the hypothesis that androgen levels had sexually differentiated the pituitary was challenged by the observation that when the pituitary of a male rat was transplanted under the hypothalamus of a female, her reproductive functions remained feminine. Likewise, when the pituitary of a female was transplanted under the hypothalamus of a male, his reproductive functions remained masculine. These experiments suggested that it was not the pituitary but the *brain* that was subject to sexual differentiation by levels of testosterone during early life.

By the late 1950s it was demonstrated that sexual differentiation of the brain not only applied to physiology but to behavior as well. Pregnant guinea pigs injected with large quantities of testosterone propionate (TP) during pregnancy gave birth to females with external genitalia that were macroscopically indistinguishable from those of their brothers. In addition, these females demonstrated a reduced capacity to display lordosis and an increase in mounting behavior. Thus, it was concluded that gonadal hormones influence the brain during both development and adulthood. Such effects have been distinguished into two categories: organizational and activational. Androgens act to *organize* the brain during perinatal life to impose permanent modifications in sexually dimorphic structures and functions. The mechanisms of organization include the growth of nerve processes, prevention of neuronal death, and promotion of differentiation. In adulthood, gonadal hormones exert *activational* effects, which involve more transient, reversible, and modifiable influences that may include temporary changes in structure and neurotransmitter systems and the regulation of ovulation and sexual behavior. The ability of a male or female rat to exhibit sex-stereotyped sexual behavior is first determined during development by the organizational influence of gonadal hormones, but later activated in adulthood by circulating levels of sex steroids.

A close relationship has long been observed between reproduction and the external environment. The female reproductive cycle in a variety of mammals studied thus far is influenced not just by early hormone exposure but also by a wide range of environmental factors, such as by light, diet, temperature, and emotional stress. Moreover, electrical stimulation of the hypothalamus can induce ovulation, and lesions of the hypothalamus can block ovulation. Thus, in adulthood, the environment can influence sexually dimorphic functions in the brain.

B. Structural Sex Differences in the Brain

In the last three decades, it has been established that there are not just functional sex differences but also anatomical sex differences in the brain. These structural differences in all species studied thus far are influenced not by genetic sex directly but by sex hormones primarily during development and occasionally during adulthood. The discovery of sexually dimorphic structures in regions controlling sexually dimorphic functions has served as a springboard for the concept that such structures may underlie differences in physiology and behavior.

1. Historical Perspective

In the early 1970s the electron microscope was used to observe a structural sex difference in a region of the brain called the preoptic area (POA) located in the anterior hypothalamus that is involved in sexual and reproductive functions. This difference involves synaptic input from various regions of the brain other than the amygdala to the POA: in the normal female, the number of nonamygdaloid synapses in dendritic spines in the POA is greater than in the male. This sex difference in brain structure, like that of brain function, follows the principles of sexual differentiation: castration of the male within 12 hr after birth causes a female pattern in the number of spine synapses and permits the cyclic pattern of gonadotropin release and the ability to show a progesterone-

facilitated increase in receptivity. Likewise, females treated on day 4 of life with TP have a masculine number of spine synapses and tonic gonadotropin release. Thus, for the first time, it was shown that there is a *correlation* between sexually dimorphic functions and structures of the brain, not necessarily because these structures determine these functions but because the same factor, the level of androgens during perinatal life, determines whether the brain develops in a masculine or feminine direction for both functional and structural characteristics.

In rapid succession came reports of more neuroanatomical sex differences: in the dendritic branching patterns of neurons in the preoptic area of the rat, hamster, and macaque monkey; in the synaptic organization of the arcuate nucleus and the medial amygdala of the rat; and in the volumes of nuclei in the bed nucleus of the stria terminalis of rats and guinea pigs and in the preoptic area of gerbils, guinea pigs, ferrets, quail, and rhesus monkeys. Sexual dimorphism also exists in regions of the brain apparently not directly related to reproduction: in rats there are sexually dimorphic patterns of cortical and hippocampal asymmetries; and possibly in the number of axons, extent of myelination, and size and shape of the corpus callosum. At the molecular level, there are sexual dimorphisms in terms of neurotransmitter systems and receptors for gonadal hormones, in regions of the brain that both do and do not influence reproductive functions.

Perhaps the most studied sexual dimorphisms are in terms of the volumes of several nuclei that are present in regions of the brain related to reproductive functions. Several sexually dimorphic cell clusters control vocal behavior in canaries and zebra finches. In these species, males sing and females do not, and the male possesses a network of vocal nuclei that is as much as 6 times larger than that of females. In the rat, there is a distinct nucleus in the preoptic area, called the sexually dimorphic nucleus of the preoptic area (SDN-POA), that is about 5 times larger in males. In the spinal cord of rats, there is a sex difference in the number of motor neurons in the spinal nucleus of the bulbocavernosus (SNB), which innervates penile muscles.

2. The Medial Preoptic Area (MPOA) and Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA)

The most studied sexual dimorphism in the mammalian brain is the SDN-POA in the rat, located in the medial preoptic area (MPOA) of the anterior hypothalamus. The SDN-POA is sexually dimorphic in terms of both volume and the number of neurons. The MPOA influences sexually dimorphic functions in both rodents and primates, including gonadotropin regulation and maternal and sexual behavior. Although we still do not know the function of the SDN-POA, there is a *correlation* in terms of the volume of this structure and male sexual behavior. This correlation exists because gonadal hormone levels in the brain during a critical period determine whether brain function and structure develop in a masculine or feminine direction.

Like other sexually dimorphic areas in the body and brain, the cells of the SDN-POA contain receptors for steroid hormones. In the presence of testosterone during a critical period of early life, the SDN-POA develops into a larger structure typical of males; relatively low levels of androgens result in a smaller structure typical of females. It is believed that androgens are required during a critical period to prevent cell death of the young neurons within the SDN-POA; likewise, steroid hormones influence the survival of neurons during development in other sexually dimorphic structures in the CNS of various species, probably including the human being.

Scientists, by altering the androgen levels during perinatal life, have determined the critical period of sexual differentiation of the SDN-POA to be between day 18 of gestation and day 5 after birth. Castration of the newborn male rat produces a reduction in the volume of the SDN-POA in adulthood that can be completely prevented by the administration of androgen 1 day later. Similarly, a single injection of TP into a newborn female significantly increases the volume of the SDN-POA in adulthood. Moreover, the volume of the SDN-POA can be *completely* sex-reversed in males by prenatal antiandrogen injections and castration on day 1 and in females by pre- and postnatal testosterone injections.

The mechanisms by which androgens act to masculinize structures and functions vary. For example, the external genitalia are sexually differentiated by the conversion of testosterone to DHT; in the SDN-POA and other structures, testosterone is aromatized to estrogen within the neurons. Therefore, injection(s) of estradiol benzoate or diethylstilbesterol can masculinize the SDN-POA in the female. The volume of the SDN-POA in the adult rat does not appear to depend strongly on gonadal hormones; however, adult levels of gonadal hormones do influence the volumes of other sexually dimorphic structures, such as certain spinal cord nuclei in the rat, an apparent SDN-POA

equivalent in the gerbil, and nuclei involved in singing in canaries and finches.

The critical period of sexual differentiation of the brain is after that of the body. Therefore, by manipulating sex hormones in laboratory animals during the period of sexual differentiation of the brain, one can have an individual with a body concordant with the genetic sex but a brain, in terms of both structure and function, characteristic of the opposite sex. Similarly, the critical periods of sexual differentiation of the brain vary between structures and functions and from species to species. It is essentially unknown when during perinatal life the sexual differentiation of the human brain occurs.

IV. SEXUAL DIMORPHISM IN THE HUMAN BRAIN

A. Sex Differences in Overall Brain Size

For over a century, it has been known that the brains of men weigh about 15% more than those of women. Historically, this anatomical dimorphism had been used to promote the notion of intellectual dimorphism, with a larger brain positively correlating with greater intelligence; however, the functional significance of sex differences in brain weight is unknown. In fact, the functional significance of every anatomical sex difference in the human brain identified thus far is unknown. The generally accepted explanation for sexual dimorphism in brain size is that it is dependent upon body size. However, brain size, although correlated with body size, is determined by other factors as well. For example, sex differences in brain size actually precede sex differences in overall height. Brain size is similar between boys and girls until 2 or 3 years of age, at which time it grows at a faster rate in boys until 5 or 6 years of age, when most of the full brain weight is achieved. The sex difference in brain size then remains relatively constant despite the fact that a sex difference in height increases throughout adolescence. Increases in gross brain weight, which may occur earlier in boys, do not necessarily correlate with brain *maturation*; in fact, *functional* differences between boys and girls during childhood and adolescence suggest that the brains of girls may actually mature earlier than those of boys.

Reports suggest that, overall, there are more neurons in the brains of men than in those of women. However, in certain regions, there are reports that women may contain more brain cells and/or neural activity than men: (1) a greater density of neurons in the planum temporale was found in women; (2) in cortical regions involved in verbal behavior, magnetic resonance imaging demonstrated that women had a greater percentage of gray matter in the dorsolateral prefrontal cortex and in the superior temporal gyrus; and (3) in certain regions women exhibit greater cerebral blood flow rate and regional cerebral glucose metabolism. However, more brain cells or neural activity does not necessitate higher brain functioning. For example, the developing human contains more neurons than the adult; however, the infant is not more neurologically capable than the adult until he or she matures through dramatic cell loss and the development of considerable connectivity.

B. What Causes Sexual Dimorphism in the Human Brain?

The presence or absence of gonadal hormones during a critical period of early life determines the sexual differentiation of the genitalia in nonhuman and human animals and of the brains of nonhuman animals. However, the role of steroid hormones in the sexual differentiation of the human brain is less understood for two reasons: (1) until relatively recently, there were few reports of sex differences in the human brain, and (2) we cannot experimentally manipulate the brains of humans during perinatal life to determine hormonal influence on structure and function.

Therefore, scientists searched the human brain for anatomical sex differences so that later the identified sexually dimorphic structures could be examined in individuals who may have been exposed to altered hormone levels during early life, including those with AIS, 5α-reductase deficiency, and CAH, and in individuals who exhibit altered sexually dimorphic behavior such as homosexuals and transsexuals, who may also have been exposed to atypical gonadal hormone levels during development.

C. Sex Differences in Regions Related to Reproduction

Because much has been learned about the SDN-POA in the rat, researchers attempted to identify a human homolog. From autopsy samples, hypothalamic areas were age-matched and prepared much like those in the rat studies. The search for the "SDN-POA" in the preoptic–anterior hypothalamic area in the human

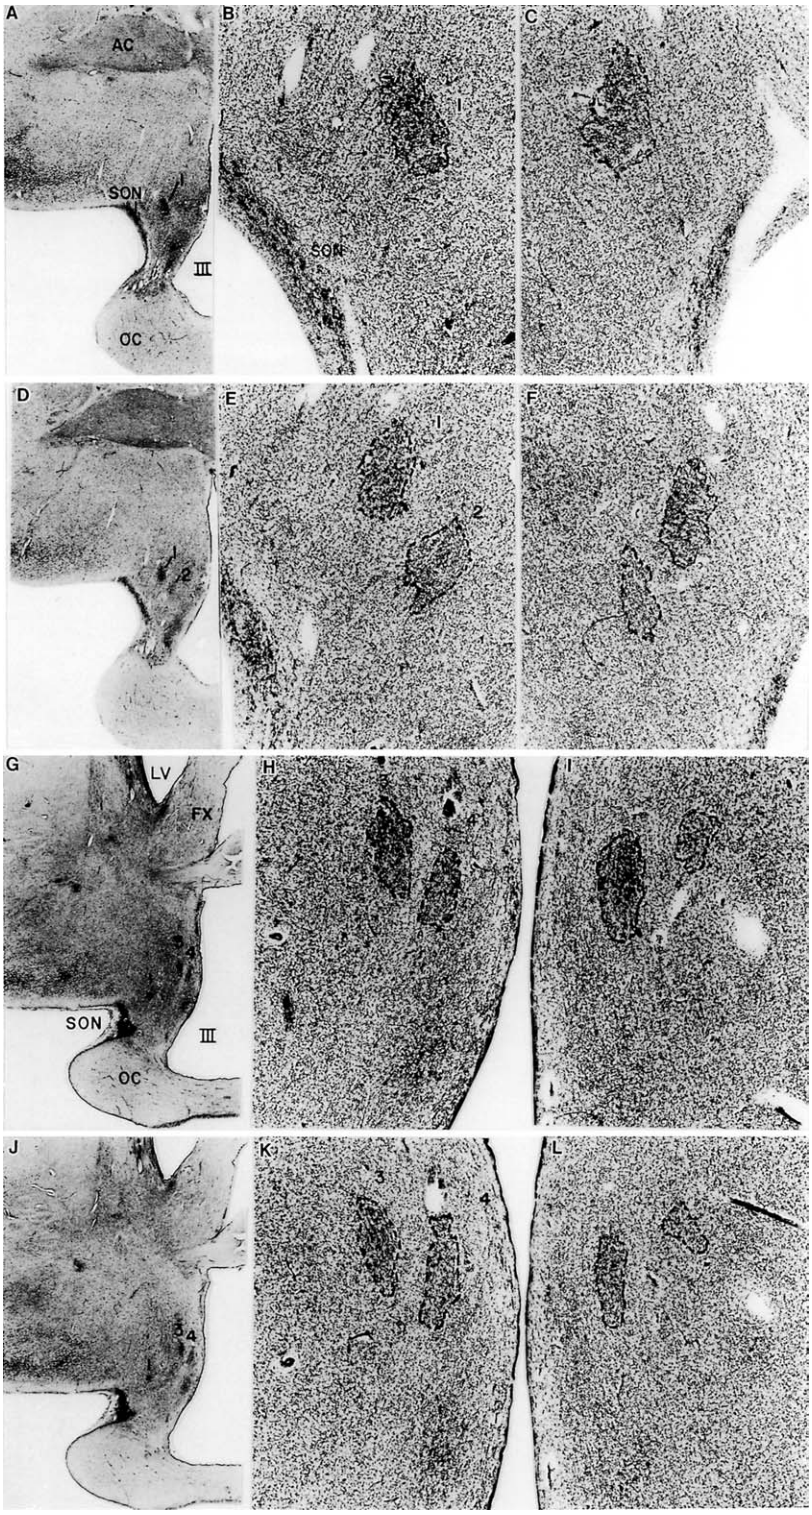

Figure 1 (A–F), Photomicrographs of thionin-stained coronal sections of the anterior hypothalamus in the human brain. A, D, G, and J are photomicrographs from a 58-year-old male, from anterior to posterior. B, E, H, and K are higher power photomicrographs of A, D, G, and J, respectively. Likewise, C, F, I, and L are female counterparts to B, E, H, and K, respectively, from a 63-year-old woman. JAI Press, a subsidiary of Elsevier Science.

resulted in the quantification of four nuclei that were termed the interstitial nuclei of the anterior hypothalamus 1–4 or INAH 1–4. INAH-2 and INAH-3 were 2–3 times larger in males (Figs. 1 and 2). Interestingly, in a very small sample it appeared that the sex difference in INAH-2 might be related to reproductive age.

Subsequently, the human bed nucleus of the stria terminalis was examined for sexual dimorphism because this area was found to be sexually dimorphic in several rodent species. Like the SDN-POA of the rat, this area has been implicated in sexually dimorphic functions, including gonadotropin regulation and sexual and maternal behavior, it concentrates gonadal hormones, and it is anatomically connected to several other sexually dimorphic regions including the MPOA. A region termed the darkly staining posteromedial region of the bed nucleus of the stria terminalis (BNST-dspm) is about 2.5 times larger in males than in females (Fig. 2).

1. Is INAH-1 the SDN-POA?

In one laboratory, a sex difference has been reported in several studies in the volume and cell number of the intermediate nucleus of the hypothalamus, subsequently called the SDN-POA and INAH-1. Because this nucleus was found to be 2–3 times larger in males than in females and is located in an area similar to the SDN-POA of rats, this laboratory named it the SDN-POA of the human. Several other laboratories have found neither INAH-1 nor INAH-2 to be sexually dimorphic. The discrepancy in findings might be partly due to the fact that INAH-1 undergoes dramatic

changes in volume and cell number throughout life, beginning at birth, and the rate at which this process occurs during adulthood is greater in males. Discordant findings in terms of the sexual dimorphism of INAH-1 remind us how vulnerable human brain research is to variations among individuals, ranging from nuances in the environment to something so fundamental as age. Indeed, examination of particular age groups or the failure to age-match males and females could contribute to a variation in results.

The suprachiasmatic nucleus (SCN) is reportedly more *elongated* in women and more *spherical* in men. Unlike the INAH, the SCN has a known function—to participate in the regulation of circadian rhythmicity. Indeed, certain circadian cycles are regulated differently in males and females. The SCN, like the INAH 1–4, has been examined for differences between heterosexuals and homosexual men, and an intriguing result was obtained (see later discussion).

2. Sexually Dimorphic Neural Circuits

In the rat, there appears to be a sexually dimorphic and interconnected network that begins with incoming chemical information from the environment to the vomeronasal organ that projects to the medial amygdala, which in turn projects to the BNST and the MPOA. Interestingly, each structure in this neural circuit appears to concentrate gonadal hormones and to be sexually dimorphic. Indeed, such a neural circuit is possibly present in human beings and may include the BNST-dspm, INAH-3, and other as yet unreported regions in the vomeronasal organ and medial amygdala.

3. Other Nuclei Located in Regions Related to Reproduction

Perhaps the only sexual dimorphism in the human nervous system with a known function is Onuf's nucleus, called the SNB in rats, which is located in the sacral spinal cord of dogs, cats, and primates and which innervates striated penile muscles, including the bulbocavernosus and ischiocavernosus muscles. In the homologous nucleus in rats, androgens have been shown to save the neurons of this nucleus from cell death during perinatal life. In humans, there was a significant decline in motoneuron number during a period of gestation that coincides with the initiation of androgen production by the human fetal testes, suggesting, perhaps, that levels of androgens in humans as well may determine this sex difference by altering cell survival during early life.

D. Sexual Dimorphism in Regions of the Brain Not Related to Reproduction

In contrast to sexually dimorphic structures in regions related to reproductive function that exhibit little overlap between males and females, those in areas with no currently known sexual function appear to exhibit considerable overlap between the sexes and, thus, require larger sample sizes to demonstrate differences. There are sex differences in non-reproductive regions, including the cerebral cortex and structures that connect the two hemispheres.

1. Structures Connecting the Two Hemispheres

Communication between the two hemispheres of the brain is limited to several structures, three of which have been reported to be sexually dimorphic, including the massa intermedia (MI), corpus callosum (CC), and anterior commissure (AC). In contrast to the sexually dimorphic nuclei that are larger in males, each of these structures has been reported to be larger, shaped differently, and/or more often present at the midsagittal plane of the brain in females.

2. The Corpus Callosum (CC)

The major communication between the two hemispheres of the brain is orchestrated by the CC, which is composed of axons that cross the midline. In the early 1980s researchers reported that the CC at the midsagittal plane exhibits sexual dimorphism. In a small sample of 14 brains, they found that the *shape* of the posterior part of the CC, the splenium, was sexually dimorphic: it was more bulbous-shaped in women and more tubular-shaped in men, and the maximum splenial width was greater in women. However, there was no significant sexual dimorphism in terms of *size*: the area of the splenium, defined as the posterior one-fifth of the CC, was *nonsignificantly* larger in females (Figs. 3A and 3B).

Despite many subsequent studies, the findings of sexual dimorphism of the CC have remained controversial for several reasons: (1) Measurements have been performed in different ways in various laboratories, in part because published reports frequently do not describe methodology in detail. Moreover, approaches to the measurement of the CC rely primarily on measures based on arbitrary subdivisions, which may mask the particular regions that exhibit the greatest dimorphism by including areas that exhibit no difference. For example, some researchers have

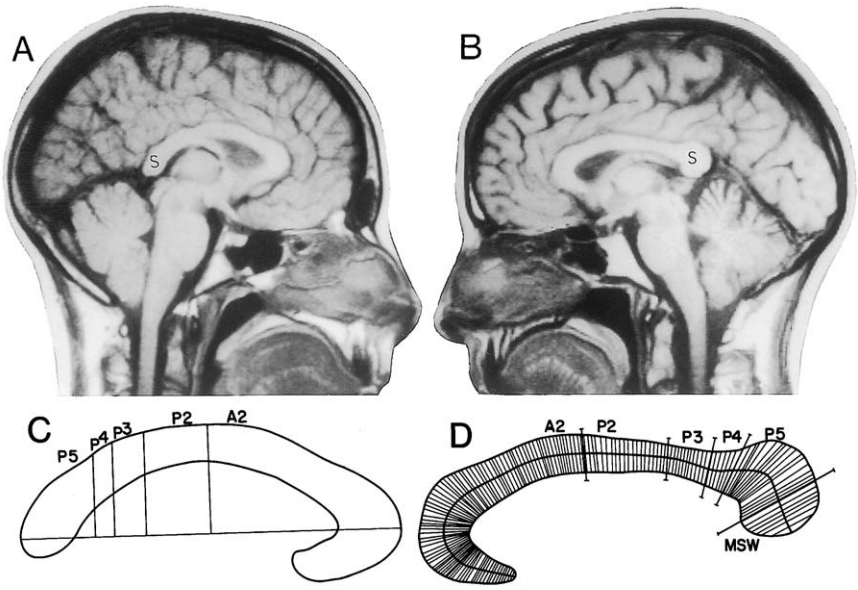

Figure 3 Magnetic resonance images of midsagittal sections of the CC through a male (A) and a female (B) brain demonstrating, in this pair, a difference in the shape of the splenium (S), and the "straight-line" (C) and "curved-line" (D) methods of dividing the CC into sections. Other abbreviations: P5, posterior fifth; P4, posterior fourth; P3, posterior third; P2, posterior half; A2, anterior half; MSW, maximum splenial width. Reprinted and modified by permission from Allen, L. S., Richey, M. F., Chai, Y. M., and Gorski, R. A. (1991). Sex differences in the corpus callosum of the living human being. *J. Neurosci.* **11**(4), 933.

partitioned the CC on the basis of its most anterior and posterior points utilizing a "straight-line method" (Fig. 3C), whereas others partitioned it on the basis of its curvature, utilizing a "curved-line method" (Fig. 3D). Although neither method is correct or incorrect, both methods arbitrarily partition the CC into slightly different components. (2) Despite age-related changes during childhood and adulthood, few investigators have explicitly age-matched subjects. (3) The shape and size of CC vary considerably among individuals, requiring large sample sizes to demonstrate significant sex differences. (4) Many people overinterpreted the original report of a *nonsignificantly* larger splenium in females to mean that the splenium *is* significantly larger in women. At its extreme, the original report was interpreted to suggest that the overall area of the CC is larger in women, and thus there is greater connectivity between the two hemispheres in females. (5) It can be difficult to obtain a precisely midsagittal section of the CC, resulting in less accurate results. Although some studies do find the splenium to be larger and/or shaped differently in women, most studies agree that one cannot correctly classify every brain as either male or female on the basis of the size or shape of the CC. In the literature, controversy remains as to whether the absolute overall midsagittal area of the CC is significantly larger in males, essentially similar in males and females, or significantly larger in females particularly when adjustments are made for sex differences in brain size.

The functional significance of differences in the CC remains unknown. It has been suggested that a larger CC subregion might reflect more axons connecting the two sides of the brain, corresponding to more cerebral symmetry. However, a sex difference in the midsagittal area of the CC does not mean that there is a sex difference in the number of axons. Moreover, more axons do not necessarily correspond to greater cerebral symmetry. Variations in (areas of) the CC could correspond to differences in myelination, differences in the number of fibers, and/or a varying arrangement of axons coursing through the CC. For example, in the splenium of rats, there are more axons in females but more myelinated axons in males, resulting in an area similar in males and females. In rhesus monkeys there is an approximately 2-fold variation among animals between the density of axons and the midsagittal area of the CC; therefore, there is no correlation between the area of the CC and the number of axons. In contrast, several human studies did not find a sex difference in the number of fibers per area when examining relatively larger fibers. However, smaller,

unmyelinated axons, whereas functionally quite significant, are difficult to measure in post mortem human tissue. Thus, the number of larger, more easily quantifiable axons does not necessarily indicate the quantity of connections between the hemispheres.

3. The Massa Intermedia (MI) and the Anterior Commissure (AC)

For decades, it has been observed that the MI is more often present in women than in men. In addition, the MI is larger in women whether all males are considered or only those that possess an MI (Fig. 2). It is possible that the sex difference in the MI is due to a progressive involution of the MI that occurs with age more rapidly in males than in females. If true, then the younger the subjects that are examined, the less of a sex difference that may be found. Although the functional significance of these differences is unknown, pneumoencephalograms demonstrated that men without an MI exhibited higher performance on the nonverbal portion of the *Wechsler–Bellevue Intelligence Scale* than men with this structure, although no association was seen in women.

In addition, the midsagittal area of the AC is reportedly larger in women, although not all studies agree (Fig. 2). It is unclear whether sex differences in the MI and AC are due to the number of axons, the thickness of myelination, or, in the case of the MI, the number of neurons, glia, and connective tissue in the thalamic nuclei that are present at the midsagittal plane. The AC of the primate brain is a tract of axons that primarily connects the left and right neocortices. In a small sample of human subjects, variations in the area of the AC reflect differences in the number of axons but not their density. In contrast, in a study of rhesus monkeys, the midsagittal surface area of the AC did not correlate strongly with the number of axons.

E. Hemispheric Specialization

The two hemispheres of the human brain exhibit differences in anatomy and function by birth that continue throughout life. An anatomical or functional difference between the two hemispheres is termed *hemispheric specialization* or *cerebral lateralization*. The greater involvement that a given hemisphere has for a given structure or function relative to the opposite hemisphere, the more lateralized or specialized it is said to be.

In terms of hemispheric specialization, anatomical differences appear to underlie functional differences. In most people, the overall size of the right hemisphere is larger than that of the left, although particular regions, such as those involved in language, may be larger on the left side. In terms of function, electrophysiological studies show that most infants exhibit left-ear superiority for musical stimuli and right-ear superiority for verbal stimuli. As one matures, the left hemisphere of a majority of right-handed people is involved in language, the execution of learned manual activities such as handwriting, and analytical, symbolic, logical, and abstract thinking. In contrast, the right hemisphere has a greater role in emotion, perceptual, literal, concrete, wholistic, and synthetic thinking, and the processes of visual imagery—the kind in which a single picture or mental image is worth a thousand words.

There are also *sex differences* in both the anatomy and function of hemispheric specialization. The left planum temporale is generally larger than its right hemisphere counterpart. However, as a group, there is greater symmetry of the planum temporale in women: more females have significantly less leftward asymmetry, and more females have a reversed pattern of asymmetry with a larger right planum temporale. The planum temporale is one of the regions of the brain involved in verbal abilities: in women, the tendency for greater symmetry of the planum temporale may underlie greater symmetry of language function.

Likewise, the primary transverse gyrus (Heschl's gyrus), which contains the primary auditory cortex, exhibits sexually dimorphic patterns. Normally, Heschl's gyrus arches onto the lateral surface of the superior temporal gyrus more frequently on the left than on the right hemisphere; however, it does so more often in men than in women. In addition, there are sex differences in the pattern of the fissurization of the Sylvian fissure.

The results of studies suggest that males have greater cerebral lateralization for both verbal and nonverbal functions than do females. Data supporting this contention come from three sources: (1) studies that involved IQ tests administered to people following stroke or tumor confined to one hemisphere have demonstrated sexually dimorphic patterns in cognitive deficits; (2) psychological tests that assess the functioning of both hemispheres suggest dimorphisms in hemispheric processing; and (3) more recently, *in vivo* imaging techniques such as positron emission tomography (PET) and functional MRI (fMRI) demonstrate hemispheric dimorphism during certain task performances.

Following unilateral brain damage by stroke, trauma, or surgical removal, there are sex differences in the pattern of impairment on the performance intelligence quotient (PIQ) and verbal intelligence quotient (VIQ) components of the *Wechsler Adult Intelligence Scale* (*WAIS*). In most adults, damage to the left hemisphere impairs VIQ more, whereas damage to the right side decreases PIQ to a greater extent. The IQ deficit in either the VIQ or PIQ, depending upon which hemisphere is damaged, is much greater in males than in females. Males exhibit a greater reduction in either the VIQ or PIQ because each hemisphere is more specialized for that particular function. In females, because both hemispheres have a similar functional role, damage to either hemisphere impairs VIQ and PIQ to a similar extent; moreover, the opposite, undamaged hemisphere, which possesses both verbal and visuospatial capacities, can compensate for the loss to a greater extent than in males.

Some psychological studies such as tachistoscopic, dichotic, and monaural listening experiments, and EEG analysis and magnetoencephalographic (MEG) auditory evoked fields combined with neuropsychological test performance, suggest greater functional hemispheric specialization in males. Similarly, some fMRI and PET studies during language tasks also show sex differences depending on the particular language task tested.

In addition to the tendency for women to exhibit more functional symmetry between hemispheres, there are also sex differences within a single hemisphere, determined by patterns of hemispheric cerebral metabolism using PET and fMRI. For example, particular language and praxic functions may be represented more diffusely within the left hemisphere in males. Likewise, males exhibit auditory evoked fields more anteriorly within the superior temporal lobes, particularly in the right hemisphere. By using fMRI, brain activation in males is found to be lateralized to the left inferior frontal gyrus, whereas in females the pattern of activation engages a more diffuse neural system that involves both the left and right inferior frontal gyri. However, there are discrepancies between different studies, which may be due to the particular test given.

F. Handedness

A complex relationship exists between sex, handedness, and brain organization. Most right-handed people have left-sided language lateralization and right hemisphere specialization for visuospatial processing, whereas as many as half of left-handed people have right-sided language dominance and left-hemisphere visuospatial processing. Less than 1% of right-handed people have the reversed pattern, whereas about half of left-handed people exhibit such a reversal.

These patterns exhibit sex differences. In terms of function, right-hemispheric language localization is more frequent in left-handed females than in left-handed males. Additionally, there are anatomical relationships between sex and handedness: (1) The structure of the Sylvian fissure correlates with handedness in men but not in women. In contrast to the generally held view that right-handed males have greater cerebral asymmetry, consistently right-handed males have longer horizonatal segments in both hemispheres than males that use the left hand for certain tasks. (2) Right-handed men and left-handed women, in comparison to left-handed women and right-handed men, have stronger rightward asymmetry of the planum parietale. (3) The planum temporale exhibits less leftward asymmetry in females and left-handed individuals than in right-handed males.

G. The Corpus Callosum, Cerebral Lateralization, and Handedness

Relationships exist between the areas of particular regions of the CC, handedness, and cerebral lateralization. In the 1980s Sandra Witelson identified the most consistent and convincing sex difference in the CC to date: certain regions vary in midsagittal area with *handedness* in a sexually dimorphic manner. In these studies, subjects were given a questionnaire to determine not just which hand they used to write with but which hand they used to perform a variety of other tasks, including drawing, brushing their teeth, throwing a ball and using scissors. Subjects were classified accordingly as consistent right-handers (CRH) (those who use their right hand to perform each item on the questionnaire), left-handers (LH), and nonconsistent right-handers or mixed-handers (NCRH) (those who use their left hand to do at least one of the tasks). In males, the CC is larger in NCRH and LH, who also have greater cerebral symmetry than CRH in a posterior region of the CC called the *isthmus* that connects the posterior parietal and temporal cortical regions. Similarly, regions of the anterior CC were larger in LH males than in CRH males. In contrast, in females, regions of the anterior CC were larger in CRH than in LH. This is reminiscent of rats, where

left-biased animals exhibit the greatest sexual dimorphism in the size of the CC.

If there are sex and handedness dimorphisms in the CC, then there may be corresponding differences in regions of the cerebral cortex with which these dimorphic areas of the CC interconnect. Some researchers have suggested that a larger region of the CC correlates with greater symmetry. Thus, there would be an inverse relationship between interhemispheric connectivity (as defined by the area of a region of the CC) and cerebral asymmetries. Such negative correlations have been reported in the following regions of the CC and the cerebral cortex: the size and total number of fibers of the isthmus and the Sylvian fissure (planum temporale) asymmetry in males but not in females; the population of relatively large fibers in the isthmus and pre-Sylvian asymmetry in males but not females; the number of fibers in the splenium and the value of Sylvian fissure asymmetry in females; and the size of the midbody of the CC and Sylvian fissure asymmetry in males but not females. The hypothesis that the greater connectivity between the two hemispheres correlates with a more symmetric brain is explained somewhat by the assumption that the axons of the CC connect structurally homologous regions of the cerebral cortex such that asymmetric brains with fewer homologous regions would, therefore, have fewer connections coursing through the CC. However, this hypothesis has not been demonstrated anatomically.

Irrespective of sex, there are correlations between the size of areas of the CC and cerebral lateralization: the CC was found to be larger in subjects with right-hemisphere speech dominance; the posterior CC, including part of the splenium, correlated with language symmetry; and the CC correlated with measures of asymmetry in dichotic listening performance in some, but not all, studies.

H. Sex Differences in Cognition

Sex differences in cognitive measures have been documented for several decades. In general, males perform better on tasks of visuospatial skills, such as the alignment of a rod to the vertical, left–right discrimination, mental rotation, point localization, and disembedding figures, and mathematical reasoning. Females, on average, score higher on tests of language fluency, grammar, speed of articulation, phonetics, and fine motor skills. The mean differences in performance between the sexes typically are not large, and individual male and female scores show extensive overlap; however, the sex differences are reliable for certain tests and are statistically significant when large enough samples are considered.

Perhaps the most striking cognitive sex difference is seen in male and female adolescents with outstanding *Scholastic Aptitude Test* (*SAT*) scores involving mathematical reasoning ability. The more outstanding the student, the greater the male prevalence. Among the top students examined, the ratio of boys to girls climbed to 13:1. Researchers have been unable to identify any *environmental* factor that accounts for this difference.

An understanding of sex differences in cognition is probably of little practical importance in terms of the individual person; moreover, it must be remembered that stereotypes applied to any given individual can be damaging. However, the knowledge regarding sex differences may have major theoretical significance in terms of understanding brain development and the physiology of cognition. Whereas the dissection of nature and nurture for these differences is difficult, there is considerable evidence that cognitive sexual dimorphism is not dependent entirely upon sociocultural factors and is at least partly innate.

(1) Certain sex differences are exhibited early in life. For example, in newborn infants, girls spend more time than boys making eye contact with a silent adult caregiver, and only in females did the eye contact increase when the person was speaking. (2) Sex differences are observed in complex learned behaviors in laboratory animals, such as maze learning in rats, that cannot be explained by cultural influences. (3) In a "natural experiment" provided by "Women in the Kibbutz" in Israel, the women chose to go against the ideology of their communities in search of traditional female roles. (4) Performance in motor and spatial–perceptual skills fluctuates across the menstrual cycle, implying an influence of sex hormones during adulthood. (5) Some sex differences interact with factors associated with neurological variations. For example, although men perform better on certain spatial–perceptual tests, spatial ability is associated with hand preference, which in turn correlates with cerebral asymmetry, and this relation differs between the sexes. Likewise, right-handed men performed better on spatial tasks than left-handed men, with the reversed pattern for women with *above* average reasoning ability. (6) Various neuropsychiatric disorders such as schizophrenia, autism, and developmental dyslexia exhibit marked sex differences in incidence, symptoms, and possibly etiology.

I. Connections: Hormones, Anatomy, Hemispheric Specialization, Handedness, and Cognition

There are correlations between sex differences in gonadal hormones, anatomy, hemispheric specialization, handedness, and cognition. Hypothetically, gonadal hormones during perinatal life result in sex differences in anatomy, both in terms of the connectivity between the hemispheres and in the structure of regions within the cerebral cortex. In turn, these anatomical differences underlie functional differences in cerebral lateralization that may lead to differences in handedness and cognition.

In nonhuman animals, perinatal hormone levels appear to influence cerebral lateralization. Hormonal manipulation influences structural aspects of lateralization in rats and asymmetrically represented motor skills in songbirds. The mechanism by which early hormone levels affect cerebral lateralization is unknown. However, studies during the development of both rats and monkeys have identified asymmetries in testosterone receptors in regions of the cerebral cortex. It is unknown how or why such asymmetries for testosterone receptors arise. If asymmetries in testosterone receptors are also present in the developing human cerebral cortex, this may explain why males in general have greater cerebral lateralization.

The number of neurons in any region of the brain depends upon the number initially produced during proliferation and that survive early cell death. Testosterone, known to influence both cell survival and cell death in laboratory animals, might similarly affect the number of neurons in the developing human cerebral cortex. Thus, a greater number of testosterone receptors on one side of the brain may enable testosterone to influence cell survival or death on that particular side, resulting in asymmetry of neuronal number and, thus, both anatomical and functional asymmetry, ultimately underlying the greater cerebral lateralization in males. These findings in nonhuman animals are consistent with the hypotheses in human males that testosterone may delay the growth of the left hemisphere, resulting in dimorphic patterns in language functions, or that it may increase the development of the right hemisphere, resulting in enhanced visuospatial abilities.

There are suggestions that some sex differences in cerebral lateralization underlie differences in cognition. For example, in children with left-hemispheric language dominance, males show an asymmetry on spatial tasks but not on verbal tasks, whereas females show the reverse pattern. In children with right-hemispheric language, males display an asymmetry on the verbal task but not on the spatial task, and girls show the reversed pattern. Girls with left-hemisphere language exhibit better scores for verbal function than for spatial ability, and boys exhibit the opposite profile. The well-known sex-related differences in cognitive function, with males being relatively superior in visuospatial skills and females in verbal fluency, may pertain only to people having language localization in the left hemisphere. If the left hemisphere of females and the right hemisphere of males are functionally enhanced regardless of their specialties, then the reverse cognitive pattern may prevail in individuals with right-hemisphere language. Furthermore, sex-related differences in cognition might be increased in populations having weak hemispheric specialization.

V. SEX DIFFERENCES IN AGING

Despite many studies evaluating sex differences in the brain during development, relatively few have addressed such changes during aging. In humans, the process of neural aging has been evaluated using post mortem tissue, MRI, and PET. Advancing age has been associated with decreased brain tissue and increased cerebrospinal fluid. In general, this process occurs faster, earlier, and/or to a greater extent in men than in women. Like other studies of sex differences in the human brain, results have not been consistent partly due to variations in the designs of studies in terms of the number and age range of subjects and methods and regions of measurements.

Several sexually dimorphic structures exhibit sex differences in size changes with advancing age. The CC and INAH-1 decrease in size with age to a greater extent in men. The sex differences in neural atrophy in INAH-1 in part may account for why there is controversy as to whether it is sexually dimorphic. In the SCN, the number of neurons containing vasoactive intestinal polypeptide (VIP) exhibits a complete inversion during life: between 10 and 30 years the SCN of males contained twice as many VIP neurons as that of females, with a subsequent decrease at a more rapid rate in males such that between 40 and 60 years of age there are more VIP neurons in women. With respect to the MI, it is possible that sexual dimorphism in atrophy may account for why this structure is both present more often and larger in women than in men.

Other neural areas that have been reported to exhibit sexually dimorphic brain atrophy, which in general is greater in males, include an increase in cerebrospinal fluid volume particularly in sulcal and ventricular areas, a decrease in overall brain volume, and volumetric reductions in the frontal and temporal lobes, temporoparietal area, parieto-occipital region, and regions of the anterior CC. Like sexual dimorphism in functional hemispheric asymmetry, elderly males exhibit more atrophy in the *left* hemisphere, whereas women exhibit more symmetric hemispheric atrophy. At the microscopic level, there is significantly greater neurofibrillary degeneration of the medial basal hypothalamus in men. Likewise, cerebral blood flow in left frontal regions decreases with age to a greater extent in men.

These data provide evidence that sex differences in human brain structure are not fixed but continue to change throughout adulthood. Neuroanatomical sex differences in aging suggest that there may be cognitive sex differences in aging as well. There are sex differences in declines in memory functions, speech capacity, and visuospatial abilities. Women may have less age-related decline in verbal memory than men, whereas men may have better preservation of visuospatial abilities.

A. Hormone Changes during Aging

It is unknown why more age-related atrophy occurs in the brains of men. It has been suggested that women show less effects of neural aging due to the protective influence of female sex hormones prior to menopause. Considerable data support the role of sex hormones and corticosteroids in both development and aging. Gonadal hormones have been shown to stimulate neural growth and synapse formation, and their removal has resulted in retarded development and atrophy. The topographical distribution, binding capacity, and associated enzyme levels of sex hormones and their receptors have been shown to vary as a function of age in a variety of nonhuman species. Thus, neural atrophy with aging may also be due to varying hormone levels and changes in their receptors.

However, the fact that women exhibit an abrupt change in circulating sex hormones during menopause, whereas men exhibit a more gradual decrease—they actually have proportionately more of their gonadal hormone levels remaining for a longer time in older age—raises doubts about this notion. Perhaps the process of neural atrophy is slow enough such that it is not apparent for many years after the menopausal reduction in estrogen. If estrogen and/or progesterone are protecting the female brain from atrophy relative to the male brain, then several possibilities exist: (1) women on long-term postmenopausal estrogen therapy might have even less brain atrophy than women who are not on such therapy; (2) estrogen and/or progesterone are protective against aging, regardless of sex; (3) estrogen–progesterone protect against aging only in the female brain; (4) androgens do not protect against aging in men or do so to a lesser extent than estrogen and/or progesterone; and (5) androgens may actually promote certain facets of aging.

B. Hormone Replacement Therapy (HRT)

Age-related symptoms have been treated with HRT since the nineteenth century. By 1900 the life expectancy was only 40 years, so that the average woman throughout most of history has not lived beyond the reproductive years. Changes in female sex hormones during the menstrual cycle, the post partum period, and menopause may result in difficulties in attention, concentration, and memory, as well as disturbances such as irritability and depression. Many, but not all, studies suggest that administration of estrogen can improve cognitive abilities and emotional function.

The results of some studies suggest that changes in estrogen levels may affect psychological characteristics by action upon various neurotransmitter systems. Hormones such as estrogen influence neurochemistry by genomic and nongenomic mechanisms, modulating receptors, enzymes, synthesis, re-uptake, and degradation. Neurotransmitter systems shown to be responsive to estrogen in laboratory animals include the opiate, GABAergic, adrenergic, cholinergic, dopaminergic, and serotonergic systems, which also influence mental status in humans. Although estrogen-sensitive neurons represent a small fraction of the total neuronal population within the brain, their action can be relatively profound due in part to their interaction directly and indirectly with other neurons.

C. Alzheimer's Disease

Although anatomical studies in general suggest greater neural atrophy in men, Alzheimer's disease (AD) appears to be more frequent in women, even after accounting for sex differences in longevity. Estrogen in women may protect against AD. Likewise, the fall in

estrogen that occurs during menopause may increase the risk for this disease. Several studies indicate that HRT improves social, emotional, and cognitive functions in women with AD. Likewise, HRT has been associated with a decreased risk and delayed onset of AD. By utilizing functional MRI, postmenopausal women on HRT exhibited brain activation during memory tasks in different regions than when they were not on HRT.

The use of estrogen for AD in elderly women may aid in its prevention, because estrogen deficiency may contribute to the development of neuronal dysfunction and cell death that occurs in AD. In the rat, estrogen clearly influences hippocampal neurons: ovariectomy in the female decreases the density of dendritic spines in hippocampal pyramidal neurons, an effect prevented by estradiol treatment.

In AD, there are pathological changes in the hippocampus and basal forebrain, particularly in terms of overall neuronal loss, cholinergic cell loss in the basal forebrain, and neurofibrillary tangle formation. Typically, the basal forebrain is the major source of cholinergic innervation to the cerebral cortex, limbic system, hippocampus, and hypothalamus. In laboratory animals, estradiol increases cholinergic markers in the hippocampus and basal forebrain, where estrogen receptors colocalize on the magnocellular cholinergic neurons that express receptors for brain-derived neurotrophic factor (BDNF). Estrogen regulates the expression of BDNF that promotes the survival of basal forebrain cholinergic neurons and cerebral cortical neurons and plays a protective role after brain injury. In AD, mRNA for BDNF is markedly reduced in the cerebral cortex and the hippocampus. Estrogen's ability to enhance the transcription of molecules such as BDNF may partly underlie the molecular mechanisms by which HRT benefits individuals with AD.

VI. SEXUAL DIMORPHISM OF NEUROLOGICAL DISORDERS

A number of other neurological disorders exhibit sex differences, and an understanding of these dimorphisms gives scientists and physicians clues to their origins and treatment. During childhood, boys are slightly more prone than girls to exhibit disorders such as mental retardation, cerebral palsy, and febrile convulsions. Males, beginning in childhood and continuing into adulthood, are several times more likely than females to be diagnosed with attention deficit hyperactivity disorder. They are 3–5 times more likely to exhibit developmental language disorders such as infantile autism, delayed speech acquisition, developmental dyslexia, and stuttering. At higher levels of intelligence, the proportion of male dyslexics increases: among children with IQs under 90, boys slightly outnumber girls at a ratio of 1.2:1; at IQs between 90 and 99 the ratio climbs to 5:1; and at IQs 100 and above the ratio reaches 10:1. It has been suggested that the greater hemispheric specialization in boys could add to their risk of dyslexia because of more exclusive reliance on the left hemisphere, thus diminishing the effectiveness of other regions critical to verbal abilities. Likewise, the higher verbal abilities in girls may be related to their ability to utilize both cerebral hemispheres.

Women tend to have a greater incidence of depression, eating disorders, and obsessive–convulsive disorder (OCD). Depression affects about 3 females for every 1 male, and eating disorders such as bulimia and anorexia nervosa affect about 10 women for every 1 man. Tourette's syndrome, which sometimes accompanies OCD, is more often present in males and is probably influenced by both autosomal-dominant transmission and androgens. In fact, it is often aggravated by anabolic steroids.

Depression, eating disorders, and OCD are frequently treated by medications that influence the serotonergic system. In humans there are sex differences in the serotonergic system in terms of receptors and synthesis rate, and in laboratory animals estrogen levels influence this system. Likewise, synthetic gonadal hormones have been used to treat women with depression and other mood disorders, some of whom are unresponsive to state-of-the-art pharmaceuticals. Depression and other mood disorders have been treated with oral contraceptives in cycling women, and HRT has been effective in menopausal and postmenopausal women, perhaps by stimulating neurotransmitter systems such as the serotonergic system, which can influence one's mental and emotional status. Women tend to have a greater incidence of multiple sclerosis and myasthenia gravis.

Sex differences in schizophrenia have been identified in terms of the premorbid history, symptoms, brain morphology and functioning, neurochemistry, genetic transmission, course, treatment response, and epidemiology. In fact, being a man or woman probably places one at differential risks for particular forms of schizophrenia. Schizophrenic men have an earlier age of onset, the preponderance of olfactory disturbances, poorer premorbid history, more negative symptoms, poorer response to neuroleptics, lower family

morbidity risk, and a 3-fold decrease in fertility relative to schizophrenic women. The earlier brain *maturation* in terms of function observed in girls relative to boys may protect females from this disease during youth, presuming that an immature brain, typical of the young male, is more susceptible to complications during childbirth, trauma, and infections. This is consistent with the fact that birth complications are more frequently linked to schizophrenia in males. In contrast to a prevalence of schizophrenia among males at an early age of onset, there is a prevalence of women among late-onset schizophrenics: among people over 75, the female to male ratio is 20:3. Again, it has been suggested that declining estrogen levels and the resulting changes in neurotransmitter systems may influence the risk and course of schizophrenia in women at this age.

More women than men on neuroleptic medications to treat schizophrenia and other psychoses exhibit movement disorders such as tardive dyskinesia and parkinsonism. These problems are often aggravated when estrogen levels drop during the menstrual cycle and menopause, suggesting a "protective" role for estrogen; likewise, they may be improved by estrogen treatment. These movement disorders involve the dopaminergic system, upon which estrogen may act. In laboratory animals, estrogen receptors are present on cells that contain tyrosine hydroxylase; therefore, by modulating tyrosine hydroxylase, the dopaminergic system may be modulated to prevent movement disorders.

VII. SEX DIFFERENCES IN CHILDHOOD

Speech and language develop earlier in girls than in boys, and girls remain ahead of boys on tests of articulation through much of grade school. Sex differences favoring females that begin in early childhood and persist into adulthood are found on tests of clerical speed and accuracy, spelling, grammatical ability, and verbal fluency. However, consistent sex differences in vocabulary and verbal memory and reasoning ability have not been established. Males perform substantially better than females on several tests of visuospatial abilities, including certain mazes, right–left discrimination tasks, judgment of horizontality, and mechanical reasoning. It is unclear whether these differences are as substantial in childhood as in adolescence and adulthood. It is believed that sex differences in childhood cognitive skills are partly related to sex differences in the rate of brain maturation.

Sex differences in childhood play behavior and interests may enhance the development of sex differences in both verbal and visuospatial skills. Males typically engage in more rough-and-tumble play and play fighting, whereas girls more often play with dolls and "dress-up" articles. There are striking sex differences in certain toy preferences that even toy companies have attempted and yet failed to alter.

Childhood play behavior clearly differs between boys and girls, and this appears to be influenced by hormone levels perinatally. Play behavior in animals, including monkeys and rats, exhibits sex differences that are dependent upon androgens during perinatal life. For example, male rats treated with antiandrogen during neonatal life engage in less rough-and-tumble play. Likewise, female monkeys exposed *in utero* to androgens exhibit more male-like play behavior as juveniles.

Groups of individuals who may have been exposed to altered hormone levels during perinatal life also exhibit sex-reversed patterns of play behavior. Homosexual men and women report a higher incidence of gender-atypical behavior during childhood than do heterosexual people. Girls with CAH who have been exposed to higher androgen levels during development exhibit more masculine patterns of childhood play behavior, including a greater degree of outdoor play activity and expenditure of physical energy.

VIII. HOMOSEXUALITY AND TRANSSEXUALITY

Homosexuals have sex-atypical sexual orientation: they are erotically attracted to people of the same sex. Transsexuals have sex-reversed gender identity: they identify themselves as members opposite of their genital and legal sex, although they may be hetero-, bi-, or homosexual in sexual orientation. The nature–nurture debate about the origin of homosexuality and transsexuality has been ongoing for over a century. Although past attention has focused on sociocultural factors, more recent studies have identified neuroanatomical, genetic, hormonal, and nonsexual behavioral differences between homosexuals, transsexuals, and heterosexuals. However, no social or biological characteristic is unique to all groups, apart from their self-proclaimed sexual orientation and gender identity.

Sex differences in the human brain are particularly relevant to the etiology of homosexuality and transsexuality because it is believed by many scientists and physicians that certain regions of the brain may differ structurally in these individuals. A prominent hypothesis

holds that the exposure to sex hormones, which sexually differentiate brain structure and function in a variety of species during a critical period in perinatal life, may have been altered during development in homosexuals and transsexuals, influencing both sexually dimorphic brain structure and the functions of sexual orientation and identity. This would result in a *correlation* between sexually dimorphic structures and functions such as sexual orientation and/or sexual identity, not because any single brain structure determines human sexuality but because the same factor—sex hormones during a critical period of early life—sexually differentiates the brain on a more *global* level.

A. Anatomical Differences

In the first published report of an anatomical difference between the brains of homosexual males and heterosexuals, two nuclei were examined: INAH-1, which had been named the SDN-POA, and the suprachiasmatic nucleus (SCN) as a control. Unexpectedly, researchers did not find that INAH-1 varied with sexual orientation. However, to their surprise, the SCN was *larger* in homosexual men than in heterosexual men and women, despite the fact that there was no sex difference between men and women in terms of volume (Fig. 2).

The following year, in a highly publicized report, LeVay reported that INAH-3 was smaller in women and homosexual men than in heterosexual men, whereas neither INAH-1 nor INAH-2 varied with sex or sexual orientation (Fig. 2). This was a classic discovery, but not for the reason that many believed. There was an underlying assumption that INAH-3, being in a region of the brain that influences sexual behavior, may also determine sexual orientation. Whereas this may be true, we still know nothing about INAH-3 except that it varies in volume with sex and sexual orientation. What is important is that INAH-3 correlates not just with sex but also with a highly sexually dimorphic behavior, namely, sexual orientation. This correlation is reminiscent in rats of the relationship between the volume of the SDN-POA and sexual behavior, both determined by sex hormones. Of course, rat sexual behavior and human sexual orientation are not the same, but both are sexually dimorphic behaviors and both correlate with sexually dimorphic brain structures. The question remains: Are both determined by sex hormone levels during perinatal life?

The following year, another structure that was sexually dimorphic, the AC, was reported to be larger at the midline in heterosexual women and homosexual men than in heterosexual men (Fig. 2). This was important for several reasons. First, there was a second structure that varied not just with sex but more specifically with sexual orientation toward a given sex. Second, the AC is not known to be related to sexual behavior, suggesting that sexual orientation involves regions in the brain not directly related to sex or reproduction. This underscores the probability that differences in sexual orientation, like differences in genetic sex, involve not just sexuality but the overall way an individual processes information. Third, it suggests that no single structure underlies sexual orientation; rather, the homosexual brain may be organized differently on a global level. No doubt, other differences in the structure of the brains of homosexuals will be discovered.

In a small sample of male-to-female transsexuals, the volume of the central division of the BNST innervated by vasoactive intestinal polypeptide was greater in heterosexual and homosexual men than in male-to-female transsexuals and heterosexual women. In this sample, the difference appeared to be present regardless of the sexual orientation of the transsexuals (Fig. 2).

There are several caveats to these four studies: (1) in the sexual orientation studies, most of the homosexual subjects died of AIDS, whereas while most of the heterosexuals did not. AIDS is associated with severe neuropathology such as atrophy. However, if mere AIDS-related complications explain why INAH-3 is *smaller* in homosexual men, it is unlikely to account for the fact that the AC is *larger* in homosexual men. (2) The homosexuals and transsexuals probably had significantly different hormone levels relative to the heterosexuals: individuals with AIDS generally have depressed testosterone levels, whereas transsexuals are treated with the gonadal hormones of the opposite sex. Circulating levels of sex hormones influence several sexually dimorphic structures in various species. (3) Sexual orientation was determined not directly from the individual but from medical records. Some subjects classified as heterosexual may have been bi- or homosexual. This problem would not create false-positive results but could obscure a difference that may even be more dramatic. (4) Homosexual women were not evaluated because sexual orientation is not stated in the autopsy records of females, because their sexual orientation is not associated with illness. These problems reinforce the importance of examining healthy living human subjects by using modern imaging technology.

In contrast to laboratory animals, it is believed that hormones play a proportionally lesser role in sex differences in the human brain. However, in view of the findings that gonadal hormones sexually differentiate nearly every sex difference in neuroanatomy and function studied thus far in laboratory animals, the correlation between sexually dimorphic brain structure and sexuality supports the notion that gonadal hormones may also sexually differentiate sexual orientation and identity during early life in human beings. An important question remains: If altered levels of sex steroids during early life can result in altered sexuality, what causes these alterations in steroid hormone levels in the first place?

B. Prenatal Stress

It has been speculated that prenatal stress slightly increases an individual's chance of becoming homosexual. This hypothesis has stemmed from studies in rats. Exposure of female rats during the last trimester of pregnancy to stressors such as heat, restraint, and/or bright light results in modifications of brain structures and function. This has been termed the prenatal stress syndrome. Researchers believe that prenatal stress increases the secretion of adrenal androgens by the mother that, in males, leads to a shift in the peak of testosterone necessary for sexual differentiation of the brain from day 18 or 19 to day 17. This change in testosterone levels influences prenatally stressed males in several ways: as juveniles, they exhibit a more feminine pattern of play behavior, with a decrease in rough-and-tumble play; as adults they show less male copulatory behavior and increased rates of lordosis; their brain structure develops in a feminine direction (the SDN-POA is significantly smaller than in the control males); and regions of the cerebral cortex that normally exhibit asymmetry in males are more symmetric as in females. Prenatal stress in females disrupts adult estrous cycles. Like prenatally stressed male rats, some male homosexuals exhibit less rough-and-tumble play during childhood than heterosexual males, and a female pattern of brain structure is observed in terms of INAH-3 and the AC.

Of course, pregnant women are not physically stressed in the same way as experimental rats, but many undergo psychological stress that can also alter adrenal function. In humans, it has been suggested that prenatal stress increases the incidence of left-handedness. Interestingly, the results of some studies suggest that there is a higher incidence of left-handedness in male and female homosexuals and transsexuals. Of course, the mothers of most homosexuals and transsexuals were not stressed while pregnant, nor are most of their homosexuals and transsexual children left-handed. Likewise, most women stressed during pregnancy do not have homosexual or left-handed children. However, the concept that hormonal alteration by a factor such as stress can lead to other clues regarding the origins of homo- and transsexuality. For example, genetic factors, which might alter prenatal adrenal activity, the timing of the testosterone surge, or the synthesis of steroid hormone receptors, might also contribute to variations in sexuality.

C. Genes of Sexual Orientation

Several studies suggest that homosexuality may be genetically influenced: homosexuals have more homosexual siblings than do members of the general population, and genetic markers have been associated with male sexual orientation. However, a family pattern of homosexuality could be caused by a similarity in genes and/or shared home environment. Researchers turned to families with twins and adopted siblings to perform studies examining the genetic component to this pattern. They reasoned that, if genes are involved in homosexuality, then the more closely related two siblings are genetically, the more likely they should be concordant for sexual orientation. Indeed, for both men and women this holds true: identical twins exhibit the most concordance, followed by fraternal twins, and finally adopted siblings. However, in only about half of the identical twins are both homosexuals; in the other half they are discordant for sexual orientation, suggesting that genes alone do not determine sexual orientation.

DNA studies in homosexual and heterosexual individuals provide the greatest chance of identifying genetic determinants of sexual orientation. A linkage between DNA markers on the X chromosome in a region called Xq28 and male homosexuality has been reported; however, not all researchers seeking such a linkage have been successful.

IX. CONCLUSION

Sex differences in the human brain have broad implications for understanding neural development and maturation, reproductive and sexual functions, cerebral lateralization, cognition and information processing, disorders and their treatment, and the

process of aging. Research in laboratory animals has profoundly influenced our understanding of the biological component of sex differences in the human brain.

In nonhuman animals, both the body and the brain are sexually differentiated by gonadal hormones during a critical period of early life. Likewise, the body of the human is sexually dimorphic as a result of androgens perinatally. Sex differences in both the structure and function of the human brain have been identified, and, in all likelihood, they too are determined not just by culture that may accentuate or diminish certain sex differences but also by levels of sex hormones during early life. In humans, variations in levels of sex hormones during development are likely to have organizational effects on the brain, possibly resulting in variations in cerebral lateralization, cognition, sexual identity, and orientation. In adulthood, sex hormones may have activational effects on the brain, influencing reproduction and sexuality, emotions, cognition, aging, and a variety of diseases.

There is a complex relationship between sex, development, gonadal hormones, brain structure, cerebral lateralization, cognition, and handedness. Although certain correlational patterns exist, the considerable overlap between males and females suggests that factors other than genetic sex and hormones participate in the determination of these characteristics and their interrelationships.

Sexual Behavior

JOHN D. BALDWIN and JANICE I. BALDWIN
University of California, Santa Barbara

GLOSSARY

erotophiles People who like and have positive attitudes about sex.

erotophobes People who have a fear or phobia about sexuality and sexual information.

operant learning Behavior that is followed by rewards tends to become more frequent in the future, and behavior followed by punishment tends to become less frequent.

Pavlovian conditioning Stimuli that precede and predict many reflexes take on the power to elicit reflexive responses.

psychogenic stimulation Excitation that has its origins in mental activity.

scripts Patterns of talk and action that people learn from other people and from books, movies, and other media. There are sexual scripts for dealing with every stage of relationships, from meeting a potential partner to engaging in intercourse.

The human brain is complexly involved in the production and enjoyment of sexual behavior. During the last 50 years, scientific research has shown how sexual behavior is influenced by multifaceted interactions of nature and nurture, brain and peripheral reflexes, thoughts and emotions, and learning and planning. We present an empirically based analysis that integrates many of the better understood elements of this complex equation along with their interactions. This discussion of sexual behavior includes emotions and subjective experiences, even though these topics are sometimes neglected in biological models: cognitive events are open to scientific study and can be included in comprehensive theories. Because sexuality is an important topic that deserves to be widely understood, we avoid overly technical vocabulary when possible.

I. INTRODUCTION

From a bioevolutionary perspective, sexual behavior functions primarily to assure reproduction, and throughout most of human evolution, sexual activity was closely related to pregnancy and childbearing. Through evolutionary processes, numerous physiological structures have emerged that usually make sexual behavior pleasurable and easy to do, though sexual pain and problems are not uncommon. The thoughts, emotions, and physiological responses involved in sexual behavior are mediated by the brain and spinal cord. The *limbic system*, which encircles the upper end of the spinal cord below the cortical hemispheres in the brain, plays a crucial role in regulating emotions and sexual behaviors. Stimulation of parts of the limbic system can produce sexual arousal. The *cerebral cortex*, which processes memory, fantasy, language, and thinking, has multiple connections with the limbic system and plays multiple roles in sexual behavior. These neural structures are, in turn, influenced by countless biological, psychological, and social factors.

Although neural and hormonal mechanisms help to explain many aspects of sexuality, they are also influenced by social and cultural factors. Countless mixes of social and cultural inputs—mediated by the brain at conscious and unconscious levels—make human sexuality far more complex than the more basic sexual activities seen in other species.

Before the development of reliable, modern contraceptive techniques, sexual behavior was closely linked

with reproduction in most societies. Whereas people in many parts of the world attempted to unlink sex from pregnancy by using potions, magic incantations, and pessaries (inventions worn in the vagina), most had little success. Given the close connection between sex and procreation, most cultures surrounded sexuality with rituals and morals that demanded and/or sanctified family commitments, even though many people failed to follow those rules in their entirety. In the last four decades, the development of increasingly effective contraception and abortion techniques has allowed increasing numbers of people to avoid "procreational sex" (except when they want babies) and explore "recreational sex" (the fun side of sex). This adds to the already considerable variability within and among cultures in their sexual values and practices.

In order to appreciate the vast complexity of human sexual behavior, let us begin with the most basic elements of sexual behavior and then repeatedly add layers of extra information. One of the human brain's main functions is to process learning, and we will see how Pavlovian, operant, and social learning all add to and complicate sexual behavior and experience.

II. THE SEXUAL REFLEXES

There are reflex mechanisms located in the lower half of the spinal cord that mediate vaginal lubrication, penile erection, and other basic genital responses that can lead to arousal, orgasm, and resolution (after orgasm). The sexual reflexes function from birth: soon after birth, boys may have penile erections and girls may have vaginal lubrication and clitoral tumescence. Even before birth, ultrasound studies suggest that erections occur in male fetuses. The reflexes are simple stimulus–response actions at first, and years of sexual learning are needed to add the multiple layers of complexity that are typical of adult sexuality.

A. Before Conditioning

The basic sex reflex occurs when touch to the genitals triggers penile erection and vaginal lubrication. With prolonged tactile stimulation of appropriate intensities, the reflex mechanisms eventually produce all of the genital changes that lead up to orgasm and resolution (which is the end of the sex reflex).

Starting from birth, the sexual reflexes in the lower spinal cord send signals to and receive signals from the brain. The brain can (1) sense inputs from the genitals and sexual reflexes and (2) cause sexual responses in the genitals. The connections between the brain and the spinal reflex centers allow sexual responses to influence and be influenced by cortical and subcortical processes, including learning, memory, emotions, thoughts, and fantasies. Nerve fibers from the autonomic nervous system connect the internal and external sexual organs to the central nervous system.

Reflexes are neural mechanisms that allow stimulus–response (S–R) activities to occur without any prior learning. Touch-sensitive nerves in the genitals send afferent signals to the reflex centers located in the lower spinal cord. Tactile stimulation of the genitals serves as the *unconditioned stimulus* (US) that activates the reflexes; the word "unconditioned" indicates that no prior conditioning is needed for these stimuli to activate the reflex. All of the sexual responses are called *unconditional responses* (URs) to indicate that no prior learning is needed for them to occur.

From birth, the sexual reflexes can be activated by gentle touch to the genitals, without inputs from the brain. By adolescence, males tend to prefer stronger tactile stimulation of the genitals than do females, but both males and females have thresholds beyond which additional stimulation elicits pain. The most sensitive parts of the female body are the glans and shaft of the clitoris (even though the shaft is hidden beneath the skin), the minor lips (surrounding the outside of the vaginal opening), and the frenulum of the clitoris (located where the minor lips connect with the glans of the clitoris). The most sensitive parts of the male body are the glans and shaft of the penis, along with the frenulum (the small strip of skin that extends along the lower side of the penis, where the glans and shaft join). Touch of these structures, with the appropriate pressure and patterns of movement, activates the spinal reflex centers, and continued stimulation produces a long chain of several distinct responses—called excitement, plateau, orgasm, and resolution—that often take from 2 to 20 min for a person to experience all four of these phases. Hence, the sex reflexes are quite different from such quick S–R reflexes as the patellar knee jerk or jerking away from electric shock. The following paragraphs present a simple summary of our current knowledge about the ways in which the sexual reflexes function.

Appropriate tactile stimulation to the genitals first activates parts of the sacral reflex mechanisms (in the lower vertebrae of the spinal cord). Early sacral activities relax the muscles in the arterial walls, allowing the arteries to dilate and carry blood into the genitals faster than usual. The excess blood in the

arteries compresses the veins, slowing the flow of the blood from the genitals. As a result, blood accumulates in the pelvic area, creating *vasocongestion* of the genitals. This vascular engorgement of the genitals produces the earliest phase of the sexual response, called the excitement phase. Vasocongestion causes the male's penis to become larger and erect. It also causes the female's clitoris to enlarge by a small amount and fluids to exude through the vaginal wall, lubricating the inside of the vagina (making it more receptive to penetration).

After the sacral reflexes are activated in the excitement phase, continued genital stimulation transfers reflex control to the thoracic and lumbar sections of the spinal cord (located above the sacral area). This initiates the plateau phase of the sexual response, when the thoracic and lumbar reflexes cause even stronger vasocongestion, resulting in additional vaginal lubrication for females and stronger erections for males.

Continued sexual stimulation eventually causes the thoracic and lumbar reflexes to initiate a several-second transition period that leads to orgasm. In males, the thoracic and lumbar reflexes cause a 2- or 3-sec-long response called "ejaculatory inevitability" during the first several seconds of the orgasm phase. At this time, men can feel pleasurable genital sensations that come from rhythmic muscular contractions in the walls of the male internal reproductive organs—the vas deferens, seminal vesicles, and prostate gland—as these organs push their contents into the tubes from which they will be ejaculated. Then reflex control is transferred to the sacral reflexes, which initiate ejaculation and orgasm. Most men learn they cannot do anything to stop ejaculation from occurring once the 2- to 3-sec period of ejaculatory inevitability starts, hence its name. After this brief preejaculatory period, reflexive control is transferred to the sacral reflexes, which now cause rhythmic muscle contractions around the base of the penis (inside the body), starting at intervals of 0.8 sec and then gradually slowing to longer intervals. These muscle contractions force the ejaculate out of the male's body at the time of orgasm, and they cause orgasm to be experienced as rhythmic pulses or surges of pleasure.

In females, the transition from plateau to orgasm is similar to that seen in males, but more subtle. During the plateau phase of the sexual response, the thoracic and lumbar reflexes produce increasing vasocongestion, which augments vaginal lubrication. Then, for about 2 or 3 sec before the sacral reflexes cause contractions in the pelvic muscles at 0.8-sec intervals, women report the onset of pleasurable experiences (at the time when males feel the pleasurable sensation of ejaculatory inevitability). After this 2- to 3-sec period, females begin to experience the rhythmic surges and pulses of orgasmic pleasure that occur as their genital muscles begin to contract at intervals of 0.8-sec, gradually slowing to longer intervals. Thus, both females and males have 2–3 sec of pleasure before reflexive control is transferred to the sacral reflexes (which cause the muscle contractions that begin at 0.8-sec intervals). Even though females do not ejaculate semen, the contractions of the pelvic muscles are experienced as rhythmic pulses of pleasure. Many females and males report that orgasm lasts for about 15 sec, though this timing shows considerable variability.

After orgasm, the final phase of the sexual reflex is resolution, in which all of the genital responses seen in the prior three phases subside. There is a reversal of vasocongestion, and blood flows out of the genitals faster than it flows in. Most muscle contractions slow and weaken, though small movements may continue for a while. Gradually, the genitals return to the relaxed condition seen before the onset of sexual stimulation. After orgasm, most males experience a refractory period during which no additional stimulation can activate the sexual reflexes. In adult men, the refractory period tends to last 30–90 min, but the period becomes longer with age. At this time, the fluids that will be ejaculated at the time of the next orgasm flow into the internal male reproductive organs. Females do not have an equivalent process and can have multiple orgasms without several-minute pauses between them.

Although the sexual reflexes usually function rather automatically, as described earlier, they can be partially or completely inhibited by pain, fear, depression, fatigue, exhaustion, illness, biomedical problems, and certain drugs, even when effective tactile stimulation is present. Before sexual therapy, a medical exam is usually conducted to determine whether a sexual problem is the result of medical or drug problems. If these causes are ruled out, psychological treatment is in order.

B. Pavlovian Conditioning

In humans, the sexual reflexes are among the reflexes that are influenced by Pavlovian conditioning, which is also known as classical and respondent conditioning. This type of conditioning allows stimuli other than the tactile genital stimuli that are the USs (unconditioned

stimuli) for the sex reflex to gain the power to elicit sexual responses. Pavlovian conditioning is adaptive from a biological perspective, because it allows an individual to learn to respond to many stimuli that are associated with crucial USs, all of which are important for survival and reproduction. Thus, the brain has evolved to be quite sensitive to correlations—or contingent relations—between reflexes and the stimuli that regularly precede them.

Pavlovian conditioning of sexual responses occurs in the brain when some neutral stimulus repeatedly precedes and predicts the onset of the US of appropriate touch to the genitals. The brain can associate stimuli from all sense modalities with the USs that trigger the reflexes in the lower spine. Neutral stimuli that predict the onset of tactile genital stimulation (the US) gradually become *conditioned stimuli* (CSs) capable of eliciting sexual reflexes and pleasurable sexual feelings. For example, the sound of an electric vibrator is a neutral stimulus that does not elicit sexual responses in children, but adults who have orgasms with vibrators learn that the sound of these electric devices is closely associated with sexual pleasures. After such sexual conditioning, some people become sexually aroused when they hear the vibrator's sounds (the CSs) before having any tactile stimulation to the genitals (the US). The cues that most reliably precede and predict the onset of USs are the stimuli that become conditioned stimuli via Pavlovian conditioning. Once a CS has been created, it can elicit *conditioned responses* (CRs), which are similar to the URs of the original reflex from which they take their power, though CRs are usually weaker than URs and slower to appear.

Although some people think that seeing naked bodies might be a US for the sexual reflexes, research does not support this supposition. Young children who see naked bodies do not respond with sexual reflexes, but they do have sexual responses to genital touches (the US for the sexual reflex). When people learn that the sight of naked bodies can precede and predict the onset of the US of tactile genital stimulation, they learn to respond to the sight of naked bodies as a CS that elicits sexual responses. In common parlance, CSs are called "erotic stimuli" or "sexual turn-ons," and they can elicit conditioned sexual responses even when the US of touch to the genitals is not present. Conditioned sexual responses (CRs) are not identical with the URs of the unconditioned reflex, because the CSs activate different brain circuits than the USs. If the sight of naked bodies is a CS for a person, it stimulates visual centers, whereas the US of genital stimulation directly activates the spinal reflexes, along with nonvisual brain areas. In addition, CSs elicit responses that are weaker and slower to appear than those elicited by the USs, which directly stimulate the spinal reflex mechanisms.

The effects of CSs can vary from weak to moderately strong. Usually, the more frequently that any given CS has preceded and accurately predicted the onset of the US of genital stimulation, the more power that CS develops for eliciting conditioned sexual responses. People who have had numerous orgasms with vibrators are most likely to respond to the hum of a vibrator as a CS for sexual arousal. However, the effects of strong sexual CSs can be opposed and suppressed by pain, fear, fatigue, illness, or other CSs that elicit aversive emotions.

Through Pavlovian conditioning, almost any stimulus that frequently precedes and accurately predicts the onset of sexual arousal can become a sexual CS. The specific stimuli that people respond to as sexually exciting differ from person to person, depending on each individual's unique history of sexual experiences. For example, foul language can affect people quite differently. Some people learn to find "talking dirty" to be sexually arousing, if such talk has been a common part of their more exciting sexual experiences. Although many people are offended by vulgar words and wonder how anyone could find obscenities to be sexually exciting, the principles of Pavlovian conditioning clarify the phenomenon: almost *any* stimulus can become a sexual CS—an erotic stimulus or sexual turn-on—for those individuals who have experienced it in conjunction with intense sexual excitement.

Because the cerebral cortex is connected with the sexual reflex mechanisms in the lower spinal cord, sexual thoughts and fantasies that include sexual turn-ons (CSs) can elicit vaginal lubrication, penile erection, and other sexual responses without any tactile stimulation of the genitals (the US). When the brain's sexual thoughts are the only causes of sexual reflexes, the sexual reactions are called *psychogenic* responses, to indicate that they are purely psychological in origin. People with little sexual learning often find that psychogenic stimulation only produces mild sexual responses, such as slight vaginal lubrication or partial penile erection. But individuals who have had many hours of intense sexual experiences can have strong psychogenic responses to the CSs present in their sexual lives.

Many people find that fantasies help their sex lives in two ways. First, during tactile sexual activities, such as masturbation or partner interactions, fantasies and

psychogenic sexual stimulation can add to the total excitement that enhances and intensifies the sexual response. Second, fantasies also help distract people from thinking about some of the negative things that can suppress their sexual reflexes, thereby reducing sexual inhibitions. Fantasies can distract people from unwanted fears of not being attractive enough to their partners, doubts about the adequacy of their sexual performance, or guilt about engaging in sexual activities. Unfortunately, some people feel guilty about having sexual fantasies while having sex with a partner: in their lives, fantasies elicit negative thoughts and emotions, which interfere with the two benefits of fantasy.

Sex is not always associated with pleasure. When sexual activities precede and predict the onset of aversive experiences, such as loss of erections or failure to reach orgasm, sexual activities can be conditioned into CSs that elicit fears that suppress the sexual reflexes. Any of a variety of sex-related stimuli can become associated with fear, worry, or anxiety. For example, fears of becoming pregnant can inhibit a person's sexual response. In this case, the onset of sexual activities can trigger thoughts about pregnancy, and these are CSs that elicit fears and worry that can interfere with the sexual response, decreasing the chances of reaching orgasm. People can combat this fear by learning about highly effective contraceptive methods, which offer genuine protection from pregnancy and reduce their users' fears of fertility that inhibit their sexual responses. Other thoughts that can become CSs associated with physical intimacy and inhibit sexual responses are fears of not pleasing one's partner, not being attractive enough, and not being the best sexual partner one's partner ever had. Both males and females can have these fears and never know that one's partner has some of these feelings, because many people are reluctant to communicate about such topics.

''Performance anxiety'' is a common sexual fear that arises when people worry that their sexual performance may not be as ideal as they would like. She may fear that she may not reach orgasm; he may fear that he will ejaculate too early to please his partner. To combat performance anxiety, people first need to realize that their sexual responses are based on reflexes that usually appear rather automatically: by increasing or decreasing the number of USs and CSs that enter the sense receptors of the body and brain, people can intensify or delay the sex reflexes. Second, knowledge of this fact and adjustment of their sexual activities accordingly will convince them that their performance anxiety is irrational, and that they can forget it.

III. OPERANT LEARNING

In humans and many other species, the sexual reflexes and Pavlovian conditioning are not adequate—in the absence of other forms of learning—to assure intercourse, successful reproduction, and the continuation of the species. Humans need considerable *operant learning* to coordinate successful sexual activities with a partner. Namely, they have to learn numerous skills for ''operating'' their way through a complex series of activities and interactions that are needed to work up to and perform sexually activities, at which time the sex reflex produces penile erection, vaginal lubrication, and orgasm.

A. First-Hand Experience with Reinforcers and Punishers

Operant conditioning, also known as instrumental conditioning, occurs when any behavior is modified by the consequences that follow it, be they pleasant or painful, or more technically, be they reinforcers or punishers. People learn to do behaviors that are instrumental in attaining pleasure and avoiding pain (attaining reinforcement and avoiding punishment). If two people try ten different sexual positions and find that three lead to pleasurable outcomes, but two other positions led to painful consequences, the couple is especially likely to repeat the three positions that brought reinforcement and avoid the two followed by pain. During operant learning, behavior that is followed by reinforcers is strengthened and made more likely to occur at future times, and behavior that leads to punishers is suppressed and becomes less likely to occur in the future.

From an evolutionary perspective, it makes sense that humans would be biologically prepared to learn countless behaviors for attaining sexual pleasures. The human cerebral cortex, which plays a central role in learning, is quite large in proportion to the human body size, and learning how to have sex in almost any kind of ecological situation guaranteed the reproduction of the species throughout most of human history. It could be argued that humans have, in fact, been too successful in reproducing to the point where our large population is destroying many ecosystems and causing other species to become extinct. Only relatively recently, with the development of modem birth control technologies have humans been able to learn how to enjoy sexual reinforcers without risking pregnancy.

During sexual activities, all of the external and internal sense organs activate the sensory centers in the brain and arouse sexual perceptions and motor activations. In addition, some sensory inputs activate the pleasure or pain centers in the brain, causing certain types of sexual stimulation to feel pleasurable, whereas other types feel aversive. The human brain is very sensitive to (though not perfectly perceptive of) contingent relationships between behavior and its consequences, especially pleasure and pain. Special neural circuits associate rewards and punishers with the behaviors that precede and predict them, strengthening behaviors associated with reinforcers and suppressing behaviors associated with punishment. This makes the sensations of pleasure and pain the prime movers that produce operant learning. Through the hippocampus, basolateral amygdala, and other areas, reinforcement and punishment also facilitate the development of long-term memories that influence later thoughts and actions.

Most operant behavior occurs as chains of activities, and sex is no exception. Two adults may spend 10, 20, or 60 min performing a long chain of varied activities before they reach orgasm or decide to end sexual activities. It usually takes years of experience to learn long behavioral chains that smoothly link many different operant activities. The following paragraphs provide examples of some of the countless routes by which children and adults learn longer and more complex chains of sexual behavior as they gain increasing operant learning experience with numerous behaviors and their consequences.

1. Infancy

Starting in the early months of life, some infants learn simple chains of sexual behavior that lead to sexual pleasures. Out of simple curiosity, infants use their hands to explore touching many parts of their bodies and things in their environments. After touching and feeling anything nearby, infants often—by accident, with no plan—touch their genitals. Touch to the genitals is the US that elicits the sex reflex and activates the pleasure centers in the brain. Next, the brain mechanisms that sense contingent relationships between behavior and rewards—and underlie operant conditioning—reinforce and strengthen the motor mechanisms that produced touching and feeling the genitals. If infants are not punished for self-stimulation, they gradually learn to repeat the operant behavior of touching and feeling the genitals.

Infant self-stimulation consists of simple chains of behaviors of repeated touches and manipulation of the genitals, and infants can learn these chains easily. Adults call the behavior masturbation, but infants learn the behavior without the adult vocabulary or any verbal awareness of society's views or values about masturbation. As the months pass, some infants gain sufficient experience to learn long enough chains of touching, feeling, pressing, and rubbing that they reach orgasm by their second or third birthday (though boys, at the time of orgasm, do not ejaculate any fluid until after the onset of puberty).

There is considerable variation among infants in early sexual self-stimulation, depending largely on their parents' responses to the activity. Some parents punish and suppress early sexual behavior, whereas others are more accepting. Children who are punished for genital exploration may learn not to touch their genitals. In fact, they may become so well-inhibited that they do not learn enough skills for tactile self-stimulation to become sexually aroused, much less reach orgasm. Once these children reach adolescence, they will not remember how they learned to feel inhibited—and perhaps even fearfull—about masturbating, because few of us can recall experiences from the first couple years of our lives.

