Dedication

Jasper's Basic Mechanisms of the Epilepsies, Fourth Edition, is dedicated to two groups: those who have committed their lives to the cause of epilepsy and those who live with epilepsy. Dr. H.H. Jasper, the preeminent founder of the neuroscience of epilepsy, is chief among the first, and this book is most appropriately named in his honor. We also dedicate this book to Dr. Frank Risch, committed in a different but no less important way in the service of those with epilepsy. Through his efforts as chief of rehabilitation at the Los Angeles VA Hospital and as an originator of the Epi-Hab training facilities, he improved the lives of countless adults with epilepsy. More than 50 to 60 million families worldwide struggle with epilepsy every day. In their honor, we recognize 21-year-old Zachary Brigido and his family in Lincoln, Rhode Island. Zachary has a severe and uncontrolled seizure disorder; he needs help with all aspects of daily living. Zachary's mother, LeeAnn has crusaded to raise awareness of epilepsy research and to find a cure for 19 years. Zachary's parents stepped forward to help sponsor the Jasper's Basic Mechanisms of the Epilepsies Workshops in Yosemite through their support of CURE—Citizens United for Research in Epilepsy. Proud to sponsor our research conference, LeeAnn wrote: "Together, maybe we can make it possible for me to someday say: My son *had* epilepsy." Zachary and LeeAnn remind us of the families who live with epilepsy and seizures. They give purpose to our work. Thus, in the spirit of Dr. H.H. Jasper, this Fourth Edition of *Jasper's Basic Mechanisms of the Epilepsies* is dedicated to those who must battle epilepsy in their daily lives and also to the community of researchers and caregivers who commit their own lives to make a positive difference. We hope this book inspires others to join our search for cures. Perhaps among them will be those who find a way to end the epilepsies.

Preface

When H. Houston Merritt was appointed by the Surgeon General of the Public Health Service in May 1966 to chair the Public Health Service Advisory Committee on the Epilepsies, he formed two subcommittees—one on Research and Research Training, led by Arthur A. Ward, Jr., and one on Service and Service Training, led by David D. Daly. A basic research task force was established under Herbert H. Jasper's leadership. "It was apparent to this task force that basic research in the epilepsies needed stimulation."[1] Thus, they developed plans for a workshop held in Colorado Springs in February 1968 and an open symposium in November 1968. A "modern definitive statement on current knowledge regarding fundamental aspects of the epilepsies" was the goal. Such a statement would "serve as a benchmark against which future progress can be measured."

Since the original workshop and symposium of 1968, basic and clinical researchers in epilepsy have gathered together every 14 years to hold workshops (at the Kroc Foundation Headquarters in Santa Ynez in 1982, at the Marina Yacht Club in San Diego in 1996, and in Yosemite National Park in 2009) with these goals in mind: to assess where epilepsy research has been, what it has accomplished, and where it should go. In a Foreword written for the Second Edition of *Basic Mechanisms of the Epilepsies*, published in 1983, Jasper reminded us that the original and ultimate goal of the Public Health Service subcommittee on Research and Research Training was to search for a "better understanding of the epilepsies and seek more rational methods of their prevention and treatment."[2] The third edition of the book was named in honor of Jasper.[3]

In line with the enormous expansion in the understanding of basic epilepsy mechanisms over the past four decades, this Fourth Edition of *Jasper's Basic Mechanisms of the Epilepsies* is the most ambitious yet. In 90 chapters, the book considers the role of interactions between neurons, synapses, and glia in the initiation, spread, and arrest of seizures. It examines mechanisms that underlie excitability, synchronization, seizure susceptibility, and ultimately epileptogenesis. It provides a framework for expanding the epilepsy genome and understanding the complex heredity responsible for common epilepsies as it explores disease mechanisms of ion channelopathies and developmental epilepsy genes. It considers the mechanisms of conditions that are comorbid with epilepsy. And, for the first time, fulfilling the original Merritt and Jasper goals of "seeking rational methods of prevention and treatment," this Fourth Edition describes the current efforts to translate the discoveries in epilepsy disease mechanisms into new therapeutic strategies. In the Foreword for the First Edition, Merritt wrote, "...it is commonly assumed that epilepsy is inherited and numerous studies attest to the importance of hereditary factors." The current edition further justifies Merritt's view of the inherited epilepsies as beacons illuminating basic disease mechanisms, which in turn define molecular targets for designing novel treatments. In keeping with the original justification of Merritt and Jasper for basic epilepsy research, there are now numerous examples of discoveries in the laboratory that intersect with and impact clinical practice. Among these are the application of epilepsy gene discoveries for clinical genetic testing/screening, as well as the use of rapamycin for the treatment of tuberous sclerosis, gentamicin to overcome nonsense mutations in Lafora progressive myoclonus epilepsy, and enzyme replacement therapy for Gaucher's disease.

In its previous editions, this book has been considered the bible of basic epilepsy research, essential to students and research scientists who conduct laboratory-based experimental epilepsy research using cellular, brain slice, and animal models, and also of interest to neurologists and clinical epileptologists. We hope this new edition will honor its venerable legacy by being as useful as these previous volumes.

—The Editors

Acknowledgments

The editors are grateful for the contributions of many capable people who generously offered their time and energy to this project in the belief that a periodic assessment of progress in basic epilepsy research is useful to moving the field forward. Their motivation, like that of the editors, is to advance the basic science of epilepsy in the service of those suffering with the condition in its diverse manifestations.

We are especially indebted to the distinguished members of the international editorial advisory board—Giuseppe Biagini, Amy Brooks-Kayal, Wolfgang Löscher, Helen Scharfman, Phil Schwartzkroin, John Swann, and Annamaria Vezzani—who assisted with the selection of topics and the peer review of each chapter. They were our indispensable editorial partners, but we assume responsibility for errors. We also thank Maxime Levesque and Gabriella Panuccio, who helped with the editorial work of Section 2. Brief summaries of each chapter were published in December 2010 as a supplement to *Epilepsia*; we are grateful again to Phil Schwartzkroin who, this time in his role as the journal's coeditor, made this opportunity available.

Essential to the development of this book was the Jasper's Basic Mechanisms of the Epilepsies International Workshops held in March 2009 at the Yosemite Lodge at the Falls in Yosemite National Park. The workshops at Yosemite provided a foundation for each of the sections of the book. The road to the Yosemite meeting included planning sessions at the annual meetings of the American Epilepsy Society in 2006 (San Diego), 2007 (Philadelphia), and 2008 (Seattle). Development of the book began in earnest at a breakfast with the members of the editorial advisory board at the end of the Yosemite meeting, with inspiration from majestic pines and glaciated peaks. It reached a crescendo at a gathering of the editors on a glorious day in August 2009 in Malibu, California—including a walk to clear the mind on cliffs overlooking the Pacific Ocean.

We thank Susan Gayle Pietsch Escueta and the Epilepsy Foundation of Greater Los Angeles, Kathy West and the Epilepsy Foundation of San Diego, and members of the international GENESS consortium who volunteered their time to staff the Yosemite meeting because they believed in the importance of this project. Financial support for the meeting was provided by Citizens United for Research in Epilepsy, the National Institute of Neurological Disorders and Stroke, the National Institute of Child Health and Human Development, the American Epilepsy Society, the Children's Neurobiological Solutions Foundation, the Savoy Foundation, and Johnson and Johnson's Scientific Affairs Division.

Finally, the editors salute our predecessors who conceived of a book on basic mechanisms of the epilepsies and, most importantly, the authors of the 90 chapters compiled in this volume who admirably rose to the challenge when we asked.

Chapter 1

The Next Decade of Research in the Basic Mechanisms of the Epilepsies

Richard W. Olsen
Antonio V. Delgado-Escueta

SECTION 1: INTRODUCTION

In 1969, H.H. Jasper, A.A. Ward, and A. Pope and the U.S. Public Health Service Advisory Committee on the Epilepsies of the National Institutes of Health published the first volume on *Basic Mechanisms of the Epilepsies*.[1] Since then, basic and clinical researchers in epilepsy have gathered together each decade to assess where epilepsy research has been, what it has accomplished, and where it should go.[2] In 1999, the third edition of the book was named in honor of H.H. Jasper.[3] In February 2010, the International League Against Epilepsy (ILAE) Commission on Classification and Terminology revised the classification of seizures and the many forms of epilepsy. Epilepsies are now classified into three types: genetic, structural/metabolic, and unknown.[4] Independently, the World Health Organization (WHO) is in the process of revising the International Code of Diseases-11 Codes (ICD-11 Codes) and may well follow the same general scheme. Conceived with an emphasis on basic mechanisms, these two new international classifications represent important changes in concept and approach, changes that the third edition of *Jasper's Basic Mechanisms of the Epilepsies* had espoused in its 1999 classification of epilepsies as necessary for answering the essential questions of how seizures start and stop, and for aligning the underlying causes of epilepsy phenotypes with their molecular and cellular disease pathways.[3] The fourth edition of *Jasper's Basic Mechanisms of the Epilepsies* continues in this strategic direction. Four major sections of this edition have been organized to address a multidisciplinary range of issues: the fundamentals of neuronal network excitability that produce seizures and epilepsy; how seizure mechanisms contribute to epileptogenesis;

Table 1–1 **Top Research Priorities: Where Should Epilepsy Research Go in the Next 10 Years?***

1. Understand mechanisms of epileptogenesis; create methods for monitoring the development of seizure susceptibility; identify approaches to prevent epilepsy
2. Understand mechanisms of neuronal synchronization and the triggering of seizures
3. Determine the genetic risk factors for the non-Mendelian epilepsies and the role of genetic background in determining epilepsy phenotype; understand how mutations produce human epilepsy phenotypes; explore the role of epigenetic factors
4. Understand the role of brain development in epilepsy and the influence of epilepsy on the developing brain
5. Characterize the role of glia and immune mechanisms in seizures and epileptogenesis
6. Develop drugs targeted to disease mechanisms
7. Explore the potential of nonconventional treatment approaches, including brain stimulation, cell and gene therapy, and approaches for influencing brain remodeling
8. Understand mechanisms of pharmacoresistance to antiepileptic drugs and develop methods to overcome refractoriness
9. Develop new targeted approaches to deliver therapies

*Top research priorities as proposed and voted on by the authors of the fourth edition of *Jasper's Basic Mechanisms of the Epilepsies* during the Yosemite workshops and subsequently modified by the editors.

genetic mechanisms of heritable susceptibility to epilepsy in the developing brain; and new mechanisms in epilepsy therapeutics.

As in previous editions of *Jasper's Basic Mechanisms of the Epilepsies*[1–3], the first chapter of this edition looks toward the next decade and prioritizes research areas where efforts should be accelerated and enhanced (see Table 1–1). For the first time, basic research in the epilepsies foresees the promise of personalized medicine based on genomic information as current efforts are described to translate the discoveries concerning epilepsy disease mechanisms into molecular and cellular therapeutic strategies that bring repairs and cures to specific epilepsies.

SECTION 2: FUNDAMENTALS OF NEURONAL EXCITABILITY RELEVANT TO SEIZURES AND EPILEPSY

Neurobiological research has progressed swiftly during the last decade, providing detailed information on the molecular, pharmacological, and functional characteristics of voltage- and ligand-gated membrane signaling mechanisms regulating neuronal network excitability. Analysis of the mechanisms of high-frequency oscillations has furthered our understanding of how perturbations in fundamental neuronal activity patterns—often overlapping those involved in learning and memory—become relevant in the generation of partial epileptic discharges as well as in epileptogenesis. Along with the views originally formulated by Herbert Jasper and his former student Peter Gloor, thalamocortical and reticulocortical mechanisms have been firmly established as the substrate for primary generalized seizures. An eminent example is the absence seizure phenotype, which is circuitry dependent, with exclusive thalamocortical expression, and where details of cellular and molecular events are defined. Burst firing in the thalamocortical circuitry of GABAergic reticular thalamus neurons is activated by low -voltage activated T-type calcium channels producing electroencephalographic (EEG) spike-wave discharges and absence seizures. Excessive gamma-aminobutyric acid (GABA) release from reticular thalamus hyperpolarizes thalamocortical neurons through an increased tonic $GABA_A$ receptor current. $GABA_B$ receptors, in turn, modulate this tonic current, explaining the antiabsence action of $GABA_B$ antagonists. The seeds of this concept were planted in the laboratory of David Prince when it was shown that the thalamic T-type voltage-dependent calcium current was a target of the antiabsence drug ethosuximide. This concept continued to flower when P/Q calcium channel mutations in mice were shown to lead to downstream elevations in thalamic T-type voltage-dependent calcium channels that, in turn, produced spike waves, and when it was shown that overexpression of T-type channels produces a spike-wave epilepsy phenotype. The animal model evidence

for thalamic T-type calcium channel involvement in human epilepsy is further supported by the association of mutations in genes for T-type channels, P/Q type channels, and *GABRB3* in individuals with absence epilepsy. In *GABRB3* knockout (KO) mice, a model of human remitting absence epilepsy, downstream changes also lead to elevations in thalamic T-type calcium channel activity. However, and in line with Gloor's corticoreticular concept that attributed to both thalamus and cortex fundamental roles in absence seizure generation, evidence obtained from rat genetic models of spike-wave discharge indicates that this epileptic discharge can also have a cortical origin.

Myoclonic and tonic-clonic convulsive seizures may also be circuitry dependent with reticulocortical expression. Audiogenic kindling in genetically epilepsy-prone rats induces tonic-clonic seizures that initially require only activation of brainstem nuclei. After audiogenic kindling, the "seizure network" permanently expands into the forebrain, involving *N*-methyl-D-aspartate (NMDA) receptor-mediated cyclic adenosine monophosphate (cAMP) changes in amygdala. Imaging and computer-based modeling of neuronal networks underlying epileptic discharges are also providing valuable information defining neuronal network synchronization under physiological and pathological conditions.

In this context, several studies have recently pointed to a peculiar role played by $GABA_A$ receptor-mediated mechanisms in synchronizing neuronal networks during some type of high-frequency oscillations (termed *ripples*) as well as during interictal discharges in partial epileptic disorders. As these basic advances continue, new properties of abnormal signaling in brain networks, such as pathological high-frequency oscillations (20–80 Hz Gamma frequencies and 200–600 Hz 'ripples'), provide useful electrocorticographic diagnostic and prognostic markers and point to disease mechanisms that link to human epilepsies and that then may translate into new therapeutic tools and antiepileptogenesis drugs.

SECTION 3: MECHANISMS OF SEIZURE SUSCEPTIBILITY AND EPILEPTOGENESIS

Major strides have been made in the last decade in describing how brain damage leads to the chronic and enduring condition of spontaneous seizures, a process defined as *epileptogenesis*. Accumulating evidence for major biological events occurring during the period of epileptogenesis in human and experimental temporal lobe epilepsy includes (1) the progressive formation of new recurrent excitatory circuits such as mossy fiber sprouting; (2) the selective and progressive loss of specific, vulnerable GABAergic interneurons; (3) the extensive molecular plasticity at the transcriptional, translational, and trafficking levels of protein expression; (4) the loss, dispersion, and proliferation of dentate granule cells; and (5) the pathogenic appearance of dentate granule cells in ectopic locations or with abnormal hilar basal dendrites.

Mossy fiber sprouting of excitatory axons and establishment of new synaptic connectivity is now accepted as a ubiquitous epileptogenic response to neocortical or hippocampal damage; the typical sprouted axon projecting into the granule cell layer and the inner molecular layer forms >500 synapses, of which >95% are with other granule cells. Granule cells with basal dendrites are highly interconnected with each other and with adult granule cells, and may act as hubs for excitatory activity and enhance hyperexcitability in the dentate network. While axonal sprouting is accepted as a common neuropathological feature in acquired temporal lobe epilepsy produced by trauma, hypoxia/ischemia, stroke, febrile seizures, status epilepticus, and infections, the time course of granule cell hyperexcitability and spontaneous epileptiform discharges following epileptogenic injuries, molecular mechanisms preceding and leading to axonal sprouting, and the construction of epileptogenic circuits within the reorganized networks are the focus of chapters in this section

Section 3 of this book should be of particular interest to clinical epileptologists who study the syndrome of febrile convulsions/hippocampal reorganization/mesial temporal lobe epilepsy. This latter syndrome has a >90% success rate in the elimination of seizures after resection of hippocampal epileptogenic zones. Excitotoxic, necrotic, and programmed (apoptotic) cell death are being analyzed experimentally in brain tissue from identified human focal epilepsy cases. Within this tissue, the roles of neurogenesis and neurotrophin biology continue to provide essential information on the mechanisms underlying reorganization and synaptogenesis. Increases of brain derived neurotrophic factor (BDNF) expression and enhanced activation of tyrosine kinase B (TrkB) in the mossy fiber pathway of hippocampus contribute to hyperexcitability,

while the integration of adult-born dentate granule cells may restore inhibition. These disease pathways may illuminate novel targets for the repair of hyperexcitable neural circuits, a new strategic goal in epilepsy therapy.

Another long-standing focus of interest discussed in this section is the field of GABA receptor plasticity. Differing approaches with new insights into the roles of pre- and postsynaptic GABA receptor-mediated transmission and chloride homeostasis are described. In temporal lobe epilepsy models, expression of the $GABA_A$ receptor δ subunit is substantially decreased in principal cells but increased in interneurons, and a change in the localization of the γ2 subunit from primarily synaptic to perisynaptic sites suggests a subunit switch. In alcohol-kindled seizures, remodeling of $GABA_A$ receptors also occurs. Alcohol-sensitive extrasynaptic α4/δ-containing $GABA_A$ receptor-mediated tonic currents in hippocampal and other cells are downregulated. Benodiazepine-sensitive synaptic α1/γ2-mediated synaptic currents are downregulated, and compensatory α4/γ2 extrasynaptic and synaptic GABA receptors are elevated in parallel with increased sensitivity to alcohol. Finally, the biology of glia-neuron interactions is assuming an increasingly central position in current pathological models of epilepsy and also provides novel therapeutic targets for antiepileptogenesis. Reactive astrocytosis leads to reduced adenosine- and GABA-dependent inhibition. Astrocytes regulate surface expression of neuronal NMDA receptors and release of glutamate and D-serine, and they are involved in the pathophysiology of brain inflammation (e.g., cytokines produce toxic autocrine or paracrine mechanisms and alter glutamate and GABA receptor function).

SECTION 4: EPILEPSY GENES AND DEVELOPMENT

The full potential of personalized medicine to revolutionize patient care in the epilepsies will be attained once the epilepsy genome is completed and treatments specific to individual patients are based on pharmacogenomic information. As widely predicted, the creation of physical and genetic maps of the human genome in 2000 led to an explosive increase in knowledge of the number of single genes linked to epilepsy phenotypes over the last decade. In human epilepsies, more than 20 syndromes previously considered idiopathic (now called *genetic generalized epilepsies* in the 2010 ILAE classification) have been shown to arise from mutations in some 45 identified epilepsy genes (Fig. 1–1 and Table 1–2). The distinction between genes expressed primarily as epilepsies and genetic disease whose phenotype includes epilepsy is becoming more blurred as cases that were previously considered primary and idiopathic epilepsies now show brain magnetic resonance imaging and fluorodeoxyglucose (FDG)–positron emission tomography scan abnormalities. Additional chromosomal loci continue to be mapped from clinical pedigrees, and we foresee more than 100 epilepsy genes identified in the coming decade. The low cost and high throughput of deep gene sequencing to discover allelic variants, and the massively parallel whole exome DNA resequencing of individual epilepsy patients, promise to enormously expand the epilepsy genome. With the identification of more epilepsy genes, basic mechanisms of epilepsies will assume even greater importance as proof of causality. The identification of genes will also inspire studies of molecular and cellular function, and of synaptic and network disease mechanisms, and will provide opportunities for the development of novel approaches for prevention, repairs, and cures. In the laboratory, genotype-phenotype relationships continue to emerge at an even faster pace with the use of a reverse strategy, namely, mutating newly discovered human epilepsy genes in engineered mouse models and screening for epileptic phenotypes. These approaches will steadily unlock a collection of epilepsy genes from a broad array of functional biological pathways that exert major control over brain excitability and synchronization. As examples, mice with mutations in auxiliary voltage-activated calcium channel subunit genes *Cacnb4* (*lethargic*) and *Cacna2d2* (*ducky*) show downstream elevations in thalamic T-type currents, enhancing rhythmicity in thalamocortical networks subserving spike-wave oscillations and producing absence; human mutations in $Na_V1.1$ channels reduce Na^+ currents and decrease electrical excitability in GABAergic interneurons and inhibition, producing downstream epilepsy, ataxia, and cognitive decline of Dravet's severe mycoclonic epilepsy. In animal models of tuberous scleroses and cortical

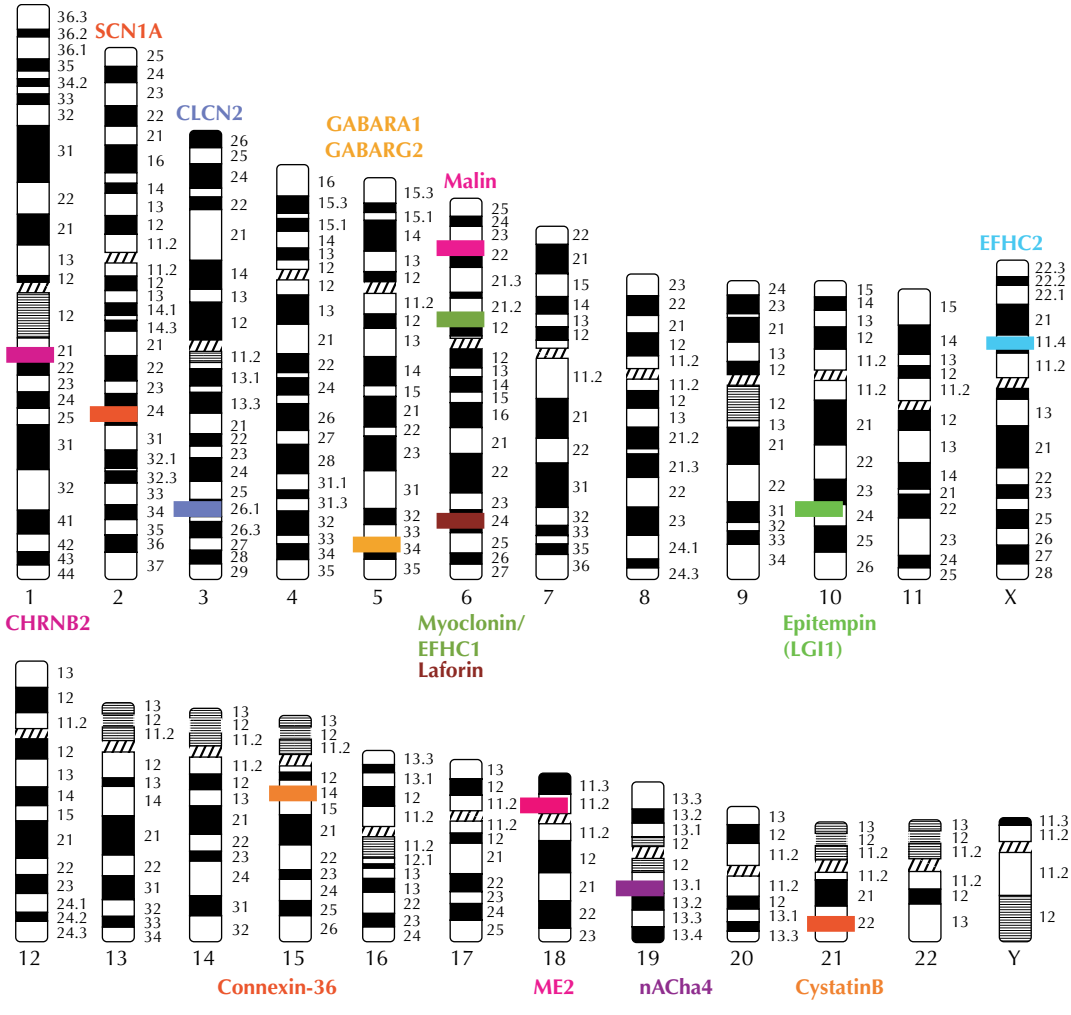

Figure 1–1. Some of the human epilepsy genes and their chromosome loci (based on chapters of this edition of *Jasper's Basic Mechanisms of the Epilepsies*).

dysplasia, hyperactivation of the mammalian target of rapamycin (mTOR) pathway promotes epileptogenesis and neuropathological abnormalities, and the mTOR inhibitor, rapamycin, prevents or reverses epilepsy and associated phenotypes. For many other epilepsy genes, much will be learned in the laboratory about how both the gain and loss of function lead to epilepsy in the developing brain and how they affect neuronal migration, proliferation, differentiation, genesis, and maintenance of synapses and dendrites. Three genes are leading examples of developmental pathways in epilepsy causing lissencephaly, epilepsy, and mental retardation in infants and young children. *LIS1*, *DCX*, and *TUBA1A* encode microtubule-related proteins involved in neuronal migration and synaptogenesis. Exploration of these functional pathways is accelerating the identification of additional candidate genes, as well as novel targets for the development of antiepileptogenesis drugs. As the revolution in genomic technology continues, the analysis of complex heredity becomes more tractable. The next decade will see increased exploration of genetic risk variants that contribute to common sporadic epilepsies and the extent to which they can modify epileptic phenotypes. The analysis of epilepsy comorbidities will become an important aspect of this search, since their association may point to new common gene pathways, converging mechanisms, and

Table 1–2 **Human Epilepsy Genes and Engineered Mouse Models***

Chromosome	Phenotype and Gene	KO Mouse Model	Kin Mouse Model
1p35-31.1	Early childhood absence epilepsy; also in epilepsy with paroxysmal exercise-induced dyskinesia; *SLC2A1*/Glut1, glucose transporter type I	Yes	None
1p36	Generalized epilepsy with febrile seizures plus (GEFS+) with absence seizures; GABRD, GABA receptor variants E177A and R220H and Arg220His	None	None
1q21-23	Familial hemiplegic migraine with epilepsy; *ATP1A2*, sodium potassium adenosine triphosphatase (ATPase) alpha 2 subunit	None	None
1q21	Autosomal dominant nocturnal frontal lobe epilepsy 3; *CHRNB2*, beta 2 subunit of nicotinic acetylcholine receptor	Yes	None
2q22-23	Idiopathic generalized epilepsy, juvenile myoclonic epilepsy; *CACNB4* with *R482X* mutation, calcium channel beta 4 subunit	Yes	None
2q24	Severe myoclonic epilepsy of infancy (SMEI) of Dravet syndrome or simple febrile seizures, intractable epilepsy, complex partial seizures with hippocampal scleroses, pain syndromes; *SCN9A*, sodium channel alpha 9 subunit	Yes	None
2q24	Intractable childhood epilepsy with generalized tonic-clonic seizures (ICEGTC); generalized epilepsies with febrile seizures plus (GEFS+); SMEI of Dravet, febrile seizures 3 (FEB3); de novo mutation in *SCN1A*, sodium channel alpha 1 subunit	Yes	Yes
2q24	Partial epilepsy; *SCN3A*, sodium channel alpha 3 subunit	None	None
2q23-24.3	Benign familial neonatal infantile seizures; febrile and afebrile seizures; *SCN2A*, sodium channel alpha 2 subunit	None	None
4q13-31	Progressive myoclonus epilepsy, Unverricht-Lundborg type, also in action myoclonus-renal failure syndrome; *SCARB2/LIMP2*, scavenger receptor class B, member 2	Yes	None
5p13	Episodic ataxia with seizures, migraine, alternating hemiplegia; *EAAT1*, excitatory amino acid transporter 1; glial glutamate transporter	Yes	None
5q34	Juvenile myoclonic epilepsy, EJM3; *GABRA1*, GABA receptor alpha 1 subunit	Yes	None
5q34	Generalized epilepsy with febrile seizures plus (GEFS+3) and childhood absence; febrile seizures only, Dravet syndrome; *GABRG2*, GABA A receptor gamma 2 subunit	None	*GABARG2* (R43Q)
6p12-p11	Juvenile myoclonic epilepsy, EJM1; myoclonin1/ EFHC1, EF hand containing 1	Yes	None
6p-21.3	Juvenile myoclonic epilepsy, EJM2; *BRD2*, bromodomain-containing 2, mitogen-activated kinase	Yes	None
6p-22	Lafora progressive myoclonus epilepsy; *EPM2B/ NHLRC1*, malin ubiquitin ligase	Yes	Yes
7q36	Focal epilepsy; developmental delay, cortical migration defects; *CNTNAP2*, contactin-associated protein-like 2	None	None

(continued)

Table 1–2 **(Continued)**

Chromosome	Phenotype and Gene	KO Mouse Model	Kin Mouse Model
8q24	Benign familial neonatal convulsions (EBN); *KCNQ3*, potassium channel	None	Yes (Kcnq3/ *G311V*)
9q33.3-q34.11	Sporadic Ohtahara syndrome of early infantile epileptic encephalopathy with EEG suppression bursts; de novo missense or nonsense mutation in *STXBP1/Munc18–1*, syntaxin-binding protein 1	Embryonic lethal	None
9q33.3-q34.11	Early-onset epileptic encephalopathy (early-onset West syndrome) with severe hypomyelination; *SPTAN1*, alpha-II spectrin de novo deletion, duplication	None	None
10q22	Generalized epilepsy and paroxysmal dyskinesia; nonconvulsive absence seizures; *KCNMA1*, BK potassium channel alpha subunit	Yes	None
10q24	Autosomal dominant partial epilepsy with auditory features; *LGI1*, leucine-rich, glioma inactivated 1	Yes	Yes
11p13	Rolandic epilepsy with centrotemporal spikes; *ELP4*, elongator complex gene	None	None
11p15.5	Neonatal seizures with EEG suppression-burst and hypotonia; *SLC25A22/GC1* encodes mitochondrial glutamate/H^+ symporters	None	None
11q14-q23	Tuberous sclerosis; *TSC1* (hamartin) gene	Yes	Yes-conditional *Tsc1* in glia
12p13	Partial epilepsy, partial epilepsy in episodic ataxia 1; *KCNA1*, voltage-gated potassium channel	Yes	None
12q22-q24.1	Tuberous sclerosis; *TSC2* (tuberin) gene	Yes	None
16p13	Autosomal recessive familial infantile myoclonic epilepsy (FIME); *TBC1D24*, binds ARF6, which is involved in neurite branching and extension	None	None
15q21	Idiopathic generalized epilepsy; *ME2*, malic enzyme involved in GABA synthesis	None	None
15q11–15	Remitting childhood absence epilepsy; *GABRB3*, GABA receptor beta 3 subunit	Yes	None
19p13	Absence epilepsy, familial hemiplegic migraine, dominant episodic ataxia2, acetazolamide-responsive spinocerebellar degeneration type 6; *CACNA1A*, voltage-gated P/Q calcium channel alpha subunit	Yes	Yes: *Cacna1a R91Q*
19q13	Generalized epilepsies with febrile seizures plus; *SCN1*β, sodium channel beta 1 subunit	Yes	None
19q13.2	Autosomal dominant nocturnal frontal lobe epilepsy 1; *NACHR*, nicotinic acetylcholine receptor alpha 4 subunit	None	*Chrna4-S284L*; *S280F*; *865–873insGCT*
20q	Benign familial neonatal convulsions (EBN1); *KCNQ2*, potassium channel subunit	Yes	*Kcnq2G279S*; *Kcnq2A306T*
21q22.3	Unverricht-Lundborg disease; progressive myoclonus epilepsy Baltic myoclonus (EPM1); *CSTB*, cystatin B (stefin B)	Yes	None
Xp22	Aicardi's syndrome with early infantile epileptic encephalopathy and EEG burst suppression; *TREX1*, three prime repair exonuclease 1, 3′-5′ DNA exonuclease	None	None

(continued)

Table 1–2 **Human Epilepsy Genes and Engineered Mouse Models* (Continued)**

Chromosome	Phenotype and Gene	KO Mouse Model	Kin Mouse Model
Xp22	X-linked infantile spasms of West syndrome, spasticity, mental retardation, Partington syndrome (ataxia, mental retardation and dystonia), Ohtahara syndrome, X-linked myoclonic epilepsy; *ARX*, Aristaless-related homeobox	Yes *lethal*	truncation, polyalanine expansion
Xp22	Infantile spasms, hypsarrhythmia, overlapping phenotypes of Angelman syndrome and atypical Rett syndrome; *CDKL5*, cyclin- dependent kinase like 5	None	None
Xq22.1	Dravet syndrome, epilepsy and mental retardation in females (EFMR); *PCDH19*, protocadherin 19	None	None
Xq22	Rolandic epilepsy with oral and speech dyspraxia; bilateral perisylvian polymicrogyria; *SPRX2*, secreted sushi-repeat containing protein	None	None
Xq22.3-q23	X-linked lissencephaly and subcortical band heteotopia, double cortex syndrome; *DCX*, doublecortin	Yes	None

* These epilepsy genes are based on chapters in this edition of *Jasper's Basic Mechanisms of the Epilepsies*, but these are not all the known monogenic causes of epilepsy or all the de novo mutations in epilepsy.

studies on pharmacogenomics and personalized medicine.

SECTION 5: EPILEPSY THERAPEUTICS

The accelerating pace of discovery in basic epilepsy research is beginning to deliver the molecular pathways and cellular mechanisms that can be targeted in the development of novel therapies. Therefore, for the first time, the editors devote a major section of *Jasper's Basic Mechanisms of the Epilepsies* to the treatment of epilepsy, with an emphasis on the scientific underpinnings. Since publication of the work of Merritt and Putnam in the 1940s, the discovery of antiepileptic drugs has been based on screening candidate drugs in predictive animal models without regard to mechanisms of drug actions. Drugs often reach the market with little understanding of their pharmacodynamic effects. Once they are well established in clinical practice, information eventually emerges on the molecular targets through which they act to protect against seizures. In contrast, over the past decade, several entirely novel antiepileptic drug targets, notably $\alpha_2\delta$, SV2A, and KCNQ potassium channels, have been identified in studies with the newer drugs levetiracetam, gabapentin, pregabalin, and ezogabine (retigabine). The efficacy of these drugs enables expanded discovery programs directed at other members within these molecular families as well as target-based screening of chemical libraries for active compounds, a new paradigm in antiepileptic drug discovery.

Even with the availability of a steady stream of new antiepileptic drugs, many of which act on unique molecular targets, many patients still do not achieve adequate seizure control. This has led investigators to look beyond drugs to nontraditional treatment approaches. Dramatic progress has been made in at least one older nonconventional treatment approach, deep brain stimulation, which has shown promise in clinical trials. Other older nontraditional approaches that continue to be investigated include hormonal and dietary strategies. At the same time, emerging cell and gene-based treatment strategies are being applied in epilepsy. Promising results have been obtained in animal models, and by the time the next edition of this book is published, we will have a better sense of the practical feasibility of these approaches. As researchers open new frontiers in biological therapies, there has been continuing interest in understanding the neurobiological bases of pharmacoresistance

to conventional small-molecule antiepileptic drugs, which is leading to new ideas on how to overcome drug refractoriness, some of which are already being tested in the clinic.

CLOSING SUMMARY

Finally, in line with the view that understanding epileptogenesis is a critical research priority (Table 1–1), investigators are seeking antiepileptogenic treatment strategies with the ambitious objective of preventing the onset of epilepsy or reversing it once it has become established. New animal models based on mutations of human genetic generalized epilepsies designed to investigate antiepileptogenic strategies are under development in order to study disease modification and cures. Successful approaches will likely have little similarity to drugs that are currently used to protect against seizures. Even with the recognition that symptomatic treatments for neurological disorders have been easier to come by than those that correct an underlying brain defect, there is nevertheless optimism that these new approaches will eventually lead to the prevention, repair, cure, and eradication of some forms of epilepsy.

Chapter 2

Herbert H. Jasper and the Basic Mechanisms of the Epilepsies

Massimo Avoli

THE EARLY YEARS

Born in La Grande, Oregon, on July 27, 1906, Herbert H. Jasper was strongly influenced by his father, whom he later described as a "thoroughly dedicated minister who excelled in mathematics and philosophy as well as practical engineering."[1] His great-grandfather arrived in Oregon by covered wagon. As a young girl, his mother emigrated with her family from Switzerland. Her ancestors were French Huguenots who had fled France to escape persecution in the 1700s. We may wish to assume that these pioneer genes provided Jasper with the exploring mind that allowed for his outstanding research achievements.

Both in his undergraduate and initial graduate studies he majored in psychology (Fig. 2–1). His first published paper, entitled "Optimism and Pessimism in College Environments,"[2] was based on his undergraduate thesis at Reed College, and soon afterward, other papers followed on similar subjects. The turning point from a sociopsychological approach to understanding the intricacies of the human mind toward more fundamental physiological questions, presumably, coincided with Jasper's move from Oregon to the University of Iowa, where he obtained his first doctorate at the age of 25, in 1931. The first publication that testifies to this new orientation appeared in *Science* in 1931 and was titled "The Iowa Eye-Movement Camera."[3] Gloor commented on Jasper's change of research orientation as follows: "To a cynic, this new approach may appear like turning from the sublime to the trivial. I suspect that for Herbert Jasper, nurtured in philosophy and psychology, it must have been a difficult step to take, but it testifies to his courageous acceptance of the belief that we shall never be able to understand the human mind unless we are willing to deal first with very fundamental, measurable processes, starting with paradigms which may appear simplistic, but provide objectively verifiable and measurable data."[4]

During the winter of 1929–1930, at a meeting of the American Physiological Society in Chicago, Jasper had a fortunate meeting with Alexandre and Andrée Monnier, who had been studying in St. Louis with Gasser. He accepted

Figure 2–1. Herbert H. Jasper in 1926, while at Willamette University in Salem, Oregon. This university was where his father had also graduated in the school of theology and social studies.

their invitation to join them in Paris, for which he obtained a fellowship from the Rockefeller Foundation. During 1931 and 1932, he worked in Paris with the Monniers, as well as with Louise Lapicque, studying the phenomenon of chronaxie in peripheral nerves, using their cathode ray oscilloscope that had been acquired in St. Louis. At that time, chronaxie was hoped to disclose basic mechanisms of neuronal function that could be applicable to central mechanisms as well.

Jasper then returned to the United States, where he worked at Brown University in Providence, Rhode Island, developing an electroencephalographic (EEG) laboratory at the Emma Pendleton Bradley Home, and in 1935 he published, in *Science*, the first paper in the United States on human EEG[5] (Fig. 2–2A). There, working with Carmichael, he described "spontaneous" fluctuations in magnitude of the alpha waves, the reduction of these waves by visual stimulation, and their consistent frequency in the same individual upon repeated examinations. He also reported that "In one or two pathological cases which we have studied, a frequency of alpha waves as low as 2–3 per second has been observed." As proposed by Feindel,[6] these were presumably delta waves associated with brain damage. Jasper and Carmichael[5] cautiously predicted: "It may well be that the electroencephalograms of the sort described in this note may prove significant in psychology and clinical neurology. It is even possible that this technique may provide information in regard to brain action which will be comparable in significance to the information in regard to heart function which is provided by the electrocardiograph." A few months later, the Harvard group (including Fredric Gibbs, Hallowell Davis, Alexander Forbes,

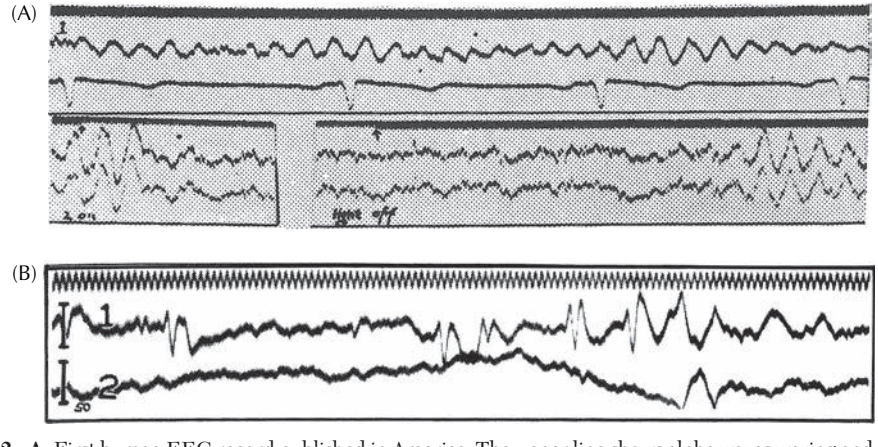

Figure 2–2. A. First human EEG record published in America. The upper line shows alpha waves waxing and waning; the bottom two lines show blocking of the alpha waves with visual stimulation.[5] **B.** Interictal activity recorded from a patient with posttraumatic Jacksonian seizures; note that spikes or sharp waves are recorded from the precentral region (1) but not from the homologous area (2).[8]

and William Lennox) reported that the EEG activity of epileptic patients was abnormal. Shortly afterward, Jasper and his team confirmed this finding[7,8] (Fig. 2–2B) and proposed that the EEG examination, in addition to being useful for the diagnosis of epilepsy, could be employed for the localization of the epileptic area in the brain. Indeed, this pioneering work led to the later development of two schools of EEG with differing emphasis and perspectives. Gibbs' school used a holistic approach, as it considered any highly integrated activity as the expression of brain function as a whole. The opposing view, by reflecting a kind of Cartesian or topistic concept of cerebral organization, was that used by Jasper: it associated even highly complex brain functions with localized neuronal substrates that had to be defined anatomically.

Jasper returned to Paris in 1935 to defend his primary thesis, titled "Recherches sur l'excitabilité et les caractères de la reponse dans le systeme neuromusculaire des crustacés. Influence des centres ganglionaires." These studies had been completed over the summers of 1932 and 1933 at the Woods Hole Marine Biological Laboratories, where he had been able to interact with many leading neurobiologists, such as Harry Grundfest, Alan Hodgkin, and Francis Schmitt. He added, however, a supplementary thesis titled "Electroencéphalographie chez l'homme" related to the EEG work he had carried out with his team at Brown University. In his autobiography Jasper recalled that "the examining committee seemed satisfied with the principle thesis on the crustacean neuromuscular system," but "All were enthusiastic about my second thesis on *electroencéphalographie chez l'homme*" and "I had to treat everyone to a champagne reception afterward as is the custom."[9]

Shortly after his thesis presentation, Jasper traveled to Germany and met Hans Berger, whose early reports on the discovery of EEG had been received with skepticism, and then visited Edgar Adrian and Brian Matthews in Cambridge, who had expanded Berger's original findings. As remarked by Andermann,[10] Jasper was not insensitive to the political turmoil of those years. He wrote of Berger's persecution by the Nazis, a preamble to Berger's suicide in 1941, and of Marthe Vogt, the daughter of Cecile and Oscar Vogt, whom he advised to leave Germany and for whom he helped to obtain a fellowship in England; Marthe Vogt, a neuropharmacologist, became a fellow of the Royal Society and a professor at Cambridge University.

WORK AT THE MONTREAL NEUROLOGICAL INSTITUTE

While at Brown University, Jasper and his colleagues had heard of Wilder Penfield's observations on electrical stimulation to map the cortex in conscious patients during surgery for the treatment of focal epilepsy at the Montreal Neurological Institute (MNI, also called "the Neuro"). They invited Penfield to give a seminar in the Psychology Department at Brown and also to visit the EEG laboratory located in the basement of the Bradley Hospital. Penfield himself described his first meeting with Jasper as follows: "He [Jasper] could, he said, localize the focus of an epileptic seizure by the disturbance of brain rhythms outside the skull. I doubted that but hoped it might be true."[11] Although skeptical at first, Penfield agreed to operate on two patients who had been studied by Jasper in Providence, and found lesions underlying the area where the EEG abnormalities had been localized. As described in detail in the letter written by Jasper to Penfield on February 5, 1938 (Fig. 2–3), this initial success started a collaboration that Penfield defined as "our almost unthinkable commuters research project." Each week, Jasper loaded a portable EEG machine into his car and on arrival at the MNI studied Penfield's patients, returning later in the week to Brown to continue his work. This was not an easy task, as there are more than 600 km between Providence and Montreal, and those were late 1930s roads (several years before the creation of the interstate highway system by President Dwight Eisenhower). Jasper's pioneer spirit was once more put to the test.

Penfield was finally convinced by Jasper that it was possible to identify the site of origin of a patient's seizure, even between attacks, by recording the EEG through the unopened skull (i.e., by studying the location of the interictal epileptic discharge), and also that it was possible to refine this localization by recording the brain activity directly from the exposed surface during neurosurgery. Penfield invited

February 5, 1938

Dr. W. G. Penfield
Montreal Neurological Institute
3801 University Street
Montreal, Canada

My dear Dr. Penfield:

The more I think about your proposal that we should join forces in our respective fields of research, the more I believe that such a collaboration should result in some very important progress in the interpretation of electroencephalograms, and I should hope that also it would make some significant contributions to our general understanding of epilepsy.

Incidentally, this should give us an opportunity for an excellent comparison of the relative value of the Roentgen encephalogram and the electroencephalogram in the localization of brain pathology. I am also very much interested in following up the operated cases to obtain a good record of the change in the electrical activity of the brain. This should yield important information in regard to some general questions of brain physiology as well as test the efficacy of the operation in removing a discharging focus and possibly result in the discovery of new focii in some cases.

I feel that this is such an excellent opportunity that you have suggested, that I would like very much to spend the next three months in Montreal, but I do not see how that can be arranged in the immediate future. I have arranged my teaching so that it will occupy only Monday, Tuesday, and Wednesday of each week, and our own research could also be carried out during this time. This would leave Thursday, Friday, and Saturday free for work in Montreal, and occasionally I could arrange also to spend an entire week with you if necessary. Do you think that our collaboration might be satisfactory if I could plan on being in Montreal Thursday, Friday, and Saturday of each week? This would necessitate considerable expense for travel, but in view of the importance of the work I believe that it would be worth the expense.

I have written Dr. Lambert to get his impressions of this arrangement, and hope to hear from him in the near future. I understand that Dr. Gregg has been on a trip west,

so that you have probably not as yet heard from him. In checking over our budget for this year, I find that I could pay the necessary traveling expenses without exceeding the total amount allowed in our grant for the year if the expenditure was authorized by the Rockefeller Foundation.

In regard to equipment, I have a very good portable set-up which could be very easily transported to Montreal in my car. It is now being used for some of our own work in the hospitals, but I will be glad to remove it temporarily in case you wish to have some cases run before your equipment is completed.

Very sincerely yours,

Herbert H. Jasper

Figure 2–3. Letter sent by Jasper to Penfield in 1938 in which he describes possible options for establishing a closer collaboration at the Neuro.

Jasper to join him at the MNI, where he was to work for the next three decades. With funds provided by the Rockefeller Foundation, McConnell, Sir Herbert Holt, and Duccan, an annex off the MNI basement dedicated to clinical EEG was built. It was dedicated to "research on the physiology of the brain with special reference to epilepsy and dementia." The EEG Department, which is still located in the same area of the building 70 years later, was opened by a symposium in February 1939. The meeting continued in the Laurentians, the first of the annual ski meets of the Eastern EEG Association. Of this period in Montreal, Jasper wrote, "My time with Wilder Penfield and his family, in which I became an adopted member, working with his splendid enthusiastic staff and hundreds of colleagues and students from all over the world who worked with us, was certainly the most pleasant and productive 27 years of my life."[12] As Penfield was fond of saying, epilepsy was their great teacher.

Shortly after the inauguration of the EEG laboratory at the MNI, World War II broke out, and both research and clinical care had to be reoriented toward war-related medical issues. Jasper became involved in research on air transport for head injuries, antibiotics for the treatment of brain wounds, studies on air-pilot blackout, and seasickness prevention. Problems related to numerous cases of nerve injury were also studied with electrophysiological techniques, and Jasper became one of the initiators of another branch of neurophysiology: electromyography.[13] Around 1940—but actually, as indicated by his curriculum vitae (see the Appendix), in 1939— feeling the need for more medical training, Jasper enrolled as a medical student at McGill University and completed the 3-year wartime curriculum while continuing with his clinical and laboratory work.

At the beginning of 1944, he was required to fulfill his military service (Fig. 2–4A). After a few weeks of formal military training at Camp Borden (Ontario), he was assigned to the MNI, where he continued to work on the various projects related to the war effort. It is fascinating to read in a handwritten note sent from Jasper to Penfield on March 9, 1944: "The stretcher drill and PT on the assault course is taken seriously—not to mention the route marches with

Re: Captain Herbert Jasper, RCAMC

Dear Colonel Penfield:

Your letter of 11 September 45 to Major General Fenwick has been passed to us for attention as this Board is immediately concerned in priority of release.

As Captain Jasper has had a fairly short term of service it will be of very great assistance if this officer is placed on the McGill Univeristy priority list.

The University priority list is intended to include those who are urgently required to make possible the rehabilitation training of demobilized medical officers. It is a very high priority. If the name is not placed on the list, the request will be considered in the same way as all other requests for premature release -- on the merits of the individual case.

We will delay action until you have discussed this matter with Dean Meakins who supervises the University priority list and await a further communication from Dean Meakins or yourself.

H.A. Proctor, Major,
Exec.Sec. CMPAB

Figure 2–4. A. H.H. Jasper as an officer in the Canadian Army. **B.** Letter sent by Major Proctor of the Canadian Army in response to Penfield's inquiry about Jasper's release from duty at the end of the war.

full pack—5 miles the first week—10 miles the second, 15 miles the third, up to 18–20 miles the final week. . . . I shall return to Montreal on Easter. . . . After that I am anxious to settle down to some serious work with you." Although Jasper was a captain (and Penfield a colonel, as is evident by reading the correspondence reported in Fig. 2–4B) in the Canadian Army, he did not sign the declaration of allegiance to the king; he maintained his American citizenship to allow his children to choose their citizenship until 1950, when he decided to stay in Canada and became a Canadian citizen.

Once the war was over, Jasper refocused his interest on epilepsy and on what epilepsy could reveal about brain function. The laboratories of EEG and of experimental neurophysiology (the latter are, in fact, still located on the seventh floor of the MNI six decades later) enjoyed a period of extraordinary growth, attracting bright young men and women from all parts of the globe (Fig. 2–5). As Jasper wrote: "We had more than 100 research fellows during the 10 years following the war."[9] Their publications covered a broad range of research topics, including the reticular formation as well as the thalamocortical and limbic systems using EEG and unit cell recordings aimed at unraveling the fundamental mechanisms of epilepsy as well as of behavior. The functional organization of the thalamocortical system as an integrating unit subserving physiological functions represented, in those years, a hot topic of research, one of the crucial points being the identification of the functional connectivity of the thalamic nuclei and their role in the phenomenon of incrementing (also termed *recruiting* and *augmenting*) responses that were recorded from the neocortex during low-frequency stimulation of the thalamus.[14] This search led Jasper to discover that generalized spike-and-wave discharges at 3 Hz—which are typically seen in human petit

mal epilepsy—can be elicited in the cat by stimulating the midline thalamic nuclei.[15] Indeed, Jasper's views on the role of thalamocortical mechanisms in generalized epilepsy have been seminal to the development of important concepts and experimental work in this area.[16–18] I should add that, as often happens in scientific research, these data were at times controversial; however, Jasper was always keen to settle on unclear scientific issues. One of these cases occurred when he agreed with Horace Magoun (another pioneer of research on the thalamocortical system) to test an ongoing dispute between the MNI and UCLA laboratories by having Robert Naquet—at that time a fellow in Jasper's laboratory—sent to California to repeat some salient experiments; these data were later published in the *EEG Journal*.[19]

In this period, Jasper was also interested in the function of the limbic system, and he asked one of his fellows, Peter Gloor, to explore, by electrophysiological means, the connections of the amygdala. These experiments revealed that this limbic area projects intensely to a large brain region comprising the basal core of the forebrain and midbrain extending to the hypothalamus and the brainstem tegmentum. These data—which were included in Gloor's Ph.D. thesis—were so novel that they became a chapter in the first edition of the *Handbook of Physiology* published by the American Physiological Society.[20] Jasper's interest in charting the brain, both anatomically and functionally, is also mirrored by the publication of an atlas of the cat diencephalon[21] that, 30 years later, was still in use in many laboratories around the world.

Jasper's school of EEG was flourishing during his years of association with Penfield at the MNI, investigating patients with intractable epilepsy being considered for surgery. The scientific output was prodigious and culminated in Penfield's and Jasper's masterpiece, *Epilepsy and the Functional Anatomy of the Human Brain*,[22] which remains an invaluable reference in our search for understanding epileptic disorders. At around this time, Jasper published another comprehensive book on the brain mechanisms of consciousness that also became a classic in the EEG literature.[23]

In the early 1950s, Jasper's pioneer genes pushed him toward new frontiers. He was no longer satisfied with the information obtained with EEG recordings, and he wanted to know more about the activity of single neuronal cells and of their contribution to the EEG rhythms. He tackled this problem with several of the young scientists who were coming to the MNI (such as Chu-Lu Li, Hughes McLennan and, a few years later, Costa Stefanis), and clarified the complex relationships between gross surface EEG potentials and cortical neuron activity that were recorded with extracellular or intracellular microelectrodes. However, although he wanted to gain a better understanding of the mechanisms underlying neuronal excitability, he did not lose his interest in how the mind works. Therefore, he began to study in the late 1950s the involvement of cortical neurons in conditioning in monkeys. To this end, Jasper sought help from his former student (and later Nobel laureate) David Hubel, who was working in Washington, D.C., and developed tungsten microelectrodes to record from single neocortical cells in waking experimental animals and humans. As Gloor remarked, "this was the first time anyone has attempted to employ single-unit recording techniques in the investigation of behavior."[4] This methodology was later applied, in collaboration with Gill Bertrand, to analyze the activity of single human thalamic neurons in patients undergoing stereotaxic treatment for the relief of parkinsonian tremor.[24]

In 1996 Jasper wrote, "It was Penfield's dream to create a multidisciplinary neuroscience institute in which the basic scientists worked closely with clinicians and the laboratories of radiology, neuropathology, neurochemistry, neuroanatomy, neuropsychology, and, of course, with electroencephalography and neurophysiology, in a fusion of clinical and basic research. This was a forerunner of what soon became what we now know as neuroscience. I was delighted to take part in the realization of Penfield's dream, which soon became my own as well; it became for me an international as well as an interdisciplinary dream."[9]

Such multidisciplinary effort received impetus from the recruitment of Allan Elliott, a brain chemist who expanded the biochemistry laboratories into the first research unit for neurochemistry. In 1953 Elliott invited Ernst and Elizabeth Florey to the MNI to study an inhibitory factor that they had found in brain extract. In 1955, the Floreys and McLennan characterized the inhibitory effects of "Factor I" on peripheral and central synaptic transmission.[25] One year

later, Florey's Factor I was identified as gamma-aminobutyric acid (GABA). This was quickly followed by the work of Iwama and Jasper, who confirmed its inhibitory action on the cerebral cortex.[26] As Jasper noted, "the reports from Drs Florey and McLennan on the isolation of the substances from brain tissue which have strong inhibitory or excitatory effects on the activity of the central nervous system were outstanding…the isolation of a naturally occurring inhibitory substance in the brain, if confirmed by further study, may be a discovery of major consequence, not only for our understanding of normal brain function, but also for the rational treatment of brain disorders."[12]

THE FOUNDING OF IBRO AND THE BME PROJECT

Jasper was keen on organizing and participating in international societies and conferences. Thus, at a meeting of the International Federation of EEG and Clinical Neurophysiology in Moscow in 1958 (Fig. 2–6), he and others voted unanimously for a resolution proposing the creation of an international organization that could cut across world boundaries and improve communication and collaboration among brain researchers. Jasper participated in the founding of the International Brain Research Organization (IBRO) and in 1960 became its first executive secretary, moving with his family to Paris for a sabbatical year. IBRO, which was linked to the United Nations Educational, Scientific, and Cultural Organization (UNESCO), was incorporated on March 29, 1961, by the Senate of Canada. At the peak of the Cold War, IBRO provided a powerful scientific platform for closer collaboration between Western and Iron Curtain neuroscientists. Jasper wrote in 1996 that "after the close of the Moscow Colloquium in 1958 I had had a private conference with the president of the Soviet Academy of Science which resulted in his agreement to collaborate

with our international efforts in this direction."[9] Fifty years later, IBRO continues to promote neuroscience, with special emphasis on assisting young investigators in the developing world.

In the 1960s, Jasper was also called on to chair the Basic Resarch Task Force of the Public Health Service Advisory Committee on the Epilepsies, which had been created by the Surgeon General of the U.S. Public Health Service. The Task Force concluded that basic epilepsy research needed stimulation, and thus it was decided to hold a workshop/symposium and to publish a comprehensive monograph. Jasper was given the assignment of developing the first workshop, which was held in Colorado Springs, Colorado, and of editing the book. The first volume of *Basic Mechanisms of the Epilepsies* was published in 1969 with H.H. Jasper, A.A. Ward, and A. Pope as editors.[27] As discussed in Chapter 1 of this book, basic and clinical researchers in epilepsy gather together approximately each decade to review their accomplishments and to identify future directions.

MOVING TO THE OTHER SIDE OF THE MOUNTAIN (MONT ROYAL, OF COURSE!)

After returning to Montreal from his IBRO assignment with UNESCO in Paris, Jasper decided to focus on experimental neurophysiology, concentrating on the combination of neurochemical and microelectrode techniques that he had developed so effectively with Elliott and his team. These studies revealed that certain functional states of the brain (e.g., arousal mediated through the activation of the brainstem reticular formation) are associated with changes in the release of amino acid transmitters and with an increased release of acetylcholine.[28,29]

In 1965 Jasper moved to the Université de Montréal, where an enthusiastic new group in the neurosciences, supported by the Medical Research Council of Canada, had been formed. There, continuing his research on the relation between neurochemical changes and brain activity, he reported that there was an increased release of acetylcholine during rapid eye movement (REM) sleep compared to that occurring during slow wave stages.[30] Moreover, he discovered that acetylcholine, when applied to the cortex after preventing its hydrolysis with eserine, caused sustained epileptiform discharges that could be triggered by weak sensory stimulation.[31] Later, with Koyama and van Gelder, he extended the analysis of the neurochemical mechanisms causing seizure activity and epileptogenesis to amino acid neurotransmitters.[32] Jasper himself reviewed these data in a paper that was written while approaching his 90th birthday.[33]

Jasper's final years of active research focused on catecholaminergic mechanisms in the cerebral cortex. At that time, there was little evidence for a central role of catecholamines. With Reader, de Champlain, and Descarries, he found a reciprocal relation between acetylcholine, on one side, and noradrenaline and dopamine release, on the other, during activation of the cerebral cortex by sensory inputs. As commented by Gloor, "at this stage of his career Jasper's search for the mind had become a search for molecules. He has traveled a long road since his early college days when he had attempted to understand why some people approach[ed] life in an optimistic frame of mind, while others were subject to a gloomy pessimism."[4] It should be emphasized that while being a key figure in the development of this new department at Université de Montréal, Jasper continued to work as consultant in neurophysiology at the MNI.