2. Childhood

As children play with each other and learn increasing social skills, some discover activities that can lead to sexual interactions. During early social exploration and play, without any intention of discovering coitus, some children undress and feel each other's bodies, simply out of curiosity, without any sexual motivations. Children are inquisitive and eager to learn about their world, including what other children's bodies look like. Because children's play is not always monitored closely by adults, sexual exploration can lead in many possible directions. Often it leads to nothing more than one child's simply looking at and briefly touching the other child's body and then losing interest, but other outcomes are possible. A 9-year-old brother and his younger sister may innocently engage in mutual sexual exploration and discover that sexual play is pleasurable. Any sex play that happens to involve genital touching is rewarded by the positive reinforcers of genital stimulation, and this strengthens any behavioral patterns that lead up genital stimulation. Due to reinforcement and operant learning, children may learn to play these "touching games"

with increasing frequency, unless they are taught to avoid these kinds of "naked games."

After weeks or months of repeated sex play, children may discover intercourse if adults have not inhibited sex play. If children learn behavioral chains that are effective in eliciting the sexual reflexes of penile erection and vaginal lubrication, they have the opportunity for discovering penile–vaginal sex. The brain has no innate sexual taboo or inhibitory mechanisms that prevent children from exploring sexual behavior, and childhood sexual interactions are not rare. Even children who are raised by parents who have strict sexual standards may accidentally discover sex play before it occurs to their parents to teach their values to the children. Only later may the children discover that these activities are called "incest," "sinful," or "dirty," and these social labels can make them feel shameful afterward.

What happens in homes where parents systematically punish early childhood sexual exploration and give their children little information about the sexual activities and experience that many children have? Such children can grow up with considerable guilt and little knowledge about their sexual organs and self-touching. Small doses of sexual inhibition may not have long-lasting effects on the person's sexuality, but high levels of guilt and sexual ignorance can make it difficult for a person to develop a happy, uninhibited sexual life in subsequent years. Children who have punitive socializations about sex often develop erotophobia, which is a fear or phobia of sexuality and sexual information, leading to negative attitudes about sex. In contrast, a more positive sexual socialization tends to lead to erotophilia, with positive attitudes about sexuality and sexual information.

In most societies, including ours, there is a double standard that imposes more sexual inhibitions, guilt, and erotophobia on girls than on boys. Parents are more likely to disapprove of masturbation and sex play for girls than for boys. They tend to withhold sexual information about sexual anatomy, feelings, and responses from girls more than from boys. Girls are often told about the joys of motherhood but given little information about the clitoris, genital stimulation, or orgasm. As a result, girls and women often start life with more erotophobia than males of their same age have, and this can limit both their Pavlovian and operant learning about sex.

3. All through Life

Operant learning can occur at any age, whenever behavior leads to reinforcers or punishers. During sexual activities, a woman may have her clitoris and frenulum touched by her partner, leading to her moaning with pleasure, and her response reinforces her partner's use of that style of stimulation. His jerking back and saying "ouch" may punish his partner for pushing too strongly against his testicles. All of the presexual behaviors, such as kissing and undressing, that occur as early links in the behavioral chains that lead up to sexual acts are also influenced by reinforcement and punishment.

B. Observational Learning

Operant learning is often hastened by *observational learning*, whenever observers learn how to do some new behavior by watching a person, who is called a *model*, perform the behavior. Observational learning has two phases: acquisition and performance. People can acquire information about a behavior but never perform it. Viewers of a modern movie may see the actors engage in sadomasochistic sexual activities, and some observers may perform the behavior within 24 hr, whereas others do it within the next month and yet others never try the behavior. People are most likely to perform a modeled behavior if (1) they would not feel guilty about doing the behavior, (2) it is clear that the behavior brings considerable pleasure and little pain to the model, (3) they feel they are similar to the model, (4) the crucial details of the modeled behavior are clearly visible, and (5) the behavior is easy to imitate. Next, the performance of an imitative act may be followed by reinforcement or punishment, and these consequences affect the future chances that the behavior will be repeated.

If attempts to replicate a sexual position modeled in a movie bring pleasure, the reinforcement speeds operant learning. If the performance of a new behavior causes one's partner to feel pain and complain, the behavior is less likely to be repeated due to punishment.

Although sexual intercourse is usually not done publicly in our society, people can learn countless things about presexual and sexual behavior from models. In private, they can learn from observing and interacting with sexual partners, who provide *real-life models* (dressed or undressed) for new sexual and presexual behaviors. People also learn sex-related information from *symbolic models* whose behavior is described in conversations, magazines, and books, or shown in movies, TV, videos, web sites, or any other symbolic medium.

1. Childhood

In our society, children learn activities that can influence sex play when they observe doctors, nurses, TV, and more. Because doctors are high-status people, some children observe and learn from them and then later imitate by playing doctor, which may involve undressing a playmate. Other children innocently imitate physical activities they see modeled on TV, without guessing what pleasures they might discover if their imitative acts lead to genital stimulation and the reinforcers that strengthen operant behavior.

Anthropologists studying several preindustrial societies have observed childhood sex play that leads all the way to copulation. In cultures where a whole family sleeps together in a hut or 1-room house with no walls between the adults and their offspring, children may see their parents engaging in coitus and learn the positions that are involved. The next day, the children may imitate their parents' coital activities during play with other children, and discover some of the pleasures of genital stimulation. In some societies, childhood sexual interactions are punished, but there are societies in which adults respond to child sex play as "natural" or "cute," and children are allowed to learn about sexuality early in life. Of course, parents in societies that do not approve of child sexual activity could create enormous problems for their child and family by condoning childhood sexual activities that the neighbors and community would condemn.

A great deal of variability exists among cultures in the treatment of childhood sexuality, and sexual exploration and play can continue throughout childhood, even in societies where parents do not approve of it. Although Freud and other Victorians knew that infants explored sexually, many thought that children between age 5 and the onset of puberty experienced a "latency period" in their sexual development—when sexual motivation was thought to be dormant—before puberty triggered the rise in adult sexual hormones and sexual interest. Modern research shows that many children in our society and other societies do not cease being sexual after early childhood, though childhood sexuality can be suppressed to a significant degree by high ratios of punishment to reinforcement.

2. Adolescence

During puberty, biology and learning interact in ways that increase the chances that teens will think, wonder, and fantasize about sex, leading increasing numbers of teens to experiment with sex with each passing year of age. Let us deal with biology first and then learning. During puberty, rising levels of adult sex hormones increase the sensitivity of the genitals and the sexual reflexes in both male and female bodies. Boys experience spontaneous penile erections during dream sleep, wet dreams, and various times during the waking day. Having a spontaneous erection can lead to masturbation. Adolescent boys report more spontaneous sexual arousal than do girls. This is in part because the penis is large enough that boys can easily notice their erections, whereas the female sexual responses of clitoral enlargement and vaginal lubrication are more subtle and difficult to notice.

Because the sexual hormones make the genitals more sensitive, stimulation to them is more pleasurable and reinforcing than it was in childhood. As a result, adolescents who explore sexual activities receive stronger rewards than they did in childhood, which leads them to think and fantasize about sex more often. These sexual thoughts and feelings lead many teens to seek sexual information from real and symbolic models or look for first-hand experience via sexual activities. As a consequence, many teens (especially boys) experience a rapid surge in learning more complex and lengthy chains of sex-related activities: how to talk with potential sexual partners, how to suggest physical intimacy, and how to explore all sorts of sex-related activities.

During adolescence, the differences between people who have learned to be erotophiles or erotophobes become especially noticeable. It is also clear that there is a continuum of responses to sex between erotophilia and erotophobia—between those people who like sex (and feel little guilt about it) and those people who feel guilt, anxiety, shame or phobia about sex. Generally, the more phobic people have so many aversive associations related to sex that they feel inhibited about seeking sexual information or education. However, their avoidance of sexual knowledge does not guarantee that they will know how to resist seductive sexual approaches by or from insistent partners. Many erotophobes have been talked out of their virginity by verbally persuasive individuals. Then we discover that erotophobes are not immune to the painful consequences of uninformed sex, such as pregnancy and sexually transmitted diseases (STDs), and their avoidance of sexual education actually puts them at a greater risk of problems than their better educated peers. All through history, many teens who have been told to remain virgins until marriage have disobeyed, experimented with sex, become pregnant and been forced into marriage, abandoned by their families, or worse.

3. All through Life

People who are exploring physical intimacies with a new partner may see sexual behavior they have never done before and acquire information about it via observational learning. Affluent nations provide their citizens with countless magazines, books, videos, and movies from which teens and adults can acquire information about sex by observational learning.

As people learn longer chains of sexual behavior, they discover the importance of many of the early presexual links of behavioral chains that come before genital stimulation and the sex reflexes of erection, vaginal lubrication, and orgasm. Through observational learning, most people discover countless ways to deal with the long chains of presexual behaviors that begin with meeting, starting a relationship, becoming intimate, suggesting sexual activities, discussing methods of protection from pregnancy and STDs, and then engaging in sexual behavior. Some links of this chain of activities are modeled in public and in the media, but others are seldom discussed openly, which deprives people of valuable information that could be useful in solving some of the problems that sexual people eventually confront. Countless people have problems in learning all of the long chains of presexual and sexual behavior needed to have optimally gratifying intimate and loving relationships, yet all of the information about each link in these long chains is not broadly available.

C. Words, Rules, and Scripts

Language facilitates the learning of operant sexual behavior, not only by presenting symbolically described models for observational learning but also by providing words, rules, and scripts that influence sexual behavior. *Words* are more important than is often recognized, as studies on sexuality clearly show. Most parents follow a double standard and give boys more useful words for the male genitals than girls receive for describing their genitals. Few young girls are told they have a clitoris, but almost all boys learn a name for their penis. Because the clitoris is smaller than the penis and most girls are not given a word to draw attention to it, few girls are empowered to ask questions such as, ''What is the clitoris for?'' As a result, girls are less likely than boys to talk or think about their genitals. In contrast, boys are verbally aware of the presence of and names for their penis, which helps them verbally describe and think about penile responses, ask for information about these things, talk with their parents and peers, and learn about their sexuality. The double standard in teaching boys more words about sex augments sexual curiosity and desire for sex information in boys and suppresses it in girls. Later, as females gain increasing access to books and symbolic media, which are great equalizers, females can begin to catch up with males in gaining access to sexual words and knowledge.

Rules are statements that tell us to perform specific behaviors or chains of behavior. Women's magazines often suggest rules for chains of presexual acts, such as, ''Give a long gaze to the person you like and when your eyes meet, give a warm and friendly smile.'' Both women's and men's magazines give rules for doing the behavior needed to help females reach orgasm, ''Using gentle circular motions, touch the frenulum, glans, and shaft of her clitoris, and gradually increase the pressure of stimulation as she becomes more aroused.''

In order to follow rules, people must understand the language and the words that others use to present rules. The words, ''Appuie moins fort, s'il te plaît,'' are meaningless to people who have not learned that these words mean ''less pressure, please,'' in French. Books, magazines, web sites, and knowledgeable friends often provide rules for directing sexual behavior, though not all sources of rules are equally accurate. People who wish to benefit from rules need to learn which sources of information are most useful.

Scripts involve long chains of rules that tell us how to talk and act with others. In one sense, we are all like actors on a stage, and each society provides countless scripts that help us learn how to act our sex and gender roles, and all other aspects of life. Society gives us countless sexual scripts, which are chains of phrases and sentences along with hints about postures, gestures, and tone of voice, that can influence every phase of a person's actions. For example, there are countless ''opening lines'' that a person can use to meet another person, ''Hi, I've noticed you in a couple of classes and would like to introduce myself.'' There are also scripts for attracting a potential partner, starting a relationship, developing intimacy, and having sexual relations. Children begin to learn male and female gender scripts early in life, long before they can see the link between female and male gender roles and sexual activities. With the onset of puberty, teens become increasingly motivated to learn the sexual scripts of their society, because mastery of smooth lines and scripts can open opportunities for rewarding presexual and sexual interactions. Peers, magazines, TV, videos, and movies provide countless models for these scripts and lines. Both females and males often repeat and creatively

alter lines they have found to be useful and rewarding in the past.

Scientific studies show that women tend to be more discerning among scripts and lines than men. Men like almost all types of friendly looks and opening lines that women use to initiate conversations. In contrast, women tend to like direct and innocuous lines from men and are turned off by cute and flippant lines.

The countless scripts for dealing with sex vary from society to society and from subculture to subculture. This can create confusion when people move from one social sphere to another or try to become intimate with someone from a different subculture. On the other hand, many people are quite creative in picking snippets from numerous scripts and chaining them together in novel and interesting ways. Thus, sexual behavior is far more varied than if each society provided only one sexual script and no one innovated or created new chains of acts and words.

Many teens are exposed to countless models, rules, and scripts that promise rewarding outcomes for hanging out, kissing, necking, hooking up, playing around, exploring, pushing limits, and seeing how far they can go with sex play. Some teens adhere to the scripts that their parents advocate, but many explore rebellious scripts if their subculture glamorizes these and provides more reinforcers than their parents can. Thus, adolescent society is a complex mixture of scripts, from tame to wild. From this tumultuous mélange, teens piece together ever longer chains of presexual and sexual behavior, though many also learn to set limits about how far they are willing to go at each point in a developing relationship.

Rewarding experiences help people learn to like behavioral links in chains that lead to good experiences in developing intimacy—from meeting and relating well to engaging in gratifying sexual acts. In contrast, punishment and painful experiences tend to inhibit future repetitions of behaviors that lead to pain. Many a teen has been punished for using "dumb come-on lines" or clumsy bedroom techniques. Especially painful are actions that expose one to being taken advantage of, hurt, or raped. Punishment motivates people to avoid future pain by setting limits beyond which they will not go at any phase of a newly developing relationship, "I don't want to have sex until I know you better." All during life, rewards and punishers lead people to learn more polished behavioral chains over time, though many people never learn as many presexual and sexual skills as they could if more accurate information were readily available.

People's preferences for scripts tend to change as they get older and move from being adolescents to young adults, then develop long-term relationships, wed, and create successful or fractious marriages. Each new generation experiences different historical settings —from Victorian properness (in the late 1800s) to e-mail and cyber-sex (today)—and these historical inputs interact with each person's unique learning experiences as the years take them from teens to twenties and beyond.

D. Cognition

Where in the body does learning leave its traces as people learn from Pavlovian and operant conditioning, assisted with information from models, words, rules, and scripts? The brain is the organ that processes and stores the inputs gained through all types of learning, including sexual learning. During learning experiences, perceptual inputs from all sense modalities trigger thoughts and feelings in both primitive and advanced brain areas. Sensory and motor experiences that are associated with reinforcement or punishment are especially likely to be entered into the brain's long-term memory systems.

Our thoughts are filled with two basic components: (1) perceptual images from present sensory inputs, along with the memory images that they arouse, and (2) the "inner words" that we "hear" in our minds as we use language to label perceptual and memory inputs in the privacy of our brains. Both nonverbal and verbal inputs can elicit emotional responses that heighten the "feelings" of inputs that are associated with reinforcers or punishers, whereas other inputs are neutral, with little or no emotional association.

Sexy images and words can come from real-life personal experiences or from indirect social learning via movies, TV, videos, and photos. When people see TV shows, videos, or movies in which certain lines, scripts, postures, or clothing lead to sexually exciting outcomes, they may find themselves repeating and rehearing those scripted events in their brains and then using parts or combinations of those scripts when interacting with others. The more that scripted words, actions, and images are associated with rewards, the more people come to like and use them.

Each person's vocabulary and verbal knowledge are gifts from society. Some people receive generous verbal gifts that allow them to cogitate about sex—and all the rest of life—in great detail. Other people receive limited or highly censored verbal labels and knowledge

about sex. People who have many detailed words for describing most aspects of sexuality can have more complex "inner verbalizations" for analyzing their sexuality in the privacy of their own brains than can people with limited vocabularies. Highly verbal people can cogitate for hours about the details of a sexual experience that a less verbal person might summarize in a few words, "It was good." Unfortunately, if the verbal information a person is given about sex is wrong, the many hours of self-analysis can lead to faulty conclusions, such as, "As long as I douche afterward, I won't be able to get pregnant."

Every human brain resides in a unique body that, in turn, is located in a singular place in time and space. Hence, each individual is influenced by his or her special position in the world. Two people living in different parts of the same city are exposed to different subsets of the multiple subcultures existing in that city; hence, they learn different information about sexual conduct from their different symbolic and real-life models. Some people obtain vast amounts of information about sex and pregnancy, relationships, birth control, and STDs, whereas others obtain little.

Each person has a singular perspective on life, and each brain learns unique thoughts about sex and gender; thus, 100 people can perceive the same event and interpret it 100 different ways. After two people see the same erotic movie, one describes it as interesting and sexually exciting, whereas the other calls it repulsive and pornographic. One person wants to imitate the behavior modeled in the movie, and the other sets limits and refuses to do the behavior. As they gain experience, people who live in pluralistic societies with many different views and values about sex often become more tolerant of sexual diversity as they hear many different points of view about life.

The brain is not a passive organ or a simple memory bank that is filled by personal and social experience. The brain is an active, dynamic, and creative organ that can modify and reconstruct the scripts and scenes it perceives in the world around it. Most people learn how to combine and recombine various inputs in creative new ways, play with ideas, free-associate, and then talk and act in creative ways. Problem solving and fantasy often enhance the brain's creative processes. Problems often cause people to search for creative solutions. When people confront new difficulties, such as increasing boredom with sex after 3 years of marriage, the problem may stimulate creative efforts to devise novel and interesting sexual experiences. Fantasies are a second stimulant of creativity. As people imagine sexual activities they have never done before, they may consciously attempt to create special sexual experiences that are uniquely their own. Through the creative recombination of different rules, scripts, fantasies, and novel ideas, people can construct sexual plans and actions that differ from anything they have ever done in the past or seen others do. Although most creative acts are not radically different from things that other people in their culture do, they do contribute to the cultural innovations that add spice to life.

E. Society

Human creativity causes societies to change and evolve as the years pass, as can be seen by contrasting Victorian sexual constraints of the late 1800s with modern sexual practices. As millions of creative people use their brains to invent novel sexual practices and share them with others, some of these innovations change the erotic practices of the larger society. Many new ideas are lost after being tried a few times, but others—usually the most rewarding ones—spread and become widely popular. Magazines and other information media may help popularize certain sexual positions or fantasies. Public debate may lead creative people to challenge old taboos or invent safer, more rewarding sexual practices.

People also change democratic societies by voting, for example, using the ballot to express their views on abortion, nude beaches, pornography, and other sex-related topics. Democratic societies need to educate each new generation to use their brains to make democracy work well. Concerned citizens need to listen to the many views voiced in their society, evaluate all options suggested by others, seek creative new directions, and take active roles in improving society, including those social conditions related to sexuality and gender.

Societies are not static, and we are in the midst of some of the most rapid social changes ever seen in history regarding the treatment of both sex and gender. The creative contributions of millions of individuals provide the raw material for these social changes. Those social practices that are most rewarding tend to gain favor, whereas practices that produce pain fall out of favor. In a large democratic society, people can have very different values about pornography, abortion, prostitution, and countless other sexual topics, so that social change concerning sexual practices is not always rapid. (The process of social evolution has parallels with biological evolution: The raw materials for biological evolution are mutations, whereas social

evolution draws on the raw materials of human creativity. Biological evolution is steered by the natural selection of the fitter individuals, whereas social evolution is shaped by the reinforcers and punishers that follow social behaviors.)

Among the countless debates about sex in our society, let us examine two that occupy many academics: the first is constructionism versus essentialism, and the second is the validity of cultural relativism. Some people argue that all human sexuality and gender roles are mental constructions, inventions of the brain that are free from any biological constraints of anatomical maleness or femaleness. Pure constructionists usually take a subjective or phenomenological point of view and state that ''everything is in the mind;'' hence, we cannot actually know the ''real world'' outside our skins because all our perceptions of the entire world are constructions located completely inside our brains. People who study human fantasies can tell you that the brain can invent almost any type of constructions about sex and gender. Constructionists also point out that our inner images of the world are biased by the words and images we inherit from our society, and, worse, there is no way to know whether these social inputs are true.

People who are critical of the scripts and images provided by their society can use the constructionist perspective for political ends. Unfair social practices (such as the subjugation of females by males) can be exposed as mere social constructions, not concrete and immutable facts. Constructionists often seek to empower people to create more liberated and utopian sex and gender roles by using their critical analyses to deconstruct and destroy old, ''status quo'' scripts and images.

Because everything we believe is basically ''in our minds,'' extreme constructionists assume that biological ''facts about sex'' are trivial—or even misleading—information for shaping our brain's constructions of sex and gender. Constructionists describe purely biological views about sex and gender as ''essentialism''—a naive belief that sex and gender are shaped solely by biological essentials, such as sex chromosomes, sex hormones, and sex differences in the brain. At its extreme, pure essentialism makes all behavior appear to be biologically determined, leading to the view that ''biology is destiny.'' For example, sociobiologists sometimes claim that ''selfish genes'' control our sex and gender behavior. This offends social constructionists for two reasons: it is a form of biological determinism, and it provides support to political causes that support very traditional and old-fashioned views of sex and gender roles. Both of these are anathemas to social constructionists.

Can our human brains determine which view is correct, constructionism or essentialism? The answer depends on the methodology we use to approach the question. If one uses introspection, one may conclude that one's brain can create the world to be anything it wants. For example, one may note that pessimists look at their world and see doom and gloom, whereas optimists look at the same physical world and see hope and happiness. Perhaps sex and gender are constructions that each brain can freely create. The methods of transcendental philosophies also suggest that brains can transcend their locations in female or male bodies and create subjective realities that are not constrained by those physical bodies.

The scientific method offers a different perspective, the one taken in this article. Scientists should use their brains to examine all types of hypotheses about sex and gender. This reveals a continuum of hypotheses, with constructionism and pure essentialism at the two extreme ends. Between the two extremes are numerous other hypotheses that interweave biological and social factors in various combinations, some being more biological than social and others having other leanings. After testing all of these hypotheses against the empirical data available from several disciplines, many scientists agree that most data on human behavior do not support theories at either extreme of the continuum of hypotheses. Most data support theories that show that both biological and social factors are important, and each influences the other. The view presented in this article is that sex and gender are shaped by biology (including sexual reflexes, neurophysiology, and hormones) and by years of learning experiences (including Pavlovian conditioning, operant learning, and social scripts). From this scientific perspective, both biological and social factors interact with the brain's creative abilities to invent new behavior patterns and social practices. Biosocial theories that blend an empirically defensible mixture of both biological and social variables may be more defensible than theories at either extreme—either total constructionism or pure essentialism.

Cultural relativism is a second major topic of academic debate. Anthropologists have conducted field studies on many societies and documented considerable variation in sexual and gender practices among cultures. For example, some societies have painful rites of passage that boys or girls have to experience before they can be treated as adults. Other societies have no such practices. Some societies allow

young people to select the person they wish to marry, whereas other societies have arranged marriages in which the parents select the spouse for their child to wed. In Japan today, many marriages are still arranged, though Western-style "love matches" are becoming more common.

Extreme cultural relativists argue that there can be countless different cultural variations on sex and gender behavior, and none is more valid than others. All through history, human brains have created a large number of different societies on our planet—with different sex and gender practices—so who can say which one is "right" or "better than others"? Hence, extreme relativists argue that no culture should sit in judgment of the sexual or gender practices of other cultures. When one nation takes the role of judging other cultures and finds faults, those other cultures often return with critical assessments of the judgmental nation, asking what right it has to condemn them. "Judge not, least ye be judged." It is so easy for people in one culture to be biased by their own values and social practices when assessing other cultures.

As powerful as this argument appears to be, some cultures have practices that many other societies consider to be quite harsh, if not brutal. Some societies virtually enslave women and restrain their movement as if they were in jails. Some societies mutilate children's genitals so badly during their rites of passage to adulthood that some children become infected and a few die, whereas the survivors suffer pain and loss of sexual pleasure when they engage in sexual intercourse after they recuperate from the ritual. According to extreme cultural relativism, there is no way to criticize these practices.

Debates about cultural relativism have resonated in the halls of academe for many decades. Again, one's conclusions about this topic depend on the methodology one uses to analyze it. People who take phenomenological perspectives—emphasizing introspection, constructionism, or transcendentalism—are reluctant to claim that any one individual or society can condemn the sexual and gender practices of any culture. Some scholars see this topic as a politically charged issue, because they fear that dominant and wealthy nations in the developed world may force their values and practices on smaller and more vulnerable cultures. Westernization of the whole world could obliterate many ancient cultural practices and reduce the cultural diversity of the planet.

The scientific method provides an alternate perspective. Anthropologists, physicians, epidemiologists, and other scientists can collect data on different cultural practices and evaluate the data according to various criteria. Does genital mutilation increase the risk of infection, sexual dysfunction, or death? Are the effects trivially small or quite noticeable? Next, these data can be made available to anyone who is interested in these issues.

There is no question that debates about cultural relativism have been useful in training people to think twice about imposing their personal values on people of different cultures. It has taught us to question individuals who criticize or disparage other societies merely because they differ from their own society. Fortunately, the scientific method allows us to go further than this. It provides numerous techniques for evaluating hypotheses about all the social practices of all cultures. Societies with painful rites of passage that mutilate the genitals do have higher infection and death rates, and some people are scarred for life, with reduced ability to enjoy sexual relations. If people want to minimize the risk of infection, death, and sexual dysfunction, they have data they can use to argue against those practices. Many cultures have practices that produce more pain than necessary, practices that increase the risks of AIDS infections, unwanted pregnancies, or sexual abuse. The scientific method can help identify those cultural practices that are best at enhancing sexual pleasure while reducing the risk of pain, STDs, and other aversive outcomes. Science can also evaluate gender roles and identify which cultural practices allow both women and men to have lives that are pleasurable and fulfilling, while minimizing suffering and pain. There are several scientific disciplines that collect data on these topics, and the Internet is making such studies increasingly available to people all around the world. We shall see what they do with the information.

Sexual Differentiation, Hormones and

SUSAN L. ZUP and NANCY G. FORGER
University of Massachusetts

GLOSSARY

androgen insensitivity syndrome (AI) A condition caused by a genetic defect in the androgen receptor, creating individuals who produce androgens but are unable to respond to them.

congenital adrenal hyperplasia (CAH) A condition in which a genetic defect in one of several adrenal enzymes causes insufficient production of glucocorticoid hormones and excessive production of androgens by the adrenal gland, beginning *in utero*.

gonads The primary sex organs; ovaries (female) and testes (male).

hypothalamus A small structure at the base of the brain that sits just above the pituitary gland; it consists of many different clusters of cells that control functions such as sexual behavior, the secretion of hormones, and the regulation of drinking and feeding.

magnetic resonance imaging (MRI) A noninvasive procedure using radio waves and a strong magnetic field for two- and three-dimensional imaging of living tissue, including the brain.

motoneuron A specialized nerve cell in the spinal cord or brain stem that directly connects to and controls muscle.

nucleus As used in this article, an identifiable cluster of neural cell bodies in the central nervous system.

organizational hypothesis The concept that testosterone permanently "organizes" the brain during fetal or neonatal development to create a male-typical pattern of brain structures.

sexual dimorphism A sex difference in form or structure.

Sexual differentiation is the process by which the two sexes become different. For all mammals, including humans, sexual differentiation of the body is driven primarily by hormones produced by the gonads. This article will review the process of sexual differentiation and will present evidence that hormones cause sex differences in the human brain.

I. SEXUAL DIFFERENTIATION: AN OVERVIEW

Almost everyone agrees that, on average, the behavior of men and women differs. By contrast, there is considerable controversy about *how* behavioral sex differences come about. The evidence is quite strong for nonhuman animals that sex differences in behavior are attributable to specific structural or functional sex differences in the brain. Logically, this must be true for humans as well: because all behaviors are controlled by the nervous system, stable, predictable sex differences in human behavior must be due to sex differences in the structure or function of some neural circuit(s). More problematic are determining the extent to which sex differences in the human nervous system are innate and sorting out the relative contributions of genes, hormones, and socialization to the development of male and female brains.

Among laboratory animals, a vast literature indicates that the brain becomes sexually differentiated, in large part, as a result of exposure to gonadal steroid hormones. The same hormones that determine the appearance of the genitalia and the structure of the urogenital tracts during embryonic development concomitantly influence the developing brain. For this reason, an overview of the process of sexual differentiation of the body will be presented first, followed by a discussion of neural sex differences and their origins in animals and humans.

A. Sexual Differentiation of the Body

The fundamental mechanism of sexual differentiation of somatic tissues (''the body'') is essentially identical for all eutherian mammals, including humans. The genetic sex of an individual is determined at the moment of fertilization. The unfertilized ovum, or egg, contains a single sex chromosome, X, inherited from the mother. If a sperm carrying a second X chromosome fertilizes the ovum, then the embryo is a genetic female (XX); a genetic male (XY) will result if a sperm carrying a Y chromosome fertilizes the egg. However, as far as anyone can tell, early development proceeds identically for XX and XY embryos. In humans, the sexes cannot be distinguished (except by a chromosome test) until the eighth week of gestation. Prior to that time, both sexes possess a pair of so-called undifferentiated or ''indifferent'' gonads located in the abdominal cavity. The undifferentiated gonads are capable of becoming either ovaries or testes. If a normal Y chromosome is present (i.e., in the vast majority of genetic males), testes will develop; the indifferent gonads will become ovaries if the Y chromosome is absent (as in genetic females).

The gene on the Y chromosome responsible for testis development is known as SRY (*S*ex-determining *R*egion of the *Y* chromosome) and was identified by studying so-called ''XX-males.'' Occasionally, men (or mice) are found that appear to be genetically female (XX) but that nonetheless are phenotypically male (i.e., possess testes, a scrotum, and a penis). In almost every case, careful scrutiny reveals that a small piece of the Y chromosome is attached to one of the X chromosomes of such XX males. This piece of the Y presumably was inherited due to an abnormal chromosome crossover event during meiosis (a step in gamete development). By progressively pinpointing the piece of the Y chromosome common to all XX males, scientists eventually isolated the SRY gene. Of course, normal development of the testes and ovaries depends on the coordinated expression of many genes. SRY may be thought of simply as a switch that turns on a genetic cascade of other essential, secondary genes.

Although chromosomes and genes are responsible for the crucial first step of sexual differentiation (i.e., differentiation of the gonads), subsequent steps are driven *not* primarily by sex differences in genes but by differential exposure to *hormones* in males and females. Soon after the embryonic testes differentiate, they begin producing two hormones: *anti-Müllerian hormone* (also known as Müllerian inhibitory substance or Müllerian regression factor) and *testosterone*. Together, these hormones determine the subsequent differentiation of the internal reproductive tract and the external genitalia. As will be discussed later, the androgenic hormone, testosterone, also has wide-ranging effects on the developing nervous system.

Prior to sexual differentiation, all human embryos possess two sets of ducts, which are the precursors of both the male and female urogenital systems (Fig. 1). The Wolffian duct has the capacity to develop into the male urogenital tract, and the Müllerian duct is the anlagen of female structures. Anti-Müllerian hormone, secreted by the embryonic testes, causes the Müllerian ducts to regress in males. Testosterone, the other major testicular secretion, causes the Wolffian ducts to develop into the epididymis, vas deferens, and seminal vesicles. The absence of anti-Müllerian hormone in females allows the Müllerian ducts to persist and give rise to the fallopian tubes, uterus, and upper vagina (Fig. 1). The Wolffian ducts degenerate in females as a result of the simple absence of testosterone. Note that, in this scenario, female differentiation occurs ''by default'' in the absence of specific hormones, and it is the presence of hormones (anti-Müllerian hormone and testosterone) that drives the differentiation of males.

In addition to its effects on the Wolffian ducts, testosterone is also responsible for differentiation of the external genitalia. The primordia of the external genitalia are indistinguishable in early male and female embryos, consisting of a genital tubercle, genital folds, and genital swellings surrounding a single urogenital opening (Fig. 2). In the absence of hormonal stimulation, these structures form the clitoris and labia of females, whereas testosterone directs these same primordia to form the penis and scrotum in males. In this case, testosterone must first be converted at the genital skin to the more potent androgen, dihydrotestosterone, for complete virilization of the external genitalia. In humans, these events are completed by the end of the first trimester of pregnancy (approximately 12 weeks gestation).

B. Mechanisms of Hormone Action

How do the testicular hormones exert their profound effects on the developing body? In general, in order for a hormone to elicit a response in a given cell, that cell must have corresponding hormone ''receptors.'' This is true regardless of whether the cell in question is

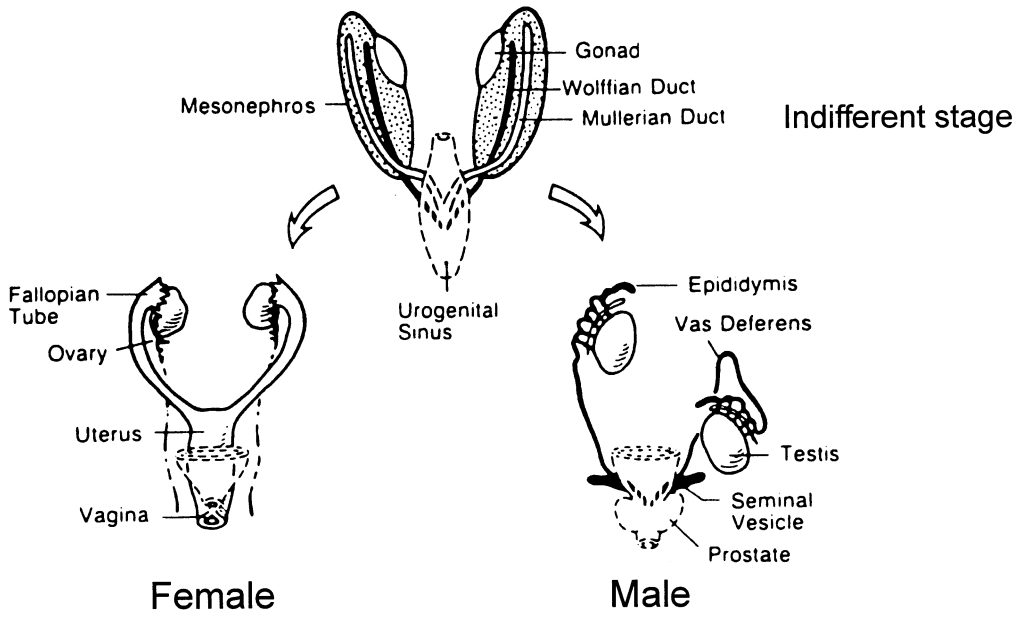

Figure 1 Differentiation of the internal genitalia in humans. Adapted, with permission from George, F. W., and Wilson, J. D. (1994). Sex Determination and Differentiation. In *The Physiology of Reproduction*, 2nd ed., pp. 3–28, (E. Knobil and J. D. Neill, Eds.). Raven Press, New York.

located in the genital skin, the embryonic urogenital ducts, or the brain. Hormone receptors are specialized proteins that bind to and interact with hormones to ultimately cause changes in target cells. Such receptors may be embedded in the plasma membrane on the surface of cells or may be found intracellularly, within the cytoplasm or cell nucleus. Anti-Müllerian hormone is itself a protein that exerts its effects by binding

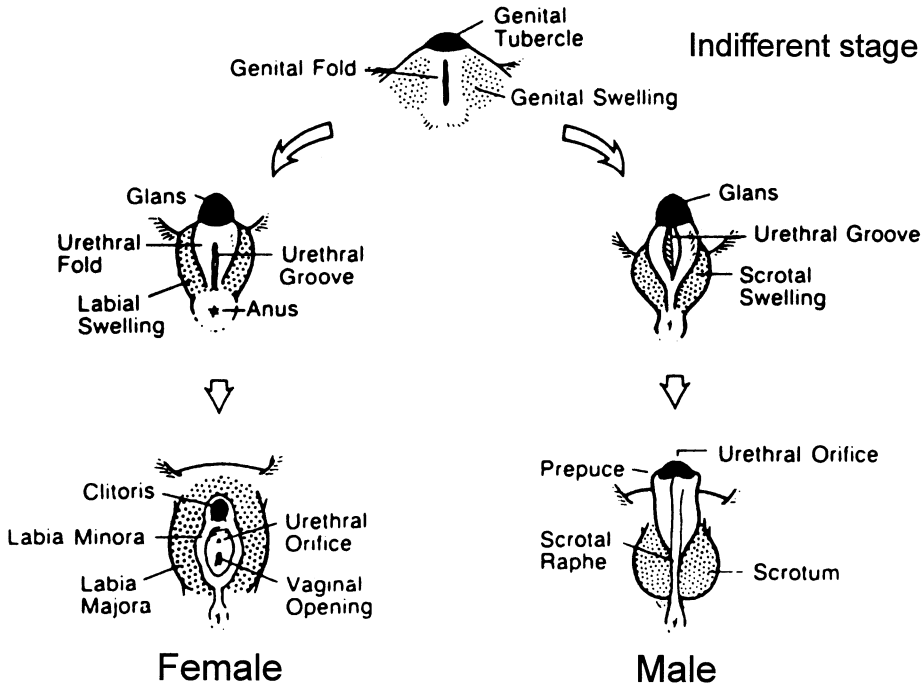

Figure 2 Differentiation of the external genitalia in humans. Adapted, with permission, from George, F. W., and Wilson, J. D. (1994). Sex Determination and Differentiation. In *The Physiology of Reproduction*, 2nd ed., pp. 3–28, (E. Knobil and J. D. Neill, Eds.). Raven Press, New York.

to cell surface membrane receptors. By contrast, most of the actions of the sex steroids are thought to be mediated by intracellular receptors.

Steroid hormones, such as testosterone, are lipophilic and can passively diffuse through the lipid-rich plasma membrane of cells. Once inside a target cell, the steroid may directly bind its receptor, or it may first be converted to another hormone metabolite. For example, after it enters a target cell, testosterone can be converted into dihydrotestosterone by the enzyme 5 α-reductase, or it can be metabolized to estradiol by the aromatase enzyme. The fate of testosterone will depend upon which enzymes are present in a given target cell. The "active" steroid metabolite then binds the corresponding receptor protein (an androgen receptor for testosterone or dihydrotestosterone, an estrogen receptor for estradiol) found in the cytoplasm or cell nucleus. These intracellular steroid hormone receptors are ligand-dependent transcription factors, which means that upon binding hormone they interact with specific DNA sequences to directly alter gene transcription (Fig. 3).[1]

If receptors to a given hormone are defective or absent, then cells cannot respond to the hormone. For example, males that, due to a genetic defect, lack receptors to anti-Müllerian hormone develop as pseudo-hermaphrodites. These individuals possess testes and fully differentiated Wolffian duct derivatives, but also a uterus and fallopian tubes. Similarly, XY individuals that lack functional androgen receptors are said to be "androgen-insensitive." The testes develop in these genetic males (due to the presence of the SRY gene on the Y chromosome) and produce plenty of testosterone. However, in the absence of androgen receptors, testosterone elicits no response: the Wolffian ducts fail to develop and the external genitalia are completely feminized in androgen-insensitive males. Such individuals are usually raised as girls and may not be recognized as androgen-insensitive genetic males until puberty, when they fail to menstruate. The foregoing examples underscore the principle that it is hormones, not sex chromosomes, that primarily drive somatic sexual differentiation. An individual's phenotype follows closely to his or her "hormonal sex," regardless of genetic sex.

[1]Although the "classical" mechanism of steroid hormone action involves binding to intracellular receptors and direct regulation of gene transcription, some effects of steroids occur too rapidly to involve changes in gene expression. These nongenomic actions of steroid hormones apparently involve hormone receptors located on the membranes of cells. At present, the extent to which nongenomic actions of steroid hormones contribute to sexual differentiation is not known.

C. The Brain as a Site of Steroid Hormone Action

Although early endocrinologists initially focused on the mechanisms of hormone action in peripheral tissues, it became clear in the 1960s and 1970s that *neurons* also express receptors for gonadal steroid hormones. Androgen and estrogen receptors are widely distributed throughout the brains of mammals. Whereas the highest concentrations of steroid receptors are found within the hypothalamus and in limbic regions providing input to the hypothalamus, brain regions associated with higher cognitive functioning (e.g., the cerebral cortex and hippocampus) also bind androgens and estrogens. This basic pattern of steroid hormone receptor distribution in the brain is present in both sexes and is similar across a wide range of species, from rats, to guinea pigs, to monkeys, to humans. Perhaps not surprisingly, many of the sex differences described so far in vertebrate brains are found in regions, such as the hypothalamus, that are rich in androgen and/or estrogen receptors. Importantly, neural receptors for gonadal steroids also are expressed in early development. Thus, the brain must be considered a target site for direct steroid hormone action during perinatal life and in adulthood.

II. SEXUAL DIFFERENTIATION OF THE NERVOUS SYSTEM: PRINCIPLES DERIVED FROM ANIMAL WORK

Although the role of hormones in sexual differentiation of the body was understood by the 1940s, the brain was initially considered immune to hormone action. In the late 1950s and 1960s, however, work on sexual behavior in rodents first led to the prediction that sexual differentiation of the brain, like other parts of the body, was controlled by gonadal steroid hormones. For example, an adult female guinea pig will normally exhibit female-typical behaviors during mating, including a stereotypical receptive posture called lordosis. However, a female guinea pig given testosterone early in development will exhibit lower levels of lordosis in adulthood and will exhibit higher levels of male-typical sexual behaviors (e.g., mounting other animals). These observations led Phoenix, Goy, Gerrall, and Young to propose the "organizational

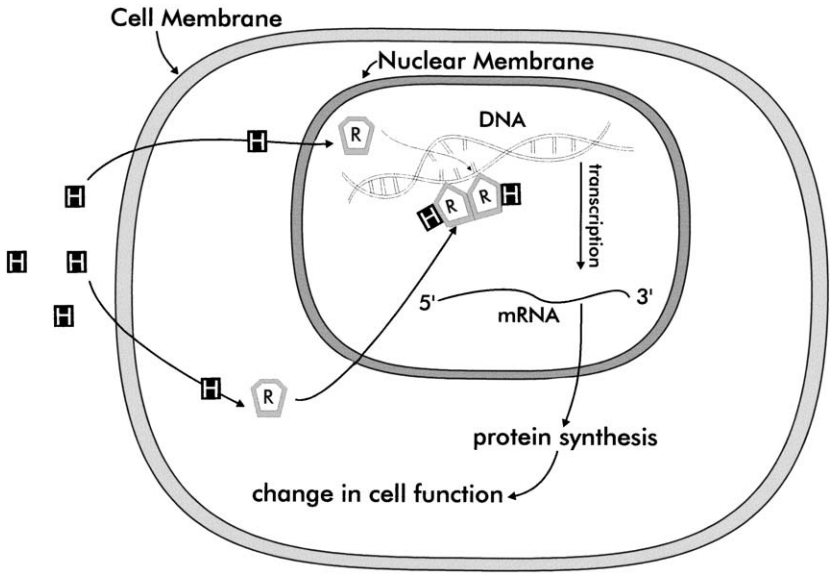

Figure 3 Simplified model of the classical mechanism of steroid hormone action. The steroid hormone (H) diffuses across the cell membrane to bind a hormone receptor protein (R) located in the cytoplasm or nucleus. Hormone–receptor complexes then bind to specific sequences on DNA to regulate gene transcription.

hypothesis:'' testosterone, present in the developing male, permanently ''organizes'' the brain during fetal or neonatal development to create a male-typical pattern of brain structures. In adulthood, gonadal steroids then ''activate'' the previously organized neural substrates, resulting in male-typical behaviors. Females are not normally exposed to high levels of testosterone and, thus, develop female-typical behaviors. The theory of hormone-directed neural differentiation was strengthened when, as previously discussed, receptors to gonadal steroid hormones were shown to exist in the brain. However, at the time the organizational hypothesis was first proposed and for a number of years afterward, no neural sex differences had actually been discovered.

One of the first examples of a sex difference in the brain came from a 1971 study by Raisman and Field, who used electron microscopy to characterize more than 25,000 synapses in the preoptic area of the rat brain. They found a sex difference in neural connectivity, such that male rats had more of a particular type of synapse than did female rats. If all sex differences had been this elusive, the field of neural sex differences might have died in its infancy. In 1976, however, a sex difference in songbird brains was discovered that was so large, it could be seen in brain sections with the naked eye. The higher vocal center (HVC) controls singing in songbirds such as zebra finches. Nottebohm and colleagues demonstrated that the HVC of male zebra finches is 5–6 times larger in volume than that of females. Because male zebra finches sing and females do not, this was an exciting finding lending credence to the idea that sex differences in the brain cause sex differences in behavior. Since then, an astonishing (and ever growing) number of sexual dimorphisms in the nervous system have been discovered in many species. Here we present just two of the best characterized sex differences in the rodent nervous system, for which possible human homologs have been identified.

A. The Spinal Nucleus of the Bulbocavernosus

The spinal nucleus of the bulbocavernosus (SNB) is a sexually dimorphic group of motoneurons in the lumbar spinal cord of rodents (Fig. 4). These motoneurons innervate muscles (including the bulbocavernosus muscle) surrounding the base of the penis, which help control erection and ejaculation. Although the muscles and motoneurons are present in both sexes during fetal development, the bulbocavernosus muscle and SNB motoneurons degenerate in females around the time of birth. Adult female rats completely lack the bulbocavernosus muscle and have only one-fourth as many SNB motoneurons as do adult males. Sexual differentiation of the SNB conforms nicely to the organizational hypothesis. Female rats given testosterone around the time of birth are permanently ''masculinized,'' in that they retain the bulbocavernosus musculature and many more motoneurons in the

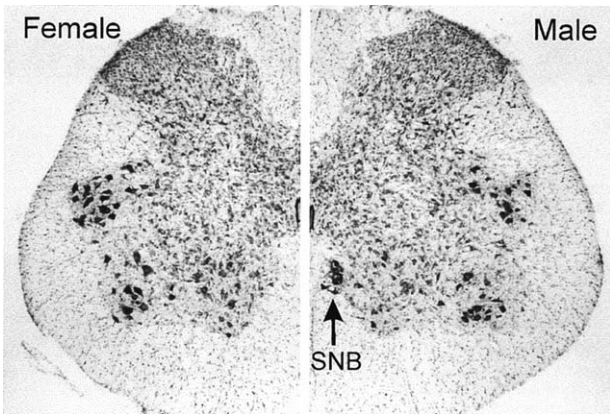

Figure 4 Photomicrographs depicting the spinal nucleus of the bulbocavernosus (SNB) in adult female (left) and male (right) rats. Androgens produced by the perinatal testes rescue SNB motoneurons in males, whereas most SNB cells degenerate in females.

SNB than do control females. Likewise, blockage of the actions of testosterone in a perinatal male rat causes the bulbocavernosus muscle to atrophy and most SNB motoneurons to die. For example, male rats with a genetic defect of the androgen receptor have no more SNB motoneurons than do normal females; this finding indicates that androgens direct the sexual differentiation of the SNB. Although first discovered in rats, homologs to the SNB have since been found in many different species, including mice, gerbils, hyenas, dogs, monkeys, and humans.

B. The Sexually Dimorphic Nucleus of the Preoptic Area

The sexually dimorphic nucleus of the preoptic area (SDN-POA) is the best characterized sex difference in the mammalian brain, and homologs have been found in species ranging from rats and gerbils to hyenas, macaques, and humans. SDN-POA volume and neuronal number are 5–7 times larger in adult male rats than in females. Similar to the SNB, SDN-POA volume is permanently increased in female rats treated with testosterone during a critical neonatal period, and castration of male rats on the day of birth permanently decreases the size of the SDN-POA. In this case, however, testosterone itself is not the active hormonal metabolite; rather, it is the conversion of testosterone to estradiol (a process known as aromatization) within individual neurons that masculinizes SDN-POA volume and neuron number. Although the aromatization of testosterone to an estrogen is crucial for a number of neural sex differences in rodents, the role of estrogens in the sexual differentiation of primate brains is less clear.

The SDN-POA is located in a region of the brain (the preoptic area of the hypothalamus) that controls male sex behavior. Large lesions of the preoptic area decrease male-typical sex behavior in snakes, lizards, birds, rodents, ungulates, and primates. Lesions confined to sexually dimorphic regions of the preoptic area disrupt scent marking and sexual behavior in male gerbils and alter sexual partner preference in male ferrets. However, the function of the rat SDN-POA has not been clearly demonstrated. Lesions limited to the SDN-POA of rats result in only subtle decrements in male sex behavior. The lack of a clear behavioral correlate for even so striking a sex difference as that in the SDN-POA illustrates the difficulty in demonstrating a cause and effect relationship between brain morphology and behavioral differences.

C. How Do Hormones Cause Neural Sex Differences?

Many sex differences in the nervous system (including the SNB and SDN-POA) involve a difference in neuron number. Sex differences in neuronal number could result from sex differences in neurogenesis (the "birth" of neurons), neuronal migration, neuronal differentiation, or neuronal cell death. At present, the evidence is strong that differential rates of cell death between the sexes contribute to neural sex differences. During nervous system development, many more neurons are born than are ultimately needed. Through a decision-making process not yet fully understood, the "extra" neurons die off while other neurons live. Gonadal sex steroids can influence this process in hormone-sensitive brain regions so that more neurons die in one sex than in the other, resulting in regional sex differences in neuron number.

In the SNB and SDN-POA, testosterone, or its hormonal metabolites, *decreases* cell death, thereby creating a sex difference in neuron number "favoring" males. This is not always the case, however. For example, in the anteroventral periventricular nucleus (AVPV), a cell group in the hypothalamus crucial for the control of ovulation, female rats and mice have more neurons than do males. This sex difference in neuronal number apparently is also due to hormonal control of cell death, although here testosterone *increases* cell death. Therefore, the same hormone seems to decrease cell death in some neural regions (e.g., SNB and SDN-POA) while increasing it in others

(e.g., AVPV). Testosterone may also cause sex differences by influencing neurogenesis, neuronal migration, and/or neuronal differentiation, although this has not yet been demonstrated conclusively.

D. Sex Differences Due to "Activational" Effects of Hormones

The organizing effects of hormones engender many structural sex differences in the developing nervous system. However, sexually dimorphic *behavior* often requires the presence of hormones in adulthood to "activate" previously organized brain circuits. For example, a normal adult female rat requires stimulation by estrogens and progestins to exhibit sexual receptivity; if she lacks these hormones in adulthood (e.g., if the ovaries are removed), then sexual behavior is abolished. However, even large amounts of estrogens and progestins may not cause an adult female rat to show normal levels of sexual receptivity, if she had previously been treated with testosterone during perinatal development.

This distinction between organizational and activational effects of hormones is a useful heuristic device, but it may be an oversimplification. Sex steroid hormones secreted in adulthood not only activate existing neural circuits but can also change neural morphology. For example, the volume of the medial amygdala is normally larger in adult male rats than in females. Breedlove and colleagues have shown that this sex difference in the medial amygdala can be eliminated by equalizing the circulating testosterone levels in male and female rats *in adulthood* (either by castrating males or by giving females exogenous testosterone). In addition, the same gonadal hormones that influence cell death during development may also influence that process during adulthood. Adult birds and mammals continue to make new neurons in specific parts of the brain throughout life, and evidence shows that gonadal hormones can modulate the life span of newly born cells. Thus, structural sex differences in the nervous system may be due to differential exposure to sex steroid hormones in adulthood as well as in development.

III. SEX DIFFERENCES IN THE HUMAN BRAIN

The prediction that sex differences *must* exist in the human brain comes from at least three different types of observations: men and women (or boys and girls) differ predictably in (1) behavioral traits (e.g., aggression, juvenile play); (2) average cognitive abilities; and (3) the incidence of neurological and psychiatric disorders. Regardless of whether these differences are due to genes, hormones, socialization, or the confluence of all three, sex differences in behavior, neuropathology, and cognitive performance must be reflected by sex differences present someplace in the nervous system. As described next, anatomical and functional differences have, in fact, been identified in the human brain, although thus far it has proven difficult to definitively link the neuroanatomical findings with specific behavioral sex differences.

A. Anatomical Sex Differences in the Human Brain

In comparison to the rich animal literature on neural sex differences, reports of sexual dimorphisms in the human brain are relatively sparse. This may suggest that sex differences in the human nervous system are not as numerous or as pronounced as they are in laboratory animals. However, animal studies routinely compare the brains of large groups of animals precisely matched for age, genetic background, and rearing conditions. Similar control over human subjects obviously is not feasible, and experimenters working with humans often must content themselves with relatively small, heterogeneous samples. The difficulty of conducting well-designed studies of the human brain almost certainly contributes to the relative lack of information about sex differences in our own species. Despite the limitations, a number of anatomical sex differences have been reported in the human nervous system (Table I). These findings have predominantly come from the examination of post mortem material, although investigators are increasingly making use of magnetic resonance imaging (MRI) to study structural sex differences in the living human brain. A caveat that must be kept in mind when examining Table I is that several of the listed findings are not firmly established. For a number of the sex differences listed, the original report has not been followed up, so that the observation is neither refuted nor confirmed. In other cases, multiple studies of a single brain area have yielded conflicting conclusions (see later discussion).

1. Overall Brain Size and Neuron Number

Perhaps the most obvious, and best established, neural sex difference in the human brain is that of overall size.

Table I
Anatomical Sex Differences Reported in the Human Nervous System

Neural structure	Nature of the difference	Reference[a]
Whole brain	Larger in men	Many reports spanning over 100 years.
Neocortex	More neurons in men	Pakkenberg & Gundersen (1997). *J. Comp. Neurol.* **384,** 312.
Language-related areas		
Planum temporale	Size of left and right more symmetrical in women; neuronal density greater in women	Wada *et al.* (1975). *Arch. Neurol.* **32,** 239; Witelson *et al.* (1995). *J. Neurosci.* **15,** 3418.
Dorsolateral prefrontal cortex and superior temporal gyrus	Proportionally larger in women	Schlaepfer *et al.* (1995). *Psychiartry Res.: Neuroimaging* **61,** 129.
Structures connecting the left and right brain		
Corpus callosum	Posterior portion is larger and/or more bulbous in women	De Lacoste-Utamsing & Holloway (1982). *Science* **216,** 1413.
Anterior commissure	Larger, and more fibers, in women	Allen & Gorski (1991). *J. Comp. Neurol.* **312,** 97; Highley *et al.* (1999). *Biol. Psych.* **45,** 1120.
Massa intermedia of thalamus	More often present, and larger, in women	Morel (1948). *Acta Anat.* **4,** 203; Allen & Gorski (1991). *J. Comp. Neurol.* **312,** 97.
Regions of the hypothalamus		
SDN-POA[b]	Larger in men	Swaab & Fliers (1985). *Science* **228,** 1112.
INAH-3[c]	Larger in men	Allen *et al.* (1989). *J. Neurosci.* **9,** 497.
BNST[d]	Subarea is larger in men	Allen & Gorski (1990). *J. Comp. Neurol.* **302**, 697.
SCN[e]	Sex difference in shape	Swaab *et al.* (1985). *Brain Res.* **342,** 37.
Spinal cord		
Onuf's nucleus	More motoneurons in men	Forger & Breedlove (1986). *Proc. Natl. Acad. Sci. USA* **83,** 7527.

[a]Where multiple references exist, the earliest reports are cited.
[b]SDN-POA: sexually dimorphic nucleus of the peoptic area.
[c]INAH-3: third interstitial nucleus of the anterior hypothalamus.
[d]BNST: bed nucleus of the stria terminalis.
[e]SCN: suprachiasmatic nucleus.

In studies spanning many decades, from laboratories all over the world, brain size is found to be about 10% greater in men than in women. Although this sex difference is minimal when brain size is mathematically "corrected" for body size, the rationale for such a correction is not immediately obvious. Body weight and body height each account for only a tiny proportion of the variance in brain size *within* each sex. Moreover, by dismissing the sex difference in brain size on the basis of a correction for body size, we risk overlooking some interesting issues: Is the relationship between body and brain size *causal*, and, if so, how do large bodies "cause" large brains? If the relationship is not causal, is there some common factor (e.g., gene or hormone) independently modulating both brain and body size?

Only very recently have scientists addressed the question of whether the larger brains of males actually contain *more cells*. For at least some neural regions, the answer appears to be "yes." Two different research groups have concluded that men have about 15% more neurons in the neocortex than do women, although there is disagreement as to whether there is a difference in neuronal *density* between the sexes. The consequences of a larger brain and more neocortical neurons are not immediately obvious, however, because general cognitive abilities such as overall intelligence and memory do not appear to differ significantly between

men and women. In addition, there is some evidence that the male advantage in cortical neuron number may be offset by an increase in neuronal processes (and, by extension, synapses) in females. The overall greater number of neurons in the neocortex of men also may belie some interesting regional sex differences in the opposite direction. For example, the volumes of several language-related cortical areas are proportionally larger in women than in men (Table I). Specifically, the planum temporale is about equal in absolute volume in men and women, despite the overall larger brains of men. This, combined with the report by Witelson and colleagues that neuronal density in the planum temporale is greater in women than in men, leads to the prediction of a greater total number of neurons in the planum temporale of females. Thus, the seemingly simple observations of sex differences in overall brain size and neocortical neuron number illustrate the difficulties encountered in attempting to ascribe a functional role to gross differences in neuroanatomy.

2. Structures Connecting the Left and Right Brain

A number of structures connecting the left and right sides of the brain have been reported to be larger in women than in men (Table I). These observations have generated considerable interest, because several neural functions, including speech and visuospatial function, appear to be less lateralized in female than in male brains. The corpus callosum is the major fiber tract connecting the left and right cerebral hemispheres, and a report of almost 20 years ago indicated that the posterior portion of the corpus callosum (the ''splenium'') is larger and more bulbous in women than in men. However, not all subsequent studies have replicated the finding, and despite a large number of reports examining the corpus callosum in men and women, no clear consensus regarding sex differences has emerged. A literature search indicates that the controversy continues to the present day, with about equal numbers of papers published in the last 5 years confirming and refuting the existence of a larger or more bulbous splenium in the corpus callosum of women. Because many studies on both sides of the argument appear to be well-designed and well-executed, the reason for the conflicting outcomes is not clear, although the great variability in size and shape of the corpus callosum *within each sex* no doubt contributes to the confusion. One must conclude that, if a sex difference in the splenium exists, it must be quite subtle.

The massa intermedia of the thalamus and the anterior commissure are also reported to be larger in women than in men. The massa intermedia is composed of neurons, neuropil, and loosely organized axons that connect the left and right thalami. This structure is completely absent from about 30% of all humans, and reports dating back to the 1940s indicate that women are significantly more likely than men to retain a massa intermedia. More recently, Allen and Gorski found that, when present, the massa intermedia is about 50% larger in women than in men. The anterior commissure is a fiber tract that primarily connects the left and right temporal lobes. This structure is reported by two independent groups of investigators to be significantly larger in cross-sectional area and to contain a greater number of fibers in women than in men.

3. The Hypothalamus

As discussed earlier, the hypothalamus is the site of many neural sex differences in laboratory animals, and several differences have also been reported in the hypothalami of men and women. Among these, the finding that appears most solid, in that it has been replicated by independent groups of scientists, is a sex difference in a small cell group known as INAH-3 (third interstitial nucleus of the anterior hypothalamus). INAH-3 contains about twice as many neurons in men as in women and is located within a region of the brain implicated in the control of male sexual behavior in virtually all vertebrates. On the basis of cytoarchitectonic criteria, Byne has argued that INAH-3 may be the primate counterpart of the SDN-POA of rats. However, nothing is known about the development of INAH-3, its function, or the role of gonadal hormones in sexual differentiation of this area. INAH-1 (also known as ''the SDN-POA of humans'') is another cell group in the anterior hypothalamus that has been proposed as the human homolog of the rat SDN-POA. Although it shares several neurochemical markers with the rat SDN-POA, not all studies find a sex difference in the overall volume of human INAH-1.

4. The Spinal Cord

There is a clear human homolog to the spinal nucleus of the bulbocavernosus (SNB) of rats, described in Section II. Motoneurons innervating the bulbocaver-

nosus muscle of humans are located in a cell group in the sacral spinal cord known as Onuf's nucleus, and men have more neurons in Onuf's nucleus than do women. The sex difference in human Onuf's nucleus (approximately 30% more neurons in men) is much less pronounced than the 3- to 4-fold sex difference in motoneuron number of the rat SNB. Should this relatively subtle sex difference in human Onuf's nucleus be taken as an indication that sex differences in the nervous systems of humans are less pronounced than they are in nonhuman animals? Probably not. Unlike female rats, women *do* have a bulbocavernosus muscle, although it is smaller and modified in form compared to that in males. The modest sex difference in motoneuron number of human Onuf's nucleus probably reflects the retention of the perineal musculature in women. In support of this conclusion, a bulbocavernosus muscle is also retained in female dogs, hyenas, and monkeys, and in each of these species males have about 20–50% more motoneurons in Onuf's nucleus than do females.

B. Sex Differences in Connectivity and Neurochemistry

In addition to the sex differences in gross anatomy listed in Table I, many sex differences are likely to exist in more subtle features of the brain, such as neural connectivity or neurochemistry. From animal work, it is clear that the size of projections from one neural region to another can vary markedly by sex and that many of these sex differences can be eliminated by manipulating gonadal hormones early in development. Sex differences in neurotransmitter levels within particular neural circuits also contribute importantly to behavioral differences in male and female laboratory animals and are modified by both organizational and activational effects of steroid hormones. Such sex differences would not be visible from routine inspection of post mortem brain tissue, which formed the basis of virtually all studies on the human brain until quite recently. Only in the last several years have investigators begun to tackle the question of ''functional'' sex differences in human neural tissue by adapting neurochemical staining techniques for post mortem human brains or by taking advantage of the development of techniques allowing for the functional imaging of the living human brain.

For example, positron emission technology (PET) can be used to examine the accumulation and distribution within the brain of radioactively labeled tracers injected into human subjects. PET studies report that the rate of synthesis of the neurotransmitter, serotonin, is significantly higher in men than in women. Men apparently also have an increased number of type-2 serotonin-binding sites in several brain regions. Because perturbations in the serotonin system are implicated in several psychiatric disorders, including unipolar depression, findings such as these may help to explain sex differences in the incidence of psychopathology (see Section III.D).

Functional MRI (fMRI) is another technique that has contributed significantly to the study of human sex differences. Based on the detection of regional changes in blood oxygenation induced by neural activity, fMRI is a noninvasive method for identifying brain regions involved in specific tasks. By using fMRI, Shaywitz and colleagues found a marked sex difference in the pattern of brain activation in men and women performing a phonological task (specifically, deciding whether two strings of nonsense words rhyme). Men predominantly used a language area in the left cerebral hemisphere, whereas more diffuse activation of both the left and right sides of the brain was observed in women performing the same task. A similar sex difference in lateralization of neuronal activity was seen in a PET study of men and women performing a grammatical task. Because the overall performance (speed and accuracy) of men and women on both tasks was equivalent, these studies raise an interesting point: neural sex differences may exist even when the behavior or performance of men and women is similar. MRI and fMRI hold tremendous promise for the study of human neural sex differences, because (1) they permit noninvasive, *in vivo* examination of carefully screened, well-matched subjects; (2) both anatomical structure and functional activation can be compared in the same subjects; and (3) it is possible to repeatedly scan the same individual. This last feature allows for longitudinal studies of the same groups of subjects, as well as before-and-after experimental designs.

C. Sex Differences in Behavior and Performance

Most of the evidence for sex differences in the human brain is indirect and comes from observations of sex differences in human behavior. Countless claims of behavioral and/or cognitive differences between men and women can be found scattered throughout the literature and in the popular press. However, the number of human behavioral sex differences that have been repeatedly confirmed in carefully designed studies

Table II
Effect Sizes for Sex Differences in Selected Human Behaviors

Behavior	Approximate effect size[a]
Aggression	Moderate
Childhood play (level of activity, degree of rough-and-tumble play, selection of toys and playmates)	Moderate to large
Tasks on which males typically outperform females:	
Visuospatial	
Three-dimensional visual rotation	Large
Two-dimensional visual rotation	Small
Spatial perception	Small to moderate
Spatial visualization	Negligible
Quantitative	
Overall ability	Small to moderate
Problem solving	Small to moderate
Tasks on which females typically outperform males:	
Verbal	
Overall ability	Negligible to small
Verbal–association fluency	Moderate
Speech production	Small
Perceptual Speed	Moderate

[a]Magnitude of effect size was defined according to J. Cohen (*Statistical Power Analysis for the Behavioral Sciences*, Academic Press, 1997). Effect sizes of approximately 0.8 standard deviation or greater were considered large, effect sizes of approximately 0.5 were considered moderate, effect sizes of approximately 0.2 were considered small, and effect sizes of less than 0.19 were considered negligible. Table adapted from Collaer and Hines (1995) with permission from the American Psychological Association. See Collaer, M. L., and Hines, M. (1995). Human behavioral sex differences: A role for gonadal hormones during early development? *Psychol. Bull.* **118,** 55–107, for supporting references.

is actually relatively small. Table II lists several of the most reliably observed sex differences in human behavior or performance. On average, males are more aggressive than females and exhibit more active, ''rough-and-tumble'' play in childhood. The sex difference in play is particularly interesting, in that it is found across cultures and can be observed in very young children. In the cognitive realm, males excel at visuospatial tasks, particularly those requiring three-dimensional mental rotation, whereas females typically excel at certain verbal skills, especially verbal fluency and perceptual speed. It is important to note that all of the sex differences described here are differences in the *average* behavior or performance of males and females. In all cases there is considerable overlap between the sexes, and the range of behavior within one sex usually is larger than the mean difference between the sexes. With large enough sample sizes, even tiny, arguably meaningless differences may be statistically significant. For this reason it is useful to categorize sex differences by ''effect size,'' as in Table II. Effect size is a measure of the size of the difference between two groups relative to the variability within groups. By one commonly accepted standard, when the mean difference between groups exceeds 0.8 times the standard deviation of scores *within* each group, the effect is said to be ''large.'' Note that, by this standard, the only sex differences listed in Table II that can be considered ''large'' are differences in three-dimensional mental rotation and childhood play. Arguably the greatest sex difference in human behavior is not listed in Table II. Most, but not all, men are sexually attracted to women, whereas most, but not all, women are sexually attracted to men. Although this gender difference is so large as to be often taken for granted, sexual partner preference must also have a neural basis.

Have any of the sex differences in behavior or performance been linked to observed sex differences in the brain? At this point, the answer is ''no;'' we cannot definitively point to any neural sex difference as the basis for any specific sex difference in human behavior. One difficulty in this endeavor is in moving from correlation to causation in human studies. For

example, LeVay has reported that the size of INAH-3 is larger in heterosexual men than in homosexual men, but it is not clear whether there is any causal relationship between INAH-3 size and sexual orientation or even how such a causal relationship could be tested. A second challenge stems from our lack of sophistication regarding the neural underpinnings of human behaviors. A case in point is the sex difference in juvenile play. Although some neural areas have been implicated in play behavior in animals (e.g., the amygdala in rats), in general we have only a weak grasp of the neurocircuitry underlying complex behaviors such as "play" in humans. Scientists cannot begin to explain sex differences in a given behavior until the neural basis for the behavior is understood.

Human language is one behavior that has received intense scrutiny and is relatively well-understood. In most people, neural regions involved in speech production and recognition are located predominantly in several interconnected cortical structures of the left frontal and temporal lobes. Several language-related areas are reported to be absolutely or proportionally larger in the brains of women than those in men (Table I). These anatomical sex differences favoring women may underlie the superior performance of women on several verbal measures. Note, however, that the relationship is purely correlational at this point. It will be very difficult to prove that larger language-related cortical areas "cause" enhanced verbal performance, but one step in that direction would be to determine whether there is a positive relationship between the size of specific language-related neural areas and verbal performance *within* each sex.

Table III
Neurological and Psychiatric Disorders That Exhibit a Sex Difference in Incidence[a]

Disorder	Ratio male:female
Primarily diagnosed in infancy or childhood	
Attention deficit–hyperactivity	80:20
Autism	80:20
Dyslexia	70:30
Gilles de la Tourette	70:30
Mental retardation	60:40
Stuttering	75:25
Primarily diagnosed in adulthood	
Alzheimer's disease	30:70[b]
Amyotrophic lateral sclerosis	62:38
Anorexia nervosa	7:93
Anxiety disorder	33:67
Bulimia	10:90
Depression	33:67
Gender identity disorder	75:25
Multiple sclerosis	33:67
Sleep apnea	90:10

[a]Data compiled from: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., 1994, American Psychiatric Association, Washington, DC, and reviews of the neurological literature. Where original sources report a range of gender ratios, the approximate midpoint of the range is given.

[b]Estimates of gender-specific incidence for Alzheimer's disease vary widely. After accounting for sex differences in life span, risk is between 1.5 and 3.0 times higher in women than in men.

D. Sex Differences in Neurological Diseases and Psychiatric Disorders

The marked sex differences that exist in the occurrence of many neurological and psychiatric diseases provide some of the strongest evidence for sex differences in the human brain. It has been argued that *most* major neurological disorders exhibit a sex difference in prevalence, disease course, or symptomatology, and some of the differences are quite striking (Table III). For example, about 80% of those suffering from autism are male; an even higher percentage of all cases of sleep apnea occur in men or boys. Conversely, females make up the large majority of cases of anorexia nervosa, and essentially all anxiety disorders are more prevalent in women than in men (i.e., simple phobia, social phobia, agoraphobia, panic disorder, and posttraumatic stress syndrome). For some disorders, such as schizophrenia, overall incidence does not vary by gender, but the disease course does.

One would think that if we understood why one sex represents the majority of those suffering from a given neurological condition or why one sex presents a different disease course than the other, we would be much closer to understanding the etiology and possible treatment of the problem. Nonetheless, surprisingly little is known about the neuroanatomical or neurochemical bases for sex differences in neurological and psychiatric diseases. Schizophrenia and dyslexia are two disorders that have received some attention in this regard. Although the overall lifetime risk for schizophrenia is about equal in men and women, the average age of onset is 3–5 years earlier in men. Women suffering from schizophrenia also exhibit less severe

symptoms and respond better to neuroleptic medication than do men. These sex differences may be due to differences in the neuropathology characteristic of male and female schizophrenics. A number of structural brain abnormalities are associated with schizophrenia (e.g., increased volume of the cerebral ventricles, reduced volume of the hippocampal area, and alterations in the corpus callosum), and each of these is seen more frequently in male than in female schizophrenics.

Dyslexia is a disorder characterized by a specific retardation in reading and spelling skills despite otherwise normal intelligence and is more prevalent in boys than in girls. In fact, as evidenced in Table III (top) and commented on by many investigators, males are at greater risk than females for almost all childhood neurodevelopmental disorders. Autism, attention deficit disorder, stuttering, dyslexia, Tourette syndrome, mental retardation, cerebral palsy, and epilepsy are all significantly more prevalent in boys than in girls. The sex difference in dyslexia is particularly interesting in light of the growing body of research suggesting that areas of the brain responsible for language are organized differently in males and females. As discussed earlier, functional imaging studies indicate that brain activation in males and females differs during phonological processing. Gender differences also are found in the morphology of language-related brain areas, and there are sexually dimorphic consequences of brain injury to the retention of language skills. In light of all this, it might be surprising if there were *not* differences in the incidence, symptoms, or causes of dyslexia in boys and girls. Post mortem studies conducted by Galaburda and colleagues indicate that dyslexia is associated with clusters of incorrectly positioned neurons, known as ectopias. Although the number of subjects examined so far has been small, ectopias appear to be much more prevalent in the brains of male than those of female dyslexics. Because malpositioned cells are thought to be indicative of disrupted neuronal migration during fetal life, this work suggests that a prenatal event may be responsible for the increased susceptibility to dyslexia in males.

IV. ARE HUMAN NEURAL SEX DIFFERENCES DUE TO HORMONES?

Virtually all of the neural sex differences described in nonhuman animals are ascribed to the actions of gonadal steroid hormones. Do sex differences in the human brain similarly depend on sex steroids? Although it would be parsimonious to assume so, the evidence thus far remains largely indirect. For example, it currently is not known whether any of the neuroanatomical sex differences listed in Table I are due to differential exposure to gonadal steroids in males and females. Many of the entries of Table I consist of tiny cell groups too small to be detected in the living brain by even the most sophisticated neuroimaging technology available today. In order to test whether there is a hormonal basis for these sex differences, scientists would have to rely on post mortem brains of individuals exposed to sex-atypical hormone levels. Such individuals are rare, and it would take years to compile an adequate sample. On the other hand, some structural sex differences (e.g., the sex difference in overall brain size) can readily be imaged in the living human brain, and it should be feasible to obtain scans from clinical populations of interest. For example, one could address whether the sex difference in brain size is androgen-dependent by comparing the brain scans of androgen-insensitive individuals with those of normal males and females. The next few years may yield investigations of this kind.

If sex steroids do cause sex differences in the human brain, they are likely to do so during one of three developmental windows when sexually dimorphic "peaks" of testosterone are observed in males: from about weeks 10 to 20 of gestation, during the first few postnatal months, and after puberty (Fig. 5). Although the ovaries are also capable of steroidogenesis beginning in midfetal life, androgen production by the ovaries is low and all mammalian fetuses are presumably exposed to estrogens and progestins of *maternal* origin. The role of *fetal* ovarian secretions in female brain development is not clear. Postpubertally, estrogen (and progestin) levels fluctuate markedly across the menstrual cycle and are higher in females than in males (Fig. 6). Ovarian androgen secretion also varies with the menstrual cycle, but at all points in the cycle, average circulating androgen levels are lower in adult females than in adult males.

By analogy with the animal literature, the perinatal exposure to testosterone in human males might be expected to be "organizational" in nature and to cause relatively permanent changes in brain structure, whereas postpubertal differences in hormone exposure are predicted to be short-lived and to "activate" existing neural circuits. The remainder of this section presents evidence for organizational and activational effects of gonadal steroids on human behavior,

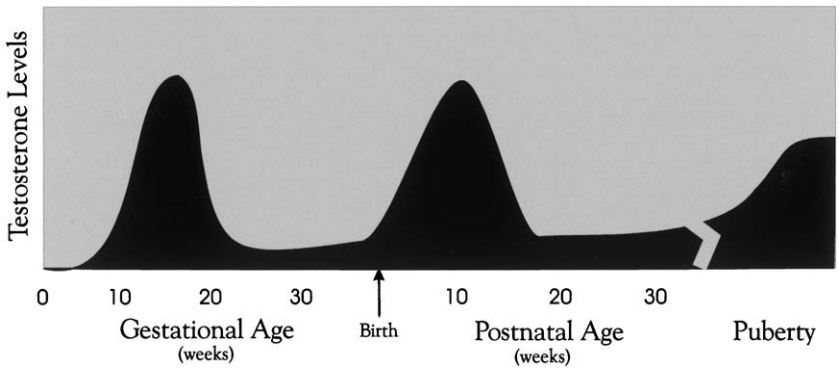

Figure 5 Human males are exposed to high levels of testicular testosterone during three different developmental windows: weeks 10–20 of gestation, the first few postnatal months, and throughout adulthood.

cognition, and psychopathology, although the reader is reminded that the distinction between organizational and activational effects of hormones can be blurry.

A. Organizational Effects of Hormones

Organizational effects of gonadal steroids are suspected when a neural sex difference is found early in life. For example, because human brain size is already larger in males than in females at birth, this sex difference cannot reasonably be attributed to differences in adult hormone levels or differences in socialization between the two sexes. Prenatal hormones, genes, or some combination of the two must be responsible for the sex difference in brain size. Similarly, several of the neuropsychiatric disorders discussed earlier (e.g., cerebral palsy, mental retardation, autism) can be diagnosed in infancy and are almost certainly due to anomalies of brain development occurring in the pre- or perinatal period. Because each of these disorders is more prevalent in boys, a sex difference in the susceptibility to developmental perturbation is indicated. Several investigators have proposed that perinatal testosterone exposure predisposes males to neurodevelopmental disorders by altering the pace of brain development. Specifically, because cerebral development is slower in human males than in females, males may experience an extended window of susceptibility to insult. Interestingly, the pace of functional cortical development is also sexually dimorphic in nonhuman primates, and this sex difference can be eliminated by treating female monkeys with testosterone during pre- and perinatal life.

Perinatal hormonal events may contribute to the sex difference in human juvenile play behavior, discussed earlier. Sex differences in play can be observed very early in life and occur during a time when gonadal hormone secretions are low and not sexually dimorphic. As mentioned previously, boys tend to exhibit more active play than do girls, and this difference is seen

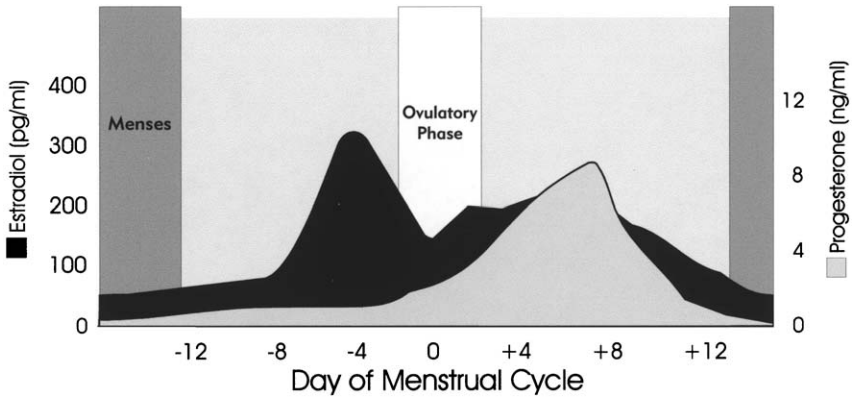

Figure 6 Schematic depiction of fluctuations in estrogen and progestin levels across the menstrual cycle in humans.

across cultures. Many nonhuman mammals, including rhesus monkeys, also exhibit a sex difference in juvenile play, with males displaying more rough-and-tumble play than females. Goy and colleagues have shown that this sex difference in monkey play behavior is due, at least in part, to hormone exposure *in utero*. When female rhesus macaques are exposed to testosterone during late fetal life, their play behavior is masculinized and they exhibit more rough-and-tumble play than do unexposed females. Similarly, play behavior in female rats is masculinized by early exposure to testosterone. Because of obvious ethical constraints, similar experimental manipulations of pre- and perinatal hormone exposure are not possible in humans. Most of the information relevant to the possible organizational effects of gonadal steroid hormones on human brain development, instead, has come from patients who experienced sex-atypical hormone exposure *in utero*, either by virtue of naturally occurring disorders ("experiments of nature") or as a result of treatment for a medical condition.

1. Excess Androgen Exposure of Females *in Utero*

One "experiment of nature" is the condition known as congenital adrenal hyperplasia (CAH). CAH is precipitated by a genetic defect in one of several adrenal enzymes. This defect causes insufficient production of glucocorticoid hormones and concomitant overproduction of androgens, beginning *in utero*. The increased level of androgens masculinizes the external genitalia of affected females to varying degrees, ranging from a mildly enlarged clitoris to fused labia and a pseudo-penis. Normally, this condition is detected at birth, and the individual has corrective surgery on the genitalia, as well as cortisol replacement therapy to correct the underlying problem. Thus, female patients with CAH are exposed to high levels of androgens only during development and are usually raised and socialized as girls.

Research on CAH girls and women offers some support for organizational effects of androgens on human behavioral development. Young girls with CAH tend to exhibit more masculine behavior and/or less feminine behavior on a number of measures. For example, some studies have shown that CAH girls exhibit higher levels of aggression, more rough-and-tumble play, better spatial ability, and greater preference for male-typical toys than their unaffected female relatives. CAH girls also tend to show less interest in infants, marriage, and motherhood, as well as a higher incidence of homosexuality and/or bisexuality than do control girls. However, several investigators have raised concerns that simply having knowledge of the condition may affect the behavioral expectations of both CAH girls and their parents. For example, parents who know their daughter was born with a pseudo-penis might expect more "tomboyish" behavior. This confound could influence retrospective reports of a child's behavior, which is a problem because most studies of CAH girls have relied on child and parent interviews rather than on direct behavioral observation. It should be noted, however, that the few studies directly examining behavior do support the finding of more male-typical play in CAH girls than in their unaffected female relatives. For example, Berenbaum and colleagues videotaped play sessions of CAH and control girls. They found that both play activity preference and playmate preference were masculinized in CAH girls in early childhood, although only play activity preference remained masculinized throughout childhood.

Another strategy for evaluating the effects of gonadal hormone exposure on female brain development comes from studies of "intrauterine position." In litter-bearing mammals, female fetuses gestating next to males are exposed to more testosterone than are female fetuses with female uterine neighbors. The testosterone exposure from male uterine neighbors somewhat masculinizes later sex behavior in female rats, mice, and gerbils. A similar mild masculinization may occur in human females with a male twin. Several studies have reported increased "tomboyism" in females with male twins. Although such observations could easily have a social explanation, intriguing evidence for *in utero* masculinization of female cotwins comes from the study of otoacoustic emissions. The human inner ear produces weak clicks, called otoacoustic emissions, that can be measured by inserting a tiny microphone into the ear. The rate of these clicks is modulated by neural input. Although the function of otoacoustic emissions is not clear, these emissions exhibit a sexual dimorphism measurable as early as 1 month of age: females produce more and stronger clicks than do males. McFadden has shown that human females with a male twin have fewer and weaker otoacoustic emissions (i.e., they are more masculinized) than females with either a female twin or no twin. Because it is difficult to see how socialization could affect otoacoustic emissions, this observation suggests that intrauterine testosterone alters development of the auditory system in humans.

2. Excess Estrogen Exposure of Females *in Utero*

As stated previously, many of the neural sex differences seen in rodents are due not to testosterone per se but to the neural conversion of testosterone to estrogenic metabolites. Children who have been exposed to excess estrogens *in utero* may allow us to determine whether prenatal estrogen similarly masculinizes the human brain. Diethylstilbestrol (DES), a nonsteroidal estrogen, was given to many pregnant women in the 1940s through the 1960s to prevent miscarriage or other pregnancy complications. In female rats exposed to DES during fetal life, juvenile play and some aspects of adult sex behavior are masculinized. *In utero* DES exposure also results in a permanent change in the gonadotropin secretion pattern in rhesus monkeys. The results from studies of the human children born to women given DES during pregnancy, however, are more ambiguous. DES exposure does increase the risk of genital tract problems (e.g., menstrual irregularities, a high infertility rate, and risk for certain types of cancers), but DES-exposed women do not differ reliably from their unexposed sisters in visuospatial ability, verbal ability, or incidence of marriage and motherhood. These findings suggest that *in utero* estrogen exposure does not masculinize a human fetus. However, there are caveats to interpreting these negative findings. Only a few published studies are available, and most of these had relatively small sample sizes. Moreover, the timing and amount of DES exposure can differ dramatically among subjects of a single study. Because different aspects of sexual differentiation have different critical periods, the various levels and durations of hormone exposure could obscure any behavioral effects of DES exposure.

3. Blockade of Androgens in Genetic Males

According to the organizational hypothesis, females can be masculinized by perinatal exposure to testicular hormones, but the hypothesis also predicts that males will be feminized or demasculinized when they are *not* exposed to testosterone. The study of individuals with androgen insensitivity (AI) is relevant to this latter prediction. As described previously, AI results from a mutation of the androgen receptor gene. Patients with complete AI are incapable of responding to testosterone or other androgens and are phenotypically female. The cognitive abilities and other behaviors of genetic males with AI also appear to be feminized. In fact, a few studies have found that these AI individuals exhibit higher verbal comprehension and lower visuospatial skills than their unaffected sisters. In other words, in the absence of any androgen stimulation, cognitive abilities may be "superfeminized" in AI males. Again, however, very few well-controlled studies have been performed. A more serious constraint is that any effect of AI on cognition or behavior could not *a priori* be ascribed to an organizational effect of hormones, because genetic males with complete AI are almost always reared as females, and sex of rearing is therefore a confounding variable.

B. Activational Effects of Hormones

Sex differences exhibited in adulthood may be caused, or modulated, by activational effects of gonadal steroid hormones. In this section, we consider evidence for the the effects of circulating hormones on human brain function and/or structure by considering activational effects of androgens and estrogens on aggression, cognition, and neuropsychiatric disorders in adults.

1. Aggressive Behavior

Males are more aggressive than females in many mammalian species, including humans. An activational effect of testosterone is implicated in this sex difference because intermale aggression increases at puberty, and castration of adult males reduces aggression across a wide range of species. In rodents, testosterone also has organizational effects on aggression, apparently by influencing the sensitivity to androgen stimulation in adulthood. However, the role of androgens in aggression among primates is somewhat equivocal. Manipulations of adult testosterone levels do not consistently alter aggression in nonhuman primates, leading investigators to conclude that either androgens are not involved or that androgens exert their primary influence on primate aggression early in development.

Studies of human aggression generally do not take into account organizational effects of steroid hormone exposure. At least five studies of male prisoners have found evidence of a positive association between adult testosterone levels and aggression, and women convicted of violent crimes also may have higher salivary testosterone levels than those convicted of nonviolent crimes. In the general population, there seems to be a small, positive correlation between circulating

testosterone levels and aggression (usually as measured on a paper-and-pencil test). The overall impression is that current circulating androgen levels account for some of the differences in aggression between sexes but only weakly predict variations in aggression *within* each sex. One problem with most studies on testosterone and human aggression, however, is that they are correlational in nature. Because violent or competitive behavior can itself increase androgen secretion, the direction of causality between aggression and testosterone levels is unclear.

2. Cognition

Several investigators have taken advantage of the fact that sex steroid hormone levels change markedly across the menstrual cycle to examine possible activational effects of ovarian steroids on cognitive abilities. In one report, Hampson found that women's articulatory and fine motor skills were facilitated at the midluteal phase of the menstrual cycle when estrogens and progestins are high. By contrast, best performance on a perceptual–spatial test was observed during menses, when estrogens and progestins are low. In other words, high levels of ovarian hormones facilitated skills normally favoring females but were detrimental to skills favoring males. If so, then activational effects of ovarian hormones may contribute to some of the sex differences in cognitive abilities described earlier. However, not all subsequent reports have corroborated Hampson's finding. Some of the discrepancies in this literature may be due to the fact that investigators have measured a single cognitive trait (e.g., visuospatial ability) using various instruments. Different tests probably tap into different aspects of a complex cognitive function such as visuospatial ability, not all of which may be responsive to hormonal variations.

At least two studies have examined the activating effects of steroid hormones on cognitive abilities in transsexuals. Male-to-female transsexuals often are treated with antiandrogens and/or estrogens, and female-to-male transsexuals frequently receive androgens as part of the sex-reassignment process. By examining cognitive abilities in the same individuals before and after cross-sex hormone treatment, one can test for an activational role of sex steroid hormones in cognition. Van Goozen and colleagues report that 3 months after androgen treatment, visuospatial ability was increased and verbal fluency decreased in female-to-male transsexuals. In other words, the androgen treatment was associated with a shift to a "male" cognitive style. Smaller changes in the opposite direction were reported in male-to-female transsexuals 3 months after antiandrogen plus estrogen treatments. In a second study, Miles and colleagues compared cognitive performance in transsexuals currently receiving estrogens (treatment duration of at least 4 months) with that of transsexuals awaiting hormone treatment. Increased performance on a memory task (Paired Associate Learning) that is normally performed better by women than men was observed in the estrogen-treated group. No effect of estrogen treatment was seen on another memory test (Digit Span), for which there is not normally a sex difference in the general population. Estrogen did not affect visuospatial ability, as measured by a Mental Rotations test in this study.

In adult rats, surgical removal of the ovaries results in a decrease in dendritic spines (a site of synapse formation) on hippocampal neurons, and this decrease can be prevented by treating the ovariectomized rats with estradiol. Because the hippocampus is critically involved in memory formation, these observations indicate a possible neuroanatomical basis for estrogen modulation of memory function. Changes in synapse density in the hippocampus are also seen over the course of the rats' 4- to 5-day-day estrous cycle, with a higher density of synapses seen on days of high estradiol levels. This latter result indicates that morphological effects of estradiol on synapse formation can be remarkably rapid. Such effects of estrogens on neuronal morphology and/or function may be direct or may be mediated by protein neurotrophic factors such as nerve growth factor and brain-derived neurotrophic factor, both of which are up-regulated by estrogens in regions of the rat brain involved in cognition. It is not known whether estrogens similarly affect the morphology of the human brain. The anatomical resolution of current neuroimaging techniques is not nearly sensitive enough to detect microscopic features such as dendritic spines in the living human brain.

3. Neurological and Psychiatric Disorders

In keeping with the salutary effects of estrogens on cognitive function in healthy women, described earlier, small clinical trials indicate that estrogens may improve the memory of women suffering from Alzheimer's disease (a neurological disorder marked by cognitive decline and profound memory loss). Postmenopausal estrogen therapy also has been reported to reduce the risk of Alzheimer's disease, leading several

researchers to postulate that the higher age-specific prevalence of Alzheimer's disease in women than in men may be related to the relative lack of estrogens in postmenopausal women. Men presumably retain access to estrogens throughout life, either via direct secretion from the testes or via locally converted testosterone. Indeed, at least one study has found a positive correlation between circulating estradiol levels and performance on a visual memory test in healthy young men.

Similarly, the well-established sex differences in schizophrenia (i.e., later onset and less severe symptoms in females) may be accounted for by a "protective" effect of estrogens in premenopausal women. In support of this idea, several studies report variations in schizophrenic symptoms across the menstrual cycle, with the lowest level of psychopathology observed at the time of peak estrogen levels. In addition, hospitalizations of women experiencing an acute schizophrenic episode are highest during the perimenstrual period, when estrogen levels are low. Finally, whereas most cases of schizophrenia are first diagnosed in late adolescence and early adulthood in both males and females, only females exhibit a second peak of new diagnoses between 45 and 49 years of age (i.e., around the time of menopause). A link between unipolar depression and the menstrual cycle has also been noted, with increased vulnerability to the onset of a depressive episode or the worsening of ongoing depression during the premenstrual phase of the cycle.

These various findings obviously do not "prove" that gonadal sex steroids, secreted in adulthood, cause any of the many sex differences in the incidence of neurological or psychiatric disorders (Table III). However, it seems clear that sex steroid hormones modulate the neuro- and psychopathology of adults and may act in concert with other factors (including, possibly, organizational effects of hormones) to influence the susceptibility to disease.

V. GENES, HORMONES, AND EXPERIENCE: INTERACTIVE EFFECTS ON BRAIN DIFFERENTIATION

A. Genes

The role of hormones in sexual differentiation has been emphasized in the foregoing discussion, and, indeed, hormones appear to be primarily responsible for sexual dimorphism of neural and somatic tissues in mammals. However, there may also be direct genetic contributions to sexual differences. For example, the work of Renfree and colleagues indicates that development of the scrotum, pouch, and mammary glands of tamar wallabies is under direct genetic control. Normally, a pouch and mammary glands are present only in female wallabies, whereas only genetic males have a scrotum. However, the scrotal anlagen develops in fetal males, and a rudimentary pouch is identified in females *before* differentiation of the gonads, indicating that gonadal hormones cannot drive the differentiation of these structures in wallabies. In this case, genes on the X chromosome apparently control sexual differentiation, with pouch and mammary glands developing whenever two or more X chromosomes are present.

Are any *neural* sex differences under direct genetic control? A few sex differences have been identified in the brains of birds and rodents that so far defy a simple hormonal explanation. A genetic basis for these sex differences therefore is suspected, but not yet proven. In principle, any gene that is present in one sex but absent from the other could contribute to neural sex differences. Because only genetic male mammals have a Y chromosome, any Y-chromosome gene that influences nervous system development or maintenance could be responsible for neural sex differences. A few Y-chromosome-specific genes (including SRY) have been shown to be expressed in the brain, although, thus far, the link to sex differences has not been made. Genes on the X chromosome may also contribute to sex differences in neural development, because females have two copies of each X-chromosome gene, whereas males have only one.

Rett syndrome provides a dramatic illustration of how genes can contribute to sex differences in a neurological disorder. Children with Rett syndrome are apparently normal at birth, but undergo developmental regression beginning at about 18 months of age, allegedly due to an arrest of normal neuronal maturation. Essentially 100% of all Rett syndrome patients are female. How can such an absolute sex difference in a neurodevelopmental disorder be explained? Rett syndrome has been linked to a gene on the long arm of the X chromosome. Genetic males have only one copy of all X-chromosome genes, and males who inherit the gene responsible for Rett syndrome apparently die *in utero* or soon after birth. Because females have two copies of each X-chromosome gene, those who inherit a single defective copy of the gene causing Rett syndrome may compensate for the defect to some extent. Viewed in this light, females are the only long-term survivors of Rett syndrome, and

males are more vulnerable to this syndrome, as they are to most neurodevelopmental disorders. Although few psychiatric or neurological disorders are exclusive to only one sex, X- and/or Y-linked genes may contribute in important ways to the likelihood of exhibiting a given disorder, to the severity of symptoms, or to the disease course. Gonadal steroid hormones likely interact with sex-linked genetic predispositions to shape sex differences in clinical profiles of many disorders.

B. Experience

In both popular and scientific thought, a distinction is often made between biological and social causes of sex differences. Although it may not be articulated, implicit in this line of thinking is the notion that hormones and gene expression affect the structure of the brain, whereas experience influences the more intangible realm of behavior. This dichotomy, however, is a false one. By definition, people exhibiting different behaviors must have differences in the function or structure of the brain, regardless of whether that difference is due to genes, hormones, experience, or the interaction of all three. The animal literature provides us with several concrete examples of how hormones and experiences may interact to alter neuroanatomy and behavior. For example, when a rat is exposed to stress during pregnancy (by restraining her under bright lights for a few hours a day), the prenatal hormone exposure and future behavior of her male offspring are altered. Specifically, the prenatal testosterone surge is blunted in the male offspring of stressed mothers, and these males are more likely to display female-typical behaviors in adulthood than are the male offspring of nonstressed mothers. Sexually dimorphic neural structures, such as the SDN-POA and SNB, are also affected in the male offspring of stressed dams.

Hormones may also influence how an individual interacts with the environment. For example, testosterone may predispose males to more active, rough-and-tumble play during childhood, and this predisposition may then be magnified or diminished by societal pressures. Regardless of how it originates, the differing play behavior of girls and boys will lead to very different childhood experiences, which can be expected to shape the brain and behavior. In this scenario then, early hormone exposure results in sex differences in adulthood behavior, but only via a circuitous route that is strongly modified by experience. Another example comes from the work of Juraska and colleagues. Male rats, when raised alone in standard cages, have more hippocampal dendrites than do females or males castrated at birth. However, this sex difference is actually reversed when the animals are reared in large cages with many cagemates and toys, indicating that the environment must interact with hormones and/or genes to produce neuroanatomical sex differences. This type of interaction is likely to be even more prevalent in a species such as humans, who are social, long-lived, and exposed to complex and varied environments over the course of a lifetime.

Sexual Dysfunction

LISA REGEV, CLAUDIA AVINA, and WILLIAM O'DONOHUE
University of Nevada, Reno

GLOSSARY

dopaminergic Relating to, participating in, or activated by dopamine or related substances.

incidence The occurrence of new disease per unit of person–time.

prevalence The percentage of a population that is affected with a particular disease or disorder at a given time.

psychogenic Originating in the mind or in mental or emotional conflict.

vasodilation Widening of the lumen of blood vessels.

Sexual functioning is a complex series of biopsychological events, which in turn is affected by other series of complex biopsychological events. Much research is needed to understand the phenomena involved. This article reviews what is known biologically and psychologically regarding male and female sexual dysfunction.

I. INTRODUCTION

From adolescence onward, sex is a very important activity for most individuals. Sex can lead to the experience of great pleasure and the giving of great pleasure. It can result in a special bond. Sex can lead to sons and daughters—another one of life's greatest joys. If can also have direct connections to our personal identities and to our self-esteem.

However, there are a number of difficulties associated with sex. Finding the right number of partners and finding partners who are satisfying and whom we satisfy comprise one set of problems. Finding certain proscribed activities arousing, such as sex with children or coerced sex, comprise another set of problems commonly called the paraphilias. However, in this article, we focus on the sexual dysfunctions, problems with desire, arousal, orgasm, or pain, as identified by the *Diagnostic and Statistical Manual of Mental Disorder* (DSM).

DSM is the generally accepted nosology when classifying mental health problems. Problems of desire, arousal, orgasm, and genital pain are currently the disorders classified as sexual disorders. When diagnosing these problems, DSM identifies three criteria for each disorder. The first criterion for each disorder is the distinguishing criterion and will be discussed later for each disorder. The remaining two criteria are similar for each of the sexual disorders. One criterion is that the problem must cause significant distress or interpersonal difficulty. For example, if an individual is not bothered by his or her inability to reach orgasm, then it is not diagnosed as a problem. The last criterion requires the clinician to rule out other possible sources for the problem. This includes another Axis I disorder (e.g., Posttraumatic Stress Disorder, Obsessive–Compulsive Disorder, and a mood disorder), the direct physiological effects of a substance (e.g., alcohol, drugs, medications), or a general medical condition.

If an individual meets criteria for a sexual disorder, it is essential to specify the onset, context, and etiology of the disorder. Regarding onset, an important distinction is between patients who have always experienced

the problem (lifelong) and those who did not experience the problem in the past but more recently have begun to experience the problem (acquired). Regarding context, it is important to specify whether the person experiences the problem in any context (generalized) or in limited situations (situational). Regarding etiological factors, it is important to specify whether the problem is due to psychological factors or a combination of psychological and organic factors. If the etiology of the disorder is found to be due exclusively to the physiological effects of a general medical condition, the individual is diagnosed with Sexual Dysfunction due to a General Medical Condition. DSM is in its fourth revision and is continually changing. The current classification will likely change in the not-too-distant future as more research in this area continues to inform clinical assessment. Whereas psychological and medical problems continually interact with one another in the development and maintenance of a sexual problem, this article will discuss these issues separately to help the clinician identify appropriate assessment and treatment modalities.

II. DESIRE DISORDERS

In 1977, sexual desire was explicated as significantly influencing sexual functioning by both Lief and Kaplan. Definitions of desire vary in terms of whether a biological component is involved and the importance of psychological, biological, and environmental components. Difficulties in defining desire arise from its subjective nature. In 1998, Leiblum and Rosen viewed sexual desire as a "subjective feeling state that may be triggered by both internal and external cues, and that may or may not result in overt sexual behavior." This definition involves neuroendocrine functioning and exposure to individual and environmental sexual cues. Since the introduction of desire as an integral component of the sexual response cycle, problems relating to sexual desire have been found to be the most common sexual disorders. DSM-IV identifies two sexual desire disorders: 302.71 Hypoactive Sexual Desire Disorder (HSD) and 302.79 Sexual Aversion Disorder (SAD).

HSD is characterized by "persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity." Additionally, the clinician is advised to take into account factors that affect sexual functioning (e.g., age and the context of the person's life). As indicated earlier, when diagnosing sexual problems, the second and third criteria are similar for all of the sexual dysfunctions.

Epidemiological data suggest that 1–15% of males and 1–35% in females suffer from HSD. Assessment of prevalence is complicated because it is likely that only those HSD patients with an unsatisfied partner who motivates the patient to seek treatment will be evaluated. Due to the nature of this disorder, HSD patients may not have a sexual partner, and some may credit low desire to the lack of sexual opportunities and, thus, may not seek treatment.

According to DSM-IV, Sexual Aversion Disorder is characterized by "persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner." This disorder was introduced in DSM-III-R to distinguish between those who did and did not experience severe disgust and avoidance regarding sexual activity. The disorder was added to the diagnostic manual on the basis of clinical experience that victims of rape and child sexual abuse experienced this sexual problem. Sexual aversion disorder describes an individual's unwillingness to participate in a sexual activity. This disorder is distinguished from sexual phobias in that it describes an intense dislike or disgust but not an excessive fear.

An adequate research base regarding the incidence and prevalence of sexual aversion does not exist. These data are unknown because sexual aversion is a poorly recognized syndrome, sexual panic has received little professional attention, and epidemiological studies on sexual disorder have not included sexual aversion. Another problem is that sexual aversion problems may be comorbid with other psychological problems. Aversion may occur with another more prominent sexual disorder such that it is undiagnosed or with other disorder such as panic so that the sexual problem is missed if clinicians fail to ask about sexual stimuli. At this point we can only make inferences from research studying general sexual disorders and likely comorbid problems.

A. Etiology and Treatment of Desire Disorders

There are multiple etiological factors that may be involved in disorders of sexual desire. These include both medical and psychological factors. The following will discuss possible etiological factors associated with each of these as well as possible interventions.

1. Medical Aspects of Desire Disorders

The pituitary–gonadal system is the major endocrine system involved in sexual behavior. Sexual desire

results from diverse hormones, neurochemicals, and neuropeptides. The hypothalamus significantly impacts sexual desire as it mediates central nervous system effects on the anterior pituitary–gonadal system. The hypothalamus is responsible for producing and releasing hormones and neurotransmitters, including gonadotropin-releasing hormones (GnRH), luteinizing-releasing hormones (LHRH), thyrotropin-releasing hormones (TRH), oxytocin, and vasopressin.

a. Neurophysiology in Males Hormones allow one group of cells to influence the activity of other groups of cells. Gonadal hormones influence sexual desire because sex hormones affect cells in the brain by way of the hypothalamus, which has receptors for gonadal steroids. The hypothalamus affects the anterior pituitary–gonadal system by secreting and transporting GnRH. GnRH then stimulates basophilic cells of the anterior pituitary to produce LHRH and follicle-stimulating hormone (FSH). LHRH is secreted from the pituitary and travels to the testes, where it stimulates the production of testosterone (also a hormone).

b. Neurophysiology in Females The endocrinology of females is analogous to that of males but is influenced by changes in the menstrual cycle. There is an increase in FSH during the first half of the menstrual cycle. A new ovarian follicle also begins to grow that secretes increasing amounts of estradiol. A surge in LH provokes ovulation. The ovarian follicle produces estrogen and progesterone after ovulation. Although one would infer that desire fluctuates with changes in estrogen and progesterone, there is minimal support for this conclusion. Additionally, prolactin, which is capable of initiating and sustaining lactation in females, is considered to be potentially important in the sexual desire of females. However, the relationship between prolactin and desire is disputable.

c. Clinical Implications for Hypoactive Sexual Desire Disorder There are a large number of etiological factors involved in sexual dysfunction. However, there is an inadequate amount of research studying the relationship between medical conditions and desire. Studies of sexual desire are limited because desire can only be assessed through self-report, and these measures have unknown or poor psychometrics.

Women with Turner's syndrome, in whom one X chromosome is missing and as a result they do not develop gonads, have confused and diminished desire due to their delayed growth and social maturity. Whereas many studies evaluate the process of menopause and its effects on women, researchers do not agree that postmenopausal women have diminished sexual functioning. In 1953, Alfred Kinsey found that up to 48% of postmenopausal women reported that their sexual response and frequency of intercourse had decreased, whereas studies in 1985 demonstrated that 50% of the sample did not report a decrease in sexual interest after menopause and less than 20% of the women in the sample indicated a significant decrease. Findings are unclear as to whether losses in sexual desire in postmenopausal women are estrogen-dependent. In a 1999 study, sexual problems in women tended to decrease with increasing age. These findings did not investigate the onset of menopause or estrogen levels in their sample.

Sexual interest and activity decrease after exogenous androgen removal in hypogonadal men. Also, ejaculation and orgasm stop after this procedure. The relationship between testosterone and desire has been supported by findings that testosterone injections increase sexual interest but do not affect erectile functioning. Dialysis patients with sexual dysfunction have a significantly higher level of prolactin, a hormone secreted by the anterior pituitary gland into the bloodstream. Endocrine diseases have been suggested to affect libido and menses during later stages of these diseases.

Many medical treatments decrease sexual desire. Antihypertensive medications such as methyldopa, clonidine, reserpine, propanolol, and spironolactate decrease sexual desire in patients taking these drugs. Some antipsychotic medications, including thioridazine and fluphenazine, decrease sexual drive and interest. This may occur by blocking dopamine effects and suppressing the hypothalamic–pituitary–gonadal axis.

It is still largely unknown whether drugs can possibly enhance sexual desire in humans. Generally, studies have been conducted with animals, and it is difficult to determine what components of an animal's sexual behavior are equivalent to human sexual desire. Specific drugs such as L-Dopa and amphetamines may potentially increase sexual desire due to their influence on dopaminergic neurotransmission. L-Dopa is used to treat Parkinson's disease, and there is some evidence that it increases sexual interest. Difficulties in interpreting these results include distinguishing whether the increase is due to the medication, amelioration of the disease, a decrease in inhibitions, or a hypomanic syndrome produced by the drugs. There are only a few preliminary reports that suggest that amphetamines may enhance sexual desire. Amphetamines release

dopamine and are dopaminergic agonists. It is difficult to draw conclusions about their effect on sexuality because a large percentage of amphetamine users have personality disorders and/or other psychological or medical problems.

d. Clinical Implications for Sexual Aversion Disorder Biological treatment for this disorder consists of medications that decrease anxiety and suppress the panic response associated with sexual aversion. Medications such as tricyclic antidepressants, MAO inhibitors, and benzodiazepines are used because they reduce the firing rate of the locus ceruleus (LC), which is potentially hyperactive in anxious individuals. It is recommended that medications be used only when the panic response is so strong that it interferes with psychological treatment.

2. Psychological Aspects of the Desire Disorders

There are a number of possible etiological factors for the desire disorders that are psychological in nature. For HSD, these factors may include poor marital adjustment, low levels of emotional closeness and romantic feelings, religious orthodoxy, affective disturbances, obsessive–compulsive personality, problems concerning gender or sexual identity, fear of loss of control, fear of pregnancy, and fear of contracting a sexually transmitted disease. Of these, anxiety has been the most frequently cited factor affecting desire. Etiological factors of a psychological nature contributing to SAD are not clear, and sexual assault may result in an aversion to sex.

There is no standard assessment procedure for assessing sexual desire disorders. Current assessment practices include the use of self-report questionnaires, interviews of the individual and/or the couple, and medical evaluations. Some of the more well-known assessment protocols for sexual desire are discussed next. These assessments may be used when evaluating any of the sexual dysfunctions.

Studies in 1983 describe a semistructured clinical interview comprising seven components: (1) assessment of the chief complaint, (2) a sexual status exam, (3) assessment of medical status, (4) assessment of psychiatric status, (5) family and psychosexual history, (6) evaluation of the current relationship, and (7) summation and recommendations. The interview involves an assessment of relevant symptoms, an assessment of onset and progress of the sexual problem, an analysis of behavior and emotional conflict, a full medical evaluation, and a meeting with the clients to share the clinician's findings and treatment recommendations. The interview is based on 12 years of experience as a sex therapist but has not been empirically supported.

Others recommended the use of interviews with the individual experiencing the sexual problem as well as with the partner. The interview inquires about the following: (1) Does the individual experience complete or intermittent loss of desire? (2) Is the loss solely partner-related or relevant to all sexual stimuli? (3) What are the other symptoms? (4) Are there other relationship changes associated with the loss of sexual desire? The interview also asks about family background, sexual knowledge, satisfaction with current relationships, medical, drug, and psychiatric histories, and sexual development and experiences. The goals of the assessment interview are to identify the problem, develop hypotheses about etiology, and commence the therapeutic alliance.

Later came recommendations for an interview that examines biological, cognitive, and motivational factors of sexual desire, with suggestions that the clinician assess the partner's reaction to low desire, past trauma, abuse, and physical disorders, the psychiatric history of the dysfunctional partner, past trauma, and gender or sexual orientation conflict. Others suggest conducting interviews with the individual and the couple that assess sexual and nonsexual stressors in the relationship, complete sexual histories, onset and history of the problem, and maintaining factors.

Additionally, a series of self-report measures may be used when assessing problems with sexual desire. These include the Sex History Form and the Locke–Wallace Marriage Inventory. Commonly used assessment instruments for sexual functioning include the Derogatis Interview for Sexual Functioning (DSFI), the Golombok Rust Inventory of Sexual Satisfaction (GRISS), and the Sexual Interaction Inventory (SII). These measures are self-report questionnaires that generally provide an overall measure of the quality of sexual functioning. They are not appropriate for diagnosing specific sexual dysfunction disorders.

Currently there is no standard assessment procedure for sexual aversion disorder. This disorder may be difficult to address because clients are not aware of their aversion or are unwilling to disclose this information. There are two self-report questionnaires that may be helpful in assessing sexual aversion: the Sexual Anxiety Inventory (SAI) and the Sexual Aversion Scale (SAS).

Whereas the SAI does not specifically assess the aversion or avoidance associated with this disorder, this measure inquires about anxiety and worry about a

number of sexual situations. The SAS assesses avoidance of sexual situations and the desire for help with a sexual problem. It also asks about appropriate fears to situations such as contracting AIDS or becoming pregnant. The SAS may be used as a preliminary screening device for identifying the specific fear underlying the aversion.

These questionnaires have not been tested with a clinical population of individuals suffering from sexual aversion. Therefore, the SAI and SAS are not appropriate for making a diagnosis of sexual aversion. Assessment should include a thorough sexual history as well as aspects commonly associated with the disorder, such as child sexual abuse, panic attacks, familial history of panic disorder, self-blame, and worry about sexual performance.

Orgasm consistency training has been found to be effective when treating women with HSD. It is presumed that by teaching women to reach orgasm more frequently, women would be more likely to enjoy sexual interactions and therefore desire to engage in these interactions more frequently. Additionally, marital therapy may be effective in treating low desire if couples problems, including emotional intimacy problems, are present within the couple.

For individuals with SAD, systematic desensitization has been shown to be an effective form of treatment. This treatment consists of desensitizing the individual to the feared stimulus. This may include fear or disgust relating to genitalia, the sexual act itself, as well as other more preliminary sexual activities. The individual is gradually desensitized by first focusing on less fear-provoking stimuli and eventually focusing on the most fear-inducing stimuli. These stimuli are repeatedly presented to the individual while the individual does not experience adverse consequences. Subsequently, the fear or anxiety is reduced. By reducing the fear, the person is able and more willing to engage in sexual behavior.

III. SEXUAL AROUSAL DISORDERS

Arousal consists of a set of physiological responses and subjective physiological responses. Problems with male arousal include difficulties attaining or sustaining an erection and is commonly termed "impotence," whereas arousal problems in females involves the lubrication–swelling response.

DSM-IV identifies two sexual arousal disorders: 302.72 Female Sexual Arousal Disorder (FSAD) and 302.72 Male Erectile Disorder (MED). According to the DSM-IV, Female Sexual Arousal Disorder is characterized by "persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication–swelling response of sexual excitement."

If a woman develops this sexual dysfunction, she is probably more likely to also lose interest in sex or have orgasm difficulties. It is not clear whether this occurs because the latter problems are more prevalent, or whether clinicians and scholars place more attention on problems of desire and orgasm difficulties than they do on problems of female arousal. However, this may be partly due to the complexities in defining female arousal. Specifically, problems in sexual arousal may be present even if the female engages in sexual intercourse, and one cannot assume that if she is engaging in coitus she is sufficiently aroused to reach orgasm. Epidemiological data are lacking because studies have failed to inquire about arousal when measuring sexual functioning. Also, the existing estimates vary greatly due to differences in the criteria being used.

According to the DSM-IV, Male Erectile Disorder is characterized by "persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection." The American Psychiatric Association has described this problem as a sustained inability to maintain an erection that allows penetration and ejaculation to take place and is caused by psychological factors. Approximately 10% of a sample of young adults in Europe and the United States suffer from MED. Erectile difficulty is estimated to be prevalent in between 3% and 9% of males. Also, this problem is increasingly found in specific populations, such as the elderly and those who suffer from diabetes, cardiovascular disease, and chronic renal failure.

A. Etiology and Treatment of Sexual Arousal Disorders

Problems of arousal may be the result of physiological or psychological problems. When presented with an individual suffering from this problem, it is important to determine which of these etiologies is the culprit. The following will discuss possible medical and psychological aspects of the disorder as well as possible treatments to pursue.

1. Medical Aspects of Sexual Arousal Disorders

a. Neurophysiology of the Male The penis becomes erect through the supply of blood from the

internal pudenal artery to that genital area. The penis has three cylinders. The two paired bodies are known as the corpora cavernose (CCP) and are located in the dorsal and lateral parts of the penis. When the penis is flaccid, the CCP are empty and collapsed. The third body is on the ventral part of the penis and is the unpaired corpus spongiosum (CSP). The inner spaces of the CSP are partly filled during the flaccid stage.

Erection occurs when neurotransmitters, including acetylcholine and vasoactive intestinal peptide, are released by higher central nervous system activation or viscerosomatic reflex activation. These neurotransmitters provoke smooth muscle relaxation, resulting in decreased resistance to arterial blood flow. The sinusoidal spaces are enlarged and compress emissary veins. Blood is then trapped in the CCP. When the penis is erect, the CCP increases in diameter and the CSP increases in the bulb region of the penis. During this time, the CCP increases more in diameter than in length, whereas the CSP increases more in length than in diameter. Erection requires an intact functioning of the arterial–venous network.

b. Neurophysiology of the Female Erectile tissues in females include the vulva, vagina, surrounding vasculature, and the clitoris. During the excitement phase, the clitoris, hidden by the anterior ends of the labia minora, undergoes a vasocongestive response and the labia minora increases in diameter. The dorsal artery of the clitoris is a terminal branch of the internal pudendal artery. The dorsal artery provides the clitoris with its blood supply. Nerves originating from T12–L1 supply the labia majora. The pudental nerve originating from S2–S3 terminates in branches to the glans, corona, and prepuce and is responsible for the innervation of the clitoris. Pelvic vasocongestion results in lubrication, a clear viscuous fluid from the circumvaginal vasculature, and any malfunction in this area results in disorder. Reflex vasodilation, labia and circumvaginal tissue swelling, heightened labial coloring, and lubrication accompany the arousal phase in women.

c. Clinical Implications for Male Erectile Disorder Impotence can be caused by any disease that impedes the blood flow through the hypogastric–cavernous arterial tree. Diabetes commonly results in MED. Men are unable to attain and sustain erection due to the impediment of arterial blood flow caused by small-vessel and large-vessel disease induced by diabetes. Neural malfunctioning, including peripheral denervation, pudendal sensory diabetic neuropathy, and nerve damage in CCP tissue, accounts for the majority of erectile disorder in this population. Other disorders such as scleroderma (a connective tissue disease involving thickening of the skin and fibrotic changes), chronic renal failure, chronic lung disease, bronchitis, asthma, emphysema, and neurogenic problems, including multiple sclerosis (MS) and spinal cord lesions and injuries, are also associated with a high incidence of MED.

Medication effects resulting in MED are comparable to findings for sexual desire. Antihypertensive agents, cardiovascular drugs, and psychiatric medications impair erectile ability. Antihypertensives and cardiovascular drugs either affect autonomic innervation by interfering with the neurovascular response to stimulation or can decrease blood pressure in diseased cavernous arteries. Psychiatric medications including antidepressants and antipsychotics may antagonize neurotransmitters by anticholinergic effects.

Internal iliac endarterectomy, transluminal balloon, and aortobifemoral graft anastomoses are medical procedures used to improve blood flow in the internal pudendal and penile arteries. Microsurgical techniques anastomosing the inferior epigastic artery to the deep dorsal artery or the cavernous artery are successful for MED caused by lesions in the internal pudendal artery or its branches. Intracavernous injection therapy consists of either instructing the patient to inject the lateral aspect of the CCP or having the physican inject papaverine every 2–3 weeks for at least three injections.

Several types of prostheses are available for men suffering from MED. Suction devices apply negative pressure to the penile shaft so that an erection can be induced by blood that fills the CCP. A tourniquet is applied to the base of the penis so that the erection can be maintained for coitus. Implants consisting of inflatable cylinders, an indwelling reservoir, and a pump in the scrotum increase girth during erections and are fairly natural looking when the penis is flaccid. Also available are prostheses consisting of a pair of silicone rods that occupy the length of the CCP but that do not detumesce.

A complete sexual history should be collected that inquires about onset, sexual practices, and quality of sexual interactions. Risk factors such as trauma, diabetes, hypertension, and smoking should also be assessed. A thorough medical examination should be employed. This may include an assessment of genital perineal sensations, tone, and reflexes. Physiological instruments for MED include assessment of nocturnal penile tumescence (NPT), which monitors erections occurring during the rapid eye movement phase of

sleep, the penile–brachial index (PBI) in which a pneumatic cuff is applied to the base of the penis and penile systolic pressure is measured, and penile pneumoplethysmography, which also utilizes a pneumatic cuff at the base of the penis and measures waveforms produced by arterial pulsation.

d. Clinical Implications for Female Sexual Arousal Disorder Estrogen deficiency results in atrophy of the vaginal endothelium (responsible for lubrication) and the underlying vasculature. Impairment in estrogen production is most commonly caused by menopause. An insufficient amount of estrogen will not support the lubrication response and decreases vaginal blood flow in older menopausal women. Diabetes also causes arousal difficulties in women. Arousal problems may be induced by clitoral nerve degeneration, blood vessel damage, and hyperargentophilia of neural fibers in the clitoris found in diabetic women. Other medical problems that can affect female excitement are gynecologic cancer, chronic liver disease, and chronic renal disease.

Vaginal dryness occurs in women with MS where parts of the spinal cord are demyelinized. These women may also experience absent clitoral sensitivity. Lubrication does not occur in spinal cord injury, disease, and/or lesions affecting the spinal cord at T10–T12. Also, when lesions around T10–T12 exist, there are no clitoral sensations during arousal.

To date, the literature does not support the relationship of certain classes of medications (discussed earlier) and the absence of lubrication. However, it is plausible that to the degree that the neurophysiology of arousal is comparable in men and women, drugs affecting MED can have similar deleterious effects and result in FSAD. Ethinylestradiol hormone replacement is generally effective in increasing sexual excitement and vaginal lubrication specifically in menopausal women. Vaginal cream or oral administration can reverse the damaging effects of estrogen deficiency on the vagina but increases the risk of endometrial cancer. A transdermal estrogen patch may also be helpful in treating difficulties with vaginal dryness. Thus far, there are no medications that increase female arousal.

FSAD is assessed by use of a vaginal photometer, which measures vaginal pulse amplitude and vaginal pulse volume through a probe and photocell, cardiovascular autonomic nerve function tests monitoring heart rate and blood pressure during specific exercises; and a heated oxygen electrode placed on the vaginal wall, which uses an index of blood flow and content obtained through the energy required to maintain the heat setting. The lubricant fluid produced by the vasocongestive response can be evaluated for its quantity, electrolyte content, and pH. Also, assessment can include the study of changes in estrogen and serum gonadotropin levels.

Pubococcygeal (PC) muscle excercises, also known as Kegel excersises, are voluntary vaginal contractions originally developed to treat stress incontinence. Consistent use of these exercises has been shown to increase intravaginal pressure as well as to increase subjective reports of sexual arousal. These reports are preliminary but suggest that the prescription of Kegel exercises for women suffering from a sexual dysfunction may be appropriate.

2. Psychological Aspects of Arousal Disorders

Arousal is the result of physiological as well as cognitive and affective changes that indicate that the person is ready to engage in sexual activity. The cognitive component consists of focusing on erotic stimuli, including fantasies and sexual cues. The affective component includes a subjective sense of sexual excitement. Psychological factors contributing to Male Erectile Disorder may include negative affect, specifically, performance anxiety and depressed affect, as well as cognitive interference. Cognitive interference may consist of underestimating the degree of erectile response. Additionally, chronic or acute stress as well as relationship problems may play a central role in erectile problems.

Psychological factors contributing to Female Sexual Arousal Disorder may include anxiety, fear, relationship problems, lack of adequate stimulation, as well as a history of sexual abuse. For both males and females it is important to understand which of these factors is the primary contributing factor so as to know what to target in treatment. This may be accomplished by obtaining a detailed description of a recent problematic interaction, including thoughts and feelings during the interaction. This may provide the clinician with invaluable information concerning problem maintenance. How does each partner feel about the other partner? Was there adequate stimulation? Was either partner experiencing thoughts that interfered with arousal? Was either partner anxious or fearful?

To date, there are no controlled psychotherapy outcome studies to attest to the efficacy or effectiveness of treatment for females with arousal problems. For men with these problems, correction of cognitive distortions associated with sexual functioning,

systematic desensitization, and psychoeducation were found to be effective treatments when compared to a control condition.

IV. ORGASMIC DISORDERS

Whereas many sex therapists and researchers do not consider orgasm to be the epitome of a sexual experience, many people do. Problems regarding orgasm may influence the individual's self-esteem, mood, sexual satisfaction, quality of relationship with sexual partners, and desire to engage in sexual activity. These problems may include the absence of orgasm, orgasm only after prolonged stimulation, or reaching orgasm quickly with little stimulation. Epidemiological data suggest that orgasmic disorders affect approximately 24% of the population.

DSM-IV identifies three orgasmic disorders: 302.73 Female Orgasmic Disorder, 302.74 Male Orgasmic Disorder, and 302.75 Premature Ejaculation. According to DSM-IV, Female Orgasmic Disorder is characterized by "persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase." The clinician is instructed that women vary in the type or intensity of stimulation that leads to orgasm. Additionally, the clinician must use judgment to determine that the woman's capacity for orgasm is less than would be reasonable given her age, sexual experience, and the adequacy of the stimulation she receives.

According to DSM-IV, Male Orgasmic Disorder is characterized by a "persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase during sexual activity that the clinician, taking into account the person's age, judges to be adequate in focus, intensity and duration."

According to DSM-IV, Premature Ejaculation is characterized by "persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it." Additionally, the clinician is instructed to take into account factors that affect the duration of the excitement phase, including age, novelty of the sexual partner or situation, and recent frequency of sexual activity.

A. Etiology and Treatment of Orgasmic Disorders

A person's ability to reach orgasm depends on the interplay of two primary factors: physiological and psychological. Physiologically, the orgasmic reflex consists of sensory components, motor components, and the sensation of orgasm. Psychologically, the ability to reach orgasm depends on the individual's cognitions pertaining to sex in general and achieving orgasm during the sexual encounter.

1. Medical Aspects of Orgasm Disorders

Little information is currently available regarding organic factors that contribute to orgasmic disorders. With few exceptions, laboratory procedures to confirm an organic basis for orgasm problems are unavailable. To date, protocols for the medical evaluation of orgasmic disorders have not been developed. Most of the information available concerns male orgasm difficulties. Much of the information that is currently thought to be true of female orgasm has been extrapolated from studies of male orgasm.

a. Neurophysiology of Male Orgasm Repeated tactile stimulation of the penis can evoke reflex vasodilatation of the penile vasculature, resulting in penile erection, seminal expulsion from contraction of the smooth muscle of the internal reproductive organs, glandular secretion, and rhythmic contraction of the striated musculature. This sequence is subject to inhibitory and/or excitatory influences from the brain. The ejaculatory reflex consists of emission and bladder neck closure, ejaculation, and the experience of orgasm.

Sensory impulses eliciting the ejaculatory reflex enter the sacral spinal cord via the pudendal nerve. The ejaculate is then emitted into the pelvic urethra. This is caused by contraction of the vas deferens, seminal vesicles, and smooth muscle of the prostate. Inflowing seminal fluid stimulates the urethral bulb, which elicits reflex closure of the bladder neck. This reflex closure prevents retrograde ejaculation. The motor fibers mediating emission are contained in the hypogastric nerve. These motor fibers consist of preganglionic fibers that arise from the thoracolumbar spinal cord, segment T12–L3. These preganglionic fibers synapse with short adrenergic nerves that lie close to the innervated organ.

Expulsion of the ejaculate through the external urinary meatus is called *ejaculation*. The ejaculate is propelled along the length of the urethra via rhythmic contractions of the urethral bulb and perineal musculature. Sensory efferents from the urethra travel in the pudendal nerve to the sacral cord, where they synapse with somatic efferents that travel in the pudendal nerve. This causes contraction of the ischio- and bulbocavernosus muscles.

Orgasm is a subjective sensory experience associated with the rhythmic contractions of ejaculation and

emission. Presumably, the sensation of orgasm is produced via tactile sensory impulses that travel to the thalamus and then to the limbic lobe.

b. Neurophysiology of Female Orgasm Female orgasm appears to be a genital reflex. The sensory component consists of tactile stimulation of the external genitalia, which travels via the pudendal nerve to spinal centers. Hormonal influences on brain centers that connect with spinal centers influence the threshold level required for orgasmic reflex. The motor component consists of efferent fibers from the T12–L1 area of the spinal cord, which travel via the hypogastric nerve to genital organs, including fallopian tubes and uterus, and which cause rhythmic contractions of these structures. Sensory fibers from these structures travel to the sacral cord via the pudendal nerve, where they synapse with motor fibers that cause contractions of the peritoneal muscles. The sensation of orgasm results when sensory stimuli from the contractions of the sexual organs travel to the spinal cord, thalamus, limbic lobes, and sensory cortex, which is presumed to produce the experience of orgasm.

c. Clinical Implications There are multiple points at which organic factors can cause orgasm disorders. When presented with an anorgasmic individual, it is important to conduct a biomedical evaluation to rule out organic factors. For example, it is important to assess for any injury to the cerebellum, including a stroke, tumor, or trauma. These injuries may result in decreased ability to reach orgasm. In addition, spinal cord injury, such as due to a tumor, trauma, multiple sclerosis, and tabes dorsalis, might result in orgasm disorders. It is easier to predict the sexual effects of a complete cord lesion than an incomplete lesion, given that in an incomplete lesion it is difficult to determine which tracts are spared. Spinal cord lesions are generally more destructive to ejaculatory function than erectile function in males. For females with spinal cord injury, relatively little information is available regarding its impact on sexual functioning. To date, it has been found that if the lesion is below T1, orgasm is not possible.

Additionally, damage to the peripheral nerves may negatively impact the ability to reach orgasm, such as due to pelvic surgery, trauma, and diabetes mellitus. For males, surgical procedures including retroperitoneal lymphadenectomy, protocolectomy, abdominoperitoneal resection, aortoiliac surgery, prostatectomy, and surgical procedures for bladder cancer can disrupt ejaculatory function. For females, less information is available regarding the impact of surgical procedures that interrupt the sympathetic innervation of the genital organs on a woman's ability to orgasm. Some surgical procedures that may impact females' ability to orgasm include proctocolectomy, abdominoperitoneal resection, pelvic exenteration, radical vulvectomy, and cystectomy. Many of these impact other aspects of sexual functioning as well.

Additionally, pharmacologic agents may impact an individual's ability to orgasm. For males, these primarily include antihypertensive and psychiatric drugs: lorazepam, reserpine, quanethidine, quanoxan, quanoclor, bethanidine, de brisoquine, phenoxybenzamine, phentolamine, thioridazine, chlorpromazine, clorprothexine, mezoridazine, fluphenazine, thiothixine, perphenazine, trifluoperazine, haloperidol, phenelzine, pargyline, mebanazine, imipramine, amitryptiline, chlomipramine, amoxapine, desipramine, chlordiazepoxide, and alprazolam.

Less is known regarding the effects of drugs on female anorgasmia. Most of the literature available concerns the effects of psychiatric drugs, including hetereocyclic and monoamine oxidase inhibitors. Anorgasmia has been associated with phenelzine, isocarboxazid, tranylcypromine, imipramine, chlomipramine, amoxapine, nortriptyline, thioridazine, trifluoperazine, fluphenazine, alprazolam, and diazepam.

Endocrinopathy, including hypogonadism and hyperprolactinemia, should be evaluated in males with orgasmic dysfunction. The removal of androgens results in the decline of sexual interest and activity. In addition, ejaculation and the capacity to orgasm cease. With the use of exogenous androgens in hypogonadal men, sexual functioning is restored. There appears to be a minimum level of androgen necessary to sustain sexual functioning. Additional androgen beyond this level does not impact male sexual functioning. Studies have demonstrated the association between hyperprolactinemia and severe difficulty ejaculating. When this condition was effectively treated, sexual functioning was restored. For men complaining of ejaculatory failure, routine serum prolactin and testosterone levels should be obtained. For females, the role of androgens and hyperprolactinemia in anorgasmia is currently unclear.

2. Psychological Aspects of Orgasm Disorders

The inability to reach orgasm or reaching orgasm prematurely may be related to the individual's thoughts and/or feelings during the sexual encounter. Negative feelings toward sex, oneself, or the sexual

partner, fear of losing control, fear of pregnancy, performance anxiety, thoughts of a previous trauma (such as a sexual trauma), and discomfort with increased vulnerability may negatively impact sexual functioning, including orgasm problems. It is important to assess the thoughts and feelings the client experiences during these encounters so as to determine what is interfering with the progression of the sexual experience.

It is possible that the individual has unrealistic expectations or goals related to sex, such as the expectation that multiple orgasms occur in each sexual interaction. If this is found to be the case, it is important to educate the individual regarding reasonable expectations. If a previous trauma appears to be influencing the individual's sexual experiences, it is important to treat the person's trauma first, the success of which may indirectly influence the orgasm problem. In addition, the individual's relationship with his or her partner may influence their sexual interactions. If this is found to be true, it is appropriate to address relationship problems prior to addressing the sexual relationship.

If the person's expectations are reasonable, there is no trauma influencing the sexual experience, and the relationship is not problematic, directed masturbation has been demonstrated to be effective in treating women with orgasmic disorder. This treatment can be effective if the woman and her partner consider masturbation to be an acceptable form of treatment. The book *Becoming Orgasmic* delineates a program for women to learn to masturbate and become orgasmic.

For men with orgasmic disorder or premature ejaculation, performance anxiety may play a central role in problem maintenance. If during the assessment phase he describes thoughts indicating anxiety related to reaching orgasm, it is important to attend to these thoughts in treatment. These thoughts may inhibit him from reaching orgasm or they may result in his reaching orgasm prematurely. Treatment may focus on educating him that orgasm is not the goal and endpoint of sex. Instead, the focus is shifted to sensual pleasure as related to arousing other parts of the body, which Masters and Johnson termed sensate focus.

Additionally, premature ejaculation may be treated by teaching him to control ejaculatory latency by means of the "squeeze" technique or the "pause" technique. The squeeze technique involves instructing him to masturbate to a point that he feels would result in ejaculation if he continued and squeeze the head of his penis for approximately 10 sec. This is continued a number of times over several occasions until he gains control over his ejaculatory latency. The same is true of the pause technique, whereby he pauses prior to ejaculation and then resumes masturbation.

V. SEXUAL PAIN DISORDERS

Sexual pain may interrupt sexual activity, reduce future desire for sexual activity, prevent sexual satisfaction, result in relationship problems due to problematic sexual experiences, and influence the individual's mood and self-image. Problems concerning sexual pain include male or female genital pain that occurs before, during, or after sex as well as the involuntary spasm of the pelvic muscles for females that interferes with penetration. Epidemiological data suggest that 7% of the nation suffer from these problems. DSM-IV identifies two sexual pain disorders: 302.76 Dyspareunia and 306.51 Vaginismus. According to DSM-IV, Dyspareunia is characterized by "recurrent or persistent genital pain associated with sexual intercourse in either a male or a female."

According to DSM-IV, Vaginismus is characterized by "recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse." If an individual meets criteria for either of these disorders, it is important to determine the onset (lifelong or acquired), context (generalized or situational), and etiological factors (due to psychological factors or due to combined factors) of the disorder. Vaginismus and Dyspareunia are often linked. Whereas both of these disorders pertain to genital pain, the distinction between them is that Dyspareunia is pain associated with intercourse and Vaginismus is pain as a result of an inability to penetrate. If Dyspareunia is caused by Vaginismus, the primary diagnosis is Vaginismus. As will be discussed later, a gynecological or urological evaluation must be conducted in order to adequately diagnose the problem.

A. Etiology and Treatment of Pain Disorders

As is true of other sexual disorders, the sexual pain disorders may result from physiological and/or psychological problems. It is important to determine which of these factors is contributing to the problem.

1. Medical Aspects of Pain Disorders

Individuals who experience pain during intercourse are more likely to present to gynecologists and urologists for symptom relief. The sexual pain

disorders are the most common sexual problems that physicians encounter, possibly because individuals view these more as medical problems.

a. Neurophysiology of Pelvic Pain The spinal segments responsible for the somatic nerve supply to the groin, vulva, and perineum are predominantly L1–L2, whose fibers form the ilioinguinal and iliohypogastric nerves, and S2–S4, whose fibers form the pudendal nerve. These nerves provide sensory innervation to the skin of the groin, mons pubis, and anterior vulva as well as the clitoris, perineum, and posterior labia. Additionally, the pelvic organs send sensory impulses via afferent fibers, both sympathetic and parasympathetic.

Pain resulting from Vaginismus is due to an involuntary spasm response of the pelvic muscles located in the outer third of the vaginal barrel. The muscle groups affected include the perineal muscles and the levator ani muscles. In several cases, the adductors of the thighs, the rectus abdominis, and the gluteus muscles may be involved. This spasm response prevents penetration and leads to pain when intercourse is attempted.

b. Clinical Implications For males, genital pain may be associated with a urinary tract infection. The pain may occur during urination as well as ejaculation. Men who are not circumcised may also describe pain during intercourse. Additionally, Peyronie's disease is sometimes associated with pain during erection. As such, it is essential that men with genital pain be referred to a urologist for a thorough examination.

Scarring following either episiotomy or vaginal repair operations may lead to painful intercourse. This includes hymeneal remnants, a pelvic tumor, prolapsed ovaries, endometriosis, childbirth pathologies, and pelvic inflammatory disease. Other possible organic influences include clitoral inflammation and adhesions, lesions of the vulva, vaginal infection, cystitis, constipation, proctitis, and allergic reactions to contraceptive and douching materials. Additionally, vulvar vestibulitis, which consists of tiny erythematous sores in the vulvar vestibule, may lead to intense superficial pain. Women may also experience pain as a result of insufficient vaginal lubrication upon penetration attempts. The risk of genital pain for this reason is increased in women using oral contraceptives, pregnant women, or premenopausal women.

c. Definition of the Pain It is important to understand the nature of the pain when assessing these sexual problems. For example, it is important to understand the quality of the pain, including whether the pain is sharp or dull, diffuse or localized, burning or itchy, superficial or deep. Superficial pain tends to be sharp, burning, and well-localizable. Deep somatic or visceral pain is usually dull, diffuse, and poorly localizable. The severity of the problem is also important. How intense is the pain? To what extent does the pain interfere with sexual activity? The location of the pain should be assessed as well. A physical examination may help determine whether the location conforms to a dermatome, to the distribution of a specific peripheral nerve, or to the position of a specific anatomic structure. The duration and periodicity of the pain should be discussed in detail. Is the pain always present? Are there times when the pain is gone? Responses to these questions may provide treatment utility. For example, anticonvulsant agents may be more effective for pain syndromes that are paroxysmal, whereas antidepressants may be more effective for pain syndromes characterized by constant burning. Severe, but short-lived pain evoked by mechanical manipulations such as vaginal intercourse with little or no pain between episodes will respond poorly to nonspecific treatments.

2. Psychological Aspects of Sexual Pain Disorders

Psychosocial problems may result in a complaint of sexual pain or may exacerbate existing pain. Possible risk factors include anxiety, fear of pregnancy, fear of contracting a sexually transmitted disease, depression, decreased self-esteem, poor body image, and religious orthodoxy. If this is the case, it is important to address the issue. For example, anxiety may be alleviated by using sensate focus. Poor body image may be targeted through psychoeducation. Negative attitudes about sex may be overcome by reviewing and processing these attitudes. Additionally, relationship problems should be considered when assessing these problems. Anger at one's partner, inadequate communication, and distrust should be considered. If this is found to be true, it is appropriate to initiate couples therapy if the couple agrees. Sexual abuse or trauma may also result in a pain disorder. If this is the case, it is important to treat the trauma prior to treating the sexual problem, which may alleviate the sexual problem indirectly.

Psychogenic Vaginismus has been explained by classical conditioning. When first attempting intercourse, a woman may experience significant pain. This

pain, the unconditioned stimulus, may lead to a natural self-protective tightening of the vaginal muscles, the unconditioned response. With repeated attempts, stimuli associated with vaginal penetration or even the thought of intercourse can become conditioned stimuli and lead to the conditioned response of reflexive muscle spasms. In the process, the woman may avoid intercourse in order to avoid the pain associated with sex.

A commonly used treatment for women experiencing these problems is desensitization using a graduated set of dilators or the gradual insertion of the woman's fingers. This treatment begins with sensate focus, whereby the client is instructed to focus on pleasurable bodily sensations. This exercise is expected to reduce the client's anxiety and underscore the notion that sexual pleasure can be achieved in many ways other than penetration. Once the client is comfortable with her body, the gradual insertion of her fingers or of graduated dilators is initiated. The exercise begins with insertion of the smallest finger or dilator, usually with the use of a lubricant. The client is instructed to control the depth of penetration and length of time of penetration. Once the client is comfortable with inserting the dilator or finger for 5 min, the next larger size should be inserted, again while the client maintains control over insertion. As she becomes comfortable with insertion, her partner can be included in the exercise. She should maintain complete control throughout, including control over the depth and length of time of penetration. It is expected that this sense of control will help alleviate the problem.

Sexual Function

MARK S. GEORGE and JEFFREY P. LORBERBAUM
Medical University of South Carolina and Ralph H. Johnson Veterans Hospital

GLOSSARY

ejaculation When the penis expulses semen.

genital tumescence (penile erection or clitoral enlargement) When the penis or clitoris fills with blood and becomes rigid or elevated.

limbic system Anatomically, the limbic system refers to a large cerebral convolution that lies medially and envelops the brain stem. Although there is no clear consensus, the following regions are generally considered part of the limbic system. Cortical structures include the cingulate gyrus, subcallosal gyrus, hippocampus, and olfactory cortex. Subcortical regions include the amygdala, septum pellucidum, epithalamus (habenula), anterior thalamic nuclei, hypothalamus, and parts of the basal ganglia. In addition, several closely linked cortical structures that appear important in emotional behavior are also considered part of this circuit and are often referred to as paralimbic. These regions include the anterior temporal polar cortex, medial–posterior orbitofrontal cortex, and insular cortex. Evolutionarily, limbic structures appear to be common to all mammals. Behaviorally, limbic structures are thought to be important in emotional behavior, although this point is strongly debated.

sexual arousal Pertaining to the emotional and cognitive state in which one is interested in having sexual relations with another. Arousal is difficult to measure or quantify in animals. Courtship displays and genital tumescence are likely the most objective markers of arousal, although these behaviors can also occur in the absence of sexual arousal–interest.

sexual function A complex series of orchestrated behaviors consisting of courtship, arousal, intercourse, ejaculation, and recovery.

social bonding Affiliative behaviors that promote proximity and contact between individuals and can be divided into several types: (1) parental behavior, such as nursing and retrieving offspring; (2) infant attachment behavior, such as clinging and signals of protest or despair (i.e., crying) on separation; and (3) adult–adult affiliative behaviors, such as playing, grooming, a propensity to be near another much of the time, and monogamous pair bonding.

Normal human sexual function involves a complex series of orchestrated behaviors consisting of arousal, intercourse, ejaculation, and recovery. The regions and circuits involved in these behaviors are becoming known from analogous studies in animals, from epilepsy and brain lesion case studies in humans, and, most recently, from human functional neuroimaging studies. Importantly, however, sexual function commonly involves the selection and courting of a mate, which can result in forming a strong emotional bond with the other person, sometimes producing the birth of children. Thus, the sexual act in humans is inextricably linked with brain systems involved in other appetitive behaviors and in the formation of bonding and social attachment (or "love"). Thus, sexual function sets the stage for procreation and the birth of children. The maternal compulsion to answer the needs of infants might be regarded as representing the germ of responsibility that in human beings generalizes to become what we call "conscience."

Therefore, for most people, sex is linked with love and love is often intermingled with sex. In this article, we review the functional neuroanatomy involved in the basic behaviors of human sexual function and then discuss brain regions and neurochemicals involved in more complex aspects of sexual function, such as courtship and pair bonding. Human sexual function thus involves the entire nervous system—from

peripheral nerves in end sexual organs, through the spinal cord and brain stem for some aspects of copulation, to limbic regions involved in pleasure, orgasm, bonding, and love.

The human brain mediates a multitude of complex behaviors, and none is more important from an evolutionary standpoint than the behaviors associated with sexual function and reproduction. Some researchers in the field of sociobiology have argued that our bodies and lives are nothing but the mechanisms by which our genes replicate and extend themselves forward in time. Viewed from this somewhat radical and distorted perspective, our brains therefore are nothing more than the complex organs that orchestrate normal sexual function. However, this view from a purely reproduction standpoint does little justice to much of the complex higher cortical functioning of our brains and how this more complex functioning relates to sexual function.

I. BASIC PRINCIPLES OF BRAIN ORGANIZATION

Different components of sexual function involve distinct brain regions. Before we address the specific aspects of sexual function and the relevant neuroanatomy, it is important to outline a few basic principles of brain organization that will be referred to throughout the article.

P. D. MacLean introduced the concept of *the triune brain*, an attractive heuristic to organize thinking about the neural mechanisms involved in sexual function (both sex and love). The triune brain consists of three concentric brain systems, resting on top of each other yet intermeshed, with each successive layer representing an evolutionary advance (see Fig. 1). Each advance simultaneously allows for new behaviors, while recapitulating older ones. Thus, the human brain can be thought of as representing a composite of three brains in one (i.e., the triune brain). The deepest layer, found in reptiles, is the reptilian brain or basal ganglia (olfactory tubercle, nucleus accumbens, caudate, putamen, and globus pallidus). This part of the brain allows for simple actions (alertness, eating, basic acts of procreating) in preprogrammed rigid routines, which lack flexibility and emotion. The next layer (paleomammalian) arose with early mammals and corresponds to the great limbic lobe of Broca and connected brain stem structures. This extension is only rudimentary in reptiles and birds. The final part of the human triune brain is the neomammalian brain, comprising of the neocortex and connected brain stem structures. These structures are thought to have an important part in organizing behaviors that are unique to mammals, such as nursing, care of the young, bonding, and play.

The term "limbic" requires more elaboration. In 1878, Pierre Paul Broca first coined the term limbic,

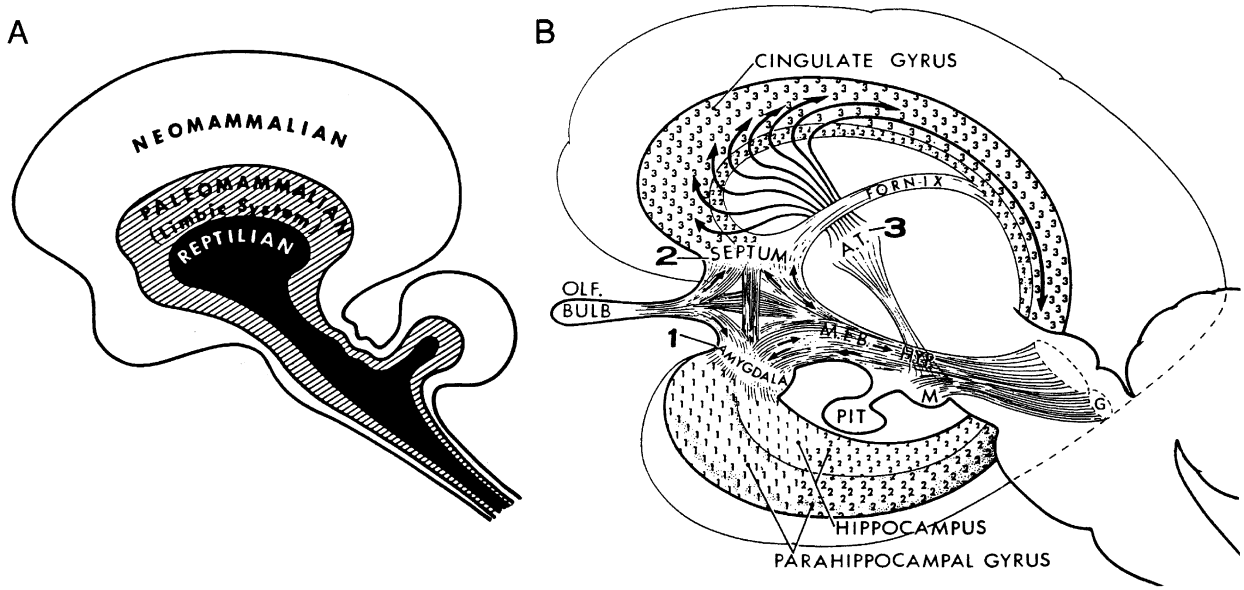

Figure 1 (A) The triune brain concept, from MacLean (1968). Alternative neural pathways to violence. In *Alternatives to violence*. (L. Ng, ed.), pp. 24–34, Time-Life Books, New York. (B) The three main subdivisions of the limbic system, from MacLean, P.D. (1990). *The triune brain in evolution: Role in paleocerebral functions*. Plenum Press, New York.

using it to refer to the structures forming a frame around the brain stem that he posited were important in regulating emotion (see Fig. 1). Early in the twentieth century, J. W. Papez detailed the circuit that he thought was important in regulating emotion. Thereafter, MacLean further elaborated the notion of a limbic brain involved in recognizing and regulating emotion and other complex aspects of behavior within the larger concept of the triune brain.

An important part of this heuristic scheme involves *the notion of the recapitulation of function within the brain*. Just as the motor homunculus is represented at the level of the spinal cord, cerebellum, thalamus, basal ganglia, and cortex, the brain structures involved in sexual function are also represented in all three components of the triune brain. Thus, the triune brain concept would be consistent with the notion that direct damage to some reptilian brain structures, such as the caudate, is associated with defects in basic sexual function. More importantly, damage to the early mammalian brain (limbic system) would more likely derange more complex aspects of sexual function, such as bonding. Mammals, in contrast to lizards, engage in three family-related behaviors: nursing and parental care, vocal communication with offspring, and play. Thus, phylogenetically, the newly emergent limbic system would be more important in producing and regulating these characteristic mammalian behaviors that involve recognizing and displaying affect in order to build social relationships. Finally, direct damage to the neocortex, which is greatly expanded in humans, might also disrupt sexual function, largely through the interruption of frontal cortical regulation of the limbic and reptilian brains.

The limbic system can be further subdivided into three divisions: the (1) amygdalar, (2) septal, and (3) thalamocingulate divisions. *Amygdalar division*: This region is involved in self-preservation behaviors such as those required in the search for food, including fighting and self-defense. Stimulation of this area in humans may produce fear and anxiety. *Septal division*: This division likely subserves behaviors related to primal sexual function and procreation. Septal stimulation in humans can produce pleasurable sensations and in animals can elicit social grooming as well as genital tumescence. *Thalamocingulate division*: This region represents the phylogenetically newest subdivision of the limbic system and is present in mammals, but not in reptiles even in rudimentary form. Several typical mammalian social behaviors are associated with this area, including extensive mother–infant bonding, pair bonding, infant crying, and play. Lesions of this region in nonhuman mammals often produce social apathy and mothers will neglect their offspring.

II. REGIONAL BRAIN BASIS OF SEXUAL INTERCOURSE

An attractive way to approach the neuroanatomy of sexual function is to divide the sexual act into its discrete phases and discuss the relevant neuroanatomy by each phase. This approach has some value, although many of the stimulation studies in animals have shown effects on several aspects of sexual function, arguing against their anatomic discreteness. As a way of organizing and discussing each aspect of sexual function, we will interleave information from animal stimulation studies with human neuroimaging and lesion data when available.

A. Arousal

The first part of the human sexual act is perhaps the most difficult to measure or quantify in animals. Stimulation of several regions, including the hippocampus, is associated with courtship displays or genital tumescence, which are likely objective markers of arousal. However, in humans, erections and genital tumescence can occur in the absence of pleasure or arousal as in states of priapism.

In humans, arousal states can now be studied directly using *functional neuroimaging*. Researchers have used functional neuroimaging to investigate which brain regions are activated during sexual arousal. In 1999, Stoleru and colleagues used oxygen positron emission tomography (PET) to image brain activity in eight healthy adult men while they viewed sexually explicit film clips (heterosexual coitus), emotionally neutral clips, and humorous control clips. During sexual arousal compared with the neutral resting state, the men had significantly more blood flow in the inferior temporal cortex (a visual association area), the right insula and inferior frontal cortex, and the left anterior cingulate. These researchers also serially measured plasma testosterone and found that activity in several of these regions increased in proportion to increased testosterone.

The insula and inferior frontal cortex are limbic regions that relate processed sensory information with motivational states. Several authors have found

a right-sided bias for processing and mediating emotional stimuli. As outlined earlier, the cingulate gyrus is an important region in which four forms of behavior are represented that distinguish the evolutionary transition from reptiles to mammals (milk secretion, infant crying, extensive maternal behavior, and play). The cingulate gyrus similarly has been implicated in studies of directed attention, particularly when there is competition for attention or divided attention.

By using a methodology similar to that of the Stoleru study, Rauch and colleagues studied brain activity in eight healthy men during script-driven imagery to produce sexual arousal (response to an autobiographical script of thinking about a sexually arousing experience) or competitive arousal (response to an autobiographical script of thinking about success in a competitive arena such as winning a sports event). In both of the aroused states compared with rest, blood flow increased in the anterior cingulate and the anterior temporal cortex, as well as in the ventral globus pallidus. The brain stem was activated uniquely in the sexually aroused state. Unfortunately, the PET camera used in this study was not able to resolve nuclei within the brain stem.

Thus, the anterior cingulate gyrus was activated in both of these PET studies, which attempted to measure brain correlates of arousal using two different stimulus forms (silent visual film clips or script-driven imagery of past experiences). In the second study, the globus pallidus also was activated, which is interesting in that this region of the R complex has been implicated in courtship displays demonstrating interest in a potential mate during experiments on nonhuman mammals (see Section IV.A on courtship). Further studies are needed before a consensus can emerge about the functional neuroanatomy of human sexual arousal. It also remains unclear which method (visual or, script-driven) is best for eliciting and measuring arousal during functional imaging studies.

B. Erection, Vasodilatation, and Intercourse

Brain pathways involved in genital tumescence have been studied mostly in males where it is evidenced by penile erection, although genital tumescence (clitoral enlargement) in females appears to involve the same pathways. Except for the posterior medial prefrontal cortex (an area that may represent a transition zone between limbic and neocortex), electrical stimulation of the neocortex generally has not been effective in eliciting genital tumescence. Within the limbic system, penile erection appears to be primarily represented in

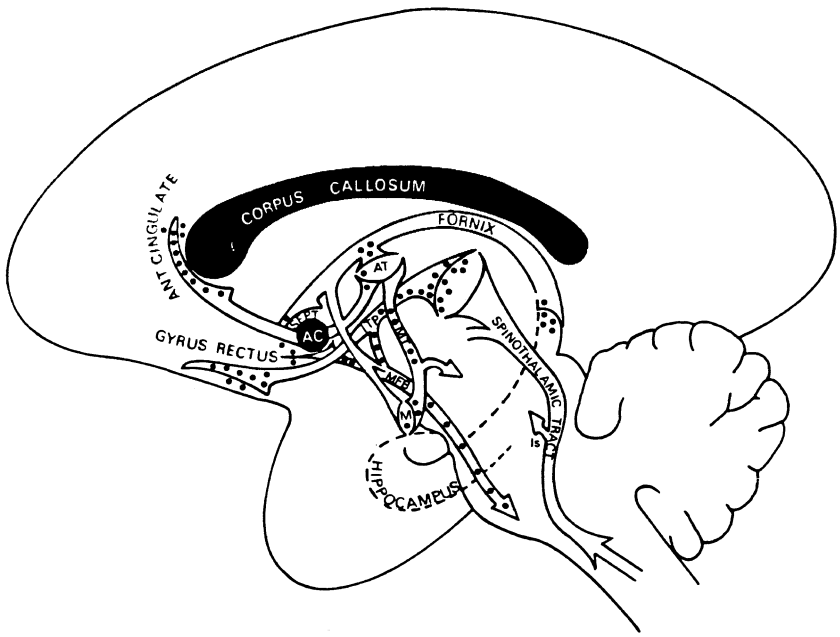

Figure 2 A sagittal diagram of brain regions summarizing regions in the squirrel monkey where electrical stimulation is highly effective in eliciting erections [after MacLean (1990). *The triune brain in evolution: Role in paleocerebral functions*. Plenum Press, New York].

the septal and thalamocingulate subdivisions, which are involved mainly in procreation and social bonding behaviors. This is an interesting finding given the intertwining of primary sexual function and social bonding in mammals. The pathways for penile erection are summarized in Fig. 2.

Regarding pathways from the septal subdivision, penile erection occurs with stimulation of *the medial septal region or its contiguous medial preoptic region of the hypothalamus*, as well as along this region's efferent white matter tract called the *median forebrain bundle* to the ventral tegmental area in the midbrain. The other major efferent white matter tract pathway from the medial septal preoptic region is the periventricular fiber system. This does not appear to be a major pathway for penile erection. Another area that consistently produces penile erection with electrical stimulation is the *dorsomedial hypothalamus*, which is bounded rostroventrally by the fornix and dorsocaudally by the mammilothalamic tract. The dorsomedial hypothalamus may also connect to the median forebrain bundle. Finally, electrical stimulation of the *proximoseptal hippocampus* also appears to be effective in eliciting penile erection. Regarding the septal subdivision, it is also of interest that electrical stimulation of the septum produces pleasurable, erotic sensations in humans. In male cats, septal and proximal hippocampal electrical or chemical stimulation produces pleasurable reactions, such as loud purring, turning over on its back, rubbing against many objects, and an invitation to be stroked by an observing experimenter while the cat gently bites and licks the experimenter's hand. Further, erections frequently occur in response to septal stimulation as well as self-grooming—behaviors that are found in feline courtship.

Regarding pathways from the *thalamocingulate subdivision*, penile erection is elicited by stimulation of the *anterior thalamic nuclei* and the *dorsomedial nucleus of the thalamus*, as well as by *stimulation of the anterior cingulate–posterior medial prefrontal cortex*, regions to which these nuclei project (i.e., the anterior cingulate and posterior gyrus rectus, respectively). Further, electrical stimulation along the entire length of the mammilothalamic tract from the anterior thalamic nuclei to the mamillary bodies elicits penile erection in squirrel monkeys. It is unclear how this pathway for penile erection enters the midbrain or brain stem, but it does not appear to depend on the median forebrain bundle (MFB). Also, stimulation of the dorsomedial nucleus of the thalamus and along its white matter projection, the inferior thalamic peduncle, elicits penile erection at least to the level at which this tract connects to the MFB.

At the level of the midbrain, the major effector pathway for penile erection follows the MFB to the ventral tegmental area (VTA). From this level, the pathways for penile erection quickly turn laterally, touching the dorsal aspect of the substantia nigra before descending to the pons (see Fig. 3). In the pons, the pathway descends through the region of the lateral tegmental process. In this region, there are positive loci for penile erection in the brachium pontis, providing possible evidence of cerebellar mechanisms in penile erection. MacLean and colleagues did not explore the erection pathways below the level of the upper medulla where the erection pathways enter the medulla just lateral to the pyramids and just medial to cranial nerve VI.

C. Ejaculation and Orgasm

Stimulation in monkeys along the spinothalamic tract and its projections to the thalamus produces genital scratching and seminal discharge. Although these behaviors are sometimes linked, detailed studies have shown that MD intralaminar thalamus stimulation can produce seminal discharge without preceding genital scratching or even penile erection. Stimulation near this spot might also elicit other visceral-related effects, such as salivation, vomiting, urination, or defecation.

In 1994, Tiihonen and colleagues used perfusion SPECT to try to image the brain regions activated during ejaculation. They studied adult men and imaged brain activity around the moment of ejaculation. With perfusion SPECT, one can inject the radiotracer during a state with a great deal of movement (like an ejaculation or a seizure) in someone outside of the scanner and then actually develop the brain image later. The SPECT radiotracer injected through a vein travels to the brain within several seconds and then undergoes metabolic changes and rests in those neurons that were most active at the time of injection. The technetium tracer continues to emit photons for several hours thereafter, allowing later positioning in the camera. This research group, with low spatial resolution, found increased activation during orgasm in the right prefrontal cortex. The crude spatial and temporal resolution of this technique precludes real comparison with the direct stimulation studies in animals noted earlier.

D. Postintercourse, Recovery, or Refractory Phase

Very little is known about the central brain mechanisms involved in postsexual recovery. The new popular medication for the treatment of male impotence, sildenafil citrate or Viagra, works by inhibiting this recovery phase. Sildenafil is a selective inhibitor of cyclic guanosine monophosphate (cGMP) specific phosphodiesterase type 5. The physiologic mechanism of erection of the penis involves the release of nitric oxide (NO) in the corpus cavernosum during sexual stimulation. NO then activates the enzyme guanylate cyclase, which results in increased levels of cyclic guanosine monophosphate (cGMP), producing smooth muscle relaxation in the corpus cavernosum and allowing the inflow of blood. Sildenafil has no direct relaxant effect on isolated human corpus cavernosum, but it enhances the effect of nitric oxide (NO) by inhibiting phosphodiesterase type 5 (PDE5), which is responsible for the degradation of cGMP in the corpus cavernosum. When sexual stimulation causes local release of NO, inhibition of PDE5 by sildenafil causes increased levels of cGMP in the corpus cavernosum, resulting in smooth muscle relaxation and the inflow of blood to the corpus cavernosum. Sildenafil at recommended doses has no effect in the absence of sexual stimulation.

III. MORE COMPLEX ASPECTS OF SEXUAL FUNCTION

A. Courtship Behavior

In MacLean's triune brain model, the reptilian complex (striatal complex) is important for ritualistic display behavior, such as challenge and courtship displays. In common green anolian lizards, partial lesions of the paleostriatum (considered by many to be the counterpart of the striatum and globus pallidus) greatly impairs the challenge display, a display similar to their courtship display in several respects. In contrast, lesions of the overlying forebrain (including an area believed to be a counterpart of the amygdala) do not inhibit courtship displays. Further, MacLean and colleagues conducted extensive experiments on squirrel monkeys to understand which regions may be responsible for challenge and courtship displays. To accomplish this, these researchers studied the *mirror display*, which is a highly predictable variation of a naturally occurring display used by male gothic-type squirrel monkeys in a show of aggression, in courtship, and in greeting. Vocalization, thigh spreading, and forward thrusts of the erect phallus are the major and most regularly occurring manifestations of the 5 features of the display. MacLean found that, in a series of lesion experiments involving more than 100 monkeys, the medial part of the globus pallidus in the R complex is a main site of coordination for evocation of the mirror display. Lesion of the medial part of the globus pallidus (especially its rostral two-thirds) resulted in either a sustained loss, decreased occurrence, or fragmentation of the mirror display. On the basis of globus pallidus lesions, it appears that the critical outputs for the display arise from the rostral two-thirds of the medial segment of the globus pallidus. Regarding outputs from the globus pallidus, destruction of the transhypothalamic pathways results in a lasting interference with the display. This is not seen with destruction of the other major pathways associated with the hypothalamus. Further, globus pallidus projections to the thalamus and midbrain tegmentum were more important than those leading to the ventral thalamus for enduring performance of the display. A wide variety of lesions, including lesions of limbic and neocortical structures, had no effect on the expression of this coordinated display.

Whereas the preceding lesion data indicate structures that appear to be important for the coordinated performance of the mirror display, specific pathways are important in individual aspects of the display: penile erection, vocalization, and thigh spread. When these other pathways are interrupted, the display becomes fragmented in that a specific element of the display such as erection is not well-performed, although the attempt to make the display as a whole still exists. In this regard, lesions destroying the inferior thalamic peduncle as well as those destroying the MFB result in a decreased magnitude of penile erection (entirely consistent with the stimulation studies discussed earlier). Decreased penile erection also occurred with lesions of the medial preoptic nucleus and adjacent anterior hypothalamus as well as lesions of the dorsomedial hypothalamus. Regarding vocalization, lesions in the tegmentum (at or near the origin of the medial longitudinal fasciculus) appeared to decrease the display vocalization.

It is unclear how homologous the squirrel monkey display is to courtship displays in humans, which may be different and depend on language and many other aspects of social context. However, in 1970 while filming a number of societies around the world,

Eibl-Eibesfeldt, a German ethologist, found what he thought was a universal flirtation display in humans. In this display, one's gaze alternates from the face of the other person to the side and down. This may be a classic example of an approach–avoidant display.