HERBERT JASPER'S LATE YEARS

During his 70s and 80s, Jasper persisted tirelessly in his research at the Université de Montréal and continued to visit the MNI. His attendance at conferences and lectures was always characterized by sharp comments on the topics under discussion. Because of his fundamental training in laboratory neurobiology, he offered valuable critiques of new work that were sometimes based on research topics which he and his collaborators had previously examined. He gave superb summaries of symposia from his well-informed perspective, and he continued to write review papers that, while being historical in their nature, also provided original and inspiring concepts on future directions.[34]

Herbert Jasper collected prizes, awards, distinctions, honorary degrees, and worldwide recognition. Among these were the Ralph Gerard Prize of the Society for Neuroscience (Fig. 2–7), the McLaughlin Medal of the Royal

Figure 2–7. Peter Gloor, Herbert Jasper, Brenda Milner, and Ted Jones at the event awarding the Ralph Gerard Prize of the Society for Neuroscience in Washington, D.C., in 1993.

Society of Canada, the FNG Starr Award of the Canadian Medical Association, and the Albert Einstein World Science Award of the World Cultural Council. He was appointed an Officer of the Order of Canada, elected to the Canadian Medical Hall of Fame, and appointed as Le Grand Officier de l'Ordre National du Québec. His work in epilepsy was recognized by the William G. Lennox Award of the American Epilepsy Society, the Carl Spencer Lashley Award of the American Philosophical Society, and the research award sponsored by the Milkin Family Medical Foundation and the American Epilepsy Society.

Gloor has remarked that from the very beginning, Jasper wanted "to use the EEG as a means to investigate fundamental aspects of brain function, rather than to merely employ it as a diagnostic test."[4] Gloor stated: "He always hoped that research directed at fundamental and even molecular mechanisms in the brain may help us to better understand the human mind." However, contrary to other giants of neurobiology research such as Eccles or Penfield, he never discussed brain, mind, and behavior from a philosophical perspective.

Herbert H. Jasper continued to be in good health up to a few months before his 93rd birthday, when on March 11, 1999, he succumbed to a sudden cardiac attack. I am sure that his prodigious contributions will continue to be appreciated by the neuroscience community of the third millennium, thus making this pioneer's life span more than two centuries.

ACKNOWLEDGMENTS

I am indebted to Ms. Marylou Jasper for reading this paper and for providing invaluable information on Dr. H. Jasper as scientist and husband. I also thank Ms. Toula Papadopoulos for skillful editorial assistance. Finally, I want to dedicate this chapter to the memory of the late Drs. Peter Gloor and Robert Naquet, two of Jasper's former fellows, who nurtured my interests in epilepsy research and neuroscience.

DISCLOSURE STATEMENT

The author has no conflicts of interest to disclose.

APPENDIX: ORIGINAL CURRICULUM VITAE OF DR. H. JASPER, DATED APPROXIMATELY 1954

JASPER, Herbert H.
M.A., Ph.D. (Iowa), D.es Sci, (Paris), M.D. (McGill)
Hon. Doctorate (Bordeaux), C.M.
McGill University
Montreal Neurological Institute
Born: July 27th, 1906
Educated: '23–'26 Willamette University, Portland Or.
'27 Reed College, Portland, Or. B.A.
'27–'29 University of Oregon, M.A.

'29–'31 University of Iowa, Ph.D.
'31–'33 University of Paris, D.es Sci, Psychology. Also Fellow, National Research Council (U.S.)
'33 Laureat, French Academy of Science
'39–'43 McGill University, M.D., C.M.
'47 Doctorate, honoris causea, University of Bordeaux.

Positions: '29 University of Iowa, Instructor in Psychology
'33–'38 Asst. Prof. Psychology and Director, Psychological clinic and Neurophysiology labs. Brown University, Providence, R.I.
'39 Seminar in Neurophysiology, McGill University
'49 Professor Experimental Neurology, McGill Neurophysiologist and Electroencephalopgrapher, Montreal Neurological Institute.
'49 First President, Am. Soc. of Electroencephalographers.
'49–'53 First President, Internat. Fed. of Societies for EEG and clinical Neurophysiology
Editor-in-chief, Journal of EEG and clinical neurophysiology.

FIELDS OF WORK:
Description of transmission of nerve impulses across artificial synapses (crustacea).
Development of techniques of localization of epileptic discharge.
Demonstrated: "psychomotor epilepsy" as a form of focal epilepsy.
Demonstration of a separate diencephalic projection system in animals, regulating electrical activity in the cortex.
Cortico-subcortical connections and action of the reticular network on the brain stem.

Chapter 3

Why—and How—Do We Approach Basic Epilepsy Research?

Philip A. Schwartzkroin

This volume and its predecessors[1–3] focus on basic mechanisms of the epilepsies. Most of us, when we open such a volume, expect to see a discussion of studies on experimental animal models and/or reduced brain preparations (i.e., not studies in humans), with an emphasis on cellular, molecular, and genetic variables that influence neuronal excitability, synaptic interactions, and circuitry dynamics. These studies are typically carried out in a laboratory, often by individuals who employ basic research skills that are quite different from those used in taking care of patients with a neurological disorder. We basic scientists are trained in exacting research techniques, use highly specialized methods, and employ critical faculties that help us avoid the potential pitfalls of experimental approaches.

These features of basic research often separate the associated laboratory activities from research carried out on patients with medical disorders—so-called clinical research. As we all know, the separation between basic and clinical research is not always easy to make. Physician scientists may move easily from the laboratory to the clinic and blur the distinctions. Highly technical approaches developed in the laboratory may be applied to patient populations, and technical advances developed for clinical assessments may eventually be applied in the laboratory. And cellular, molecular, and genetic variables that once were investigated primarily (or exclusively) in animals and in vitro preparations are now routinely applied to clinical populations. Indeed, many of the basic imaging and genetic insights into neurological disorders were identified initially in clinical studies.

Given how blurred this basic-clinical distinction is, it has become increasingly important for basic scientists to break down the basic-clinical separation, and particularly to give up the idea that clinical research is somehow inferior—lacking, perhaps, the rigor or the insights associated with laboratory work. There is, however, an important aspect of research that often (not always) separates basic from clinical studies—the availability of normal control groups. One of the major advantages of laboratory work—aside from enabling the researcher to apply invasive approaches that would not be ethically appropriate in human subjects—is the possibility of separating variables of interest and therefore creating control groups that differ only in the variable of interest. This laboratory advantage provides the basic scientist with an especially powerful (but narrow) means of drawing strong conclusions from his or her work. It is important to recognize, however, that depending on the goal of the study, isolation of single variables may not provide answers that are of clinical value, since real-life pathologies rarely appear to be dependent on single variables.

WHAT DO WE MEAN BY "BASIC" RESEARCH?

Basic research can take a number of different pathways in the attempt to provide insights and advances. The basic research enterprise can be divided into at least three somewhat different activities, each of which involves different approaches and different goals.

Exploration and Discovery

Historically and conceptually, scientific research begins with exploration, an attempt to see what's out there. Exploration has not always been respected as a scientific research activity, especially since it may be poorly focused or biased, so that the explorer finds what he or she is looking for. Yet, modern research is almost inconceivable without the exploration of a Galileo or a Darwin. Indeed, where would today's disciplines of molecular genetics be without the exploratory research that resulted in the description of the human genome?

In years past, a grant review that included a phrase such as "this is an exploratory study" or "this is a purely descriptive study" was an inevitable death knell. More recently, we have begun to appreciate the importance of exploratory studies and to understand that exploration can be pursued on many different levels (e.g., within a large animal population or within the DNA components of the genome). We now seem to allow exploratory research if it is sufficiently molecular (i.e., if the study uses sophisticated modern molecular/genetic tools), but we still reject such studies if they use more ordinary approaches (e.g., macroscopic or even microscopic observation). Is there a good rationale for accepting descriptive studies at one level but not at another? Why reject detailed descriptive studies (or label them as second-rate science) if such studies provide a basis for asking important questions?

Hypothesis Testing

Scientific training usually emphasizes the need for well-designed experiments, which typically involve the development of clear hypotheses that can be tested using established (or newly developed) scientific methods. Key features of this type of research include (1) asking questions (posing hypotheses) that can be definitively addressed in the laboratory; (2) applying appropriate control/comparison groups; (3) replicating the results of the study; (4) analyzing the results with appropriate statistical tests;

and (5) being careful not to overinterpret the data. We are all taught that, in the laboratory, hypotheses can never be proved, only disproved. We are taught that experimental data can be used to support a hypothesis. We are cautioned against making the jump from one well-controlled experimental context to a general statement of truth. Thus, this type of research is carried out in a very narrow, specialized context—and yet it is now the gold standard for what we think of as good science. Why should that be the case?

Hypothesis testing is a means by which one can use the results of exploration and discovery (i.e., observations and descriptions) to make predictions about our world. A hypothesis often reads "If…, then…." That is, given a certain initial condition and/or manipulation, one can reasonably expect a given outcome. Prediction is, indeed, the basis for much of scientific research, and has been the driving force underlying the development of the scientific method and techniques. Providing a reliable basis for prediction is the job of the researcher.

Invention and Technological Advancement

Inventors have been among our most illustrious scientists, but modern invention—with its association with financial gain—has often been viewed as a nonscientific function (or at least a less than respectable scientific activity). Inventors have been looked at as tinkerers or engineers—but not as true researchers. Yet, technological invention drives modern science, and the findings from basic laboratory (and clinical) research drive technical innovation. Why, then, would one want to separate the technological enterprise from research (either exploratory or hypothesis testing)? It is often the technological advance that is the ultimate goal of even the most basic forms of research.

WHAT CAN WE ACCOMPLISH BY ENGAGING IN BASIC RESEARCH?

Even if we know *what* we're doing, it is often unclear *why* we should be doing it. Why would a bright young student want to spend his or her lifetime doing research in the laboratory? What rewards await the researcher? What value does this activity have for our society? The answers to these questions are often assumed by teachers and students, by researchers and granting agencies, by grant applicants and reviewers. But the answers are not simple. Indeed, at least at the general level, they may vary dramatically from individual to individual, from discipline to discipline, and from generation to generation.

Knowledge for the Sake of Knowledge

At every point in history, in every civilization, there have always been individuals who were inherently curious about their environment, who inevitably asked "why" and "how" questions. In modern society, for those who just "want to know," there is no better way to pursue that goal than in the laboratory. In this sense, scientific research is the modern religion. The young research scientist is provided with powerful tools, introduced to complex and intriguing questions, and encouraged to attack difficult problems as a challenge (for the sake of obtaining an answer). While some young scientists enter the field with specific practical goals in mind, most are simply intrigued by the opportunity to study something "cool," to become good at what they do—and eventually to be recognized for their expertise and contributions. Obtaining knowledge for its own sake is an old and sacred pursuit, one that is respected (implicitly) in the philosophy of many granting agencies that have very practical agendas. Accordingly, since it is impossible to know how a given discovery or insight might be used (in a practical way) in the future, we should encourage and support even research that doesn't seem to offer any immediate application or have any obvious relevance to real issues and problems. Because of the uncertainty about what insights might become important in the future, because what seems irrelevant or unusable at one time might provide the basis for important future developments, basic research without a specific practical rationale should be encouraged and supported. This position is certainly not universally held, and it represents a somewhat fragile rationale for basic research in an environment in which resources are scarce.

Control

Inasmuch as research studies allow us to make more and more accurate predictions, they provide us with better and better control over our environment. With an understanding of how things work (i.e., "If…, then…") comes the opportunity to develop more effective interventions and means for exploiting these mechanisms. Exploratory research provides a starting point for such developments; for example, the description of the human genome has opened up important possibilities for treating—and even curing—many diseases. However, real control (e.g., effective treatments) depends on an understanding of basic mechanisms (e.g., those processes that connect genetic structure with behavioral phenotype)—which, in turn, comes as the result of hypothesis-testing research.

One can, to be sure, rely on serendipitous data to obtain control of one's world. For example, many effective medical treatments have been discovered without an understanding of the underlying mechanisms of the disease. Given this history, there is an ongoing debate about the relative efficacy of research strategies that depend on insights into basic mechanisms. This debate is an important one within the context of epilepsy research. Regardless of the strategy, however, the key rationale for basic research is that the chosen approach will improve our ability to predict outcomes—and to intervene to alter those outcomes.

Quality of Life

This capability of effective intervention leads, in theory, to a better quality of life—more effective energy generation, better methods for dealing with climate change, or development of improved drugs/treatments that make us healthier and help us live longer. While it may not always have been the case that research could affect the quality of life of the average person, public support for research is now based on this assumption. We, as scientists, should be aware of this assumption, which brings with it a social responsibility that perhaps did not exist in the past. Research scientists can no longer think of themselves as isolated agents. As scientists, our goals (as well as our approaches) are shaped by the interrelatedness and interdependence of research laboratories and by our ties and obligations to the supporting society. We do not really have a *choice* about whether our research should be geared to making improvements for our society. This goal is now an obligatory aspect of the research enterprise.

WHY DO BASIC *EPILEPSY* RESEARCH?

How does all of this general philosophical musing relate to our specific discipline, epilepsy research? In particular, what justifications can we give—to ourselves, each other, and the society that supports us—for pursuing this line of work? The usual rationale involves some reference to the identification of better treatments and cures. If that's the case, then we should be prepared to point to specific accomplishments in our history that show how basic research has led to a better quality of life for people with epilepsy. Indeed, in today's world, our answers to these questions need to be not only theoretically satisfying (and correct) but also practical. If one accepts our obligation, as scientists, to contribute to the society that supports us, then the "Because…" response must reflect a feasible activity and achievable goals.

Because It's Interesting

There's no getting around the fact that many young researchers are attracted to epilepsy research simply because the problems are intellectually fascinating, the phenomena are dramatic, and the potential experimental approaches allow/encourage the use of a broad array of technical weaponry. There are few neurological phenomena as dramatic as a seizure—whether you monitor it behaviorally, electrophysiologically, or molecularly. Further, there is a broad range of still unexplored but very important questions that beckon enticingly to the ambitious young scientist anxious to make his or her mark in a complex field. In recruiting young investigators, and in discussing the advances in our field with the public, we need to take advantage of the inherent

drama of epilepsy, of its complex nature, even of the beauty of so many different systems interacting to produce a clinically important disorder. In short, the traditional stigma associated with epilepsy can (and should) be turned on its head to reveal a scientifically compelling mystery.

Because It Sheds Light on General Brain Function

For better or worse, one could make the argument that basic epilepsy research has shed more light on normal brain function than on the underlying bases of seizures (and their treatments) (e.g., see [4, 5]). Because seizure-related phenomena appear to use normal brain mechanisms, but involve a dramatic exaggeration of these processes, it is sometimes easier to see what's going on in the epileptic brain. Nowhere is this relationship more obvious than in the general area of brain plasticity. Synaptic modification (e.g., as in kindling[6]), anatomical reorganization (e.g., sprouting[7]), and changes in gene expression associated with seizure activity[8] have shed light on normal plasticities associated with development, learning and memory, and aging. This interplay between normal and pathological was evident early in studies using strychnine neuronography to map out functional connections in the brain (e.g., see ref. 9) and the Jacksonian march of epileptic activity to determine the topography of brain motor areas (as explored by Jasper, among others; see ref. 10). Epilepsy patients subjected to split brain procedures have given investigators the opportunity to further explore brain localization of function (e.g., see ref. 11), and imaging techniques developed to localize seizure onset zones have been refined to explore higher brain processes (e.g., see ref. 12). Cellular mechanisms importantly associated with normal brain function—such as soma/dendritic calcium flux,[13] regulation of extracellular potassium by astrocytes,[14] and recurrent excitation[15]—were studied early (and in some cases first identified) in seizure models in which these processes were exaggerated. Research approaches can be honed and investigative tools optimized in studies of seizure phenomenology to gain the sensitivity needed for studying more subtle changes in normal brain function.

In many epilepsies, the brain functions normally most of the time. Since a variety of research protocols—including invasive procedures—can be justified to study the epilepsy in those brains (because they are epileptic), it may be possible to gain insight into normal brain function by examining the baseline state. A clear understanding of the normal neurological baseline is absolutely critical if we are to test theories of epileptogenesis (i.e., how the brain changes from its normal state to the epileptic state); hypotheses focusing on aberrations of normal brain development,[16] reversion of the mature brain to an immature state,[17] loss of homeostatic controls,[18] and uncontrolled plastic processes[19] all implicitly demand that we define normal brain function that is pathological in the epileptic state.

Not only do epilepsy studies shed light on normal brain function, they also often have considerable relevance for understanding other neurological disorders. For example, epilepsy research now includes studies of mechanisms that are key to neurodegenerative disorders (e.g., mechanisms of cell damage/death,[20] traumatic brain injury such as postinjury reorganization,[21] and gene-related change [loss or increase] in function[22]). The overlap is apparent not only at the laboratory level but also clinically, where it is now clear that epilepsy can/should be viewed as a syndrome that often includes important comorbidities beyond the seizure itself (e.g., see refs. 23, 24).

Because It Offers Real Opportunities for Research Career Development

In modern biomedical research, an investigator's choice of a research focus is molded not only by his or her interests, but also by opportunities for making a significant impact and for obtaining long-term funding for his or her research activities. One can, of course, argue about whether basic epilepsy research has been adequately funded (relative to other neurological disorders? relative to other conditions that affect such a large percentage of the population? relative to the impact of the epileptic condition on medical costs/spending?). In the United States, the National Institutes of Health and many private funding

agencies provide significant research support, not only for the well-established investigator with a track record of productivity, but also for young investigators (presumably with fresh ideas). And relevant support is available in somewhat unexpected places if one looks for it (e.g., the Department of Defense). Despite these funding opportunities, it often appears that the field has lost, or failed to attract and maintain, many high-quality researchers; these individuals have chosen to focus their work in other research areas, presumably because they see more opportunity to participate at the cutting edge of biomedical research or because they view disease-related research as second-class (compared to pure basic research). One of the major challenges to the epilepsy field is to lure outstanding young investigators into this area of research—and retain them for the long term. Success in this effort will be determined by how well we can promote epilepsy as an exciting field of opportunity.

What features of a basic research program are likely to attract top-quality investigators? A list of such features is likely to include the following: (1) interesting problems that have research-based solutions; (2) opportunities to learn and apply modern technologies; (3) activities that involve links/collaborations with outstanding researchers in related fields; (4) high-profile publication opportunities that will gain the respect of colleagues and thus enhance one's career; and (5) the potential for making contributions to a significant health/societal issue. In the epilepsy research field, we have generally relied upon the intrinsic interest of the problem and have done relatively little to present relevant research opportunities in a way that explicitly targets these goals. Indeed, until recently, we have been rather imprecise about the research challenges that energize our research efforts, and have not been effective in presenting them in a way that is understandable and intriguing to an investigator who is not already committed to this area of research. For example: How many would-be researchers have any idea of the prevalence, varieties, and neurological consequences of clinical seizure disorders? Do we simply want to suppress seizure activity—and if that is our goal, haven't we already solved the problem with available antiepileptic drugs? What are the long-term opportunities and challenges in the field, and how are they related to general neuroscience (or other neurological disorders) research?

Because It May Lead to Development of Better Treatments and Cures

However an epilepsy researcher might start out (whatever the feature that first attracts him or her to this field), sooner or later the researcher is likely to realize that his or her laboratory activities could have significant consequences for people with seizure disorders. The realization that one's work in the laboratory could (should?) provide the bases for new treatments (and even cures) is a potent motivator. Given that motivation, a particularly exciting feature of the current state of epilepsy research is the proximity of the laboratory to the clinic. While that potential has always existed in theory (the epilepsy field has always implicitly involved translational research), it has never been so real as it is today. Modern neuroscience offers the tools and the concepts that can link, in a direct and impactful manner, laboratory insights with clinical practice/treatment. Enhancing that relationship by encouraging interactions between basic and clinical researchers provides a strong answer to the question "Why do basic epilepsy research?"

HOW DO WE CHOOSE AND PRIORITIZE RESEARCH GOALS?

It's fine to make a theoretical commitment to epilepsy research—but what does that commitment really mean? What are the strategies for pursuing meaningful research goals in our field? There are many ways of approaching the challenge, many directions and means for generating meaningful data. Rather than (or in addition to) encouraging a search for the "silver bullet" treatment/cure, it is important to recognize the diversity inherent in the problem and the need for many different hypotheses and approaches. Researchers may find themselves considering the following issues as they determine how they will choose and pursue their experimental goals.

Identification of Important Problems

In a field as diverse and complex as epilepsy research, a search for "the" critical research questions can be a daunting task. Further, the focus of research tends to shift from decade to decade (indeed, from year to year)—a normal result of changes that occur as our research tools and conceptual understanding change and become more powerful. In the recent past, as a result of evolving techniques in molecular genetics and of our growing appreciation of the social impact of epileptic disorders, there has been an emphasis on such issues as genetic causes of the epilepsies, the involvement of molecular pathways recruited during seizure activity, and the cognitive alterations associated with seizures (or brain conditions that give rise to seizures). In recent publications devoted to an exploration of current and future research priorities, there has been a shift in our research focus to exploring the underlying bases of epileptogenesis (mechanisms and treatments), to examining brain development and catastrophic epilepsies (aberrant processes during brain development that lead to difficult-to-control epilepsies and to associated long-term cognitive deterioration), to studying comorbidities associated with seizure conditions, and to developing new therapeutic strategies (new targets for antiepileptic drugs and nondrug treatment/cure strategies).[25,26] The shift in focus is driven, at least in part, by new insights at the clinical level, as well as by an appreciation for what can be productively investigated in the laboratory. And the new strategies and targets are made possible by insights and achievements with respect to previous research targets.[27] Given the rich complexity of the field, there is no reason to think that there will not be new sets of research priorities when the next edition of *Jasper's Basic Mechanisms of the Epilepsies* is published.

Understanding Basic Mechanisms versus Empirical Testing

The issues that call for our research attention can be attacked in what appear to be two fundamentally different ways. On the one hand, investigators can seek the underlying bases of a seizure-related phenomenon. The rationale for this approach seems obvious: If we understand the underlying mechanism, we can design an appropriate intervention/treatment. On the other hand, investigators may choose to test various treatment strategies without knowledge of the underlying mechanisms. This approach has been historically quite productive; for example, the identification of most current antiepileptic drugs (AEDs) was carried out without an understanding of their potential mechanisms of action. There is a strong tendency in the current research environment to give priority to the first approach—even though there remains considerable disagreement about the feasibility of, for example, rationale drug therapy based on pharmacological mechanisms.[28,29] Part of the problem, of course, is that although we may understand the potential molecular targets of a given drug, we don't understand (in most cases) the underlying abnormality that gives rise to the epileptic condition. An additional difficulty is that most treatments (pharmacological and nonpharmacological) have multiple effects, and it is difficult to determine which action is the antiepileptic one. Does that matter? Should the fact that we don't understand, for example, the anticonvulsant basis of deep brain stimulation or vagus nerve stimulation lead to a discriminatory bias against (or delay in) using such treatments? Some may argue that most of our current antiepileptic treatments (whether pharmacological, surgical, or otherwise) have come out of empirical *clinical* experiences, not from laboratory research and insights into basic mechanisms. The value of elucidating underlying mechanisms is rarely contested. But there is a basic research tendency to dismiss empirical clinical studies as bad science. This point of view may have a discouraging effect on the development of novel treatments.

Detailed Analyses versus the Big Picture

A related dichotomy that tends to divide research strategies in different laboratories is whether to seek detailed mechanistic analysis of a narrow variable or invest one's resources in gathering data that will yield a descriptive picture of a broader nature. Obviously, these

two approaches are not mutually exclusive, and most research involves aspects of both. A given laboratory (or researcher) will tend to emphasize one over the other but will operate somewhere in the middle of this continuum. Interestingly, in most Ph.D. programs, we work hard to train young investigators to focus narrowly on a well-defined problem, to generate a fine-grained analysis of a narrow research target. This mechanistic approach has obvious strengths—offering would-be researchers an opportunity to make a significant mark in the field and thus establish a reputation. This approach suffers, however, from the danger of producing rather myopic researchers who don't really understand the broader context in which they work. It is also clear that what one laboratory sees as mechanistic may be simply descriptive to another. Finally, given that mechanistic analysis is dependent on accurate description as a first step, and given that most clinically relevant problems in the epilepsy field are complex and involve multiple variables, careful descriptive studies are critical. Critique of a research program as unacceptably descriptive or irrelevantly narrow ignores the important question of if/how such studies might contribute to an important research goal.

WHAT APPROACHES—CONCEPTUAL OR TECHNICAL—ARE LIKELY TO YIELD SIGNIFICANT RESULTS?

All research—in particular, all basic epilepsy research—is not created equal. One's goals will determine, in large measure, how one approaches the problem(s) of interest and the techniques/methods that will most effectively move the study forward. While this point seems obvious, it is not so easy to realize in practice. Indeed, it is often the case that an investigator's methodological expertise will largely determine the types of experiments that are carried out in his or her laboratory—and thus will limit the investigator's ability to address the real goals of the research. While a single investigator cannot be expected to have sufficiently broad expertise to allow his or her laboratory to choose the most appropriate methodological approaches to a problem of interest, we can expect—and should urge—that the methods and experimental design employed to address a research problem are consistent with the investigator's stated goals. In the epilepsy field, one might also argue that those goals should provide insights into the mechanisms, behaviors, and treatments of epilepsy *as a real clinical target*.

Conceptual Goals

As is the case in any field, the conceptual goal(s) of the basic epilepsy researcher should ideally be well focused, clearly articulated, and significant. As a journal editor and grant reviewer, I routinely ask why the author/applicant has chosen to carry out the experiments described in his or her manuscript or grant application. If the researchers can't answer that question, then I rapidly lose interest. Because epilepsy is a complex set of disorders, because it is common, and because it has many connections to normal brain function, it is sometimes difficult for an investigator to articulate a clear rationale for his or her work—not only for the reader (or reviewer) but also for him- or herself. Why is it important to be focused and clear in one's goals? There are a number of ways to answer that question. Clear research goals lead to (1) well-designed experimental protocols; (2) less confusion in choosing what variables to study and what experimental models to use; and (3) a baseline from which one can discuss the significance of the research. Confusion about what one can conclude from an experimental study is a common result of insufficient clarity with respect to one's experimental goals. Conceptual fuzziness in basic epilepsy research often involves such confusions as (1) identifying a cellular/molecular feature in the epileptic brain and concluding that—simply because it's there—it contributes to the epileptic (or epileptogenic) process; (2) assuming that some abnormality described in an animal model of epilepsy (or in an in vitro/reduced preparation) is a feature of a human clinical condition (or is responsible for the development or expression of the epilepsy); or (3) drawing conclusions about epilepsy (or the epileptic brain) based on findings associated with seizures in a normal brain. Establishing clear experimental goals and drawing appropriate, well-supported conclusions from experimental data, are not always

easy—especially since there may be significant considerations that limit what one can actually study. While such methodological limitations are a fact of experimental life, there is no such restriction on elaboration of one's conceptual goals.

Technical Approaches

As mentioned above, technology (and methodology) often limits what we *can* study, and the technical capabilities of a given laboratory often determine what that laboratory actually does study. Collaborative interactions enlarge a given investigator's experimental scope. But the investigator is constantly challenged to be sure that the methods and techniques offer an appropriate approach to the problem of interest. Laboratory techniques seem to go in and out of fashion, and there has been a tendency for research directions to change as a function of the availability of new technologies. The investigator must therefore make decisions about if/how to change the direction of his or her research, based not only on whether a given technique has the appropriate power to address the experimental question but also on whether it is currently fashionable. Grant and manuscript reviewers are unquestionably biased in favor of studies that employ state-of-the-art technologies and may question the value of research based on old- fashioned approaches. For example, advances in molecular/genetic techniques have given us a new capability for assessing phenomenology and mechanisms at these levels—but molecular/genetic studies do not always provide better answers to all questions. Identifying a gene associated with a certain type of epilepsy does not tell us how that epilepsy occurs or how it should be treated; gene discovery is, in fact, only the start of an investigation to answer those questions. Similarly, gene array studies that show changes in gene expression in the epileptic brain provide only a starting point. These studies do tell us that the epileptic brain is different from the normal brain—but we know that. The real issue is to determine the differences that are critical to (causal of) the epileptic (or epileptogenic) condition. That is not to say that we should not take advantage of new technologies. There is no question that modern technologies have provided the researcher with previously unheard-of opportunities for addressing questions that might provide significant insights into important issues. These technologies should certainly be incorporated into our arsenal of research tools. But in doing so, investigators need to remain aware that these techniques do not make it any easier to ask, or answer, the right questions.

Model Development

Among the many challenges and opportunities faced by the basic epilepsy researcher is the often bewildering proliferation of models. The investigator almost invariably will need to determine which model(s) best addresses his or her experimental goals, which includes asking such questions as: What is this a model of? What questions can be effectively addressed? What laboratory techniques are compatible with studying this model? What variables and endpoints can be measured? Depending on their research goals, some experimenters may not need to work with an animal/tissue model at all (i.e., the investigation can focus on epilepsy in the human patient[30] or can employ computer modeling approaches[31]). One must ask also: What should be modeled? To find out what? How? Why? These questions have been addressed in some detail in the recent volume *Models of Seizures and Epilepsy*,[32,33] so the following discussion will summarize only key points that are directly relevant to the general question "Why do basic epilepsy research?"