B. Affiliative Behavior

Affiliative behaviors promote proximity and contact between individuals and can be divided into several types: (1) parental behavior, such as nursing and retrieving offspring; (2) infant attachment behavior, such as clinging and signals of protest or despair (i.e., crying) on separation; and (3) adult–adult bonding behaviors, such as playing, grooming, a propensity to be near another much of the time, and monogamous pair bonding.

In MacLean's triune brain model, the brain region viewed to be central in affiliative behaviors is the limbic system's thalamocingulate division, which includes the cingulate gyrus and anterior thalamic nuclei. These are the phylogenetically newest part of the limbic system and are present in mammals but not in lizardlike reptiles. Extensive maternal behavior, infant crying, and play are three very basic affiliative behaviors that are found in mammals but not in lizardlike reptiles. The thalamocingulate gyrus may be an important brain region for all three of these behaviors.

1. Thalamocingulate's Role in Infant Crying

When separated, all mammalian infants that have been studied emit a species-specific isolation call that is an affiliative behavior because it causes mammals to search and care for the infant. Early mammals are believed to have been nocturnal creatures living on the forest floor. Infant separation from a parent therefore would be catastrophic and audiovocal communication would be important for reestablishing contact in the dark. Lesions of the anterior cingulate and the immediately adjacent medial prefrontal cortex (which in turn cause retrograde degeneration of anterior thalamic nuclei) impair crying upon separation in infant and adult squirrel monkeys, but more anterior prefrontal lesions do not impair crying. Structures strongly connected to the thalamocingulate circuit near the thalamic–midbrain junction (i.e., the thalamic tegmentum, thalamic periventricular gray matter, tegmentum, and the midbrain's central gray matter) are important as well not only in the actual production of the isolation call but also in forming its distinctive vocal characteristics.

2. Thalamocingulate's Role in Maternal Behavior

Animal studies and preliminary results in humans suggest that the brain's cingulate and anterior thalamic nuclei (a region we collectively refer to as the thalamocingulate circuit) may be involved in mammalian maternal behavior. First, cingulate lesions impair maternal behavior in rodents. Impaired behaviors include (1) nest-building, (2) adopting the correct nursing position, (3) retrieving pups when separated, and (4) sustaining pups through the time of weaning. Interestingly, female hamsters deprived of a neocortex soon after birth have seemingly normal maternal behavior, whereas those also deprived of their cingulate gyrus and underlying dorsal part of the hippocampus have impaired maternal behavior. This suggests that, in MacLean's triune brain model, the thalamocingulate circuit is necessary for maternal behavior. This experiment also suggests that both an intact reptilian brain and a paleomammalian brain are sufficient for normal maternal behavior in the rodent. Second, the anterior cingulate cortex is abundant in both opiate and oxytocin receptors, which are thought to be involved in social bonding. In fact, electrical stimulation of the anterior cingulate in female rabbits and cats can cause oxytocin release, milk ejection, and uterine contractions. Third, two functional MRI studies in humans by our group suggest that the thalamocingulate circuit activates when human mothers listen to recorded, standardized infant cries. This is a potentially important measure of maternal behavior because mammalian mothers usually respond to infant crying with care-taking behavior. In fact, in humans, the more responsive a human mother is to infant crying, the more likely she is to be responsive to other infant cues, and the more likely her child will become securely attached. Thus, examination of a mother's brain activity when she hears crying infants is potentially one way to measure the brain basis of maternal behavior.

Specifically, in 1998, Lorberbaum and colleagues measured regional brain activity in healthy mothers using BOLD–fMRI while they listened to recorded infant cries and white noise control sounds matched for intensity and temporal pattern with the cries. On the basis of the animal studies mentioned earlier, they hypothesized that mothers would have more thalamocingulate circuit activity in response to the cries in

comparison to the control noises. A first study consisted of 7 premenopausal, physically healthy mothers aged 21–46 having a youngest child less than 4 years old (range = 3 wks to 3.5 years). Four subjects had fMRI data suitable for analysis. When fMRI data were averaged over these 4 subjects, the anterior cingulate and right medial prefrontal cortex showed statistically increased activity with the cries compared with the control sounds.

We have replicated and extended this finding in a larger cohort and have found that the degree of self-reported bonding corresponds to increased blood flow while hearing cries. Further imaging studies are warranted to understand the role of the thalamocingulate circuit in both maternal behavior specifically and social bonding more generally. Given the importance of bonding for all later behaviors, some would argue that improved understanding of the regional brain basis of social bonding would likely aid in research into normal emotions such as love, separation anxiety, and grief.

There is also a large literature on the potential facilitary role that the septal subdivision of the limbic system and its projections (medial preoptic region of the hypothalamus, ventral bed of the stria terminalis, and ventral tegmentum) may play in mammalian maternal behavior. Lesions of these structures appear to diminish maternal behavior. The medial preoptic region of the hypothalamus and ventral bed of the stria terminalis are likely important. These regions have a great proliferation of oxytocin receptors just before delivery in the female rat, an event that is believed to be important in maternal behavior. The amygdala subdivision of the limbic system has also been implicated in maternal behavior. Some evidence suggests that it may promote, whereas other data suggest that it may inhibit, maternal behavior. In wild, free-ranging Old World monkeys, lesions of the amygdala or strongly interconnected regions (the anterior temporal region and posterior orbitofrontal cortex) may decrease maternal and affiliative behavior. On the other hand, in the rat, medial amygdala lesions (as well as lesions of its projections to the bed nucleus of the stria terminalis and ventromedial nucleus of the hypothalamus) appear to increase maternal behavior, suggesting an inhibitory role for the amygdala in maternal behavior. Given the amydala's role in aversive and defensive behavior, such lesions perhaps may facilitate maternal behavior because nulliparous female rats generally have an aversive reaction to pups. This is thought to be mediated by the smell of the pups because, if the adult female is made anosmic, she will display maternal behavior.

3. Thalamocingulate's Role in Play Behavior

Removal of the cingulate (as well as the underlying dorsal part of the hippocampus and neocortex) impairs play-fighting behavior in hamsters. Conversely, removal of the neocortex alone does not impair this species-typical play behavior in both male and female hamsters.

So far in this article we have concentrated on studies of the functional anatomy of sexual function as discovered through stimulation or lesion studies in nonhuman animals or in relatively crude measures of brain activity (blood flow or glucose use) in humans. Obviously, within this neuroanatomy is an important neurochemistry, and ultimate understanding of sexual function will involve an integration of neuroanatomy with regional neuropharmacology. The pharmacology of sexual function is a relatively new area but one that is capturing popular attention with new medications such as Viagra (sildenafil), which can improve sexual function in humans. Next we outline some of the more recent studies of the regional pharmacology of sexual function, realizing that an exhaustive discussion is beyond the scope of this article.

4. The Neurochemistry of Affiliation

a. Pair Bonding Only 3% of mammals are monogamous, although 15% of primate species are monogamous. Much of the work on the neurochemistry of monogamy has involved the role of oxytocin and vasopressin, two nine amino acid length peptides that are synthesized in the hypothalamus and that differ by only two amino acids. Although these nonapeptides are part of a family of nonapeptides that can be traced phylogenetically to invertebrates, oxytocin and vasopressin are found only in mammals. Oxytocin appears to be important for monogamy in females, whereas vasopressin appears to be important for monogamy in males.

Much of the work on the neurochemistry of monogamy has been performed on voles, a mouse-sized rodent. Two types of voles, called prairie voles and montane voles, physically look very similar and have similar nonsocial behavioral repertoires. They differ in that prairie voles are monogamous, whereas the montane vole is promiscuous. For the monogamous female prairie vole, puberty does not occur at a particular age, but rather when she is exposed to a chemical signal in an unrelated male's urine. This causes her to become sexually receptive within 24 hr of

exposure. When she then mates with a male, they form an enduring monogamous pair bond and become in a sense "addicted" to one another. They share the same nest and territory, remain near each other much of the time, prefer their mate to an intruder, and become attentive parents. Further, the male attacks adult intruders if they come near. The promiscuous montane vole, on the other hand, is a loner. Adult montane vole males and females do not share a nest and come together only briefly to mate. Montane vole females are parental only briefly, and males do not demonstrate parental behavior.

Oxytocin and vasopressin appear to be the important factors in forming the monogamous pair bonds of female and male prairie voles, respectively. For a female prairie vole, if an oxytocin antagonist is centrally administered just prior to mating, mating proceeds normally but she is no more interested in being near her mate than a stranger, just like the montane vole. If oxytocin is given in the absence of mating to a mature, virgin female prairie vole, she prefers a currently present male. For a male prairie vole, if a vasopressin antagonist is centrally administered prior to mating, mating proceeds normally but he is no more interested in being near his mate than a stranger and does not attack adult intruders who come near his mate, just like the montane vole. If vasopressin is given in the absence of mating to a mature, virgin male prairie vole, he prefers a currently present female and will attack intruders. Of importance, centrally administered oxytocin to female montane voles and centrally administered vasopressin to male montane voles does not make them less promiscuous or more social.

Montane and prairie voles have brain oxytocin and vasopressin receptor patterns that are widely different, which likely accounts for their differing monogamy and promiscuity. These vole species differ in *oxytocin receptors* in the prelimbic region, lateral septum, anterior olfactory nucleus, accessory olfactory bulb, nucleus accumbens, and thalamus. Species differences in vasopressin exist in the main olfactory bulb, lateral septum, and thalamus. Other types of monogamous voles have brain receptor patterns similar to those of the prairie voles, and other types of polygamous voles have brain receptor patterns similar to those of the montane voles. In a fascinating experiment, the gene for the vasopressin type 1a receptor in the prairie vole was transplanted into male mice that are usually not very social, and they became much more social than usual, although they did not become monogamous. Interestingly, the brain vasopressin 1a receptor pattern in these transgenic mice was transformed into a pattern similar to that of the normally social and monogamous prairie voles.

The specific implications of these studies for human sexual function remains unclear, but these studies begin to explain the neurochemical bases of bonding and love and perhaps of psychiatric disorders of decreased social bonding such as autism or schizoid behavior. Both vasopressin and oxytocin are released into the blood during human sexual behavior. In males, vasopressin peaks during arousal, whereas oxytocin peaks with ejaculation. In humans, oxytocin receptors are concentrated in the basal forebrain cholinergic nuclei, the nucleus basalis of Meynert, the diagonal band of Broca, and the preoptic areas of the hypothalamus. Vasopressin receptors are concentrated in the lateral septum and the amygdala. This is a pattern of receptor location different from that of either the montane or prairie voles. Therefore, it cannot be assumed that oxytocin and vasopressin have the same exact functions and effects in humans as in voles.

b. Parental Bonding In the laboratory rat, oxytocin appears to be important for maternal bonding with offspring. Prior to the end of pregnancy, female rats show little interest in rat pups. Starting about a day before delivery and persisting through lactation until the time of weaning, they change from avoiding their pups to showing marked interest, including nest-building, retrieval behavior, and guarding of infant rats in experiments. These behavioral changes occur simultaneously with a proliferation of oxytocin receptors in two key regions—the bed nucleus of the stria terminalis and the ventromedial nucleus of the hypothalamus. If a central oxytocin antagonist is given prior to a mother showing interest in her pups, then she does not bond well with her pups. If the oxytocin antagonist is given after she bonds with the pups, maternal behavior is not affected, suggesting that oxytocin is important in the onset but not the maintenance of maternal behavior. Further, when oxytocin is given to estrogen-primed, nulliparous female rats, maternal behavior is facilitated.

Whereas paternal care is minimal in the laboratory rat, vasopressin appears to be important for paternal behavior in the prairie vole. Central injection of vasopressin into the lateral septum increases, whereas central injection of a vasopressin inhibitor into the lateral septum decreases, the time a male prairie vole spends with a pup.

c. Infant Bonding Behaviors During the first 2 weeks of life in both rodents and nonhuman primates, there is a proliferation of oxytocin and vasopressin receptors in limbic regions (especially the cingulate, the region postulated to be involved in separation cries) relative to the adult. These receptors largely disappear by the time of weaning. Interestingly, administration of oxytocin or vasopressin reduces separation responses in rat pups. However, in oxytocin receptor knockout mice, there is a decrease in the separation call rate, suggesting that, perhaps in the absence of oxytocin, rat pups do not experience separation as stressful. Whereas it is intuitively appealing that oxytocin secreted during a mother's lactation may decrease infant crying, this has not been well-studied. Further, oxytocin appears to facilitate, whereas an oxytocin antagonist inhibits, the emergence of conditioned associations and preferences for things linked to one's mother, such as maternal odor.

Regarding mammalian infant bonding behavior, opiate-blocking agents (i.e., naloxone, naltrexone) increase, whereas opiates (such as morphine) given in low, nonsedating doses, decrease pup isolation calls. Regarding maternal behavior, opiate-receptor-blocking agents appear to increase maternal motivation to be near separated crying pups but decrease the maternal competence in retrieving these pups.

Rat pup isolation calls are decreased by serotonergic lesions or by the administration of selective serotonin re-uptake inhibitors and 5-HT1a receptor agonists. Isolation calls appear to be increased by 5-HT2 antagonists and 5-HT1b agonists. In nonhuman primates, grooming of other individuals appears to be important for forming and maintaining both alliances and dominance hierarchy ranking. Studies in various social types of male monkeys have found that the higher the level of cerebrospinal fluid 5-hydroxyindoleic acid (5-HIAA), which is a serotonin metabolite that is a rough measure of brain serotonin activity, the more time a monkey spends grooming others and the higher the dominance status. Further, in vervet monkeys, drugs that increase serotonergic transmission increase dominance status, whereas drugs that decrease serotonin transmission decrease dominance status. In this study, male vervet monkeys that were on fluoxetine or tryptophan (which increased serotonin transmission) appeared to become dominant by increased grooming and affiliation with the females in the group. Of note, in humans, serotonin re-uptake inhibitors are effective in treating social phobia, a condition in which individuals often avoid social encounters.

IV. COMPLEX HUMAN SEXUAL BEHAVIOR

In humans, basic sexual function is carried out within the concept of self-identity and then integration of tastes and preferences about arousing stimuli. Other articles within this encyclopedia describe aspects of this complex behavior in a more detailed fashion. It is important to note, however, that one's own sense of sexual identity is likely determined at an early age, probably within the first year or two of life. The complex brain regions involved in this sense of self-gender are beyond the scope of this article.

Similarly, little is known about the functional neuroanatomy of one's choice of sexual partners or sexually arousing objects. For example, there is considerable controversy about whether there are brain differences between homosexual and heterosexual men, and whether critical exposure to gonadal hormones during brain development may influence later aspects of sexual partner preference. There are numerous examples in nonhumans in which exposure to changes in gonadal steroids for even a brief time during development has lifelong impacts on sexual behavior.

In humans as well there are now a host of classified and recognized disorders of sexual behavior, including compulsive and paraphilic sexual behaviors. The functional and structural neuroanatomy of these areas is not well-understood, although it is of note that pharmacological treatments with antiandrogens, dopamine agonists, or serotonin-modulating medications may alter some of these behavior patterns.

V. SUMMARY AND CONCLUSIONS

The studies described earlier convincingly demonstrate that the limbic cortex receives visual connections as well as input through the vagus nerve about the viscera. Thus, the limbic system serves as an assimilating region in which visual and visceral information is compared and bound. This integration of higher cortical input with visceral and primitive reflexes and urges appears to be essential for what is visually remembered—memory and dreaming. Through the articulation of the anterior thalamus, the limbic system extends its relationship to the phylogenetically new prefrontal cortex, which is involved in insight and in foresight and planning for ourselves and others. Thus, in the complex organization of old and new structures, the human brain has a neural ladder for ascending from the most primitive sexual feelings to the highest altruistic elements.

Thus, human sexual function involves a complex, orchestrated series of behaviors that involve many areas of the brain. Animal stimulation work has identified many of these key regions for the basic aspects of sexual function. In humans, as in most mammals, sexual function also involves selecting and choosing a mate and bonding (love). The functional neuroanatomy of these more complex aspects of sexual function is becoming better understood. Knowledge of the triune brain with the overlapping and interconnected nature of limbic and more basic brain functions reveals why, for most people, sex and love are inextricably linked.

Short-Term Memory

GIUSEPPE VALLAR

Università degli Studi di Milano-Bicocca and IRCCS Fondazione S. Lucia, Roma

GLOSSARY

articulatory suppression A paradigm whereby subjects are required to utter an irrelevant speech sound (e.g., *''the, the, the''*) while engaged in another task, such as the short-term retention of a list of words. This concurrent articulatory activity disrupts the process of verbal rehearsal and has little, if any, general interference effects.

buffer/store A limited capacity system concerned with temporary retention; with reference to short-term memory, the term is frequently used as a synonym of ''store.''

double dissociation A pattern of impairment whereby (i) a patient or a group of patients exhibits a defective performance in task A (with respect to normal control subjects) but not in task B, in which the performance level is within the normal range, and (ii) another patient or group shows an opposite disorder (impairment in task B and normal performance in task A). In its ''strong'' or ''classical'' form the double dissociation concerns tasks of comparable difficulty. The double dissociation allows the inference that two functions (e.g., short- and long-term memory) are independent. If this pattern of impairment is associated with different neural correlates (e.g., defective performance in task A but not in B in patients with parietal damage and impaired performance in task B but not in A in patients with frontal damage), the double dissociation is anatomofunctional. The same logic may be applied to neuroimaging activation studies.

recency effect A phenomenon whereby the final events in a series are recalled better than the preceding ones; in immediate free recall the recency effect reflects retention in a short-term memory system.

rehearsal A process that supports temporary retention in a short-term store, reviving a memory trace; rehearsal may involve translation between two different representations or codes.

similarity effect A phenomenon whereby recall of lists of items similar for some specific coding feature (e.g., phonological, visual, and semantic similarity) differs from that of lists including items dissimilar with respect to that particular feature. In short-term memory paradigms similarity effects typically disrupt performance and provide indications as to the representational format of the memory trace.

span A classical measure of short-term memory involving the immediate serial recall of a sequence of events, such as a list of digits, words, visual patterns, and locations of objects.

store A component of short-term memory that secures the temporary retention of a limited amount of material.

trace A term that denotes the event stored in memory and is frequently used in a physiological context.

unattended speech An interfering auditory stimulation consisting of phonological material presented to the subject, who is engaged in another task such as immediate memory span.

working memory This term is widely used in the domain of cognitive psychology, neuropsychology, and cognitive neuroscience. In a more restricted sense, working memory refers to limited capacity systems involved in temporary retention (short-term stores) but with emphasis also on the cognitive operations performed on the stored material. The concept of working memory, however, has expanded to include the efficient monitoring and coordination of mental activity during the simultaneous execution of two or more tasks, the planning of complex actions, and, more general, the organization of behavior. In the latter broader sense, the relationships of the term working memory with its original roots in the specific domain of memory are less close.

The term short-term memory refers to a number of memory systems with limited capacity, concerned with the temporary (in the range of seconds) retention of a variety of materials. This article presents current knowledge concerning the functional and anatomical organization of short-term memory in humans. Behavioral and functional neuroimaging activation studies in normal human subjects, engaged in tasks assessing

short-term retention, as well as neuropsychological evidence in patients with brain damage are considered. The article is mainly concerned with the more extensively investigated aspects of short-term memory: verbal and visuospatial. Much of the data come from studies in the adult, but some pertinent evidence from different populations (children and elderly subjects) is also mentioned.

I. INTRODUCTION

The general idea that the faculty of memory is not unitary and monolithic, comprising instead multiple systems, dates back at least to the "Essay Concerning Human Understanding" by the British philosopher John Locke (1700), who suggested a broad distinction between two types of memory, one concerned with temporary retention and the other a storehouse of materials that have been laid out of sight. This distinction between two memory systems, one shorter and one longer term with respect to the duration of the trace, was revived by the North American psychologist William James (1895), who suggested the existence of a limited-capacity "primary memory," embracing the present and the immediate past and supporting consciousness. Psychological research in the 19th century and in the first half of the 20th century was mainly concerned with the diverse factors affecting learning and retention, in the context of a basically unitary view of human memory. It was only in the 1950s that short-term memory became the object of systematic scientific investigation in normal subjects. Figure 1 shows a model of short- and long-term memory popular in the 1970s.

II. FUNCTIONAL ARCHITECTURE

A. Behavioral Studies in Normal Subjects

The main empirical evidence suggesting the existence of a discrete limited-capacity system, concerned with short-term retention, was provided in the 1950s and 1960s by the extensive investigation in normal human subjects of three behavioral phenomena, which subsequently provided reliable paradigms for exploring the behavior of pathological populations. The majority of empirical studies focused on verbal material, such as words or letters, and therefore on the hypothetical construct of "verbal" or "phonological" short-term memory. Evidence was also provided, however, for the existence of a separate visual short-term store. Examples of stimuli used to investigate short-term retention are shown in Fig. 2.

First, short-term forgetting is assessed by the recall or recognition of individual items after short time intervals filled by interfering activity. The accuracy of

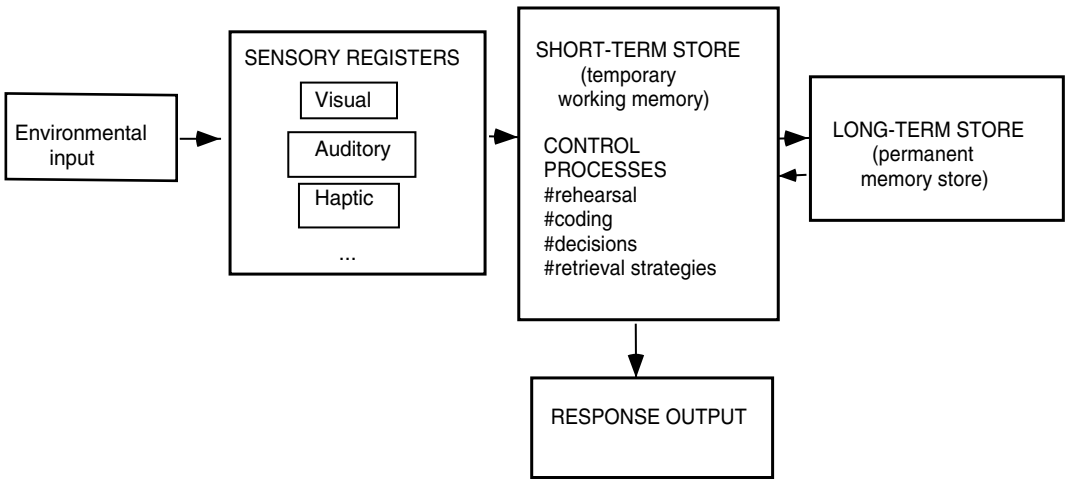

Figure 1 Short-term and long-term memory. This flowchart illustrates a functional architecture of human memory proposed in the late 1960s by Richard Atkinson and Richard Shiffrin that summarizes the main features of a number of models put forward at that time. The model draws a distinction between short- and long-term memory. The two systems are organized serially, with temporary storage in short-term memory being a necessary condition for retention in long-term memory. The short-term store is a unitary system that is not specific for sensory modality, receiving input from different sensory registers, and includes a number of control processes such as rehearsal. This store plays a central role in cognitive activity, being equated with consciousness [based on Atkinson, R. C., and Shiffrin, R. M. (1971). The control of short-term memory. *Sci. Am.* **225,** 82–90].

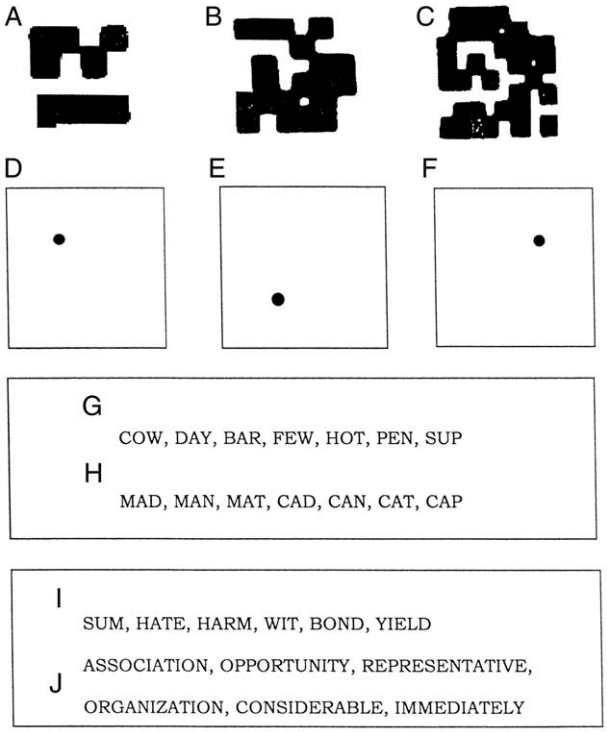

Figure 2 Stimuli used in short-term memory tasks. (A)–(C): patterns used to assess visual short-term memory [based on Phillips, W. A. (1974). On the distinction between sensory storage and short-term memory. *Perception and Psychophysics* **16,** 283–290]. (D)–(F): stimuli used to assess visuo-spatial memory (location of a dot in a square) [Dale, H. C. (1973). Short-term memory for visual information. *British Journal of Psychology* **64,** 1–8]. (G)–(J): stimuli used to assess verbal short-term memory; phonologically dissimilar (G) and similar (H), short (I) and long (J) sets of words. [("G" and "H" sets) Baddeley, A. D. (1966). Short-term memory for word sequences as a function of acoustic, semantic and formal similarity. *Quarterly Journal of Experimental Psychology* **18,** 362–365. ("I" and "J" sets) Baddeley, A. D., Thomson, N., and Buchanan, M. (1975). Word length and the structure of short-term memory. *Journal of Verbal Learning and Verbal Behavior* **14,** 575–589].

recall of a short list of stimuli (e.g., trigrams of consonants or of words) decreases dramatically in a few (<10) seconds if the subjects' repetition of the memory material (rehearsal) is prevented by a distracting activity such as counting backwards by threes (Fig. 3). A broadly similar forgetting occurs for visual and spatial stimuli (e.g., the location of a dot and random patterns) and auditory nonverbal stimuli (e.g., a tone). This rapid short-term forgetting may be contrasted with the long-lasting persistence in memory of other types of records, such as autobiographical events, which may last for years to the entire life.

Second, in immediate recall, normal subjects presented with a sequence of events such as a list of words or visual patterns, which they are required to recall in any order they wish (free recall), produce first and best the final, more recent stimuli. A comparatively minor advantage of the first one or two items is also present, giving to the recall curve a nonsymmetrical U-shaped form. A similar curve occurs when the subject produces the stimuli of the list in the presentation order (serial recall). The recall superiority of the final items, a phenomenon termed the recency effect (Fig. 4), vanishes after a few seconds of distracting activity. In a typical free recall experiment with verbal material, such as a list of 10–15 words, the recency effect involves the final 5–7 stimuli. The recency effect for verbal stimuli is minimally influenced by factors such as age, rate of presentation, and word frequency, which in turn affect recall performance in the pre-recency positions. This pattern is taken as evidence of a dissociation between short- and long-term memory processes, with the former being associated with the recency effect and the latter with recall in the preceding positions.

Finally, in immediate serial recall (memory span), the ability of normal subjects to recall a sequence of events in their presentation order (e.g., a list of digits, letters, words, or a sequence of locations of objects) is limited (George Miller's "magical" number 7 ± 2 items). Regarding the paradigm of short-term forgetting, if a succession of different lists is presented, subjects become unable to remember the previous ones in a few minutes.

These three sets of empirical observations illustrate the main characteristics of short-term memory: a retention system with limited capacity, holding recent (in the time range of seconds) events, in which the memory trace decays in a few seconds unless this is prevented through rehearsal.

The material stored in short-term memory has a specific representational format. In the verbal domain this involves phonological codes, which may be distinguished from lexical–semantic representations stored in long-term memory. In immediate verbal span, the subjects' performance is primarily affected by factors such as phonological similarity and word length (Fig. 5), with the effects of lexical–semantic factors being comparatively minor. The phonological similarity effect is illustrated by the superior immediate serial recall of sequences of dissimilar words compared to lists comprising similar items (Fig. 2, "G" vs "H" sets). The word length effect is illustrated by the superior immediate serial recall of sequences of short words compared to lists comprising longer items (Fig. 2, "I" vs "J" sets). Also, lexical factors contribute to

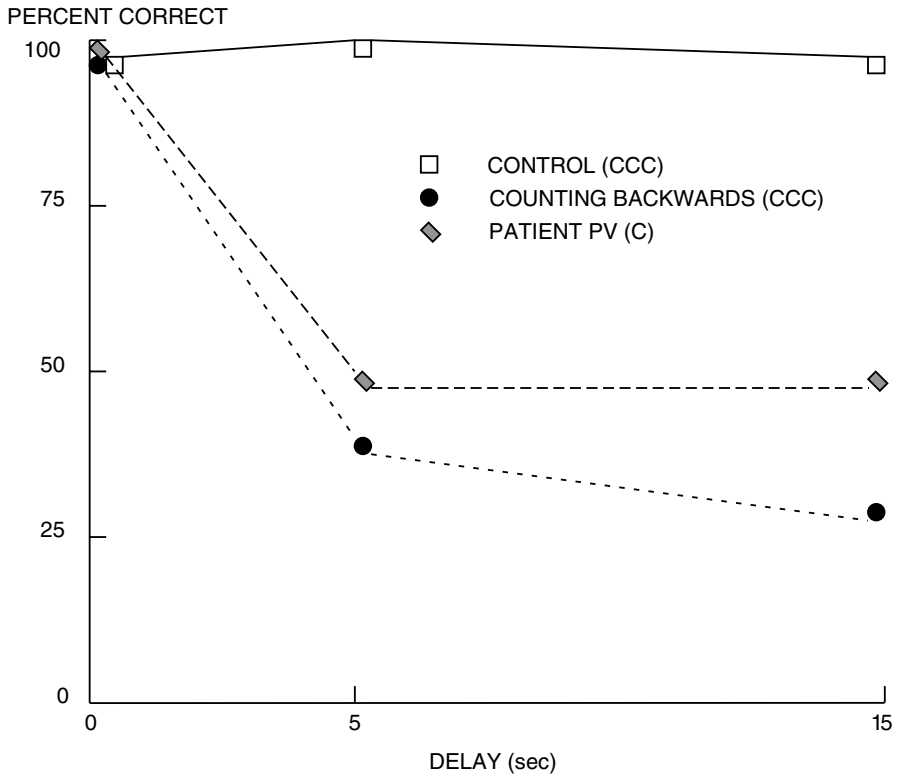

Figure 3 Short-term retention of individual letters. Normal subjects: control, recall of consonant trigrams (CCC) with no interpolated distracting activity; counting backwards, recall of CCC with interpolated distracting activity. Patient PV, recall of single letters (C) with no interpolated distracting activity. In normal subjects the counting task has dramatic detrimental effects on short-term retention of CCC sequences. In the patient who has an auditory span of 2.5 digits, a C stimulus is forgotten in a few seconds, even under conditions of no interference. The errorless performance at the 0-sec delay rules out the possibility that the patient's deficit reflects a perceptual impairment [data from Basso, A., Spinnler, H., Vallar, G., and Zanobio, M. E. (1982). Left hemisphere damage and selective impairment of auditory–verbal short-term memory. *Neuropsychologia* **20,** 263–274; Vallar, G., and Baddeley, A. D. (1982). Short-term forgetting and the articulatory loop. *Q. J. Exp. Psychol.* **34A,** 53–60].

immediate retention, with subjects showing a higher level of performance in span tasks involving word stimuli compared to nonwords or words in a foreign language unknown to the subject, namely, meaningless pronounceable sequences of letters that do not possess a representation in the lexicon.

The three paradigms of short-term forgetting, free recall, and immediate memory span provided the initial impetus for studies in normal subjects aimed at dissociating short- vs long-term memory processes. They also provided the basic tools for assessing this putative dissociation in brain-damaged patients. Each of the phenomena mentioned earlier subsequently proved to be considerably more complex than initially thought. In short-term forgetting the counting backwards task has more complex disruptive effects than the mere interference with the process of rehearsal. In addition, although forgetting in the first 5 sec is likely to reflect the decay of a short-term memory trace, subsequent forgetting involves other mechanisms such as interference. The recency effect is a general memory phenomenon, which may also be observed under conditions involving only long-term memory processes, such as recall of remote autobiographical events. Furthermore, factors such as the relative temporal interval among the events in the sequence influence the occurrence of the recency effect in long-term retention. Immediate memory span is also influenced by lexical factors, which reflect long-term memory processes. Initially, attempts were made to explain the three phenomena in terms of the then dominant view of human memory as a unitary system. Such a monolithic account proved untenable, however, mainly on the basis of neuropsychological evidence from patients with brain damage.

The functional architecture of the system concerned with the short-term retention of verbal material (phonological short-term memory) has been

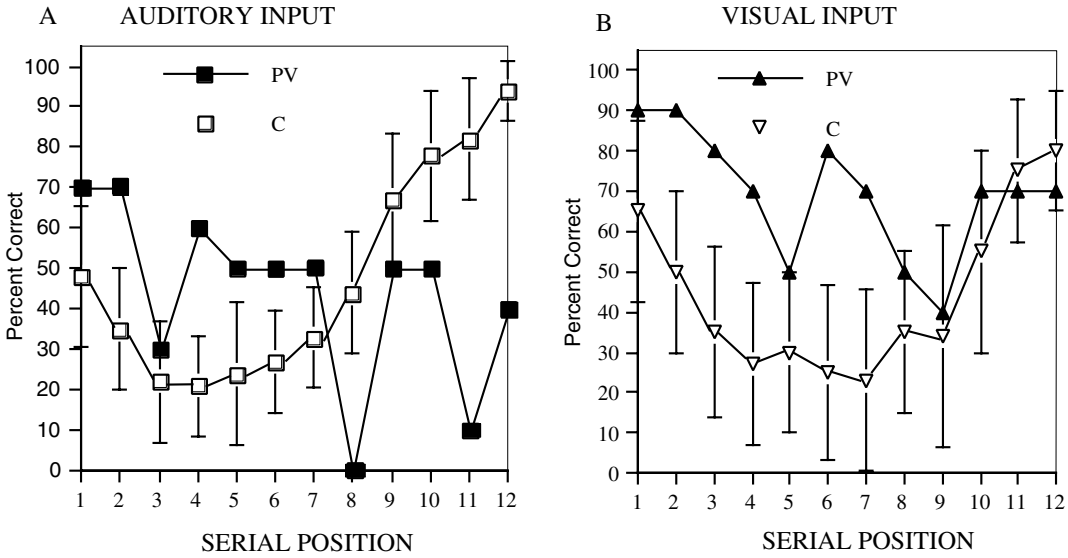

Figure 4 Immediate free recall of sequences of words. Average free recall performance with lists of 12 Italian words by patient PV (see Fig. 2) and normal subjects (C) by serial position of each stimulus in the presentation order and modality of presentation [auditory (A) and visual (B)]. In this task subjects are presented with lists of words, which they subsequently recall in any order they wish. Normal subjects show a higher level of performance in the final positions of the list (recency effect), with recall accuracy steadily increasing in the last six serial positions (in this particular sequence from about the sixth to the final 12th stimulus). The recency effect is present with both auditory and visual presentation of the stimuli, even though an auditory advantage (modality effect) is typically found. Normal subjects also show a minor advantage of the initial one–two positions in the sequence. In immediate free recall, the recency effect reflects the output of short-term memory systems, whereas recall from the preceding positions is mainly based on long-term memory systems. With auditory presentation of the stimuli, patient PV shows no recency, but this is within the normal range with visual input. Patient PV also shows a well-preserved recall performance in the initial and middle positions of the recall sequence [based on Vallar, G., and Papagno, C. (1986). Phonological short-term store and the nature of the recency effect. Evidence from neuropsychology. *Brain Cognition* **5,** 428–442].

investigated in further detail by studying the effects of phonological similarity and word length and the concurrent task of articulatory suppression, teasing apart storage vs rehearsal components. Suppression has three relevant effects on immediate retention in span tasks: (i) It brings about an overall reduction of memory performance; (ii) it abolishes the effect of phonological similarity when the stimuli are presented visually, but not with auditory input; and (iii) it eliminates the effect of word length both with auditory and with visual presentation of the stimuli.

This pattern suggests a fractionation of phonological short-term memory into two components, both contributing to immediate retention in span tasks: (i) a passive input system, the phonological short-term store, to which auditory input has a direct access—this phonological system is nonarticulatory in nature, as witnessed by the persistence of the effect of phonological similarity during suppression; and (ii) a more controlled process of articulatory rehearsal, which has the twofold function of refreshing the phonological trace, preventing its decay, and of conveying visual–verbal information to the phonological short-term store, after recoding, or phoneme-to-grapheme conversion. Suppression, interfering with the operation of rehearsal, reduces span performance and prevents access of visual–verbal material to the phonological store, as witnessed by the disappearance of the effect of phonological similarity. The word length effect, being abolished by suppression, likely reflects articulatory factors, such as the spoken duration and complexity of the stimuli, and may be taken as an index of the activity of the rehearsal process. A model of phonological short-term memory is shown in Fig. 6.

In line with the phonological store/rehearsal fractionation illustrated in Fig. 6, unattended auditory speech disrupts immediate memory span for verbal material, presented in both the visual and the auditory modality, preempting the storage capacity of the phonological short-term input store. Suppression, however, abolishes the disruptive effect of unattended speech on immediate retention of verbal material presented in the visual modality. This effect occurs because suppression, interfering with the operation of rehearsal, prevents visual–verbal material from entering the phonological short-term input store, which is

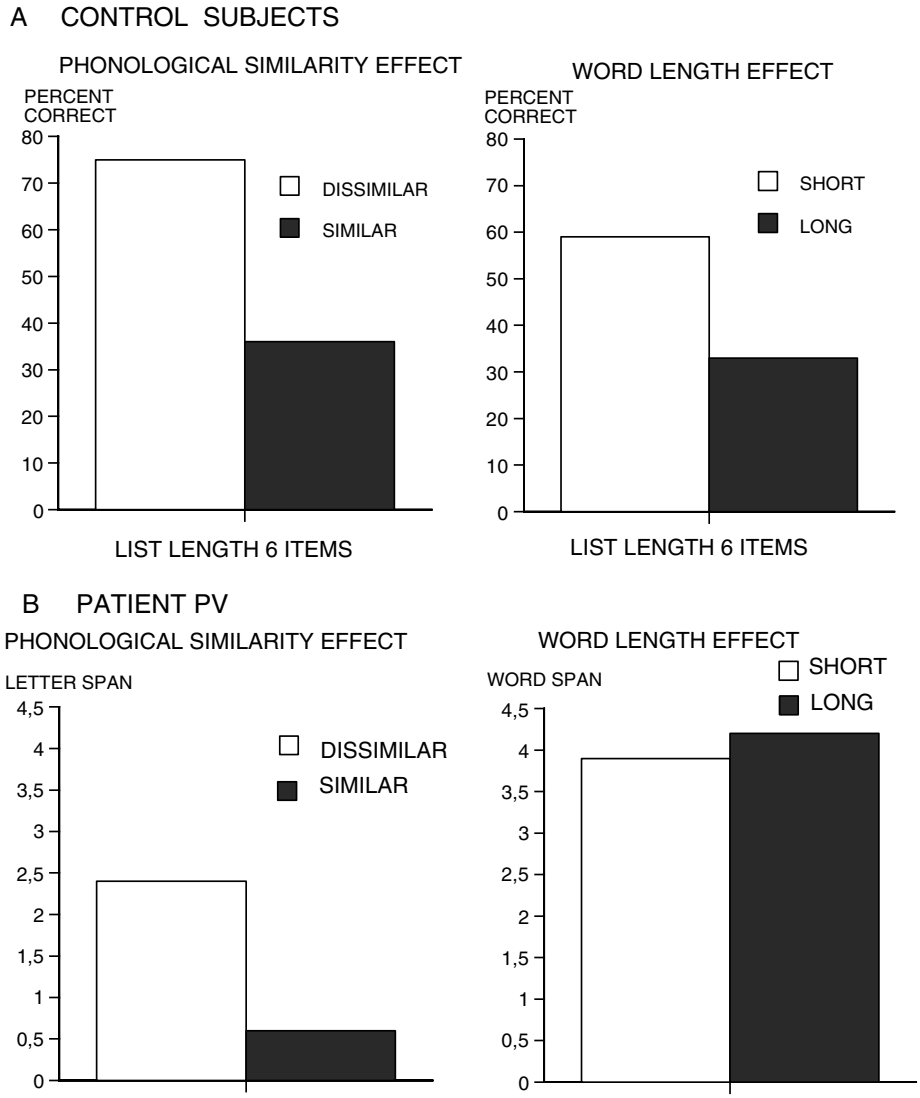

Figure 5 Coding in phonological short-term memory. (A) In immediate serial recall the memory performance of normal subjects is better when the stimuli are phonologically dissimilar rather than similar (phonological similarity effect) and shorter rather than longer (item length effect). Normal subjects exhibit these effects with both auditory and visual presentation of the stimuli. For each effect, the recall performance of normal subjects with six-item auditory sequences of similar and dissimilar letters and long (five-syllable) and short (two-syllable) words is shown. These effects are taken as evidence of phonological coding in verbal short-term memory. (B) Patient PV shows a dramatic reduction of auditory span performance (less than 2.5 letters) and a preserved effect of phonological similarity, which indicates that auditory–verbal material is, as in normal subjects, coded in a phonological format, even though the capacity of the phonological short-term store is dramatically reduced. The absence of any effect of word length with auditory input indicates that the process of articulatory rehearsal is not used by the patient [data from Vallar, G., and Baddeley, A. D. (1984). Fractionation of working memory: Neuropsychological evidence for a phonological short-term store. *J. Verbal Learning Verbal Behav*. **23,** 151–161].

corrupted by unattended speech. Finally, some perceptual phonological judgments are held to specifically involve the articulatory components of rehearsal because the performance of normal subjects is slightly but significantly impaired by suppression. The term phonological judgment refers to the conscious processing (phonological awareness) of a number of phonological aspects of strings of letters, either words or nonwords. In most studies the material is presented visually in order to prevent the direct activation of acoustic–phonological representations. These judgments include deciding whether or not two letter

strings "rhyme" (i.e., their final segments sound the same) or whether their initial sounds are identical or not.

In the nonverbal domain a similar distinction is drawn between visual and spatial short- and long-term memory systems, with the relevant representational format being in terms of the shape or the spatial location of the stimulus. Visuospatial short-term memory is likely to comprise storage and rehearsal (pictorial and spatial) components. In the case of spatial locations, rehearsal may be conceived in terms of planned movements (e.g., ocular, manual reaching, and locomotion) toward a target coded in a spatial reference frame (e.g., egocentric).

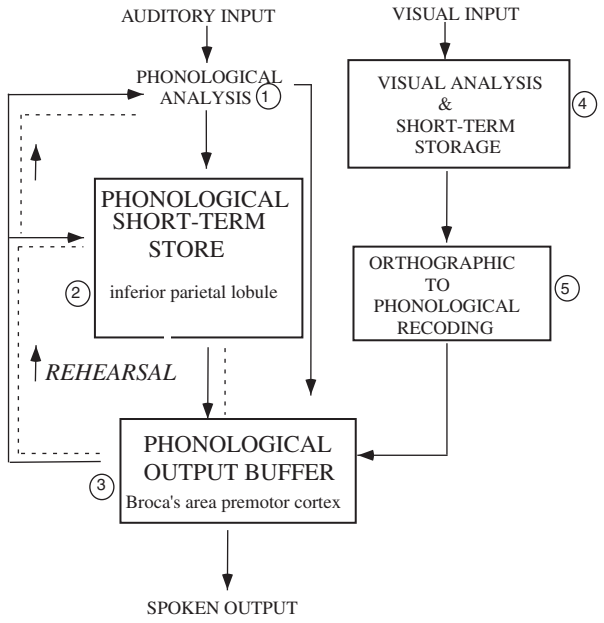

Figure 6 A functional model of phonological short-term memory. After early acoustic and phonological analysis (1), auditory–verbal material enters the main retention component of the system, the phonological short-term store (2), where material is coded in a phonological format. The phonological short-term store is an input system to which auditory material has a direct and automatic access. The process of rehearsal is conceived as involving a recirculation of the memory trace between the phonological short-term store and a phonological output system, the phonological output buffer or phonological assembly system (3), primarily concerned with the articulatory programming of speech output, with a recurring translation between input (acoustic) and output (articulatory) phonological representations. The phonological output buffer provides access of visually presented verbal material to the phonological short-term store after phonological recoding or grapheme-to-phoneme conversion (5). The model also illustrates the multiple-component nature of short-term memory, showing a visual short-term store (4), where material is likely to be encoded in terms of shape [based on Vallar, G., Di Betta, A. M., and Silveri, M. C. (1997). The phonological short-term store-rehearsal system: Patterns of impairment and neural correlates. *Neuropsychologia* **35,** 795–812].

B. Neuropsychological Studies in Brain-Damaged Patients

Studies of patients with memory disorders associated with brain damage provide unequivocal evidence that supports the independence of short- and long-term memory systems, conjuring up a double dissociation of deficits. The hallmark of global amnesia, characterized as a selective impairment of the declarative or explicit component of long-term memory, is the inability to learn verbal and visuospatial material as assessed by recall or recognition tasks (anterograde amnesia). The deficit of these patients also concerns memory for autobiographical events and facts that occurred prior to the onset of the disease (retrograde amnesia). This dramatic memory deficit, which disrupts patients' everyday lives, contrasts sharply with their unimpaired performance in the three paradigms mentioned earlier. Short-term forgetting and immediate memory span are within the normal range for both verbal and nonverbal material. In immediate free recall, amnesic patients show a preserved recency effect associated with a defective performance in the pre-recency positions of the list. These results suggest a functional characterization of amnesia in terms of defective long-term memory, with a preserved function of short-term memory. Second, the pattern of impairment of amnesia is compatible with a serial organization of the two systems, with temporary retention in short-term memory being a necessary condition for long-term storage (see Fig. 1).

Since the late 1960s selective impairments of different components of short-term memory have been reported. The more extensively investigated areas concern auditory–verbal (phonological) and visuospatial short-term memory.

1. Impairments of Phonological Short-Term Memory

Neuropsychological deficits of phonological short-term memory comprise two different types of impairment: a reduced capacity of the store component of the system and a dysfunction of the process of rehearsal.

a. Disproportionately Reduced Capacity of the Phonological Short-Term Store Although it had long been known that patients with dysphasia may show a

disproportionate impairment of repetition of verbal material, such as a sentence or a list of words or digits, it was only in the late 1960s that this deficit was interpreted as a specific disorder of verbal short-term memory rather than as a linguistic impairment (conduction aphasia). The hallmark of this memory disorder is a selective and disproportionate deficit of immediate repetition of all kinds of verbal material (digits, letters, words, and sentences). Patients with this short-term memory deficit, engaged in the three tasks discussed earlier, exhibit the following pattern of performance: (i) Short-term forgetting is abnormally rapid (Fig. 3), (ii) the recency effect in immediate free recall of auditory–verbal lists of words is abolished or severely reduced (Fig. 4), and (iii) auditory–verbal span is disproportionately reduced to an average of less than three items (digits, letters, or words; see Figs. 5b and 7). The retention deficit cannot be explained in terms of defective sensory or perceptual analysis. The patients' immediate reproduction of individual items is entirely spared, as is their ability to perform tasks requiring phonological discriminations, under conditions of minimal memory load. Speech production is also entirely preserved in a number of patients, ruling out interpretations in terms of defective response (articulatory) processes. In addition, the memory deficit does not improve when a response modality that does not require speech production (e.g., recognition by pointing) is used. These features distinguish this "mnestic" disorder of repetition from a type of conduction aphasia in which both the repetition deficit and spontaneous speech are characterized by phonological errors (phonemic paraphasias). Taken together, these findings suggest the impairment of a short-term storage system.

In the majority of these patients the disorder is modality specific, with the level of performance being better when the material is presented visually (Fig. 7). This input-related dissociation has two main implications: (i) Discrete phonological and visual short-term memory components exist, and (ii) in the input–output processing chain, the phonological short-term store should be conceived as an input perceptual system rather than as an output production buffer store. This fractionation also argues against a monolithic view of the system as a single amodal store, which is not specific for the different sensory modalities. Additional support for this input locus of the system comes from the observation that in some of these patients the production of articulated speech is entirely preserved.

Patients with defective phonological short-term memory may show unimpaired long-term verbal

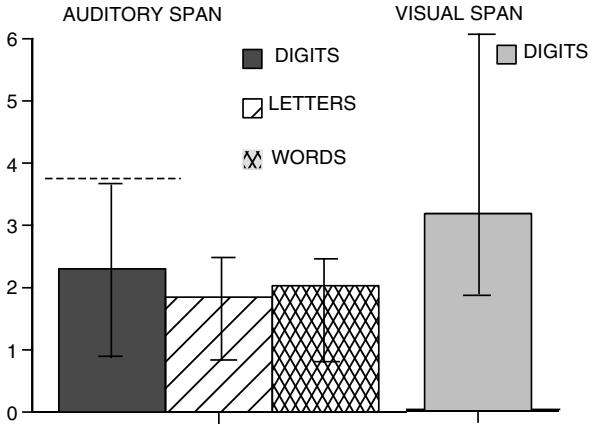

Figure 7 Auditory and visual span in patients with defective phonological short-term memory. Auditory repetition span for all types of verbal material (digits, letters, and words) is defective, whereas the level of performance is higher with visual presentation. In contrast, a minor advantage of the auditory modality is typically found in normal subjects (modality effect). The histograms indicate average spans, the vertical bars indicate the ranges of the patients' span performances, the horizontal dashed line indicates the cut-off for auditory digit span [meta-analytic data from Vallar and Papagno (1995)].

[e.g., paired-associate learning (Fig. 8) and learning of a short story] and visuospatial (e.g., visual maze learning) memory. This observation supports the notion of complete independence of short- and long-term memory systems. However, it is incompatible with a serial organization in which defective short-term memory entails a long-term memory impairment (Fig. 1), suggesting instead a parallel architecture: After early perceptual analysis, information may enter short- or long-term memory, either of which may be selectively disrupted by brain damage. The learning abilities of these patients are dramatically impaired when the phonological material to be learned does not possess preexisting lexical–semantic representations in long-term memory. This is the case for pronounceable meaningless sequences of letters—nonwords or words in a language unknown to the subject (e.g., "svieti" and "tevome") (Fig. 9). This deficit of phonological learning indicates that within a specific representational domain, temporary storage in short-term memory is necessary for stable long-term learning and retention, as predicted by the serial model illustrated in Fig. 1.

b. Impairment of the Rehearsal Process Investigations concerning the precise nature of verbal rehearsal and of its impairments have been performed more recently, with major advances in the past 20 years. The

process of rehearsal has traditionally been described as an activity that, through rote repetition, refreshes the short-term memory trace, preventing its decay. Rehearsal may be conceived in terms of the recoding of the memory trace from input (auditory–verbal) to output-related (articulatory) representations and vice versa (Fig. 6). Specifically, rehearsal of verbal material has long been regarded as an "articulatory" activity ("inner" or "internal" speech), which involves output-related verbal processes, including the motor programming of speech production in a phonological assembly system (Fig. 6), the actual articulation of the material to be rehearsed, making use of the peripheral musculature ("subvocal" rehearsal), or both. Anarthric subjects who, due to congenital disorders or brain damage acquired as adults, are unable to utter any articulated speech sound may show an entirely preserved immediate memory, including verbal rehearsal, as revealed by normal span, similarity, and length effects. This suggests that the process is "central" and does not necessarily require the activity of the peripheral musculature. Brain-damaged patients with a selective impairment of rehearsal show a defective immediate verbal span, as do patients with damage to the phonological short-term store, because both components of phonological memory contribute to immediate retention. Damage confined to the rehearsal process (but not to the phonological store) disrupts the ability to perform phonological judgments, such as rhyme and initial sound. This result, together with the previously mentioned interference effects of articulatory suppression found in normal subjects, suggests that phonological processes such as segmentation and deletion involve output phonological codes. Conversely, a defective rehearsal leaves largely unimpaired the recency effect in immediate free recall of auditory lists of words. This recency effect is grossly reduced or absent in patients with damage to the phonological short-term store (Fig. 4). This dissociation elucidates the precise mechanisms underlying the recency effect in immediate free recall, as reflecting the output of the phonological input short-term store.

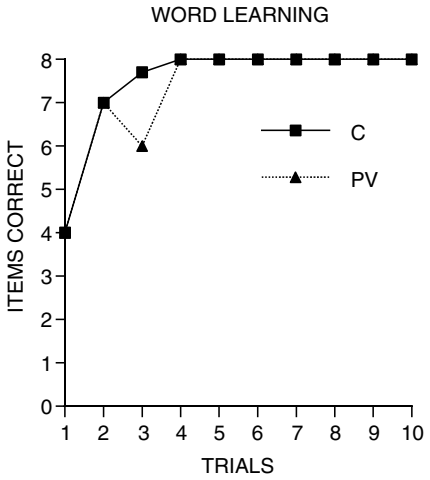

Figure 8 Long-term verbal learning in a patient with defective phonological memory. Patient PV shows unimpaired paired-associate learning of Italian words (C, control subjects). In a paired-associate learning paradigm, subjects are presented with a list of pairs of stimuli (e.g., unrelated words such as "dog"–"pint" and "hammer"–"truth"). Immediately after presentation, or after a delay, subjects are presented with the first member of each pair in an order different from presentation and are required to provide the second member (e.g., "hammer" … → "truth" and "dog" … → "pint") [based on Baddeley, A. D., Papagno, C., and Vallar, G. (1988). When long-term learning depends on short-term storage. *J. Memory Language* **27,** 586–595].

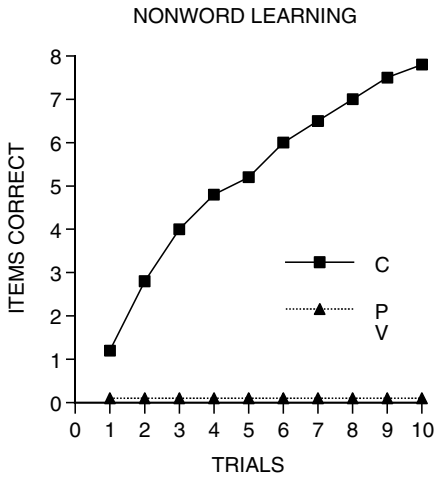

Figure 9 Long-term phonological learning in a patient with defective phonological memory. Patient PV is entirely unable to learn pronounceable nonwords (Russian words transliterated into Italian, e.g., "orange"–"apielsin" and "bear"–"miedvied") in a paired-associate word–nonword paradigm. C, control subjects [based on Baddeley, A. D., Papagno, C., and Vallar, G. (1988). When long-term learning depends on short-term storage. *J. Memory Language* **27,** 586–595].

2. Impairments of Spatial and Visual Short-Term Memory

Two main patterns of short-term memory impairment have been described in brain-injured patients: impairments for spatial locations and for visual patterns. The relationships of these disorders with visuospatial learning have also been investigated. A number of caveats should be considered, however. These deficits

have been explored less extensively than the phonological disorder, and much fewer patients have been adequately described. In addition, the distinction between visual and spatial component processes in memory may be intrinsically blurred because visual objects have spatial properties (e.g., their location in egocentric space and the spatial relationships between their component parts). Finally, no definite distinction between storage and rehearsal components has been drawn.

a. Impairments of Short-Term Memory for Spatial Locations These patients show a defective immediate retention of short sequences of spatial locations, as assessed by a block tapping task (a spatial analog of digit span; Fig. 10a), with verbal memory being unaffected, in both its short- and long-term components (Fig. 10b). Regarding the deficits of phonological short-term memory, the impaired retention of spatial locations cannot be accounted for in terms of visuoperceptual or response-related disorders (e.g., unilateral spatial neglect and misreaching). These patients may show no evidence of topographical disorientation or impairment in long-term learning of visuospatial information, such as the path of a visual maze. These findings suggest a complete independence of short- and long-term memory spatial systems concerned with spatial locations.

b. Impairments of Short-Term Memory for Visual Patterns The short-term visual recognition of unfamiliar faces, objects, voices, and colors may be impaired following brain damage. These deficits may be associated with defective short-term memory for spatial locations. The disorder of patients with defective visual imagery (e.g., as assessed by tasks requiring color or size comparisons) may also be interpreted in terms of a defective visual short-term memory store. A deficit of visual short-term memory may disrupt long-term learning of unfamiliar nonverbal material, as assessed by recognition memory for unfamiliar faces and objects. This extends to the visuospatial domain the conclusion that long-term acquisition requires short-term storage.

III. NEUROLOGICAL ARCHITECTURE

Investigation of the neural correlates of short-term memory systems takes advantage of two main sources of evidence: (i) the traditional anatomoclinical correlations between the site and the size of the cerebral lesion and the behavioral impairment and (ii) the recent functional neuroimaging methods involving the measurement of regional cerebral activity in normal subjects engaged in behavioral tasks probing the function of the component of interest.

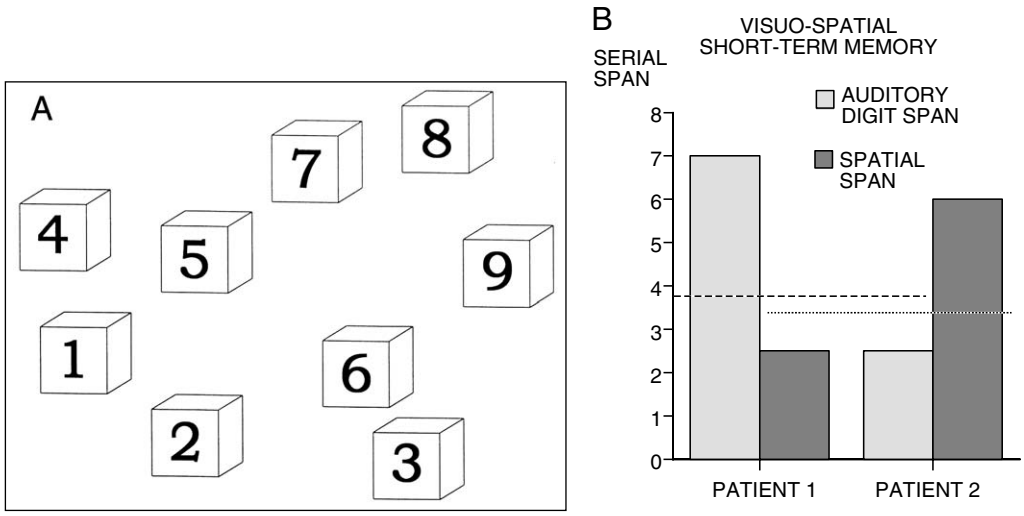

Figure 10 Impairments of short-term memory for spatial positions. (A) The board of the block tapping test. The patient's task is to reproduce the sequence of spatial positions pointed to by the examiner. Like verbal span, sequences of increasing length are presented. In the actual board, the numbers are on the examiner's side. (B) Patient 1 shows a defective visuospatial span associated with a normal auditory digit span; patient 2 shows the opposite pattern of performance. The dashed line indicates the cutoff for digit span, and the dotted line indicates the cutoff for visuospatial span. This double dissociation illustrates the independence of short-term memory for spatial locations from phonological short-term memory [data from De Renzi, E., and Nichelli, P. (1975). Verbal and non-verbal short-term memory impairment following hemispheric damage. *Cortex* **11,** 341–354].

A. Phonological Short-Term Memory

1. Anatomoclinical Correlation Studies in Brain-Damaged Patients

Correlations performed in a large number of patients with defective auditory–verbal span suggest a definite association between damage to a number of areas in the left cerebral hemisphere, located around the Sylvian fissure, and the dysfunction of phonological short-term memory. The parietal association cortex in the left hemisphere [supramarginal gyrus of the inferior parietal lobule (Brodmann's area, BA, 40) at the temporoparietal junction] represents the main neural correlate of the short-term store component of phonological memory. The frontal premotor regions in the left hemisphere and other structures such as the insula constitute the major neural correlates of the rehearsal component, even though the available anatomoclinical data are much more limited. Damage to the right hemisphere does not affect immediate verbal memory, suggesting a left-sided lateralization of the system.

2. Measurement of Regional Cerebral Activity in Normal Subjects

Studies in normal subjects using functional neuroimaging methods support the previously mentioned pathological evidence suggesting a left hemisphere-based network. The short-term store component of phonological memory is associated with activation in the left supramarginal gyrus (BA 40) at the temporoparietal junction, and the rehearsal component is associated with activation in the left frontal premotor regions (BA 44, BA 6, and supplementary motor area) and in the left insula. In these studies, in line with behavioral evidence from normal subjects and brain-damaged patients, an immediate verbal span task activates both the inferior–parietal region at the temporoparietal junction (phonological short-term store), and the premotor cortex (rehearsal process) in the left hemisphere. Conversely, a rhyme judgment task selectively activates the left premotor regions but not the supramarginal gyrus.

As usually found in neuroimaging studies in normal subjects, the network activated by an immediate verbal retention task tapping phonological short-term memory is more extensive and bilateral compared to the anatomoclinical observations in brain-injured patients. The activation observed in normal subjects extends to Wernicke's area (BA 22) in the left hemisphere and to a number of regions in the right hemisphere homologous to the ones active in the left hemisphere (inferior frontal gyrus, BA 44 and BA 6; supramarginal gyrus, BA 40; superior temporal gyrus, BA 20; insula). Similarly, a rhyming task in normal subjects also activates Wernicke's area in the left hemisphere and the insula in the right hemisphere. The difference between the evidence from lesion and activation studies may be related to the redundancy of any neural system subserving a given function. Although the active network is bilateral, its major component is lateralized to the left hemisphere, where the regions necessary to the execution of the task of interest (in this case, immediate memory span) are localized. Accordingly, only damage to the necessary regions brings about behavioral consequences in brain-damaged patients. This approach implies that the complete understanding of the neural correlates of cognitive functions requires evidence from both lesion studies in brain-injured patients and activation experiments in normal subjects.

The activation and lesion-based data support, from an anatomofunctional perspective, the behavioral distinction between a storage component and a rehearsal process in phonological short-term memory. Furthermore, they qualify rehearsal as a process that makes use of components (Fig. 6) also concerned with the planning (i.e., programming in the left premotor cortex) of articulated speech. Finally, from this perspective, phonological memory may be regarded as a component part of the language system.

The neural correlates of the phonological short-term store–rehearsal system are shown in Fig. 11. The system comprises posterior–inferior parietal and premotor components, concerned with the storage and rehearsal aspects of short-term retention. When subjects are engaged in tasks that require more "executive" processes in addition to storage (e.g., free recall and matching a target one, two, or three back in a sequence), the pattern of activation becomes more anterior, extending to the dorsolateral prefrontal cortex, and bilateral.

B. Visual and Spatial Short-Term Memory

1. Anatomoclinical Correlation Studies in Brain-Damaged Patients

Short-term memory for spatial locations, as assessed by tasks requiring the reproduction of sequences of positions in near extrapersonal space, is disrupted by damage to the posterior (parietooccipital) regions of both the left and the right hemisphere, but the role of

right hemisphere damage appears to be more relevant. Damage to the right hemisphere may also affect short-term memory for unfamiliar faces. In contrast, phonological short-term memory is not impaired by lesions in the right hemisphere.

Some deficits of visual short-term memory are associated with damage to the posterior (parietooccipital) regions of the left hemisphere. One such impairment concerns the immediate retention of sequences of visual stimuli, such as straight or curved lines. This deficit may occur in the presence of a normal auditory–verbal span. A second type of impairment concerns the recognition of more than one visual stimulus at a time (defective simultaneous form perception): Patients who are able to identify single meaningful forms visually (letters, numbers, and geometric figures) are disproportionately impaired if two stimuli are presented, misidentifying one of them.

In summary, lesion studies in brain-damaged patients provide support for the distinction between short-term memory for spatial locations and for visual patterns, the former being more closely associated with right hemisphere damage and the latter with left hemisphere damage. The lateralization of visuospatial short-term memory systems appears less pronounced than that of phonological memory.

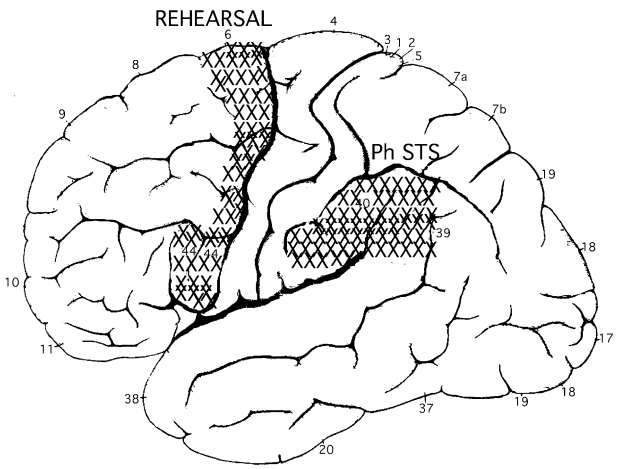

Figure 11 The anatomical basis of phonological short-term memory. This system comprises two components: the phonological short-term store (ph STS), whose main neural correlate is the left inferior parietal lobule (supramarginal gyrus, BA 40) at the temporoparietal junction, and the process of "rehearsal," whose neural basis includes Broca's area (BA 44), the premotor area (BA 6), and the supplementary motor area in the left hemisphere. These two neural short-term memory systems are likely to be connected through the arcuate fasciculus and white matter fiber tracts in the insular region.

2. Measurement of Regional Cerebral Activity in Normal Subjects

Neuroimaging activation studies in humans support and further qualify the distinction between primarily spatial (location) and visual (recognition) short-term memory components. The anatomical differences between them concern both the relevant cerebral areas and their prevailing lateralization. When normal subjects are engaged in tasks involving short-term memory for spatial location, the activated areas include the occipital extrastriate (BA 19), posterior–inferior parietal (BA 40), dorsolateral premotor (BA 6), and prefrontal cortices. Short-term recognition memory for visual patterns (e.g., faces and designs) is associated with activation in a more ventral network, including the occipital and temporal (BA 37) regions, the posterior–inferior parietal region (BA 40), and the prefrontal cortex. Within the prefrontal cortex (BAs 45, 46, 47, and 9), more dorsolateral areas have been associated with short-term memory for spatial location and more ventral areas with short-term memory for patterns. Activation has frequently been found to be bilateral, but there is evidence suggesting more sustained activity in the right hemisphere when the task assesses recognition memory for spatial location and in the left hemisphere when the task probes recognition memory for visual patterns.

These nonoverlapping patterns of activation indicate an association between the dorsal visual stream and short-term memory for spatial locations and between the ventral visual stream and recognition memory for visual patterns. These findings also suggest the existence of some hemispheric asymmetry, with right-sided areas being more concerned with the spatial (location) aspects of short-term retention and left-sided areas with the visual (pattern recognition) aspects. The relative contribution of different cerebral regions of the two sides of the brain may also be related to the format of the cerebral representation involved. For instance, a left lateralization for visual object working memory may reflect a more symbolic or verbal encoding and a right-sided lateralization a more image-based encoding.

Finally, the different cerebral areas participating in the network may provide distinct contributions to the short-term retention process. The occipital and temporal regions may participate in perceptual analysis, the posterior parietal cortex in computing the coordinates of the stimulus, and the premotor and prefrontal cortices in the retention process (storage and rehearsal) proper.

IV. SHORT-TERM MEMORY AND COGNITION

In the preceding sections, behavioral and anatomical evidence for the existence of a number of discrete systems concerned with short-term retention was considered. In this section, short-term memory systems are discussed from the perspective of their relationships with other components of the cognitive system and their role in cognitive activity. Is there a use for a system providing the temporary retention of a limited amount of stimuli, besides infrequent situations, such as the following: a friend tells you an unfamiliar eight-digit number that you have to dial on a telephone on the other side of a major street and you have no paper and pencil to write down the number.

Serial models of memory (Fig. 1) imply that short-term retention is a necessary stage for the stable acquisition of new information in long-term memory. Specifically, there is definite evidence that phonological short-term memory plays an important role in learning new vocabulary. In addition, this system participates in the processes of speech comprehension and production. The evidence concerning visual and spatial short-term memory is less definite.

A. Long-Term Learning

The observation that patients with defective auditory–verbal span are also impaired in learning unfamiliar

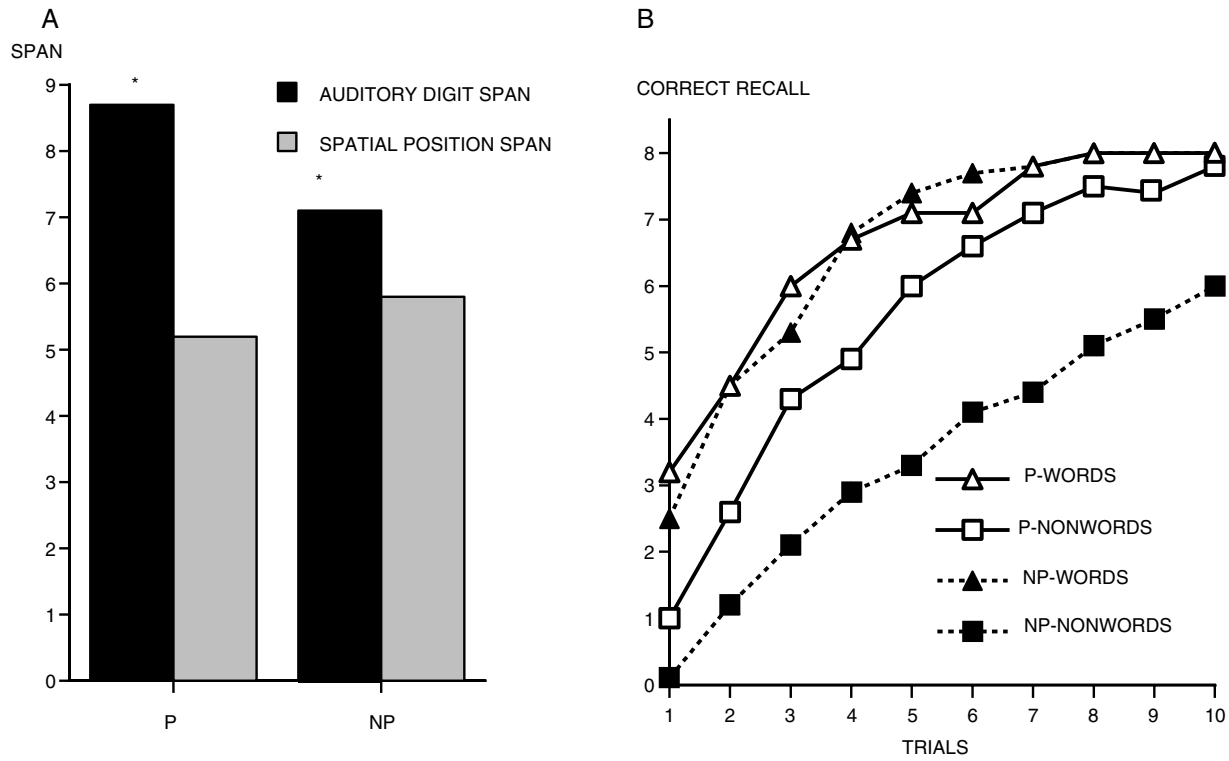

Figure 12 Phonological short-term memory and learning of nonwords by polyglot and nonpolyglot subjects. (A) Polyglot (P) subjects have a higher average immediate auditory–verbal digit span (*), whereas their average spatial span is comparable to that of nonpolyglot (NP) subjects. (B) In a word–nonword paired-associate learning task, P subjects show better learning of pronounceable strings of letters not corresponding to any lexical item known to them. The P subjects' superior learning of new phonological information does not reflect higher learning skills in general, as shown by their word learning performance, which is comparable to that of NP subjects. Similarly, the comparable performance of the two groups in spatial span indicates that the short-term memory advantage of P subjects is confined to the phonological system [based on Papagno, C., and Vallar, G. (1995). Verbal short-term memory and vocabulary learning in polyglots. *Q. J. Exp. Psychol.* **48A,** 98–107].

pronounceable letter sequences raises the possibility that phonological memory may contribute to a relevant aspect of language development—the acquisition of vocabulary (Fig. 9). Similarly, subjects with a developmental deficit of phonological memory are impaired in vocabulary acquisition and in nonword learning. An opposite pattern occurs in subjects with a congenital cognitive impairment that selectively spares phonological short-term memory: Acquisition of vocabulary, foreign languages, and nonword learning are also preserved. Evidence from different subject populations supports this view. First, correlational studies in children have shown that the capacity of phonological memory is a main predictor of the subsequent acquisition of vocabulary, both in the native and in a second language. Second, in normal adult subjects, the variables that disrupt immediate memory span (phonological similarity, item length, and articulatory suppression) also impair the acquisition of nonwords. Third, polyglot subjects have a higher auditory–verbal span compared to nonpolyglots and a better ability to learn novel words (Fig. 12). This advantage of polyglots in nonword learning is not related to differences in general intelligence and long-term verbal or spatial memory, and it likely reflects a greater capacity and superior function of phonological short-term memory. This system may be considered as a learning device for the acquisition of novel phonological representations and the building up of the phonological lexicon. Some observations in brain-damaged patients suggest a similar role for visuospatial short-term memory in the acquisition of new visual information, such as unfamiliar faces and objects. The relevant evidence is much more limited, however.

B. Language Processing

1. Sentence Comprehension

The general idea that temporary retention in phonological memory may contribute to aspects of speech comprehension is far from novel, dating back at least to the 1960s. Phonological memory may hold incoming auditory–verbal strings while syntactic and lexical–semantic analyses are performed. Patients with defective phonological memory exhibit preserved comprehension of individual words and many sentential materials and also a normal ability to decide whether or not sentences are grammatically correct. This may reflect the operation of on-line lexical–semantic processes, heuristics, and pragmatics with a complete independence of syntactic and lexical–semantic processes from phonological memory. However, patients are impaired with complex sentences, where complexity refers to a number of non-mutually exclusive factors, such as (i) a high rate of presentation of the material, which prevents the immediate building up of an unambiguous cognitive representation; (ii) word order conveying information crucial for meaning (e.g., in sentences in which a semantic anomaly is introduced by a change in the linear arrangement of words: ''The world divides the equator into two hemispheres, the southern and the northern''); and (iii) extralinguistic presuppositions biasing the interpretation of the spoken message. Under conditions of this sort an adequate interpretation may require backtracking to the verbatim (phonological) representation of the sentence temporarily held in phonological memory. This may provide a ''backup'' or ''mnemonic window'' resource for performing supplementary cognitive operations necessary for comprehension.

2. Speech Production

In spontaneous speech some errors involve the sequential misplacement of consonant or vowels (phonemic Spoonerism, e.g., ''You have *m*issed all my *h*istory lectures'' → ''You have *h*issed all my *m*istery lectures''). This type of error provides evidence that parts of speech several words in length are planned in advance and stored in a phonological format before actual articulation. The short-term retention system (phonological output buffer or phonological assembly system) in which such errors are generated may be conceived as a working memory space, in which phonological segments are temporarily stored prior to the application of various output processes, such as planning and editing of the articulatory procedures needed to produce speech. In addition, this output retention system, participates in the process of rehearsing material held in the phonological short-term input store (Fig. 5). Seen in this perspective, rehearsal is an activity that makes use of components primarily concerned with a basic linguistic function—speech production. Finally, the phonological output buffer provides a working memory space where operations such as segmentation and deletion may be performed. These may support phonological skills involving a comparison between segments of pairs of stimuli (e.g., rhyme judgments).

C. Spatial Orientation and Navigation

Spatial orientation and navigation in three-dimensional space are complex human skills that require, among other things, keeping track of the current position of the body with reference to previous locations in the environment. A spatial short-term memory system is likely to be involved in the retention of the successive body displacements occuring during navigation. Such a system is likely to integrate multiple sensory inputs (visual, proprioceptive–somatosensory, vestibular, and auditory) and to interact with relevant spatial information stored in long-term memory. These spatial memory systems likely make use of multiple reference frames along the egocentric–allocentric dimension.

V. CONCLUSIONS

Behavioral observations and neuroanatomical evidence from normal subjects and brain-injured patients suggest that short-term memory should be conceived as a multiple-component system with specific functional properties and discrete neural correlates. Current evidence suggests the existence of phonological, spatial, and visual short-term memory systems, each including storage and rehearsal components. These systems secure retention of a limited amount of material in the time range of seconds and contribute to relevant aspects of cognition, such as long-term learning. Specifically, the phonological short-term memory system is closely related to a number of aspects of language: Vocabulary acquisition, speech production, and sentence comprehension.

Sleep Disorders

CLETE A. KUSHIDA
Stanford University School of Medicine

GLOSSARY

actigraphy Method of estimating sleep–wake patterns by activity/movement-sensitive devices, usually placed on the wrist.

apnea Cessation of airflow lasting at least 10 sec associated with a decrease in blood oxygen saturation.

continuous positive airway pressure A device consisting of a mask, usually placed over the nose, connected via a hose to a pump, which draws in room air and gently pushes the air into the patient's airway to prevent it from collapsing during sleep.

hypopnea Decrease, but not complete cessation, of airflow lasting at least 10 sec and typically associated with a decrease in blood oxygen saturation.

non-REM sleep Comprises the majority of a night's sleep and is divided into four stages based on electroencephalograph (EEG) frequency, amplitude, and specific EEG waveforms.

polysomnogram or sleep study A test consisting of assessment of breathing, heart rate, snoring intesity, and activity of the brain, eyes, and chin and leg muscle activity.

REM sleep A type of sleep in which the majority of dreams occur, the EEG patterns are similar to those of wakefulness, and most of the muscles under voluntary control are paralyzed.

sleep latency Time to onset of sleep after the lights are turned off in the bedroom.

slow-wave sleep Deep sleep, also called non-REM stages 3 and 4 sleep, during which time the brain electrical activity is characterized by high-amplitude, low-frequency waveforms.

Sleep disorders are highly prevalent but are largely unrecognized, misdiagnosed, and untreated. The *International Classification of Sleep Disorders, Revised: Diagnostic and Coding Manual* by the American Sleep Disorders Association classifies sleep disorders into four broad categories: (i) The dyssomnias are disorders of either difficulty initiating or maintaining sleep or excessive daytime sleepiness; (ii) the parasomnias are disorders that encroach into the sleep process; (iii) sleep disorders associated with mental, neurologic, or other medical disorders; and (iv) proposed sleep disorders, in which insufficient data are available to confirm the existence of these disorders. Based on this classification system, there are currently 77 recognized sleep disorders and 11 proposed sleep disorders. This article describes these sleep disorders and identifies key elements of the history, physical examination, and diagnostic evaluation for the patient presenting with a sleep complaint.

I. EVALUATION OF A PATIENT PRESENTING WITH A SLEEP COMPLAINT

A. Sleep History

A thorough sleep history is important to assess the patient's chief complaint and to derive a differential diagnosis. Typical questions useful to a clinician evaluating a patient with a sleep problem are listed in Table I. The disorders described later are recognized sleep disorders from the *International Classification of Sleep Disorders*. Although the majority of patients with sleep problems typically present with dyssomnia complaints, it is not unusual for a given patient to have more than one type of sleep disorder.

An interview with the bed partner at the same time as the patient is important; the partner can frequently provide important symptoms about which the patient is not aware. For example, the bed partner can report

Table I
Typical Sleep History Questions[a]

- Bedtime and awakening times; is this schedule consistent during the week? (Consider circadian rhythm disorders)
- Works a nighttime or rotating shift? (Consider circadian rhythm disorders)
- Uses medications to fall asleep or stay awake? (Consider insomnias and hypnotic- or stimulant-dependent sleep disorders)
- Time to fall asleep after lights turned out? (Consider insomnias vs disorders with excessive daytime sleepiness)
- Number of awakenings during the night, cause (if known), and time to fall back asleep? (consider dyssomnias)
- Feels refreshed in the morning? (Consider disorders with excessive daytime sleepiness)
- Number of naps per week; timing and duration of naps? (Consider disorders with excessive daytime sleepiness)
- Amount, timing, and frequency of caffeinated beverages? (Consider disorders with excessive daytime sleepiness)
- Falls asleep inappropriately during the day or while driving? (Consider disorders with excessive daytime sleepiness)
- Snoring, witnessed breathing pauses, or awaking with gasping, gagging, choking, snorting, or dyspnea? (Consider obstructive sleep apnea syndrome)
- Frequent difficulty falling asleep or staying asleep? (Consider insomnias vs disorders with excessive daytime sleepiness)
- Unusual sensations in the legs that are relieved by movement? (Consider restless legs syndrome)
- Leg twitching or kicking during the night? (Consider periodic limb movement disorder)
- Unusual movements or walking during sleep? (Consider parasomnias)
- Any limb movements associated with dreams? (Consider REM sleep behavior disorder)
- Unable to move during the transition from sleep to wakefulness? (Consider narcolepsy)
- Auditory, visual, tactile, or kinetic hallucinations at sleep onset? (Consider narcolepsy)
- Episodes of sudden muscle weakness precipitated by strong emotion? (Consider narcolepsy)

[a]This is not intended to be a comprehensive screening questionnaire; however, some of these questions, in addition to a thorough clinical evaluation, may be useful in screening a patient for a specific sleep disorder.

that the patient has gasping or choking episodes during sleep, which would be characteristic of a sleep-related breathing disorder such as obstructive sleep apnea syndrome.

Children with sleep complaints deserve special mention. A higher prevalence of parasomnias, such as sleep terrors and sleepwalking, is found in children compared to adults, and children often do not manifest daytime sleepiness in the same manner as adults. For example, instead of appearing drowsy or sleepy, children may be hyperactive and irritable, even to the degree of being misdiagnosed as having attention-deficit hyperactivity disorder.

At the time of the initial evaluation, sleep specialists frequently use questionnaires, such as the Sleep Disorders Questionnaire by Douglass *et al*., to aid in the diagnosis of these disorders. The Stanford Sleepiness Scale (SSS) by Hoddes *et al.* and the Epworth Sleepiness Scale (ESS) by Johns have been used to assess the subjective level of daytime sleepiness, although there has been criticism that these scales do not correlate well with objective measures of daytime sleepiness. Daily sleep logs are helpful in documenting subjective sleep–wake patterns. These logs are frequently useful for the clinician in evaluating patients suspected of having irregular sleep–wake schedules or circadian rhythm disorders. The logs are typically 2-week sleep diaries in which the patients record their bedtime and awakening times, estimated sleep-onset time, time and duration of nocturnal awakenings and daytime naps, and time of medication use. Lastly, quality of life questionnaires have been used to assess the impact of treatment of sleep disorders.

1. Dyssomnias

a. Insomnias Patients with insomnia have difficulty initiating and maintaining sleep, characterized by difficulty falling asleep and frequent awakenings; they also typically suffer from chronic fatigue and tiredness, irritability, and concentration and memory impairment. Patients who have inadvertently conditioned themselves to have difficulty falling or staying asleep in their normal bedroom environment indicate a diagnosis of psychophysiological insomnia. A lifelong history of insomnia, typically starting in childhood, characterizes idiopathic insomnia. Insomnia in relation to a significant stress event, such as divorce or death of a parent, typifies adjustment sleep disorder. Patients with poor sleep habits may suffer from inadequate sleep hygiene, and sleep state misperception, in which the patient's sleep complaints do not accurately reflect objective measures of sleep, is commonly found in insomniacs. Insomnia due to elevations above 4000 m and sleep disturbances due to

environmental factors are hallmarks of altitude insomnia and environmental sleep disorder, respectively. Lastly, insomnia found in children may be characteristic of limit-setting sleep disorder (unenforced bedtimes), sleep-onset association disorder (the absence of certain conditions, e.g., watching television), food allergy insomnia, or nocturnal eating (drinking) syndrome.

The completion of daily sleep diaries may be useful in detecting the sleep–wake patterns of insomniacs; it is particularly beneficial in demonstrating poor sleep habits indicative of inadequate sleep hygiene as well as circadian rhythm disorders coexisting with insomnia. Actigraphy, the use of movement-sensitive devices to assess sleep–wake cycles, may be beneficial in screening for sleep state misperception and circadian rhythm disorders in insomniacs. However, an unknown number of insomniacs may remain in bed without moving or restlessness; this behavior may incorrectly register as sleep by actigraphy since it may be below the movement threshold of the actigraphic device for recognition of wakefulness. The coexistence of psychiatric conditions, such as depression or anxiety disorders, as well as circadian rhythm disorders should be screened for in all patients presenting with insomnia since the proper identification and treatment of these conditions usually hastens the patient's recovery from insomnia.

The mainstay of insomnia treatment is implementation of behavioral techniques. These include the adoption of a strict sleep–wake schedule of regular bedtimes and awakening times coupled with the avoidance of naps. Patients should avoid remaining in bed for extended periods of time while awake since this may result in the patients being conditioned to being awake in their bedroom environment. Decreased caffeine, nicotine, and alcohol use, especially prior to bedtime, and limiting heavy exercise, meals, and fluid intake near bedtime frequently aid in reducing the time to fall asleep as well as the frequency and duration of nocturnal awakening. Avoidance of reading and watching television in bed, unless these activities result in drowsiness, may also help initiate sleep. Other specific behavioral approaches, such as stimulus control therapy, sleep restriction, and relaxation therapy, can be beneficial. Stimulus control therapy involves reassociating the bedroom environment with rapid sleep onset. Sleep restriction is the programmed reduction in the duration of time spent in bed, with the goal of increasing sleep efficiency (time spent asleep/time in bed). Relaxation therapy includes meditation, self-hypnosis, progressive muscle relaxation, and electromyographic biofeedback. Lastly, a mild hypnotic medication with a short elimination half-life (e.g., zolpidem) may be used as a supplement to behavioral therapy in intractable cases of insomnia.

b. Disorders with Excessive Daytime Sleepiness Patients with excessive daytime sleepiness have decreased cognitive functioning during the day as well as frequent periods of falling asleep at inappropriate times, such as during meetings or while driving. Although patients with the following disorders may present with insomnia, the more typical presentation is that of excessive daytime sleepiness.

Daytime sleepiness combined with a history of witnessed nocturnal breathing pauses or awaking with gasping, gagging, choking, snorting, or dyspnea characterize the obstructive sleep apnea syndrome. Based on epidemiology studies by Terry Young and colleagues in 1993, it is estimated that up to one-fourth of men and one-tenth of women between the ages of 30 and 60 years have polysomnographic evidence of this condition. Besides placing the patient at greater risk for motor vehicle and work-related accidents, this disorder is associated with cardiovascular conditions such as hypertension, stroke, myocardial infarction, dysrhythmias, and cardiac failure as well as neurocognitive problems such as decreased short-term memory. The diagnosis of obstructive sleep apnea syndrome is confirmed by a sleep study (Fig. 1), which reveals the repetitive abnormal breathing events (apneas and hypopneas) characteristic of this disorder. Treatment consists of weight loss, cervical positioning devices, oral appliances (devices that move the tongue or mandible anteriorly), nasal continuous positive airway pressure (CPAP), or upper airway surgery. The upper airway surgery may involve a uvulopalatopharyngoplasty (i.e., removing redundant tissue from the soft palate and tonsillar pillars), mandibular osteotomy with genioglossus advancement (moving the tongue base anteriorly), and a hyoid myotomy (stabilizing the tongue muscles). Newer technologies such as radiofrequency surgery may offer patients a near painless, rapid, outpatient procedure for reducing snoring and obstructive sleep apnea. Seasonal allergic rhinitis and significant nasal obstruction (e.g., nasal polyps and adenoidal hypertrophy) may worsen the patient's obstructive sleep apnea syndrome; the patient may need antihistamines, nasal steroids, or corrective surgery to alleviate these conditions. The upper airway resistance syndrome is a mild variant of obstructive sleep apnea syndrome; this disorder is characterized by excessive daytime sleepiness resulting from frequent

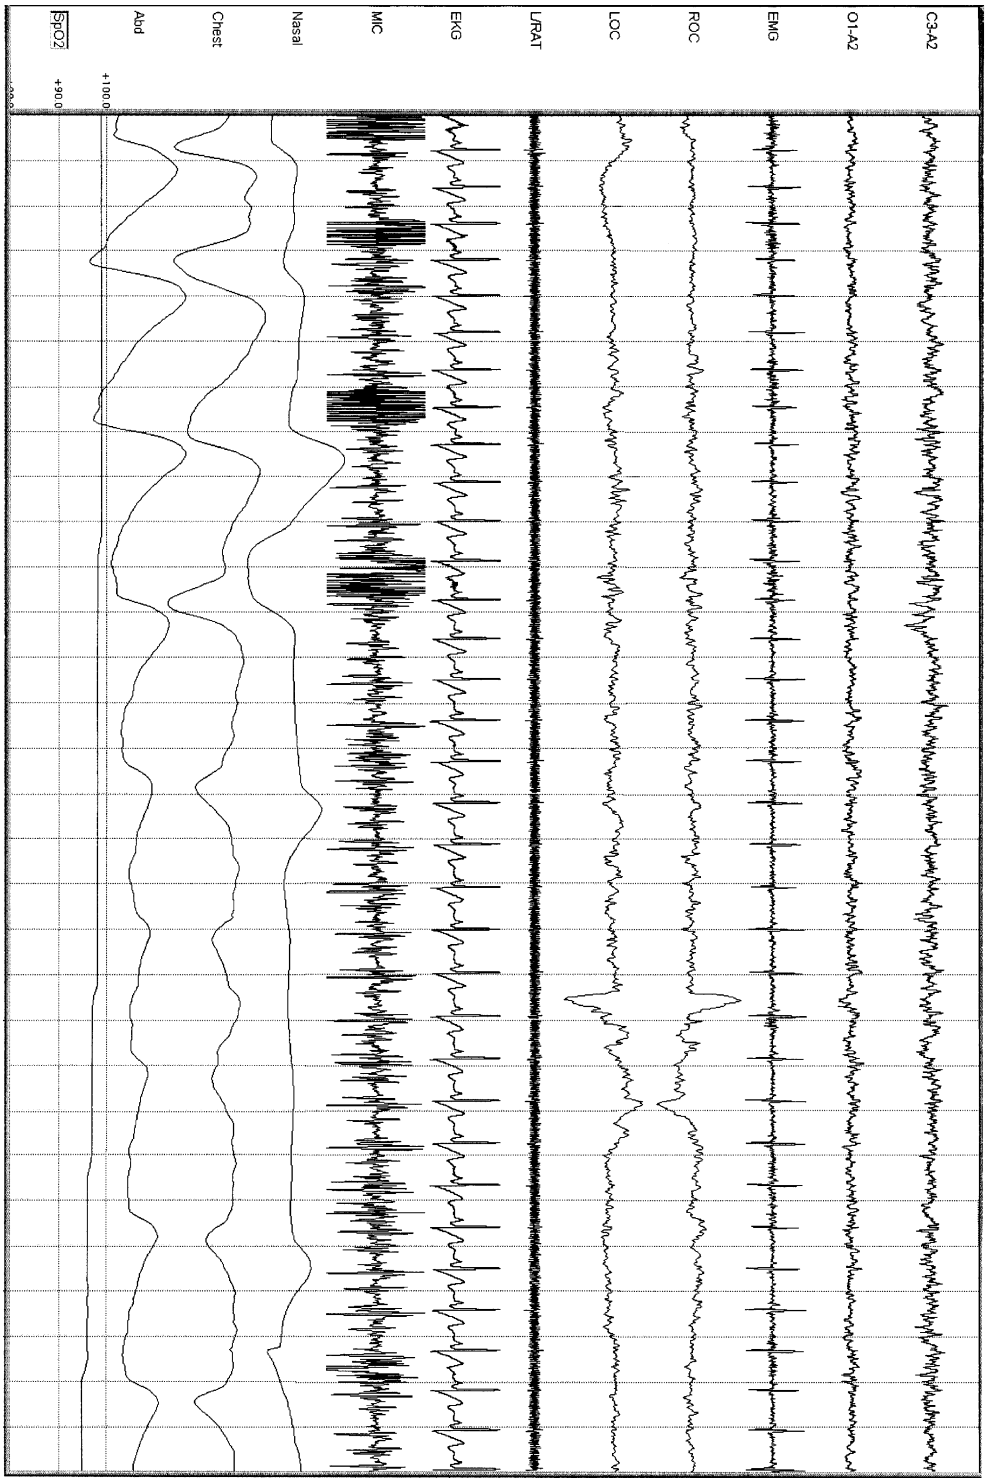

Figure 1 Polysomnographic recording for a patient with obstructive sleep apnea syndrome. This represents a 30-sec period of a polysomnogram. The patient is in REM sleep, as evidenced by the EEG (C3-A2 and O1-A2 electrode derivations) with a low-amplitude, mixed frequency pattern; the EMG (EMG representing chin muscle activity, and L/RAT representing left and right anterior tibialis leg muscle activity) with relatively suppressed muscle activity; and the EOG (ROC and LOC representing right and left eye muscle activity, respectively) with rapid eye movements. Snoring is evidenced in the MIC (microphone) channel. An obstructive apnea is apparent in the right half of the figure, with a cessation of nasal airflow despite chest and abdominal wall movement. As a consequence of this apnea, the SpO_2 (oxygen saturation) decreases from approximately 99 to 95% by the right edge of the figure.

arousals that, in turn, are a consequence of increased work of breathing (detected by esophageal pressure monitoring). Patients with the rarer central sleep apnea syndrome or central alveolar hypoventilation syndrome may present with complaints or a history similar to those of obstructive sleep apnea syndrome. CPAP or bilevel pressure (increased pressure during inspiration and decreased pressure during expiration) may similarly help patients with these conditions.

Narcolepsy is a sleep disorder estimated to affect approximately 200,000 Americans, and there appears to be a genetic predisposition for the development of this condition. This disorder commonly occurs in the second decade of life with an equal distribution in men and women. Narcolepsy is suspected in individuals with the following symptoms: (i) attacks of daytime sleepiness, which typically appear suddenly and irresistibly throughout the day; (ii) cataplexy, or the sudden loss of postural muscle tone typically precipitated by strong emotion (subtle cases of cataplexy may involve only slight weakness of the neck muscles); (iii) hypnagogic (sleep-onset) hallucinations, which may be fleeting sounds (e.g., voices), visions, or full-blown auditory, visual, tactile, or kinetic hallucinations; and (iv) sleep paralysis (which may occur in individuals without narcolepsy), that occurs at the transition from sleep to wakefulness. This paralysis may frequently accompany the hypnagogic hallucinations. The diagnosis of narcolepsy is established by symptoms and confirmed by the multiple sleep latency test. This disorder is typically treated by scheduled naps, stimulants (e.g., methylphenidate, modafinil, and dexedrine) to ward off daytime sleepiness, and anticataplectic medications (typically tricyclic antidepressants).

Daytime sleepiness combined with hypersomnia (prolonged sleep periods) characterize idiopathic, recurrent, and posttraumatic hypersomnia. These disorders may be differentiated from narcolepsy and other disorders of excessive daytime sleepiness by symptoms, polysomnography, and multiple sleep latency tests. Treatment typically consists of scheduled naps and stimulant medication in order to control the irresistible sleepiness throughout the day. Lastly, daytime sleepiness with evidence of voluntary sleep deprivation suggests insufficient sleep syndrome; lifestyle modification to reduce work or family commitments may be necessary to increase the patient's sleep requirements.

c. Restless Legs Syndrome and Periodic Limb Movement Disorder Restless legs syndrome is characterized by dysesthesias or unpleasant sensations in the legs that result in an irresistible urge to move the legs. The dysesthesias may be described as a "creeping," "crawling," "itching," or pain and are relieved by movement. Although these symptoms can occur anytime throughout the day, they may worsen at night, thus interfering with the ability to initiate sleep and ultimately resulting in insomnia symptoms or daytime sleepiness. It commonly occurs in middle age, affects equally both men and women, and pregnant women and individuals with uremia and rheumatoid arthritis appear susceptible to developing this disorder. The diagnosis is typically made by history, although a sleep study will frequently detect the limb movements resulting from the dysesthesias. First-line treatment consists of dopaminergic agents (e.g., carbidopa and levodopa); benzodiazepines (e.g., clonazepam), opiates, and anticonvulsants (e.g., tegretol and gabapentin) have variable effectiveness in treating this disorder.

Periodic limb movement disorder is characterized by daytime sleepiness resulting from repetitive limb movements during sleep. The leg movements are typically stereotyped, with extension of the big toe and partial flexion of the ankle, knee, and hip. Although peak onset of this disorder is in middle age, the incidence increases with age. Patients suspected of having this disorder are evaluated by polysomnography, and specific polysomnographic criteria for the frequency and duration of individual limb movements have to be met for confirmation of the diagnosis. The clinical decision to treat this disorder is usually made by the severity of the symptoms and frequency of the periodic limb movements associated with arousals. Treatment consists of the same medications used to treat restless legs syndrome; as in restless legs syndrome, dopaminergic agents remain first-line therapy for periodic limb movement disorder.

d. Circadian Rhythm Disorders Circadian rhythm disorders should be considered in patients who have an unusual sleep–wake pattern, and these patients may present with either insomnia or excessive daytime sleepiness. Time zone change (jet-lag) syndrome and shift work sleep disorder are characterized by the effect of external factors on the patient's sleep. These disorders are usually easy to diagnose by patient history; strict application of sleep hygiene recommendations and, if needed, a short-acting hypnotic medication (e.g., zolpidem) may be beneficial in helping these patients. Delayed or advanced sleep-phase syndromes correspond to disorders of the timing

of the sleep period, in which there is either a chronic delay or advance, respectively, in the major sleep period with respect to the desired bedtime and awakening time. For example, an individual with delayed sleep-phase syndrome may desire to sleep at 10 PM and awaken at 6 AM but finds that he or she usually becomes sleepy at 2 AM and spontaneously awakens at 10 AM on a chronic basis. These disorders are frequently recognized by careful history taking; sleep logs and actigraphy may be useful in establishing the diagnosis. Treatment consists of behavioral conditioning techniques such as stimulus control therapy and relaxation therapy, and a mild hypnotic medication may be necessary to initiate sleep at the desired bedtime. Irregular sleep–wake pattern and non-24-hr sleep–wake disorder are characterized by a disorganized and a progressively delayed sleep–wake pattern, respectively. These disorders also rely on careful history taking, sleep logs, and actigraphy to establish the diagnosis. The prognosis for these latter disorders is poor, often relying on major lifestyle accommodations (e.g., adapting the work schedule to fit the wake–sleep schedule) in addition to the behavioral and pharmacologic treatment, described previously used to treat other circadian rhythm disorders.

e. Disorders Associated with Exposure to Toxins, Substances, or Drugs Exposure to substances or toxins (e.g., organic chemicals and heavy metals) can produce insomnia or excessive daytime sleepiness. The toxin-induced sleep disorder and hypnotic-, stimulant-, and alcohol-dependent sleep disorders are characterized by sleep complaints arising from the use or withdrawal of these compounds. In particular, hypnotic and stimulant disorders frequently coexist with other sleep disorders. It is not uncommon to find patients with insomnia who have abused various hypnotics for many years and to find narcoleptics or patients with obstructive sleep apnea syndrome who have abused stimulants in order to maintain daytime alertness. Patients with alcohol-dependent sleep disorder often find that their time to sleep onset is reduced; however, the frequency and duration of nocturnal awakenings increase.

2. Parasomnias

Unusual behaviors, sensations, or movements are characteristic of parasomnias. Since the patient is often unaware of these abnormal episodes, the patient's bed partner is often more helpful in describing these events.

a. Sleep Terrors and Sleepwalking Sleep terrors and sleepwalking (somnambulism) occur during slow-wave sleep typically during the first third of the night and are characterized by screaming and ambulating, respectively, in addition to amnesia for the episodes. The individual with sleep terrors will frequently awaken screaming and confused, unresponsive to the environment and intensely fearful, with dilated pupils and rapid respiratory and heart rate. These disorders are thought to be related, and it is not uncommon for individuals to have both of these conditions. Typically, the incidence of these disorders is between 1 and 15% of the general population, and it is estimated that 15–30% of healthy children have had at least one episode of sleepwalking. Both disorders are thought to be familial, with a peak age of onset of approximately 4–8 years, and above the age of 15 years the incidence of sleepwalking and sleep terrors is about 1%. The etiology of sleep terrors and sleepwalking is unknown, but certain factors, such as antipsychotic or antidepressant medications, fever, sleep deprivation, and other sleep disorders that fragment sleep, increase the probability of these episodes in susceptible individuals. In the case of sleepwalking, sleep-related violence, such as assault or homicide, may occur; the legal system classifies true sleepwalking as a "noninsane automatism," in which the behavior is not under volitional control. The diagnosis is established by clinical history and polysomnography, although the chance of witnessing sleep terrors or sleepwalking episodes in the sleep laboratory is slim. However, polysomnography is important to exclude nocturnal seizures, which mimic sleepwalking, and certain polysomnographic features, such as repetitive arousals out of slow-wave sleep, frequent sleep stage shifts, and hypersynchronous delta activity, are often found in sleepwalkers. Nocturnal safety precautions (e.g., removal of nearby weapons or dangerous objects, alerting house guests, and assigning the sleepwalker to a ground floor bedroom) and treatment by medications (benzodiazepines and tricylic antidepressants), and occasionally hypnosis and psychotherapy, may control these conditions.

b. Other Parasomnias REM sleep behavior disorder is a condition that may be confused with sleepwalking. However, individuals with this disorder are typically men older than the age of 60 years and they frequently "act out" their dreams during REM sleep (as opposed to sleepwalking, which occurs during slow-wave sleep, typically without dream mentation). The etiology of the majority of cases is unknown,

although vascular, degenerative, and neoplastic conditions affecting the brain may be associated with this condition. The diagnosis is established by history and polysomnography, and nocturnal safety precautions combined with medications (clonazepam and desipramine) are usually effective in decreasing the frequency of this condition.

Rhythmic movement disorder is a disorder of infancy or early childhood and is characterized by repetitive movements, typically of the head and neck, that occur prior to sleep onset and in the transition to sleep. Typical movements are repeated banging of the head on the sleep surface, rolling of the head, or rocking of the torso or entire body; polysomnography can be useful in distinguishing this condition from epilepsy. Nocturnal safety precautions combined with behavior modification and benzodiazepine or tricyclic medications may be useful in controlling this condition.

The following parasomnias are specific phenomena witnessed by the patient, bed partner, or parent and, as with other parasomnias, can often be confirmed with a sleep study. Sleep-related abnormal swallowing syndrome is a rare condition characterized by awaking with coughing or choking from sleep as a result of aspirated saliva, which in turn may be due to deficient swallowing. Nocturnal paroxysmal dystonia manifests as stereotyped, repetitive dystonic or dyskinetic episodes lasting up to 1 hr per episode, with a possible familial pattern but without identifiable pathology. Anticonvulsants such as carbamazepine may be helpful in patients with this condition. Sudden unexplained nocturnal death syndrome is the occurrence of sudden death during sleep, particularly in healthy young Southeast Asian men. Abnormal respiratory symptoms such as gasping or choking may precede the cardiorespiratory arrest, although postmortem examinations have failed to reveal significant pathology in the victims. REM sleep-related sinus arrest is characterized by repeated periods of asystole during REM sleep in otherwise healthy, typically young adults. No significant cardiac pathology has been identified in these cases, and polysomnography is essential in documenting this phenomenon. Impaired sleep-related penile erections (organic/physiologic impotence or the failure to sustain erections during sleep) and sleep-related painful erections are most frequently found in patients older than age 40, and in the case of impaired sleep-related penile erections, polysomnography is critical in evaluating this condition.

A few parasomnias are observed during infancy. Infant sleep apnea is characterized by central or obstructive apneas occurring during sleep in infants; apnea of prematurity afflicts infants younger than 37 weeks of gestation, apnea of infancy afflicts infants older than 37 weeks, apparent life-threatening event associated with an apnea is typically accompanied by cyanosis and limpness, and obstructive sleep apnea syndrome involves repetitive upper airway obstruction. Polysomnography is essential to the diagnosis of these conditions, and continuous positive airway pressure or upper airway surgery may be necessary to treat these infants. Congenital central hypoventilation syndrome, or failure of the control mechanisms of breathing, is a rare condition affecting otherwise normal-appearing infants without identifiable lung disease and may require nocturnal or 24-hr ventilatory support. Benign neonatal sleep myoclonus is a rare, self-limited, and benign condition without identifiable pathology, usually involving the arms and legs and consisting of frequent jerking movements during sleep in neonates. Sudden infant death syndrome (SIDS) is characterized by unexplained death in infants, usually while asleep. It is estimated to occur in less than 1 of every 1000 live births, and factors such as sleeping prone, preterm birth, multiple births, affected siblings, maternal drug abuse, tobacco smoke exposure, lower socioeconomic status, and prior history of apneic events increase the risk for occurrence of SIDS.

Sleep paralysis (at sleep onset or upon awakening), confusional arousals (brief periods of disorientation following arousals from sleep), sleep talking, sleep starts (sudden contractions of the body at sleep onset), nocturnal leg cramps, nightmares, bruxism (teeth grinding), enuresis (bedwetting), and primary snoring are typically more nuisances rather than clinically significant problems, unless the episodes are frequent, severe, and/or disruptive to the patient or bed partner's sleep.

B. Past Medical History

Significant medical, neurologic, and psychiatric problems must be thoroughly evaluated, since these conditions typically adversely affect sleep. Medical problems such as nocturnal asthma, chronic obstructive pulmonary disease, cardiac ischemia, and peptic ulcer disease disturb sleep; neurologic conditions such as Parkinson's disease and other dementing illnesses, neuropathies, degenerative arthritis of the spine and joints, seizure disorders, and migraine headaches similarly disrupt sleep. Although behavioral and pharmacologic treatments, may be beneficial in

reducing the symptoms of these conditions, close monitoring and treatment of the patient's underlying medical problem by the patient's internist often helps the patient's sleep. Pierre Robin, Treacher Collins, hypothyroidism, Cushing's syndrome, acromegaly, and Marfans syndrome are disorders that have been associated with obstructive sleep apnea syndrome. In the case of Pierre Robin and Treacher Collins, corrective surgery by maxillofacial and oral surgeons may be necessary to correct the craniofacial abnormalities predisposing the patient to obstructive sleep apnea syndrome. A history of surgery to remove lower teeth (indicating a small mandible), tonsillectomy and adenoidectomy, nasal septoplasty, jaw reconstruction, cleft palate repair, or bariatric surgery (for weight loss) are important factors to note for the patient suspected of having obstructive sleep apnea syndrome. Closed-head injury may result in hypersomnia or, rarely, narcolepsy. A history of uremia or low iron stores are significant in a patient with suspected restless legs syndrome or periodic limb movement disorder; awareness and treatment of these predisposing factors may improve the latter two sleep disorders.

Depression and bipolar disorder are frequently associated with patients who present with excessive daytime sleepiness or insomnia; a patient with seasonal affective disorder may frequently experience an increased need for sleep and a significant delay in morning awakening times. Patients with a diagnosis of posttraumatic stress disorder, or who have experienced significant trauma, abuse, or stress in the past, may suffer from lifelong insomnia. Anxiety, panic, and psychotic disorders can severely impair sleep and result in insomnia. A team approach by the sleep specialist and psychologist or psychiatrist to effectively manage the patient's sleep disorder and coexisting psychiatric problem is frequently beneficial for the patient.

Frequently, patients with insomnia have tried a variety of nonprescription and prescription hypnotics; as discussed previously, a diagnosis of hypnotic-dependent sleep disorder is common among this patient population. It is also not uncommon for these patients to abuse stimulants, ranging from over-the-counter appetite suppressants to prescribed stimulants such as pemoline, methylphenidate, and amphetamine, in order to counter their daytime fatigue. Patients with disorders with excessive daytime sleepiness (e.g., obstructive sleep apnea syndrome and periodic limb movement disorder) may also abuse these stimulants. Medications such as those used to treat asthma and chronic obstructive pulmonary disease may independently disrupt sleep, particularly the xanthine derivatives such as theophylline. It is important to evaluate all medications and substances the patient is currently using; for example, cough medication may contain alcohol, which can fragment sleep, and herbal preparations may contain sleep-promoting substances such as melatonin.

C. Family History

There are several sleep disorders in which familial or genetic influences have been proposed. Genetic markers for narcolepsy have been identified. HLA DQB1-0602 is the most specific HLA marker associated with narcolepsy across all ethnic groups; however, this haplotype is neither sufficient nor necessary for the diagnosis of narcolepsy. There is also evidence that restless legs syndrome, periodic limb movement disorder, enuresis, sleep terrors, sleepwalking, snoring, and obstructive sleep apnea syndrome may be subject to familial influences. Thus, patients with one or both parents or siblings afflicted with these conditions may be at a greater risk for developing these disorders compared to individuals without a family history of these conditions. Physician awareness of the family history of the patient with respect to sleep disorders may help to reduce the differential diagnosis of the patient and may be helpful in special cases (e.g., if a patient being evaluated for restless legs syndrome has a son with insomnia, it would be prudent to evaluate the son for possible restless legs syndrome as well).

D. Social History

The impact of the patient's sleep problems on his or her life must be thoroughly assessed. In the case of children, school performance is frequently affected by disorders of excessive daytime sleepiness; school-authorized naps and stimulant administration during school hours may be necessary. The adult patient with excessive daytime sleepiness or a shift work sleep disorder, for example, may be on probation at work or disability. It may be necessary to become a patient advocate in the these situations, particularly when the patient's school or work performance is severely affected by the sleep disorder. Additionally, a strain on the patient's marriage may be the result of the patient's loud, disrupted snoring or decreased libido as a consequence of obstructive sleep apnea syndrome. However, if the patient is at risk for drowsiness while driving or operating heavy machinery, it is prudent to expedite the diagnosis and treatment of the underlying

sleep disorders. In cases in which the patient already has a history of falling asleep at the wheel or is at great risk for harming himself or herself as well as others while driving, the physician should notify the state public health department, which in turn will notify the state department of motor vehicles for consideration of suspension of the patient's driver's license until the patient's daytime sleepiness is effectively treated.

Heavy caffeine use can result in difficulty initiating and maintaining sleep. A patient may also use caffeine to mask excessive daytime sleepiness from other causes, such as obstructive sleep apnea syndrome. Heavy tobacco use may result in chronic obstructive pulmonary disease, which in turn may result in nocturnal awakenings due to coughing or dyspnea. Nicotine, as a stimulant, may also result in episodes of insomnia. Alcohol use frequently results in shortened, disrupted, and nonrefreshing sleep. In a patient with sleep-disordered breathing, alcohol can worsen the abnormal respiratory events, resulting in a vicious cycle in which the patient has progressively disrupted sleep and daytime sleepiness. Use of illicit stimulants, hallucinogens, and hypnotics can greatly influence sleep; chronic usage of one or more of these classes of drugs frequently results in chronic insomnia.

E. Review of Systems

A complete system review will frequently provide evidence that implicates medical problems as an underlying source of the patient's sleep disorder or may provide additional symptoms that can aid the clinician in arriving at a sleep diagnosis. Significant nasal congestion and obstruction during allergy season and recent weight gain or increased neck circumference can place the patient at risk for obstructive sleep apnea syndrome. Complaints of obstructive apneas in addition to lethargy, constipation, cold intolerance, muscle cramps and stiffness, menorrhagia, intellectual and motor activity decline, poor appetite, weight gain, dry skin, and hair loss would indicate a diagnosis of hypothyroidism. In this situation, confirmatory laboratory tests are important since the patient's sleep apnea may well resolve with thyroid supplements. Respiratory (dyspnea and wheezing) and cardiac (palpitations, angina, and nocturnal paroxysmal dyspnea) symptoms typically result in nocturnal awakenings and may suggest an undiagnosed case of obstructive sleep apnea syndrome. Gastroesophageal reflux disease, in addition to being an associated symptom of obstructive sleep apnea syndrome, may independently produce nocturnal awakenings from choking or gagging episodes at night. Pain due to conditions such as sciatica, lumbar strain, or disk disease may disrupt sleep. Sensitivity of teeth to cold or frequent temporomandibular joint pain upon awakening may indicate bruxism, which may fragment the patient's sleep. Pregnancy, uremia, and iron deficiency can be risk factors for restless legs syndrome and/or periodic limb movement disorder. Nocturia, frequently the result of benign prostatic hypertrophy or detrusor instability in the elderly, can produce nocturnal awakenings. However, nocturia can also be a common complaint of patients who awaken from sleep disorders such as obstructive sleep apnea syndrome or periodic limb movement disorder; these patients often mistakenly believe they awaken because of the urge to urinate rather than due to sleep-disordered breathing or leg movements.

F. Physical Examination

A complete and thorough physical examination is important in establishing a differential diagnosis or confirming a specific diagnosis. Measurement of the height and weight is important for determining the body mass index [BMI; weight (kg)/height (m^2)] described by Khosla; patients with a BMI higher than 25 are considered obese, although frame size and body fat percentages should be taken into consideration. This is important in the assessment of patients suspected of having obstructive sleep apnea syndrome, although it is estimated that 30–67% of patients with obstructive sleep apnea syndrome are obese. Pulse and respiration rate as well as blood pressure are important for assessing cardiopulmonary status and the impact of conditions such as sleep-related breathing disorders on the cardiac and respiratory systems.

Examination of the head is critical for evaluation of sleep-related breathing disorders. Craniofacial abnormalities, specifically a narrow, posteriorly displaced mandible and a high, arched soft palate, are characteristic of obstructive sleep apnea syndrome. In fact, a morphometric model recently developed by Kushida and colleagues enables the prediction of obstructive sleep apnea syndrome based on measurements of these typical craniofacial features. Hypertrophied adenotonsillar tissue, particularly in children, produces increased airway resistance, which in turn may result in sleep-related breathing disorders. Redundant, erythematous, and edematous peritonsillar

tissue, a long, thick uvula, and/or an obscured posterior wall of the pharynx by an elongated soft palate or an enlarged tongue are typically found in patients with snoring, obstructive sleep apnea syndrome, or upper airway resistance syndrome (a milder variant of obstructive sleep apnea syndrome). A deviated nasal septum and erythematous and edematous nasal mucosa may predispose the patient to developing sleep-disordered breathing; these conditions may also worsen an existing case of obstructive sleep apnea syndrome.

As described by Young and colleagues, a neck circumference more than 17 in. (43 cm) is associated with a higher likelihood of obstructive sleep apnea syndrome in habitual snorers, but it is by no means necessary nor sufficient for this diagnosis since the exact relationship of neck circumference to body weight is unknown and not all patients with obstructive sleep apnea syndrome are obese. Examination of the thyroid may enable the assessment of the goitrous variety of hypothyroidism, which may result in obstructive sleep apneas. Assessment of jugular venous pressure and pulses may provide additional information on the cardiovascular status of patients with suspected obstructive sleep apnea.

Examination of the chest and lungs by ascultation is important to detect wheezing and airflow limitation, which may be diagnostic of sleep-related asthma or chronic obstructive pulmonary disease, both of which result in nocturnal awakenings. A cardiac impulse that is increased in amplitude, prolonged in duration, and located at the third, fourth, or fifth interspace, and also subxiphoid, can be found in patients with right ventricular enlargement secondary to pulmonary hypertension, a late cardiac sequela of obstructive sleep apnea syndrome. A right-sided fourth heart sound and a pulmonic ejection sound best heard in the second and third left interspaces are also characteristic of right ventricular enlargement.

Abdominal examination may reveal hepatomegaly, suggestive of alcohol-dependent or toxin-induced sleep disorders. Focal or diffuse muscle tenderness may be indicative of fibromyalgia, which may produce chronic fatigue and nonrefreshing sleep. Degenerative joint disease, resulting in tenderness and inflammation of the joints as well as decreased range of motion, may result in disrupted sleep. A digital examination of the rectum may detect prostatic enlargement for a male patient who reports nocturia. In the case of a male patient who presents with a complaint of impotence, baseline measurement of the penile base and tip is important for comparison if the patient undergoes a nocturnal penile tumescence test, an important tool for distinguishing physiologic versus psychologic causes of impotence.

A mental status examination can assess short-term memory and attention, which are impaired in sleep-deprived subjects, such as those with sleep-disordered breathing or periodic limb movement disorder. An anxious, manic, or depressed mood state can assist in the diagnosis of an underlying psychiatric disorder affecting sleep. Speech and sensory changes may underlie chronic substance abuse. Alterations in coordination, muscle strength, and reflexes, in addition to mental status changes, may indicate a degenerative or dementing illness. Back pain and tenderness may be an important cause of insomnia; these symptoms combined with leg pain, paresthesias, and weakness may be indicative of a peripheral neuropathy, which may also awaken the patient at night. Focal neurologic deficits combined with a history of unusual movements at night may indicate a lesion or stroke resulting in nocturnal seizures.

G. Diagnostic Tests

Diagnostic tests are frequently useful in confirming the patient's preliminary diagnosis. Polysomnographic testing can be used to confirm the presence of a sleep disorder, particularly those that fragment sleep, such as obstructive sleep apnea syndrome, sleep terrors or sleepwalking, nocturnal epilepsy, or periodic limb movement disorder. This test can also be used to determine the severity of the condition by the frequency of occurrence of the abnormal events per recording night or per hour of recorded sleep. The subject is connected to electrodes that measure activity of the brain, eyes, heart, and chin and leg muscles in addition to snoring intensity, oronasal airflow, chest and abdominal impedance, and oxygen saturation throughout the night. Esophageal manometry is useful in measuring transmitted intrathoracic pressure or the work associated with breathing; these pressure measurements can aid in the diagnosis of mild sleep-related breathing disorders, such as upper airway resistance syndrome.

Assessment of the level of daytime sleepiness can be objectively measured by tests such as the multiple sleep latency test, in which a subject's tendency to fall asleep is assessed with polysomnography during five daytime naps lasting 20 min each, with naps separated by 2 hr. This test can also be used to confirm a diagnosis of narcolepsy, in which the mean sleep latency (average of

the time from lights out to sleep onset for the five naps) is in the pathologic range of sleepiness (less than 5 min) and REM sleep is present in two or more of the naps. A urine toxicology screen is obtained during the day of testing to detect any medications or substances that may influence the test results. A maintenance of wakefulness test uses the same equipment and schedule with the exception that the subject is sitting and instructed to resist sleep. Pupillography and continuous polygraphic monitoring are other methods that are less commonly used to assess daytime sleepiness, and vigilance tests such as the psychomotor vigilance task are used by some investigators.

Lastly, other tests used by sleep specialists to aid in the diagnosis of specific sleep disorders include pulmonary function tests, for patients with nocturnal asthma or chronic obstructive pulmonary disease; thyroid function tests for patients with obstructive sleep apnea and symptoms of hypothyroidism; renal function tests and ferritin levels, useful in identifying causes of restless legs syndrome; HLA typing, helpful in a diagnosis of narcolepsy, using markers such as HLA-DQB1-0602; actigraphy, or detection of activity typically by a wristwatch-like device, which is used in evaluating insomnia, misperception of sleep states, or circadian rhythm disorders; video monitoring and sleep-deprived electroencephalography to aid in the diagnosis of nocturnal seizures; and nocturnal penile tumescence test to distinguish between physiologic and psychologic impotence.

II. CONCLUSIONS

Sleep medicine is a relatively new subspecialty but has experienced steady growth in numbers of patients, physicians, and sleep centers. The number of recognized sleep disorders and the high prevalence of these disorders in the general population attest to the fact that the appropriate diagnosis and management of a patient presenting with a sleep complaint are far from trivial. Nevertheless, although a patient presenting with a sleep complaint is frequently a diagnostic challenge, successful evaluation and management of the sleep disorder, the majority of which are treatable, typically results in a dramatic improvement in the patient's quality of life.

Spatial Cognition

BARBARA LANDAU
Johns Hopkins University

GLOSSARY

dead reckoning A process by which small changes in position are summed as an animal moves through space, resulting in continual updating of the animal's representation of its current position.

neglect A neurological syndrome in which the patient ignores or fails to acknowledge the presence of stimuli in a region of space, usually contralateral to the site of the person's brain lesion.

reference system A set of orthogonal axes with a common origin, used to specify the location of some target. Examples include location in retina-centered, body-centered, and environment-centered reference systems.

Spatial cognition is the capacity to discover, mentally transform, and use spatial information about the world to achieve a variety of goals, including navigating through the world, identifying and acting on objects, talking about objects and events, and using explicit symbolic representations such as maps and diagrams to communicate about space. Although some functions of spatial cognition such as language and mapping use are exclusively human, other aspects of spatial cognition can be found in all mobile species. Growing evidence suggests that the multiple functions of spatial cognition in humans may be represented in specialized subsystems of the mind and brain. Such specialization raises important questions about how different subsystems interact with each other in order to support our capacity to act on and communicate about the spatial world. Furthermore, these issues raise important questions about how spatial cognition develops in young children (e.g., whether specialization is present from the earliest points of development and how the specialized subsystems come to interact with each other). This article discusses spatial cognition in the context of specialization, interaction, and development.

I. CENTRAL ISSUES AND CONCEPTS

Perhaps the most fundamental capacity of all mobile species is their negotiation of the spatial world. For nonhumans, the range of activities that engage some aspect of physical space includes locating and gathering food, searching for mates, reproducing and caring for young, and virtually all other activities fundamental to survival. Each of these requires that the animal obtain and store spatial information about the world that will be used at some later point to make predictions that will allow the animal to generate some new activity in space. The form of this spatial information in the mind and brain is referred to as a *spatial representation*. Spatial representations support our capacity to perceive, act upon, and think about space. Human spatial activities include the ones already discussed as well as many other functions that are species specific. Chief among these are the use of language and external physical representations of space (such as maps) to communicate about space.

A. Preliminary Arguments for Specialization and Interaction

The three-dimensional physical world in which we live serves as the stage on which the diverse set of spatial

activities is carried out. Because of this, each aspect of spatial cognition must map onto one and the same physical reality. However, the functional requirements of spatial activity differ considerably across domains, raising the question of whether spatial cognition draws on one monolithic set of spatial representations or on multiple separate representations that are specific to different domains. This article reviews growing evidence suggesting that specialized spatial representations underlie different kinds of spatial activities. For example, in order to identify an object, we must represent the parts of the object and their spatial relationships, and this spatial structure is invariant as observers and objects move through space. Thus, a representation that preserves the enduring shape of the object would be useful for object recognition. Such a representation of the object's enduring shape may also be useful for object naming; however, naming also requires that we group together under the same name objects that vary in their precise shape. Thus, the visual system might compute the shape of a particular dog in order for recognition to proceed, but the object name "dog" will be used as a cover term for many objects whose shape commonality is quite abstract because it must cover, for example, both Dalmatians and Pekinese dogs. In contrast with either object recognition or naming, the spatial system that supports our capacity to reach and grasp the object that we see might have quite different functional requirements: Depending on our current posture, and whether the object is moving, the spatial system guiding action will have to account not only for the object's enduring shape but also for its current disposition relative to the moving effectors of our body (hands, arms, torso, etc.). The different functional requirements of recognizing objects vs acting on them suggest the existence of separate representational systems dedicated to each (see Section II.B). Similarly, the different functional requirements of object recognition vs naming suggests only a partial mapping between these two systems. Navigating through space may have different constraints, and accordingly, some have suggested that it is guided by a highly specialized representational system (see Section II.A).

Thus, functionally different requirements may give rise to differences in the form of spatial information that is preserved by spatial systems across different domains, such as perception, action, and language. However, these differences must also be reconcilable: In order for us to recognize and name the objects we can reach or to talk about the spatial layout of an environment through which we have moved, there must be some connection or mapping among the different kinds of spatial representation. Such mapping among systems is necessary in order for the spatial systems to communicate with each other as information is passed between them.

Both specialization and interaction are fundamental aspects of human spatial cognition that emerge early and easily, with little formal tutoring. For example, infants learn to reach and grasp the objects they see, and toddlers learn to name those objects. Toddlers learn to navigate their environments, and early productive language is dominated by talk of where things are in space. By the age of about 3 years, children can use external representations of space (such as simple physical maps) to locate objects in a corresponding space. This is long before "map use" is formally taught in school. This evidence suggests that the multiple systems of spatial cognition emerge as a consequence of native biases to represent spatial information in particular ways. These native biases provide the foundation for early development of spatial cognitive systems. At the same time, they leave room for further developments that depend on particular kinds of experience that may modulate the foundational structures. Variations in early experience that can modulate foundational structures include congenital deafness or blindness and brain damage due to certain genetic syndromes or environmental insult (see Section IV).

If the precise nature of spatial representations differs considerably across domains, then what holds them together? Two important organizing ideas pervade the literature on spatial cognition and permit us to think across domains to the kinds of properties that are shared by (and differ across) the different domains. One concerns those geometric properties that are preserved in our spatial representations. The second concerns reference systems, which serve as further organizers of geometric properties.

B. The Geometries of Spatial Representation

We have already observed that spatial cognitive systems must resonate to spatial aspects of the physical world in which we live. However, the physical world can be formally described in terms of many different kinds of spatial–geometric properties. The critical question is which of these many different geometric properties best captures our mental representations of space.

Several theorists have drawn on formal theories of geometry as the framework within which this question

can be addressed. Two key examples of this approach can be found in work by Jean Piaget, whose goal was to describe the development of spatial cognition in the child, and that by C. R. Gallistel, whose goal has been to describe the representational system guiding navigation in mobile species. Both have drawn on Felix Klein's Erlangen program, which considers geometries in terms of the sets of properties left invariant under transformation. Different geometries are characterized by different kinds of transformations and thus leave different sets of properties unchanged. If an organism represents the geometric properties left invariant in a particular geometric system, then it can be said to have a representation that can be formally characterized by that geometry.

An intuitive sense of what this means can be illustrated using the example of a simple shape, for example, say a 2-in square (Fig. 1). By definition, a square is a figure composed of four equal sides; each pair of sides intersects at a 90° angle. The properties of this geometric object—its four equal sides (each 2-in.), and its four 90° angles—are left invariant under certain geometric transformations but not others. For example, if we translate, rotate, or reflect the square, the lengths of its sides and their angles of intersection will remain the same. Thus, the geometric properties of distance and angle remain invariant under the transformations of translation, rotation, and reflection: The 2-in. square that has undergone these transformations can be said to be the "same" square with respect to each transformation. These are part of the Euclidean metric geometry, and so our representation of the 2-in. square can be defined within that geometry.

However, the properties left invariant under Euclidean transformations are not necessarily preserved under the transformations of other geometries. For example, topological geometries preserve only quite general geometric properties, such as the closedness or openness of a segment (contrast a closed loop with a curved but nonclosed line), but not properties such as distances or angles. Topological geometry is often called "rubber sheet" geometry because the properties that it preserves are those that would be retained if one drew a figure on a rubber sheet and then applied nonuniform stretches to the sheet. If we did this with our 2-in. square, the result would be a range of figures that are enormously distorted, as shown in Fig. 1. Among the only geometric properties that would be preserved under such a transformation would be the closedness of the segment (i.e., the edges of the original square). The only way that this property could be destroyed would be if the rubber sheet were cut. For example, a single cut could produce an open line formed from the (closed) edges of the original square.

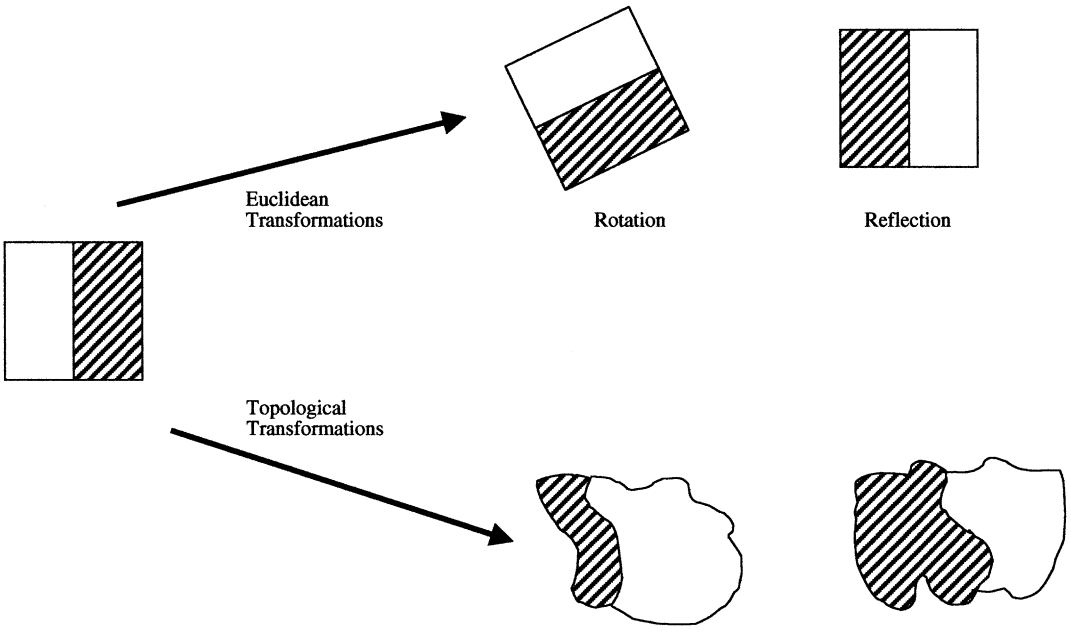

Figure 1 Two different kinds of geometrical transformation. Under Euclidean transformations such as rotation or reflection, the lengths of the figure's sides and its angles of intersection are preserved. However, under topological transformations, the figure's size and shape may be destroyed, preserving only highly general geometric properties such as whether the figure is closed or open.

Table I
Examples of Geometries and the Properties That Are Preserved under Each[a]

Geometry	Properties
Metric	Linear distance
	Angular distance
	Congruence of line segments
	Congruence of angles
Projective	Straightness (of "curves") (i.e., the property of being a line)
	Collinearity
	Type of conic section (ellipse, hyperbola, or parabola)
	Betweeness
Topological	Concurrence of curves at a point
	Openness/closedness of curve

[a]The geometries are hierarchically related to each other, with each successive geometry preserving all of the properties of the first plus new ones. For example, topological geometry preserves only highly general properties such as whether a figure is closed or open, projective geometry preserves these properties plus straight lines and collinearity, and metric geometry preserves these properties plus angles and distances.

Thus, although we would not normally consider the original square to be equivalent to a radically distorted closed figure, these two figures are, in fact, topologically equivalent.

Euclidean geometry and topological geometry illustrate two extremes in the set of geometries that Klein described, with the metric geometry preserving the most and most specific properties and the topological preserving the fewest and most general properties. Within the entire set, the geometries are hierarchically related to each other. This fact allows us to conduct strong tests of the nature of the geometric representation guiding a particular aspect of spatial cognition (Table I). As we move from topological to metric geometries, each successive geometry preserves all the properties of the preceding geometry plus some new ones. Thus, for example, whereas topological geometry preserves openness/closedness of segments, projective geometry includes this property plus straight lines and collinearity. Farther up the hierarchy, metric geometry includes all properties preserved under the others plus the new properties of linear distance (or length) and angular separation of lines.

The importance of Klein's Erlangen program for understanding the nature of spatial cognition derives from the fact that it provides a formal, testable theory that can be used to understand the nature of spatial representations. Sections II.A and II.C discuss evidence within this framework. Briefly, the evidence for both nonhuman species, such as rats, and human adults and young children shows that the spatial representations underlying navigation preserve metric properties of space. Moreover, evidence on young children shows that metric properties are preserved in early use of simple maps. Finally, evidence on spatial language in children and adults suggests that natural languages may preferentially encode nonmetric aspects of space in their basic vocabulary, using specialized vocabulary to fill in metric details. Questions about the links between different spatial cognitive systems can profitably be organized around the issue of how different geometric properties can be converted or translated into others.

C. Reference Systems

The notion of a *reference system* is the second crucial aspect of spatial representation that is pervasive in discussions of spatial cognition. The representation of location in terms of reference systems is common to many different spatial domains; hence, it is likely to be crucial to our understanding of how spatial representations come to be coordinated across domains. In this article, reference systems are defined as a set of orthogonal axes with an origin. Note that this kind of representational system requires preservation of the geometric properties "straight line" and "intersection" as well as the properties of "angle," which define the intersection of the axes. Within such a reference system, a target may be located by a precise set of coordinates, representing its distance and direction (or angle) from the origin. It is also possible for a target's location to be defined in terms of more general regions within each quadrant or within each half (vertically or horizontally divided). In much research, the distinction between reference systems and coordinate systems is not made carefully, and it is important to note that much of the evidence supporting use of a particular reference system does not necessarily also provide support for use of a coordinate system. It is an open question whether all spatial cognitive functions that engage reference systems also represent location in terms of metrically specified coordinates for distance and angle.

Given that spatial reference systems are crucial organizers of spatial information, how are their origins

determined? Objects have definite locations in space, but as we move our eyes, head, hands, or body through space, the location of the object will shift relative to our perceptual and motor effectors. Therefore, it is critical to specify the reference system in terms of its origin or the location that serves as the point of intersection of the axes. Axes and origins can be centered on a wide range of different spatial regions, and each reference system must therefore be defined in terms of its referent region. For example, if I observe an apple on a table in front of me, I can define the location of that apple in terms of a variety of reference systems: Its position may be defined in terms of the retina (retinocentric, with the origin at the center of the retina), the head (head-centered, with the origin at the center of the head), the body (egocentric or body-centered), the arm, or other parts of the body. I can also define the apple's location in terms of the table, other objects on the table or other objects in the world. The apple has some definite location on the table, in the room, in the building, and on the earth. In each case, a different reference system is used. This means that an object's location can only be defined relatively—with respect to a particular reference system (Fig. 2).

In principle, there exist infinitely many different reference systems—as many as there are objects that can serve as an origin. However, the ones most commonly considered in discussions of spatial cognition include retinocentric, head-centered, body-centered (or egocentric), object-centered, and environment-centered. The latter is used to refer to both local environments (such as rooms, buildings, or campuses) and larger environments, such as the earth, for which we can specify coordinates in a north/south/east/west reference system.

The logical requirement for reference systems in defining locations does not answer the question of how such systems are represented by the brain or, indeed, even whether the notion of a reference system as a set of Cartesian axes with coordinates is psychologically meaningful across all tasks and all domains. Moreover, one might wonder whether the entire range of different kinds of reference systems—centered on the retina, the eye, the head, the body, etc.—is actually deployed in our spatial representations. Evidence from a wide range of areas suggests that most of the reference frames commonly discussed are indeed represented in the mind and brain at some level.

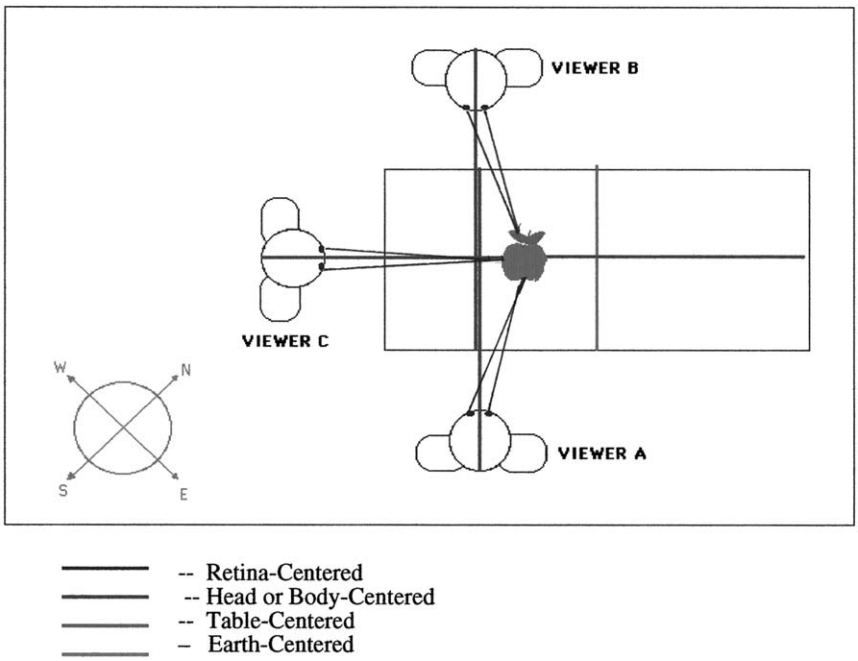

Figure 2 Where is the apple? The apple is in front of viewer A in a retina-centered frame of reference, to the viewer's right in a head- or body-centered frame of reference, and on the left side of the table from his viewpoint. For viewer B, the same apple is in front of him or her using a retina-centered frame of reference, to his or her left in a head- or body-centered frame of reference, and on the right side of the table from his or her viewpoint. The locations are defined differently for viewer C. The apple's location can also be defined in terms of reference systems centered on the room, the building, the earth, etc.

1. Multiple Spatial Reference Frames in Perception and Imagination

One source of evidence is neuroscientific studies showing that the brain represents space in terms of multiple reference systems. For example, studies of alert monkeys performing spatial tasks show that certain neurons in one area of parietal cortex respond selectively to stimuli in receptive fields defined by a head-centered system, whereas neurons in an adjacent area respond selectively to stimuli in receptive fields defined by an eye-centered system. Moreover, certain of the latter neurons are responsible for updating the location of the stimulus over eye movements. They are activated at the start of saccades that bring the receptive field onto the location of the stimulus or when a saccade brings the receptive field to a location that was previously occupied by the stimulus. The latter shows that the neurons essentially update the location of the stimulus from initial to final eye position, whether the stimulus is present or a recent memory.

Studies in human neuropsychology also reveal that the brain represents location in terms of multiple reference frames. Pertinent evidence comes from the study of neglect, a syndrome in which the patient ignores or fails to acknowledge the presence of stimuli in the region of space contralateral to the lesion. Neglect patients often show lesions in the parietal lobe, especially in the right hemisphere. Thus, the patients often neglect the "left" region of space. In one classic task used to diagnose neglect, patients are shown a sheet of paper with a large set of randomly oriented lines. When they are asked to cross out all the lines, patients often cross out only the lines on one side of the paper (e.g., the right side), leaving the lines on the left side intact. Thus, the patients are said to neglect the left side. However what does "left" mean? In the context of the current discussion, it should be clear that left must be defined relative to a reference frame in order to be meaningful: Is the region left relative to a retina-centered frame of reference, a head-centered frame, a body-centered frame, an object-centered frame, and so forth?

Investigators have found that neglect can affect different kinds of reference frames. For example, Edoardo Bisiach and colleagues described a neglect patient who was asked to imagine himself in a salient location in his hometown (e.g., on the steps of a church in the center of a piazza) and then was asked to describe the rest of the piazza. The patient described only the buildings and landmarks that were on one side of the piazza, omitting those that were on the side of his body contralateral to his lesion. Then he was asked to imagine himself at a location, at the other end of the piazza, facing the opposite direction, toward his original location, and he was again asked to describe the piazza. From this location, all buildings originally to his right (hence included in the description) would now be to the left of his body midline in the layout and vice versa. The patient now tended to describe the buildings and landmarks that he had neglected in the first condition; that is, he again described only those buildings and landmarks imagined on his "right" side, omitting those now imagined on his left side. These striking observations show that neglect affects not only the current perception of space but also remembered space, and that it can affect locations defined in a reference system that is centered on the body, head, or retina but not the environment as a whole.

Other studies have shown that neglect can affect object-centered representations. For example, Marlene Behrmann and Steven Tipper asked neglect patients to detect a flashing light presented at one of

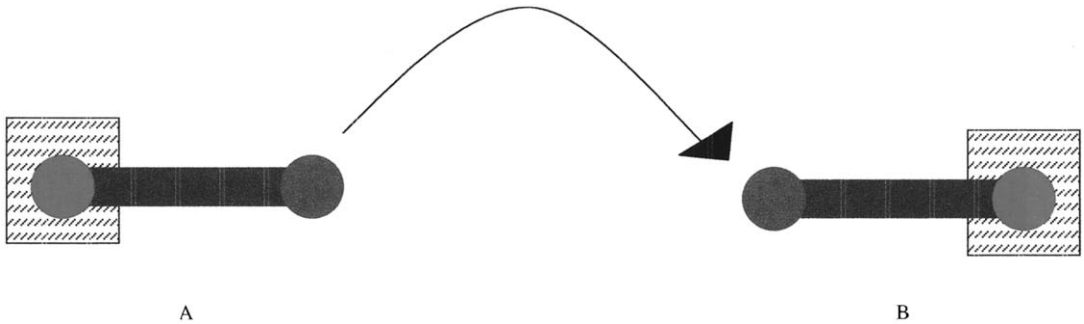

Figure 3 Behrmann and Tipper asked neglect patients to detect a flashing light presented at one end of an object both before and after rotating the object (A and B, respectively). Patients showed neglect for the same side of the object, indicating that they represented the location of the flashing light in terms of an object-centered frame of reference. (Reprinted by permission from Behrmann and Tipper, 1994, *Nature* **370,** 57–59, copyright 1994, Macmillan Magazines Ltd.)

two ends of a single object (a "dumbbell"; Fig. 3) that was presented in the center of their visual field. Patients showed the typical neglect for the side that was currently contralateral to their lesion. Behrmann and Tipper then rotated the dumbell around the center-point, with the result that the side of the object that had been neglected now moved to the other side of the viewer's visual field. Patients continued to neglect the exact *side* of the object that they had originally neglected, even though it was no longer in the visual field contralateral to the lesion. This result suggests that the patients were neglecting one side of the object as defined in an object-centered reference system.

Although the foregoing studies do not provide evidence for spatial coding in terms of specific coordinates within each reference system, recent studies by Michael McCloskey and Brenda Rapp have revealed the existence of coordinate representations. These investigators studied a young woman who had a developmental deficit in the visual perception of location. Although she showed no frank neurological insult, the woman systematically erred in indicating the location of visual stimuli presented on a computer screen in front of her. Her errors systematically preserved the distance of the stimulus from the origin of the reference system but not its direction. In particular, when asked to indicate the location of a stimulus, she typically erred by indicating locations that were the coordinate equivalents of the target under reflection around either the horizontal or vertical axis. Thus, for a stimulus that was located 9 in. *above* the origin, she would indicate a location 9 in. *below* the origin; if the stimulus was location 7 in. to the *left* of the origin, she would indicate a location 7 in. to the *right* of the origin. This evidence shows that the target's location was represented in terms of coordinates within the relevant reference system, preserving the distance along each axis but not preserving direction. Thus, it appears that the two parameters of the coordinate system—distance and direction—are separable in at least some visual representations of space.

2. Multiple Spatial Reference Frames in Navigation and Search

Classical studies of spatial learning in rats have documented the capacity to represent space in terms of either body-centered (egocentric) or environment-centered (sometimes called "allocentric") frames of reference. Early in the 20th century, evidence for each was gathered in the context of a debate between behaviorists (such as C. L. Hull) and cognitivists (such as E. C. Tolman), who sought evidence in support of more general learning theories. In key studies, rats were trained to run a simple maze and were rewarded at the end of the maze with food. The mazes were often simple, in the shape of a cross or a T. Initially, rats were trained to run the maze from a starting point (e.g., point A in Fig. 4) and then "turn right" at the intersection of the arms to reach the food at the end of the next arm (Fig. 4, point B). Rats learned this quite rapidly, indicating that something had been stored in memory that could guide their behavior. The key question was what had been learned. Behaviorists argued that the rats had learned a set of specific chained motor responses, which could then be run off in the context of the right set of cues (e.g., hunger and being placed in the maze) and that would result in success reaching the goal. In contrast, cognitive theorists argued that the rats had learned a "cognitive map"—a layout of the maze that allowed them to generate actions appropriate to reaching the goal, which was defined as a "place" in space. The critical tests were ones in which the rats' initial position was changed. For example, if the rats had been trained in a cross-maze, starting at point A, they could now be tested with a starting point at point C. If the rats were simply running off a sequence of motor responses, then

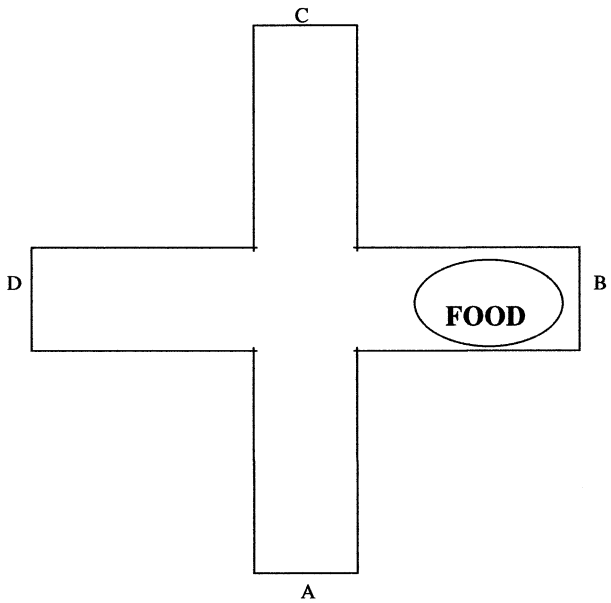

Figure 4 When rats are trained to run a maze, starting at point A and turning to find the food at B, they encode the location of the food in either a body-centered or an environment-centered frame of reference, depending on the circumstances of training and testing.

they would continue to turn right as they had done during training, now reaching D (which had no food). If, in contrast, rats were running toward a place, then they would have to turn left from their new starting point, reaching B (the location of the food).

The outcome varied depending on the particular circumstances of testing. In some cases, rats moved to the "same" location defined in terms of an egocentric, body-centered code (whereby they would continue turning right in our example); in other cases, they moved to the same location defined in terms of an allocentric, object-centered code (whereby they would now turn left from the new starting point, always reaching the correct place). In retrospect, the differences in results were due to a number of factors. One of the most critical, however, was the extent to which the animals could use information about the environmental layout beyond the maze to guide their behavior. For example, if the rats were trained and tested in a maze that was completely enclosed within a homogeneous environment (e.g., a heavily curtained space within which the maze sat) and the maze was rotated between training and testing, the animals tended to use the body-centered reference system. In contrast, if trained and tested in an open environment, such as a typically cluttered laboratory, the animals tended to run to the place where the food was located, thereby using the room layout as the reference system. Although much ink was spilled on using these different outcomes to defend different theories of learning, it appears that the best interpretation of the evidence suggests that, unless deprived of information about external layout, rats will use environmental frames of reference.

Abundant behavioral evidence exists to show that animals represent their environments in terms of both global and local layout, and that these representations guide their capacity to generate novel routes to known places in space. Moreover, work initiated by John O'Keefe and Lynn Nadel has shown that selective cells in the rat's hippocampus and surrounding regions respond when the rat is in specific places. Thus, the brain represents *places* in space. Layouts representing places are bound together as "cognitive maps," which share a number of similarities with real physical maps and are likely to be constructed by specialized mechanisms in the brain (see Section II.A). Because these cognitive maps must represent stable properties of the world through which the animal moves, they are not likely to be anchored to the body (which moves) and instead are anchored to frames of reference pertinent to the environmental layout.

Similar issues regarding use of reference frames were considered in some of the earliest studies of spatial learning among human infants. Jean Piaget proposed that the infant's earliest actions in space were confined to repetitions of sensorimotor activities that resulted in desired goals. Goal-directed spatial behavior, such as searching for objects, was thought to be guided by memories of the motor programs that had been successful in the past. A natural extension of this view was that the infant's representations of places in the world were intimately linked to the actions of its body in space—a different way of saying that place was defined in terms of the infant's body-centered reference system. According to Piaget's theory, it was only later in development that the child would come to represent object locations in a form other than a body-centered system.

Although the parallel was never sharply recognized, the formal experimental tests of this proposed developmental sequence were strikingly similar to those that had been used decades before in the animal literature. For example, in several studies Linda Acredolo and colleagues trained 6-, 12-, and 18-month-old infants to look, on cue, to either their right or left in order to gain a reinforcement, which was an animated face and voice. The environment was homogeneous, except that the left and right sides were marked with "windows" from which the animation would come. Infants rapidly learned to turn on cue to the target side. After this learning period, infants were moved along a circular path from their starting point, ending up at a point directly opposite their starting point, where what had been on their right was now on their left and vice versa. The question was whether infants would now turn their head in the same direction as before (e.g., looking to their right if trained to look to their right before) or toward the same place in space (now to their left, if originally to their right, and vice versa). Functionally, this is the same question as researchers asked regarding rats in the maze experiments. Results showed that 6-month-old infants tended to turn their heads in the same *direction* as they had before, whereas 18-month-olds turned their heads toward the same *place* as before. This pattern was interpreted as confirmation of the idea that infants initially act in space guided by egocentric frames of reference, which in this case could not take into account self-movement through space, only later coming to represent space in terms of other kinds of reference frames.

Later experiments by many investigators, however, revealed that such a developmental progression is unlikely. Rather, like the rat, the infant's and toddler's

responses to spatial tasks such as the one just described typically depend on the environmental layout available to them as well as the particular method used to test their spatial knowledge. The method used in the training study may have encouraged the development of body-centered representations because the infants underwent numerous training trials in which this kind of response resulted in an affectively positive event. In other studies, when infants are not trained extensively at an initial location, their performance at new locations improves. Moreover, in the studies carried out by Acredolo, infants were moved along a curved path, which is a combined rotation and translation, possibly obscuring their capacity to update their position over movement. Evidence shows that 6-month-old infants can update their own position in space over simple rotations (without translations) and simple translations (without rotations) but much less well over combined rotation–translations. It thus appears likely that infants have the capacity to represent places in space in terms of multiple reference systems; the choice of reference system is probably a complex function of task requirements and available information. However, the basic capacity to use different reference systems is unlikely to change substantially over development.

3. Multiple Spatial Reference Frames in Language

Multiple reference frames are represented in the mind and brain; however, different sets of reference frames are deployed for different spatial functions. Languages have the resources to encode location relative to any of the reference systems described; for example, one can describe a location as "to the left, in a *retinocentric* frame of reference." However, such words are technical, specialized terms used in restrictive settings. The basic terms of a language—those that are morphologically simple, widely used, and learned early in life—do *not* include *separate* terms that specially mark each reference system. Thus, for example, we can speak of "retina-centered," "head-centered," or "body-centered" reference systems, but in each case we refer to locations within these reference systems using the same basic set of terms, i.e., "*above*," "*below*," "*right*," and "*left*." That is, this basic set of terms is used to describe location over a number of reference systems, without further special marking. This might suggest that languages do not mark reference systems at all. However, this is false. There are two clear exceptions in English and other languages. First, locations defined in an object-centered system draw on a special set of terms—the *top*, *bottom*, *front*, *back*, and *side* of objects. These terms are used to describe locations within objects, not between objects. For example, if we wish to refer to the "*top*" of a sugar bowl, this region is the same regardless of the bowl's location or orientation in space. Similarly, the "*bottom*" is usually at the opposite end of the main axis of the object from the *top*. Terms marking these object-centered regions are seen across a variety of languages and are sometimes derived from the names of body parts (e.g., in Tzeltal and related languages). In these cases, as with the English terms *top*, *bottom*, etc., the application of the terms appears to be guided by perceptual representations of the object's shape, particularly, its main and subsidiary axes. This is an example of an interaction between two spatial systems, in this case, object perception (which also encodes axes) and language (see Section II.C).

A second set of terms specially marks location relative to the earth's coordinate system. In English, these terms are *north*, *south*, *east*, and *west*; many other languages specially mark these locations as well. Some languages also have terms describing location relative to local geographic features, e.g., *uphill*, *downhill*, or *seaward* (though the latter tend to be morphologically complex, i.e., compounds). Thus, languages appear to engage representations of a variety of reference systems, as do other spatial cognitive functions. However, locational terms in natural languages do not specially mark certain of the reference systems, even though these play a major role in action (e.g., retinocentric and body-centered).

II. SPECIALIZATION

The notion of a specialized cognitive system assumes that the structures and computations characterizing the system are unique, compared to other cognitive systems. For example, the structures underlying various aspects of spatial cognition depend on representation of geometric properties of the world, compared to the structures underlying aspects of language, which depend on representing units such as noun, verb, and subject of sentence. Similarly, the computations that allow us to manipulate geometric information might include the possible mental transformations that we can apply to our spatial representations (e.g., translation and rotation), whereas these transformations are simply irrelevant to our knowledge of language (except insofar as the two systems interact). If a system is

specialized, then it may qualify as a "module" in Jerry Fodor's sense, especially if other conditions are met. These conditions include developmentally early emergence of the system under conditions of informal (i.e., nontutored) learning, universality, and "impenetrability." The latter is the system's essential "blindness" to information that is not of the proper form for processing by the system, even though the information might be available in the environment and thus could in principle be used by the organism. One example of this is the rat's cognitive blindness to certain properties of spatial layouts that are not computed by the system dedicated to navigation (see Section II.A).

The idea of specialization in spatial cognition contrasts sharply with a different view that has recently gained currency. That is, all cognitive systems share both formal and computational characteristics, and they emerge in development through the operation of domain-general acquisition processes. Abundant evidence suggests that this latter view is wrong. Rather, many (if not all) foundational cognitive systems, including space, time, number, and systems of communication, appear to possess a rich internal structure that serves as a specialized foundation for further refinement and learning.

A. Navigation

All mobile species navigate through their environment to find food, care for young, etc. Abundant evidence shows that animals of diverse species have the capacity to construct and use cognitive maps of their environment, which are then used to guide their search in the world and return them safely home. The impressiveness of such spatial activity in animals can be conveyed with a few examples. One is the case of the desert ant, which travels many meters from home to search for food. The paths that the ant travels can be enormously long and indirect. Once the animal reaches the food, it must return to the home nest. Tracking the path of the ant on its return route, compared to its venture out from the nest, shows a striking fact: Although the initial path was long, indirect, and geometrically quite complex, the path home is direct, along a straight-line path. Experimental evidence shows that this route is not guided by "beacons" (i.e., perceptually available information emanating from the nest and serving as a continually present guide). For example, if the animal is picked up at the food source and displaced to a remote location, it will immediately move directly along a path whose angle and distance would have been appropriate for reaching its nest had it never been displaced (Fig. 5). Furthermore, when the ant has moved along the path for the appropriate distance and does not find the nest, it begins to search the area by tracing continuously enlarging circular paths whose end point falls each time in the vicinity of its initial guess.

The capacity of the ant to explore its environment and then return directly home rests on the brain's capacity to carry out "dead reckoning" (or "path integration"), a process by which small changes in position are summed as the animal moves through space, resulting in a continual updating of the animal's current position in space. This capacity is shared by many species, including humans. Recently, Gallistel proposed that spatial navigation in many mobile species rests on the capacities of dead reckoning together with "piloting," the capacity to use landmarks to correct the errors that can accumulate during the process of dead reckoning. Moreover, Gallistel

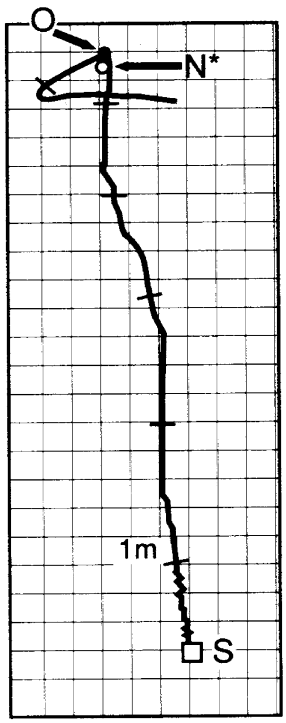

Figure 5 Homing behavior in desert ants. Ants traveled from their home nest to a feeding station. After they emerged from the feeding station, they were displaced to point S, far from their true nest. From point S, the ants traveled to their "home" nest, moving along a path that would have had the correct distance and direction had they never been displaced. The path shown is that of a single ant [N is the location of the fictive nest (i.e., where they ended up after moving along the path)]. (Reprinted with permission from Gallistel (1990)).

proposed that animals use dead reckoning to construct a cognitive map, or spatial representation in the brain, of the environments through which they move. These cognitive maps are thought to preserve the metric properties of angle and distance as well as the property of "sense"—the left–right relationships among parts of the layout. Once the map is constructed, the animal moves through space guided by dead reckoning in conjunction with this mental representation of space. Periodically, the animal checks to determine that its estimated position (based on dead reckoning) is consistent with its actual position in the environment. It does this by consulting the visible environment (i.e., salient aspects of the physical layout) and determining whether what it sees is consistent with where it thinks it currently is based on its mental map and its record of its own movements.

The capacity of the brain to represent the animal's location in space has been shown in extensive neurophysiological research. For example, John O'Keefe and Lynn Nadel found that neurons in the rat's hippocampus respond selectively when the animal is in a particular spatial location, documenting the existence of place cells and the capacity to use dead reckoning as well as information from landmarks to establish its current location. Recent work by Bruce McNaughton and colleagues has further defined the neural circuits responsible for dead reckoning.

Recent studies have investigated the possibility that the representations constructed during human navigation are also based on dead reckoning. Evidence from Jack Loomis and colleagues has shown that adults can keep track of their own location in space using mechanisms of dead reckoning. This mechanism is also available to children by the age of approximately 2 years and possibly earlier. Barbara Landau and colleagues showed that the blind and sighted toddler can represent spatial layouts in terms of angle and distance relationships and that these representations are most likely constructed by mechanisms of path integration. Figure 6 (left) shows an experimental layout in which a young congenitally blind child was walked along three paths between objects in a novel layout and then asked to travel between these objects along paths she had never traveled before. The resulting paths (Fig. 6, right) indicate that she constructed a cognitive map from her experience traveling the first set of paths, and that she was able to generate novel paths between the objects. The only information available to her to construct the map was her own guided movement during the initial walks; therefore, it is likely that mechanisms of path integration were

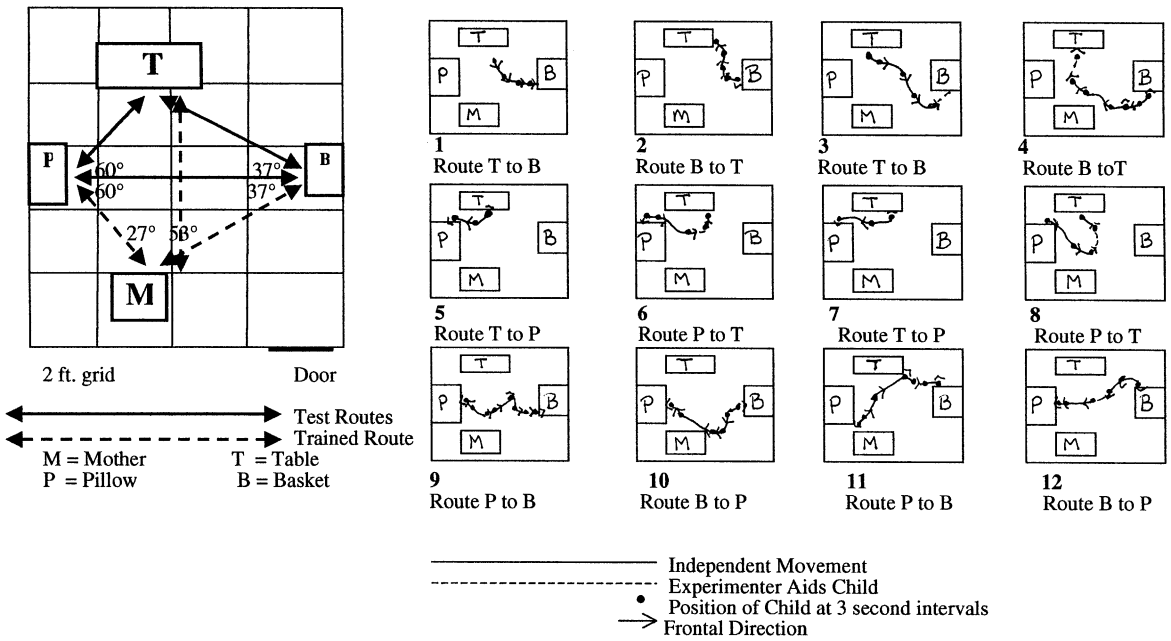

Figure 6 Layout of room used for testing the blind child's construction of a cognitive map (left). The child was trained by guiding her along paths indicated with dotted lines. She was then tested on her ability to independently move between landmarks along the test routes indicated by solid lines. Paths of movement shown in the individual panels (right) indicate that she used information from her own movement to construct a representation of the overall layout of the space and could use this representation to guide further movement among landmarks.

crucial to the development of her cognitive map of the layout. The accuracy of the novel paths that she generated immediately thereafter suggests that the cognitive map preserved both angles and distances between the pairs of landmarks.