BECAUSE IT'S INTERESTING AND FUNDABLE (PROVIDES OPPORTUNITIES FOR CAREER DEVELOPMENT)

As indicated above, there are many features of the epileptic brain that are attractive because of their general relevance to normal brain function and/or to other neurological disorders, and/or because of the ease with which they can be approached with modern techniques. The choice of appropriate models for this type of research can be overwhelming. Investigators routinely use in vitro preparations of single neurons (or neuron-like cells) and glia to study the function of channels, receptors, intracellular messenger systems, protein trafficking,

and so on, all with the rationale that alterations in the function of these variables can give rise—in some way, at some point in a complex process—to the abnormal electrical activity that defines seizures. Some critics have disputed whether such reduced preparations are accurately labeled *epileptic* (or whether individual neurons can produce epileptiform activities or seizures). It is nevertheless certainly worthwhile to study the underlying bases of aberrant cellular development and activity on their own merits. And arguably, this type of information will provide insights into epileptic phenomenology that could not be obtained from more complex systems. Simplified preparations also often allow for the application of powerful genetic, molecular, and electrophysiological methods that are difficult to employ in complex models. A striking example of successful pursuit of an epilepsy-relevant problem, using molecular genetic insights applied at the cellular level, is the recent identification of the mTOR pathway in tuberous sclerosis.[34] Analysis of many epilepsy-relevant mechanisms is facilitated by reduced preparation models, but relevant insight may require a more complex system of synaptically interacting neurons (or neurons and glia), as provided in acute slice and organotypic culture preparations (e.g., modulation of tonic inhibition[35]). Because of the methodological sophistication often associated with studies on reduced preparations, these models are often seen as particularly attractive when applying for research support. Many investigators have developed successful and productive epilepsy research careers based on a focus on simplified preparations, and there is a temptation to assume that these models are somehow superior to more complex models (because they are amenable to sophisticated manipulations, one can control and study a small number of variables, etc.). We need constant reminders about the limitations involved in interpreting data from such experiments with respect to our goal of explaining epilepsy phenomena or elucidating epilepsy mechanisms. For example, to study the interactions between neurons and endogenous inflammatory molecules requires a system that includes immune system elements.[36] Similarly, recent interest in the role of the blood-brain barrier[37] or of hormonal modulation of epileptogenicity[38] requires models in which those elements are present and normally functional.

Seizures are inherently interesting as a dramatic neurological output, and many laboratory manipulations can induce seizure-like phenomena. It is not always clear, however, that all of these experimentally induced seizure-like activities have anything to do with epilepsy. In past years, much of the basic research focus in epilepsy laboratories has been on models in which seizure-like electrical activities (or molecular changes) were induced in an otherwise normal brain. While we now know that seizure discharge in the normal brain may be different from output from an epileptic brain, the ease of inducing such activities and the strong attraction to the seizure output per se have encouraged studies in normal tissue. There is no doubt that many of these investigations have provided important insights into potential epileptic (and epileptogenic) mechanisms. But investigators who choose to focus on these types of models (i.e., in which seizure phenomenology is induced in normal brain tissue) should be aware, at the outset, that these studies may be of primarily intrinsic interest, since the results may not be relevant to clinical epilepsy phenomena.

BECAUSE IT SHEDS LIGHT ON HOW THE BRAIN WORKS

Many investigators have, over the years, argued that epilepsy provides a unique opportunity to understand normal brain function. For example, the key role of calcium—so much the key to research on synaptic plasticity and excitotoxicity—was an early focus of epilepsy researchers studying neurons that produce epileptiform burst discharge.[39,40] Comorbidities associated with epilepsy have begun to receive more attention, and investigators can now look to a large list of epilepsy models to study, for example, cognitive deficits, psychiatric abnormalities, and aberrations in brain development (e.g., see ref. 41). Investigations in animal models of seizure-related anxiety, depression, and other mood/psychiatric disorders[38,42,43] parallel the clinical focus on these comorbidities.[23,44] Historically, lesions that have been associated with temporal lobe epilepsy have also led to a greater understanding of memory mechanisms,[45] of the cognitive decline associated with neurodegenerative disorders such as Alzheimer's disease,[46] and of neurogenesis.[47] It is important to realize, in approaching studies

of brain function through the use of epilepsy models, that it is critical to place such studies into a relevant theoretical framework in order to make any sense of experimental results. The observation of seizures in an animal model of Alzheimer's disease doesn't necessarily tell you anything about epilepsy *or* about Alzheimer's disease. But if approached within a framework that links seizure mechanisms and Alzheimer's disease–related neurodegeneration and/or circuitry reorganization, this observation may provide the basis for interesting and insightful investigation.

BECAUSE IT CAN LEAD TO BETTER TREATMENTS AND CURES FOR A COMMON (AND DISABLING) NEUROLOGICAL DISORDER

Historically, it has been very difficult to model human epilepsy in animals, and investigators have developed a variety of strategies for making findings from animal models relevant to the human disorder. Most commonly, the approach has been to choose some feature of epilepsy (or, more accurately, one of the many different types of epilepsy) to study in detail. For example, many basic research investigations have employed models of temporal lobe epilepsy, examining such features as mossy fiber sprouting,[7] changes in inhibition in various hippocampal brain regions,[48,49] recurrent excitation,[50] and so on. This approach provides a host of research possibilities, offering many different methodological approaches. One can look at genetic, molecular, electrophysiological, pathological, and behavioral variables. One can study seizure events, interictal activities, postictal behaviors, or even phenomena that are not apparently linked to a seizure but that occur in the brain of an epileptic individual. The investigator can create the relevant phenomenon experimentally (e.g., by injecting a drug) or look at phenomena that occur spontaneously in a model system (e.g., a genetically epileptic mouse).

There is a long ongoing argument about how completely a model of epilepsy should recapture the key features of the human clinical disorder in order to be considered a relevant model. This argument has had no winner. Ideally, a relevant animal model should exhibit spontaneous seizure discharges that resemble—behaviorally, clinically, and electrically—the seizure type(s) of interest. Such a rigorous criterion may be unrealistic, however, when one considers how different the human brain is from a rodent brain (in which most such models are developed), the differences in developmental maturation and aging, and the difficulties in assessing seizure expression in nonhuman subjects. Particularly if the epilepsy type is complex, holding out for such a relevant model may impede research rather than encourage it (see ref. 51 for an interesting discussion of modeling infantile spasms). Alternatively, many investigators have turned to rodent models in which the key defining feature is a gene mutation that parallels a clinically occurring genetic mutation in humans. In these models, one can certainly make the case for the genetic cause of the epilepsy—but not necessarily for the relevance of subsequent gene expression. A number of drug treatments (and other experimental interventions) also give rise, over the long term, to spontaneous seizures, often associated with the pathological features that resemble those seen in human epilepsy (e.g., hippocampal sclerosis, as seen in temporal lobe epilepsy[52,53]).

The decision to use one of these models should certainly be based on the question the investigator wants to answer. For example, a genetic model may provide important insight into the molecular pathways that determine brain epileptogenicity (e.g., in models of cortical dysplasia). But is such a model relevant if one is to use it to study/understand the cognitive dysfunction seen in the epileptic brain? Is the time frame of seizure onset important (e.g., how well does the rodent recapitulate the human maturational sequence with respect to the mechanism under study)? If one uses such models to examine, for example, seizure-related changes in gene expression, can one successfully dissociate expression changes associated with seizure activity from expression patterns that characterize epileptogenicity (i.e., the seizure-sensitive state) or epileptogenesis (i.e., the development of the seizure-sensitive state) or an underlying brain lesion? One might choose a genetic model based on its clinically relevant neuropathological characteristics, as opposed to a model that mimics seizures discharge/electrical excitability. The long-term functional consequences of the associated structural abnormality, with respect to epileptogenicity or cognitive comorbidity, may

be explored in such a model even if the animal is not spontaneously epileptic. Under what conditions would such a model be relevant? Whatever approach one takes, it is important that the choices be made on the basis of a coherent theoretical framework.

Modern epilepsy research has yielded a new set of variables that appear to be characteristic of the epileptic brain, ranging from high levels of neurogenesis to robust expression of immune system variables to subtle changes in baseline tonic inhibition.[36,54,55] That these changes are seen in epileptic tissue seems clear. The salience of these phenomena for epileptogenesis and/or seizure activity remains to be established. Further, as is often the case in research, the more we learn, the less clear are our assumptions about epilepsy mechanisms. For example, it is becoming increasingly clear that many (most?) epileptic conditions are not easily attributable to a single genetic/molecular/electrophysiological abnormality, but are reflections of multiple changes—each one often subtle—that together give rise to aberrant brain activities. Thus, the models we choose must eventually provide us with the possibility of exploring the interaction among contributing variables. Two-hit hypotheses have become fashionable when thinking about developmental insults that give rise to seizure activities,[56,57] and they provide examples of how models may be manipulated to explore multifactorial contributions to the epileptic state.

Much of the research focusing on basic mechanisms of the epilepsies has revolved around identifying new treatment options—whether involving new drugs or focusing on novel therapeutic strategies. Both strategies can be pursued in a plethora of models. A major concern in these studies is whether treatment efficacy must be assessed against spontaneously occurring seizure activity in an epileptic animal, or whether some other measure of excitability (or synchrony) would provide an equally useful assessment. The verdict is still out, and investigators are looking for appropriate epilepsy-related phenomena—biomarkers—against which they can measure the effects of their treatments (e.g., a stable frequency of spontaneous seizures[58]; fast ripples[59]). In drug studies, it is also important to understand the relative concentration effects (absorption, blood-brain barrier penetrations, uptake into parenchyma, etc.) in humans (and particularly epileptic humans) compared to the chosen animal model and at different developmental ages. Since many animal models involve a normal brain in which seizures are generated, the question of if/how such neural tissue compares to epileptic tissue with respect to pharmacokinetic and pharmacodynamic issues must be addressed.

CONCLUDING THOUGHTS

There are multiple factors that go into the decision to carry out basic research, as well as additional influences that will determine whether an investigator decides to devote a lifetime to the study of epilepsy-related issues. The motivation for these decisions, and the subsequent choices that must be made about what problems to tackle and what techniques to employ, often play out in the absence of conscious attention. Just as it is important to give careful consideration to the choice of laboratory techniques or animal models, it is also helpful to be aware of the factors influencing one's research directions. As indicated above, there are no correct choices to be made. What is important is that the choices be consistent, coherent, and defensible.

Chapter 4

Voltage-Gated Na^+ Channels

Structure, Function, and Pathophysiology

Massimo Mantegazza
William A. Catterall

Voltage-gated Na^+ channels initiate action potentials in neurons and other excitable cells, and they are responsible for propagation of action potentials along nerves, muscle fibers, and the neuronal somatodendritic compartment.[1] They are complexes of a large pore-forming α subunit and smaller auxiliary β subunits.[2,3] Multiple genes encode Na^+ channel subunits, and the distinct Na^+ channel subtypes have subtle differences in functional properties, differential expression in excitable cells, and differential distribution in subcellular compartments.[2,4] These differences in function and localization contribute to the specialized functional roles of Na^+ channels in neuronal physiology and pharmacology.

Na^+ CHANNEL SUBUNIT STRUCTURE

Na^+ channel proteins in mammalian brain are complexes of a 260 kD α subunit in association with one or two auxiliary β subunits (β1–β4) 33 to 36 kD in size.[2,3]. The primary sequence predicts that the Na^+ channel α-subunit folds into four internally repeated domains (I–IV), each of which contains six α-helical transmembrane segments (S1–S6) (Fig. 4–1). In each domain, the S1 through S4 segments serve as the voltage-sensing module, and the S5 and S6 segments and the reentrant P loop that folds into the transmembrane region of the channel between them serve as the pore-forming module. A large extracellular loop connects the S5 or S6 transmembrane segments to the P loop in each domain, whereas the other extracellular loops are small. Large intracellular loops link the four homologous domains, and the large N-terminal and C-terminal domains also contribute substantially to the mass of the internal face of Na^+ channels. This view of Na^+ channel architecture, derived originally from hydrophobicity analysis and structural modeling,[5] has been largely confirmed by

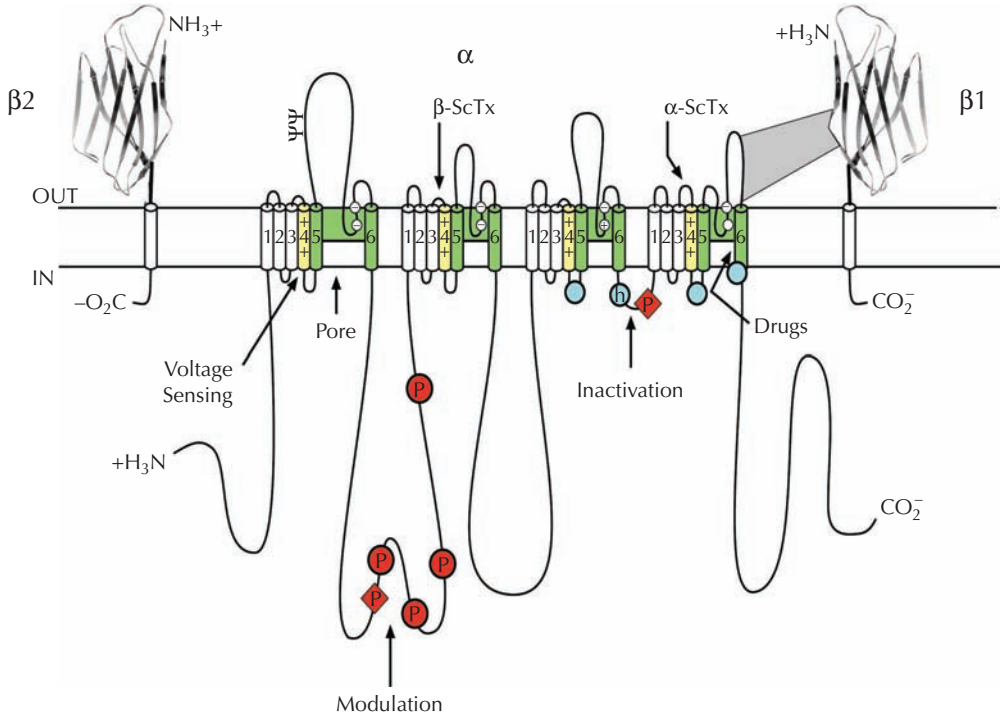

Figure 4–1. Transmembrane organization of Na^+ channel subunits. The primary structures of the subunits of the voltage-gated ion channels are illustrated as transmembrane folding diagrams. Cylinders represent probable alpha-helical segments. Bold lines represent the polypeptide chains of each subunit, with the length approximately proportional to the number of amino acid residues in the brain Na^+ channel subtypes. The extracellular domains of the β1- and β2-subunits are shown as immunoglobulin-like folds. Ψ, sites of probable N-linked glycosylation; P, sites of demonstrated protein phosphorylation by protein kinase A (PKA, circles) and protein kinase C (PKC, diamonds); shaded, pore-lining S5-P-S6 segments; white circles, the outer (EEDD) and inner (DEKA) rings of amino residues that form the ion selectivity filter and the tetrodotoxin binding site; ++, S4 voltage sensors; h in the shaded circle, inactivation particle in the inactivation gate loop; open shaded circles, sites implicated in forming the inactivation gate receptor. Sites of binding of α- and β-scorpion toxins and a site of interaction between α- and β1-subunits are also shown.

biochemical, electrophysiological, and structural experiments.[3]

Na^+ CHANNEL GENES

Na^+ channels are the founding members of the ion channel superfamily that includes voltage-gated Ca^{2+} channels, TRP channels, voltage-gated, inward rectifying, and two-pore-domain K^+ channels, and cyclic nucleotide-regulated CNG and HCN channels.[6] In evolution, the four-domain Na^+ channel was last among the voltage-gated ion channels to appear, and it is only found in multicellular organisms. It is thought that Na^+ channels evolved by two rounds of gene duplication from ancestral single-domain bacterial Na^+ channels like NaChBac found in *Bacillus halodurans,* which may also be the ancestral single-domain channel from which Ca^{2+} channels arose.[6,7] Voltage-gated Na^+ channel genes are present in a variety of metazoan species including fly, leech, squid, and jellyfish. The biophysical properties, pharmacology, gene organization, and even intron-splice sites of these invertebrate Na^+ channels are largely similar to those of the mammalian Na^+ channels, adding further support for the idea that the primordial Na^+ channel was established before the evolution of vertebrates.[8]

The human, mouse, and rat Na^+ channel genes and proteins are the best characterized to date. Ten related Na^+ channel genes are found in mammals (Fig. 4–2), which map to four paralogous chromosome segments.[8] More than 20 exons comprise each of the nine Na^+ channel α-subunit genes. Genes encoding Na^+

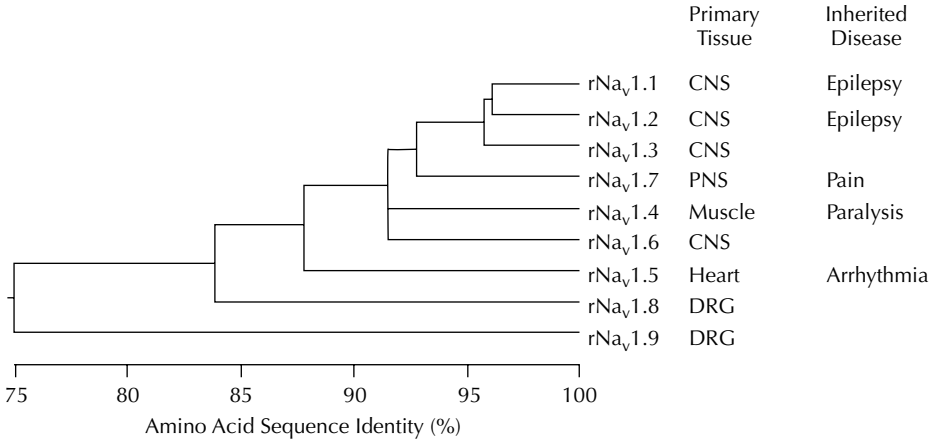

Figure 4–2. Amino acid sequence similarity of voltage-gated Na^+ channel α-subunits. Phylogenetic relationships of rat Na^+ channel sequences Nav1.1–Nav1.9. To perform the analysis, the amino acid sequences for all of the isoforms were aligned using Clustal W. Divergent portions of the terminal regions and the cytoplasmic loops between domains I–II and II–III were excluded. Primary tissue of expression and diseases caused by mutations are indicated.

channels $Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.7$ are localized on chromosome 2 in the human and mouse, and these channels share similarities in sequence, biophysical characteristics, block by nanomolar concentrations of the potent pore-blocking toxin tetrodotoxin (TTX), and broad expression in neurons. A second cluster of genes encoding $Na_v1.5$, $Na_v1.8$, and $Na_v1.9$ channels is localized to human chromosome 3p21–24 (and to the orthologous region of chromosome 3 in the mouse). Although they are more than 75% identical in sequence to the group of channels whose genes are located on chromosome 2, these Na^+ channels all contain amino acid substitutions that confer varying degrees of resistance to TTX. In $Na_v1.5$, the principal cardiac isoform, a single amino acid change from phenylalanine to cysteine in the pore region of domain I is responsible for a 200-fold reduction in TTX sensitivity compared to those channels whose genes are located on chromosome 2.[9] At the identical position in $Na_v1.8$ and $Na_v1.9$, the amino acid residue is serine, and this change results in even greater resistance to TTX.[10] These two channels are preferentially expressed in peripheral sensory neurons.[11] In comparison to the Na^+ channels on chromosomes 2 and 3, $Na_v1.4$, which is expressed in skeletal muscle, and $Na_v1.6$, which is highly abundant in the central nervous system (CNS), have greater than 85% sequence identity and similar functional properties, including TTX sensitivity in the nanomolar concentration range.[4] In spite of these similarities, phylogenetic analysis by parsimony comparisons suggests a more distant evolutionary relationship, consistent with their distinct chromosomal localizations (Fig. 4–2). $Na_v1.4$ and $Na_v1.6$ are located on human chromosome 11 (mouse chromosome 17) and human chromosome 15 (mouse chromosome 12), respectively.[4]

A 10th Na^+ channel, Na_x, whose gene is located near the Na^+ channels of chromosome 2, is evolutionarily more distant. Key differences in functionally important regions of voltage sensor and inactivation gate and lack of functional expression of voltage-gated Na^+ currents in heterologous cells suggest that Na_x may not function as a voltage-dependent Na^+ channel. Consistent with this conclusion, targeted deletion of the Na_x gene in mice causes functional deficits in sensing plasma salt levels.[12]

The Na_vβ-subunits are encoded by four distinct genes in mammals.[13–15] The gene encoding β1 maps to 19q13, whereas β2 and β4 are located on 11q22–23 and β3 is located nearby at 11q24. The β1 and β3 subunits associate noncovalently with the α subunits, whereas β2 and β4 are covalently linked by a disulfide bond. All four β subunits have a single transmembrane segment, a large N-terminal extracellular domain, and a small intracellular C-terminal domain (Fig. 4–1). The Na_vβ subunits are dual-function proteins. Coexpression

of $Na_V\beta$ subunits alters the kinetics and voltage dependence of activation and inactivation of Na^+ channel complexes.[15] Moreover, their extracellular domain forms an immunoglobulin-like fold, similar to many cell adhesion molecules, and the β subunits are involved in interactions of Na^+ channels with proteins in the extracellular matrix, with other cell adhesion molecules, and with intracellular regulatory proteins like protein kinases and phosphoprotein phosphatases.[13,15,16] The importance of the functions of the $Na_V\beta$ subunits is underscored by the dramatic effects of deletion of the genes encoding $Na_V\beta1$ and $Na_V\beta2$, which include failure of myelination and axonal conduction, epileptic seizures, and premature death.[17,18]

MOLECULAR BASIS OF Na^+ CHANNEL FUNCTION

Classical work by Hodgkin and Huxley defined the three key features of Na^+ channels: (1) voltage-dependent activation, (2) rapid inactivation, and (3) selective ion conductance.[19] Building on this foundation, extensive structure-function studies employing molecular, biochemical, structural, and electrophysiological techniques have provided a clear understanding of the molecular basis of Na^+ channel function.[2] The narrow outer pore is formed by the reentrant P loops between transmembrane segments S5 and S6 of each domain (Fig. 4–1). Four amino acid residues in analogous positions in the P loops in each domain (aspartate in domain I, glutamate in domain II, lysine in domain III, and alanine in domain IV, DEKA) are crucial for Na^+ selectivity. Mutation of these four residues to glutamates confers Ca^{2+} selectivity, indicating that the side chains of these amino acid residues are likely to interact with Na^+ ions as they are conducted through the ion selectivity filter of the pore.

Similar to other voltage-gated ion channels, the voltage dependence of activation of Na^+ channels derives from outward movement of gating charges driven by changes in the transmembrane electrical potential. The S4 segments of each homologous domain serve as the primary voltage sensors for activation.[2] They contain repeated motifs of a positively charged amino acid residue followed by two hydrophobic residues in S4 segments creating a transmembrane spiral of positive charges. Upon depolarization, outward movement and rotation of S4 is thought to initiate a conformational change that opens the Na^+ channel pore.[5,20,21] This *sliding helix* or *helical screw* model is supported by strong evidence.[22] For example, neutralization of the positively charged residues in S4 reduces the voltage dependence of gating. The outward and rotational gating movement of S4 segment has been detected directly by reaction of substituted cysteine residues in S4 segments with extracellular sulfhydryl reagents following channel activation. A structural model of the voltage-sensing and pore-forming modules of Na^+ channels in the resting and activated states is presented in Fig. 4–3.

Fast inactivation of the Na^+ channel is a critical process that occurs within milliseconds of channel opening. The generally accepted model of this process involves a conserved inactivation gate formed by the intracellular loop connecting domains III and IV, which serves as a hinged lid that binds to the intracellular end of the pore and blocks it[2] (Fig. 4–1). Intracellular perfusion of proteases[23] or intracellular application of antibodies directed to this loop[24] prevents fast inactivation. The latch of this fast inactivation gate is formed by three key hydrophobic residues (isoleucine, phenylalanine, methionine, IFM), and an adjacent threonine (T).[25,26] Mutations of these amino acid residues destabilize the inactivated state, and peptides harboring the IFM motif can restore inactivation to Na^+ channels having mutated inactivation gates.[27,28] The closed inactivation gate is thought to make multiple interactions with hydrophobic amino acid residues near the intracellular mouth of the pore that may constitute the inactivation gate receptor. Scanning mutagenesis experiments implicate hydrophobic residues in intracellular S4-S5 loops of domains III and IV, as well as the intracellular end of the S6 transmembrane segment in domain IV in forming the inactivation gate receptor.[29–31]

The other intracellular domains of Na^+ channels are also functionally important. The C-terminal cytoplasmic domain is important for setting the properties of fast inactivation and contains several binding sites for interacting proteins,[32,33] and the cytoplasmic loop between DII and DIII binds to ankyrin G, which is important for clustering Na^+ channels in axon initial segments through interactions with the cytoskeleton.[34]

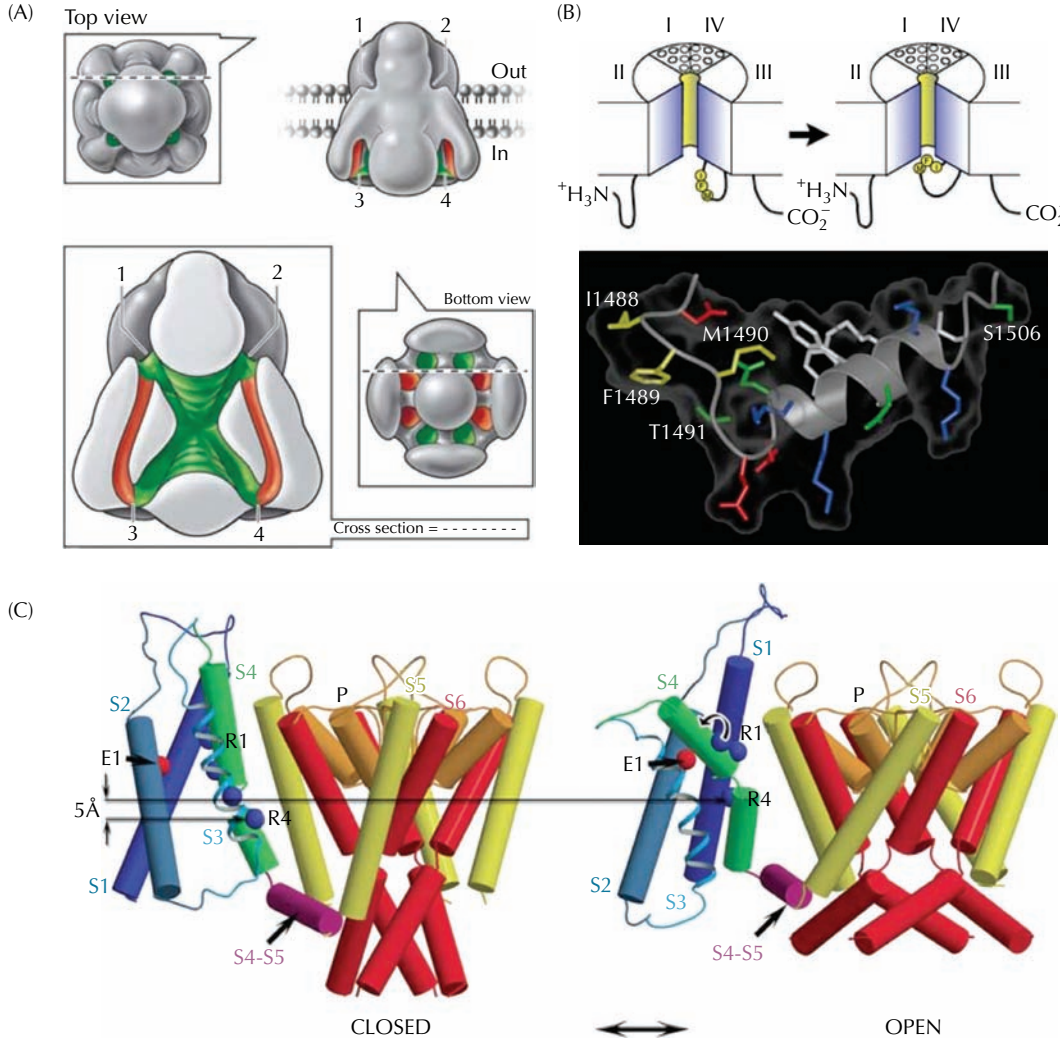

Figure 4–3. Three-dimensional structure of Na^+ channels and a related potassium channel. **A.** The three-dimensional structure of the Na_V channel α-subunit at 20 Å resolution, compiled from electron micrograph reconstructions. Adapted from ref. 43. **B.** Three-dimensional structure of the central segment of the inactivation gate as determined by multidimensional NMR. Isoleucine 1488, phenylalanine 1489, and methionine 1490 (IFM) are illustrated in yellow . Threonine 1491, which is important for inactivation, and serine 1506, which is a site of phosphorylation and modulation by protein kinase C, are also indicated in the lower panel. **C.** $K_V1.2$ models of the closed and open states shown in cylinder representation. Only a single voltage-sensing module is shown attached to the tetramer of the pore-forming module for clarity. Transmembrane segments S1 through S6 and the P loop are colored by a rainbow scheme from blue to red. The S4-S5 linker is colored purple. Approximate positions of the alpha carbon atoms of the first and fourth gating-charge-carrying arginines in the S4 (labeled R1 and R4 and colored blue) and E226 in the S2 (labeled E1 and colored red) are shown in sphere representation. All intracellular and extracellular loops, except for the S4-S5 linker, are represented by curved lines for simplicity. Vertical translation of the R4 between the closed and open states along the membrane normal vector and relative to the plane of the membrane is indicated by arrows. The S3 is represented by a ribbon to show clearly the positions of the gating-charge-carrying arginines in the S4 segment.

Na^+ channel functions are dramatically modulated by phosphorylation.[35,36] The large intracellular linker between domains I and II contains at least five well-characterized phosphorylation sites for protein kinases A and C, which induce a reduction in Na^+ currents by enhancement of the slow inactivation process.[37,38] Moreover, a recent mass spectrometry study has suggested that the number of active phosphorylation sites in brain in vivo may be much larger than was

previously thought and may be isoform-specific.[39] Serine residues in the intracellular linker between domains II and III are phosphorylated by casein kinase-2, which can modulate the interaction between ankyrin G and Na^+ channel α subunits and therefore the clustering of the channel at the axon initial segment.[40] Na^+ channels are also regulated by protein tyrosine kinases, which reduce the current through multisite phosphorylation and modification of fast inactivation.[41,42]

THREE-DIMENSIONAL STRUCTURE OF Na^+ CHANNELS

The three-dimensional structure of the Na^+ channel is not yet completely known, but some limited structural information has emerged. Structural determination at 19 Å resolution by cryoelectron microscopy and image reconstruction techniques show that Na^+ channels have a bell shape (side view), a fourfold symmetry of transmembrane masses, and large intracellular and extracellular masses through which several inlets and outlets allow aqueous access[43] (Fig. 4–3A). Unexpectedly, this image of Na^+ channels reveals a central pore that does not directly connect the intracellular and extracellular spaces, instead splitting into four branches near the membrane surface. Moreover, it suggests the presence of four peripherally located transmembrane pores, which may function as gating pores for voltage-sensor movement, as described below.

The only high-resolution structure of Na^+ channels is the solution structure of the inactivation gate in the intracellular loop connecting domains III and IV, as determined by nuclear magnetic resonance (NMR) analysis of this intracellular loop expressed in bacteria[44] (Fig. 4–3B). This structural analysis reveals a rigid alpha helical structure, preceded by two turns that position the key hydrophobic sequence motif IFMT such that it can interact with and block the inner mouth of the pore.

The global fold of the Na^+ channel pore region is predicted to be similar to that of voltage-gated potassium channels[21,45,46] (Fig. 4–3C). The structure of the open state of this channel has been determined by x-ray crystallography, and the structure of the closed state has been determined by structural modeling using the Rosetta method. This structural view shows the S5 and S6 regions of the Na^+ channel arrayed in fourfold symmetry around the aqueous ion-conduction pathway, the pore being lined mostly by S6 and the reentrant loop that form the ion-selectivity filter. A single voltage-sensor module is illustrated for simplicity. In the resting (closed) state of the channel, the S4 segment is in an inward position. Activation of the voltage sensor causes outward and rotational movement of the S4 segment and complementary movement of the S1, S2, and S3 segments around it. These two coupled molecular movements translocate the gating charges in the S4 segment from exposure to the intracellular milieu to exposure to the extracellular milieu, as required for voltage-dependent gating.

Comparison of the primary structures of the auxiliary β subunits to those of other proteins reveals a close structural relationship to the family of proteins that contain immunoglobulin-like folds, which include many cell adhesion molecules.[47, 48] The extracellular domains of these type I single-membrane-spanning proteins are predicted to fold in a manner similar to that of myelin protein P0, whose immunoglobin-like fold is known to be formed by a sandwich of two beta sheets held together by hydrophobic interactions. Myelin P0 is a cell adhesion molecule involved in tight wrapping of myelin sheets, and many related cell adhesion molecules with extracellular Ig folds and a single membrane-spanning segment are involved in cell-cell interactions among neurons and glia. As expected from their structure, $Na_V\beta$ subunits interact with extracellular matrix molecules, other cell adhesion molecules, and intracellular cytoskeletal proteins and signaling proteins.[13] These interactions are thought to be important for localization and stabilization of Na^+ channels in specific subcellular compartments such as axon initial segments and nodes of Ranvier, where they are present in high density.

EXPRESSION, LOCALIZATION, AND FUNCTION OF Na^+ CHANNEL SUBTYPES IN THE NERVOUS SYSTEM

Na^+ channel subtypes are differentially expressed in tissues and differentially localized in subcellular domains of individual cells. $Na_V1.3$ is

highly expressed in rodent fetal nervous tissues, whereas $Na_v1.1$, $Na_v1.2$, and $Na_v1.6$ are abundant in juvenile and adult CNS.[49–51] Subcellular distribution and properties of Na^+ channels are essential for neuronal functions.[34,51,52] Excitatory and inhibitory synaptic inputs are integrated at the axon initial segment (AIS), where Na^+ channels are clustered at particularly high density and generate the depolarizing phase of action potentials. Excitability propagates along the axon through the activity of Na^+ channels, which in myelinated fibers are clustered at nodes of Ranvier, and reaches synaptic terminals where Na^+ channels regulate excitability and thus the activation of Ca^{2+} channels and the initiation of neurotransmitter release. Na^+ channels are also present in the somatodendritic compartment, where they boost synaptic inputs and generate action potentials that backpropagate from the AIS into the dendrites. These action potentials can be considered retrograde signals of the integrated neuronal output that are sent to the dendritic tree in order to modulate synaptic plasticity.

The AIS is a proximal part of the axon about 40 µm in length in which the high density of Na^+ channels (about 20–50 times greater than in the soma or proximal dendrites[34,53]) produces a high Na^+ current density and a particularly low action potential threshold. These properties make the AIS the primary site of initiation of action potentials in neurons. Most of the studies on AIS have focused on excitatory cells, in which the action potential initiation site is located in the distal region of the AIS. Interestingly, the AIS contains specialized subdomains; the distal part is enriched in $Na_V1.6$, whereas the proximal part is enriched in Nav1.2.[34] This subdivision is functionally important. In fact, patch-clamp recordings from axon cut ends have revealed a higher density of Na^+ current and a progressive reduction in the half-activation voltage in the AIS with increasing distance from the soma. A recent study has shown that $Na_V1.6$ channels in the distal AIS promote action potential initiation, whereas $Na_v1.2$ channels in the proximal AIS promote its backpropagation to the soma.[54]

Myelinated axons are characterized by regularly spaced gaps of about 1 µm in the myelin sheath, the nodes of Ranvier, in which Na^+ channels are clustered at high density and allow saltatory conduction. During development, $Na_v1.6$ replaces $Na_v1.2$ in maturing nodes of Ranvier in myelinated axons.[55,56] Similar to neurons with myelinated axons, the AIS is also the site of action potential initiation in unmyelinated glutamatergic neurons, which contain $Na_v1.2$ and, to a lesser extent, Nav1.6 channels.[57] However, in these neurons, the AIS lacks the structural and morphological characteristics of myelinated axons, and action potentials are usually initiated in the proximal part.

Recent studies have shown that $Na_v1.1$ is particularly important for the excitability of GABAergic neurons[58,59] (see Chapter 58), and these channels are clustered at the AIS of some types of interneurons, including parvalbumin-positive, fast-spiking interneurons. However, several studies have shown that $Na_V1.1$ (or $Na_V1.3$ in immature neurons) is also present in the somatodendritic compartment of several types of neurons, including glutamatergic pyramidal cells in cortical systems, where it may control neuronal excitability through integration of synaptic impulses and regulation of the threshold for action potential propagation to the dendritic and axonal compartments.[51,57,58,60,61] At axon terminals, the Na^+ channel subtype that is most often found concentrated near presynaptic terminals in cortical areas is $Na_V1.2$. Some discrepancies in the results of immunocytochemical studies of Na^+ channel subcellular localization in the AIS may be explained by the high density of proteins that makes it difficult for antibodies to reach epitopes, which can be better exposed with antigen retrieval techniques.[62]

Na^+ channels in central neurons do not only generate the classical fast-inactivating Na^+ current. In fact, fast inactivation of Na^+ current in neurons is generally incomplete, resulting in a small, persistent Na^+ current (I_{NaP}) with kinetics of inactivation on the order of tens of seconds.[63] I_{NaP} can be generated by all of the neuronal Na^+ channel isoforms and can be modulated by several neurotransmitter systems.[61,64–66] Although I_{NaP} is usually only about 1% of the transient Na^+ current, it is important for several neuronal functions because it is the main depolarizing current in the subthreshold voltage range. It contributes to amplifying postsynaptic potentials, shaping repetitive firing, generating rhythmicity, and maintaining prolonged depolarized plateau potentials.[63,67,68] Thus, even small modifications of I_{NaP} amplitude can substantially modify neuronal properties.

Another subthreshold current generated by Na^+ channels is the resurgent current,[64]

an unusual transient Na^+ current elicited by repolarizations that follow strong depolarizations and that can contribute to spontaneous and to high-frequency firing. It has been proposed that this current is produced by a putative intracellular blocking factor (possibly the intracellular domain of the β4 accessory subunit) that binds to open Na^+ channels and prevents fast inactivation; the blocking factor would unbind during repolarizations generating a transient current that decays because channels deactivate.[69] The resurgent current is substantially reduced in neurons isolated from $Na_V1.6$ or $Na_V1.1$ knockout mice,[61,64] indicating that both of these Na^+ channel types can contribute to its generation. Slowing of Na^+ channel inactivation with application of toxins can induce resurgent currents in neurons from $Na_V1.6$ knockout mice, providing further evidence that other Na^+ channel subtypes can generate resurgent currents.[69] In fact, a recent study has shown that pathogenic mutations of $Na_V1.4$, $Na_V1.5$, and $Na_V1.7$ that cause slowing and destabilization of inactivation can induce increased resurgent Na^+ current at least in some cell types.[70] Thus, increased resurgent current may be a common feature of several pathogenic mutations of Na^+ channels.

Na^+ channels can also have important roles in glia. In microglia they can regulate phagocytic activity,[71] whereas in oligodendrocytes and astrocytes their functional roles are not clear yet, but may involve the regulation of cytoplasmic Na^+ homeostasis.[72] Glial cells usually are not excitable, but action potential-like events have been observed in glial precursor cells and in cultured astrocytes. In addition, a subset of glial cells can generate action potentials when depolarized, receive excitatory and inhibitory synaptic inputs from neurons, and are especially sensitive to excitotoxicity.[73]

$Na_v1.1$, $Na_v1.2$, and $Na_v1.6$ are also expressed at low levels in the peripheral nervous system. However, the three isoforms that have been cloned from sympathetic and dorsal root ganglion neurons, $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$, are much more abundant.[74] The $Na_v1.7$ channel is localized in axons, where it functions in initiating and conducting the action potential. More restricted expression patterns are observed for $Na_v1.8$ and $Na_v1.9$; these channels are highly expressed in small sensory neurons of dorsal root ganglia and trigeminal ganglia, where they have a key role in nociception.[75–77] $Na_v1.4$ and $Na_v1.5$ are the primary muscle Na^+ channels that control the excitability of the skeletal and cardiac myocytes, respectively.[11] $Na_v1.5$ is transiently expressed in developing skeletal muscle but is replaced by $Na_v1.4$ in the adult.

Na^+ CHANNEL PHARMACOLOGY

Na^+ channels are the molecular targets for drugs used in the treatment of epilepsy, cardiac arrhythmias, bipolar disorder, and migraine and in the prevention of acute pain; Na^+ channel-blocking drugs are also in development for the treatment of chronic pain.[78,79] Local anesthetics bind to a specific receptor within the pore of Na^+ channels, formed by the S6 segments in domains I, II, and IV[80,81] (Fig. 4–4). Their binding blocks ion movement through the pore and stabilizes the inactivated state of Na^+ channels.[82] Antiarrhythmic drugs and antiepileptic drugs share similar overlapping receptor sites.[78,81] Complete blockage of Na^+ channels would be lethal. However, these drugs selectively block Na^+ channels in depolarized and/or rapidly firing cells, such as axons carrying high-intensity pain information and rapidly firing nerve and muscle cells that drive epileptic seizures or cardiac arrhythmias.[82,83] This selective block arises because the drugs can reach their binding site in the pore of the Na^+ channel more rapidly when the pore is repetitively opened, and they bind with high affinity to inactivated Na^+ channels that are generated in rapidly firing or depolarized cells. This use-dependent action of the Na^+ channel blocking drugs is essential for their therapeutic efficacy. Notably, I_{NaP} is also reduced by antiepileptics and other Na^+ channel blockers, often at concentrations that are lower than those required for reducing the transient component.[79] Na^+ channel blockers used in epilepsy therapy include phenytoin, carbamazepine, lamotrigine, valproate, topiramate, and lacosamide; phenytoin, carbamazepine, lamotrigine, and lacosamide are thought to act selectively on Na^+ channels, whereas the other drugs have multiple targets.[79] Na^+ channels are also the molecular targets for several classes of neurotoxins that bind at six or more distinct receptor sites on the channel, blocking it or modifying its gating properties.[84,85]

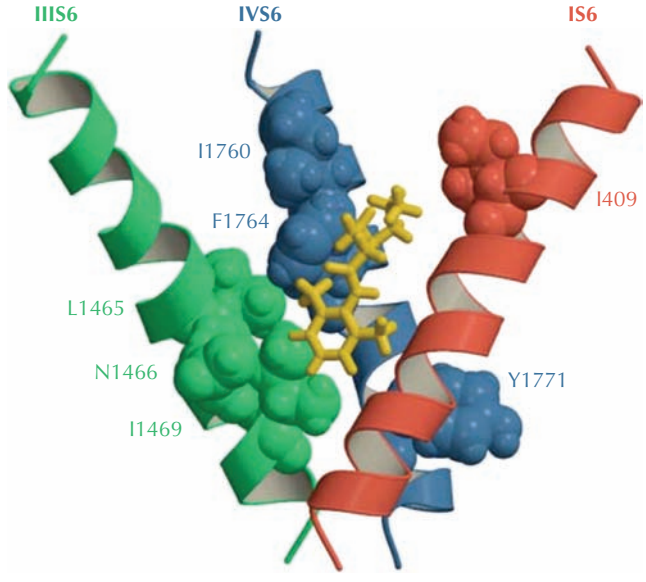

Figure 4–4. Model of etidocaine binding to the local anesthetic receptor site formed by transmembrane segments IS6, IIIS6, and IVS6 of the $Na_v1.2$ channel. A three-dimensional model of the proposed orientation of amino acid residues within the Na^+ channel pore with respect to the local anesthetic etidocaine is presented. Only transmembrane segments IS6 (red), IIIS6 (green), and IVS6 (blue) are shown. Residues important for etidocaine binding are shown in a space-filling representation.

Na^+ CHANNEL AND EPILEPSY

Growing experimental evidence points to a role for abnormal expression and/or function of Na^+ channels in the pathophysiology of epilepsy. Numerous studies have shown altered levels of mRNA and protein for α-subunits $Na_V1.1$, $Na_V1.2$, $Na_V1.3$, and $Na_V1.6$ and for β subunits in animal models of epilepsy[86–89] and in human epileptic brain tissue.[90, 91] An upregulation of Na^+ channels has also been reported in astrocytes from human epileptic tissue, suggesting that pathological glial excitability may contribute to epileptic disorders.[92]

Induction of epileptiform activity can also be correlated with changes in Na^+ channel function. For instance, temporal lobe neurons exhibit larger than normal I_{NaP} in both the pilocarpine[93] and kindling[89] animal models of epilepsy and in the human temporal lobe surgically resected from patients.[94] An increase of I_{NaP} may predispose these neurons to hyperexcitability, as demonstrated in transgenic mice expressing an incompletely inactivating $Na_v1.2$ mutant, which show chronic seizures and hippocampal sclerosis.[95] These data show that Na^+ channels can be implicated in acquired epilepsy, either in the process of epileptogenesis and/or in the maintenance of the epileptic state. Their implication in epileptogenesis has been indisputably demonstrated by the identification of several hundred mutations in Na^+ channel genes leading to genetic epileptic syndromes.

GENETIC Na^+ CHANNELOPATHIES

Mutations that alter Na^+ channel function lead to human diseases of hyperexcitabilty (Table 4–1). Multiple mutations of $Na_v1.4$ that yield hyperactive skeletal Na^+ channels have been shown to cause hyperkalemic periodic paralysis and paramyotonia congenita.[96] In contrast, mutations in S4 gating charges that cause reduced function of these channels and induce a Na^+ or proton leak through their voltage-sensing domains (termed the *gating pore current*) cause hypokalemic periodic paralysis.[97,98] Mutations of $Na_v1.5$ that impair inactivation or alter activation lead to inherited long QT syndrome type 3 and Brugada syndrome, in which

Table 4–1 **Major Inherited Diseases of Na^+ Channels**

Disease	Gene	Channel
Generalized epilepsy with febrile seizures plus	*SCN1A*	$Na_V1.1$
	SCN1B	$Na_V\beta1$
Dravet syndrome (severe myoclonic epilepsy in infancy)	*SCN1A*	$Na_V1.1$
	SCN1B	$Na_V\beta1$
Familial hemiplegic migraine type III	*SCN1A*	$Na_V1.1$
Benign familial neonatal-infantile seizures	*SCN2A*	$Na_V1.2$
Hypokalemic periodic paralysis type II	*SCN4A*	$Na_V1.4$
K^+-sensitive normokalemic periodic paralysis	*SCN4A*	$Na_V1.4$
Hyperkalemic periodic paralysis	*SCN4A*	$Na_V1.4$
Paramyotonia congenita	*SCN4A*	$Na_V1.4$
Long QT syndrome type III	*SCN5A*	$Na_V1.5$
Brugada syndrome	*SCN5A*	$Na_V1.5$
Erythermalgia	*SCN9A*	$Na_V1.7$
Paroxysmal extreme pain disorder	*SCN9A*	$Na_V1.7$
Congenital indifference to pain	*SCN9A*	$Na_V1.7$

the risk of fatal cardiac arrhythmias is greatly increased.[99] Gain-of-function mutations in the gene that encodes $Na_V1.7$ channels cause erythermalgia and paroxysmal extreme disorder, and loss-of-function mutations cause congenital indifference to pain.[76]

Like these channelopathies in cardiac and skeletal muscle and in peripheral nerve, mutations in Na^+ channels expressed in the brain cause multiple forms of epilepsy, as well as familial hemiplegic migraine (FHM), a rare severe autosomal dominant inherited subtype of migraine with aura characterized by hemiparesis during the attacks.[79,100,101] Even though the functional effect of some of these mutations is still debated and often depends on the experimental system used for the study,[101] it has been indisputably demonstrated that they have a causative pathogenic role. The vast majority of epileptogenic mutations are in $Na_v1.1$, which is thus far the most clinically relevant epilepsy gene (for databases of $Na_v1.1$ mutations see http://www.molgen.ua.ac.be/SCN1AMutations/ and http://www.scn1a.info/). In fact, generalized (genetic) epilepsy with febrile seizures plus (GEFS+) type II and severe myoclonic epilepsy of infancy (SMEI or Dravet syndrome) result from mutations of $Na_v1.1$ channels, as well as from one mutation of the $\beta1$-subunit[100,102] (and see Chapter 58). Severe myoclonic epilepsy of infancy is caused by inactivation of one allele of the gene encoding $Na_V1.1$ channels, and the hyperexcitability and comorbidities of that disease result from disinhibition caused by selective loss of Na^+ current and action potential firing in GABAergic inhibitory neurons[100] (and see Chapter 58). Generalized epilepsy with febrile seizures plus []may be caused by milder loss-of-function mutations and, at least in some families, by folding defects that can be rescued with pharmacological chaperones and interacting proteins[100,103,104] (and see Chapter 58). Notably, FHM mutations could cause a gain of function.[105]. Benign familial neonatal-infantile seizures (BFNIS) are caused by mutations in $Na_V1.2$ channels.[106,107] The relationship between the functional alterations in $Na_V1.2$ channels, the hyperexcitability, and epilepsy is not completely clear, but several mutations induce a gain of function.[107] These inherited epilepsy syndromes are discussed in detail in Chapter 58.

FUTURE DEVELOPMENTS AND CHALLENGES

We expect that in the future, Na^+ channels will be found to be involved in a larger spectrum of epileptic phenotypes and in other diseases of the CNS. Besides epilepsy, mutations of $Na_v1.1$ can cause FHM, as noted above. Moreover, $Na_V1.1$ missense mutations have recently been identified in two unrelated families presenting with elicited repetitive daily blindness (ERDB), a visual phenotype that cosegregates with FHM but is independent of FHM attacks,[108] suggesting that $Na_V1.1$ mutations may alter retinal functions. Mutations

of $Na_v1.1$ channels have also been found in families presenting with both seizures and psychiatric phenotypes, and possibly predisposing genetic variants of Na^+ channels have been found in autistic patients.[109] Interestingly, SMEI patients carrying $Na_v1.1$ mutations can show cognitive impairment even if they present with infrequent seizures.[110] Therefore, modification of Na^+ channel functions might cause psychiatric disorders or confer susceptibility, consistent with the increased use of Na^+ channel-blocking drugs in the treatment of psychiatric diseases.[111] Interestingly, a loss-of-function mutation of $Na_v1.6$ has been identified in a single patient with cerebellar atrophy, behavioral deficits, and ataxia, further extending the spectrum of pathogenic Na^+ channel genes and diseases.[109] Moreover, Na^+ channels may be involved in the generation of altered neuronal excitability in Alzheimer's disease, in which Na^+ channel β subunits can be cleaved by the same enzymes that process amyloid precursor protein, generating active peptides that can modulate Na^+ channel expression and functions, leading to pathological excitability.[112] Furthermore, Na^+ channels have a pathogenic role in the inflammation and neurodegeneration that occur in multiple sclerosis and other demyelinating diseases, as well as in hypoxia-induced neuronal damage.[79] Future challenges in the field will be to identify the properties that differentiate Na^+ channels from other voltage-gated channels at the molecular level, to reveal the interacting partners that localize different isoforms in defined subcellular domains and modulate their functions, and to shed light on the functions that different Na^+ channel isoforms have in the physiology of different neurons and different subcellular regions. Na^+ channel blockers, which have been used for decades as antiepileptic drugs, poorly discriminate between Na^+ channel isoforms and have similar mechanisms of action. The development of new compounds that selectively target different isoforms and/or differently modify Na^+ channel functions will probably allow the treatment of some diseases that are thus far drug-resistant, including epilepsy.

Chapter 5

Potassium Channels (Including KCNQ) and Epilepsy

Edward C. Cooper

The brain runs on electricity. Because K^+ channels contribute to nearly all aspects of cellular electrical signaling, they were already prime suspects when the search for molecular causes of epilepsy began a quarter of a century ago. Slow initially, efforts to identify K^+ channel genes grew into a flood of clones. At the latest count, the human genome includes about 100 K^+ channel subunits;[1,2] most are expressed in brain. Some of the cloned brain K^+ channels have been the subjects of intense multidisciplinary studies combining structural biology, genetics, electrophysiology, biochemistry, and imaging techniques. Those efforts have yielded many long-sought answers. For example, mechanisms of ion permeation, selectivity, voltage gating, and modulation by posttranslational modifications, drugs, and neurotransmitter receptors have been elucidated with spectacular detail.[3,4] We have learned how specific signals and interactions cause individual channel types to be distributed in unique patterns within neural circuits and how that localization underlies distinctive contributions to excitability.[5,6] Currently, the pace of progress in knowledge and technical power shows no signs of diminishing; instead, it seems to be increasing exponentially.

However, the scope and expectations of epilepsy research have changed during this same time. Demonstrable improvement in seizure control has been replaced as a measure of success by the goals of "no seizures, no side effects," prevention of epilepsy per se, and amelioration of cognitive, motor, and emotional disabilities that limit opportunities for many patients with recurrent seizures.[7] Fundamentally new approaches have emerged, for example through exploitation of stem cells, miniaturized prosthetic electronic stimulators, or diet, which aim to complement or supplant improved molecular pharmacology as a strategy

in epilepsy therapy. Our understanding of epilepsy has also deepened dramatically through clinical and genetic scholarship. The diversity of "the epilepsies" is now much more broadly appreciated. So, assessment of research in channels (including K^+ channels) is now viewed in a context that is at once more rigorous, competitive, and demanding than a decade ago.

This chapter aims to provide a perspective on the achievements and future potential of studies of potassium channels in epilepsy research. The thesis is that the understanding obtained from recent studies justifies continued investment in K^+ channels by academic and industry-based researchers. We first reintroduce the K^+ channels, highlighting progress that appears particularly relevant to epilepsy. Then, as an example, we provide a detailed account of one K^+ channel subfamily, the KCNQ/Kv7 family. Members of this family are mutated in benign familial neonatal seizures, an autosomal dominant syndrome. Moreover, these channels have been found to be practical targets for antiepileptic drug development, perhaps providing a model for studies of other K^+ channel subgroups. We conclude with a discussion of directions for future work.

K^+ CHANNELS: A DIVERSE SUPERFAMILY DERIVED FROM AN EXTRAORDINARILY USEFUL TEMPLATE

Considered together, the recent cloning of the entire genomes from many species of eukaryotes, and of many additional K^+ channels from prokaryotes, now provides a previously unseen view of how the great diversity apparent in the human K^+ channel set emerged. Remarkably, all human K^+ channel pore-forming subunits are derived by gene duplication from a single, likely prokaryotic, ancestor gene. What is gene duplication?[8,9] It is now understood that, in addition to the more familiar deletion, insertion, missense, and nonsense mutations that can occur DNA, duplications of entire genes can occur through errors during replication. The frequency of such gene duplications is low but occurs continuously, at a rate on the order of once per 100 million years for every gene.[9] Given the billion-year history of animals and this exponential process, why aren't the genomes and gene families of living animals larger than they are? Because, in most instances, gene duplications are deleterious or of no advantage. In such unfavorable duplications, random mutations gradually inactivate one of the duplicate genes. Many so-called pseudogenes are the relics of such unselected gene duplicates. Eventually, the pseudogenic region accumulates enough mutations to become undetectable—lost in the genomic background. However, in cases where two duplicated genes can evolve distinct functions—for example, through mutations that cause different patterns of expression or divergence in functions—both may survive. The K^+ channels are an example (kinases and G-protein coupled receptors are others) in which an ancient gene provided an exceptionally useful template for variation. In fact, for several generations, K^+ channel offspring themselves produced successfully divergent duplicates, resulting in exponential growth in the size of the family. Through this process, the current superfamily of human K^+ channel pore subunit genes was derived. Along the way, other mutations took place as well, resulting in channels that lost their permeability to K^+ and/or gained permeability to other ions. Thus, the voltage-gated calcium and sodium, transient receptor potential, and hyperpolarization-activated cyclic adenosine monophosphate (cAMP)–gated nonselective (HCN) channels, and ionotropic glutamate receptors all arose from ancient K^+ channels through gene duplication and divergence.

I think this genomics-based, top-down view is exceptionally important as we attempt to discern how alterations in excitability result in epilepsy. This view highlights how individual channel subtypes expressed in human brain are survivors of a lengthy, rigorous, evolutionary winnowing. A channel gene's survival per se requires both that it has unique function(s) and that it functions in the context of other surviving channels. Although we have made progress in recent years in understanding individual channel functions through in vitro and in vivo mutagenesis studies, including the study of *channelopathies* in both human and model animals,[10,11] we have barely begun to explore how groups of channels, ancient companions in the genomes of animals, have evolved in parallel to jointly carry out novel functions through the combination of their activities.

K^+ Channel Variant 1: Two-Transmembrane (2TM)

The most basic (and ancestral) functional and genetic component of a K^+ channel is the pore itself. The ion-conducting pores of all K^+ channels are built similarly, namely, by four polypeptide domains arranged symmetrically around a central water-filled transmembrane channel. Each of the four pore-forming domains consists of intracellular N and C termini, two transmembrane segments, and an extracellular loop that dips partially back into the pore to line its narrowest part, forming the K^+-selective filter (Fig. 5–1A; see also Fig. 5–2D). All K^+ channels are variants or elaborations of this common template.

Humans possess 15 genes for K^+ channel subunits that adhere to this simplest two- transmembrane (2TM) topology. In spite of this relative simplicity, these channels are important and quite diverse in their functions, patterns of expression, and modes of regulation. Some of these channels exhibit *inward rectification*, a property that means that they are closed by membrane depolarization. Strongly inward-rectifying channels close completely when the membrane is depolarized near the action potential threshold but open at the resting or hyperpolarized potentials. This allows them to function like a magnetic catch on a cabinet door, that is, they hold the membrane hyperpolarized when it is at or near rest, but when Na^+ and Ca^{2+} channels cause a sufficiently strong depolarization, they become inactive.

One group of channels, with weak inward rectification, are regulated by metabotropic G-protein coupled receptors, such as the $GABA_B$, and (subsets of the) dopamine and acetylcholine receptors. In the absence of ligand, these receptors bind G-protein trimers intracellularly. When ligand activates the receptor, the linked βγ G-protein subunits are released, translocate to the nearby GIRK (g-protein coupled, inwardly rectifying K^+) channel, and bind, causing the channel to open. K^+ channels in glia, including inward rectifiers, allow transient elevations in extracellular K^+ resulting from high levels of neuronal firing to be rapidly buffered. Human and rodent data implicate mutations in KCNJ10, a 2TM channel subunit expressed most prominently in glia, in epilepsy and seizure susceptibility, highlighting that channels may cause seizures through multiple mechanisms, even non-neuronal ones.[12]

Structural Variant 2: Two-Pore (4TM)

Humans possess 15 genes for K^+ channels of the two-pore, or 4TM type. These channels are derived from an ancestor in which a 2TM channel gene underwent a tandem duplication (Fig. 5–1B). Channels are formed by two polypeptides, each containing a pair of pore domains. These channels function prominently in setting the resting membrane potential and often underlie the majority of the resting membrane K^+ conductance. Mutations in these genes have not yet been found in human epilepsy syndromes, and limited pharmacological tools are available. Nonetheless, the effects of inhaled general anesthetics depend in part on these channels, and some members of this group are regulated by metabotropic neurotransmitters, highlighting their roles in plasticity and their potential as drug targets.