Gallistel's theory of navigation also proposes that the representations that constitute the cognitive map qualify as a module in Fodor's sense. In particular, they are impenetrable to information that is not of the proper form for processing by the mechanisms dedicated to map construction. The hypothesized module in the animal's brain constructs a geometric map that preserves angle, distance, and sense relations using mechanisms of dead reckoning.

Behavioral evidence for the geometric module hypothesis has been found by Gallistel and colleagues in a series of elegant experiments. In one series of experiments, Cheng and Gallistel allowed rats to search for food in a homogeneous rectangular space, in which one container was placed in each corner. Each corner was distinguished by a variety of local cues, including surface textural and odor differences. Rats learned to search for the food and then were disoriented and returned to an identical but separate search space (which the rats assumed was the original, as shown by search patterns). The rats searched in the correct corner of the space on about half of the trials, searching the majority of the remaining trials in the corner that was diagonally opposite to the correct one (Fig. 7). This pattern held even when one of the walls had a distinctive covering, and it could in principle provide information critical to correct searching. Cheng and Gallistel concluded from this pattern of errors that the rat had constructed a geometric representation of the space in which sense was preserved along with distances and angles. Moreover, they concluded that the representation was modular, in that it was blind to information not properly admitted by the module, though clearly available in the environment.

In particular, if the rat's cognitive map preserved the different lengths and angles of intersection of the walls, and their sense relationships relative to each other, they would have represented the correct location of the food as something like "the corner in which the long wall is the left of the short wall." This relationship holds for two corners in the experimental spaces: the correct one and its rotational equivalent. Thus, the rat's geometric representation would lead it to search in the corner that yields a match between the location in its cognitive map (long wall left, short wall right) and the location in the current array. This will lead it to equally divide guesses about the location of the food between the two rotationally equivalent corners. A modular interpretation of the results emphasizes the fact that the additional, nongeometric cues about the target location, such as surface texture and odor, were available to the rat and used in certain contexts but were *not* used by it during search (compare Figs. 7A and 7B).

Other studies by Linda Hermer and colleagues have provided tentative evidence that the system guiding search after disorientation in humans is modular as well as metric and sense–preserving. In a modified replication of Cheng and Gallistel's experiments, Hermer tested toddlers' capacity to find a target object after disorientation in a featureless rectangular room. The toddlers, like rats, made clear errors confusing the two rotationally equivalent corners of the room (Fig. 8). In contexts in which surface information was provided to distinguish the two corners, the toddlers ignored this information (although they, like the rats, were capable of detecting it in other circumstances). The striking similarity between the pattern of responses of toddlers and rats suggests that some foundational aspects of navigation systems may be shared across species. The pattern shown by humans, however, changes by approximately 3 years of age, with increasing use of surface characteristics under conditions of disorientation. It is currently an open question whether such a developmental pattern is robust and, if so, what kinds of learning mechanisms might support the change.

B. Perceiving and Acting on Objects

In a different domain of inquiry, there is also considerable evidence in favor of specialization of spatial functions in the mind and brain. A key starting point is the work of Leslie Ungerleider and Mortimer Mishkin, who proposed in 1982 that the visual system in the macaque monkey brain is divided into two "streams," which they dubbed the "what" and "where" systems. Ungerleider and Mishkin proposed that visual information is processed beyond the primary visual cortex along two distinct anatomical pathways, each of which processes information differently. The "what" system processes information along the ventral stream of the brain that projects to the inferotemporal cortex, whereas the "where" system processes information along the dorsal stream of the brain, projecting to the posterior parietal cortex. Early evidence in support of these two streams came from

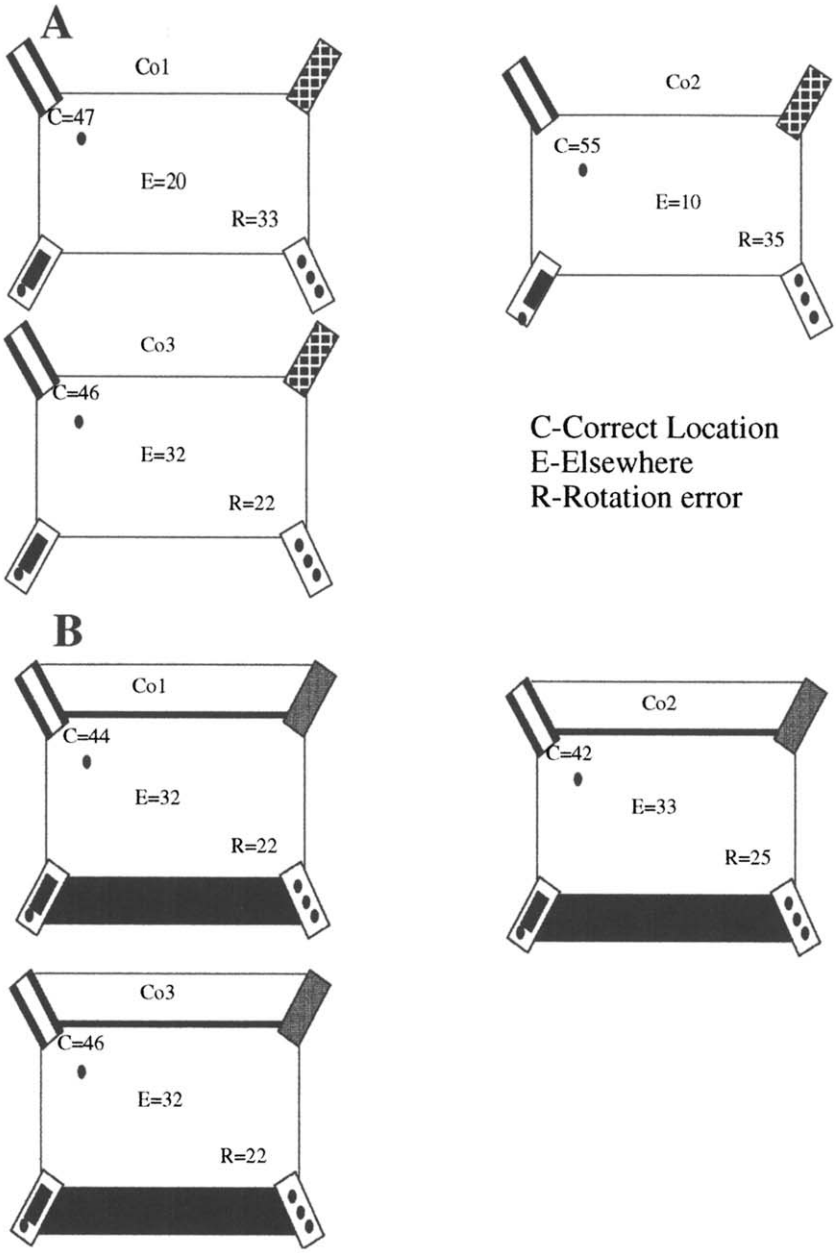

Figure 7 Results of Cheng and Gallistel's experiments on navigation in rats. (A) The search results for three rats that were tested in completely homogeneous rectangular spaces. (B) The search results for rats tested in a rectangular space that included one distinctive wall. In both cases, the rats tended to search at the correct location or its rotational equivalent. (Reprinted with permission from Gallistel (1990)).

studies of the behavioral effects of lesions in monkey cortex: Lesions of the inferotemporal cortex led to impairment in the visual discrimination of objects (on the basis of object properties such as form) but no impairment in a task requiring identification of objects on the basis of their spatial location. In contrast, lesions of the posterior parietal cortex led to impairment on object location tasks but no impairment in object discrimination based on (nonspatial) object properties. Related evidence from patients sustaining damage to corresponding locations of the brain suggests that a similar distinction between the two processing streams may exist for humans.

Recently, a different hypothesis regarding division of labor in the visual cortex has been proposed by Melvyn Goodale and A. David Milner. They suggest

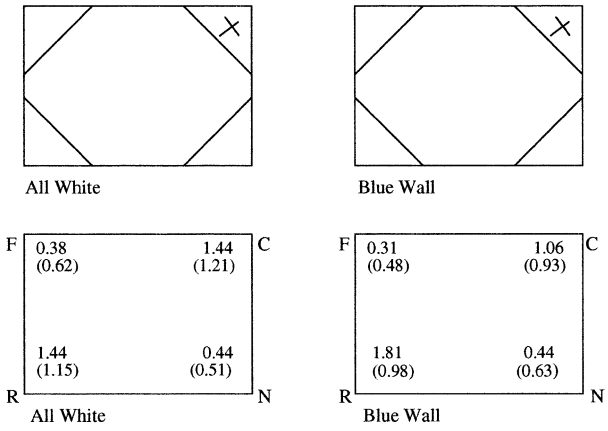

Figure 8 Results of studies by Hermer and Spelke showing that toddlers who are disoriented in space use geometric properties of the layout to search for hidden objects. Toddlers observed an object being hidden (X), were disoriented, and then allowed to search for the object. They searched primarily in the correct location or its rotational equivalent (bottom), whether or not the room had distinctive surface markings (compare right and left panels). [from L. Hermer and E. S. Spelke (1994). A geometric process for spatial reorientation in young children, *Nature* **370,** 57–59. Reprinted with permission from Macmillan Magazines Ltd.].

that the functions of the ventral and dorsal streams might better be characterized as the guidance of visual perception vs visually guided action, respectively. Specifically, the ventral system is thought to support perceptual judgments underlying object recognition and explicit judgments of location, and its contents are accessible to consciousness (required for explicit reporting). The dorsal system is thought to guide visually directed action, including reaching, grasping, and other action tasks, and the contents of this system are not accessible to consciousness. The specialization characteristic of each system means that the visual information arriving at primary visual cortex will later be represented differently; that is, different aspects of the same stimulus will be preserved.

One of the key distinctions here can be described in terms of different reference systems. As noted earlier, the action system requires that the shape, size, and orientation of an object be coded in terms of its location relative to the effectors as they move through space. As we reach and grasp, the location of our arm, hand, and fingers changes relative to the target. The action system must therefore be capable of constantly updating the representation of the target's location as an actor moves through time and space. Milner and Goodale suggest that this characteristic of the "how" system naturally entails that it will have little or no memory—there is no point in retaining information about an object's orientation and location relative to the momentary disposition of one's hand, and so this information is not retained over time. In contrast to this momentary nature of the action system, Milner and Goodale propose that the "what" system is dedicated to representing the enduring qualities of objects, including their permanent size and shape. These qualities are retained over time as a more permanent property of the object's representation.

Evidence supporting this functional distinction between the two visual streams has come both from adults sustaining brain damage and normal adults. For example, Milner and Goodale reported a case study in which they observed a patient, D.F., who had sustained brain damage due to carbon monoxide poisoning. D.F. was severely impaired in perceiving objects; for example, she could not judge the size, shape, or orientation of simple objects. However, she was quite capable of acting on objects in a way that suggests that she does represent these characteristics. In a frequently cited experiment, D.F. was asked to judge whether the orientation of a card was appropriately positioned to put through a mail slot. She was incapable of doing this accurately. However, when asked to "post" the card through the slot as if mailing it, she was quite accurate. These findings, along with complementary ones from studies of patients sustaining damage to other areas of the brain, suggest that the two streams can be dissociated under different conditions of pathology.

Earlier results from normal adults also provide support for such a dissociation between the two visual systems. For example, Bruce Bridgeman and colleagues showed that people can experience visual illusions that lead to inaccurate reports of a target location, but at the same time they can accurately point to the same location. Such findings show that the two visual systems operate in at least partial independence under normal (i.e., nonpathological) conditions.

Recently, the two-visual system distinction has come to the attention of cognitive developmentalists, in the context of the infant's representation of objects and space. Decades ago, Piaget observed a striking pattern of behavior among infants who were enticed to search for an object that disappeared from their view. Before the age of 6 months, infants show very little reaction at all, simply staring at the spot where the object disappeared or, at best, searching in inconsistent locations for it. By 9 months, infants actively search in these contexts. However, they still often search at the

wrong location, and this is often the location where they have successfully retrieved the object on past occasions rather than the location where they saw the object disappear. Piaget theorized that infants do not, at this developmental stage, understand that objects are independent entities that occupy stable locations in space and can move or be caused to move to other stable locations. Piaget proposed that this concept—part of the notion of a "permanent object"—develops slowly over the first 2 years.

Many researchers have noted, however, that the tasks Piaget used to test object permanence rely on two capacities: The infant must first observe the object being hidden, and then he or she must perform an action based on the representation of the object's location before its disappearance. In the context of the two-visual systems approach, a developmental independence between the products of perception and the system used for action could lead to a pattern in which the infant could establish and maintain a representation of a permanent object but not act appropriately on the basis of that representation. Research by Renee Baillargeon and colleagues, among others, has shown that infants can indeed represent hidden objects by the age of 4 months (and perhaps earlier). The tests depend on infants' looking patterns during and after events in which an object is hidden. For example, in one experiment, the infant observes an object that is subsequently occluded by a barrier (thus, the object goes out of view). If the occluder then continues to move, passing through the space previously occupied by the object, the infant will show surprise, indexed by lengthy looking at the event. In contrast, if the occluder stops moving at the point where it would have contacted the hidden object, the infant does not show surprise. Thus, by 4 months—considerably earlier than active and accurate search—the infant apparently knows that the object still exists when hidden. There is apparently a contrast between the knowledge shown by the infant when the perceptual system is engaged and that shown when the action system is engaged. This is consistent with the idea that the infant can represent an object's existence, but that this representation is not engaged by the action system until considerably later.

This and other findings have led a number of researchers to propose that there is a developmental dissociation between the systems guiding perception and those used to guide action in infancy. The development of action is considerably complex and, importantly, is driven by functional constraints that are different from those engaged by the perceptual systems. The fact of different developmental timetables is consistent with the idea of functional specialization, possibly corresponding to the two different visual streams.

C. Symbol Systems

The construction and use of symbolic representations of space is one of the hallmarks of human cognition, permitting the transmission of spatial information over time and space. One clear example of this capacity is the formation and use of physical maps to convey spatial information to oneself and others. Another example is the use of spatial language to talk about the objects, motions, and spatial relationships around us. The symbolic representation of space by language seems to have special priority for humans, providing a natural format for the expression of concepts and relationships that are not inherently spatial. For example, linguists such as Ray Jackendoff have shown that our spatial vocabulary is easily extended to temporal concepts: Words such as "ahead" and "behind" are predominantly spatial in meaning but can be used to express temporal meanings such as "ahead of/behind schedule." Spatial representations also provide natural means for solving problems, even those that are not inherently spatial. Thus, people seem to find it natural to solve nonspatial problems by converting the informational content of the problem into a spatial format—a fact that has significant applied importance.

1. Maps

A map is a physical layout of symbols that stands for a set of objects and places. Critically, the spatial relationships among these symbols stand for the spatial relationships in some corresponding layout in the physical space around us. The particular formal means for expressing these objects, places, and spatial relationships varies widely over history and cultures. Thus, it is clear that some aspects of map use must be learned with each new generation. However, it is also clear that certain fundamental properties are general to the very notion of a map. These properties are presumably universal among human cultures. Recent evidence suggests that appreciation of certain fundamental properties of maps emerges early in development, without explicit tutoring.

The functional requirements of maps suggest that, like other systems of spatial knowledge, only certain kinds of information will be preserved. For example,

because maps are highly condensed forms of information, they will not necessarily preserve the detailed microstructure of paths or the detailed geometry of landmarks and places. Nevertheless, in order to be used for locating objects, maps regularly preserve the angular and distance relationships among places in space—information that is also represented by our cognitive mapping system. Angle and distance are preserved in metric geometries; hence, the capacity to use a map entails the capacity to represent metric information. Because maps usually preserve metric information using a function (i.e., a scale), map use also entails the capacity to recognize the conversion from represented distances and angles (on the map) to their correspondents in real space.

Although cognitive maps and physical maps share many characteristics, being able to construct a cognitive map of a territory through navigation does not guarantee the capacity to use a real map. Many species construct cognitive maps to guide their navigation, but only humans are capable of using external physical representations to guide their locomotion and search. Careful experiments by David and Ann Premack showed that chimps cannot learn to use even a simple map to guide spatial search.

To understand the nature of this peculiarly human representational system, we can ask what kind of mental representation would be required to understand the most basic properties of physical maps. First, the map contains a set of symbols in which it is understood that each "stands for" a real object, place, or other part of the space it is meant to represent. Second, the observer must be able to represent the spatial relationships among symbols and use these to locate objects in the represented space. Angular relationships among objects are usually preserved, thereby allowing the user to compute the angular direction required in order to get from one point to another. Distance must also be represented. However, because maps are compressed representations of physical space, actual distances among objects and places are almost always altered and must be reinstated using a metric conversion. Thus, the user must be capable of understanding the "stand for" relationship between maps and the physical layouts that correspond to them; preserving angular information contained on the map and using it to predict corresponding angular relationships in the physical layout; and computing distances on the map and converting them to another metric distance, determined by the proportional relationship between map and physical space.

Knowledge of these fundamental aspects of maps emerges relatively early in life and does not appear to rely on formal tutoring. By the age of approximately 2½ years, children appear to understand the "stand for" relationship between symbols for objects and the real corresponding objects. Judy DeLoache showed children miniature three-dimensional models of real rooms, including scale furniture arranged in exactly the same layout as the represented room. She went to great pains to show the children each object and how they corresponded to each represented object. She then showed the children a small toy being hidden in the model room and asked them to find the corresponding toy, which was hidden in the same place in the represented room (Fig. 9). DeLoache found that 3-year-olds were quite accurate at finding the object in the represented room, but that 2-year-olds were quite poor, searching at chance in the represented room. After their attempted (but unsuccessful) search, children were asked to find the toy in the location where it had been hidden in the model. Both 2-year-olds and 3-year-olds performed at ceiling in this task, showing that the 2-year-olds' problem in retrieving the toy from

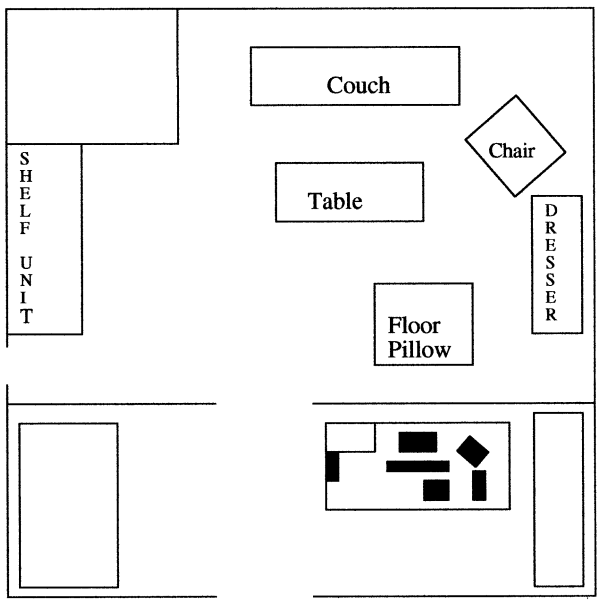

Figure 9 DeLoache showed toddlers a room and its scale model (bottom right). She hid an object in the model and then asked toddlers to find the corresponding hidden object in the real room (or vice versa). Two-and-a-half-year-olds had great difficulty using the model as a representation of the room, but 3-year-olds found the task trivial [from DeLoache, J. (1989). Young children's understanding of the correspondence between a scale model and a larger space. *Cognitive Dev.* **5,** 121–139. Reprinted with permission of Elsevier Science].

the represented room was not due to their failure to remember the hiding location in the model.

DeLoache argued that the rapid change between 2 and 2½ years was due in part to "representational insight"—the ability to recognize the relationship between a symbol and what it stands for. She also argued that the capacity to use this insight might be facilitated or dampened by changing the extent to which the children regarded the model as a symbol rather than an (nonsymbolic) object per se. In several clever experiments, she was able to confirm this hypothesis. For example, she found that, although 2½ year-olds failed to find the toy in the represented room using an explicit three-dimensional model of the room, they were successful when the model was a photograph of the room. The photograph, argued DeLoache, is a more felicitous symbol of the room because it is less like a real object. Similarly, DeLoache found that children were more successful in using the three-dimensional model when they observed it behind glass, and were not able to interact with it, than when they were allowed to touch and explore it. This too shows that young children are capable of using symbols to guide search, but only when they can best be interpreted as symbols. Thus, the ability to recognize the "stand for" relationship between map and physical layout appears early in life, well before children are formally taught about these correspondences.

Other findings show that young children are capable of using metric information, including angle and distance, to locate objects using rudimentary maps. In one study, Barbara Landau showed a 4-year-old congenitally blind child a small layout including several wooden blocks representing key landmarks and the child in a room. The child had never been exposed to tactual representations of objects or layouts. Nevertheless, the child understood the "stand for" relationship between the abstract objects on the map and the corresponding objects in the represented layout and could use the "map" to find the landmarks in the represented room. The symbols on the map were arranged to preserve angular information among objects, and the child successfully used this information to guide her search for the represented objects in space.

Young children can also use distance information conveyed in simple maps. Nora Newcombe and Janellen Huttenlocher showed 3- and 4-year-olds a piece of paper on which they had drawn a rectangle with a small dot positioned inside. The children were told that the drawing represented the location of a toy that had been hidden inside of a rectangular box of the same proportional lengths as indicated on the drawn rectangle. Children were quite successful at retrieving the toy, showing metric errors that were quite small relative to the entire space. Thus, by the age of 3 or 4 years, children are capable of representing the angular and distance relationships among objects in explicit representations of space.

2. Language

Like the construction and use of maps, our capacity to represent objects, motions, and their spatial relationships through language is species specific and emerges early in development without formal tutoring. Because spatial language must encode our spatial experience, one might expect to find exact reflections of nonlinguistic spatial representations in language. However, like other specialized systems of spatial cognition, language selectively encodes only certain properties of space.

The fundamental linguistic tools for talking about space include expressions for objects, motions, and spatial relationships. In English, objects are typically represented by noun phrases, motions are typically represented by verbs, and spatial relationships are represented by spatial prepositions (including, "in," "on," "under," and "between"). In English, there are approximately 85 spatial prepositions, which encode basic spatial relationships. By assembling these basic spatial terms in various combinations, we can construct an infinite set of descriptions that encode detailed spatial relationships (e.g., "in the middle of the front edge of the table"). Furthermore, we can add metric information to spatial descriptions by using the number system (e.g., "3 inches left of the middle of the front edge of the table").

Linguists such as Leonard Talmy and Ray Jackendoff have proposed that the basic linguistic expression used to encode a spatial relationship contains three fundamental elements: One represents the "figure" object—that is, the object that is to be located by the expression; a second represents the "ground" or "reference" object—that is, the object in terms of which the figure is located; and a third represents the geometric relationship between figure and ground. In English, these relationships are usually encoded by spatial prepositions, which are highly selective in the kinds of relationships they encode.

For example, common spatial prepositions such as "in" and "on" encode relationships that, informally, can be dubbed "containment" and "support." In fact,

these labels understate the complexity and subtlety of the relationships that are encompassed by the terms. For example, the term "in" can describe the relationship between two concrete objects, where one object sits in the cavity of another (e.g., "the apple in the bowl"), one object sits in the virtual volume created by the other (e.g., "the owl in the tree"), or one object sits completely outside of the volume of the second (e.g., "the apple in the bowl" when it is on top of other fruit and extends above the bowl's lip). In English, the term "on" can describe a relationship of gravitational support (e.g., "the jar on the table"), nongravitational support (e.g., "the gum on the table"), or transitive support (e.g., "the book on the table," when the book sits on the top of a pile of other books). The very same physical array can be aptly described by more than one spatial preposition, depending on what kind of relationship the user has in mind. For example, one can say "the fruit on [not "in"] the *plate*" or "the fruit in [not "on"] the *bowl*." The use of one preposition rather than the other depends on the conceptual nature of the reference object: We conceptualize bowls as containers, hence we must use the preposition "in"; we conceptualize plates as surfaces, hence we use "on."

Because of these constraints, different spatial prepositions "select" different kinds of objects. The examples just discussed show that "in" selects reference objects that can be conceptualized as "containers" (albeit in some very abstract sense), whereas "on" selects reference objects that can be conceptualized as "surfaces." Leonard Talmy described this as the "schematic" nature of spatial language: Spatial terms select only certain geometric properties as relevant and discard others. Talmy suggested that spatial prepositions in English (and corresponding terms in other languages) encode only nonmetric properties of objects, for example, objects as surfaces, containers, and lines. Talmy also suggested that the range of relationships encoded by languages is limited to nonmetric properties, such as support or contact, containment, parallelism, and intersection. Of course, metric information can be encoded by language, but this is done by a different subset of the vocabulary, particularly metric terms (feet, inches, and degrees) and the number system. The spatial prepositions thus might be regarded as a special subset of terms that are dedicated to expressing only selective aspects of location. Notably, the prepositions are part of the "closed class" system of English. That is, there is a restricted number of terms, and new terms are not freely admitted to the class. Thus, for example, English has terms expressing support and containment but no terms specifying exact metric relationships such as "2 inches from a reference object's border." Such a term is unlikely to be invented by speakers, and if it were it would be difficult to learn. This contrasts with the vocabulary of object words, which is an "open class" and thus readily admits new members (e.g., fax and e-mail).

Recently, Barbara Landau and Ray Jackendoff argued that the division of labor in language between the coding of objects and the coding of places parallels and possibly stems from the division of labor in the brain between the nonlinguistic representation of objects and places. Landau and Jackendoff observed that although spatial terms typically respect only nonmetric properties of objects, more detailed geometric information is respected by the naming of objects as figure and ground. Thus, in the sentence "The pear is in the bowl," the representations of "pear" and "bowl" might be linked to shape-based representations of the objects, possibly carried by the ventral stream in the brain. The spatial relationships encoded by the spatial prepositions, however, encode the very same objects without reference to detailed geometric structure—objects as figure and ground are represented as "blobs" or as containers, surfaces, lines, etc. The division of labor between the encoding of objects vs places (i.e., the nouns vs the prepositions in English) might therefore correspond to the distinction made in the brain between representations of objects (in the "what" system) and representations of location (in the "where" system) as conceptualized by Ungerleider and Mishkin.

To summarize, spatial language reveals a high degree of selectivity in its representation of spatial information about objects and locations. Only certain geometric properties of objects and only certain properties of locations and spatial relationships are respected by the language's stock of basic spatial terms. This information is clearly different from that required for navigation, for reaching or perceiving, or for map use. The distinctive nature of linguistic representations of space raises the intruiging question of how it maps onto other systems in order to allow us to talk about what we see and to use language to direct activity.

III. INTERACTION

Having considered several systems of spatial cognition that appear to engage different kinds of spatial information, one can ask how these systems interact. We do not consciously experience space as a set of separate systems, each preserving different kinds of

geometric information. Rather, our experience is of a seamless spatial world in which we navigate, reach and grasp objects, construct and use maps, and talk about objects and their spatial relationships relative to ourselves and to each other. How, then, are these interactions carried out in the mind and brain?

A distinction can be made between two different kinds of interaction, which are not always clearly specified in the literature. One kind of interaction supports the translation of information from one system into another. Because spatial systems differ, the translation is unlikely to be a one-to-one correspondence. Rather, there must be some function mapping the spatial information in one system to that of another. An example is the mapping between spatial language and other spatial cognitive systems, in which information from perception and action must be converted into a format suitable for linguistic description, in part by stripping away the metric properties of space. Such conversion is necessary in order to support our capacity to talk about our spatial experience.

A second kind of interaction, which is be considered here, is the capacity of one system to penetrate and thereby either guide or, more strongly, modulate and change the representations in another. One arena in which such interactions have been examined is navigation, considering the effects of imaginal and linguistic representations on our capacity to update our own location in space. A second, hotly debated arena concerns the relationship between cross-linguistic differences in spatial language and spatial cognition. Here, researchers have tried to determine whether language-specific encoding of space can affect the nature of nonlinguistic spatial representations or, more broadly, whether spatial language can mold spatial thought.

A. Imagery and Language as Modulators of Navigation

Although humans and other species readily update their own location as they move through space, the deployment of this capacity depends heavily on actual movement through space. Studies by Roberta Klatzky and colleagues have shown that there are substantially more errors in updating in humans when it is guided by language and imagery, by simulated motion, or by the observation of another person moving along the target path. In Klatzky's studies, people were asked to solve the following problem: Given two segments of a path, with a turn between segments, they had to turn to face the origin, as they would if they had walked along the third route back to home (Fig. 10). In one group, people were blindfolded and walked along the first two segments and then were asked to turn to face the origin (i.e., their starting point). People in a second group were given a verbal description, with which they were to construct an image of walking along the two segments. For example, people were told to imagine they would "Go forward 3 m, turn clockwise 90°, then go forward 3 m." Then they were blindfolded and told "Now face the origin." People in a third group observed another person walking along the first two segments and then were blindfolded and instructed to turn as the person would turn in order to face the origin.

Results showed that people who had physically walked along the segments were accurate, turning by the correct number of degrees to face the origin from their testing point. This indicates that they had updated an internal representation of their heading and location and could use this to generate the final

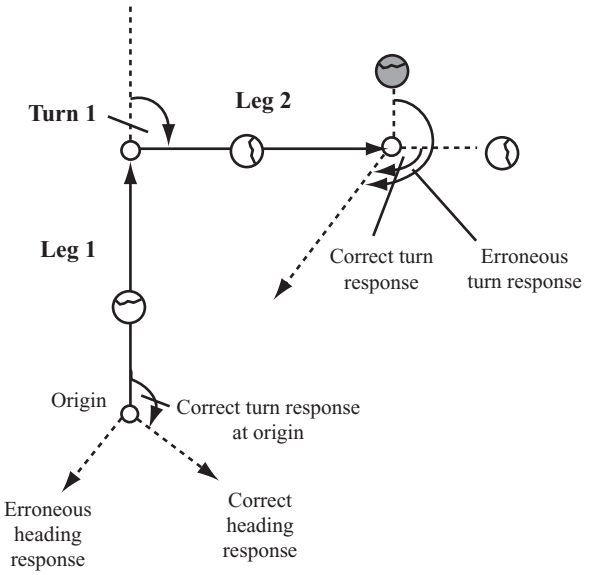

Figure 10 Schematic of the task used by Klatzky and colleagues. The participant is shown a path comprised of Leg 1, Turn 1, Leg 2 and is then asked to turn and face the origin. If people update their own location over movement, they should turn to face the origin accurately. Klatzky and colleagues found that people are accurate when they have moved through the array themselves. However, when instructions about the paths are given via language or observation of another person, they fail to update [from Klatzky, R., Loomis, J., Beall, A., Chance, S., and Golledge, R. (1998). Spatial updating of self-position and orientation during real, imagined, and virtual locomotion. *Psychol. Sci.* **9**(4), 293–298. Reproduced with permission of the American Psychological Society].

change in their own orientation so as to face the origin. Clearly, their representations preserved angle and distance information. However, people in the verbal/imagery condition and the observation condition failed to accurately update. Instead, people in both groups systematically overturned by the magnitude of the turn between segments one and two. Thus, as Klatzky and colleagues argue, in the imaginal and observational conditions, subjects did not encode the degree to which they had ''turned'' between the first and second segment. This is a striking finding, in view of the fact that the verbal instructions clearly specified exactly how much should be turned and that the observer witnessed someone carrying out the 90° turn, something that could be represented quite clearly by language. The findings suggest that neither linguistic information nor perceptual observation can modulate the representation of one's location in space. Specifically, these types of information cannot update one's heading. In contrast, the capacity to update is a foundational characteristic of the system underlying human navigation through real space.

Updating through one's own imagined movements is not impossible, however, and compared to other mental manipulations of spatial scenes it may even be relatively accessible. Early studies by Janellen Huttenlocher and Clark Presson showed that when children are instructed to imagine that they have moved to another location, they are more successful at predicting what the layout will look like than when they are instructed to imagine that the layout has moved. This finding has recently been discussed in the context of scene perception and offered as evidence supporting the view that one's representation of scenes relies on updating the viewer's representation of his or her own location in space. However, the Klatzky studies reveal that actual movement through space engages updating mechanisms that yield much more accurate representations of one's location in space. A reasonable conclusion from these studies is that the systems of spatial perception and spatial language cannot, with any precision, penetrate and modulate the system of updating used during real navigation.

B. Cross-Linguistic Differences in Spatial Language as Modulators of Spatial Thought

Spatial language is generally assumed to rest on nonlinguistic representations of space, which are presumably universal. However, recent cross-linguistic studies have revealed substantial differences in the encoding of space, some of which are quite surprising. For example, as shown in Fig. 11, English uses the spatial term ''on'' to encode the relationship of a bowl on a table and a handle on a door but distinguishes these relationships from that of an apple ''in'' a bowl. To English speakers, this partitioning is perfectly natural, which makes it surprising that the three relationships are categorized differently in other languages. For example, Dutch categorizes each of the three relationships differently, using three distinct terms, and Spanish collapses them together, using a single term to express all three relationships. Finnish partitions the handle-on-door and apple-in-bowl together and separates these from the cup-on-table. These differences, along with many others that have been recently documented, have naturally led to a resurrection of the classic question raised by Benjamin Whorf: Does the language we learn affect the way we think? In the case of spatial cognition, the question is whether early learned differences in the linguistic coding of space can modify or change aspects of nonlinguistic spatial cognition. If the answer is yes, then this would suggest that the relationship between

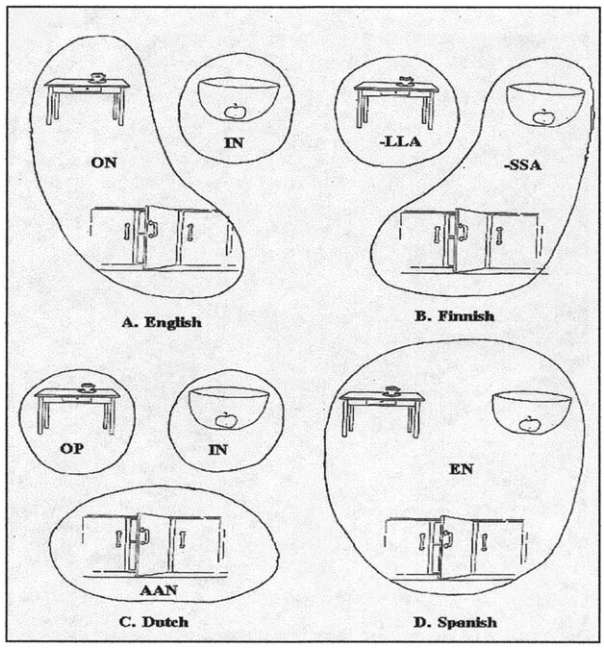

Figure 11 There is substantial cross-linguistic variation in the encoding of spatial relationships. The physical relationships shown in the figure are categorized differently by the languages shown [Reproduced with permission from Bowerman, M. (1996). Learning how to structure space for language: A cross-linguistic perspective. In *Language and Space*. (P. Bloom, M. Peterson, L. Nadel, and M. Garrett, Eds.). MIT Press, Cambridge, MA].

spatial language and nonlinguistic spatial cognition is one of substantial interaction and, more important, that this interaction can result in changes to nonlinguistic spatial cognition. If the answer is no, it would suggest the absence of such interactivity, at least in the strongest sense.

The empirical evidence to date does not support the strong form of interactivity. For example, in one widely cited study reported by Stephen Levinson and colleagues, people were asked to solve a variety of spatial problems that required them to code the location of objects relative to one or more reference systems. As discussed in Section I, languages regularly distinguish between earth-centered reference system (using terms north, south, east, and west in English) and environment-centered or body-centered reference systems (using terms such as right and left in English). Speakers of English typically reserve the former for cases in which they wish to describe large geographic layouts (e.g., ''north of New York'' but not ''north of the cup''). Levinson observed that speakers of Tzeltal follow quite a different pattern, regularly using the terms of the earth-centered reference system to encode the locations of most objects, including small moveable ones. Thus, a speaker of Tzeltal might describe the location of an apple on the kitchen table as ''to the north'' rather than ''to my left'' or ''to the right of the sink.'' Levinson speculated that lifelong usage of this reference system in linguistically coding location might modify people's spatial representations such that they would solve *nonlinguistic* spatial problems using this reference system as well. The results from a variety of spatial problems were that speakers of Tzeltal showed a bias—though far from an absolute bias—to code spatial relationships in terms of the earth-centered rather than environment-centered reference system. This contrasted with the performance of Dutch speakers, who tended to encode location in an environment-centered reference system.

Such findings might suggest a bias toward the use of one kind of reference system, but they do not prove that the underlying nonlinguistic representations have been modified. Moreover, biases to use one reference system rather than another are common in many spatial tasks; for example, evidence reviewed in Section II showed that navigation in animals and humans can engage different reference systems, depending on the context of the task. Recent research by Peggy Li and Lila Gleitman has shown that biases such as those shown by Tzeltal speakers can also be induced in native English speakers if the context is suitably altered to enhance the likelihood of encoding location in terms of a geographic reference system. This suggests that the effects of linguistic experience in Levinson's task are shallow.

A number of other studies have shown that certain aspects of nonlinguistic spatial representation are immune to the effects of linguistic experience. In one study, Edward Munnich and colleagues gave native English and Korean speakers a nonlinguistic spatial task that tested their memory for the location of a ball, either on or above a table. Adults of both speaking communities were much more accurate in remembering the locations that were in contact with the table (''on'' it) than those that were not in contact with it (''above'' it). This pattern of performance contrasted sharply with the people's *linguistic* categorization of the same locations: Whereas English speakers uniformly distinguished the two categories of relationships by using two different spatial terms (e.g., ''on'' vs ''above''), the Korean speakers did not. Consistent with their native language, Korean speakers used just a single term across both contact and no-contact locations, only occasionally marking the distinction with different terms. Thus, a clear, lifelong difference in the linguistic encoding of contact vs no contact apparently had no impact on the two groups' nonlinguistic memory for location, which showed a strong contact/no-contact distinction regardless of whether it was coded by their language.

Results such as these indicate that at least some aspects of nonlinguistic spatial representation are immune to the effects of cross-linguistic differences. It remains to be determined whether some aspects of nonlinguistic spatial representation can indeed be restructured by linguistic experience.

IV. DEVELOPMENT

The early emergence of specialization in spatial cognition is consistent with the idea that there are innate constraints on the kinds of spatial information that the brain can represent, and that these vary for different aspects of spatial cognition. At the same time, the existence of constraints does not preclude learning, development, or change. The developing brain is a dynamic structure, and there is much evidence for its plasticity during the early years of life. However, this plasticity is not unlimited. Rather, studies showing effects of early experience often suggest change that is constrained by the lines of normal cognitive architecture. Studies of variation in early experience have led to insights about the early localization of spatial

cognitive functions in the brain, the existence and nature of specialization across spatial cognitive domains, and the causes of reorganization.

A. Localization

Studies of adults sustaining lesions to the brain suggest that the two hemispheres preferentially represent different aspects of spatial information. People with right posterior lesions tend to show disorders in which they have difficulty assembling parts into a coherent global whole. People with left posterior lesions tend to show a different pattern, with difficulties representing individual elements of global patterns. The question then arises whether these patterns of hemispheric difference are shown early in development, which would suggest that the two hemispheres have native preference for processing different aspects of spatial information. Joan Stiles and colleagues studied young children who sustained early injury to the right vs left hemisphere. They found that the patterns seen in adulthood are also present in early childhood. For example, children with right hemisphere damage typically perform more poorly than those with left hemisphere damage on tasks requiring them to assemble blocks to copy an existing spatial design. In contrast, children with left hemisphere damage tend to have more difficulties breaking up a global pattern into its individual components. These different patterns are not as pronounced as in adults, but according to Stiles they are qualitatively similar. Moreover, children recover to some extent, ultimately producing constructions that are qualitatively similar to those of normally developing children. The mechanisms by which such recovery takes place are not well understood, but compensation by recruiting new kinds of strategies is likely to be partly responsible for recovery of function. The early existence of some degree of hemispheric specialization for spatial cognitive functions suggests that the right hemisphere may be innately privileged in its capacity to represent the spatial relationships among elements.

B. Specialization

Early specialization is also suggested by recent studies of individuals with Williams syndrome (WS), a rare genetic disorder caused by a hemizygous submicroscopic deletion of chromosome 7q11.23, which includes the gene for elastin (ELN) as well as a number of other genes, including the gene for protein LIMK1. Children and adults with WS show a characteristic cognitive pattern that includes overall mild to moderate mental retardation (mean IQ = 55–60) as well as a unique profile of profoundly impaired spatial cognition, together with relatively spared language. These relative strengths and deficits are shown from quite early in development, suggesting a link between the deleted genes and the development of the brain's functional capacities. The gene producing the LIMK1 protein is thought to be implicated in the spatial disorder because it is strongly expressed pre- and postnatally in the brain, whereas ELN is not.

The spatial impairment shown by individuals with WS has been demonstrated most often in tasks requiring them to copy a model, either by drawing it in an adjacent space or by assembling individual blocks to create an overall design. Typically, individuals with WS have great difficulty in creating the appropriate spatial relationships between individual elements, as shown by the sample drawings in Fig. 12. Although individuals with WS do show some developmental progression, they do not show the same degree of recovery as children with right hemisphere lesions; even adults with WS show striking and profound spatial impairment in this task.

Currently, the causes and nature of the spatial impairment in WS are not well understood. Hallmark tasks such as drawing and block construction most likely draw on numerous capacities that are difficult to isolate for tasks of such complexity. However, there is growing evidence that the spatial impairment does not affect all domains of spatial organization equally. For example, individuals with WS do not appear to be significantly impaired in the capacity to recognize faces, even under conditions of unusual orientation and lighting. They are capable of recognizing familiar objects under nonoptimal viewing conditions, such as when the images are blurred, or present objects in unusual orientations. They are capable of perceiving biological motion displays, which require the construction of coherent global figures from information conveyed through the motions of individual points of light. The uneven profile within spatial cognition thus suggests that the genetic deficit may target certain spatial cognitive capacities while leaving others unaffected.

C. Causes of Reorganization

There is strong evidence for plasticity in the developing brain. Recovery of function among children with right hemisphere damage is one example of such plasticity.

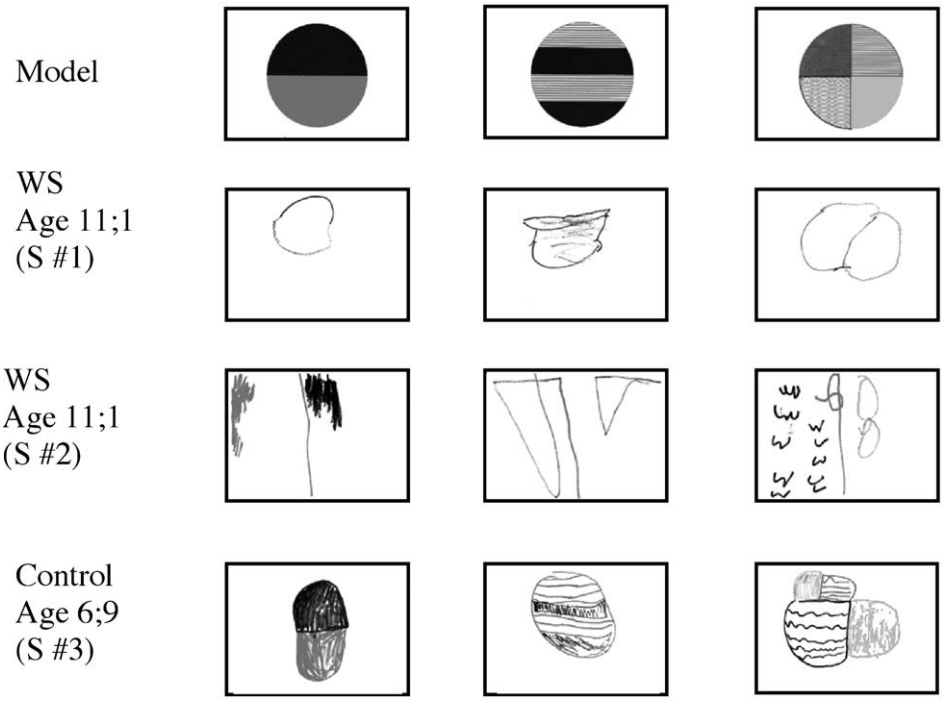

Figure 12 Children with Williams syndrome have great difficulty copying visible models. The top row shows three models that were copied by two children with Williams syndrome (rows 2 and 3) and one normally developing child who was their mental age match (row 4).

Other evidence suggests that changes in early experience can have a major impact on the organization of the cortex. A number of studies have shown that depriving the organism of input from a given set of sensory receptor surfaces leads to reorganization in which the cortical areas normally representing the input are "taken over" by other kinds of input. For example, in adults, amputation of a limb can lead to reorganization of the cortex whereby the area of the cortex that previously represented the limb becomes responsive to stimuli from inputs that are normally represented in adjacent areas of the cortex. Congenitally blind individuals show activation of areas normally considered visual cortex during tasks that engage the somatosensory systems. This suggests that the area normally "designated" as visual cortex may be commandeered to represent other systems when a person has no vision. Thus, the cortical representation of a particular input may become expanded or contracted through major alterations in the organism's experience.

A clear example of such reorganization in the spatial domain has been described by Helen Neville and colleagues, who studied spatial attention in congenitally deaf individuals compared to hearing individuals. They found that responses to stimuli presented *centrally* (i.e., to the fovea) in the visual field were similar in both groups, both in terms of behavioral accuracy and event-related potential (ERP) responses. In contrast, responses to stimuli presented *peripherally*, either in the right or left visual field, showed significant differences across groups. Deaf individuals showed increased ERP responses to peripheral stimuli, relative to hearing people, and the distribution over scalp regions was different. Whereas hearing individuals predominantly showed responses over the parietal region contralateral to the stimulus, deaf individuals also showed bilateral responses over the occipital region. Complementary studies of hearing individuals who were born to deaf parents and whose native language was a sign language showed that congenital deafness, and not the experience of acquiring a spatial–manual language, was responsible for the pattern of brain activation among the deaf individuals. These results suggest that congenital auditory deprivation can lead to cortical reorganization in which there is enhanced responsiveness to peripheral stimuli.

Additional evidence, from both animal models and studies of the human visual system, suggests that the representation of peripheral visual space is carried along the dorsal pathway toward the posterior parietal cortex, which is important for the representation of spatial location. In contrast, the representation of central visual space is carried along the ventral pathway, which is important for the representation of form.

Based on evidence from comparative studies of deaf and hearing individuals, as well as evidence from animal models and neuroanatomy, Neville and colleagues suggested that the development of the dorsal stream may be more subject to effects of early experience than that of the ventral stream. The modifiability of peripheral visual attention consequent on deafness (relative to central visual attention) is consistent with this notion. Additional studies have shown that congenitally deaf individuals exhibit selectively enhanced processing of stimuli that are normally processed by the dorsal stream.

V. CONCLUSIONS

Spatial cognition is a broad area of inquiry that can be informed by studies of the mind and brain, including their organization, function, and development. This article provided a selective summary of evidence supporting a high degree of specialization within the domain of spatial cognition, limited and highly specialized interactions among these subsystems, and a strong native basis through which developmental process can act to modify spatial organization. We are only beginning to understand the detailed nature of the spatial systems the nature of the mechanisms that support the interface among these systems. However, the progress that has been made shows that rich and detailed organization in the mind and brain supports our capacity to negotiate the spatial world.

Spatial Vision

RUSSELL L. DE VALOIS and KAREN K. DE VALOIS
University of California, Berkeley

GLOSSARY

adaptation Change in sensitivity to a pattern resulting from prolonged exposure to that pattern.

columnar organization The cells extending in a column from the surface of the cortex to the white matter, all of which share common stimulus selectivities.

modular organization The subdivision of the striate cortex into about 1500 modules, each containing approximately 200,000 cells analyzing information from a specific region of the visual field.

receptive field The receptive field of a cell consists of all those receptors that provide input to the cell or, equivalently, the delimited directions in visual space from which stimuli activate the cell.

receptive field organization The spatial and temporal arrangement of the excitatory and inhibitory portions of a cell's receptive field.

retinotopic organization An arrangement of the cells at some processing level in which the general topographic arrangement with relation to the photoreceptors is maintained, even though some portions might be magnified with respect to others.

spatial frequency The frequency of sinusoidal variations in light across space, specified in cycles per degree visual angle.

visual angle The angle at the pupil subtended by an object in the visual field.

The information obtained by the photoreceptors in the eye provides the primary basis for our information about objects in the world around us, about their characteristics and their spatial locations. Obtaining useful information about the world from the receptor outputs, however, involves a number of very complex computational tasks. The visual information from objects, most of which do not emit light but only reflect a certain proportion of light that falls on them, needs to be disentangled from that from the illuminant. There is a massive amount of information in the visual image and the computations need to be completed in a very brief amount of time. The image of the environment on the receptors is greatly underspecified since there are many possible stimuli that could have produced any particular image. Approximately one-third of the brain is devoted to vision, and many of the processes by which it solves these and other problems are not well understood. We discuss how the initial stages of spatial vision appear to operate.

I. PROBLEMS TO BE SOLVED

One of the most difficult problems in understanding how the visual system works is in realizing that there is a problem to be solved. We open our eyes and instantly see in front of us a scene made up of, for example, trees and grass and people coming out of a building, objects of different colors and shapes at different distances, some moving and some stationary. We perceive all this so effortlessly that it feels as if it must be a simple process. Nothing could be further from the truth. It is in fact an incredibly complex process, by far the most difficult problem the brain must solve. Tens of billions

of cells, about 35% of the whole neocortex, are devoted to analyzing and interpreting the output of the visual receptors. Although we perceive objects of various shapes and characteristics, those percepts are constructs of the brain. The only signal coming from each photoreceptor (100 million rods and 3–5 million cones) is in effect a single number corresponding to how many photons that receptor has absorbed at a particular instant. The brain must determine what in the outside world could have reflected light into the eye to produce that particular enormous set of numbers. Furthermore, the brain has only about 200 msec or less to carry out this computation before an eye movement leads to a new set of millions of numbers.

The problem facing the visual system is made even more daunting by the fact that the numbers put out by the receptors are by themselves largely meaningless. Unlike some other senses, the visual system does not obtain information directly from objects in the world but only visual echoes from light reflected from objects. Objects make sounds and emit odors and can be identified by the auditory and olfactory systems from these emissions, but with few exceptions objects in the natural world do not emit light; they merely reflect a certain proportion of whatever light falls on them. Furthermore, almost all the variations in photon absorption over a day are due to the variations in the intensity of the illuminant and have nothing to do with the color, brightness, or any other identifying characteristic of visual objects. The intensity of illumination from the sun rises and falls by huge amounts over the course of the day and as clouds pass by. The difference in the amount of light reflected from one object as opposed to another is very much smaller. The whitest object in a scene reflects perhaps 80% of the incident light and the blackest object perhaps 10%. The variations due to the object of interest are thus at most only about eightfold, whereas the illuminant may vary by a factor of 10 million. Strictly speaking, this is an unsolvable problem because each receptor puts out only one number (corresponding to the number of photons it has absorbed) and this is a product of both the illuminant and the reflectance of the object at that point in the image. Since we have no independent knowledge of the illuminant, this is in effect one equation with two unknowns. The only way the visual system can gain information about visual objects is to compare the outputs of different receptors and make certain assumptions about how objects differ in their visual properties from the illuminant. Much of the early processing of spatial information reflects the way the visual system deals with this problem.

The analysis of spatial information, from the capture of light by the photoreceptors to the cortical levels associated with perception and the organization of a motor response, is a sequential process involving about a dozen synaptic levels—a dozen successive levels of analysis. At the early stages, there is massively parallel processing: Each small region of visual space is analyzed largely independently by a few of the millions of neurons at that level. At successive early stages, the information is combined over increasingly larger regions but still in a massively parallel way. Such parallel processing enables the nervous system, with its relatively slow processing abilities, to nonetheless carry out the immense computations required in the brief time available between fixations.

The first five or six processing stages [in the retina, the lateral geniculate nucleus (LGN) of the thalamus, and the striate cortex] isolate and encode in a useful form that component of the retinal image that is due to reflective objects. We understand fairly well the anatomical structures, the physiological processes, and the contribution to vision of these early processing levels. Beyond the striate cortex, however, are 25 or more later visual areas. Here, the visual system must be dealing with the problems of segregating the visual information from different parts of the scene into separate objects and identifying the nature of each object. We currently have only very fragmentary evidence about and a very incomplete understanding of how this is accomplished.

II. OPTICS, SAMPLING, AND VISUAL ACUITY

The cornea and, to a lesser but variable extent, the lens form a two-dimensional image of the visual world at the level of the receptors at the back of the eye. The receptors sample the image as the first step in spatial vision. The optical quality of the human eye is not very good—well below that of the cheapest camera lenses. Two of the most prominent imperfections are spherical and chromatic aberrations. The former results from the cornea's imperfect shape, and the latter occurs because the cornea and lens differentially refract light of different wavelengths. Both of these aberrations become worse as the pupil of the eye increases in diameter, as it does in order to capture more light under dim light conditions. An imperfect image also results from the imaging of a three-dimensional world on a two-dimensional surface since objects at different distances are not all simultaneously in focus. Finally, the eye is mechanically unstable. It floats in fat within

the orbit, held fixed only by the tension in six relatively massive eye muscles. These muscles can rotate the eye in different directions very rapidly, but they cannot hold it very still because of the random firing of the individual muscle fibers. The eye thus oscillates rapidly in a random fashion and drifts about to some extent as well. The resulting blur is made worse by observer movement, both translating the eye through space (which blurs the image) and jarring it.

Visual stimuli can be equivalently described in the space domain (i.e., by how much light is present at each location in space) or the spatial frequency domain (by the frequency, amplitude, and phase of sinusoidal variations in light intensity across space). Although space–domain descriptions are more familiar, there are sometimes heuristic advantages to examining visual problems in the spatial frequency domain instead. The various optical imperfections of the eye mentioned previously all blur the image on the retina, and blur selectively attenuates high spatial frequencies. Our ability to detect sinusoidal gratings of different spatial frequencies is described by the spatial contrast sensitivity function (CSF) (Fig. 1). In photopic (daylight) vision under optimal conditions, the CSF function peaks at about 4 cycles per degree, and a person with excellent acuity can resolve gratings as high as about 60 c/deg visual angle at the fixation point. "Normal" acuity (20/20 in American notation) is equivalent to a high spatial frequency cutoff of 30 c/deg. Under many viewing conditions, however, such as when the illumination level decreases (see Fig. 1), with increasing retinal eccentricity, or when we are moving and thus blurring the retinal image, the resolution of a normal observer does not exceed 10–20 c/deg. In these circumstances, tasks such as reading that require high acuity become impossible, but we still have excellent ability to segment the visual world into different objects and to recognize these objects and their spatial relationships.

The CSF shows both high and low spatial frequency attenuation. The decrease in sensitivity of the CSF at high spatial frequencies is in part a consequence of the various types of optical blur discussed previously, but it is also related to sampling by receptors and later neural components. The reduction in sensitivity at very low spatial frequencies has another, purely neural, explanation (discussed later).

Studies of the spatial characteristics of natural scenes have shown that most of the important visual information lies not in fine detail but at much coarser scales. The amplitude spectrum of most natural scenes decreases with increasing spatial frequency by approximately 1/f. Thus, most of the information is at

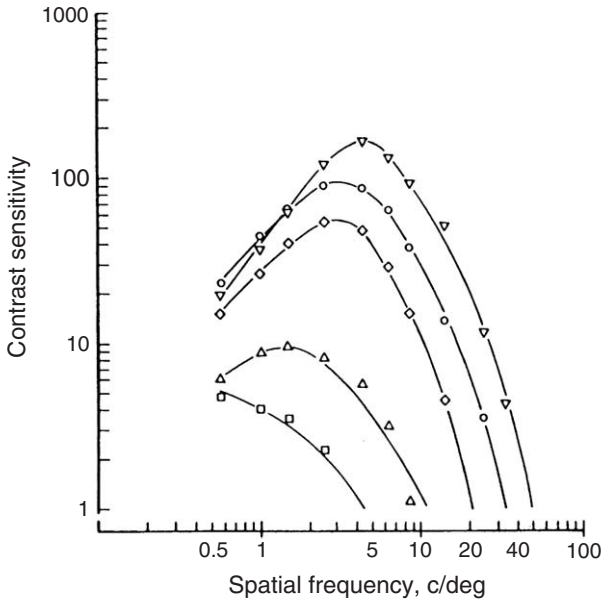

Figure 1 The mean spatial contrast sensitivity of five observers for gratings of different spatial frequencies at each of five different luminance levels, in one log unit steps from photopic (top curve) to scotopic (bottom curve) levels (reproduced with permission from De Valois *et al.*, *Vision Res.* **14,** 75–81, 1974).

mid to low spatial frequencies, and gaining information about the low spatial frequency content of the image is doubtless much more important in most circumstances than detecting the very highest spatial frequencies. This is fortunate because the optic nerve bottleneck would not allow the huge number of fibers required to transmit all the high spatial frequency information in any case.

Just more than two samples per cycle of a sine wave of a particular frequency are necessary and sufficient to resolve it and all lower frequencies. Thus, if the optics of the eye pass up to 60 c/deg, sampling by 120 receptors/deg should capture all the information in the retinal image. This is in fact approximately the spacing of cones in the very center of the human fovea, the foveola, where the cones are very thin and tightly packed together. Furthermore, there are advantages in having the neural sampling comparable to, neither better nor worse, the highest frequencies passed by the optics. Thus, our eyes' optics are approximately optimally matched to the density of cones in the fovea.

Outside the central 20–30′ of the foveola, the cones become increasingly larger and widely spaced. Near the edge of the fovea, rods begin to appear interspersed among the cones, and by 2° from the center rods

surround each cone, further separating them. With increasing eccentricity, there is also increasing convergence of cones onto later neural elements, with a further loss of detailed vision. The highest spatial frequencies the system can resolve photopically (when only cones are functional) must and does therefore decrease as retinal eccentricity increases, but low spatial frequency information is captured even out to the far periphery. This system of gaining high spatial frequency information only within a very limited region of the image only works because we can move our eyes and inspect in greater detail any desired part of the visual world. Animals with less mobile eyes have quite a different organization.

Rods are as small as foveal cones and are densely packed between cones so they could potentially sample the image with high resolution. However, our acuity under scotopic conditions (dim light levels when only rods are functional) is very poor, with contrast sensitivity cutting off at less than 10 c/deg. In this case (and also to a lesser extent for cones in the far periphery), it is clear that the effective sampling unit is not the receptors but the later neural elements. Anatomical observations support this, showing considerable convergence of rods onto rod bipolars and rod bipolars onto ganglion cells. Two adjacent scotopic "samples" of the image, then, would each cover an area containing dozens to hundreds of rods, not just one, and would be separated by the diameter of dozens or hundreds of rods.

III. TRANSDUCTION AND ADAPTATION

Two of the most critical retinal functions are to transduce light energy into neural activity and to transform the information into a usable form. The transduction of light energy into the flow of ions across nerve membranes, the language of the nervous system, takes place in the outer segments of the receptors. The capture of a single photon of light by a uniquely sensitive photopigment, rhodopsin (or the similar cone opsins), converts rhodopsin into an enzyme and initiates a cascade of chemical reactions within the cell. The cell membrane is maintained in a partially depolarized state at any illumination level. Variations in the chemical cascade produced by momentary increases or decreases in the amount of light absorbed produce momentary changes in polarization of the membrane. A decrement in light absorbed depolarizes the membrane; an increment in light absorbed hyperpolarizes the membrane. The resulting current flow is conducted to the synaptic region of the receptor, which then secretes synaptic transmitter in proportion to the amount of depolarization.

The cascade of chemical reactions within the outer segment provides the amplification necessary to bridge the enormous energy gap between a single photon and the flow of ions across a membrane. It also has other effects directly relevant to spatial (and temporal) vision. It is a slow process spread out over several milliseconds. This introduces a significant delay into the visual response, but it also provides for useful temporal integration to increase sensitivity. The resulting smearing in time filters out high temporal frequencies that, in the case of vision (as opposed to audition), are not informative because they are mostly noise due to quantum fluctuations. Few objects in the natural world produce informative variations in light at very high temporal frequencies. Temporal information in vision is particularly useful for detecting motion, but this can be accomplished without sensitivity to high temporal frequencies.

The chemical cascade within the receptor outer segment also contributes to the solution of the problem of separating the signal due to reflective objects from that due to the illuminant. Although we cannot know the illuminant, there are certain differences between visual objects and illuminants that the visual system exploits to deal with this problem (although not without occasional large errors). The visual system correctly makes the assumption that light from the illuminant tends to be uniform over large spatial and temporal extents, whereas reflective objects of visual interest usually vary across space and also across time as we move our eyes. Therefore, the visual system in effect treats any part of the image that is largely invariant in space and time as if it were due to the illuminant and ignores it, whereas parts of the image that change more rapidly in space and time are considered to come from reflective objects and are further analyzed. Any process that strongly attenuates very low spatial and temporal frequencies will selectively attenuate signals from the illuminant, thereby allowing the visual system to detect and process the small variations due to objects in the presence of larger variations in light intensity due to the illuminant.

The attenuation of very low temporal frequencies starts within the photoreceptors. A feedback circuit in the receptor outer segment reduces responses to steady illumination while passing responses to transient increments and decrements. Functionally similar interactions occur at later neural levels as well so that most cortical cells respond poorly to any unchanging

stimulus. The attenuation of very low spatial frequencies is also a multistage process, and it starts at the first synaptic level.

To deal with the vast, but largely irrelevant, changes in light level over a day, not only low temporal and spatial frequency attenuation but also variations in sensitivity with light level are required. Light and dark adaptation refer to the processes by which the visual system adjusts its sensitivity as the illumination level increases and decreases. A white object might reflect 80% of incident light and a slightly grayer one 70%. In bright daylight, there might be 10 million incident photons/sec/unit area so these two surfaces would reflect 8 million and 7 million photons/sec/unit area, respectively. However, on a dark night, the illumination might be only 1000 photons/sec/unit area and the two surfaces would then reflect only 800 and 700 photons/sec/unit area, respectively. To distinguish between the two surfaces under these dim conditions, the visual system would need to be 10,000 times more sensitive. Furthermore, if the visual system did not change its sensitivity as illumination levels changed, objects would not maintain constant appearance.

Many of the adaptational sensitivity changes required to maintain object constancy take place within the receptors. The decrease in sensitivity going from dark to light is fast, but the reverse change can be very slow (as one notices on entering a dark theater from a brightly lit street). The breakdown of photopigment molecules upon light capture is fast but the regeneration of the photopigment is very slow, and the presence of unregenerated photopigment molecules sends a signal that slows the increase in sensitivity when one suddenly enters a dark environment.

IV. RETINAL ORGANIZATION

The optic nerve is a serious bottleneck in the visual path, constraining early processing. This is largely a consequence of the inversion of the retina in the vertebrate eye. The photoreceptors lie at the very back of the eye, distal to all the retinal circuitry. The ganglion cell axons, which carry the eye's output to the brain, are inside the eye. They exit through a hole in the receptor layer of the retina (at the optic disk, forming the blind spot). There are approximately 100 million receptors in each eye, and perhaps 2000 million cells in the cortex that process their output, but each optic nerve contains only 1 million axons. Getting even this relatively small number of fibers out of the eye produces a blind spot large enough to encompass more than 50 nonoverlapping images of the moon. Any larger number of ganglion cell axons would be self-defeating. This organization puts a considerable constraint on the visual system, limiting the extent and nature of processing that takes place in the retina.

The output of the receptors is processed at two synaptic levels in the retina and at one level in the LGN of the thalamus before arriving at the cortex. There is a direct anatomical path from receptors to bipolars to ganglion cells, with lateral connections made by horizontal and amacrine cells at their respective levels bringing in information about neighboring regions. At each stage, the output of a small group of receptors (to which the bipolars, and through them the ganglion cells, are directly connected) is compared with the output of a larger group of receptors (to which the bipolars and ganglion cells are connected through the horizontal and amacrine cells). The lateral inputs at each level are opposite in sign to the direct inputs, so each ganglion cell reports the difference between the extent of activation of two different populations of receptors. All the receptors that feed into a particular cell constitute its receptive field (RF). The RF of a ganglion cell thus consists of a center region responding to light decrements and a surround responding to light increments or vice versa. The spatial extent of an RF can vary from a tiny region in the foveal representation to a much larger region in the periphery.

A neural organization that is seen only to a limited extent in the retina but very frequently at cortical levels is a second type of parallel processing. In addition to parallel processing of information from different retinal regions, the visual system separately processes different types of information within each small region. The output of each receptor feeds up to the brain along several paths, in each of which its output is compared with different combinations of other receptors. There are three main paths or channels in the retina, with various subtypes of cells within each. The magnocellular or (Mc) pathway leads from receptors to diffuse bipolar cells to parasol ganglion cells. Their axons, in turn, project to the Mc layers of the LGN. The parvocellular (Pc) path leads from receptors to midget bipolars to midget ganglion cells, the axons of which project to the Pc layers of the LGN. All the long (L)- and middle (M)-wavelength-sensitive cones feed into both of these paths, but different analyses of their outputs are carried out in the two cases. In addition, the relatively few short-wavelength-sensitive (S) cones feed down a separate koniocellular (Kc) path. This system is involved almost exclusively with color vision and will not be further discussed here.

A diffuse bipolar cell in the central retina makes direct contact with about six cones, but it receives indirect input from many other cones by way of the lateral contacts made by the horizontal cells. The direct bipolar connections and the horizontal inputs come from both L and M cones but not from S cones. The important point is that the direct and indirect inputs produce opposite effects; that is, if the direct input from receptors depolarizes the bipolar, then the indirect input from receptors by way of the horizontal cells hyperpolarizes the bipolar. This variety of bipolar thus sums the output of a small group of L and M cones in a region and subtracts that from the sum of the outputs of a larger group of L and M cones.

There are two subtypes of diffuse bipolars that feed separately up the Mc pathway. One subtype receives direct excitatory input from receptors. Its center mechanism is depolarized by decrements in light absorption, just as are receptors. The other bipolar subtype inverts the receptor signal, so it is depolarized by increments in light. Each L or M cone feeds into one or more of each of these bipolar types. Recall that the crucial information for vision is not the absolute light level, which is due mainly to the illuminant, but the increments and decrements from this mean level that characterize reflective objects. For a single cell to encode both increments and decrements equally well would require a very high (and thus metabolically expensive) average maintained firing rate. By having some cells that respond with excitation to increments and others that are excited by decrements, the visual system doubles its capability to transmit the information, eliminates the need for a high maintained firing rate, and ensures that the important signals about increments and decrements are equally represented in the message to the brain.

In addition to the synapses each L and M cone makes with diffuse bipolars, each L and M cone also feeds into two midget bipolar cells, one sign retaining and one sign inverting, in the Pc pathway. In the whole central 70° or more of the retina, each midget bipolar cell makes direct contact with just a single cone. Of course, other cones are contacted indirectly by way of the horizontal cells. Thus, there are four types of midget bipolars and four types of midget ganglion cells into which the midget bipolars feed. The midget bipolars also make contact with several horizontal cells, which bring in opposing information from neighboring L and M cones. These cells thus report the difference between the activation in one particular L or M cone and the activation of a small group of neighboring L and M cones.

Cells in the Mc and Pc pathways thus differ with respect to their chromatic properties since color information lies in the difference between the activation of receptors with different spectral sensitivity. The cone inputs to RF center and surround are the same in Mc cells (M + L in each case), whereas the RF center of each Pc cell (in the central retina) is derived from one cone type and its surround from a different cone type. The Mc cells can thus convey information about increments and decrements from the mean luminance level, luminance contrast, but they cannot convey information about chromatic differences. Cells in the Pc pathway, on the other hand, convey information about both color and luminance. They multiplex these parameters. Because of their radially symmetric RFs, cells at this level have minimal selectivity for the shape of objects, nor do they have selectivity for motion or, of course, for depth. All of this changes at the cortex.

V. RETINOTOPIC ORGANIZATION AND CODING

The optics of the eye forms an image of the world on the receptors. Except for the fact that the image represents a two-dimensional projection of a three-dimensional world, spatial relationships in the visual world are faithfully represented in the receptor activation pattern. Adjacent receptors receive light from adjacent visual directions, and two receptors spaced, for example, 100 μm apart are stimulated by points about equally far apart in visual angle in the image, regardless of whether the two are in the fovea or in the far periphery. Both of these properties break down in the retinal processing and projection to the cortex—the adjacency relationship to a relatively minor extent and the equal separation one to a major extent.

There is an approximate retinotopic organization through the retina and geniculate in terms of adjacency relationships, with neighboring retinal regions projecting to neighboring cortical areas. However, the topographical map becomes grossly distorted because of the far greater number of cells processing information from the fovea than from the peripheral retina. To a first approximation, the number of ganglion cells decreases approximately proportional to the log of the distance from the fovea. Thus, an annulus on the retina extending from 1° to 2° contains about the same number of ganglion cells as an annulus from 10° to 20°, although the latter covers a region 100 times as large in visual space.

The striate cortex, as opposed to the retina, contains many cells that are selective for the presence of certain

precise local stimulus characteristics. They show excitation only if the local stimulus contains their particular set of required features. Retinal information, however, is compactly coded for maximum efficiency of transmission through the bottleneck of the optic nerve. Each ganglion cell responds to many different spatial patterns, independent of the local orientation and largely independent of spatial frequency, whether the object is moving or stationary, etc. The fact that a particular ganglion cell responds thus indicates relatively little about the nature of the stimulus. The information is carried instead in the relative firing rates and locations within the array of each of a number of cells. In the striate cortex, on the other hand, the information is more sparsely coded. Each cell responds if and only if the information in its local region is within the particular range of spatial frequencies, orientations, etc. to which the neuron is tuned. The majority of the cells within a cortical region will not fire at all to most stimuli (hence the term "sparse coding"), but when a particular cell fires it conveys a great deal of information about the stimulus in that region: It must be a pattern of *this* orientation and *this* spatial frequency, and so forth.

VI. MODULAR RETINOTOPIC AND COLUMNAR ORGANIZATION

There is a purely spatial representation of visual information at the level of the receptors, in which adjacent receptors respond to light from adjacent points in visual space. The first visual cortical area (V1) is broken up into approximately 1500 cortical modules, each containing about 200,000 neurons that deal with a particular separate subregion of the visual field; thus, the cortical locus of activity also specifies to some extent the location of the stimulus in visual space. But within each cortical module, there is a functional organization, as a consequence of which adjacent neurons may be receiving input from the same region in visual space but differ from each other in their functional properties. Each striate cortex cell receives input from a particular combination of geniculate fibers, with neighboring cells receiving different combinations of outputs from the same group of fibers. Thus, if one cell as opposed to an adjacent one fires, this does not necessarily signal that the stimulus is in one location rather than another but rather that the stimulus in a particular location has a certain orientation or spatial frequency rather than another. This modular arrangement in the cortex can be seen as a compromise between a purely spatial, retinotopic representation and a functional representation. Each individual V1 neuron thus carries information both about the spatial location of the stimulus and about the nature of the stimulus at that location. The cells within each of the V1 modules perform the same sorts of stimulus analyses, although over different scales depending on eccentricity.

VII. SELECTIVITIES

The most important spatial processing within the striate cortex is the production of cells selective for only certain values along each of various spatial stimulus parameters. Correlated with this stimulus selectivity is the production of multiple channels of a group of neurons each responsive to a different portion of a given stimulus dimension. Cells in the striate cortex receive input from larger spatial regions than do cells earlier in the path, but they still perform a local analysis of the visual information, being only minimally responsive to whatever is present in any but their relatively small part of the visual field. However, they do not respond to every pattern within their local region. Rather, the effective stimulus for any given cell must have certain specific properties.

Most neurons in V1 are selective for stimulus orientation. They respond to a bar or grating within their RF only if it is within a certain range of orientations, with the optimum orientation varying from cell to cell. There is a considerable range of orientation bandwidths among cells in the primate striate cortex, with the median bandwidth at half-maximum-amplitude response being about 45°. Therefore, although LGN cells have little or no orientation tuning, responding equally well to patterns of any orientation, a typical striate cortex cell will respond only to patterns of about one-fourth of the total range of possible orientations. Within each cortical module are cells tuned to each of many different orientations.

Most V1 cells are also quite narrowly tuned to sinusoidal gratings of different spatial frequencies. LGN cells have a small degree of spatial frequency selectivity for luminance-varying patterns, but a typical neuron in V1 is much more selective, with a median bandwidth of about 1.4 octaves, which (like their orientation selectivity) encompasses about one-fourth of the total range to which we are sensitive. Cells tuned to each of many different spatial frequencies are found within each cortical module. The overall CSF is thus the envelope of the contrast sensitivity functions

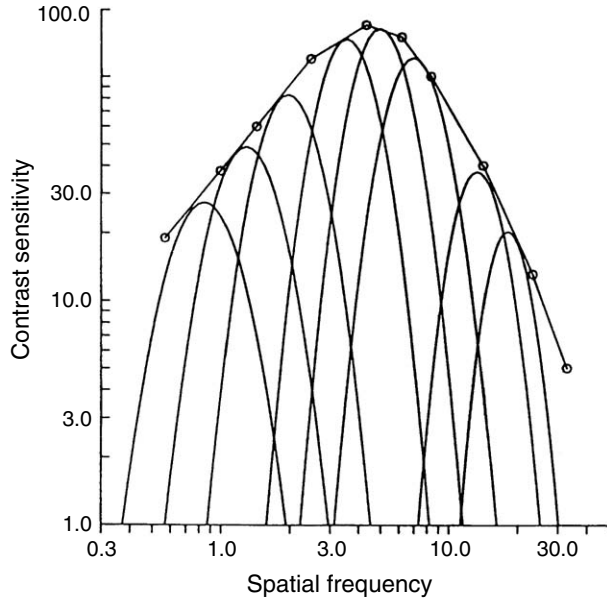

Figure 2 A diagram of how the overall contrast sensitivity function reflects the sensitivities of multiple separate spatial frequency channels whose selectivities correspond to that of various cells within a single module of a foveally related region of striate cortex.

of these multiple units tuned to various different spatial frequency ranges (Fig. 2). Cells in the foveal representation are tuned to various points covering the total spatial frequency range to which we are sensitive, but those cells tuned to the highest spatial frequencies are progressively lost with increasing retinal eccentricity. In V1 are also found, for the first time, neurons selective for the spatial frequency of chromatic- as well as luminance-varying patterns.

Evidence for the kinds of selectivity found in V1 neurons comes from psychophysical as well as physiological studies. After inspecting a high-contrast grating of a particular spatial frequency and orientation for approximately 1 min, an observer becomes less sensitive to that pattern for a short period of time. This reflects a type of gain control process by which the visual system deemphasizes unchanging aspects of the environment to facilitate the capture of information about change. However, adaptation to a grating of one spatial frequency produces no loss in sensitivity to patterns of a quite different spatial frequency, thus indicating the presence of cells with fairly narrow spatial frequency tuning and of multiple spatial frequency channels. This loss in sensitivity to a grating of one spatial frequency may also result in a temporary change in apparent spatial frequency of patterns seen shortly afterwards. A grating of a slightly higher spatial frequency than the adapting pattern will appear to be higher still, and one lower in frequency will appear to be lower still. Similar selective sensitivity losses and aftereffects are seen following adaptation to a pattern of a particular orientation.

Masking experiments also reveal spatial frequency and orientation selectivity. Detection of a pattern of a particular spatial frequency and/or orientation is interfered with (masked) by a high-contrast grating of similar spatial frequency and orientation but not by gratings of very different spatial frequency or orientation. The relatively narrow bandwidths of the masking and adaptation losses in spatial frequency and orientation sensitivity are similar to the bandwidths of spatial frequency- and orientation-selective cells in the striate cortex.

Cells with both particular orientation and particular spatial frequency tuning encode the two-dimensional spatial frequency spectrum of the pattern within the small region of the visual world with which they deal. At the receptors, spatial information is encoded purely in the space domain. Through the retina and particularly at the striate cortex, spatial information is transformed from the space domain into the local spatial frequency domain (combined space and spatial frequency) by filtering through these multiple cells within each cortical module that are selective for a certain narrow range of spatial frequencies and orientations (Fig. 3). Given the typical orientation and spatial frequency bandwidths of cells, the two-dimensional spatial frequency spectrum of a pattern could be specified by the relative activity of cells tuned to each of about six different spatial frequencies at each of six orientations, thus about 36 cells in each region. A sine-wave grating pattern of a particular spatial frequency and orientation might significantly activate only 1 of these 36 cells; more complex patterns would activate a small number of cells. Therefore, which few cells in a region fire would uniquely define the spectrum of the local stimulus in that region.

Spatial frequency and orientation selectivity not only play important roles in encoding useful spatial aspects of a stimulus but also contribute crucially to two other types of selectivity seen at the striate cortex level: selectivities for motion and for stereoscopic depth.

About 20% of V1 cells will respond to a pattern of a particular two-dimensional spatial frequency only if that pattern is moving in the cell's preferred direction. Such neurons thus extract a local motion signal. A moving object is by definition at one location at time 1 and at a different location at time 2. The motion can be

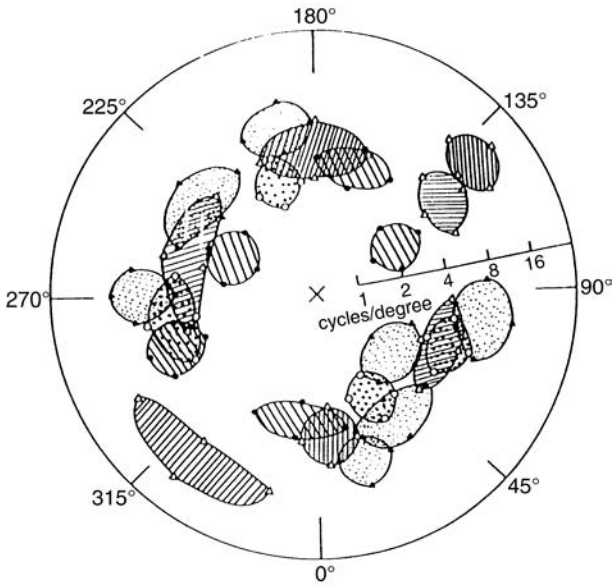

Figure 3 The two-dimensional spatial frequency response fields of 20 neurons recorded from within a single region of macaque monkey striate cortex. It can be seen that each of these cells responds to only a limited range of spatial frequencies and orientations (reproduced with permission from De Valois *et al*., *Vision Res*. **22,** 545–559, 1982).

detected by comparing the activity at these two locations at these two times. However, deciding what to compare with what at the two time intervals is a nontrivial task known as the correspondence problem. It can be demonstrated by considering how one might detect the motion of certain dots in a random dot pattern, in which each dot at time 1 could potentially be related to any one of several different identical dots at time 2, with each combination signaling local motion in a different direction. With prefiltering of the pattern into multiple local two-dimensional spatial frequency channels, the problem is vastly simplified. Neighboring regions would differ in their two-dimensional spatial frequency spectra rather than having numerous identical dots. Because only two local patterns of the same orientation and spatial frequency at the two different times would be combined, there would thus be many fewer false matches. Within each cortical module, dealing with stimuli from a certain small region of the visual field, there are thus multiple local motion detectors. Each responds only to patterns of a particular spatial frequency moving in a particular direction.

The light from a point that is binocularly fixated stimulates corresponding locations in the two eyes (e.g., a point 2° to the right of fixation in the visual field would stimulate a point 2° to the temporal side of the fovea in left eye and a point 2° to the nasal side in the right eye). Objects in the visual field that are closer or further than the fixation plane, however, stimulate noncorresponding, disparate points in the two eyes, with the direction and amount of disparity signaling whether the point is nearer or further than the fixation plane and by what distance. The visual system uses this stereoscopic information as one of many cues to depth. The local binocular disparity is computed in the striate cortex by cells that combine input from the two eyes. Some cells receive input from corresponding regions in the two eyes and respond maximally to objects in the fixation plane. Other cells receive binocular input from various noncorresponding regions in the two eyes and respond best to objects in front of or behind the fixation plane. Again, as in the case of motion, only cells with similar two-dimensional spatial frequency tuning are combined, thus simplifying the correspondence problem. As with motion, there are separate systems processing stereoscopic information over each of a number of different spatial frequencies.