Structural Variant 3: Voltage-Gated (6TM)

The largest subgroup of the K^+ channels are formed by subunits in which the gating of the 2TM pore is controlled by a linked voltage sensor domain (Fig. 5–1C; see also Fig. 5–2). Genetically, the voltage sensor is inserted upstream of the pore-encoding region, so the resulting subunit polypeptide includes the 4TM segments of the voltage sensor on the N-terminal side. Critically, a short, very highly conserved length of peptide links the voltage sensor to the pore on the intracellular side of the membrane, allowing movement of the voltage sensor to pull open the pore upon depolarization and push it closed at rest (Fig. 5–2).

Voltage-sensor domains arose very early in evolution and are present in some prokaryotic Na^+ and K^+ channels. It is not known whether the voltage sensor evolved by incremental mutation of a preexisting channel or as a separate protein that then was fused upstream of a channel gene in a random recombination event. Support for the second alternative came from the discovery of a 4TM voltage sensor protein that functions as a proton channel, without an

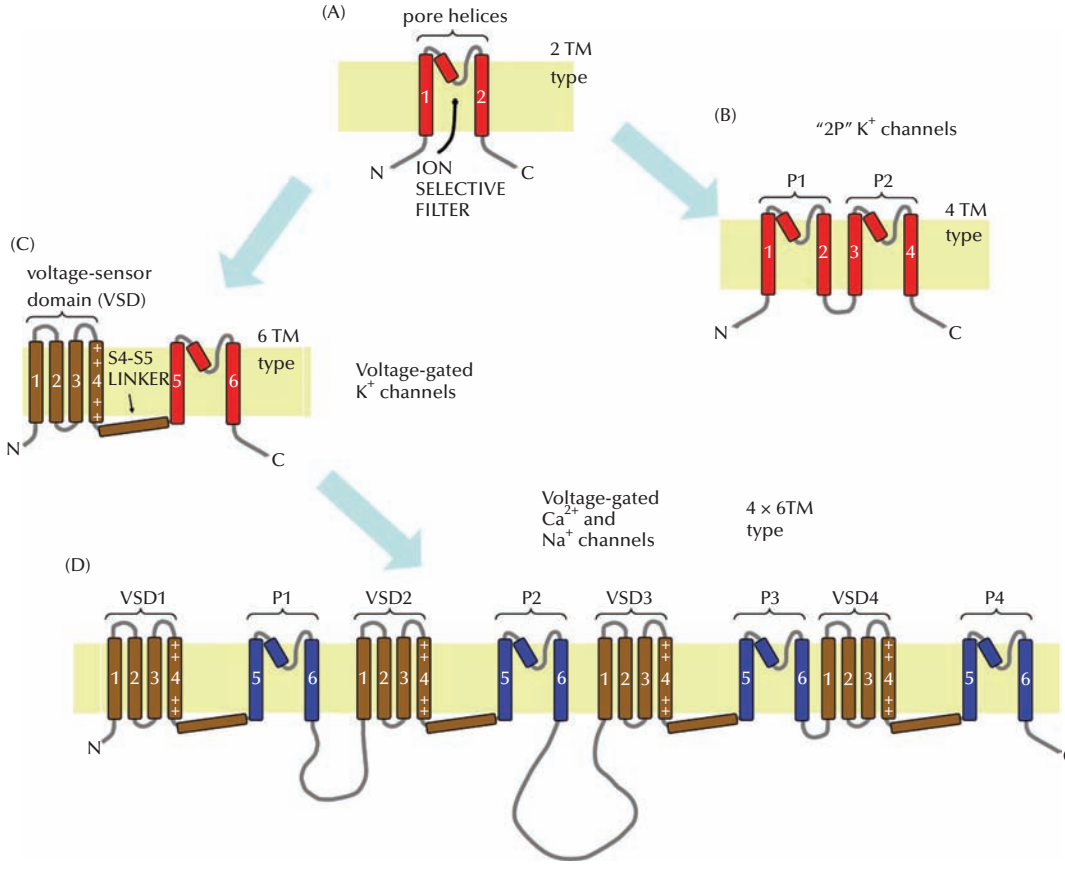

Figure 5–1. Structural features and evolutionary relationships among major groups of K^+, Na^+, and Ca^{2+} channels. **A.** Structure of the simplest ancestral K^+ channel, consisting of 2TM (transmembrane segments), a pore loop, and intracellular N and C terminals. This structure is found in a large group of human 2TM channels, including inward rectifier and G-protein coupled families. **B.** Structure of the 4TM group, produced by tandem duplication and fusion of two 2TM channels. This structure is preserved in mammalian leak channels. **C.** Structure of the 6TM K^+ channels, produced by fusion of a 4TM voltage-sensor domain and a 2TM channel. The fourth transmembrane segment (S4) bears positively charged arginine residues and moves in response to changes in the membrane potential. Movement of S4 is communicated to the pore, resulting in voltage-sensitive opening and closing of the transmembrane ion path. **D.** The structure of human voltage-gated Na^+ and Ca^{2+} channels, produced by two duplications of a 6TM channel. In addition, the ion selectivity of the pore has been altered through mutations.

(*continued from page 59*)

in green (labeled "r"). K^+ molecules, and the direction of net ion flow is indicated in red. **C.** Ribbon diagram showing the crystal structure of a part of one subunit, as seen from within the pore. For clarity, S1 through S3 are not shown. Ions passing through the channel are shown in red. The S4-S5 linker is covalently associated with S5, and side chains (indicated by colored arrowheads) of the linker and S6 interact noncovalently. This allows outward movement of S4 in response to membrane depolarization to pull S6 outward and upward, opening the channel gate (drawing generated using Swiss PDB Viewer, using coordinates of Kv1.2[62]). The position corresponding to the tryptophan residue, critical for activation of KCNQ channels by retigabine, is shown (green side chain on S5). **D.** Side view of the assembled pore domain. In the open state (left), S6 helices (blue) appear bent and the S4-S5 linker tips toward the extracellular side of the membrane. In the closed state (right), S6 helices are straight and the linker tips downward toward the cytoplasm. A stick model of the retigabine molecule is shown (within the black box), approximately to scale. As in C, the positions of the tryptophan residues required for retigabine's effects on KCNQ channels are indicated (green). An added gray (dashed line) box delimits a region on the outside surface of the pore domain adjoining the retigabine-critical residue. Modified from ref. 63.

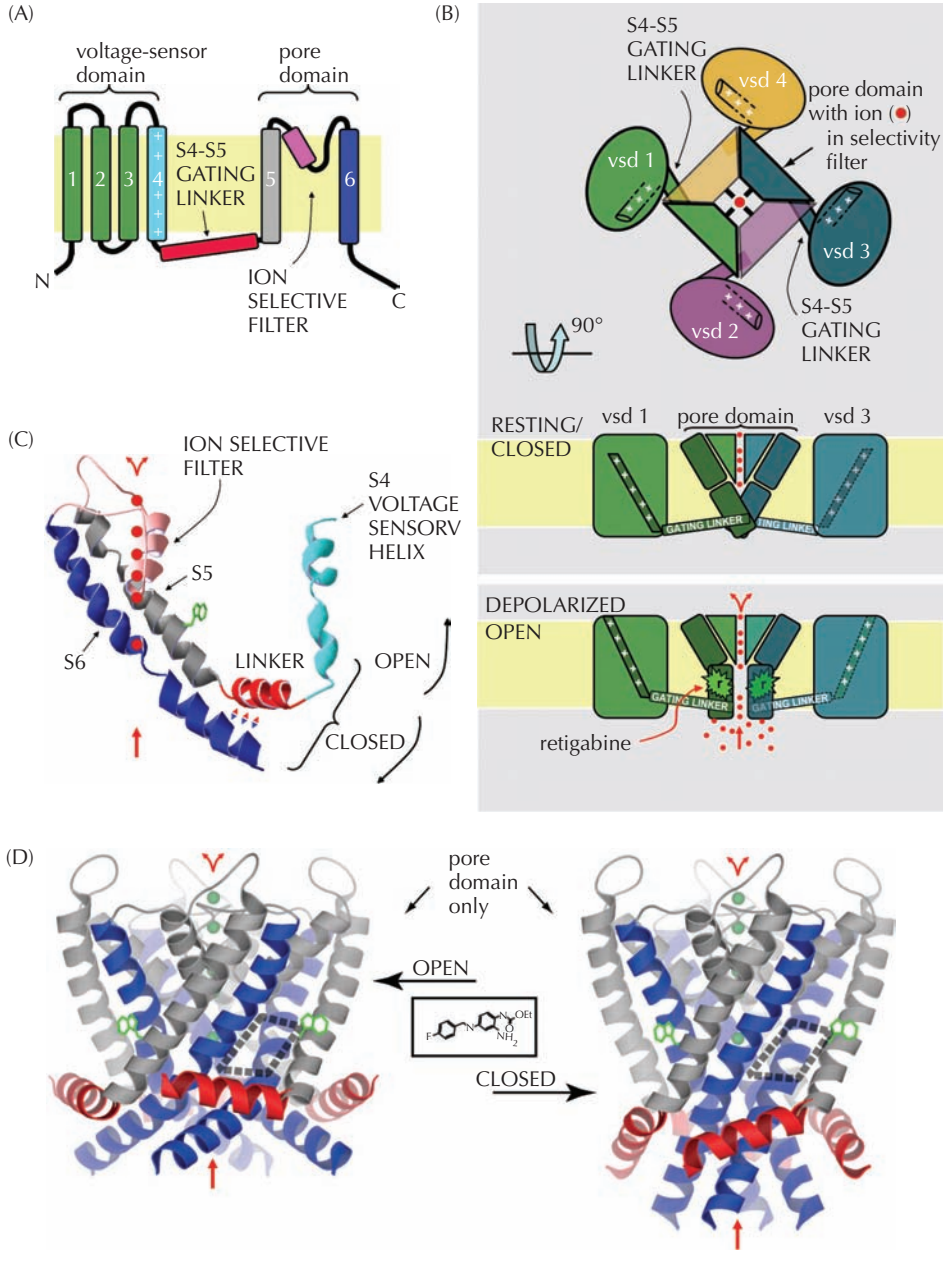

Figure 5–2. Mapping the site of retigabine binding on the structure of a voltage-gated K^+ channel. A. Cartoon showing the membrane folding pattern (topology) and functional domains of a voltage-gated K^+ channel subunit. The first four transmembrane segments constitute the voltage- sensor domain, with the S4 segment carrying a series of positively charged arginine residues (+ signs). The S5 and S6 segments, along with the loop that connects them, form a part of the pore. The two domains are connected by an intracellular helical linker, the S4-S5 linker. Amino and carboxy terminal regions are intracellular. For S4-S6, the color scheme matches that of panel C. **B.** Cartoons showing four voltage-gated K^+ channel subunits assembled into a functional tetrameric channel as viewed from outside the cell (upper) and cutaway sections through the center of the channel showing movements associated with open and closed states (lower). The subunits are color coded, so that the distance between each subunit's pore-forming and voltage-sensor helices, and the critical role of the S4-S5 gating linker, are clear. The positions of the positive-charged S4 helix within each voltage-sensor domain (vsd) are indicated. In the lower cartoon, channel opening results when the S4 helices move outward, pulling the linker up and causing the inner portions of the pore to pull apart. The proposed location of retigabine interaction with KCNQ2–5 subunits is indicated

(*continues on page 58*)

associated K^+ channel-like pore.[13] Regardless of its mechanism of origin, the 6TM voltage-gated template has exhibited extraordinary evolutionary success.[1,2] Humans possess 34 6TM voltage-gated K^+ channel subunit genes. In addition, genes for the pores of Ca^{2+} gated K^+ channels (8 in humans), HCN channels (4), cyclic-nucleotide gated channels (6), transient receptor potential channels (TRPs, 29), voltage-gated Na^+ channels (10), and voltage-gated Ca^{2+} channels (10) are all derived from this template.

The diversity in the voltage-gated K^+ channels includes differences in several separate categories of features. Among these are the midpoint voltage and steepness of voltage-dependent opening and closing; the rates at which transitions from resting to open and open to inactivated states occur; the ability to interact with particular scaffolding proteins that control subcellular localization; the ability to be modulated by receptors, phosphorylation, and intracellular messengers; and the ability to bind accessory subunits.

Structural Variant 4: Non-Pore-Forming Accessory Subunits

In addition to the pore-forming subunits, some K^+ channels include accessory subunits. The accessory subunits are a genetically and structurally diverse collection, all unrelated to the pore subunits and incapable of conducting K^+ ions independently. What these peptides have in common is that they have evolved the ability to bind specifically to particular subtypes of K^+ channel pores. Association is thought to be cotranslational, and the accessory subunits have functions that include modulation of voltage gating and subcellular targeting.

KCNQ CHANNELS: FROM CHANNELOPATHY TO NOVEL THERAPY

The fundamental goal of epilepsy research involving K^+ channels is the development of novel therapies, preventions, and cures. The most complete example of this process so far is research concerning the KCNQ/Kv7 family of voltage-gated K^+ channels and their genes. In 1964, Andreas Rett, memorialized as the discoverer of Rett's syndrome, published the first description of an autosomal dominant epilepsy syndrome later called *benign familial neonatal convulsions* (BFNCs).[14] In this syndrome, onset of partial or generalized clonic convulsions occurs at around 3 days of age; these attacks remit within about 3 months. Although affected infants have been thought to grow and develop normally, a significant proportion (16%) experience additional isolated or recurrent seizures as children or adults.[15] Benign familial neonatal convulsions was the first idiopathic epilepsy for which a genetic locus was identified.[16] Two loci were ultimately associated with the syndrome, with most pedigrees linked to chromosome 20q13.3 and a few linked to 8q24.[17,18]

While these clinicogenetic studies were progressing, completely independent work by cellular electrophysiologists revealed the existence of two unusual voltage-gated K^+ currents. Brown and Adams found in sympathetic neurons a noninactivating voltage-dependent K^+ current with much slower opening and closing kinetics than the classical action potential *delayed rectifier* current.[19] They called this the *M-current*, because it could be transiently suppressed by application of muscarinic cholinergic agonists. Such muscarinic suppression caused membrane depolarization and increased responsiveness during subsequent excitatory synaptic stimulation. M-current was later found in many central neurons.[20] Soon after the first studies of M-current appeared, voltage-clamp recording of peripheral nerves of frogs revealed the presence of a similar K^+ current in myelinated axons.[21] Subsequent work showed that this axonal K^+ current, termed I_{Ks} (slow K^+ current) was concentrated at the nodes of Ranvier.[22] In mammalian myelinated nerves, I_{Ks} is particularly important, because mammalian myelinated axons have a very low density of fast K^+ channels at their nodes.[23] Although the similarities between I_M and I_{Ks} were noted early on,[24] subsequent cloning efforts failed to reveal the genes underlying either current.

In 1998, two novel closely related related K^+ channel subunit genes, *KCNQ2* and *KCNQ3*, were identified at the two BFNC loci. *KCNQ2* and *KCNQ3* were shown to be expressed exclusively by neurons and to be mutated in patients with BFNC.[25–27] Soon after the genes were cloned, study of the kinetics, pharmacology, and expression patterns of heteromeric

KCNQ2/KCNQ3 channels showed that they represented the basis of the M-current in sympathetic[28] and hippocampal neurons. An additional insight was gained when a family was described in which patients with BFNC due to a mutation in *KCNQ2* also suffered from myokymia, a symptom indicative of hyperexcitability in myelinated motor axons.[29] Immunostaining of brain sections and peripheral nerves showed that KCNQ2 was universally present at nodes of Ranvier, and KCNQ3 was also present at a fraction of nodes.[30–32] Indeed, a detailed physiological study using KCNQ-selective blockers and openers showed that, in large myelinated nerves from rat sciatic nerve that stain for KCNQ2 but not KCNQ3, homomeric KCNQ2 channels mediate the slow nodal K^+ current.[31]

Heteromeric KCNQ2/KCNQ3 channels were also detected widely in the central nervous system (CNS) at the axonal initial segments, which are believed to be the site of action potential initiation in most neurons.[30] Although the KCNQ channels found at the axonal initial segments remain to be recorded directly, a growing body of indirect physiological evidence indicates that these channels contribute to control of action potential initiation and firing frequency in the CNS.[33–35] It is also possible that the BFNC phenotype results partly from a loss of channel activity in somatodendritic domains where M-channels have also been recorded in some cell types.[35,36]

Two additional closely related KCNQ channel subunits have also been identified (KCNQ4 and KCNQ5).[37] *KCNQ4* expression is apparently somewhat restricted, including auditory hair cells and neurons in the central auditory pathways (mutations in KCNQ4 give rise to a dominant progressive hearing loss syndrome). KCNQ5 is widely expressed, but its neuronal function is just beginning to be explored.[38] In vitro, KCNQ2–5 subunits can form functional homotetrameric channels. In addition, a variety of heteromeric combinations—including KCNQ2/3, KCNQ3/4, or KCNQ3/5—can assemble functionally. The subunit combinations found in the CNS are only beginning to be explored, although evidence for both KCNQ2 monomers and KCNQ2/3 heteromers has been found.[32,39–41]

The KCNQ family includes one more distantly related gene, *KCNQ1*. Owing to its greater divergence, KCNQ1 cannot form heteromers with KCNQ2–5.[42] Unlike KCNQ2–5, however, KCNQ1 does heteromerize with accessory subunits of the KCNE family. KCNQ1 was first found in the heart, in gastrointestinal tract epithelial cells, and the cochlea. KCNQ1/KCNE1 heteromeric channels underlie an important current in cardiomyocytes that activates very slowly to end the Ca^{2+}-mediated plateau phase of the action potential, promotes ventricular relaxation, and prevents aberrant re-excitation.[43] Mutations in *KCNQ1* are associated with abnormal ventricular repolarization, causing the long-QT syndrome of arrhythmia and sudden death.[44] Recessive mutations in either *KCNQ1* or *KCNE1* cause a related syndrome combining this arrhythmia with congenital deafness.[45] Recently, Goldman et al. used electroencephalography (EEG) to study mutant mice bearing *KCNQ1* mutations known to cause human long-QT syndrome.[46] Remarkably, in addition to cardiac abnormalities, these mice exhibited frequent seizures and, occasionally, death in association with a seizure. Further, biochemical and immunohistochemical experiments provided evidence of previously overlooked *KCNQ1* expression in brain. The implications of these findings are broad, and more studies of *KCNQ1* function in the CNS are merited.

In contrast to the *KCNQ1* example, where murine studies revealed a broader phenotype than was previously appreciated in humans, introduction of *KCNQ2* and *KCNQ3* mutations associated with BFNC has resulted so far in mice without seizures or any described behavioral changes beyond somewhat increased sensitivity to seizure provocation by electrical or chemical treatments.[47–49] Because the human phenotype is so developmentally restricted, it is apparently difficult to recapitulate it in a species as distant as the mouse. At the cellular level, however, functional consequences of *KCNQ2* and *KCNQ3* mutations responsible for BFNC have been studied by expression of mutant channels in cell lines and neurons. Intriguingly, some mutations caused very slight reductions (20%–30%) in channel activity when expressed in *Xenopus* oocytes, which has been interpreted as suggesting that very modest reductions in the M-current might be sufficient to augment or cause seizures.[37] Recent studies show, however, that some mutations dramatically disrupt the trafficking of channels to axons, and this may be the main factor contributing to the disease phenotype.[50] Although the developmental factors

leading to the seizure remission at around 3 months are not understood, delayed postnatal maturation of GABAergic inhibition is a potential contributing factor, rendering neonatal brain especially dependent on K^+ channel activity to prevent excessive excitation.[51]

In parallel with the early studies of BFNC and the M-channel, retigabine emerged as a candidate antiepileptic drug (AED) after successful results in the National Institute of Neurological Diseases and Stroke (NINDS) antiepileptic drug screening program.[52,53] Retigabine was derived from flupirtine, a compound approved for use as an analgesic in Europe but not used in the United States. Retigabine was found to possess the ability to open K^+ channels in neurons.[54,55] Once *KCNQ2* and *KCNQ3* were cloned, independent efforts by several groups rapidly showed that they were molecular target of retigabine.[56–58] Retigabine shifts the voltage dependence of the channel to hyperpolarized potentials, speeds the rate of activation in response to membrane depolarization, and slows the rate of closing (deactivation). Testing retigabine more broadly with combinations of expressed subunits revealed that the degree of potentiation varied, depending on channel composition, in the order (most potent) KCNQ3 > KCNQ2/KCNQ3 > KCNQ2 > KCNQ4, KCNQ5 (least). The KCNQ1 subunit is retigabine insensitive.[59] This observation is clinically significant, since this eliminates one potential source of cardiac toxicity. Swapping domains between the retigabine-sensitive KCNQ2 or KCNQ3 subunits and retigabine-insensitive KCNQ1 made it possible to identify the pore domain as the site of retigabine action.[60,61] Mutagenesis of individual pore residues showed that the action of retigabine requires the presence of a key tryptophan (located near the cytoplasmic end of the fifth transmembrane segment, or S5) that is conserved in KCNQ2–5 but absent in KCNQ1.

To better appreciate the significance of this tryptophan, I aligned the KCNQ2 and Kv1.2 amino acid sequences, and then mapped the location of the crucial residue on the published three-dimensional coordinates of the Kv1.2 crystal structure[62,63] using the Swiss PDBviewer software.[64] This revealed that the residue is located near the components of the channel protein involved in the coupling of movement of the voltage sensor to opening of the gate (Fig. 5–2B–D). The critical tryptophan forms one side of a pocket that also include surfaces of S6, the S4–5 linker, and the S5 and S6 of the adjoining subunit (indicated in dashed grey boxed region in Fig. 5–2D; the molecular structure of retigabine is also indicated at equal scale). Clearly, more than the indicated tryptophan is important, since, for example, both KCNQ3 and KCNQ5 possess the residue but differ more than 10-fold in their sensitivity to retigabine. High-throughput screening has revealed additional chemical classes of KCNQ channel openers that are also potential antiepileptic drugs, including various benzanilides and acrylamides.[65] Their activity in preclinical models of epilepsy provides further proof of the concept of KCNQ2–5 as AED targets. An additional compound (Maxipost, BMS-204352) has been shown to open both KCNQ channels and high-conductance Ca^{2+}-activated K^+ channels.[66,67] This drug blocks ischemic brain damage in rodent models, but a large stage III trial for stroke failed due to lack of efficacy, though subsequent analysis suggests that the trial dosing may have been insufficient.

Retigabine has recently been approved for use in parts of Europe, and by the Food and Drug Administration (FDA) in the USA. Because clinical drug development is slow and expensive, retigabine was studied in American and European clinical drug trials that were designed and set in motion before molecular studies had revealed much about its mechanism of action.[68] A number of recent preclinical studies have attempted to build on molecular findings in order to both enhance the utility of retigabine and aid the rational design of next-generation KCNQ channel openers. One rat study showed that retigabine was particularly effective in suppressing seizures in immature animals, suggesting that it may be useful in pediatric cases.[69] Another suggested that this class of drugs may be potently effective in symptomatic neonatal seizures and status epilepticus.[70]

KCNQ CHANNELS AND BEYOND: PROSPECTS FOR FUTURE POTASSIUM CHANNEL STUDIES IN EPILEPSY RESEARCH

Progress in exploiting the KCNQ2–5 channels as anticonvulsant drugs was hastened, very fortuitously, by the coincidence of independent

efforts to identify the genes, identify the channels, and exploit already discovered channel ligands. However, general and encouraging implications about the prospects for developing K^+ channels further as targets can be gleaned from the KCNQ outcomes so far. Exploitation of the growing number of available K^+ channel crystal structures should facilitate follow-up mutagenesis studies aimed at further defining the mechanisms through which retigabine and other compounds open neuronal KCNQ channels. Crystallization of a KCNQ channel (perhaps in the presence of drug) would also be of enormous utility. Detailed understanding of this drug-channel interaction may serve as a path for rational design of more selective KCNQ activators, and ultimately of drugs able to activate other K^+ channel types. Future basic studies will seek to understand how channels interact to generate neuronal excitability at the level of the subcellular domain and circuit.

Chapter 6

Voltage-Gated Calcium Channels in Epilepsy

Stuart M. Cain
Terrance P. Snutch

Voltage-gated calcium channels are integral membrane proteins that form calcium-selective pores in the plasma membrane (Fig. 6–1). Calcium ions flowing into the cell are driven by an electrochemical gradient generated by a high concentration of calcium outside the cell to a low calcium concentration inside. In neurons the rapid influx of calcium depolarizes the cell membrane potential due to its divalent positive charge and mediates biophysical processes such as action potential firing and membrane potential oscillations. A second effect of calcium ion influx is to regulate the intracellular signaling pathways and biochemical machinery required for physiological functions such as neurotransmitter release. Cells contain numerous calcium-sensitive proteins, such as enzymes and DNA transcription factors

that can be up- or downregulated by the binding of calcium ions. Due to the highly complex and widespread effects of calcium channels, even small alterations in their expression or biophysical properties can induce pathophysiological changes in the brain with the potential to induce epileptic seizures.

CALCIUM CHANNEL NOMENCLATURE

Calcium channels are generally classed as either high voltage-activated (HVA) or low voltage-activated (LVA), depending on whether they open at more positive (e.g., –40 mV) or more negative (e.g., –60 mV) membrane potentials, respectively[1,2] (Fig. 6–1). High voltage-activated channels can be further classified according to their pharmacological sensitivities and genetic α_1 subunit protein (Ca_V) composition into L-type ($Ca_V1.1$–$Ca_V1.4$), P/Q-type ($Ca_V2.1$), N-type ($Ca_V2.2$), and R-type ($Ca_V2.3$). Low voltage-activated channels, also known as *T-type*, for their comparatively "tiny" or "transient" currents are further classified to according to their α_1 subunit composition ($Ca_V3.1$–$Ca_V3.3$).[1] Additional structural and functional variants of each Ca_V subtype can be generated by alternative splicing to produce a large number of different *splice variants* and therefore increase the repertoire and complexity of calcium channel properties. It should be noted that $Ca_V1.3$ L-type and $Ca_V2.3$ R-type channels can exhibit characteristics of *mid-voltage-activated* channels, opening at membrane potentials that are more negative than HVA channels and more positive than LVA channels. For simplicity in this chapter, $Ca_V3.1$–$Ca_V3.3$ will be referred to as *T-type channels* and all other calcium channels will be referred to as *HVA channels*.

While each calcium channel α_1 subunit contains the molecular machinery necessary to conduct calcium ions (calcium-selective pore, voltage-sensing and -gating mechanisms), a number of ancillary proteins (β, $\alpha_2\delta$, and γ subunits) are associated with the HVA channel types and modify channel biophysical properties and expression[2] (Fig. 6–1). Four β subunit genes ($\beta1$–$\beta4$), four $\alpha_2\delta$ subunit genes ($\alpha_2\delta_1$–$\alpha_2\delta_4$), and eight γ subunit genes ($\gamma1$–$\gamma8$) have been identified in vertebrates. There is no firm biochemical evidence as yet that T-type calcium channels require ancillary subunits for native functioning. Nine of the ten calcium α_1 subunits (all but $Ca_V1.1$) are widely expressed in the central and peripheral nervous systems, and several have been implicated in contributing to epilepsy pathophysiology.

CALCIUM CHANNEL BIOPHYSICAL PROPERTIES

From their closed/resting state, calcium channels open once the membrane potential depolarizes to a threshold point, at which the internal voltage sensor moves and the channel conformation changes to an open-pore calcium-conducting state. Calcium channels conduct ions only in the open state, and with ongoing depolarization an internal inactivation mechanism induces additional conformational changes to prevent further conduction. Once in the inactivated state, the channels can only be reopened by repolarization to hyperpolarized membrane potentials, allowing the voltage sensor to return to its original closed conformation and the inactivation machinery to return to its deinactivated position. Only from this state can further membrane depolarization reopen the channels to their ion-conducting state. The membrane potentials and the rates at which these steps occur vary among the calcium channel subtypes and splice variants, producing channel variants with widely differing conducting properties.[2–4]

Calcium channels are generally slower at opening (activation) and closing (deactivation) than typical voltage-activated sodium channels. Among the calcium channel subtypes, HVA channels generally display slower activation and faster deactivation than LVA channels. Further, HVA channels generally inactivate much more slowly than LVA channels. Together these properties result in HVA channels generating longer-lasting calcium influxes upon sustained depolarizations, with T-type channels conducting more rapid and shorter calcium influxes under both brief and sustained depolarizations (Fig. 6–1). Of particular note, T-type channels also exhibit a distinct overlap of the membrane potentials at which they both activate and inactivate, uniquely enabling them to regulate subthreshold excitability including mediating intrinsic oscillatory behaviors and firing rates.