The spatial frequency and orientation filtering of inputs to the motion and stereoscopic systems not only contributes to solving the correspondence problem —that of knowing what to combine from one eye or at one moment with what from the other eye or next moment—but also allows for the perception of transparency. Often, there are different objects at different depths within a given region, such as a lion seen through grass in a field, or two objects moving in different directions in a region. The presence of multiple motion and stereoscopic systems, each selective for a different spatial frequency range, allows the visual system to deal with these situations.

Those with trichromatic color vision (about 99% of the human population) have in effect at least three of each of the previously mentioned sets of maps; we can discriminate the spatial frequency, the orientation, the motion direction, and the depth of patterns along each of three color axes (e.g., red-green, yellow-blue, and black-white). In fact, there are cells in striate cortex that have a variety of color specificities, and these color-specific cells also have spatial frequency and orientation selectivity, suggesting that local color-spatial maps (perhaps more than three) are produced at this level.

There are two quite distinctive cell types in the striate cortex, termed simple and complex cells, and these reflect two successive levels of processing. Like cells earlier in the pathway, simple cortical cells are color specific (using color in the broad sense to include black and white), and thus in response to grating patterns they are selective for spatial phase. The RF of a simple

cell might consist of an elongated region responsive to light decrements (black), with flanking regions responsive to white. This cell will be most sensitive to a black-white grating of a particular spatial frequency and orientation, in such a location that the black bars fall on the RF center and the white bars on the flanking sidebands. If black and white are reversed (if the grating is shifted 180°), the cell will be inhibited and a 90° shift will produce no response.

Complex cells within a given region of the striate cortex have much the same orientation and spatial frequency tuning as simple cells in the same cortical column, but they lack phase selectivity. In the previous example, a complex cell would respond to the black-white grating regardless of its spatial phase—to either a white or a black bar (or to red or green) in any position within its RF. Complex cells are first found in the striate cortex, and they are the predominant cell type in later cortical regions.

Simple cells have little if any maintained discharge in the absence of stimulation. Since they cannot fire less than zero even to a highly inhibitory stimulus, they give a half-wave rectified output to a grating pattern in different locations. Complex cells appear to sum the half-wave-rectified (and approximately squared since most simple cells have an expansive response nonlinearity) outputs of simple cells in different spatial phases in a local region. They thus maintain the two-dimensional spatial frequency selectivity of the simple cells but lose the phase selectivity.

Complex cells undoubtedly play many important roles in spatial vision. One probable role is in texture perception. Although some objects are spatially uniform over their extent, like a sheet of white paper, most objects and many backgrounds are textured to various extents. By characterizing the spatial spectrum of such textured regions, the visual system can differentiate an object from its background or distinguish one background from another. However, it is not necessary to identify the location of all the millions of edges in a patch of sand to distinguish it from say a patch of grass. Which cell, out of an array of complex cells tuned to different two-dimensional spatial frequency ranges, is most active would provide a very economical abstraction of the needed information over a small region.

VIII. LOCAL VERSUS GLOBAL PROCESSING

The RFs of bipolar cells extend over only a tiny area comprising just a small number of receptors; the RFs of ganglion cells are only slightly larger. At these retinal levels, each element in the visual system processes information locally, over just a few minutes of arc in the fovea. One of the primary changes that occur at the striate cortex is the development, in the foveal representation as elsewhere, of RFs of various sizes. These form the substrate for multiple spatial frequency channels. The largest of these striate cortex RFs can subtend a degree or more, even in the foveal representation. An area 1° in diameter in the fovea encompasses inputs from approximately 20,000 cones, but this is still a very small region compared with the sizes of many visual objects that the system must analyze. For instance, a person's face at ordinary conversational distance may subtend 10° or more. The processing beyond V1 must have a more global character, and one of the few clear facts we know about the properties of cells in various later cortical regions is that the RFs become increasingly larger at successive processing stages. Many neurons in the parietal and temporal lobes have RFs that encompass half the visual field or more. From the stand-point of the earlier discussion of retinotopic versus functional organizations, with successive synapses through the visual path there is a progressive decrease in a spatial, retinotopic representation and an increase in a functional representation.

More global processing is required in later cortical areas not only to encompass large objects but also to resolve ambiguities in local signals. One example is that of separating luminance variations due to reflected objects from those due to the illuminant. As discussed earlier, the primary assumption the visual system uses in accomplishing this task is that light from the illuminant is uniform across space. The attenuation of responses to spatially uniform patterns begins in the retina, but the larger RFs of neurons later in the pathway allow the system to discount the illuminant over larger areas than was possible in the retina.

A second type of stimulus ambiguity that can only be resolved at higher cortical levels is related to motion. Within the image of an object moving in a particular direction, local contours may be moving in a variety of different directions. A more global analysis is required to detect the overall direction of pattern movement.

IX. SEGMENTATION OF IMAGE INTO OBJECTS AND BACKGROUND

When we look at a natural visual scene, we perceive it to be made up of various objects: in a rural scene,

perhaps a group of trees, a cow or two in a grassy field, a barn, and a stream. It is so easy and natural for us to see the world in this way that it is difficult to realize that segmentation of the image into separate objects against a background is not automatically given by the visual input to the eye but rather is a product of visual processing. It represents a theoretical conclusion about the world reached after an elaborate analysis of the input by the visual system. The vast array of numbers put out by the receptors are transformed by the processing up through the striate cortex into the local two-dimensional spatial frequency domain. Although this domain has certain advantages for representing the spatial information, it is clear that the cells at this level "know" almost nothing about objects. They respond to the pattern in their local regions in much the same way whether that pattern is part of one object or another or just part of the background. A particular striate cortex cell might respond virtually identically to a vertical trunk of a tree, a vertical stripe on a zebra, or a vertical shadow of a branch as long as each of these patterns had the same two-dimensional spatial frequency content within the local region covered by the cell's RF. To parse a visual scene into objects requires a higher level, a more global analysis than takes place in the striate cortex. There is increasing evidence that the RFs of V1 cells are more complex than initially thought, with the responses to patterns within the classical RF being influenced to some extent by stimuli in neighboring regions and by feedback from later cortical areas. However, the influences of the "nonclassical" RFs of striate cortex cells are at best the first stage in object segregation. There must be further processing.

The problem of image segmentation, the grouping of local image components into visual objects, was first recognized and extensively studied in perceptual experiments by the Gestalt psychologists at the beginning of the 20th century. They explicitly raised the question of the principles by which the visual system puts together some but not other local components to form the percept of an object and to recognize its shape. Among the principles they identified were those of proximity (nearby components are more likely to be grouped together and seen as parts of one object than components further apart), similarity (components similar in characteristics such as color or orientation tend to be perceptually grouped together as parts of the same object), common fate (grouping can be based on common motion direction), and good continuation (a smooth contour is more likely than one with an abrupt change in curvature to be seen as forming the contour of a single object). The relative depths of different parts of a scene, based on stereopsis or other kinds of depth information, also provide powerful cues for breaking a scene into different objects and separating objects from the background. Although there have been many modern investigations of grouping principles, we understand relatively little about the rules for how the different grouping principles combine in image segmentation and about what happens when the different grouping cues conflict.

The early stages of neural processing through V1 provide analyses necessary for object segregation, with cells selective for spatial frequency, orientation, motion, color, and stereopsis. We can distinguish thousands of different colors and brightnesses, and this allows us to distinguish the contours of a chair of almost any color, for instance, on almost any color of background. However, it would not be feasible to have separate object segregation and form recognition systems for chairs of each of thousands of different colors against each of thousands of different backgrounds. Furthermore, upholstered chairs may differ from their backgrounds in thousands of different textures as well as in color. Required for scene segmentation and object recognition is a system that uses the information from the selectivities of V1 cells but then generalizes across various dimensions and combines like information from neighboring regions.

Complex cells in V1 generalize across dimensions to a limited extent in that they respond to a pattern of a particular spatial frequency and orientation regardless of color or spatial phase. This type of processing is further extended in V2, in which some cells have an orientation and direction tuning to contours regardless of whether the contour is formed by luminance or texture. The circuitry by which such cells are constructed has not been established, but a plausible mechanism is that these V2 cells sum the outputs of those cells in extended regions of V1 that have the same orientation and/or direction tuning but different spatial frequency and color tuning.

A common problem faced by the visual system in image segmentation and object identification is that an object is often partially occluded by other objects. A deer in a forest, for instance, might be partially obscured by a nearby branch. Such occlusion not only changes the shape of the object's image, thus making object recognition more difficult; it may also break the image of a single object into separate pieces, thus making it difficult to see all the separate parts as

belonging to a single object. Some cells in the second cortical visual area (V2) appear to deal with the problem of occlusion over limited regions. They respond to two colinear borders even if there is a gap in the middle, as would be produced by a nearby occluding object.

X. TWO PROCESSING STREAMS

Approximately 35% of the human cortex is involved in visual processing (depending on how one wants to categorize the late stages of the process), including all of the occipital cortex and large parts of the parietal and temporal cortices. Approximately 25 visual cortical areas have been identified anatomically, with V1 and V2 being the largest. Some of these areas are labeled on the basis of presumed sequential order (V1–V5), and others are labeled on the basis of anatomical location with respect to various other anatomical landmarks such as gyri (in the macaque monkey). If one diagrams the interconnectivity among these regions, the resulting map resembles something that might have been produced by a drunken spider. Everything is connected to everything else. However, a consideration of just the largest pathways reveals evidence for sequential processing and for two main processing streams from the striate cortex going anterior (hence "prestriate") in the brain. One of the streams is from cells in V1 layer IVB to MT, MST, and from there to various regions in the parietal lobe. The other path is from cells in V1 layers II and III to V2, V4, and from there to various regions in the temporal lobe.

The temporal stream appears to be principally involved in processing information about form and color, and the parietal stream processes information about motion and spatial location, but this division of labor should not be taken too literally. Not only are there numerous anatomical connections between cells in these two paths but also it is clear from functional considerations that the two systems cannot be independent. For instance, motion is one of the strongest cues for the segregation and identification of form, so its analysis cannot be completely independent of the form system. Nonetheless, there is considerable evidence for some degree of specialization of function among the various prestriate visual regions and for this rough division between "what" (temporal) and "where" (parietal) systems.

Lesions in the temporal lobe of humans sometimes lead to loss of the ability to recognize certain types of objects or specific characteristics of objects. For instance, lesions in a particular temporal lobe region may lead to a loss of the ability to recognize the color of objects (although basic color discrimination ability may be unaffected). Strokes affecting certain parts of the temporal lobe produce a loss of the ability to recognize faces. For both monkeys and humans, hands and especially faces are of great importance, both for recognition of different individuals and for social interactions and communication. To distinguish one person from another on the basis of the slight differences in facial features is surely among the most complex of visual tasks. It is perhaps not too surprising that there are many cells in the temporal lobe that seem to be involved specifically in processing the images of faces and hands. The visual system seems to treat these particular stimuli in a special way. Unfortunately, there are no good theories or data on the transformations involved in going from cells in V2 and V4 (which appear to be only marginally different from striate cortex cells except for their larger RFs) to the neurons in the temporal lobe that have such complex tuning properties.

At early and middle stages in visual processing (through the striate cortex and perhaps V2), the visual system processes information from the whole visual field simultaneously and in parallel. It is of course such massive parallel processing that allows the very slow neural elements to carry out the huge computations required in real time. It is apparent from psychophysical experiments, supported by recordings from cells in V4 and later, that at later stages the system continues to process only selected portions of the scene—those parts to which one is attending. There is in fact some indication from patients with Balint's syndrome that object recognition may operate on only one object at a time.

Lesions in the parietal lobe produce quite different types of visual losses from those in the temporal lobe. Lesions in a particular occipitoparietal region that presumably correspond to area MT in macaque monkeys can lead to a loss of the ability to see motion, with no loss in the ability to recognize objects. Lesions in other parietal regions (presumably later in the processing stream) can leave an individual with the ability to recognize whatever object is attended to but an inability to determine where that object is in the visual field. Such an individual may be totally unaware of the presence of other, unattended objects, including ones that had been attended to and recognized just a moment earlier. This suggests that the temporal lobe systems identify objects one at a time and feed this information to the parietal lobe regions, which then fit

them into their appropriate relative locations in the visual field, like a collage of separate photographs, to construct our perceptual world.

One reason for having multiple visual areas is the need for analysis over large visual extents in order to accomplish object segregation and image recognition. Cells in V1 carry all the information about all aspects of visual perception since the whole path goes through this area. A typical visual object may extend over several degrees, and the neurons in V1 responding to different portions of it may be separated by tens of millions of other cells. For all cells to interact with each other over such a vast array would require an enormous set of interconnections. However, if the cells from all parts of V1 processing a certain type of information (e.g., motion) were brought together in a separate region, they would comprise a sufficiently small subpopulation to permit interactions over greater distances in visual space without requiring an impossible number of interconnections.

The visual system may also have evolved separate parallel processing areas to bring together cells processing common features so as to organize them in optimal ways for their particular functions. In the striate cortex, cells are organized in columns selective for orientation and spatial frequency. Within a motion area, however, a columnar organization by motion direction, which is seen in area MT, is presumably more useful. In a color area, a columnar organization by hue might be optimal.

Speech

KEITH R. KLUENDER
University of Wisconsin

GLOSSARY

categorical perception Stimuli that vary systematically along one or more dimensions are perceived relatively discretely. Identification of stimuli shifts abruptly at some point along one or more dimensions, and discrimination is much better for two stimuli that are identified differently than for two physically equidistant stimuli that are labeled the same.

formant A resonance of the vocal tract that is reflected in the speech signal as a frequency band of relatively higher energy. This band of energy is described in terms of both the center frequency and the bandwidth.

fundamental frequency The lowest frequency of a periodic signal. For speech sounds, the fundamental frequency ($f0$) reflects the frequency at which vocal folds vibrate. The harmonic spectrum consists of the fundamental frequency (first harmonic) with higher harmonics at multiples of the fundamental.

lack of invariance There is no simple one-to-one correspondence between attributes of speech sounds (or articulations) and linguistic units such as phonemes. Thus, phonemes are variably specified. The lack of necessary and sufficient attributes specifying phonemes is classically described as the problem of lack of invariance.

The most important sounds for humans are speech. Speech sounds are defined within the design and capabilities of vocal tracts, and languages have come to use different collections of sounds that are relatively distinct from one another in multiple ways. Perception of speech entails using multiple characteristics of the signal, and experience with reliable patterns across sounds within a language profoundly affects how speech sounds are heard. Understanding speech perception requires knowing both how complex signals such as speech are encoded in the auditory system, and how experience with speech shapes the use of speech sounds within a language.

I. RELATIONSHIP BETWEEN PRODUCTION AND PERCEPTION

In some ways, one could address the production and perception of speech much like one would consider other motor and perceptual behaviors. A talker executes some motor sequence engaging various structures, including the diaphragm, vocal folds, and speech articulators such as the tongue and lips. One could then study perception of the resultant sounds much as one would investigate perception of other complex sounds. In large part, this has been a fruitful approach to understanding speech perception. However, there is one aspect of speech communication that is not typical of most other motor and perceptual events. The relationship between production and perception of speech is an especially intimate one. All perceptual systems must maintain relatively close agreement between organisms and their environments, but the relationship between things that are perceived and the act of perception is not usually as close as it is for speech. A tree does not strike a pose that deliberately conveys strength and longevity, but talkers do speak so that they can be understood. The structure of speech is presented for the listener, and

listeners' perception of speech hews closely to dependable characteristics of speech production. One cannot know much about either speech production or speech perception without knowing a fair amount about the other. Most of this article focuses on aspects of speech perception, but first, some understanding of speech production is necessary.

II. SPEECH PRODUCTION

There are three basic components to production of speech: respiratory (lungs), phonatory (vocal chords), and articulatory (vocal tract). First is the respiratory system through which air is pushed out of the lungs, through the trachea, and up to the larynx. At the larynx, air must pass through the two vocal folds that are made up of muscle tissue that can be adjusted to vary how freely air passes through the opening between them. In some cases, such as voiceless sounds like [p] and [s], vocal folds are apart; they do not restrict airflow and do not vibrate. For voiced speech sounds such as [b] and [z], vocal folds are closer together, and the pressure of airflow causes them to vibrate with a periodicity referred to as the fundamental frequency ($f0$) much like a string on a musical instrument vibrates at a particular frequency. Owing to variations in the pressure of airflow from the lungs and muscular control of vocal fold tension, talkers can vary the fundamental frequency of voiced sounds. If one were to consider the nature of speech at this point, it could be depicted as a spectrum of energy spread across frequency and concentrated at the fundamental frequency and at multiples of the fundamental with decreasing energy at each successive multiple as seen in Fig. 1a.

The area above the larynx, the oral tract and the nasal tract combined, is referred to as the vocal tract. The nearly continuously varying configuration of the vocal tract is responsible for shaping the spectrum differently for different speech sounds. There are many ways the jaw, lips, tongue body, tongue tip, velum (soft palate), and other vocal tract structures can be manipulated to shape the sounds that emanate from the mouth and nose. Widening and narrowing of points along the vocal tract selectively attenuate some frequencies while making others more prominent. Figure 1b illustrates the filtering effects of the vocal tract for the vowel [a] as in "father." Figure 1c portrays the net result from passing the glottal source (Fig. 1a) through the vocal tract (Fig. 1b).

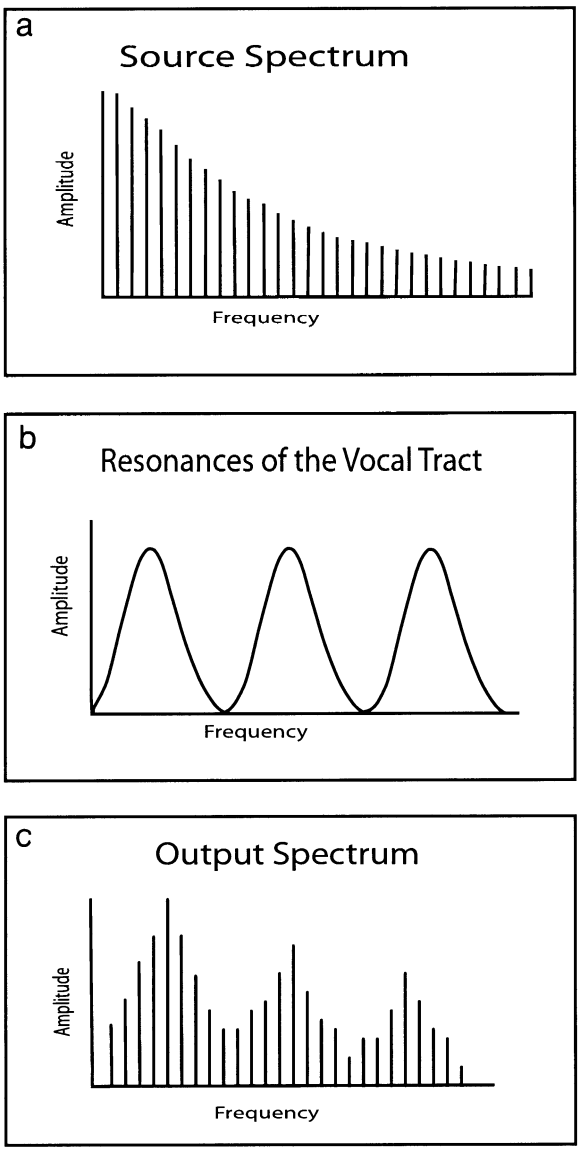

Figure 1 (a) Speech depicted as a spectrum of energy spread across frequency and concentrated at the fundamental frequency and at multiples of the fundamental with decreasing energy at each succesive multiple. (b) Filtering effects of the vocal tract for the vowel [a] as in "father." (c) Net result from passing the glottal source (a) through the vocal tract (b).

The peaks in the resultant spectrum are referred to as formants, and formants are described by number, lowest to highest (F1, F2, F3,...). Only the first three formants are depicted in Fig. 1, and for the most part, speech sounds can be identified on the basis of energy in the region of these lowest three formants. However, additional formants exist with lower amplitudes at higher frequencies (F4, F5, F6, etc.) and are

relatively more acoustically prominent in the speech of children.

Airflow can be channeled, constricted, or obstructed to produce different vowel and consonant sounds. Vowels are made with a relatively open unoccluded vocal tract. In terms of articulation, vowels vary mostly in how high or low and how forward or far back the tongue body is in the oral tract. In addition, some vowels are produced with rounded lips (e.g., [u] as in "boot") or with modestly different fundamental frequencies among other variations. Figure 2 displays the vowel sounds of English with respect to how high or low the tongue is placed, which corresponds to the frequency of the first formant (F1), and how far back or forward (front) the tongue is placed, which corresponds to the frequency of the second formant (F2). Not shown is the fact that high vowels such as [i] and [u] typically are made with higher *f*0 (more vocal fold tension).

In part because early linguists had greater access to their own vocal tracts than to sophisticated audio analysis equipment, it is a general convention that speech sounds are described in terms of the articulations necessary to produce them. In addition to variation in tongue height, frontness/backness, and lip rounding as descriptions for vowels, consonants also are described by articulatory characteristics. For example, consonants are described in terms of the manner in which constrictions are introduced along the vocal tract. Stop consonants or plosives such as [b], [p], [d], [t], [g], and [k] include complete constriction such that no air may pass through. Nasal consonants such as [n], [m], and [ŋ] (as in "sing") are like [b], [d], and [g], respectively, with complete constriction at some point in the oral tract, but air is allowed to escape through the nasal tract because the velum is lowered. Fricative consonants are caused by nearly complete obstruction of the vocal tract, with a noisy sound being produced by turbulence of airflow passing through a very small opening. Some examples of English fricatives are [s], [z], [š] (as in "ash"), and [ž] (as in "azure"). Affricate consonants are produced by a combination of complete occlusion (like a stop) followed by nearly complete occlusion (like a fricative). Examples of

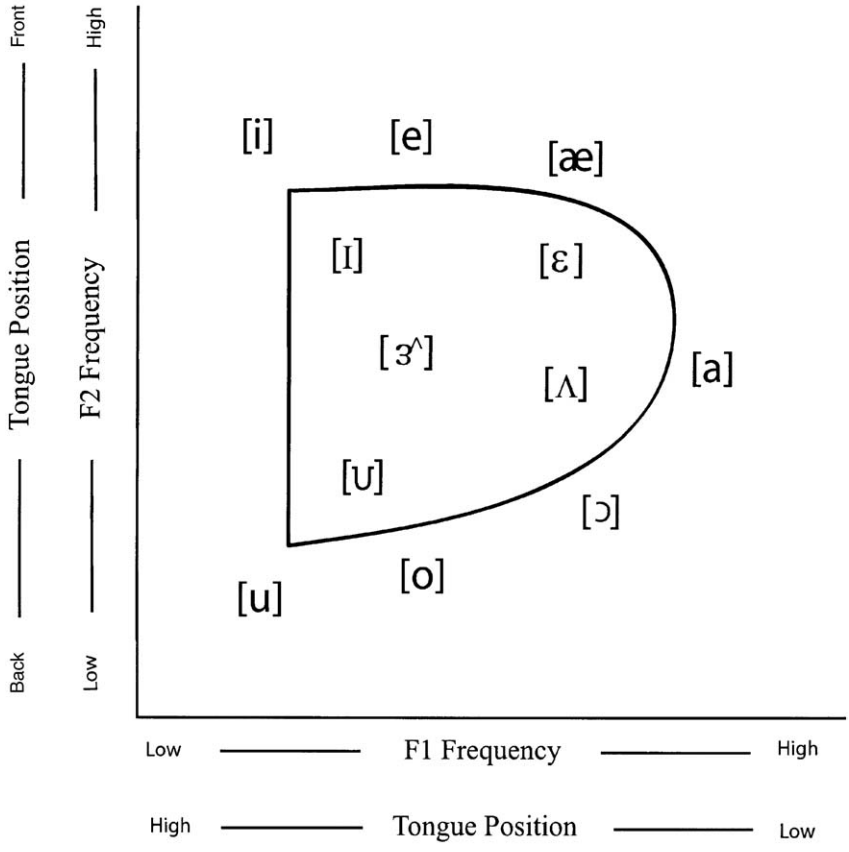

Figure 2 Vowel sounds of English defined by tongue position and acoustics.

affricates in English are [tš] (as in "chug") and [dž] (as in "jug"). The least constricted consonants in English are laterals and semivowels, such as [l], [w], [r], and [j] (as in "yet").

Consonants are also described in terms of whether the vocal folds are close and vibrating (voiced) or further apart and not vibrating (voiceless). Thus, sounds such as [b], [d], [g], [z], [ž], [dž], [l], [w], [r], and [j] are voiced, And [p], [t], [k], [s], [š], and [tš] are voiceless. Finally, consonants are described on the basis of place of articulation. Constrictions can be placed along a number of places in the oral tract. In English, the three major places of articulation are bilabial (lips: [p], [b], and [m]), alveolar (alveolar ridge behind teeth: [t], [d], and [n]), and velar (soft palate or velum; [k], [g], and [N]). The major anatomical features of vocal tracts are shown in Fig. 3.

III. LINGUISTIC SOUND SYSTEMS

This description does not exhaust all the distinctions among the approximately 40 sounds used by English, and it is a vast underdescription of variation among languages more generally. Humans are capable of producing an impressive range of sounds with potential to be included within the speech sounds of a language. Owing primarily to unique characteristics of supralaryngeal anatomy, the adult human possesses sound-producing abilities unrivaled among other organisms. This capacity is revealed in a grand assortment of more than 850 different speech sounds used contrastively by the more than 5000 distinct languages used throughout the world—more than 550 consonants and 300 vowels (including diphthongs such as [e^{y}] and [o^{w}]). Such capacity dwarfs that of other animals, being more than an order of magnitude larger than the largest inventory of nonhuman primate calls. Although the comparison between nonhuman primate vocalizations and human speech sounds is not straightforward, it can be suggested that, owing to supralaryngeal adaptations, the number of functionally different mouth sounds for humans is more than an order of magnitude larger than for any other primate. The number and variety of speech sounds producible by human vocal tracts has been taken as evidence of human specialization for speech production.

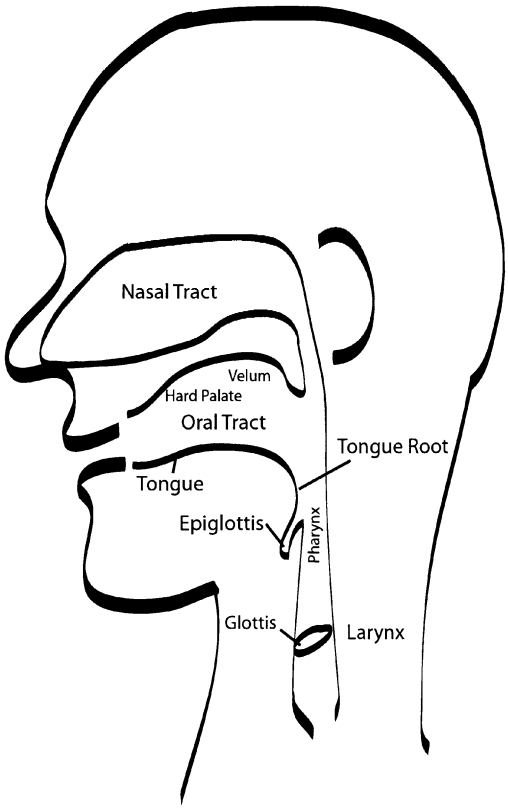

Figure 3 Selected anatomical structures of the vocal tract.

In contrast to this diversity in potential speech sounds, systematic inspection reveals that the collections of consonants and vowels used by individual languages are anything but random. The vast majority of speech sounds are relatively rare, whereas a handful are extremely common. For example, all known languages have stop consonants. The overwhelming majority of languages have three places of articulation for stop consonants, typically the three described previously for English. More than 80% of languages include a distinction in voicing (e.g., [p] and [b] vs [s] vs [z]), usually at these three main places of articulation. Regarding consonants, diversity does not imply entropy.

The structure of vowel systems is as much or more orderly than that for consonants. There is a fair amount of variety in the particular number of vowels used by languages, with some languages using as few as 3 vowels, whereas others use as many as 24. English uses about 15 depending on dialect. However, the most common number of vowels used by languages is only five, and other numbers of vowels appear to be relatively favored. Especially for the five- to nine-vowel systems that predominate across languages, the particular sets of five, seven, or nine vowels are typically used. Figure 4 displays some of the more common three, five, and seven vowel systems. Although there are relatively fewer languages that use more than seven

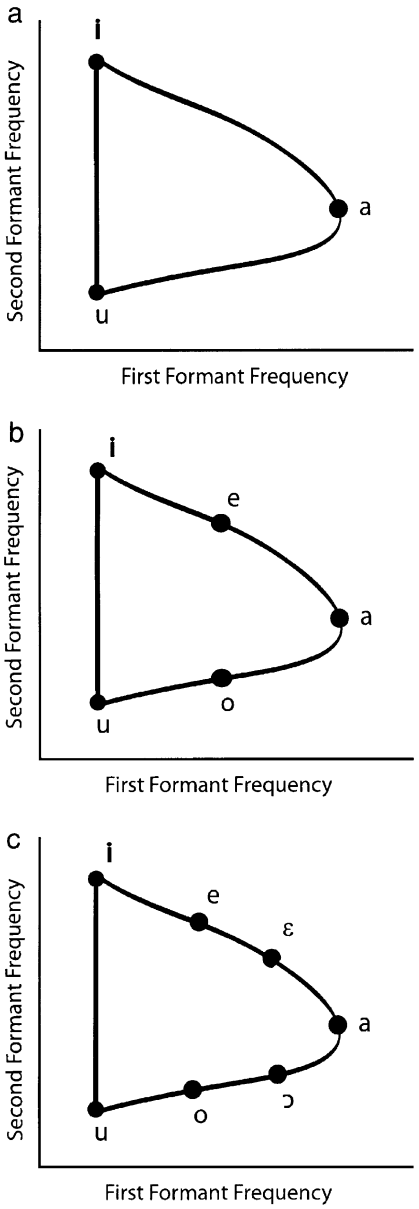

Figure 4 Common three- (a), five- (b), and seven-vowel systems (c).

vowels, there remains a good deal of commonality among systems with the same number of vowels.

What are the forces acting on languages that encourage the selection of some sounds and groups of sounds over others? It may be that some sounds are easier to produce than others. Although the number of possible speech sounds is prodigious, one guiding factor explaining regularities is how easy some sounds are to produce either in isolation or in sequence with others. The role of articulatory ease is perhaps best evidenced by the fact that languages tend to use articulatorily simpler consonants before incorporating more complex consonants. A least effort principle contributes to the selection of sounds used commonly by languages, although the precise degree to which producing some sounds may require more energy or greater coordination has proven very difficult to quantify.

Consistent with the close tethering of speech production and speech perception, there are many ways in which languages have come to use sets of speech sounds that enhance perceptual effectiveness. It is quite clear that talkers are willing to expend effort for communicative robustness. For example, the tense high vowels [i] and [u] (as in "beet" and "boot") require more effort to produce relative to their lax counterparts [ɪ] and [ʊ] (as in "bit" and "book"). The vowels [i] and [u], however, are acoustically more distinct, not only from each other but also from other possible vowel sounds. Also, across languages, these tense vowels [i] and [u] occur five times more frequently than lax vowels [ɪ] and [ʊ].

Aside from music and visual art, there may be no other instances of perceptual events being created with such deference to the perceiver's interests as is human speech. Common examples of talkers molding their utterances to the needs of the listener include instances in which conditions for communication are not optimal. Talkers speak more clearly to young or nonnative listeners for whom distinctions are not obvious. When environments are noisy or reverberant, talkers strive to produce contrasts that are maximally distinctive. Generally, speech sound repertoires of languages have developed over generations of individuals toward greater communicative effectiveness. Humans talking are not like leaves rustling or turbines whining. An important part of understanding speech perception rests on learning the ways generations of talkers have come to capitalize on auditory predisposition of listeners.

Sound systems of language communities have adapted to be fairly robust signaling devices by exploiting general characteristics of auditory systems whenever possible. An obvious way that a language community achieves such robustness is by developing an inventory of phonemes so as to optimize distinctiveness acoustically and auditorily. Inspection of regularities in vowel sounds used by languages, such as those shown in Fig. 4, provides some of the most illuminating examples of auditory processes operating as a driving force. Different languages use different sets of vowel sounds, and languages use subsets of vowels that are most easily discriminated from one

another. In particular, those vowels favored for languages with five vowels are vowels that are as acoustically distant as possible from one another. As a general rule, the set of vowels selected by a language, whether it uses 3 or 10 vowels, is composed of sounds that tend toward maximal discriminability.

There is another way that differences between speech sounds are perceptually more dependable. The speech signal is very rich owing to speech production giving rise to multiple acoustic consequences from the same basic speech articulation. Acoustic products of the larynx and vocal tract are quite complex. In many cases, multiple acoustic attributes are effortless consequences of passive interactions between articulators and/or airflow. In other cases, languages use systematic variation between relatively independent articulatory maneuvers to enhance auditory distinctiveness. One well-known example of multiple attributes and redundancy involves the distinction between voiced [b] and voiceless [p] when they occur between two vowels such as in [aba] and [apa]. There are at least 16 identifiable acoustic differences between these two utterances. The following are among the most significant for [aba]: The duration of silence (corresponding to closure of the lips) between the two syllables is shorter, the initial vowel is longer, there is more low-frequency energy (corresponding to vocal fold vibration) between the vowels; and the frequency of F1 both ends lower and begins lower around the medial silence. There are many other instances such as this, with the most consistent theme being that there are no distinctions that are signaled by only a single acoustic attribute.

In general, there are a large number of ways sound systems of languages have come to be structured in a manner that exploits characteristics of auditory systems. It bears note that ease of production and perception do not explain all the variance across inventories of speech sounds because many cultural or sociolinguistic factors play a significant role. However, beginning with the most basic descriptions of speech, the synergy between talkers and listeners is a robust characteristic of speech communication.

IV. CONTRIBUTIONS OF THE PERIPHERAL AUDITORY SENSORY SYSTEM

Languages have developed to be robust signaling systems, and distinctions between speech sounds do not rely on the ability to make fine-grained discriminations bordering on thresholds of auditory systems. In this way, perception of speech bears little likeness to classic psychophysical studies of absolute thresholds and just noticeable differences. Determining the differences between vowels such as [æ] (as in ''bat'') and [ɛ] (as in ''bet''), on the basis of gross spectral differences, shares little in common with psychoacoustic studies that demonstrate humans' abilities to detect changes as small as 1 Hz from a 1000-Hz sinusoid tone. It is widely appreciated that the performances of listeners detecting tones in quiet or detecting differences in pitch between two tones are poor predictors of the ability of the same listeners to understand speech. Listeners who suffer significant hearing loss can nonetheless manage to understand speech until the level of impairment becomes severe or there is substantial background noise competing with the speech signal. Perhaps predictably, the ability of normal-hearing listeners to understand severely degraded speech is impressive. If the entire signal is filtered away above 1.5 kHz, listeners can still understand it nearly perfectly. If, instead, one filters away all energy below 1.5 kHz, listeners can also understand it nearly perfectly. Also, across a fairly wide range of frequencies, one can present only a relatively narrow frequency band of the speech signal and still achieve high intelligibility. Profoundly deaf people who have received cochlear prosthetics (electrodes implanted into the cochlea) and who consequently receive extremely degraded signal via as few as one to four electrode contacts, can often understand speech, sometimes sufficiently well to talk on the telephone.

Because languages use distinctions that maximize acoustic differences and exploit auditory capacities, several observations follow. First, human infants are quite proficient at discriminating differences between speech sounds from a very early age. Three decades of studies document the impressive abilities of human infants, some less than 1 week old, to discriminate a wide variety of consonants and vowels from across many languages. A plethora of positive findings indicate that infants have the discriminative capacity necessary for most or all of the speech distinctions they will need to use in their language. Languages tend to use distinctions that are relatively easy to detect, and infant auditory abilities appear to be quite well developed. By 3 months of age, the human auditory system is nearly adult-like in absolute sensitivity and frequency-resolving power within the frequency range of most speech sounds.

A second observation, perhaps more telling than the first, is that discrimination of speech contrasts by nonhuman animals appears to be generally quite good.

There have been a number of demonstrations that animals can distinguish human speech sounds with facility. Differences between vowel sounds present no apparent difficulty for nonhuman animals. Several species have been shown to distinguish voiced from voiceless stop consonants or to distinguish consonants on the basis of place of articulation (even beyond the basic three places described previously for English). Although such findings are expected on the basis of languages tending to use distinctions that are relatively easy on ears, currently the number of speech distinctions tested with animals is small relative to the very large set of possible contrasts. Also, the number of animal species used is limited.

Because nonhuman animals appear to provide an adequate model for simpler aspects of speech perception, such as distinguishing one sound from another, many neurophysiological studies have been conducted in the interest of describing neural representation of speech sounds. Most of this work has focused on neural responses in the auditory (VIIIth) nerve, but there have been a number of studies concerning successive stages of the auditory system, such as ventral cochlear nucleus, inferior colliculus, medial geniculate, and auditory cortex. Owing to the preponderance of work having been done with auditory nerve, there is greater understanding of the neural representation of speech at this level.

For the most part, neural representations of speech at peripheral levels [e.g., auditory nerve (AN)] are fairly well predicted by neural responses to other sorts of simpler sounds. Individual AN fibers have their origin at inner hair cells in the basilar membrane of the cochlea. Just as the basilar membrane embodies a tonotopic mechanical sensitivity, AN fibers are most sensitive to particular frequencies [characteristic frequencies (CFs)] as a function of the region of the basilar membrane from which they originate. AN fibers have greater neural firing rates at their CF, and the rate of neural firing diminishes for frequencies further from CF. Attenuation firing to frequencies not at CF is much more pronounced for frequencies higher than CF relative to those lower than CF. In addition, the extent to which energy lower than CF encourages firing is highly dependent on the intensity of the signal. Although individual fibers appear to be fine-tuned to a limited frequency range at or near threshold, this is not the case for higher intensity sounds. This broadening of tuning at higher stimulus levels is most pronounced toward lower frequencies. For example, at 70-dB sound pressure level (SPL), which is representative of conversational speech, an AN fiber with CF of 8 kHz may respond reliably to energy below 1 kHz, possibly including energy in the region of F1 or even *f*0. Neural firing rates across frequencies for an AN fiber with CF of 2 kHz are shown in Fig. 5, which shows that, at intensity levels common for speech perception, individual fibers are not narrowly tuned to detect fine-grained spectral differences. Because the intact organism is not limited to responses of an individual fiber, greater spectral resolution could be gained by a pattern of responses across a population of AN fibers.

Although frequency selectivity becomes broadened at higher levels, rate as a measure of neural response also has the appearance of being compromised at intensity levels common for speech. The effective range of hearing is much greater than the dynamic range of firing for individual AN fibers. Although human listeners can hear loudness differences over a range from 1 to 120 dB (about 10^{12}:1), the range of neural firing rates is only about 0–1000 spikes per second (10^3:1). For most neurons, increases in rate of neural firing occur over only the first 30–40 dB above threshold before a steady maximum is reached. Because not all AN fibers have the same threshold and are sensitive to changes in intensity over different intensity ranges, a broader range of intensities can be encoded across a broader population of neurons.

Changes in firing rate are not the only source of information in the firing patterns of AN fibers. The firing of neurons is not temporally random. Instead, at a given signal level, the probability of firing at any given point in time is related to the phase of some frequency or frequencies in the signal to which the neuron is sensitive. The term ''neural synchrony'' is typically used to refer to synchronization between the firing pattern of a neuron and the frequency or frequencies of the signal. In response to lower frequency signals (<4 kHz) fibers tend to fire predominantly during a restricted portion of the stimulus cycle. Synchrony encoding of lower frequency energy can be observed in AN fibers with CFs at much higher frequencies, presumably because at moderate to high SPLs typical of conversational speech filtering characteristics of AN fibers are broadened toward lower frequencies. Consequently, synchrony (versus rate) encoding of spectral information, particularly for *f*0 and F1, could be of substantial value for speech. However, there is a complication. Although synchrony encoding in the auditory nerve appears robust for lower and mid frequencies, this temporal encoding seems to become more diminished in ascending auditory structures. By the level of the cortex, thalamocortical temporal encoding appears to have an

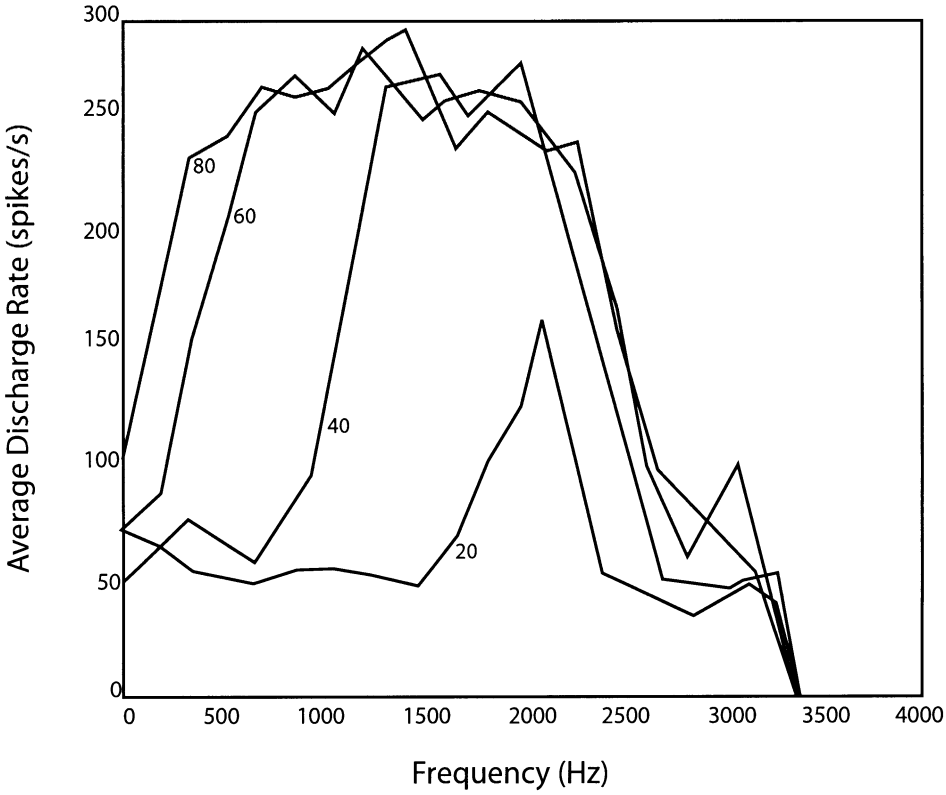

Figure 5 Neural firing rates across frequencies for auditory nerve fiber with characteristic frequency of 2000 Hz.

upper limit of 400–600 Hz. Either the auditory system does not exploit temporal encoding despite apparent virtues at intensity levels characteristic of speech or synchrony encoding is translated to some other form of neural code at higher levels of processing.

Taken together, there are a number of important issues to consider with respect to encoding of speech and other complex sounds in the auditory periphery. There is sufficient information about the ability of humans and animals to make use of acoustic information necessary for speech perception that it is clear that apparent limitations on the separate contributions of individual neurons are not realized as real obstacles to understanding of speech. In part, this is because ample information is conveyed across the assemblage of 15,000 AN fibers. In part, it is because high-fidelity representations are unnecessary. Finally, redundancy in the signal makes it possible for one or more of the details of the stimulus to be compromised with little or no decrement in performance. Subsequent work will better illuminate the contributions of populations of neurons at low and at higher levels. In the remainder of the article, discussion of cortical organization for speech perception is presented following the depiction of more sophisticated aspects of speech perception, including the use of multiple stimulus attributes.

V. CONTRIBUTIONS OF EXPERIENCE

Producing and perceiving differences between speech sounds is only a part of understanding how speech is perceived. One reason is because the mapping between production and perception of speech is complex. As noted previously speech production results in a host of identifiable acoustic attributes. Although one can view this as a positive state of affairs owing to redundant acoustic attributes, the matter is complicated by the fact that no single acoustic attribute dependably signals a given consonant or vowel. It is generally accepted that consonants and vowels do not have unique identifying properties, and this is referred to as the classic problem (and double negative) of "lack of invariance." The problem of variance or variability is that, for most or all phonemes, there are no individually necessary and sufficient cues that uniquely identify

speech sounds. Although there have been many attempts to identify invariant cues, these have not been broadly successful. In general, multiple acoustic attributes of the speech signal must be combined in some way to identify speech sounds. Even the most definitive description of individual acoustic or auditory attributes falls short of explaining how multiple attributes are combined to perceive the consonants and vowels of one's language.

Consequently, the ability to discriminate speech sounds on the basis of some acoustic attribute is not synonymous with the functional use of speech as part of language. Although a relatively complete understanding of the auditory representation of speech sounds is an essential step in understanding how consonant and vowels are recognized, mapping acoustic information onto either neural representations or some more abstract perceptual space is only part of understanding speech perception.

Among the many variations in the speech signal, some are relevant to the linguistic message and many are not. Part of speech perception includes ignoring linguistically irrelevant variation while using relevant changes. For example, different talkers produce different renditions of speech sounds. Males have lower pitched voices not only because their vocal folds are larger following puberty but also because males are taller than women in general and their vocal tracts are longer resulting in lower formant frequencies. Children, of course, produce speech that is acoustically distinct from that of adults, and the acoustics of their speech change through age. Listeners must recover sequences of consonants and vowels despite substantial changes to the speech signal owing to differences in talker characteristics. Other changes that do not change the linguistic content of speech include acoustic consequences of distance, room reverberation, or competing sounds in the environment including the voices of other talkers.

Finally, because many speech sounds are used across the languages of the world, another very substantial problem arises. Perceiving distinctions in one's language requires becoming attuned to one's native language. Acoustic differences that matter critically for one language may be irrelevant or even distracting with respect to distinctions from another language. In order to perceive speech in a way that is appropriate to one's language, speech perception must be tuned in a way that most of the many possible differences between speech sounds are relatively ignored. In contrast, distinctions between speech sounds that are used by one's native language must be preserved or even enhanced. This ability to use some acoustic distinctions between sounds but not others is part of what defines being a native listener.

Many readers have had the experience of listening to speech produced by native speakers of Spanish, one of the many languages that uses only the five vowels [i] (an in "beet"), [u] (as in "boot"), [a] (as in "hot"), [e] (as in "bake"), and [o] (as in (boat"). Consequently, a native Spanish speaker may produce English [ɪ] (as in "bit") as [i] or English [ɛ] (as in "bet") as [e]. These differences in speaking are not due simply to being incapable of producing English vowels. In part, these differences are due to difficulty clearly perceiving distinctions between English vowels following experience with only Spanish. Many can remember such difficulties as high school students learning a new language, with both perceiving and producing differences between sounds in the new language being difficult. Perhaps the most widely appreciated effects of experience are those found for native speakers/listeners of Japanese whereby both perception and production of the distinction between English [r] and [l] can be dramatically diminished.

Now, consider the prospects for an infant. How is it that, whether born in New Delhi, New England, or New Guinea, an infant comes to hear speech contrasts in a fashion appropriate to Hindi, English, or Tok Pisin, respectively? In addition to becoming attuned to useful contrasts within the native language, infants must come to understand the consonants and vowels of their language independent of whether father, mother, sister, brother, or stranger utters them.

Many of the most difficult problems in understanding speech perception concern how listeners come to be able to understand speech on the basis of multiple acoustic attributes, some of which are helpful in a given language, some of which are not, and none of which are wholly reliable.

A. Lack of Invariance

Even for utterances by the same speaker, acoustic qualities of a consonant or vowel could be different, thus giving rise to the concept of lack of invariance. The major reason for this is that production of a consonant or vowel varies depending on the consonants or vowels that precede and follow. This context sensitivity is a consequence of coarticulation, the temporal spatial overlap in production of successive sounds. One classic example is the stop consonant [d] as depicted schematically in Fig. 6. Depending on the following vowel,

changes in formants across time (referred to as formant transitions) can differ dramatically. This is only one of many examples of lack of invariance, and this context sensitivity resulting from coarticulation has presented one of the most substantial difficulties in developing computer recognition of speech.

For some time, the fact that human listeners effortlessly understand speech despite context sensitivity suggested to many investigators that there might be something unique about human speech perception relative to other forms of perception. In particular, it was suggested that because acoustics were not sufficiently invariant to signal reliably vowels or consonants such as [d] across different vowel contexts, listeners must instead make access to something that was assumed to be more nearly invariant—the articulation of speech sounds. During the past 40 years, a number of theories of speech perception have been proposed that, in one way or another, have suggested that perception must be accomplished through some sort of reference to articulation. The most significant and widely influential is the motor theory of speech perception advocated by Alvin Liberman. In several ways, such an idea is very attractive. As noted previously, humans are the only organisms with such an exquisite vocal repertoire, quite likely owing to vocal tracts that are specially adapted for production of speech. Even if perceptual theories in other domains do not rely on some link between producing some object or event and perceiving it, it seems reasonable that speech may provide a special case for which humans have evolved specialized perceptual processes complementary to speech production. There have even been attempts to develop computer speech recognition based on working back from the speech signal to articulations instead of the more traditional approaches based on some type of acoustic pattern matching; however, these articulation-mediated attempts have not been as successful as more traditional approaches.

Although theories of speech perception that make reference to articulation have been attractive, there are problems with such approaches. There is a lawful relationship between acoustics and the structures that produced the sound. For a given state of mechanical affairs in any sound-producing structure including vocal tracts, there is a single predictable outcome. The physics of sound are constant, so the acoustic products of the same sound-producing event are always the same. Thus, variance in the acoustic speech signal must be the direct result of variance in production. If one were to rely on production for the defining features for speech perception, then the problem is at least as complex for articulation as it is for acoustics unless one adopts a level of description for production that is considerably more abstract than actual physical articulations.

In Liberman's last revision of the motor theory during the mid-1980s, this is evident from his claim that speech perception is the result of human specializations that serve to detect intended (not actual) gestures. Given the variance in physical realization, articulatory gestures have been difficult to measure precisely, and intentions for gestures are even more difficult to define or measure. Appeals to production do not provide as much simplification to models of speech perception as was initially hoped. Another line of evidence against uniquely human specializations for perception of speech can be found in demonstrations that nonhuman animals can learn to sort consonants (e.g., [d] versus [b] and [g]) across the same sort of acoustic variation depicted in Fig. 6. Although descriptions of speech contrasts in either articulatory or acoustic terms appear quite complex, this apparent complexity does not seem to provide insurmountable obstacles for perception by human or nonhuman biological systems.

Issues concerning context sensitivity and lack of invariance remain among the most central to

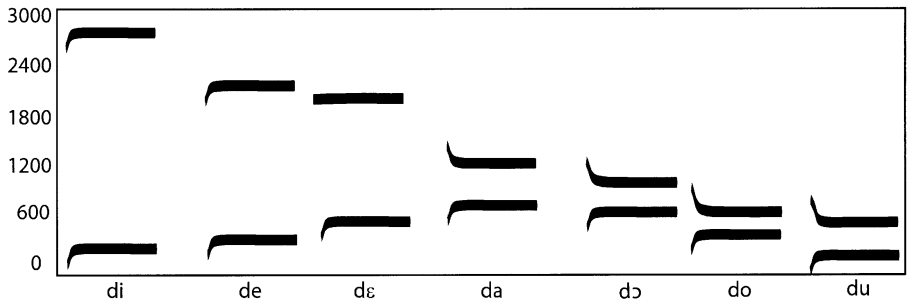

Figure 6 Stop consonant [d] depicted schematically.

understanding speech perception. It is well-known that in the absence of necessary and sufficient stimulus attributes, multiple stimulus attributes contribute to perception of speech sounds. Many experiments have revealed a phenomenon referred to as a "trading relation" between stimulus attributes. In these experiments, attributes of the signal that naturally covary with one another are altered independently. When one attribute is held constant, often at some intermediate value, the value of the second attribute is sufficient to tilt perception one way or the other. Also when this second attribute is held constant, variation in the first attribute can dictate perception. Across such experiments, it was shown how listeners use multiple stimulus attributes for speech perception.

Studies of trading relations in speech perception bear a striking likeness to issues in other domains of perception. One of the central classic problems for theories of perception, extending to the British Empiricists of the 17th and 18th centuries, is perceptual constancy (e.g., color, shape, and size). Common to instances of visual perceptual constancies is that objects or scenes are recognized as maintaining identity despite transformations in the optical array owing to changes in distance, lighting, perspective, etc. Each of the visual constancies represents an instance for which the sensory attributes can vary, but perception is relatively stable across such variation. No single aspect of the stimulus can be counted on as a necessary and sufficient condition for perception. For more than three centuries, a pervasive approach to understanding perceptual constancy has been to assume that experience is required to develop perceptual constancy, and that multiple aspects of the signal are used together via associationist processes. It is now known that one of the things that neural systems do best is to use multiple sources of modestly reliable information. Recent simulations of neural connectivity and activity in so-called neural network or connectionist models are designed to mimic the use of multiple attributes and associations between attributes as a function of experience with natural covariation. Among some of the most interesting findings for computer simulations of vision are demonstrations that performance can be very robust across degradations of the signal such as adding noise, spectral filtering, or deleting portions of the signal—a close analogy to examples of the robustness of speech perception described previously.

There have been many efforts to simulate speech perception within connectionist simulations; although there has been a fair degree of success, these simulations vary in the extent to which they include authentic auditory representations of speech or operate on stimuli that are representative of infant experience. Studies of development using human infant subjects address some of the same issues, including several reports that infant perception of speech and words can be driven by statistical regularities in the speech signal. In the meantime, there have been a small number of studies in which animals, instead of infants or computers, serve as surrogates to investigate how experience with natural covariation between acoustic attributes of speech serves to maintain perceptual constancy for speech sounds.

B. Becoming a Native Listener

Given the enormous variation in the particular subsets of the hundreds of sounds that are used by individual languages, the next major question concerning experience is how infant listeners come to understand speech in a fashion appropriate to their language community. In the multidimensional space of stimulus attributes, experience plays a critical role in parceling speech sounds into functional classes with linguistic significance—the consonants and vowels of one's language. The simple fact that different languages partition the domain of possible speech sounds differently implies that functional use of speech sounds depends on linguistic experience.

There have been ample demonstrations that during the first year of life, before infants produce much speech, infants become attuned to the differences between vowels and consonants that are functionally appropriate to their language environment based on their experience with speech sounds. By 6 months of age, infants are more likely to respond to acoustic differences that distinguish two vowels in their native language than to respond to equivalent differences that do not distinguish vowels in their language. This is true even though the differences to which infants do not respond are linguistically significant in other languages. Infants have been shown to respond to differences between speech sounds that would signal a linguistically significant change, such as from one vowel to another, while apparently ignoring greater acoustic variation relating to changes in talker.

At least for the relatively small number of contrasts that have been tested thus far, it appears that perception of analogous changes in consonants is developmentally more extended than for vowels. There have been several demonstrations that, at approximately 6 months of age, infants respond fairly

equivalently to differences between stop consonants independent of whether or not the differences are functionally significant within the native language. However, by the time infants are about 1 year old, they exhibit a tendency to respond more reliably to acoustic differences that distinguish consonants from within their native language. This pattern of performance rests on 1-year-old infants not responding to the same acoustic differences to which 6-month-old infants respond. What may be most surprising about the data from infant listeners is that the well-known adult difficulty in perceiving differences between nonnative speech appears to develop very early, before infant speech (babbling) includes most of the differences they will use in their language.

In addition to many studies concerning the ability of adult Japanese listeners to perceive or learn to perceive the difference between English [r] and [l], there have been many studies of perceiving and producing contrasts when learning a second language. Although the basic effects concerning initial inability to detect and produce differences among sounds in a second language are relatively consistent across other consonants and vowels, difficulty with [r] and [l] appears to be much more recalcitrant than contrasts more generally. A number of models have been proposed to explain processes underlying second language acquisition, some more explicitly developmental than others. Currently, such models can be broadly summarized in a fashion that acknowledges the importance of prior experience. They all attempt to account for patterns of performance showing that perception of speech sounds in a second language can be predicted on the basis of similarity or dissimilarity with sounds from the native language. When two sounds from a second language are both most similar to only a single sound in the native language, there will be difficulty perceiving that difference, with both being heard as renditions of the single sound from the native language. For example, when a native-Spanish listener confronts English vowels, for which English [i] and [ɪ] are both most similar to only [i] in Spanish, the Spanish listener will have difficulty with the distinction between [i] and [ɪ].

When the distinction between two sounds from a second language is most similar to a distinction between two sounds in the native language, listeners will tend to perceive differences between the two new sounds in a pattern much like that for the two sounds in the native language. Finally, in cases in which two new sounds in the second language bear little to no likeness to sounds used in the native language, listeners typically have no difficulty perceiving these differences in the absence of interference from sounds in the first language. In all cases, the effects of early experience with speech sounds in the native language predict the ease with which new speech contrasts can be adopted for the second language. There are a number of additional observations that have been made depending on duration of experience with the first or the second language, and of course, things become more complicate when more than two languages are considered.

C. Categorical Perception

Among experimental phenomena related to speech perception, perhaps none is more widely known than categorical perception. This classic pattern of perceptual data is studied in the laboratory using a series of stimuli that vary systematically in one or more acoustic attributes that distinguish two speech sounds, typically consonants. Listeners are asked to label each stimulus in the series as one or the other speech sound, and they are asked to discriminate between pairs of speech sounds drawn from series. Discrimination is usually measured using tasks that require subjects to listen to three sounds and report either which of three stimuli is different (AXB) or which of the first two stimuli sounds most like the third (ABX). Across these identification and discrimination procedures, three features define categorical perception: a sharp labeling (identification) function, discontinuous discrimination performance (near perfect across identification boundary and near chance to either side), and the ability to predict discrimination performance on the basis of labeling data. The classic patterns of identification and discrimination are displayed in Fig. 7.

For a while, such patterns of data stood in contrast to the way investigators thought about perception of continuously varying stimuli in other domains. For example, if one were to ask subjects to judge the pitches of tones that varied in frequency, it may be possible to have listeners divide the series in half, labeling some low and some high. However, listeners would not appear to lose their ability to detect the difference in pitch of two stimuli that both were labeled low or high. Many speech scientists initially took categorical perception to be indicative of perceptual processes that were unique to human perception of speech.

Throughout the years, however, a number of additional findings conspired to indicate that categorical perception was not unique to human perception

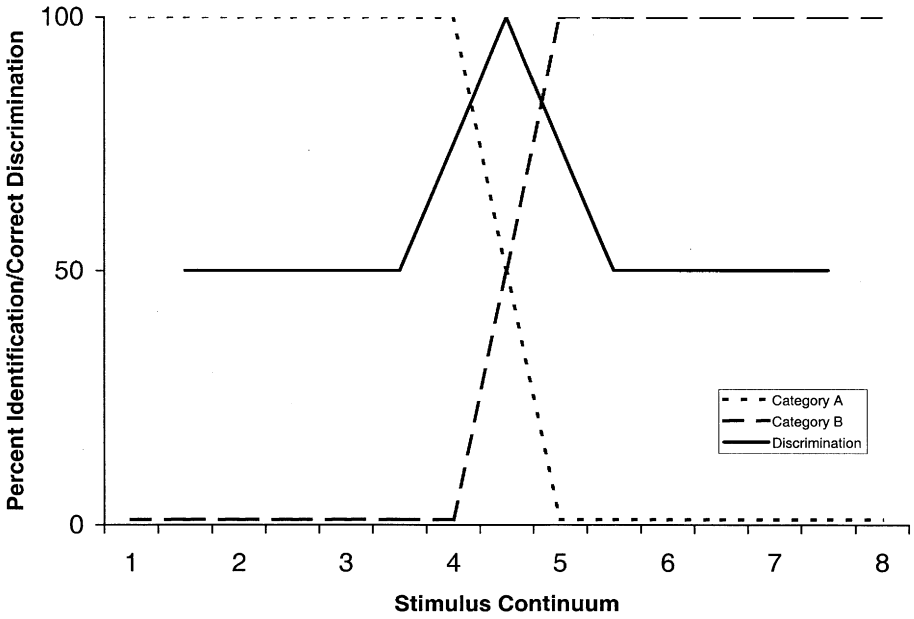

Figure 7 Categorical perception: idealized patterns of identification and discrimination.

of speech. First, it was demonstrated that nonhuman animals, responding to the same speech stimuli used in some of the experiments with human listeners, demonstrated the classic criteria defining categorical perception. In addition, it was demonstrated that with training, human listeners could accurately discriminate between stimuli that were labeled the same before training, contrary to the criterion that discrimination of speech sounds should be near chance if these sounds are labeled the same. Similar to learning a new language, which requires distinguishing between two new sounds that are perceived as examples of the same consonant or vowel in the native language, experience or training with the new distinction improves discrimination. As might be expected given the wealth of experience with natural distributions of speech sounds, the addition of memory variables also serves to predict performance on categorical perception tasks. When associative memory is simulated using neural network models, it appears that signature response patterns for categorical perception may be an emergent property of learning following exposure to distributions of speech sounds. Consistent with such a conclusion is the fact that categorical perception has been observed with a number of visual and nonspeech auditory stimuli with which observers and listeners have much experience.

Despite the fact that categorical perception does not distinguish speech perception from perception in other domains, it does illuminate principles of perception more generally. Psychophysicists often interrogate the operating potential of sensory systems by measuring thresholds at the limits of detection or discrimination, and such studies provide important data demonstrating the absolute potential of sensory systems, usually under ideal conditions for listening or observing. In such experiments, participants typically have little or no experience with the stimuli prior to coming to the laboratory. Most functional purposes of perception, however, do not require making minimal distinctions between unnatural stimuli. Instead, they require providing sufficient information to function adaptively, and this must be accomplished under conditions that are often not optimal. This usually requires using multiple stimulus attributes in many cases, this requires not using some differences between physical stimuli that do not have functional consequences. In addition, contrary to psychophysical studies that typically use unfamiliar stimuli such as pure tones for hearing or sine-wave gratings for vision, perception is very much driven by experience with a structured world. Speech perception is emblematic of both these points. Sound systems of languages are structured to avoid minimal differences, and many of the most important issues concerning speech perception highlight the powerful effects of experience for adapting perception to fulfill its functional role.

VI. CONTRIBUTIONS OF THE CENTRAL AUDITORY SYSTEM

In Section IV, some observations about peripheral neural encoding of speech and other complex sounds were described. Here, processing of speech at higher levels of the central nervous system is considered. Two of the most classic early observations of cortical functions related to speech were made by surgeon Pierre Paul Broca and neurologist Carl Wernicke in the 19th century. Broca conducted an autopsy on a patient who apparently could understand everything that was said to him but could not speak more than a few syllables. Autopsy revealed a large lesion to the third convolution of the frontal lobe on the left side of the brain. This area in left frontal cortex, shown in Fig. 8 anterior to motor cortex, became known as Broca's area. Damage to this area results in expressive aphasia —difficulty in producing speech despite maintaining the ability to understand spoken language. Approximately a decade after Broca's observations, Wernicke reported that damage to the posterior superior left temporal lobe (Fig. 8) resulted in a complementary disorder. Patients with damaged Wernicke's area suffered from receptive aphasia, being able to produce fluent but meaningless speech, but left relatively unable to comprehend language.

Owing to the spatial proximity of Wernicke's area to posterior auditory cortex, Wernicke suggested this is where speech sounds are converted into meaning. Because Broca's area is close to areas of motor cortex related to face and neck, Wernicke suggested that disconnecting Broca's area from Wernicke's area should result in intact language comprehension and fluent but meaningless speech. There is a fiber tract, the arcuate fasciculus (Fig. 8), that does make such a connection. In fact, Wernicke's predicted outcome, known as conduction aphasia, is obtained when the connection between Broca's and Wernicke's areas is severed.

There are several obstacles to making strong claims concerning speech perception on the basis of observations such as those made by Broca and Wernicke. The first is a quite general concern regarding the accuracy with which one can draw inferences between substantial brain areas containing a lesion and a specific process. The most common lesions from stroke follow patterns of vascularization, not function. Thus, a lesion can disable only part of some putative process or an entire region plus other regions that may or may not be related to the process of interest. Further weakening

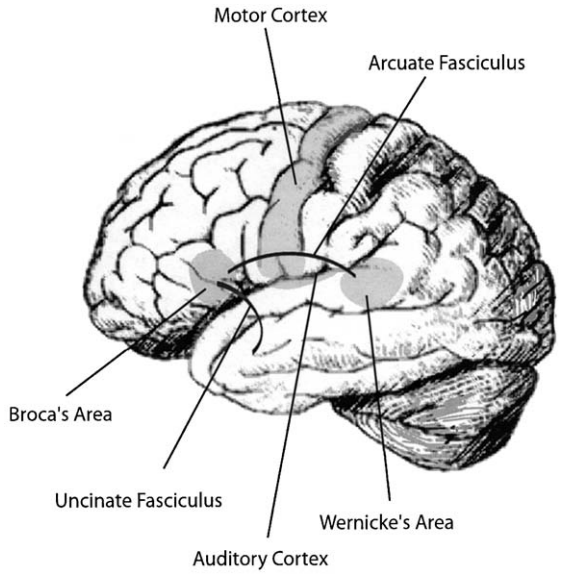

Figure 8 Broca's and Wernicke's areas: damage resulting in either receptive or expressive aphasias, respectively.

the ability to make strong claims from lesion data is the difficulty dissociating between localization of some process per se and damage to some pathway between two areas of primary interest. In later years, it became increasingly apparent that precisely defining either Broca's or Wernicke's areas is very difficult owing to the previously mentioned considerations and to considerable differences between individuals' cortical organization, and these terms are now often abandoned in lieu of more precise anatomical description.

A more specific difficulty for assessing cortical neural processes and locations for speech perception is revealed by Wernicke's hypothesis regarding conversion of speech sounds into language with meaning. Although speech without meaning (nonsense words or pseudowords) can be perceived, perceiving speech that has no meaning does not imply that neural processes related to higher linguistic processes and meaning are not engaged. Listeners can perceive the sounds of pseudowords such as "tig" and "gup." However, use of pseudowords may not eliminate involvement of higher language processes because such processes may be drawn to the task.

Another approach to distinguishing processing of speech and nonspeech sounds might be to use nonspeech sounds that maintain the most important structure and complexity of speech sounds without being speech—something more complex than noise or simple tones but not speech. This is difficult to do in

practice. First, owing to the great diversity of sounds used by languages (or even for a single language such as English), the range of acoustic attributes for speech is so large that constructing acceptably complex nonspeech stimuli without any such attributes is very difficult. Second, listeners can understand extremely degraded speech. How does one construct nonspeech stimuli that escape being heard by some listeners as speech based on even the most limited resemblance?

These last two experimental concerns extend beyond the neuropsychological study of patients who have suffered brain insult to modern methods for noninvasive study of cortical processing by unimpaired listeners. Modern methods of electrophysiology, magnetoencephalography, positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) can be compromised by trade-offs between temporal and spatial resolution. Although measures of neural activity via electrophysiology have good temporal resolution, it is very difficult to be confident about the location of activity one is measuring. Magnetoencephalography is a related measure that offers better spatial resolution, but application has been fairly limited to date. Imaging methods that measure changes in cerebral blood flow or oxygen use (PET and fMRI) have much greater spatial resolution at the expense of temporal resolution. Consequently, the duration of a trial often exceeds 1 min, during which the acoustic stimulus of choice is presented dozens of times. This presents a clear limitation for understanding the relatively rapid processing of acoustic signals of any kind, and when one considers that the duration of a syllable can be less than 200 msec shortcomings of such a time base are apparent. Consequent to these difficulties, most conclusions regarding cortical processing of speech are tentative. However, some broad findings can be summarized.

As expected, presentations of sounds of any kind tend to result in activation of primary auditory cortex. In addition to auditory cortex, ventral, anterior, and posterior, there is a belt of cortex that is activated by more complex sounds. Ventrally, a second belt, sometimes referred to as a parabelt, can be described. For these belt areas, often referred to as ''secondary'' or ''associational'' areas, there is decreasing activation in response to very simple sounds such as sine waves and white noise, particularly when stimuli have limited temporal structure. This appears analogous to the visual system for which there is a hierarchy such that as processing proceeds from simple to more complex stimuli, areas that respond selectively to more complex stimuli tend to respond less to simpler stimuli. In addition to responding to more complex acoustic structure, there is evidence of cross-modal encoding (e.g., acoustic and optic), particularly in parabelt areas. In contrast to multiple observations of language usually being lateralized in the left hemisphere, activation in response to speech in core, belt, and parabelt areas of auditory cortex is usually found to be relatively balanced bilaterally in the absence of higher level linguistic effects.

This bilaterality, in contrast to laterality for language, does not imply that there is nothing exceptional about processing of speech in the human cortex. There are other ways that processing of speech can be distinguished from perception of other sounds. Cortical organization is critically linked to the amount and nature of experience, and there are no acoustic signals with which humans have more experience than with speech. An example from vision is perception of faces, which appears to have some special status in the middle fusiform gyrus of the cortex. This area is disproportionately activated when subjects view faces versus viewing other objects or scenes. Later work has demonstrated that similar patterns of activation can be found in response to other types of stimuli with which subjects have a great deal of experience. One may well expect that as more becomes known about cortical processing of complex sounds, cortical areas that appear dedicated to speech sounds will be revealed.

There is a second way in which cortical processes underlying speech processing could turn out to be atypical. If much of speech perception must be explained in terms of experience and, by extension, associationist processes, two types of cross-modal organization might be predicted. First, owing to a wealth of experience simultaneously hearing speech and viewing talkers' faces, one may expect substantial interaction between auditory and visual speech. The so-called McGurk effect, achieved by placing auditory and visual speech information in conflict, provides a powerful behavioral demonstration of this interaction, and there is brain imaging evidence for cortical areas related to these perceptual effects.

Second, there is reason to expect that some of the classic ideas concerning interactions with production processes may be true, albeit in a form different from what was considered in the latter part of the past century. Since the time of Wernicke's hypothesis concerning the conduction from Wernicke's area to Broca's area via the arcuate fasciculus, many who study neuropsychology have focused most attention on that conduit. There is another connection between

temporal and frontal areas of cortex, however. The uncinate fasciculus extends from anterior temporal cortex to inferior frontal gyrus within Broca's area. Thus, anatomical connections are in place if one were to hypothesize associations between areas involved in perception of speech with areas involved with production. Given that speech provides an unusual case for which, at least when one is talking, there are simultaneous activities of producing and perceiving one's own speech, the potential for such an association existing and being significant for speech perception is substantial but undocumented.

Stress: Hormonal and Neural Aspects

BRUCE McEWEN
Rockefeller University

SONIA LUPIEN
McGill University

GLOSSARY

adrenalin A catecholamine; released by the adrenal medulla.

allostasis Achieving stability through change; active process that leads to adaptation of many body systems in the face of challenge.

allostatic load The cost to the body of responding to challenges and/or mismanaging the adaptive response to challenge.

amygdala A brain region involved in fear and emotional expression.

cortisol A glucocorticoid; a product of the adrenal cortex.

hippocampus A region of the brain involved in declarative, spatial, and contextual memory

hypothalamic–pituitary–adrenal axis The neuroendocrine system that produces cortisol in response to stress and the internal clock that determines diurnal rhythm.

prefrontal cortex Region of the cerebral cortex linked to integration of information between emotion and cognition.

socioeconomic status Social status of an individual based on income and educational attainment; often determined by type of job.

Stress is an almost universal topic in the modern world. There are many uses of the word "stress," including its usefulness in promoting conversation and empathy among friends and colleagues and even among strangers. In this article, stress is defined as a threat, real or implied, to the psychological or physiological integrity of an individual. As a result of the perception of threat, an individual makes behavioral and physiological responses that are intended to protect and defend the body and psyche from damage. Many factors contribute to individual differences in interpretation of and response to threat. Early life events, experiences throughout life, genetic factors, and the actions of hormones on the brain combine to produce major differences among individuals in how they react to potentially stressful situations; for example, the physical condition of the body determines how "stressful" shoveling snow may be. Because psychological and physiological systems are linked through the brain, the behavioral and physiological consequences of stress reflect two sides of the same coin.

Stress involves a stressor and a stress response. A stressor may be physical, such as trauma or injury, or physical exertion, particularly when the body is being forced to operate beyond its capacity. Physical stressors include environmental factors such as noise, overcrowding, and excessive heat or cold. Stressors also include primarily psychological experiences such as traumatic life events as well as daily hassles in the family and workplace, but many of these stressors have real physiological consequences, such as increased blood pressure and altered functions of the metabolic system, immune system and brain.

A broader concept that includes stress is that of "allostasis" and "allostatic load," which take into consideration aspects of lifestyle, genetic factors, and developmental influences that determine the degree to which life experiences exact a toll on the body over the

life course. Allostasis and allostatic load help to resolve the ambiguity inherent in the multiple uses of the word stress and they emphasize that there is an almost inevitable cost to the body of adapting to challenges of many kinds.

Stress is a term popularized by Hans Selye in 1936 that has taken on great significance in modern life. Many people refer to being "stressed out" by the pressures of commuting, working, studying, caring for children, and the generally increasingly faster pace of life. However, stress as a subjective experience does not always predict increased activity of the hormonal systems that are linked to stress, namely, the sympathetic nervous system and the hypothalamic–pituitary–adrenal (HPA) axis. In addition to the reporting of subjective stress, challenges to the individual that may be stressful lead to physiological and behavioral responses that can be measured.

The physiological stress response can be measured by monitoring levels of cortisol and ACTH in blood or cortisol in saliva or urine, whereas activity of the sympathetic nervous system is measurable as levels of catecholamines in blood, urine, or saliva or by monitoring heart rate and blood pressure. The stimuli that activate these systems involve novelty and unpredictability, a lack of sense of control, and threats to the sense of self. In addition, for the sympathetic component, arousal and physical activity are potent stimuli.

When stress hormones are released into the bloodstream, they reach tissues and organs throughout the body, on which they produce a variety of effects. These effects are mediated by receptors residing on the cell surface for the catecholamines and inside the cell for cortisol. Both types of receptors alter expression of genes in the cell nuclei of target cells, and the catecholamines also signal changes in activities of enzymes and ion channels and receptors in the cell membrane or cytoplasm.

The physiological stress response appears to be one aspect of a broader range of biological and behavioral processes that can protect, on the one hand, and cause damage and facilitate disease, on the other hand. For example, the "stress mediators," such as cortisol and catecholamines, also vary in their basal secretion according to a diurnal rhythm that is coordinated by the light–dark cycle and sleep–waking patterns. For example, chronic elevation of diurnal levels in cortisol is associated with pathophysiological states such as accelerated bone mineral loss and hyperglycemia. Therefore, over a long period of time, the measurement of hormone levels and the processes that they control, such as cholesterol, blood pressure, and waist–hip ratio, constitutes the primary means of connecting experience with resilience or the risk for disease. It also represents a final common path for assessing the impact of both the perturbations in diurnal rhythm and the stress response.

The process of adaptation has been termed allostasis, and the cost the body pays for this adaptation is referred to as allostatic load. Many systems of the body are subject to allostatic load, and the brain is a particularly important target because of its coordinating role with respect to the physiological stress response and also the adaptive and maladaptive behaviors that are associated with the response to stressful situations. This article discusses the hormonal and neural aspects of the response to stressful events in terms of allostasis and allostatic load.

I. PROTECTIVE AND DAMAGING EFFECTS OF STRESS MEDIATORS

A. Allostasis and Allostatic Load

Understanding the nature of the final common biological path for resilience or disease requires a discussion of a number of contributing factors, such as the protective and damaging role of the physiological mediators of stress and the diurnal rhythm, as well as the role of behavior, the importance of genetic factors, the role of gender, and the biological features of resilience.

An attempt at formulating the relationship among environmental challenges, physiological responses, and outcomes such as resilience or disease uses two terms: allostasis and allostatic load. Allostasis, literally meaning "maintaining stability (or homeostasis) through change," describes the process of adaptation to challenge. It was introduced by Sterling and Eyer in 1988 to describe how the cardiovascular system adjusts to resting and active states of the body. This notion was generalized to other physiological mediators, such as the secretion of cortisol and catecholamines, and the concept of allostatic load was proposed to refer to the wear and tear that the body experiences due to the repeated use of allostatic responses as well as the inefficient turning on or shutting off of these responses. One example of allostatic load is the persistent activation of blood pressure in dominant male cynomologus monkeys vying for position in an unstable dominance hierarchy, which has been shown to accelerate atherosclerotic plaque formation. This can

be prevented by β-adrenergic blocking drugs, which suggests that repeated activation of β receptors by blood pressure surges accelerates the atherosclerotic process.

The concepts of allostasis and allostatic load apply to all systems of the body and focus attention on the protective (adaptive) and damaging roles of primary stress mediators, such as catecholamines and cortisol. There are four important aspects of this formulation that are summarized in Fig. 1. First, the brain is the integrative center for coordinating the behavioral and neuroendocrine responses (hormonal and autonomic) to challenges, some of which qualify as "stressful" and others of which are related to the diurnal rhythm and its ability to coordinate waking and sleeping functions with the environment. Second, there are considerable individual differences in coping with challenges that are based on interacting genetic, developmental, and experiential influences. Third, inherent within the neuroendocrine and behavioral responses to challenge is the capacity to adapt (allostasis); indeed, the neuroendocrine responses are set up to be protective in the short term. For the neuroendocrine system, turning on and turning off responses efficiently is vital (Fig. 2); inefficiency in allostasis leads to cumulative effects over long time intervals. Fourth, allostasis has a price (allostatic load, referring to cumulative negative effects) that is related to how inefficient the response is or how many challenges an individual experiences (i.e., many stressful events). Thus, allostatic load is more than chronic stress and can also reflect a genetically or developmentally determined failure to efficiently handle the normal challenges of daily life related to the sleep–wake cycle and other daily experiences.

For behavioral responses to challenge, there are also protective and damaging aspects. Individuals can act to increase or decrease further risk for harm or disease: for example, antisocial responses such as hostility and aggression vs cooperation and conciliation; risk taking behaviors such as smoking, drinking, and physical risk taking vs self-protection; and a high-calorie and/or fat-rich diet and poor health practices vs a moderate calorie, lower fat diet and regular exercise. The linkage of allostasis and allostatic load probably applies to behavioral responses as well as to physiological responses to challenge insofar as the behavioral response, such as smoking or alcohol consumption, may have at least perceived adaptive effects in the short term but damaging effects in the long term. Behavior also plays a role in modifying the physiological response (e.g., eating rich food synergizes with elevated physiological mediators to increase the metabolic syndrome, whereas even a brief period of exercise can reduce insulin resistance of muscle and enhance glucose uptake).