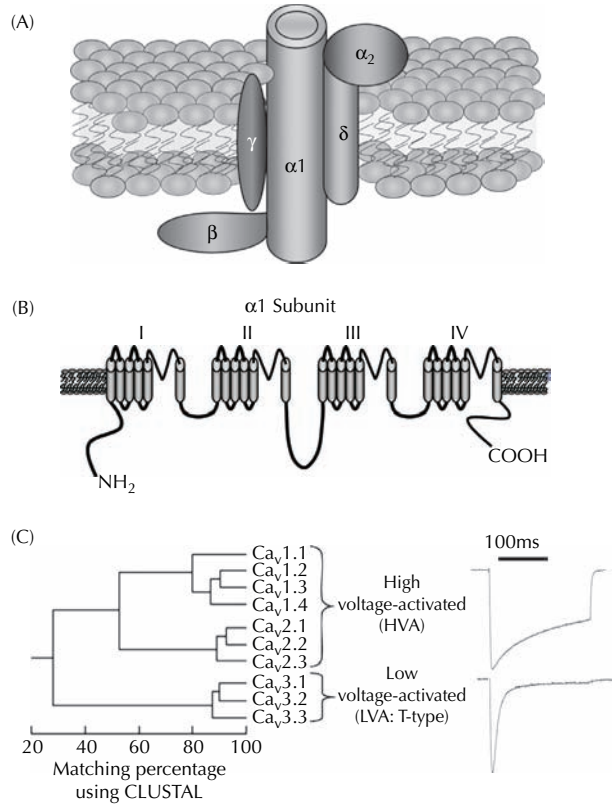

Figure 6–1. Voltage-gated calcium channels. **A.** Schematic illustrating the topography of the HVA calcium channel complex showing the main pore-forming α_1 subunit and ancillary subunits. The α_1 and δ subunits are integral membrane proteins, the β subunit is intracellular and binds directly to the α_1, and the α_2 subunit is thought to be largely extracellular. **B.** Schematic diagram showing the structure of the calcium channel α_1 subunit with its four-domain structure. **C.** The left panel shows the phylogenic relationship between the 10 known calcium channel α_1 subunits. Ca_V1 subunits form the L-type subfamily; Ca_V2 channels form the P/Q-type, N-type, and R-type; and the Ca_V3 subunits form the LVA T-type calcium channels. The right panel shows representative traces of calcium currents recorded from reticular thalamic neurons in response to depolarization of the membrane potential. The upper trace shows a slow inactivating HVA current, and the lower trace shows a fast inactivating LVA current.

CALCIUM CHANNELS AND EXCITABILITY

T-Type Channels and Excitability

T-TYPE CALCIUM CHANNELS AND BURST FIRING

T-type channels typically open at membrane potentials of about –70 to –50 mV, more negative than those required to open both typical HVA calcium channels and sodium channels (~ –40 to –30 mV).[4] The comparatively smaller depolarization required to open T-type channels from resting bestows a particular importance with regard to cellular excitability. Small depolarizations induced by, for example, *N*-methyl-D-aspartate (NMDA) receptor activation can cause T-type calcium channels to open, leading to further membrane depolarization, which in turns leads to the opening of additional T-type calcium channels.[5–7] If the expression of these channels is of sufficient density, this cascade depolarization induces a *calcium spike*, also known as a *low- threshold spike* (LTS), similar to an action potential, but slower in activation and inactivation rate and peaking at more hyperpolarized membrane potentials (~ –45 to –35 mV).[8,9]

This calcium spike can depolarize the membrane to a level whereby sodium channels and potassium channels then open and initiate high-frequency action potential (AP) firing on the crest of the LTS. The AP firing can continue until the T-type calcium channels inactivate and the membrane is repolarized by

small-conductance calcium-activated potassium (sK) channels. This type of event is known as a *burst*, and burst firing is thought to underlie the spike-and-wave discharges (SWDs) that are both the hallmark of absence epilepsy seizures on electroencephalography (EEG) recordings and that can also be observed in some other generalized and partial epilepsies (Fig. 6–2).[10,11] The "spikes" in these events are thought to correspond to summated neurotransmission, whereas the "wave" complexes are predicted to correspond to a period of neural quiescence. Together, they represent the oscillatory nature of absence seizures as they progress and resonate in the brain.

Different T-type channel subtypes contribute to particular parts of the burst due to their differing activation/inactivation kinetics (*fastest* $Ca_V3.1 > Ca_V3.2 >> Ca_V3.3$ *slowest*), deactivation kinetics (*fastest* $Ca_V3.3 > Ca_V3.1 > Ca_V3.2$ *slowest*), and rate of recovery from inactivation (*fastest* $Ca_V3.1 > Ca_V3.3 > Ca_V3.2$ *slowest*).[8,12] $Ca_V3.1$ channels are predicted to generate very-fast-activating, short-lasting bursts, $Ca_V3.2$, to generate fast-activating, longer-lasting bursts and $Ca_V3.3$ slow-activating and very-long-lasting bursts. Neuronal bursting properties likely depend on the relative proportion of the three T-subtypes that are expressed within a given neuron.

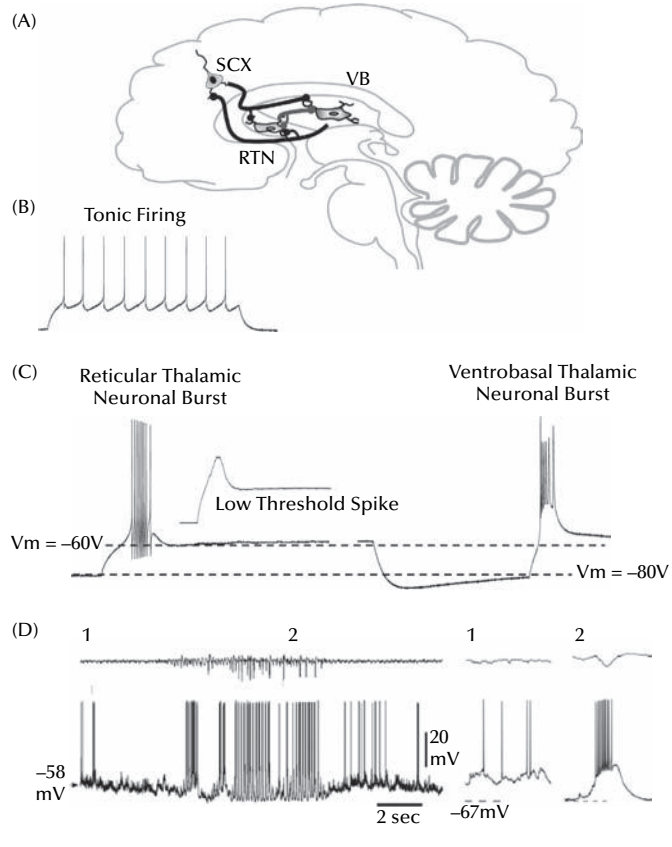

Figure 6–2. The thalamocortical network and burst firing. **A.** Diagram of the thalamocortical network showing connections between the somatosensory cortex (SCX), the sensory relay neurons of the ventrobasal posterior thalamic groups (VB), and the reticular thalamic nucleus (RTN). **B.** Under normal physiological conditions, as sensory signals from the periphery are relayed to the cortex, the VB and RTN neurons fire tonically in response to depolarization. In this state, there is minimal T-type calcium channel activity. During epileptiform activity, burst firing becomes predominant (**C**) and the TC network becomes locked in a self-propagating oscillatory loop (Vm = membrane potential). **C.** Inset: In the absence of sodium channel activity (600 nM tetrodotoxin applied), the low-threshold spike that underlies burst firing is evident. **D.** Burst firing in the RTN of the GAERS epileptic rat model of absence epilepsy correlates with burst firing in the RTN. Upper panels in show EEG recordings, and lower panels show corresponding intracellular recordings in an RTN neuron with expanded time scales on right side. Note that tonic neuronal firing does not correspond to spikes in the EEG trace (1), however burst firing correlates closely with spikes observed on the EEG trace during spike-wave discharges (2).

T-TYPE CALCIUM CHANNELS AND SLOW OSCILLATIONS

In addition to the oscillations generated by burst firing, T-type calcium channels are involved in generating a number of other types of oscillations, especially in the thalamocortical network, which are of particular importance in some epileptic disorders. The membrane potentials at which T-type channel variants open, close, inactivate and deinactivate are known to overlap and vary among subtypes. At potentials of overlap in conducting and nonconducting states, some percentage of channels is always open, although the entire population is constantly shifting between open, closed, and inactivated states. This produces a constant inward calcium current known as a *window current*.[4,8,13,14] Whether a given neuron is at a membrane potential where the window current is on or off can have a great effect on excitability, and the switching between these states, controlled by different leak, hyperpolarization-activated depolarizing and cation-activated depolarizing conductances, is thought to underlie a number of neural rhythms and oscillations.[15–19] While burst firing is a critical propagator of seizure activity, intrinsic oscillations within cells and networks potentially underlie the actual initiation of seizures.[20] This can be observed by artificial enhancement of T-type channel expression in inferior olivary neurons using computer modeling combined with patch clamp (known as *dynamic clamp*) and is sufficient to induce spontaneous oscillations.[21] This likely occurs because subtle changes in T-type channel current density can lead to large changes in electrophysiological oscillatory behavior.[21,22] For example, overexpression of the $Ca_V3.3$ channel alone in neuroblastoma cells induces spontaneous oscillatory activity and low-threshold firing.[23]

HVA Calcium Channels and Excitability

The HVA channels are involved in many different aspects of neuronal excitability, and a comprehensive discussion is beyond the scope of this chapter. However, some of their roles relative to epilepsy are of particular note. Postsynaptically expressed HVA channels generate large, long-lasting depolarization, and modification of their biophysical properties or expression can have substantial effects on the intrinsic firing properties of neurons. While HVA channels all play a role in low-threshold burst firing in that they conduct large amounts of calcium during bursts, especially during action potentials, they do not appear to be crucial for bursting activity to occur.[6,24] R-type channels, however, are becoming increasingly linked to a role in burst firing, as they have a lower threshold for activation than typical HVA channels, are capable of transient surges of current, and are linked to afterdepolarization, which is required for repetitive bursting.[25,26] Furthermore, R-type channels may be involved in generating adequate activation of sK channels to ensure sufficient repolarization following a burst, which is requirement for T-type deinactivation over a series of multiple bursts. In addition, R-type channels have been proposed to contribute to sustained depolarizations, known as *plateau potentials*, which have been implicated in pro-epileptic neuronal activity.[27]

A number of the HVA calcium channel subtypes are also expressed presynaptically and are critically involved in neurotransmitter release.[28–30] With an absolute dependence of neural functions on synaptic neurotransmission, it follows that even small alterations in the biophysical properties of presynaptic calcium channels could have a significant impact on the firing properties of nerve cells and neural networks, with the potential to lead to epileptic seizure activity.

CALCIUM CHANNELS IN ABSENCE EPILEPSY

T-Type Calcium Channels in the Thalamocortical Network and Absence Seizures

The thalamocortical (TC) network components involved in absence seizures appear to be comprised of three primary nuclei: sensory relay neurons including those located in the ventrobasal posterior thalamic groups (VB), the corticothalamic pyramidal neurons in layers V–VI of the sensory cerebral cortex

(SCX), and the reticular thalamic nucleus (RTN; Fig. 6–2). In this network, glutamatergic axonal efferents from the SCX synapse on VB neurons, which send reciprocal glutamatergic projections back to the SCX. The RTN forms a shell around the dorsal-anterior face of the thalamus, and as axons from SCX and VB neurons by de-inactivating the T-type calcium channels expressed in VB neurons the RTN, they synapse upon RTN neurons, inducing depolarization. Reticular thalamic nucleus neurons are GABAergic and send projections both to VB neurons and to other RTN neurons, inducing hyperpolarization in both neuronal types. Ventrobasal thalamic neurons are thought to respond more faithfully to hyperpolarizing inputs via the RTN than to those directly from depolarizing inputs from the SCX.[31]

During wakefulness or seizure-free periods, VB neurons act as a simple relay by forwarding sensory signals from the periphery to the cortex. In this mode, thalamic neurons are relatively depolarized and T-type channels in both VB and RTN neurons are, in general, inactivated. In this state, thalamic neurons follow a generally "tonic" or repetitive firing pattern of variable frequency with regular action potentials and little bursting (Fig. 6–2).

However, during absence seizures (which follow a pattern similar to that of nonrapid eye movement [REM] sleep) the SCX, VB, and RTN neurons become locked in a self-propagating oscillatory loop. During this state, RTN neurons are more hyperpolarized, allowing burst firing to occur via the deinactivation of $Ca_V3.2$ and $Ca_V3.3$ T-type channels expressed in these cells in response to depolarization from VB and SCX collaterals[32–35] (Fig. 6–2). Close correlation is observed between the timing of burst firing in neurons of the RTN and the spikes observed in (SWDs) on EEG recordings during absence seizures in the Genetic Absence Epilepsy Rats from Strasbourg (GAERS) model of absence epilepsy[36,37] (Fig. 6–2). Burst firing in the RTN induces hyperpolarization of VB neurons via $GABA_A$ and/or $GABA_B$ receptor activation, deinactivating $Ca_V3.1$ T-type channels, and as hyperpolarization-activated channels (HCN; I_h) and corticothalamic inputs depolarize the neuron back toward the resting potential, a *rebound burst* is induced by opening of the deinactivated $Ca_V3.1$ channels[33,38,39] (Fig. 6–2). This process, in turn, induces depolarization in the SCX, which sends excitatory signals back to the thalamus, and the absence seizure propagates.[18,39] Overall, although RTN neurons are GABAergic, they actually drive excitatory behavior in their burst-firing state by de-inactivating the T-type calcium channels expressed in VB neurons.

The role of T-type calcium channels in the SCX is less clear. All three T-subtypes exist in the cortex, with $Ca_V3.1$ and $Ca_V3.3$ being expressed throughout, but with greatest expression in layer V; also, this layer is the only layer to express $Ca_V3.2$.[33] While oscillatory activity and low-threshold spiking have been identified in the cortex, burst firing is generally uncommon in cortical neurons.[40–44] Correspondingly, T-type currents are generally either absent or of small magnitude in cortical neurons, while HVA calcium channels are abundant.[45–50] However, evidence from genetic rat models of absence epilepsy suggests that seizures actually initiate in the SCX, which then recruits the thalamus and spreads to other cortices.[43,51–53] Whether intrinsic normal oscillatory activity in this region recruits a hyperexcitable thalamus to induce seizures, or whether pathophysiological hyperexcitability in the cortex is responsible for inducing seizures directly, is still unknown.[20,54,55]

Calcium Channels in Human Epilepsy

T-TYPE CALCIUM CHANNEL MUTATIONS IN HUMAN EPILEPSY

A number of apparent mutations have been identified in the human *CACNA1G* ($Ca_V3.1$) and *CACNA1H* ($Ca_V3.2$) genes within subpopulations of idiopathic generalized and childhood absence epilepsy patients.[56–59] Some of the alterations in $Ca_V3.2$ have been shown to induce altered biophysical properties or increase channel expression when examined in exogenous expression systems. However, some have no apparent effect, potentially reflecting the polygenic nature of idiopathic generalized epilepsies and/or that a subset of the changes represent single nucleotide polymorphisms.[60–68] Taken together these findings provide a strong indication that T-type calcium channels play a role in human idiopathic generalized epilepsies, supporting a large volume of data provided by experiments on animal models.

P/Q-TYPE CALCIUM CHANNEL MUTATIONS IN HUMAN EPILEPSY

The $Ca_V2.1$ subunit encodes both P-type and Q-type channels through an alternate splicing mechanism.[69] These channels are highly expressed presynaptically, where they are critically involved in neurotransmission and synaptic efficacy and therefore have a great influence on neuronal excitability.[70, 71] This aspect is reflected by a number of mutations in the $Ca_V2.1$ gene identified in patients suffering from severe neurological disorders, including ataxias and congenital migraine.[66] While instances in which HVA channel mutations have been identified in human absence epilepsy patients are rare, such cases do exist for $Ca_V2.1$. Within three generations of a single family, five members suffered from a combination of absence seizures/episodic ataxia and were found to possess a missense mutation (*E147K*) in the $Ca_V2.1$ subunit gene.[72] In another study, an 11-year-old boy was identified with primary generalized epilepsy, episodic and progressive ataxia, and mild learning difficulties. Analysis of his genome revealed a truncation mutation (*R1820*-stop) in the $Ca_V2.1$ channel.[73] Both of these distinct mutations result in a loss in P/Q-type channel function. Another missense mutation (*I712V*) has been reported in the $Ca_V2.1$ subunit gene of an 11-year-old girl suffering from episodes of seizures, ataxia, and other neural disorders, although no functional effects have yet been observed on the channel properties.[74] Furthermore, a small proportion of patients with familial hemiplegic migraine type-1 and with underlying mutations in the $Ca_V2.1$ channel also display both generalized and complex partial seizures. [66,67,75–79]

T-Type Calcium Channels in Absence Epilepsy Animal Models

GENETIC ABSENCE EPILEPSY RATS FROM STRASBOURG (GAERS)

Genetic rodent models of epilepsy have been useful in understanding the mechanisms that underlie absence seizures. Some of these models are generated by inbreeding rats that have developed epilepsy naturally to produce fully epileptic strains. The GAERS inbred Wistar rat model displays spontaneous absence seizures with characteristics similar to those of the human condition, with the exception that SWDs occur at a higher frequency (3–4 Hz in humans vs. 7–9 Hz in GAERS).[80,81] Calcium channels have been implicated in SWDs in GAERS since an early experiment wherein the injection of cadmium into the RTN at a concentration that blocks all calcium channel subtypes (1 mM) was found to abolish SWDs.[82] An increase in T-type current density has been found in the RTN neurons of GAERS with a corresponding increase in expression of $Ca_V3.2$ but not $Ca_V3.3$ mRNA.[83,84] Furthermore, GAERS has been shown to possess a missense mutation (*R1584P*) in the *Cacna1h* gene encoding $Ca_V3.2$ that correlates closely with seizure expression when GAERS rats are outcrossed with nonepileptic control rats[85] (Fig. 6–3). The *R1584P* mutation induces a gain of function in a particular $Ca_V3.2$ splice variant (+exon 25), increasing the rate at which channels recover from inactivation and allowing enhanced charge conduction during high-frequency depolarizations such as those that occur during burst firing. Since a greater number of $Ca_V3.2$ channels will recover from inactivation during multiple bursting in GAERS, the LTS magnitude is predicted to decrease less over a series of bursts. As LTS magnitude has been shown to correlate directly with the number of APs per burst,[86] the resultant effect in GAERS RTN neurons is that over a series of multiple bursts, the number of APs per burst decreases to a lesser degree throughout a burst train. In addition to the *R1584P* mutation's effect on $Ca_V3.2$ channel biophysical properties, the thalamic expression of the affected splice variant (+exon 25) also increases with development, potentially exacerbating hyperexcitability and underlying the temporal nature of seizure expression in GAERS animals.

WISTAR ALBINO GLAXO RATS FROM RIJSWIJK (WAG/RIJ)

Wistar Albino Glaxo Rats from Rijswijk (WAG/Rij) comprise another well-studied genetic absence epilepsy model that displays spontaneous seizures.[87] Like GAERS, these rats also display upregulation of T-type calcium channel expression, although in WAG/Rij this involves the $Ca_V3.1$ subtype in thalamic centrolateral and lateral geniculate (visual cortex projecting) neurons and $Ca_V3.3$ in centrolateral and RTN neurons (Fig. 6–3).[88] Despite increased T-type currents in all three neuron types, no differences

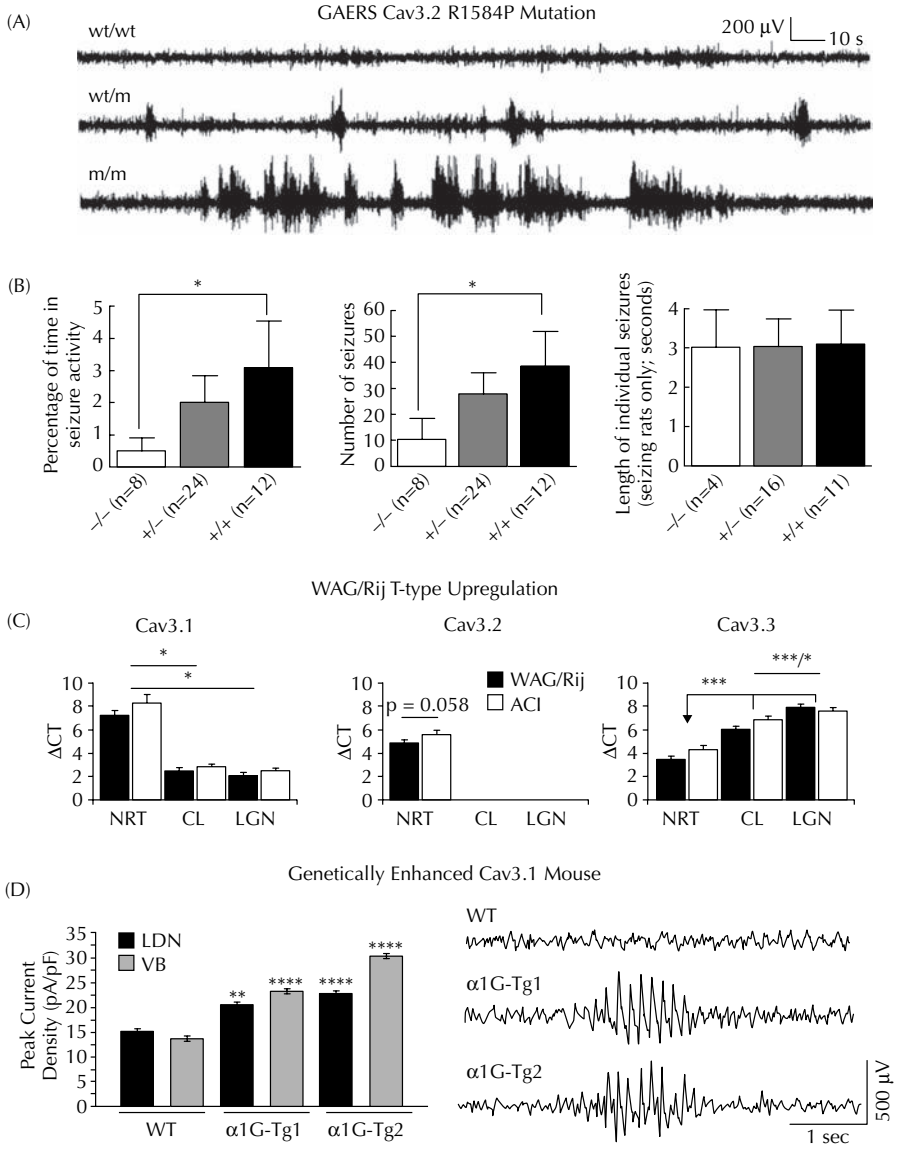

Figure 6–3. T-type calcium channels and absence epilepsy. **A, B.** In the GAERS rodent model of absence epilepsy, an arginine to proline missense mutation at position 1584 (*R1584P*) correlates with the expression of seizure activity. Mating GAERS with a nonepileptic strain (NEC) through two generations produces offspring that have no copies (*wt/wt*), one copy (*wt/m*), or two copies (*m/m*) of the *R1584P* mutation in an otherwise similar genetic background. Animals with two copies of the mutation spend increased time in seizure activity and experience more seizures than animals with no copies of the *R1584P* mutation. The missense GAERS mutation does not affect either the duration or the morphology of individual seizures. **C.** The WAG/Rij model of absence epilepsy displays increased expression of the $Ca_V3.1$ T-type calcium channel in thalamic centrolateral (CL) and lateral geniculate (LGN) neurons and of the $Ca_V3.3$ T-type in CL and RTN neurons. **D.** In mice with a genetically enhanced expression of $Ca_V3.1$ channels (*Tg1* and *Tg2*), larger T-type currents are observed in lateral dorsal (LDN) and ventrobasal (VB) thalamic neurons, and the mice display spontaneous bilateral spike-wave discharges in EEG recordings.

have been observed in the number of APs generated per burst. However, modeling studies predict that smaller depolarizations would be required to induce burst firing in lateral geniculate neurons of WAG/Rij animals. In addition, as with the $Ca_V3.2$ T-type in GAERS, alterations in the expression of specific splice variants of $Ca_V3.1$ have been noted in the WAG/Rij model, which is of particular interest since this occurs in the same , domain III-IV linker region where

seizure-related splice variation was observed with $Ca_V3.2$ in GAERS (exon 25–26).[89] In support of the involvement of $Ca_V3.1$ channels in seizure generation in this model, specific block of $Ca_V3.1$ using indomethacin-related compounds has been shown to attenuate seizures in WAG/Rij.[90] Interestingly, the systemic administration of the L-type calcium channel blocker, nimodipine, apparently exacerbates seizures in this model.[91]

MANIPULATION OF $CA_V3.1$ CHANNELS AND ABSENCE SEIZURES

In support of a role for $Ca_V3.1$ T-type channels in absence seizures, genetic enhancement of $Ca_V3.1$ expression in mice results in spontaneous bilateral SWDs[92] (Fig. 6–3). Accordingly, genetic knockout of the $Ca_V3.1$ channel in mice generates a phenotype whereby thalamic relay neurons cannot burst fire, and *in vivo* the mice show resistance to classic pharmacologically induced absence seizures using $GABA_B$ agonists, baclofen, and butyrolacetone (a prodrug of γ-hydroxybutyric acid).[38]

Overall, it appears that an increase in the activity of any of the three T-type channel subtypes in the TC system may have the effect of enhancing or inducing absence seizures as a direct result of increased burst firing in any of the TC regions, whether it occurs from increased expression or increased function of a T-type calcium channel subtype. Certainly, enhancement of either $Ca_V3.1$ or $Ca_V3.2$ channels seems to have strong pro-epileptic effects in the TC system.

HVA Channels in Absence Epilepsy Animal Models

HVA CHANNELS IN WISTAR ALBINO GLAXO RATS FROM RIJSWIJK

In the WAG/Rij model of absence epilepsy, in addition to an increase in T-type currents, an increase in the expression of P/Q-type channel protein occurs in the RTN.[93] This appears to occur presynaptically, although experiments have yet to be conducted to determine the functional significance of this expression change on synaptic neurotransmission and absence seizure activity.

HVA CHANNELS IN ABSENCE EPILEPTIC MICE MODELS

Mice generated or identified with mutations that suppress P/Q-type channel function exhibit many features of absence epilepsy. $Ca_V2.1$ gene knockout mice suffer from severe ataxia and seizures and die in early life following massive neuronal damage, in particular in the cerebellum, where P/Q-type channels play a vital role in movement control.[66,67,94–97] *Tottering* mice ($Ca_V2.1$ *P601L*) display absence and motor seizures, whereas *Leaner* (C-terminal truncation) and *Rolling Nagoya* mice (*R1262G*) display absence seizures only.[98–100] Each of these mutations results in decreased P/Q-type current density and a number of other biophysical alterations, generally considered as loss of function.[66,101] The reduced activity can be observed physiologically as attenuated excitatory synaptic neurotransmission in cortical and thalamic neurons.[102,103] Similarly, *Rocker* mice (*T1310K*) display absence-like seizures; however, the effects on channel biophysics are not currently known.[104] It should be noted that all of these mouse models display ataxia, likely due to the critical role of cerebellar P/Q-type channels in movement control, although they may have pro-epileptic downstream effects concerning the production of secondary seizures. In this regard, it should be noted that with the *Tottering* mouse, an increase is observed in the T-type currents ($Ca_V3.1$) in thalamic relay neurons.[105]

Of further note, seizures in $Ca_V2.1$ knockout mice can be abolished by introducing a second mutation to also knock out $Ca_V3.1$ T-type channel function.[106] Although similar investigations have not been reported for the other absence model mice carrying $Ca_V2.1$ mutations, this finding implies that decreased activity of P/Q-type channels may lead to a compensatory increase in T-type currents, which may be responsible for the absence seizures observed. However, since in the WAG/Rij model an *increase* in P/Q-type channel expression is observed in conjunction with increased T-type activity, a compensatory decrease in P/Q-type/increase in T-type model cannot be accepted as absolute. In addition, combined knockout studies must be treated with caution since the absence seizures observed in $Ca_V2.1$ knockout mice can be abolished by a second mutation to knock out shaker-like potassium channels,

which normally increases excitability.[107] Thus, it might be argued that any number of mutations that interfere with excitability in the TC network may block the epileptic phenotype caused by a first mutation.

The mid-voltage activated R-type channel has been shown to play a role in modulating TC rhythmicity, altering the frequencies displayed during pharmacologically induced SWD.[108] Mice lacking $Ca_V2.3$ channels do not display spontaneous absence seizures; however, they do exhibit increased susceptibility to the absence seizures and motor arrest induced by systemic administration of γ-hydroxybutyrolactone.[108] Conversely, a more recent study suggests that $Ca_V2.3$ deficient mice display reduced sensitivity to γ-butyrolactone-induced absence seizures as a result of attenuated sK channel-mediated after-hyperpolarization, and therefore T-type calcium channel de-inactivation, following a burst.[109] This is of particular interest since these mice also demonstrate resistance to generalized convulsive and limbic seizures (discussed in "$Ca_V2.3$ R-type channels in the kainic acid-Induced limbic epilepsy model" and "Generalized seizures in $Ca_V2.3$ transgenic mice").[110,111]

Calcium Channel Ancillary Subunits in Absence Epilepsy Models

The β, $\alpha_2\delta$, and γ ancillary calcium channel subunits that modulate the biophysical properties and expression of the HVA α_1 subunits have also been implicated in absence epilepsy.[112] Mice containing a mutation that genetically deletes the β4 subunit, known as *lethargic*, express SWDs and ataxia, along with defects in presynaptic function.[113] In addition, two strains of mice with mutations in the $\alpha_2\delta_2$ subunit, known as *ducky* and *ducky*^{2J}, both also display SWDs and ataxia.[114,115] Furthermore, a mutation that renders the $\alpha_2\delta_2$ subunit nonfunctional (the *entla* mouse) has also been linked to SWDs.[116] All three $\alpha_2\delta_2$ mutated mice models possess reduced P/Q-type currents and display absence and/or ataxia phenotypes similar to those of the $Ca_V2.1$ gene knockout/mutated mice described above, suggesting that at least part of the mechanism by which they induce seizures may be due to attenuated $\alpha_2\delta_2$ -mediated modulation of the $Ca_V2.1$ P/Q-type calcium channel. A similar mechanism may underlie the β4 knockout *lethargic* mice since β subunits are essential for P/Q-type channel function.