Although allostasis and allostatic load are general concepts, it is essential to describe and understand the mechanism of the protective and damaging effects that take place in each system of the body. The mediators [adrenal steroids, mainly catecholamines, but also

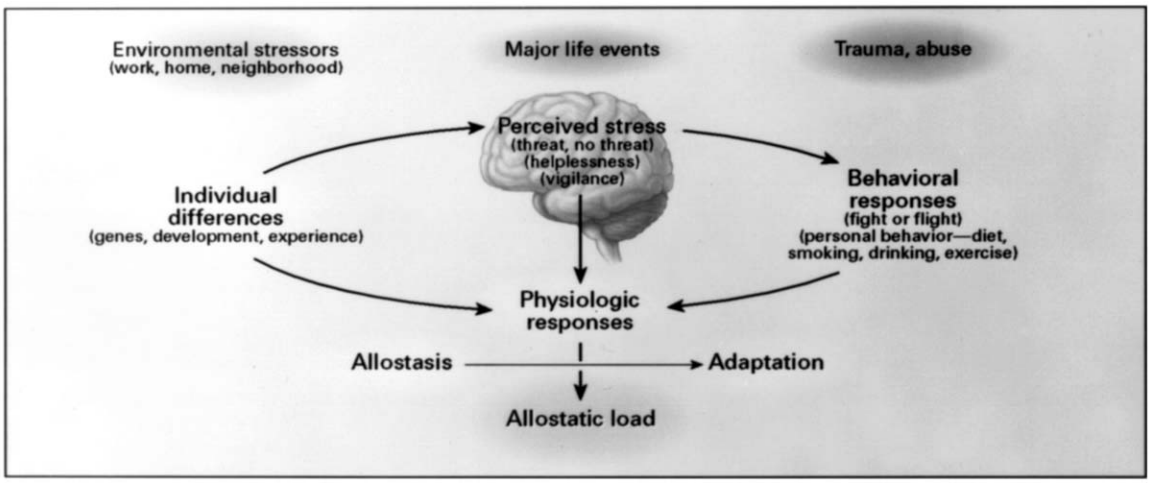

Figure 1 The stress response and development of allostatic load. Perception of stress is influenced by one's experiences, genetics, and behavior. When the brain perceives an experience as stressful, physiologic and behavioral responses are initiated leading to allostasis and adaptation. Over time, allostatic load can accumulate, and the overexposure to neural, endocrine, and immune stress mediators can have adverse effects on various organ systems, leading to disease (reproduced with permission from McEwen (1998). Figure 2 Allostasis in the autonomic nervous system and the hypothalamic–pituitary–adrenal axis. Allostatic systems respond to stress (top) by initiating the adaptive response, sustaining it until the stress ceases, and then shutting it off (recovery). Allostatic responses are initiated (bottom) by an increase in circulating catecholamines from the autonomic nervous system and glucocorticoids from the adrenal cortex. This sets into motion adaptive processes that alter the structure and function of a variety of cells and tissues. These processes are initiated via intracellular receptors for steroid hormones, plasma membrane receptors, and second messenger systems for catecholamines. Cross talk between catecholamines and glucocorticoid receptor signaling systems can occur (see text) (reproduced with permission from McEwen (1998). Copyright © 1998 Massachusetts Medical Society. other hormones such as dehydroepiandrosterone (DHEA), prolactin, and growth hormones and the cytokines related to the immune system] affect many systems, but their effects are organ or system specific in many cases. Once the mediators are secreted, they produce effects on systems and organs of the body by acting on receptors. The effects can be classified as primary effects, secondary outcomes that are risk factors for disease, and tertiary outcomes that are the diseases.

In Fig. 2, the actions of two mediators, the glucocorticoids and the catecholamines, are shown. The mediators act via receptors that trigger changes throughout the target cell in processes, including changes in gene expression that have long-lasting consequences for cell function. Thus, every time a hormone is secreted, it is important to consider the short-term and long-term consequences of hormone action on cell function.

The following are adaptive (allostasis) and damaging (allostatic load) aspects of four systems, and the roles of some of the mediators are presented. Later, we discuss these systems in-depth:

Cardiovascular. *Adaptive*: The autonomic nervous system, involving catecholamines, promotes adaptation by adjusting heart rate and blood pressure to sleeping, waking, and physical exertion. *Damaging*: Repeated surges of blood pressure or failure to shut off blood pressure surges efficiently accelerate atherosclerosis and synergize with metabolic hormones to produce type II diabetes.

Metabolic. *Adaptive*: Adrenal steroids promote food intake and promote replenishment of energy reserves. *Damaging*: Elevated evening cortisol and hyperreactivity of the HPA axis promote insulin resistance and accelerate progression toward type II diabetes, including abdominal obesity, atherosclerosis, and hypertension.

Brain. *Adaptive*: Adrenal steroids, together with catecholamines, promote retention of memories of emotionally charged events, both positive and negative. *Damaging*: Adrenal steroids, acting with excitatory amino acid neurotransmitters, promote cognitive dysfunction by a variety of mechanisms that involve atrophy and, in extreme cases, death of brain cells, particularly in the hippocampal region of the brain.

Immune. *Adpative*: Adrenal steroids, together with catecholamines, promote ''trafficking'' (i.e., movement) of immune cells to organs and tissues in which they are needed to fight an infection or other challenge, thereby enhancing immune responses in those sites. Adrenal steroids also modulate the expression of the hormones of the immune systems, the cytokines and chemokines. *Damaging*: Adrenal steroids and

catecholamines both have immunosuppressive effects when these mediators are secreted chronically or not shut off properly. On the other hand, the absence of sufficient levels of these mediators allows other immune mediators to overreact and increases the risk of autoimmune and inflammatory disorders. An inadequate response of the HPA axis and autonomic nervous system is thus another type of allostatic load, in which the dysregulation of other mediators, normally contained by cortisol and catecholamines, is a primary factor in a disorder.

The long-term cost to the body (allostatic load) may be categorized into at least four subtypes, as summarized in Fig. 3. The first type is simply too much stress in the form of repeated, novel events that cause repeated elevations of stress mediators. For example, the amount and frequency of economic hardship predict decline of physical and mental functioning as well as

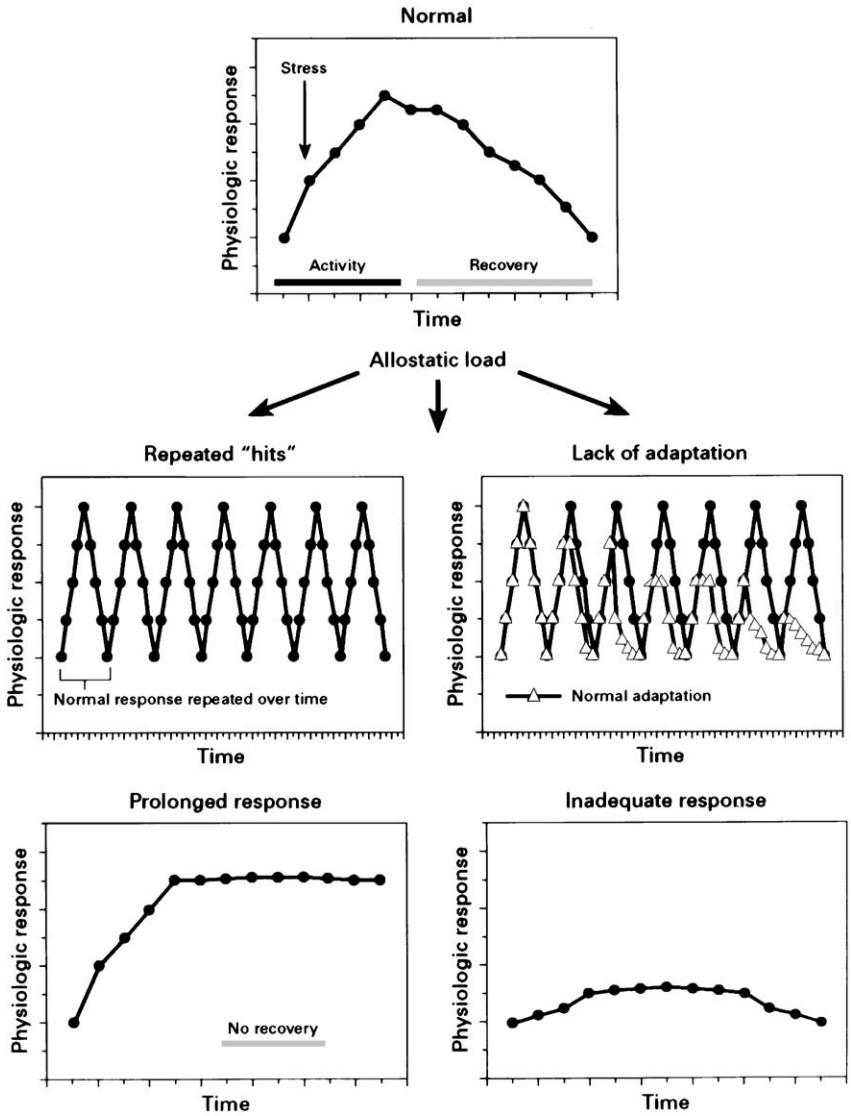

Figure 3 Four types of allostatic load. (Top) The normal allostatic response, in which a response is initiated by a stressor, sustained for an appropriate interval, and then turned off. (Bottom) Four conditions that lead to allostatic load: (i) repeated "hits" from multiple novel stressors, (ii) lack of adaptation, (iii) prolonged response due to delayed shut down, and (iv) inadequate response that leads to compensatory hyperactivity of other mediators (e.g., inadequate secretion of glucocorticoid, resulting in increased levels of cytokines that are normally counterregulated by glucocorticoids) (drawn by Dr. Firdaus Dhabhar, Rockefeller University; reproduced with permission from McEwen (1998).

mortality. A second type of allostatic load involves a failure to habituate or adapt to multiple occurrences of the same stressor. This leads to the overexposure to stress mediators because the body fails to dampen or eliminate the hormonal stress response to a repeated event. For example, when confronted with repeated public speaking challenges, most individuals habituated their cortisol response but a few individuals continued to show cortisol response. A third type of allostatic load involves the failure to shut off either the hormonal stress response or the normal trough of the diurnal cortisol pattern. Examples of this include blood pressure elevations in work-related stress, sleep deprivation leading to elevated evening cortisol and hyperglycemia within 5 days, and depressive illness leading to chronically elevated cortisol and loss of bone mineral mass.

The fourth type of allostatic load involves an inadequate hormonal stress response that allows other systems, such as the inflammatory cytokines, to become overactive. The Lewis rat is an example of an animal strain in which increased susceptibility to inflammatory and autoimmune disturbances is related to inadequate levels of cortisol.

Allostatic load can be measured. In the initial validation study, data were used from the MacArthur Successful Aging Study that pertain to levels of physiologic activity across a range of important regulatory systems, including the HPA and sympathetic nervous systems as well as the cardiovascular system and metabolic processes. The measure of allostatic load reflects only one of the two aspects of physiologic activity postulated to contribute to allostatic load—namely, higher, chronic, steady-state levels of activity related to the diurnal variation and any residual activity reflecting chronic stress or failure to shut off responses to acute stressors. The parameters that have been measured for determining allostatic load scores include urinary cortisol, adrenalin, noradrenalin; serum DHEA, waist–hip ratio, diastolic and systolic blood pressure, glycosylated hemoglobin, serum HDL, and total cholesterol.

One of the problems with the original conceptualization of allostatic load and its measurement is that the components are not organized and categorized with regard to what each measure represents in the cascade of events that lead from allostasis to allostatic load. Nor is there any suggested organization in choosing those original measures that would facilitate systematically relating measures to specific disease outcomes or systematically adding new measures. Allostasis and allostatic load are concepts that are mechanistically based and only as good as the information about mechanisms that lead to disease.

A new way of classifying the measures must provide a way to relate what is measured to a pathophysiological process and allow for the incorporation of new measures as more is known about underlying mechanisms leading to disease. This new formulation is based on the notion of primary mediators leading to primary effects and then to secondary outcomes, which finally lead to tertiary outcomes that represent actual diseases. In the original allostatic load measures, urinary cortisol, adrenalin, noradrenalin, and serum DHEA are primary mediators, whereas the other six (waist–hip ratio, diastolic and systolic blood pressure, glycosylated hemoglobin, serum HDL, and total cholesterol) represent secondary outcomes.

B. Modulators of Protection and Damage

There are a number of modulators of the processes of protection and damage, including genetic factors and developmental processes. These are briefly outlined before we discuss the impact of gender and socioenvironmental influences on the ability of the body to show allostasis and resist allostatic load in terms of resilience.

1. Role of Genetics

Genes are a major factor in risk for many disorders, but the environment and experiences of the individual play a major role in regulating the genetic traits throughout the life span. Many of the genetic traits are complex and reflect the operation of many genes. There has been enormous progress in the identification of genes and the mapping of the human genome. However, identifying a gene is only the first step, and understanding its regulation is critical. Fortunately, there is rapid progress in understanding how genes are regulated by hormones and other environmental signals such as neurotransmitters.

2. Developmental Influences

The susceptibility of an individual to stress-related disorders is likely to reflect developmental influences as well as genetic risk factors. Early life experiences play a major role in determining the long-term cost to the body, or allostatic load, over a lifetime. Animal models provide a useful way of understanding some environmental and developmental influences on individual differences that are relevant to human stress reactivity.

3. Gender Differences

An important aspect of development deals with sex differences in brain function and behavior. Sex differences are developmentally regulated and reflect not only the presence or absence of gonadal hormones during sensitive periods in pre- and postnatal life but also the interactive effects of a lifetime of experiences related to being male or female. Hormones, particularly testosterone, act during early pre- and postnatal development to shape the structure and function of brain regions, including both the hypothalamus and extrahypothalamic brain regions such as the hippocampus. Testosterone secretion by the testes during gestation and early neonatal life masculinizes and defeminizes the brain, and these processes affect the connectivity between nerve cells, the number of nerve cells, and the functional capacity to respond to hormones and other chemical messengers. However, hormones and experience can change brain structure and function in adult life; thus, there is a considerable range of plasticity throughout the life span.

Behavioral sex differences develop as a result of the interaction of a sexually differentiated neural substrate with experiences, and these sex differences pertain to reproduction-related events, such as establishment and defense of territory and mating and sexual behavior, as well as to nonreproductive behaviors such as strategies used to solve spatial learning tasks. Sex differences are also recognized in the prevalence of psychiatric disorders, with females showing higher rates of anxiety and depression and males having higher incidences of substance abuse and antisocial behavior. Moreover, in animal models and possibly also in humans, there are sex differences in the vulnerability to brain damage or brain remodeling. Although the role of hormones is a hallmark of sexual differentation, the role of experience and social factors cannot be underestimated, particularly in infrahuman primates and humans. As noted previously, the impact of experience to change brain structure and function is one of the emerging areas of neurobiological research. However, in humans as in lower animals, there are certain basic patterns or tendencies that characterize each gender.

In animals, and possibly also to some extent in humans, the role of basic sex differences in attitudes toward ''nurturing'' may provide a fundamental difference in response to a variety of life events and therefore in the types of long-term cost, or allostatic load, that are manifested. Within the concept of ''inclusive fitness,'' the male is more prone to show a ''fight or flight'' response to stressful challenges, whereas female responses to such challenges are more likely to follow a pattern referred to as ''tend and befriend.'' ''Tend'' refers to nurturant activities designed to protect self and offspring, promote safety, and reduce distress, whereas ''befriend'' means the formation and maintenance of largely female networks that aid in protecting and nurturing offspring and self. Possible underlying mechanisms for these differences include oxytocin, female and male reproductive hormones, and endogenous opioid mechanisms as well as neurotransmitters such as serotonin, low levels of which promote hostility, aggression, suicide, and depression.

Regarding allostatic load, the tend and befriend behavior promotes social support, which reduces the hormone levels associated with allostatic load. In contrast, the fight or flight response pattern can either put the individual at greater risk for harm and futher allostatic load (fight or confrontation) or remove the individual from danger, which may be beneficial for health (flight or withdrawal). On the other hand, defeat, which can result from confrontation and fighting, can have devastating effects on health and survival among males even in the absence of physical injury. Subordination and conflict in social groups of animals reveal more subtle sex differences. For example, unstable social hierarchies among male cynomologous monkeys increase the rates of atherosclerosis in coronary arteries, although subordinate status of males in a stable hierarchy does not increase atherosclerosis; however, subordinate female cynomologous monkeys are known to have increased risk for atherosclerosis and depression in both stable and unstable social hierarchies.

4. Socioenvironmental Conditions

We previously discussed what happens to the individual and how the individual's behavioral and physiological responses and risk for disease are determined by genetic, developmental, and experiential factors. Individuals make up groups that differ, for example, in education and income [referred to as socioeconomic status (SES)]. SES appears to be an important factor in disease, and new evidence points to gradients of health across SES in the British Civil Service as well as in other Western countries. Hardship also compromises health, including cognitive and physical function and mental health. The collapse of communism resulted in worse health in Eastern Europe, particularly in Russia, between 1989 and 1993, and behavioral problems (alcoholism, suicide, homicide, and cardiovascular disease) accounted for much of the increased mortality.

5. Resilience

From a physiological standpoint, we know very little about positive influences on health (e.g., resiliency in recovery from illness, injury, or surgery and the overcoming of adversity). Undoubtedly, resilience is more than just the absence of allostatic load but, rather, the product of cellular processes that protect and build cells and tissues and provide some reserve capacity and resistance to the damaging effects of stress mediators. In particular, the role of anabolic hormones, such as growth hormone and insulin, and the neurotrophic factors in the brain needs to be explored in relation to such phenomena as voluntary exercise and recovery from illness, injury, or surgery. One example of this is the ability of voluntary exercise in rats (running on an activity wheel) to increase the expression of the messenger RNA for a neurotrophin, which protects nerve cells from dying and promotes aspects of cellular plasticity and synaptic transmission. It is not known what advantages this increased level of neurotrophins may confer on the brains of the exercising animals, for example, whether they are more resilient in the face of severe stress or whether their brains will age more slowly. One possible consequence of this neurotrophin regulation is that voluntary exercise has been reported to increase production of new nerve cells in the dentate gyrus of the hippocampal formation, a brain region that is important in spatial and declarative memory.

More research is needed to relate the production of neurotrophins and other mediators related to growth and repair of tissues to human life histories and to identify the role of social support mechanisms and individual attitudes in promoting beneficial physiological states associated with the ability to repair damaged tissues and to protect against pathogens and toxic agents such as free radicals. Though poorly defined, this area of inquiry is very important as a complement to the more traditional approach of studying the damaging aspects of stress mediators.

II. ALLOSTATIC LOAD IN THE BRAIN

A. Protective and Damaging Effects of Stress Mediators in Brain

Stress mediators have both positive and negative effects on the brain, just as they do on other systems of the body. The stress mediators enhance formation of the so-called ''flashbulb memories'' of events associated with strong emotions, including fear but also positive emotions. These involve the amygdala, and the pathway for encoding these memories involves the interaction between neurotransmitters in the amygdala and in related brain areas such as the hippocampus along with circulating stress hormones of the adrenal cortex and adrenal medulla. Indeed, encoding of these memories is strengthened by glucocorticoids acting in the amygdala and hippocampus, among other brain regions, and epinephrine acting in the sensory vagus outside of the blood–brain barrier, with information transmitted into the brain via the nucleus of the solitary tract. These findings may have relevance to posttraumatic stress disorder and also to symptoms of depression, in which an overactive amygdala appears to be involved.

At the same time as the brain encodes information and controls the behavioral responses, it is also changed structurally and chemically by those experiences. Studies of learning and memory have revealed levels of plasticity involving structural changes in brain cells and changes in gene expression. On the one hand, this can be seen by the remodeling of neuron structure brought about by training. On the other hand, transcription factors involved in regulating expression of groups of genes in brain cells appear to be essential for the formation of long-term memories in species ranging from fruit flies to mice.

Although short-term response of the brain to novel and potentially threatening situations may be adaptive and result in new learning and acquired behavioral strategies for coping, as may be the case for certain types of fear-related memories, repeated stress can cause cognitive impairment via at least four different mechanisms:

1. Impairing neuronal excitability: Adrenal steroids biphasically modulate long-term potentiation (LTP), with low levels enhancing it and high levels impairing LTP in regions of the hippocampus that use NMDA receptors; other measures of excitability are also affected by adrenal steroids.
2. Causing atrophy of nerve cells in the Ammon's horn region of the hippocampus: Adrenal steroids facilitate a remodeling of apical dendrites of pyramidal neurons in the CA3 region of the hippocampus that is caused by excitatory amino acids; such remodeling is reversible as long as stress is terminated after a number of weeks.
3. Inhibiting neurogenesis in the dentate gyrus region of the hippocampus: The adult hippocampus continues to produce nerve cells in adult life, and this

process is inhibited by certain stressors and by activation of NMDA receptors as well as by elevated glucocorticoids.

4. Causing permanent loss of nerve cells in hippocampus: Prolonged psychosocial stress causes damage and apparent neuron loss in the hippocampus.

These processes may occur somewhat independently of each other and contribute in various degrees to different pathophysiological situations involving traumatic stress, depression, or aging.

B. Effects of Stress and Stress Hormones on Cognitive Function

Having reviewed the potential mechanisms by which stress and stress hormones can biphasically modulate learning and memory processes, we now consider the information available on stress and glucocorticoid effects on cognitive function in human subjects.

The cognitive effects of elevated concentrations of glucocorticoids in human populations have been studied in disorders affecting corticosteroid levels and by using exogenous administration of the synthetic compound to healthy subjects. Mental disturbances mimicking mild dementia (such as decrements in simple and complex attentional tasks, verbal and visual memory, encoding, storage, and retrieval) have been described in depressed patients with hypercortisolism and in those with steroid psychosis following corticosteroid treatment. Similar cognitive deficits are also reported in patients suffering from Cushing's disease. During human aging, a significant proportion of elderly individuals present an endogenous increase of glucocorticoid levels, and this increase has been related to impaired memory performance. Moreover, many investigators have reported inverse relationships between mean 24-hr cortisol levels and severity of cognitive decline in Alzheimer patients.

Studies in both animals and humans have shown that the glucocorticoid-induced memory impairment is related to an atrophy of the hippocampus. Hippocampal atrophy associated with chronic exposure to high levels of glucocorticoids is reported in Cushing patients, elderly individuals, depressed patients, and individuals suffering from posttraumatic stress disorders. This is a significant finding and implicates the hippocampus since the declarative memory impairments that are induced by chronic exposure to high levels of glucocorticoids are those attributed to the hippocampus in memory function.

It is known that the hippocampus plays a significant role in declarative memory function, whereas it has little function in nondeclarative memory function. Declarative memory refers to the conscious and voluntary recollection of information that was previously learned, whereas nondeclarative memory function refers to the facilitation in performance observed after exposure to a given information, without necessary consciousness of recall of this information. Many studies have shown that hippocampal damage in animals and humans leads to declarative memory impairments, whereas nondeclarative memory is unimpaired. This is the pattern of memory dysfunction reported to occur in all cases of chronic exposure to high levels of glucocorticoids.

However, studies of endogenous disorders generally fail to discriminate the cognitive deficits related to HPA hyperactivity from those due to the underlying illness. Thus, most of the cognitive deficits associated with corticosteroids are derived from those observed during acute exogenous administration of synthetic glucocorticoids to healthy subjects. In general, studies measuring the acute impact of glucocorticoids on cognitive function report that this steroid impairs selective attention (i.e., the ability to discriminate relevant from irrelevant information), which thus impairs encoding of incoming information. This finding is in accordance with electrophysiological results showing that acute administration of cortisol to human subjects reduces the average evoked potential response to relevant but not to irrelevant stimuli. These findings are also consistent with studies showing that glucocorticoids can impair neuronal electrophysiology and hippocampal long-term potentiation.

Recent studies have reported that an acute increase of glucocorticoids also impairs working memory function. Working memory is the cognitive mechanism that allows us to keep a limited amount of information active for a limited period of time. Working memory impairments have been found in several experiments using a variety of delay task procedures. In these tasks, a temporal gap is introduced between a stimulus and a response, which creates the need to maintain the stimulus in a temporary memory storage. Interestingly, data obtained in monkeys show that cells in the lateral prefrontal cortex become particularly active during delayed response tasks, suggesting that these cells are actively involved in holding on to the information during the delay. This result is in accordance with studies reporting a high density of corticosteroid receptors in the cerebral cortex of both rat and human. Receptor binding studies in rats have

shown the presence of adrenal steroids in the cortex, particularly in the medial prefrontal regions. Further studies in rats and humans have shown that the prefrontal cortex is a significant target for the negative-feedback actions of circulating glucocorticoids, which suggests that this area could play a significant role in the acute effects of corticosteroids on cognitive function.

Thus, the hippocampus is not likely to be the only brain area affected in this way since atrophy of the amygdala and prefrontal cortex has also been reported in depressive illness. Reversibility and/or preventability of such atrophy is a major topic for future research, as is the implication of such treatment for cognitive function. A recent study showed that treatment of Cushing's patients induces a 10% reversibility in the hippocampal atrophy that was induced by chronic exposure to high levels of glucocorticoids.

III. DEVELOPMENTAL INFLUENCES ON ALLOSTATIC LOAD

The susceptibility of an individual to stress-related disorders is likely to reflect developmental influences as well as genetic risk factors. A major advance in behavioral neuroscience during the past decade has been the establishment of a life course perspective for understanding environmental influences on stress reactivity during development that persists for a lifetime. Prenatal stress increases emotionality and stress hormone reactivity for the life of the individual; conversely, postnatal "handling" of neonates leads to reduced emotionality and reduced stress hormone reactivity for a lifetime. In animal models, brain aging is increased by elevated stress reactivity and reduced by lowered stress reactivity. In addition, studies in infrahuman primates have shown that early maternal neglect increases anxiety and emotional lability in the offspring.

These animal studies are also directly relevant to and should encourage further studies of the adverse consequences for mental and physical health of abuse and neglect during childhood. Although data on human subjects are limited, there is a report that abuse in childhood is associated with substantial increases in substance abuse, depression, and suicide and also increased incidence of heart disease, cancer, chronic lung disease, skeletal fractures, and liver disease. There are also indications that individuals with posttraumatic stress disorder who were abused as children have a significantly smaller hippocampal volume. In addition to its relevance to structural plasticity within the brain, this finding raises questions about when in an individual's life these changes actually occur—whether they occur early in life or are initiated by the traumatic experience later in life.

Besides exposure to traumatic events during childhood, another pathway by which individual differences in physical health and/or cognitive function could be slowly established is through differential exposure to stress. In children, it has been hypothesized that stress experienced in the early years may have long-term effects on future development of psychosomatic diseases. However, immediate effects of stress on children's health have also been reported. In classic study, Cohen *et al*. compared children from schools that were beneath the flight path of the Los Angeles International Airport with children from schools in quieter areas. These investigators showed that children from the noisy schools presented higher blood pressure than children from the quieter schools. Moreover, they reported that children from the noisy areas had difficulty learning how to discriminate between irrelevant noise and the relevant task, which is in agreement with results of studies showing that stress affects selective attention. In a subsequent study, Cohen *et al*. evaluated the effects of living in apartments near congested highways in New York City. They showed that despite the relatively higher noise levels on lower floors of the buildings, residents of lower floors did not differ from neighbors on upper floors in their subjective ratings of noise level or degree of annoyance. However, children on the lower floors adapted to the noise by "tuning out" sounds, which resulted in a lower responsiveness to differences in spoken words. This further affected their reading ability, as demonstrated by long-term reading impairments. These results suggest that stress at an early age may affect health (e.g., blood pressure) as well as cognitive processing.

As noted previously, SES is another pathway by which significant individual differences in stress reactivity might evolve. It has been shown that individuals from lower SES report greater exposure to stressful life events and a greater impact of these events on their lives than do individuals from higher SES. Given the known impact of glucocorticoids on immune function, this suggests that individuals from lower SES may have greater vulnerability to stress and, subsequently, to disease. The association between SES and stress may also stem from environmental and social/psychological factors. With regard to environmental factors, it is known that as one moves down the

SES ladder, residential choices become more limited and many of the environments in which individuals lower on the SES hierarchy live are associated with increased mortality rate and crime. It has been suggested that these differences in environments vary objectively in chronic exposures to stressor events. With regard to sociological/psychological factors, it has been shown that higher SES decreases the likelihood of exposure to negative events such as social aggression and risk behaviors. Members of lower SES are exposed to a higher rate of change and/or instability in their lives and this instability has been found to produce a higher level of individual distress in lower SES individuals.

The relationship between SES and health begins at the earliest stages of life. In children, an SES–health linkage has been found with the following health problems: lead poisoning, vision problems, otitis media and hearing loss, cytomegalic inclusion disease, and iron deficiency anemia. In addition, mental retardation, learning disorders, and emotional and behavioral problems occur at greater frequency among children of lower SES. In order to assess whether the development of the relationship between SES and mental health is sustained, at least in part, by exposure to high levels of glucocorticoids, Lupien and collaborators measured morning salivary cortisol levels as well as cognitive function (memory, attention, language, and emotional processing) in 396 children (6–16 years of age) from low versus high SES in the Montreal area. Depressive symptomatology and exposure to stressful events were also assessed in each child's mother through a semistructured phone interview. The results revealed that low SES children from 6 to 10 years of age presented significantly higher salivary cortisol levels when compared to children from high SES. This difference disappeared at the time of school transition (i.e., at 12 years of age), and no SES differences were observed at 14 and 16 years of age. Neuropsychological data showed that although children from low and high SES do not differ with regard to memory, attentional, and linguistic functions, children from low SES (at all ages) presented a significantly higher level of negative emotional processing. Scores on the depression and stress questionnaires were significantly higher for low SES mothers compared to high SES mothers. More important, the authors reported a significant positive correlation between the mother's depressive symptomatology and her child's cortisol level. This showed that the higher the mother's score on the depressive scale, the higher the cortisol level of her child. Altogether, these results showed that low SES in young children is related to increased cortisol secretion and negative emotional processing. Moreover, they showed that depression in the mother, in conjunction with low SES, is a significant factor predicting high cortisol levels in children.

Further study of these topics is important because data indicate potentially beneficial effects for antisocial behavior and success in school of early life interventions by nurses visiting the home and providing support and education to the parents.

IV. CONCLUSIONS

The concepts of allostasis and allostatic load are inclusive of what we mean by stress, but they are much broader because they include aspects of lifestyle as well as genetic influences and developmental effects, including early life experiences and gender differences. In this way, allostasis and allostatic load provide a general conceptual framework in which to evaluate the overall impact of the physical and social environment on individuals and groups of individuals. It should be emphasized that although most of the work done so far has focused on the role of HPA activity and autonomic nervous system reactivity in these nature–nurture interactions, the allostasis/allostatic load model can be generalized to other physiological systems that respond to environmental stimuli. In other words, allostasis and allostatic load attempt to embody a general biological principle that the systems that help protect the body and promote adaptation in the short term can also participate in pathophysiological processes when they are overused or inefficiently managed.

The most important feature of allostatic load is that it operates gradually over long periods of time in the life of an individual. In fact, as summarized in this article, influences of genetic factors and early experiences, when coupled with the subsequent life experiences of each individual, exert a life-long effect on the physiology of an individual and alter the risk for developing a variety of pathophysiological conditions and diseases later in life as well as the rate of certain aspects of the aging process.

This multidisciplinary view of stress as a form of allostatic load should eventually allow us to identify very early in the life of an individual the potential risk factors for the negative effects of stress on physical and mental health. For example, personality traits such as anger, negative affect, and emotional inhibition

increase HPA and autonomic nervous system reactivity on an acute and/or chronic basis. These elevations, in turn, contribute to allostatic load when they represent a life-long pattern of response to challenges. We have seen that the personality traits cited previously may be the result of early life experiences as well as reflections of genetic factors. Fortunately, none of these traits, or the genetic and environmental factors that produce them, reflect an irreversible change in either behavior or allostatic load, and there are many intervention strategies that are likely to be very helpful early in development as well as later in life.

Stress

D. JEFFREY NEWPORT and CHARLES B. NEMEROFF
Emory University School of Medicine

GLOSSARY

corticotropin-releasing factor Both a neurotransmitter and a neurohormone; the primary secretagogue of the hypothalamic–pituitary–adrenal axis.

diathesis A vulnerability or predisposition to illness; dependent on both genetic and acquired factors.

homeostasis Maintenance of constant conditions within the internal environment of the body.

limbic system Complex of central nervous system structures responsible for the regulation of emotions and behavior; consists of the amygdala, hippocampus, certain regions of the thalamus, and basilar cortex.

locus coeruleus The site of origin of nearly all norepinephrine-secreting neurons in the central nervous system.

norepinephrine The primary neurotransmitter utilized in activation of the sympathetic nervous system.

stress Any challenge to homeostasis that requires an adaptational response.

Stress as a concept has in recent years so preoccupied our collective imagination that it has altered the very way we speak and think. Consequently, we customarily talk of being stressed out, being under stress, taking a stress test, managing stress, relieving stress, reducing stress, suffering a stress fracture, enduring corporate stress, practicing stress medicine, or suffering from stress incontinence or posttraumatic stress disorder. However, moving beyond common discourse to a scientific discussion of stress is not a simple straightforward transition. Considerable debate remains as to the definition of stress, the nature of normal versus pathological responses to stress, and the elucidation of a neurobiology of stress that is distinct from the neurobiology of stress-related or stress-responsive psychiatric and medical disorders. In this article, we endeavor to provide a relatively comprehensive yet concise discourse on this topic. First, we offer a definition of stress that is operationally suitable for scientific discussion. Second, we describe the phenomenology of stress and the stress response in normal individuals. This includes both behavioral and biological alterations during the response to a stressor. Third, we discuss the role that stress plays in the pathogenesis and ongoing pathophysiology of stress-responsive psychiatric disorders. This incorporates a discussion of so-called diathesis:stress models of the disease process, the role that stressful life experiences play in precipitating specific psychiatric syndromes, and the functional alterations in stress-respondent biological systems observed in particular psychiatric illnesses. Finally, we briefly discuss the impact of psychopharmacological intervention on stress-induced neurobiological changes with a view to the development of novel antidepressant and anxiolytic agents.

I. STRESS: TOWARD AN OPERATIONAL DEFINITION

Most people have a reasonable understanding of what is meant by stress. When using the term in everyday

conversation, we are seldom misunderstood. Nevertheless, attaining universal agreement on a precise yet comprehensive definition is more problematic. This should not be surprising. Stress is an inherently nonspecific term that is applied in an overarching manner to a heterogeneous array of life experiences. We intuitively associate stress with negative life experiences, such as life-threatening illnesses, loss of employment, or impending divorce. However, intrinsically positive experiences such as moving into a new home, beginning a new job, or having a baby can be stressful as well.

How can we arrive at a scientifically meaningful definition of stress when such diverse life experiences are encompassed by the term? When communicating in a scientific forum, it is imperative that we speak with accuracy and precision. Unfortunately, ill-defined terms such as stress do not readily lend themselves to the empirical rectitude demanded by science. It is precisely for this reason that some investigators have advocated abandoning the concept altogether on the grounds that we too often resort to the nonspecificity inherent in abstract terms such as stress. However, the tenaciously enduring presence of stress as a scientific concept speaks to its ultimate relevance. If there were not some underlying commonality to the myriad experiences that we deem stressful, then there would be no impetus for applying the single word stress to such a broad range of life events. Similarly, there would be no reason to formulate the term "mind" had we not recognized the connections between the concepts of memory, cognition, emotion, and volition.

Just what is it that is common to the experiences that we deem as stressful? Most formulations incorporate the concepts of change and adaptability. However, before we can properly understand stress, we must first describe the concept of homeostasis. Homeostasis refers to the maintenance of constant conditions within the internal environment (milieu) of the body. It is necessary for survival because cells are capable of living, growing, reproducing, and performing their specialized functions only so long as proper concentrations of nutrients (i.e., energy sources) and other precursors to constituent molecules are readily available.

The external environment, however, is not subject to such constancy. In fact, change is often the only certainty in our surroundings. Perturbations in the external environment frequently impact the body's internal milieu. In order to maintain the constancy of the body's internal environment, we must be equipped to make adaptive changes in response to these external forces. Otherwise, homeostasis is compromised, and survival is in jeopardy. These adaptive responses include conscious efforts to manipulate the external environment so that the challenge to homeostasis is reduced. Adaptation also includes unconscious internal mechanisms that alter the function of one or more body systems in an effort to maintain constancy for the body as a whole. A simple example is our body's requirement to maintain a constant temperature of 37°C. When we walk outside on a cold, wintry day, we are faced with an environmental challenge to our ability to maintain that constant body temperature. We respond with conscious manipulation of the external milieu when we drink a cup of hot coffee, wear an overcoat, or build a fire. Our bodies also respond unconsciously by activating the sympathetic nervous system and perhaps by increasing thyroid hormone secretion. The increase in sympathetic activation in turn produces shivering that generates body heat aimed at maintaining the optimal body temperature.

In this context, we can construct an operational definition of stress that is suitable for scientific inquiry. Stress is defined as any challenge to homeostasis that requires an adaptational response. Often, stress is a consequence of a change in the external environment that perturbs the internal milieu. However, stress can be a direct result of dysfunction in one or more organ systems within the body's internal environment.

The stressfulness that we assign to an event is not solely contingent on the innate characteristics of the event. Coping mechanisms exist such that two individuals exposed to the same stressor will experience different degrees of stress. The stress experienced by a particular individual in a given circumstance depends both on the demands placed by the event and on the individual's sense of control in that situation. For example, a child's first attempt at riding a bicycle is highly stressful, but as the child learns to balance the bicycle, a sense of control is gained. Eventually, the child develops mastery over bike riding and virtually no stress is encountered. Consequently, it is meaningless to ask, "How stressful is riding a bike?" However, it may be reasonable to ask, "How stressful is learning to ride a bike?"

II. PHENOMENOLOGY OF STRESS AND THE STRESS RESPONSE

A. Adaptive and Maladaptive Stress Responses

In discussing the phenomenology of stress, the focus obviously cannot be exclusively on the stressor.

Equally important is the stress response, the biobehavioral sequelae of stress. All stress responses are intended to preserve homeostasis. In reality, however, stress responses may be adaptive or maladaptive. An adaptive response promotes the maintenance of homeostasis. A maladaptive response fails to achieve homeostasis and illness may result. When this occurs, the maladaptive response to a stressor becomes a stress and a pathophysiological cascade may ensue. For example, a stressful life event may precipitate an episode of major depression. Depression, in turn, is associated with changes in certain neurobiological systems that often have persistent adverse consequences, thereby increasing the vulnerability to future episodes of depression. The depressive episode is then partially a result of a maladaptive response to an initial stressor, but it may evolve into a stressor in its own right that persists long after the triggering life event has resolved.

The adverse consequences of stress with a particular emphasis on its psychiatric sequelae are highlighted in the ensuing discussion. This is certainly consistent with the typical negative connotations of undue stress in modern society. However, stress often has beneficial effects. For example, tempered steel is exposed to the stress of intense heat followed by sudden cooling to purge impurities. This process improves the durability, hardness, and strength of steel. Without undergoing the stress of the tempering process, steel is not a reliable building product.

Stress can offer similar benefits to organisms. Darwinian theory is predicated on the notion that stress plays a vital role in ensuring the fitness of a species by eliminating unfit organisms from the reproductive pool. Overcoming stress confers strength. As Nietzshe stated, ''That which doesn't kill you makes you stronger.'' We argue that stress is likewise the impetus behind much human ingenuity. The proverb ''necessity is the mother of invention'' illustrates this beneficial function of stress. The demands placed on human adaptability by stressful life events instigate human resourcefulness and eventuate in technological and philosophical advances. In fact, the unprecedented success of the human species is certainly, at least in part, a consequence of our superior capacity for adaptation in the context of environmental change.

It is a misnomer to think of a single invariable response to stress. Recognizing that stress is a heterogeneous phenomenon, a monolithic stress response would hardly be adaptive. Instead, an adaptive stress response is by definition tailored to respond appropriately to the particular intensity and quality of the stressor. For example, the stress of infection is met with a swift response by the immune system. In contrast, immune system changes are present but less prominent in the response to psychosocial stress. Nevertheless, there are certain behavioral characteristics common to most stress responses. In particular, physical manifestations suggestive of increased sympathetic tone are often seen in both humans and animals under stress. This has been the basis for a plethora of psychophysiological research that has demonstrated physical responses to stress, such as tachycardia, hypertension, diaphoresis, dizziness, elevations in skin temperature and skin conductance, and increased electromyographic activity.

Here, three points of paramount importance should be considered. First, there are profound differences in the central nervous system (CNS) response to physical (e.g., hypovolemia) and psychological stressors. Second, although adaptation to homologous stressors has been demonstrated, this does not generally hold true for heterologous stressors. Third, the developmental/life cycle period in which the stressor is applied is critical to the nature and course of the stress response.

B. Stress Patterns and the Characteristics of the Stress Response

In life, the events that constitute stress are often largely beyond our control. In the laboratory setting, however, the characteristics of the stressor can be delicately manipulated. This includes both qualitative and quantitative aspects of the stressor. Qualitatively, experimental stressors are composed of those that represent an addition to the environment and those that consist of a subtraction from the environment. Additions to the environment include unpleasant stimuli, such as air puffs to the face, electric shock, temperature extremes, disturbing loud noises, or intense lights. Stressful subtractions from the environment entail some form of deprivation, including food deprivation, maternal deprivation, and isolation (i.e., deprivation of stimuli).

Equally important is the quantitative presentation of the experimental stressor. This refers to the temporal schedule of stressor presentation and includes single short-term exposure, single long-term exposure, and repeated exposure. The temporal characteristics of stressor presentation often exert a marked impact on the stress response. For example, a single short-term stress exposure initially elicits an

orientation response. During orientation, the experimental subject ceases its prestress activity and directs its attention toward the source of the stress stimulus.

Single long-term stress exposure typically consists of placement into a novel environment. The initial response is commonly fear and inactivity (i.e., freezing) that is followed by exploration. This exploration is less a product of curiosity than an effort to reduce anxiety by eliminating the uncertainty precipitated by placement into an unknown environment.

Repeated stress exposure can elicit two primary patterns of stress response: sensitization and habituation. During the initial repetitions of a stressful stimulus, the characteristic orientation response may be exaggerated. Although stress sensitization can be persistent [as is perhaps the case in some patients with posttraumatic stress disorder (PTSD)], continued repetition of the stressor usually results in a habituated response. Through habituation, the ability of a stressor to elicit the characteristic orientation response is lost. Repeated presentation of the stressor thus results in an adaptive response that enables the organism to gain a sense of control over the stress stimulus. Thus, the requirement for an orientation response is diminished.

An important variant is repeated uncontrollable stress exposure. The best example is the uncontrollable shock paradigm used in rodents. This experimental animal model is believed to be homologous to depression in humans and is popularly known as the learned helplessness model. In this application, the initial exaggerations in the orientation response are also lost after repeated administrations of shock. The test animals instead become less active after repeated shocks, but the conception of this as a manifestation of learned helplessness is far from certain. The animal's inactivity may instead be a consequence of extreme fear and anxiety and thus represent an extension of the freezing response typically seen in the initial aftermath of a single long-term stress exposure. The distinction is that learned helplessness would essentially represent surrendering to the uncontrollable stress, whereas prolonged freezing is a consequence of anxious indecision.

III. STRESS AND PSYCHIATRIC ILLNESS: DIATHESIS/STRESS MODEL

Stress is generally acknowledged to play a paramount role in the pathogenesis of many psychiatric disorders. However, not everyone exposed to a given stressor generally considered likely to precipitate a psychiatric syndrome becomes ill. For example, pancreatic cancer has long been believed to convey a substantial risk for developing a major depressive episode. In fact, depression commonly predates the onset of physical symptoms of the cancer. Nevertheless, one-half of patients with pancreatic cancer do not become depressed. Similarly, PTSD remains a significant burden to many Vietnam combat veterans nearly 30 years after the conclusion of that war. However, most Vietnam combat veterans (85%) do not suffer from PTSD. Why do some individuals succumb to a particular stressor and become ill while others do not?

Stressful life events can obviously serve as acute precipitants to psychiatric and medical illness. However, some individuals tolerate stress of great magnitude and long duration without becoming ill. Others exhibit a constitutional vulnerability to the effects of stress (i.e., a lower threshold of tolerance for stress that predisposes them to stress-induced illness). This inherent vulnerability to the adverse effects of stress is known as a diathesis and provides the basis for the *diathesis/stress disease model*.

The diathesis/stress model has in recent years been applied to a broad range of psychiatric and medical disorders, including major depression, schizophrenia, chronic fatigue syndrome, PTSD and other anxiety disorders, sexual disorders, and pain disorders such as fibromyalgia and arthritis. This model theoretically has practical application to other psychiatric syndromes, including somatoform disorders, eating disorders, attention-deficit hyperactivity disorder, and impulse control disorders. In addition, neurological disorders including epilepsy and migraine headaches, rheumatological diseases such as systemic lupus erythematosus, and other illnesses such as irritable bowel syndrome and diabetes mellitus may be appropriate to consider from the framework of a diathesis/stress model.

What is the origin of the diathesis? The relative contributions of genetic inheritance and environmental exposure to the susceptibility to illness have been deliberated in often contentious nature versus nurture debates. Such arguments are often couched in overly absolute terms, but the diathesis/stress model permits a more balanced consideration. Diathesis/stress models recognize that both inherited and acquired factors may contribute to the vulnerability to stress.

A full accounting of the genetic contribution to the predisposition to stress-related illness is beyond the scope of this article. Nevertheless, human twin studies have clearly revealed a significant genetic contribution to the vulnerability to many psychiatric syndromes,

including depression, bipolar disorder, and schizophrenia. To date, it has not been possible to identify with certainty the chromosomal localization much less the precise gene(s) that forms the basis of the genetic contribution to the diathesis for psychiatric disorders. From years of largely unsuccessful research by psychiatric geneticists, it is clear that the genetic contribution to the vulnerability for psychiatric illnesses is unlikely to arise from simple single gene Mendelian transmission. It is more likely that the heritable vulnerability to psychiatric illness arises either from complex polygenic patterns of inheritance or from even more complex epigenetic modification of genotypic risk. For example, in recent years, the existence of resistance genes that interact with susceptibility genes has been postulated.

Epidemiological research also indicates that the environment makes a substantial contribution to the vulnerability to psychiatric illnesses. Environmental contributions to the diathesis may emerge from any of a variety of biopsychosocial stressors. Consequently, stress plays a dual role in the pathogenesis of psychiatric illness. When stress is coincident with the onset of an illness, it serves as an acute precipitant to the disorder. In contrast, when stress predates the onset of a disorder, it may well shape the predisposition to future illness. Although the major environmental contributions to the diathesis occur during the formative childhood years, the diathesis remains mutable throughout adult life. Stresses during adulthood continue to modify the predisposition to illness. In fact, disease is a stressor that can increase the risk for future episodes of illness. Theoretically, the stress-induced predisposition to illness should be both psychometrically and biologically measurable. It is this impression that underlies a burgeoning line of research investigating the persistent neurobiological sequelae of early life adverse experiences.

IV. NEUROBIOLOGY OF THE STRESS RESPONSE

A. Norepinephrine and the Sympathetic Nervous System

Among classic neurotransmitters, norepinephrine (NE) is by far the most thoroughly studied and arguably the most crucial in the biological response to stress. Long-standing psychophysiological research has demonstrated physical responses to stress suggestive of increased sympathetic nervous system activity. Like dopamine (DA) and epinephrine (EPI), NE is a catecholamine that is formed from the enzymatic conversion of the precursor amino acid tyrosine. The rate-limiting enzyme in the production of the catecholamines is tyrosine hydroxylase, which converts tyrosine to L-DOPA. L-DOPA is subsequently converted in the neuronal cytosol to DA by the enzyme DOPA decarboxylase. DA is then packaged into storage vesicles in both DA-secreting and NE-secreting neurons. In the NE neurons, another enzyme, dopamine β-hydroxylase, resides in the storage vesicles and transforms the stored DA into NE.

There are two stress-respondent components to the NE neuronal system. One resides in the CNS, and the other resides in the peripheral sympathetic nervous system (SNS). Within the CNS, the cell bodies of NE-containing neurons are primarily located within the locus coeruleus, a small area in the brain stem at the posterior junction between the pons and mesencephalon. The axons of these neurons extend from the locus coeruleus to distribute widely throughout the cerebral cortex, subcortical limbic structures, cerebellum, and brain stem. The vast majority of the CNS NE neurons project unilaterally from the locus coeruleus. The phenomenological significance of this unilateral distribution remains obscure; however, it may in part explain the clinical discrepancy in psychiatric outcome between patients with right versus left hemispheric strokes.

NE neurons are also a key component in the SNS. The SNS is composed of a chain of ganglia outside the CNS. Each ganglion is an aggregation of neuronal cell bodies. The SNS is therefore composed of preganglionic and postganglionic neurons. The preganglionic sympathetic (and parasympathetic) neurons utilize the neurotransmitter acetylcholine to transmit signals from the CNS to the ganglion. Each postganglionic neuron transmits signals from a ganglion to receptors on nonneuronal cells. All postganglionic sympathetic neurons secrete NE. These neurons are distributed throughout much of the body and are responsible for mediating the acute physical manifestations of the stress response.

Each ganglion has a well-defined anatomical distribution. Certain of the postganglionic SNS neurons projecting from the celiac ganglion extend to the adrenal medulla, a region of the adrenal gland that is of embryonic neuroectodermic origin. When stimulated by the preganglionic splanchnic nerve, the adrenal medullae, a homolog of the postganglionic neuron, secretes vast amounts of EPI (80%) and NE (20%)

into the peripheral circulation. The SNS and the adrenal medulla together have also been termed the sympathoadrenal system. The biobehavioral effects of adrenally secreted catecholamines are fundamentally identical to those of SNS activation; however, the effects produced by the circulating EPI and NE last up to 10 times longer.

Circulating NE causes vasoconstriction. In addition, NE and EPI increase the contractility and rate of the heart, dilate the pupils, and diminish the activity of the digestive system. EPI, however, does have a more significant impact on cardiac output than NE because it increases cardiac contractility to a greater degree than blood vessel constriction. The marked increase in cardiac output induced by EPI provides a critical increase in blood supply to the muscles during times of stress. Finally, EPI has profound effects on metabolism, triggering the release of glucose into the bloodstream from glycogen stores in liver and muscle.

B. Corticotropin-Releasing Factor, the Limbic System, and the Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (HPA) axis ultimately regulates the secretion of glucocorticoids, adrenocortical steroids, that act on target tissues throughout the body in order to preserve homeostasis during stress. Properly understood, the HPA axis is not simply an endocrine system but a neuroendocrine system. The hypothalamus, long considered the pinnacle of the HPA axis, is in reality a relay point for information exchange between limbic components of the CNS and the HPA axis. Because the hypothalamus has numerous bidirectional communication pathways with the limbic system that modulate HPA axis activity, the HPA axis in its broader sense might be better labeled the limbic–hypothalamic–pituitary–adrenal axis.

Literally meaning border, the term limbic was originally used in reference to the anatomical structures bordering the interface of the cerebrum with phylogenetically more primitive CNS regions. It has since been discovered that one of the primary functions of the structures in the limbic region is the modulation of emotions and motivational drives. Thus, the typical conception of the limbic system has evolved to refer more globally to the complex of CNS structures responsible for the regulation of emotions and behavior. The key components of the limbic system include the amygdala and hippocampus, certain regions of the thalamus, and a circle of basilar cerebral cortex including the cingulate gyrus, the orbitofrontal cortex, the prefrontal cortex, the parahippocampal gyrus, and the uncus. The limbic structures each have a unique function in the regulation of emotion and behavior. The amygdala in lower animals (that are dependent on a well-developed sense of smell for survival) facilitates the sensory association of olfactory stimuli. In humans, the role of the amygdala in olfaction is negligible. Instead, the primary function of the human amygdala is to modulate behavioral responses to emotionally charged stimuli. Coordinating the interplay between thoughts and the environmental context at a preconscious level, the amygdala shapes the intensity and direction of human behavioral responses to esure that they are contextually appropriate. The hippocampus also processes sensory input. However, the hippocampus's primary function is to consolidate emotion-laden and other experiences into long-term memory. It is important to recognize that the hippocampus is a remarkably plastic structure. Recent evidence from both rodents and nonhuman primates indicates that granule cell neurogenesis in the hippocampus persists well into adulthood and likely throughout life. Equally important is the fact that glucocorticoids, in conjunction with the excitatory neurotransmitter glutamate, interfere with hippocampal neurogenesis. This may well explain, in part, the oft-observed decremental effect of stress on memory and the reported association between chronic stress and hippocampal atrophy.

The ring of limbic cortex that encircles these subcortical limbic structures is perhaps the least understood component of the system. As a whole, the limbic cortex serves as an association area for behavioral regulation acting to coordinate the exchange of information between higher regions within the neocortex and the subcortical limbic structures. The prefrontal cortex plays a key role in the working memory component of explicit memory and may perform a counterregulatory function in the stress response through inhibitory effects on the amygdala. The anterior cingulate gyrus is responsible for the maintenance of social mores, fear-related behavior, and selective attentional processing. Finally, the orbitofrontal cortex is involved in conditioned fear processing and its extinction.

Although anatomically segregated from the remainder of the limbic structures, the hypothalamus, from a physiological standpoint, is a central component of the limbic system. Neuronal transmission from the hypothalamus travels in three directions: downstream

within the CNS to autonomic control regions within the brain stem such as the locus coeruleus, upstream within the CNS to the cortical and subcortical limbic structures, and outside the CNS via the infundibulum to the pituitary gland.

The HPA axis is the primary biological stress response system in mammalian species. A broad range of experimental stressors reliably induce the cascade of HPA axis activation. Stressors shown to induce HPA activation in human and animal studies include psychosocial stress, thermal extremes, infection, surgery or anesthesia, physical or emotional trauma, forced restraint, and the administration of NE and serotonin (5-HT) agonists. Although other biological systems often participate in the stress response, the HPA axis is unique in its reliable induction by such a wide assortment of stressors. It may be assumed that HPA axis activation represents the final common pathway of the mammalian stress response.

A cascade of biological events presumably beginning in the hypothalamus and proceeding through the anterior pituitary gland and ultimately the adrenal cortex comprises HPA axis activation. Within the context of the HPA axis, the primary CNS chemical mediator in the hypothalamus is corticotropin-releasing factor (CRF). CRF is a 41-amino acid neuropeptide that was structurally characterized in 1981. It is well established as the primary secretagogue stimulating HPA axis activity. CRF functions as both a CNS neurotransmitter and a hormone. In its latter role, CRF is secreted from hypothalamic neurons with nerve terminals in the median eminence, an enlarged area of the infundibulum just inferior to the hypothalamus. From the median eminence, CRF enters an extensive capillary bed that flows into a venous network known as the hypothalamic hypophysial portal system. This portal system travels directly to the anterior pituitary gland, where another capillary bed enables the CRF to gain access to a class of secretory cells in the anterior pituitary known as corticotrophs. Comprising about 20% of the anterior pituitary gland's overall volume, the corticotrophs increase the production and release of adrenocorticotropin hormone (ACTH) when stimulated by CRF. Although other hormones, including vasopressin, oxytocin, and somatostatin, act either to enhance or diminish ACTH release, CRF is by far the primary regulator of ACTH secretion.

ACTH is a 39-amino acid peptide that is derived from a larger precursor molecule known as proopiomelanocortin (POMC). The enzymatic cleavage of POMC produces three bioactive peptides: ACTH, β-endorphin, and melanocortin. Consequently, stress exposure typically induces parallel increases in serum concentrations of ACTH and β-endorphin. ACTH travels via the circulatory system to the adrenal cortex, where it stimulates the production and release of glucocorticoids such as cortisol.

The glucocorticoids are a group of structurally similar adrenocortical hormones that are synthesized from cholesterol. In humans, 95% of the circulating glucocorticoid is cortisol, whereas corticosterone comprises most of the remaining 5%. More than 90% of the circulating glucocorticoids are bound to serum proteins such as cortisol-binding globulin (CBG), leaving less than 10% in the unbound bioavailable state. In addition to increasing the adrenal secretion of cortisol, stress-induced HPA axis activation also decreases the circulating concentration of CBG. Therefore, the circulating level of the biologically active free form of the hormone is increased by two distinct mechanisms.

The name glucocorticoid is derived from the demonstration that these hormones increase glucose production. Glucose is a ready energy source that is used by nearly all cells of the body. When responding to stress, it is obviously adaptive to increase the availability of this fuel source in a rapid fashion. However, increasing the circulating levels of glucose comes at a price. Glucose production is increased by cortisol through the catabolic mobilization of protein stores from muscle and by the concomitant activation of hepatic enzymes that convert glycogen into glucose. Cortisol also increases the availability of a secondary energy source by inducing the mobilization of fatty acids from adipose tissues. Thus, HPA axis activation sacrifices muscle mass and adipose tissue in order to provide energy sources necessary to meet the challenges of stress.

In the short term, cortisol-induced catabolic effects are biologically critical to the mounting of an adaptive stress response. However, persistent HPA axis hyperactivity can lead to a depletion of protein, carbohydrate, and fat stores. This would eventually produce adverse (and hence maladaptive) consequences. The HPA axis is therefore served by negative feedback mechanisms that decrease its activity once sufficient glucocorticoid release has been attained. This negative feedback effect is mediated by glucocorticoid receptors at all levels of the HPA axis, including the hippocampus, the hypothalamus, and the pituitary and adrenal glands. Once the cascade of HPA axis activation has triggered sufficient cortisol release from the adrenal cortex, this hormone is carried via the circulatory

system to target tissues throughout the body. Some of the cortisol finds its way to these "feedback" receptors. Cortisol feedback at the hypothalamus reduces CRF release, at the pituitary it inhibits ACTH release, and at the adrenal gland it inhibits further cortisol release. Cortisol feedback at the hippocampus inhibits CRF secretion from the hypothalamus (and decreases granule cell neurogenesis). In addition, there are other feedback and feedforward mechanisms that render the HPA axis an exquisitely tuned and balanced stress response system.

V. NEUROBIOLOGY OF STRESS-RELATED PSYCHIATRIC ILLNESS: FOCUS ON DEPRESSION AND PTSD

As we examine the neurobiology of psychiatric disorders, the clinical significance of stress is evident. The very biological systems that are most intimately involved in the mammalian stress response (i.e., the HPA axis and NE neuronal systems) are those that are clearly awry in psychiatric patients. By far, the psychiatric disorder most extensively studied is depression. Consequently, our discussion emphasizes the neurobiological alterations in depressed patients. A second stress-related psychiatric disorder, PTSD, is also associated with neurobiological changes in these same systems, although the pattern of alteration differs from that seen in depression. Therefore, the neurobiology of PTSD is compared to that of depression in an effort to provide a comprehensive view of the range of dysfunction in biological stress response systems that occur in the context of psychiatric illness.

A. Neurobiology of Depression

The bulk of the extant data regarding the pathophysiology of depression address the role of monoamines, including NE, 5-HT, and, to a lesser extent, DA. Accordingly, modulation of the synaptic activity of these neurotransmitters is the principal pharmacodynamic mechanism thought to underly the action of all currently available antidepressants. Dating back to the mid-1960s, the earliest modern neurobiological hypothesis of depression proposed that the illness (or at least some forms of it) is a consequence of a deficiency in catecholaminergic neurotransmission, particularly NE. An abundance of research regarding the role of NE in the pathophysiology of depression has since accumulated. Although controversial, the majority of data still suggest a relative NE deficiency, although discordant results are available.

Recently, neurobiological inquiry has increasingly focused on changes in neuroendocrine function in depressed patients. The most intensely scrutinized of the neuroendocrine systems has been the HPA axis. The earliest reports of HPA axis dysfunction in depression emerged more than 40 years ago when it was recognized that many depressed patients have higher baseline serum cortisol concentrations. Shortly thereafter, the dexamethasone suppression test (DST), the first functional assessment of HPA axis physiology, was developed as a diagnostic tool in the evaluation of Cushing's Syndrome. A synthetic analog of cortisol, dexamethasone, is used in the DST to evaluate the activity of the HPA axis. Dexamethasone activates HPA negative feedback and thus suppresses the circulating concentrations of ACTH and cortisol. However, cortisol release is not suppressed by dexamethasone in many depressed patients. This suggests that the HPA feedback mechanism is dysfunctional.

A myriad of studies have subsequently confirmed these early reports of HPA axis hyperactivity in depressed patients. Several plausible theories of the ultimate cause of hypercortisolemia have been proffered. It may be that adrenal ACTH receptors are upregulated in depressed patients and therefore hypersensitive to ACTH stimulation. Administration of pharmacological doses of exogenous ACTH does in fact elicit an exaggerated cortisol response in some depressed patients. However, administration of lower physiological doses of ACTH to patients with depression after pretreatment with dexamethasone does not potentiate increased cortisol release. This suggests that adrenal sensitivity to ACTH stimulation is not appreciably elevated in depressed patients, although adrenocortical capacity may be increased.

Indeed, anatomical studies of depressed patients, utilizing either imaging techniques or postmortem dissection of the adrenal glands in suicide victims, demonstrate adrenal gland enlargement. Pituitary gland enlargement in depressed patients has also been reported. Future studies combining volumetric pituitary and/or adrenal imaging with physiological dose CRF and/or ACTH stimulation tests may help clarify the relative contribution of glandular hypertrophy to HPA axis hyperactivity.

However, impressive accumulation of data indicates that the predominant cause of HPA axis hyperactivity in depressed patients is likely hypersecretion of CRF. Several lines of evidence indicate that depressed patients hypersecrete CRF. First, administration of

CRF directly into the CNS of laboratory animals produces behavioral alterations homologous to those observed in depressed humans. These changes include decreased appetite, disrupted sleep, and diminished libido. Second, similar behavioral changes are witnessed in transgenic (i.e., genetically engineered) mice that overexpress CRF. Third, baseline CRF concentrations in the CSF of depressed patients have repeatedly been reported to be increased. Fourth, depressed patients commonly demonstrate a blunted ACTH response in the CRF stimulation test. In this test, serum samples of ACTH and cortisol are collected at baseline prior to the administration of exogenous CRF and at regular intervals post-CRF administration. The change in ACTH and cortisol concentrations induced by CRF provide an indication of pituitary and adrenal responsivity to hormonal stimulation. The blunted ACTH response in depressed patients is believed to be a consequence of pituitary CRF receptor downregulation that occurs as a result of chronic CRF hypersecretion. However, it should be recognized that pretreatment with metyrapone (a potent inhibitor of cortisol production that in effect temporarily eliminates HPA axis negative feedback) before CRF administration increases the ACTH response in depressed patients. This implies that mechanisms other than CRF receptor downregulation contribute, at least in part, to the blunted ACTH response to CRF stimulation. Nevertheless, potential genomic effects of metyrapone on glucocorticoid receptor density make these data difficult to interpret. Finally, the most persuasive evidence of CRF hypersecretion comes from the postmortem histological analysis of depressed patients. Patients who died with untreated depression exhibited a threefold increase in the number of hypothalamic CRF-secreting neurons and an increase in CRF mRNA expression, indicating that neurons that do not normally secrete CRF are recruited to do so during episodes of depression.

These data raise the crucial question of whether CRF hypersecretion only occurs during a depressive episode or exists during periods of remission. At issue is whether CRF hypersecretion is a trait marker for the risk of becoming depressed or a state marker for active illness. This question is important on two counts. First, it is critical to our understanding of the pathophysiology of depression. If CRF hypersecretion is a trait-dependent variable, then alterations in CRF activity likely contribute to the vulnerability for depression but other biological mechanisms induce an episode of illness. If, however, CRF hypersecretion is state dependent, then it is likely necessary in the development of the disorder. If CRF hypersecretion is state dependent, then the next step in studying the neurobiology of depression is to investigate the mechanisms that induce persistent CRF hypersecretion. If CRF hypersecretion is trait dependent, then the next step is to determine why someone who chronically hypersecretes CRF suddenly becomes depressed. This question is also important from a clinical standpoint. If CRF hypersecretion is trait dependent, then it may afford an opportunity to devise a screening test that reliably identifies those at risk for becoming depressed. If it is state dependent, then we may ultimately be able to devise tests to guide medication selection and monitor treatment response.

A definitive answer to the state vs trait question could be obtained by measuring CRF activity in healthy volunteers who had never been depressed and then repeating the measure if and when any of those subjects ever become depressed. Unfortunately, such research would be costly, unwieldy, and is unlikely to ever be undertaken. Short of this, assessing CRF activity during an episode of depression and repeating that measure once the depression has resolved can provide some insight. These studies do exist. In fact, both elevations of CRF concentrations in the CSF and ACTH blunting in the CRF stimulation test have been shown to normalize when depression resolves after treatment with an antidepressant or a course of electroconvulsive therapy. Of course, this indicates that CRF hypersecretion is likely state dependent in patients with depression. Some have argued, however, that indirect effects of these somatic therapies on HPA axis activity in depressed patients may confound these results. In other words, did the CRF hypersecretion resolve because the depression remitted or because the patient was treated with an antidepressant (a fine distinction but a fair and important one nonetheless)? Although HPA axis activity has been demonstrated to remain normal in successfully treated patients even after the course of antidepressant medication has been discontinued, a more satisfying answer to this question will no doubt be provided when future studies investigate HPA axis activity before and after a successful nonpharmacological treatment (e.g., psychotherapy). However, using a very sensitive measure of HPA axis activity, the combined dexamethasone–CRF stimulation test, Holsboer and colleagues not only confirmed the HPA axis abnormalities in depressed patients but also, most important in relationship to the state-trait issue, identified abnormalities in this test in asymptomatic first-degree relatives of a cohort of depressed patients.

We have long assumed that stress has a detrimental impact on immune system function; however, research results have been inconsistent. Investigations of the association between stress and immune system disturbance include measures of both cellular and humoral immunity. Cellular immunity studies measuring cellular enumeration and immune cell proliferative responses in depressed subjects suggest a pattern of cellular immunosuppression. The most consistent finding has been decreased natural killer cell activity and decreased T cell responses to mitogen stimulation. However, components of the humoral immune system that are activated as part of an acute phase response are enhanced in depressed patients. In particular, depressed patients exhibit increases in serum concentrations of numerous proinflammatory cytokines, including IL-1, IL-2, and IL-6.

How can immunosuppressive measures such as decreased natural killer cell activity be reconciled with this apparently contradictory evidence of immunoactivation? One hypothesis is that stress induces bidirectional, homeostatic interactions between the HPA axis and the immune system. In depression, increased CRF secretion has been associated with humoral immunoactivation as evidenced by increased proinflammatory cytokine release. These cytokines in turn appear to augment HPA axis function by promoting additional CRF release and by inducing glucocorticoid resistance that impairs HPA axis negative feedback. Conversely, HPA hyperactivity, presumably via a direct effect of glucocorticoids, also elicits immunosuppression. In summary, depression produces a mixed picture of immunological activation, immunological suppression, and HPA axis hyperactivity.

B. Neurobiology of PTSD

NE is certainly the most thoroughly studied and undoubtedly a most critical neurotransmitter involved in the biological response to traumatic stress. An extensive array of evidence indicates that psychophysiological measures suggestive of SNS activation are accompanied by NE hypersecretion in patients with PTSD. For example, many studies have reported increased urinary concentrations of both NE and EPI in numerous groups of patients with PTSD, including combat veterans, civilian assault victims, and abused children.

However, the pattern of NE hyperactivity in PTSD is not characterized by elevations in baseline plasma NE concentrations. Instead, markedly abnormal increases in NE and MHPG plasma concentrations occur in response to provocative stimuli such as exercise or exposure to trauma-related cues. Interestingly, both oral and intravenous administration of the α_2-adrenergic receptor antagonist yohimbine (which increases NE activity by blocking presynaptic negative feedback) exacerbates reexperiencing symptoms and triggers panic attacks in many patients with PTSD. Noradrenergic dysfunction remains a major focus of PTSD research, but forthcoming studies will increasingly investigate interactions between NE activity and other biological systems.

Not surprisingly, the HPA axis has also been relatively well studied in PTSD patients. HPA axis dysfunction in these patients appears to distinguish them not only from healthy volunteers but also from patients with major depression. Like patients with depression, PTSD patients hypersecrete CRF as evidenced by elevated levels of CRF in cerebrospinal fluid (CSF) and a blunted ACTH response to exogenous CRF. However, despite CRF hypersecretion, most, but not all, studies of PTSD have paradoxically demonstrated not elevated but rather reduced serum cortisol concentrations. The pathophysiology underlying the relative hypocortisolemia in patients with PTSD remains obscure; however, some have postulated this to be a consequence of exaggerated HPA axis negative feedback. Two lines of evidence support this contention. First, DST studies of HPA axis feedback indicate that patients with PTSD may be supersensitive to cortisol suppression, in marked contrast to cortisol nonsuppression often seen in depressed patients. Second, enhanced negative feedback may be a consequence of glucocorticoid receptor upregulation as evidenced by their increased density on peripheral lymphocytes. These receptor changes in humans are paralleled by findings from preclinical laboratory animal research utilizing a stress sensitization model. In this model, rodents exposed to an acute stress paradigm exhibited the enhanced HPA axis feedback observed in PTSD. Furthermore, these acutely stressed animals demonstrated increased hippocampal glucocorticoid receptor mRNA expression.

The limited immunological research in PTSD suggests immune system alterations in this disorder are as distinct from those seen in depressed patients as the HPA axis alterations. PTSD research indicates that circulating proinflammatory cytokine concentrations (particularly IL-6) are increased in patients with PTSD, as also reported in depression. However, cellular immune measures in PTSD and depression appear to differ. Although most cellular immunity

studies in depression indicate immunosuppression, the limited available data suggest that cellular immunity may in fact be enhanced in PTSD. Increases in total leukocyte count, total T lymphocyte count, CD4 and CD8 T cell counts, and the proportion of activated to nonactivated lymphocytes have all been reported in PTSD patients.

Although immunological findings in PTSD patients are at best preliminary, they suggest potential differences in the immune system responses between depression and PTSD that are of heuristic value. CRF hypersecretion and humoral immunoactivation are common to both disorders and may represent a shared pathophysiology. In depression, CRF hypersecretion precipitates hypercortisolemia that may in turn produce cellular immunosuppression. However, most PTSD studies have demonstrated low to normal cortisol levels despite increased CRF secretion. Consequently, the relative hypocortisolemia of PTSD may preserve or even exaggerate cellular immune activity.

In comparing the biological findings of depression and PTSD, we can learn much regarding stress-associated pathophysiology. Several key biological changes are common to the two disorders (e.g., CRF hypersecretion and humoral immunoactivation). However, other alterations are unique to each particular syndrome. Their common cooccurrence represents another difficult complexity in this field. Just as the phenomenological response to stress may vary, the neurobiological consequences of stress exposure may take distinct paths as well.

VI. TOWARD A NEUROBIOLOGY OF DIATHESIS

There is convincing evidence that stressful early life experiences confer a heightened vulnerability to psychiatric illness during adulthood. The contribution of stress during the formative years to a psychiatric diathesis appears to be particularly relevant for the depressive disorders, certain anxiety disorders such as PTSD, and perhaps substance use disorders. Consequently, an expanding line of research has searched for evidence of persistent neurobiological alterations induced by early adverse experiences that may represent the biological substrate of illness predisposition. Such neurobiological changes would theoretically represent a trait marker for a subset of patients vulnerable to depression and other forms of stress-related psychiatric illness. To date, the bulk of this data derive from animal research in which young animals are exposed to a stressor and then assessed at a later date for evidence of enduring behavioral and neurobiological changes precipitated by the earlier stress. Recent work has extended this research to human populations that have suffered traumatic experiences during childhood.

A. Laboratory Animal Studies of Early Life Stress

Among the earliest animal studies of early life stress were those that implemented handling of neonatal rodents by laboratory personnel as the initial stressor. In these protocols, infant rats or mice are removed each day from their cages and handled briefly by laboratory personnel. The handled pups are subsequently returned to the maternal cage. If it is our contention that early life stress increases the vulnerability to subsequent stress, we would expect heightened biological measures of stress responsivity in animals subjected to the stress of handling as infants. However, neonatal handling paradoxically decreases anxiety-like behaviors and lowers the magnitude of the biological response to later stress. Handled pups are resistant to stress-dependent decrements in learning ability and demonstrate increased exploratory behavior in novel environments. Although neonatal handling induces transient increases in noradrenergic neuronal activity, it reduces HPA axis activity. Indeed, HPA axis sensitivity to stress is lower in rodents that were exposed to the stress of neonatal handling than in those exposed to no neonatal stress. This appears to be a consequence of decreased CRF secretion and enhanced HPA axis negative feedback.

Certainly, these results are counterintuitive and seem to undermine the notion of a diathesis/stress model. However, on closer inspection, the findings from the neonatal handling studies do not necessarily refute this model. Although posthandling stimulation of maternal care may explain the apparently beneficial effect of neonatal handling, another potential explanation is that rodent pups do not experience handling as a particularly unpleasant experience. Neonatal handling introduces an environmental change that in turn induces homeostatic responses (as evidenced by acute changes in noradrenergic activity), but it is not an empirically noxious laboratory stimulus. It may be that the mild stress associated with a novel but nonnoxious environmental perturbation such as handling may improve the animal's adaptability to subsequent environmental changes. In that case, the mild

stress of handling may be beneficial to the development of the young animal's adaptive repertoire.

Other attempts to study the effects of early life stress utilized protocols patterned after those previously implemented to induce stress in adult animals. In these models, young animals (typically rodents) are exposed to a noxious stimulus, such as temperature extremes, pin-prick, surgical procedures, or surgical anesthesia. Interestingly, such noxious stimuli evoke a subnormal HPA axis response during the first 2 weeks of life in the rat. During this so-called stress hyporesponsive period, noxious stimuli do not induce CRF hypersecretion and only minimally increase ACTH and corticosterone (the principal glucocorticoid in the rat). This indicates that the HPA axis is a dynamic system that (in the rat) continues to undergo maturational adaptations during postnatal development. Although the young rat's failure to mount a full stress response during early development may increase its immediate vulnerability, this likely provides an adaptive evolutionary trade-off that protects the growing pup from the potentially devastating catabolic effects of heightened glucocorticoid secretion.

The two early life stress paradigms that have produced the most robust findings are maternal deprivation studies and variable foraging studies. In maternal deprivation studies, immature animals are separated from their mothers for a defined interval (or repeated intervals). These studies have been conducted using both rodent and nonhuman primate models. Not only are the separated pups deprived of maternal care during the separation period but also the separation frequently produces aberrant changes in maternal behavior even after the pups are returned. Maternal deprivation produces abrupt increases in HPA axis activity as indicated by elevations in the serum concentrations of corticosterone (the rodent equivalent to cortisol) and ACTH, in conjunction with CRF hypersecretion.

More relevant to the diathesis/stress model, the HPA axis changes induced by maternal deprivation persist into adulthood. When exposed to a stressor during adulthood, rats that were maternally deprived as pups exhibit an increased ACTH and corticosterone response compared to nondeprived controls. Furthermore, maternally deprived adult rats demonstrate increases in hypothalamic expression of CRF mRNA in the hypothalamus, increased CRF concentrations in the median eminence, and increased CSF CRF concentrations.

Maternal deprivation research has also been conducted in nonhuman primates, although these are perhaps better termed social deprivation studies because the young animal is separated from the social group as a whole. Later refinements in which the infant's absent mother is replaced by one of a series of incrementally more realistic maternal surrogates have provided an opportunity for assessment of varying degrees of early life social deprivation in these animals. These older studies did not take place in the modern era of neurobiology; as such, few validated neuroendocrine measures are available from such experiments.

The most significant recent advance in early life stress research in non-human primates is the variable foraging studies. This protocol has the advantage of minimizing direct human contact with the young animal. Instead, the researchers modulate an environmental factor that does not directly stress the infant but tests the mother's ability to provide adequate maternal care. The purpose is not to starve the animals but to increase the work of parenting while allowing sufficient nutrition for both mother and infant. Three experimental conditions exist in the variable foraging paradigm: low foraging demand (LFD), high foraging demand (HFD), and variable foraging demand (VFD). In the LFD condition, food is always readily available with minimal effort. In the HFD condition, the primate mother must always expend some effort (e.g., digging through wood chip bedding) to obtain food. Finally, in the VFD condition, the amount of maternal effort necessary to obtain food varies randomly from the LFD to the HFD condition.

Adult primates raised under VFD conditions demonstrate higher baseline CSF CRF concentrations than either the HFD and LFD groups. However, the VFD offspring exhibit lower CSF cortisol concentrations than the comparator groups, a finding that is strikingly similar to the HPA axis changes reported in PTSD. CSF concentrations of somatostatin, another peptide with HPA axis activity, are also elevated in adult primates raised under VFD conditions.

B. Human Studies of Early Life Stress

Clinical research on the impact of early life stress on HPA axis function is scant. There is increasing evidence, however, that children exposed to traumatic events (e.g., childhood sexual or physical abuse) exhibit alterations in HPA axis activity. It appears that these HPA axis changes persist into adulthood. For example, nondepressed adult women who were abused as children exhibit enhanced ACTH responses to the administration of exogenous CRF and in

response to performance of a standardized psychosocial stress test. However, these same women demonstrate normal cortisol responses to both the hormonal and the psychosocial challenges. If these women are currently depressed, then the ACTH and cortisol responses to the CRF stimulation are blunted but the hormonal responses to the psychosocial stressor are dramatically enhanced.

These findings suggest that traumatic early life experiences may precipitate a persistent sensitization of the anterior pituitary with a counterregulatory adrenocortical adaptation. However, the adrenal adaptation is apparently overridden when survivors of child abuse become depressed. Perhaps the most intriguing finding arises when we compare the pituitary responses of depressed women who were abused during childhood to the two types of stressors (i.e., hormonal and psychosocial). Administration of exogenous CRF produces a blunted ACTH response in depressed survivors of child abuse, but exposure to a psychosocial stress precipitates marked increases in ACTH concentration in this same group. How can we understand this seeming contradiction? If CRF is not driving the ACTH response to the psychosocial stressor, as the results of the CRF stimulation test suggest, then what biological substrate is inducing the release of ACTH in the depressed/abused group? There is no clear answer to this question, although potentiation of CRF release by vasopressin is one possibility.

These represent the first human studies to follow up on animal research in moving beyond the neuroendocrinology of psychiatric disorders to address instead the neurobiology of diathesis. The importance of this line of research should not be underestimated. First, diathesis research has the potential to answer questions not only about the pathophysiology of psychiatric disorders but also about the pathogenesis of these disorders. Second, as future studies more clearly characterize the neurobiology of diathesis, the possibility of finding not only biological state markers for illness but also trait markers for the risk of illness is within our reach. Such markers would be useful in screening at-risk populations such as abused children, assault victims, combat veterans, and public servants who contend with emergency situations. Finally, improved understanding of the neurobiology of diathesis may ultimately guide prophylactic treatment decisions for those exposed to early life stress before the neurobiological changes that convey the risk for adulthood psychopathology become irreversible.

VII. THE PSYCHOPHARMACOLOGY OF STRESS

A variety of psychopharmacological agents are used to treat patients with stress-related disorders and those vulnerable to the adverse consequences of stress. Foremost among these medications are the anxiolytics and antidepressants. The most widely used anxiety-reducing medications have traditionally been the benzodiazepines, which act primarily by enhancing GABA neurotransmission. GABA is an inhibitory neurotransmitter that reduces neuronal activity. The principal therapeutic benefit of benzodiazepines lies in their calming effect that alleviates anxiety. The effects of a benzodiazepine can be experienced within minutes. For this reason, benzodiazepines can be used acutely on an ''as-needed'' basis to reduce the immediate consequences of stress. In addition, these medications can be used long-term on a prophylactic basis for patients especially prone to stress-induced symptomatology. Unfortunately, benzodiazepines are not without problems. They may cause drowsiness and motor and cognitive impairment, and they may be abused by individuals with substance use disorders. Furthermore, physical dependence can develop with prolonged usage. In addition, benzodiazepines are not effective antidepressants.

Antidepressants are the most widely used agents in the treatment of stress-related psychiatric illness. These medications act primarily by increasing the neuronal transmission of NE and 5-HT, or some combination of the two. Although antidepressants are primarily used to treat depression, they have a wide array of uses. Antidepressants have demonstrated efficacy for certain anxiety disorders (e.g., PTSD, obsessive–compulsive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder), eating disorders, impulse control disorders, and chronic pain disorders. Remarkably, preclinical animal research indicates that administration of selective serotonin reuptake inhibitors confers some degree of protection from the adverse impact of stress-induced hypercortisolemia on hippocampal neurogenesis. In addition, antidepressants reverse the alterations in HPA axis activity that occur during episodes of depression. This is likely an indirect effect on the HPA axis that is mediated via 5-HT/CRF interactions.

Advances in the treatment of stress-related illness will utilize agents that directly modulate CRF activity. In fact, numerous CRF receptor antagonists are currently under development and testing. These agents appear to possess both potent antidepressant and anxiolytic properties. In addition to alleviating psy-

chiatric illness, CRF antagonists may provide prophylactic benefit for those with a predisposition to stress-related psychopathology.

Prophylactic intervention is of paramount importance for those exposed to the traumatic stress of combat, violent assault, child abuse, natural disaster, etc. If we can respond with appropriate pharmacological interventions in the acute aftermath of a trauma, might we be able to circumvent the pathogenesis of trauma-induced psychiatric illness? Recognizing that CRF and NE systems play a pivotal role in the pathophysiology of stress-related psychiatric illness, these systems are likely targets for treatment. Indeed, limited research on the viability of clonidine and propranolol (agents that interfere with NE) and serotonergic antidepressants (which have been shown to reduce serum levels of NE and MHPG) for such prophylactic benefit is under way. This will doubtlessly be a fruitful area for research with CRF receptor antagonists when they become available.