Mutations in the γ_2 subunit protein, also known as *stargazin*, have been found in *stargazer* and *waggler* mouse epilepsy models and result in increased inactivation of P/Q-type channels.[117,118] These mice both display SWDs as well as head-tossing behavior, which are exacerbated in *waggler* mice due to an additional knockout of the γ_4 subunit.[119] As a note of caution, in addition to the modulatory role of this subunit on HVA calcium channels, stargazin is known to be involved in the synaptic trafficking and biophysical modulation of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. Therefore, some or all of the phenotypes associated with mutations in these mice could involve AMPA-mediated signaling. This may also be reflected in the GAERS model, where the stargazin subunit is upregulated in both the SCX and thalamus, key areas involved in absence seizures, although no alterations in P/Q-type channel activity have yet been reported in this model.[120]

CALCIUM CHANNELS IN TEMPORAL LOBE/COMPLEX PARTIAL EPILEPSY

T-Type Calcium Channels in the Pilocarpine Model of Temporal Lobe Epilepsy/Complex Partial Epilepsy

In the pilocarpine model of temporal lobe epilepsy (TLE), status epilepticus is induced by systemic administration of the muscarinic receptor agonist, pilocarpine.[121,122] During an initial acute phase lasting for up to approximately 24 hours, rodents suffer from seizures resembling those of TLE. Following this event, a seizure-free period lasting for a few days to weeks occurs until a chronic phase resembling that of complex-partial seizures develops (Fig. 6–4). Immediately after the acute phase, significant pathophysiological damage can be observed in hippocampal, thalamic, cortical, and striatal structures. During this period, $Ca_V3.2$ expression is upregulated and a corresponding upregulation of T-type currents

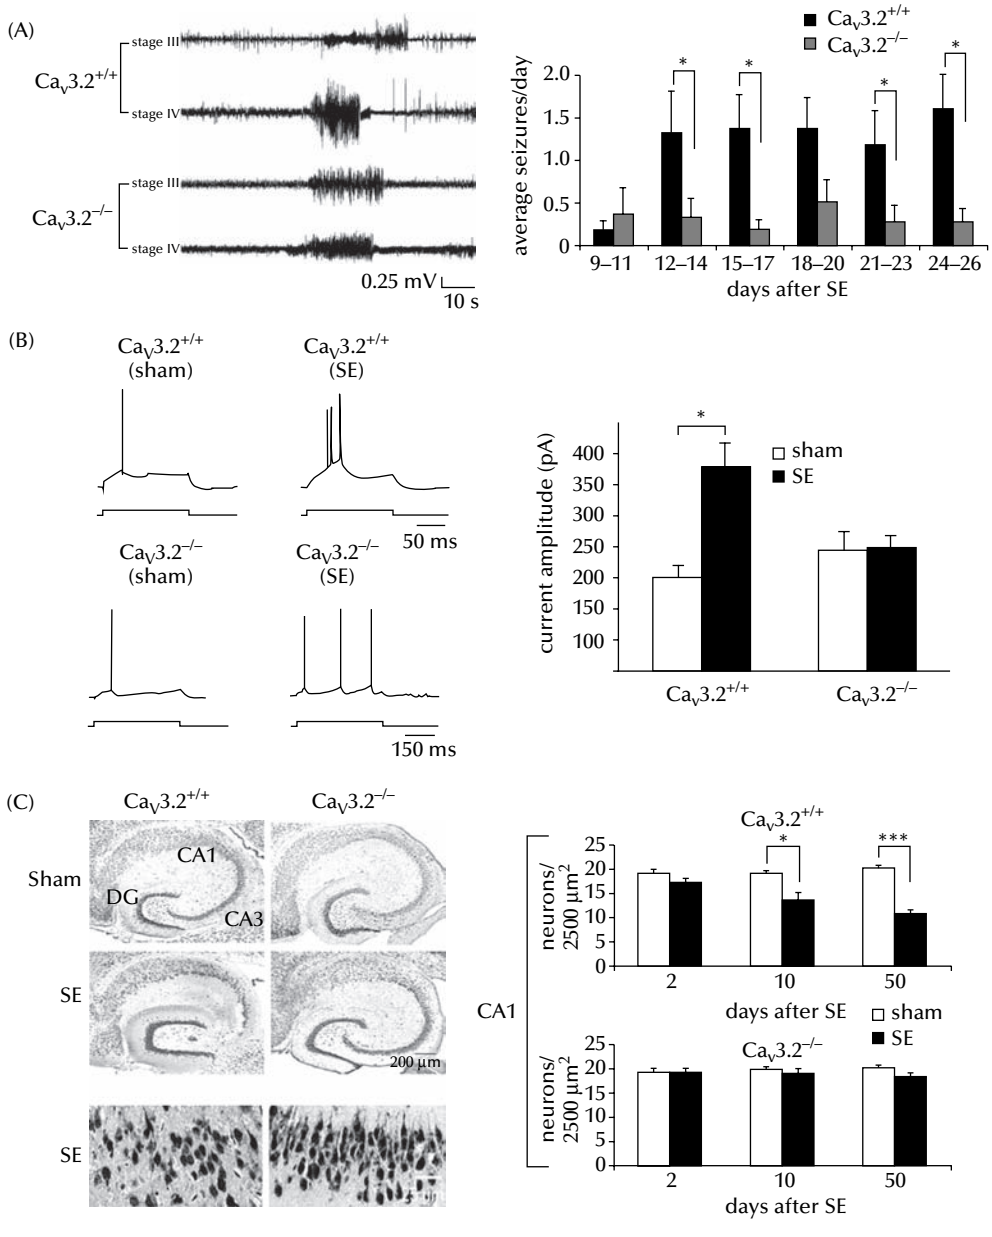

Figure 6–4. T-type calcium channels in temporal lobe/complex-partial epilepsy. **A.** Systemic injection of pilocarpine in mice induces the development of complex-partial seizures, as observed with EEG recording. Seizure morphology and duration are similar in wild-type ($Ca_V3.2^{+/+}$) and $Ca_V3.2$ gene knockout mice ($Ca_V3.2^{-/-}$); however, $Ca_V3.2^{-/-}$ mice display fewer seizures per day than $Ca_V3.2^{+/+}$ mice following status epilepticus (SE). **B.** CA1 hippocampal neurons do not display burst-firing activity in response to depolarization in sham-treated $Ca_V3.2^{+/+}$ mice (top left panel); however, in $Ca_V3.2^{+/+}$ mice displaying pilocarpine-induced seizures 7–15 days after SE (top right panel), clear burst firing is observed. Conversely, in $Ca_V3.2^{-/-}$ mice, burst firing is not observed in either sham-treated (bottom left panel) or pilocarpine-treated (bottom right panel) animals. **B,** far right panel: Increased T-type tail currents are detected in CA1 neurons of $Ca_V3.2^{+/+}$ mice treated with pilocarpine but not in CA1 neurons of sham-treated controls or $Ca_V3.2^{-/-}$ mice. **C.** Neuronal cell loss occurs via a $Ca_V3.2$-dependent mechanism. Representative hippocampal sections from sham-control and SE-experienced $Cav3.2^{+/+}$and $Cav3.2^{-/-}$ mice stained with an antibody directed against the neuron-specific epitope NeuN 50 days after treatment. Note the pronounced neuronal cell loss in CA1 and CA3 areas after SE in Cav3.2 mice but not in $Cav3.2^{-/-}$ mice. The higher-magnification micrographs of representative CA1 subfields of SE-experienced animals highlight the substantial neuronal degeneration in $Cav3.2^{+/+}$ but not $Cav3.2^{-/-}$ mice (bottom). Neuronal cell loss is quantified in the right panel.

is thought to occur in the apical dendrites of hippocampal CA1 neurons.[123–126] Some small changes have also been observed in the biophysical properties of the T-type currents in these neurons.[126] Burst firing is increased in CA1 neurons after the induction of status epilepticus, as would be expected with increased T-type conductance, and can be reversed by specific blockade of $Ca_V3.2$ channels (Fig. 6–4). Furthermore, in $Ca_V3.2$ knockout mice, the number of seizures is attenuated, burst firing is abolished, and neuronal damage in the CA1 region (cell loss and mossy fiber sprouting) is reduced.[125] Therefore, T-type channels, specifically $Ca_V3.2$, appear to be upregulated by temporal lobe seizures and/or have a strong influence on the development of complex-partial seizures in the pilocarpine model. In addition, there is a direct correlation between seizure-induced neuronal damage and upregulated expression of $Ca_V3.2$ channels; however, whether increased $Ca_V3.2$ expression induces neuronal damage or if damage itself increases the expression of $Ca_V3.2$ is unknown.

T-Type Channels in the Electrical Kindling Model of Limbic Epilepsy

Seizure *kindling* is another established model for studying epilepsy in both rodents and higher animals.[127] In this model, low-intensity focal electrical stimulation of a particular area of the brain is used to induce seizures, which increase in intensity and duration as the induction is repeated, due to the fact that seizures lower the threshold for further seizures. For example, electrical stimulation of limbic structures can induce TLE. In rats, similar to what is seen in the pilocarpine model, kindling increases T-type currents in CA1 hippocampal neurons following stimulation applied to CA3 hippocampal efferents (Schaffer collaterals) that innervate the CA1.[128] The increase in T-type currents remains 6 weeks following the cessation of kindling stimulation. Simultaneous increases in neuronal hyperexcitability and damage are also observed in this model, implying that increased T-type currents may drive neurons into a pathophysiological, hyperexcitable state wherein overexcitability induces neuronal damage. Conversely, and again similar to the pilocarpine model, the reverse may be true: seizure-induced damage may lead to an upregulation of T-type currents.

HVA Channels in Electrical Kindling Models of Limbic Epilepsy

In the same electrical kindling model using rats, HVA currents increase by ~50% in comparison to controls in hippocampal CA1 neurons.[128] Correspondingly, $Ca_V1.3$, $Ca_V2.1$, and $Ca_V2.3$ channel mRNA is increased in the CA1 and dentate gyrus hippocampal regions in the initial stages of epileptogenesis as seizures are developing.[129] In contrast, at these stages, the expression of $Ca_V2.2$ N-type channel mRNA is decreased. However, once kindling is fully developed, a significant *increase* is observed in expression of the $Ca_V2.2$ subtype alone. Therefore, alterations in both HVA and T-type calcium channel expression occur at different levels and rates in the kindling model in a subtype-specific manner, making elucidation of the specific role of each subtype somewhat complicated. Nonetheless, there is a clear correlation of calcium channel expression with the development and maintenance of seizures in this limbic epilepsy model.

$Ca_V2.3$ R-Type Channels in the Kainic Acid-Induced Limbic Epilepsy Model

$Ca_V2.3$ knockout mice exhibit altered susceptibility to absence seizures and decreased susceptibility to generalized seizures, as discussed in detail in "HVA channels in absence epileptic mice models" and in "Generalized Seizures in $Ca_V2.3$ transgenic mice" and are thought to contribute to epileptogenic plateau potentials in CA1 hippocampal neurons.[27,108–111] Further studies have revealed that $Ca_V2.3$-deficient mice are also resistant to limbic seizures and secondary generalized seizures induced by systemic administration of the glutamate receptor agonist, kainic acid.[110] It should be noted that this only applies to the more severe stages of seizure in this model and that less severe seizures actually display signs of increased sensitivity, as has been suggested for absence seizures in these mice.[108] In addition, these mice show reduced neuronal cell loss and neurodegeneration within the CA3

region in response to seizures, and their survival rate is significantly improved.

CALCIUM CHANNELS IN GENERALIZED CONVULSIVE SEIZURES

HVA Calcium Channels in Genetic Epilepsy-Prone Rats

Genetic Epilepsy-Prone rats (GEPRs) are inbred Sprague-Dawley strains that develop either a moderate (GEPR-3) or severe (GEPR-9) predisposition to, and expression of, spontaneous as well as audiogenic and kindling-induced complex-partial seizures leading to secondary tonic-clonic seizures. Seizures are thought to originate from the forebrain and/or brainstem circuitry as well as the inferior colliculus.[130,131] High voltage-activated calcium currents have been shown to be increased in inferior colliculus neurons of the less severe seizure-expressing GEPR-3 strain.[132] Corresponding increases in $Ca_V1.3$ L-type and $Ca_V2.3$ R-type protein levels are observed in neurons from this region in GEPR-3 rats that have not yet suffered seizures.[133] Following a single audiogenic seizure, GEPR-3 rats display a further increase in the expression of both $Ca_V1.3$ and $Ca_V2.3$ calcium channels and also an increase in the expression of the $Ca_V2.1$ P/Q-type. Interestingly, these are the same calcium channel types upregulated in limbic electrical kindling models, further supporting their role in epileptic susceptibility.

Generalized Seizures in $Ca_V2.3$ Transgenic Mice

The $Ca_V2.3$ knockout mouse model displays altered susceptibility to pharmacologically induced absence and limbic seizures.[108,109,110] While these mice display no spontaneous seizures, it has been demonstrated that $Ca_V2.3$ knockout mice show resistance to generalized convulsive seizures and reduced lethality induced by systemic administration of the GABA receptor antagonist, pentylenetetrazol.[111] However, these mice do not show any altered susceptibility to seizures induced by administration of the potassium channel blocker, 4-aminopyrridine.

Calcium Channel Ancillary Subunits in Genetic Convulsive Animal Models

In addition to the alterations in HVA channel α_1 subunit expression in GEPRs, expression abnormalities of the calcium channel ancillary subunits have been observed in this model. Expression of the β_3 subunit is increased in seizure-naive GEPR-3 rats and increases further following induction of a single audiogenic seizure.[133] In contrast, expression of the $\alpha_2\delta$ subunit is decreased in seizure-naive GEPR-3 rats and decreases further following induction of a single audiogenic seizure. The overall effect on calcium currents remains difficult to establish due to the altered expression of the HVA channel subunits that also occurs in GEPRs.

CONCLUSIONS

A number of currently used antiepileptic drugs (AEDs) have been shown to block calcium channels.[134] These include front-line absence treatments such as ethosuximide[49,135–150] and valproic acid,[49,138,151–152] zonisamide[153–157] and leviteracetam[160,172,173] in the treatment of partial-onset and generalized seizures, lamotrigine[49,158–163] and gabapentin/pregabalin[174–182] for partial seizures and primary/secondary generalized convulsive seizures and phenytoin,[49,164,] and carbamazepine[49, 165,166] and topiramate[160, 167–170] to control complex-partial and tonic-clonic seizures. In many cases, the exact relevance of the *in vitro* pharmacological findings is difficult to interpret since the cells in which the AEDs have been tested *in vitro* are often not from the region where the drug has its intended effect *in vivo*. Further difficulties arise from the drug concentrations used since the accurate measurement of clinical AED concentrations in specific human brain areas is often not possible; as a result, the drug concentrations for *in vitro* testing are estimated from human plasma concentrations combined with animal cerebral spinal fluid concentration to plasma concentration ratios. The result is often that higher or lower concentrations may be tested in comparison to those existing in the brains of epileptic patients. Within these limitations, in most *in vitro* studies, 100% block of calcium channel activity is rarely observed with clinical concentrations of AEDs. Despite this, convincing evidence for

the involvement of subtype-selective calcium channels in AED pharmacology is mounting for some of the currently used AEDs. As a result, calcium channels are more commonly being viewed as attractive targets for novel epileptic therapies. While small molecules with the ability to specifically block individual calcium channel subtypes are not presently available, considerable effort is ongoing to develop new and selective calcium channel–blocking compounds aimed at the treatment of epilepsy.

Chapter 7

Hyperpolarization-Activated Cyclic Nucleotide-Gated (HCN) Ion Channelopathy in Epilepsy

Nicholas P. Poolos

Hyperpolarization-activated, cyclic nucleotide-gated (HCN) ion channels represent a unique class of voltage-gated ion channels. Initially characterized in the heart as "pacemaker" channels,[1] they are now understood to be an essential modulator of neuronal excitability in cortex, hippocampus, and thalamus. Their diverse contributions to neuronal excitability stem from a constellation of unusual features: they are both voltage- and ligand-gated; they open with hyperpolarization of membrane potential rather than with depolarization; and in the principal neurons of cortex and hippocampus, they are localized almost exclusively to the apical dendrites, where they exert a strong influence on the flow of excitatory synaptic inputs to the cell soma. Because of the influence of HCN channels on neuronal physiology, they also play an important role in epilepsy. Genetic deletion of the HCN2 channel subtype causes absence epilepsy in mice,[2] while deletion of the HCN1 subtype exerts a proconvulsive effect and accelerates epileptogenesis.[3] Loss of HCN1 channel expression and function also occurs during epileptogenesis in animal models of acquired epilepsy, contributing to neuronal hyperexcitability and promoting further seizures.[4] Conversely, upregulation of HCN channel function by antiepileptic drugs may constitute part of their anticonvulsant mechanism of action.[5] Thus, substantial new evidence that has emerged just in the past 10 years links HCN channel dysfunction with epilepsy.

In this chapter, I describe how the unique biophysical properties of HCN channels lead to an influential role in seizure generation; whether recent evidence truly supports the existence of HCN channelopathy in human epilepsy; and how the mechanisms underlying acquired HCN dysfunction could be targeted by antiepileptic therapies.

HCN CHANNEL BIOPHYSICAL PROPERTIES

HCN channels are voltage-gated ion channels that structurally resemble K^+ channels, with a six-transmembrane domain topology, including a pore region that conducts ion flow. However, HCN channels possess biophysical properties that make them virtually unique in comparison to other voltage-gated channels.[6] First, despite structural similarity to K^+ channels, HCN channels are relatively less selective for K^+ ions, allowing inward passage of Na^+ ions. Because at typical neuronal resting potential the driving force for Na^+ is so much greater than for K^+, HCN channels primarily conduct Na^+ current under physiological conditions, thus depolarizing neuronal membrane potential. Second, the voltage-dependent activation of HCN channels is also anomalous compared to most other channels: HCN channels are fractionally open at resting potential, and their activation increases with hyperpolarization from rest rather than with depolarization, as is common with other channels. Thus, neuronal depolarization tends to turn off HCN channels, while hyperpolarization tends to activate them. Third, HCN channels do not display inactivation, and thus are constitutively active around the resting potential. The current mediated by HCN channels, I_h, is estimated to comprise about half of the resting conductance of many neuron types. This allows HCN channels to exert a strong influence on the passive properties of the neuron, such as resting potential and input resistance. (The term *passive*, of course, is a misnomer, since these properties are modulated by HCN and other voltage-gated channels that by definition are active conductances.) Fourth, HCN channels open remarkably slowly, with activation time constants that range from tens to hundreds of milliseconds, that is, several orders of magnitude slower than those of most ion channels. Finally, HCN channels are partly gated by intracellular levels of cyclic nucleotides such as cyclic adenosine 3′,5′-monophosphate (cAMP). This allows channel activity to be modulated by both voltage and intracellular second messengers.

The net result of these biophysical features is a current that inherently stabilizes the neuron at its resting potential, minimizing the influence of synaptic inputs. When the neuron becomes depolarized by a synaptic input, the tonic depolarizing Na^+ current mediated by HCN channels is turned off, since the channels deactivate with depolarization. This hyperpolarizes the membrane potential back towards rest. Conversely, a hyperpolarizing input (such as an inhibitory postsynaptic potential, IPSP) will turn on I_h, depolarizing the neuron back toward rest. Thus, I_h displays an inherent negative-feedback property that imparts a stabilizing effect on neuronal excitability. While it might seem that this stabilizing action might equally apply to excitation and inhibition, it turns out that I_h will disproportionately modulate these two types of synaptic inputs, depending on how the conductance is distributed throughout the cell. One of the most intriguing themes to emerge in the last 15 years of research on ion channel function is the nonuniformity of ion channel distribution within the neuron, particularly in pyramidal neurons. HCN channels represent a prime example of this nonuniform or segregated distribution at a subcellular level, causing them to disproportionately diminish the impact of excitatory postsynaptic potentials (EPSPs). This is discussed further below.

HCN channels are encoded by four separate genes, *HCN1–4*.[7] Ion channels encoded by each of the isoforms have differing biophysical properties (such as speed of gating and sensitivity to cAMP), and are differentially distributed throughout the brain. HCN1 and HCN2 are the main brain isoforms, with HCN1 predominant in the neocortex and hippocampus and HCN2 predominant in the thalamus. HCN3 has a diffuse but low-level distribution in the brain, while HCN4 is present mostly in thalamic relay neurons.[6] In this review, we will mainly consider HCN1 as the cortical/hippocampal subtype; it has relatively fast activation times (tens of milliseconds) but virtual insensitivity to cAMP. HCN2 is the main subcortical (e.g., thalamic) isoform, with an intermediate (several hundreds of milliseconds)

activation time constant and a depolarizing shift in its voltage dependence on exposure to cAMP. As described below, these biophysical differences among HCN subtypes account for their functional roles in the brain regions in which they are found.

HCN CHANNEL EFFECTS ON NEURONAL EXCITABILITY

As discussed above, HCN channels tend to stabilize neuronal membrane potential against either excitatory or inhibitory inputs. Interestingly, their slow activation time course, particularly for the HCN2 and HCN4 subtypes, can be exploited to produce membrane potential oscillations. This occurs when an inward current that activates at hyperpolarized potentials, such as the T-type Ca^{2+} current, is paired with I_h. Indeed, the first characterization of HCN channels was in the sinoatrial node of the heart, where HCN2 and HCN4 channels help set the frequency of firing that produces the sinus rhythm. In fact, it is the modulation of I_h by changes in intracellular cAMP concentration that contributes to the autonomic control of heart rate by β-adrenergic and cholinergic receptor activation.[1] A similar oscillatory function occurs in thalamocortical projection neurons that underlie synchronization of cortical rhythms seen in sleep and in primarily generalized seizures such as absence seizures.[8] An interesting feature of this interaction is that HCN channels need to function in a narrow range of activity in order to mediate oscillations. Either downregulation or upregulation of steady-state I_h has the potential to abolish oscillations.[9] Similarly, blockade of the T-type Ca^{2+} channels will abolish the thalamocortical burst firing underlying absence seizures, a well-described mechanism of action of the antiepileptic drug (AED) ethosuximide (ETX).[10] Because of these contributions to oscillatory activity, HCN channels have often been labeled *pacemaker* currents. However, in principal neurons of cortex and hippocampus, their role is quite different.

In neocortical and hippocampal pyramidal neurons, the actions of HCN channels have been intensely investigated over the past decade. As was first described in 1998, HCN channels in pyramidal neurons show a strikingly nonuniform pattern of distribution: rather than being homogeneously distributed across the cell membrane, they are instead arrayed in a gradient pattern along the somatodendritic axis, being present at low levels in the cell body but at increasingly high density (7- to 10-fold compared to the soma) in the apical dendrites.[11] The high dendritic density of HCN channels places them in proximity to excitatory inputs, the vast majority of which arrive in the dendrites. Because HCN channels are open at rest, they diminish the input resistance of the dendrites to incoming synaptic currents, decreasing the voltage change produced by an EPSP; conversely, when HCN channels are inactivated, input resistance is higher, and EPSPs are increased in magnitude. In essence, I_h makes for "leaky" dendrites that do not faithfully transmit excitatory inputs. While I_h also causes resting potential depolarization that opposes its inhibitory effect on action potential firing, it appears than in pyramidal neurons the high dendritic density of I_h and its attenuating action on synaptic inputs (particularly repetitive inputs) predominate. This is illustrated in Fig. 7–1, where it can be seen that the inhibitory actions of I_h on input resistance and EPSP summation outweigh its excitatory actions on resting potential.

In the early years following the first characterization of I_h in central nervous system (CNS) neurons, much was made of its dual influence on neuronal excitability, with suggestions by more than one reviewer of the field that I_h could be described as neither an excitatory nor an inhibitory conductance.[12,13] Now, with many investigations of its action published, it is clear that I_h has a net inhibitory action in the principal neurons of cortex and hippocampus: it reduces temporal summation (TS) and action potential (AP) firing from dendritic EPSPs; it inhibits forward propagation of dendritic APs and increases the threshold for dendritic calcium spikes; and dendritic HCN channels reduce acquisition of learning and memory in several in vivo paradigms. These findings are summarized in Table 7–1.

In nonpyramidal inhibitory interneurons of cortex and hippocampus, it appears that I_h has a predominantly somatic localization; therefore, its influence on excitability is mediated more through its depolarization of the resting potential, opposite to its action in principal neurons.[14] Thus, inhibition of HCN

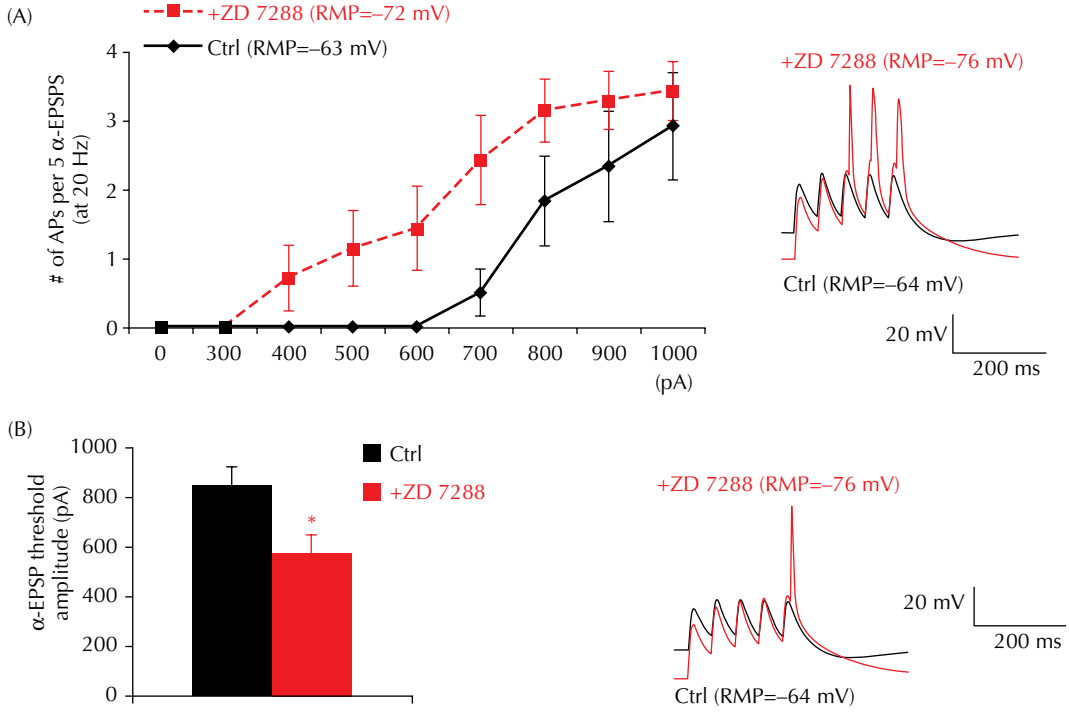

Figure 7–1. Blockade of HCN channels increases excitability in pyramidal neurons. **A**. Action potential (AP) firing elicited by current injection of α waveforms during dendritic current clamp recordings (~200 µm from the soma) under control conditions and after blockade of HCN channels with ZD 7288. Despite the hyperpolarization of the resting membrane potential (RMP) that occurs after HCN channel blockade, increased temporal summation produces increased AP firing through a wide range of α-EPSP amplitudes. **B**. Measurement of the threshold α-EPSP amplitude needed to produce a single AP shows that the threshold is decreased following HCN channel blockade, again showing increased excitability.

Table 7–1 Actions of HCN Channels in Pyramidal Neurons

Neuron	Action of HCN Channels on Excitability
CA1	Reduces and normalizes TS; reduces AP firing from dendritic inputs;[5,11,48,63] inhibits dendritic Ca^{2+} spikes[64]
	Reduces LTP and spatial learning;[65] reduces intrinsic excitability after LTP via CAMKII;[66] loss of I_h increases intrinsic excitability after LTD via mGluR[67]
	Increases rebound AP firing after hyperthermia-induced seizures[31,39]
	Loss of I_h post-SE increases TS and AP firing[4]
NC	Reduces and normalizes TS;[68,69] inhibits dendritic calcium spikes;[70] inhibits dendritic calcium spikes and burst firing in WAG/Rij epileptic rats[26,27]
EC	Inhibits AP firing; loss of HCN post-KA increases excitability;[33] inhibits AP firing after D1 receptor activation[71]
	Knockout of HCN1 increases excitability and sensitivity to convulsants[3]
PFC	Reduces spatial learning in primates and rats; I_h blockers in vivo increase neuronal firing;[72] inhibits excitability and dendritic calcium spikes; α2-NARs inhibit I_h and increase excitability[73,74]

Abbreviations: AP, action potential; CA1, hippocampus cornu ammonis area 1; CAMKII, Ca2+/calmodulin-dependent protein kinase II; D1, dopamine receptor type 1; EC, entorhinal cortex; KA, kainic acid; LTD, long-term depression; LTP, long-term potentiation; mGluR, metabotropic glutamate receptor; NAR, noradrenergic receptor; NC, neocortex; PFC, prefrontal cortex; TS, temporal summation.

channels in interneurons reduces AP output, while activation of HCN channels increases firing. However, this opposite sign of HCN influence in inhibitory neurons is concordant with its excitatory effect in principal neurons: both actions of HCN channels serve to diminish the overall excitability of cortex and hippocampus.

CONTRIBUTION OF HCN CHANNELS TO EPILEPSY

Evidence for Human HCN Channelopathy

Evidence for HCN channelopathy in human epilepsy is thus far limited. Since virtually all clear-cut evidence for any ion channelopathy in epilepsy derives from the inherited or genetic epilepsies, we must first consider these conditions. There are no descriptions yet of genetic epilepsy with Mendelian inheritance of an HCN channel mutation, as have been reported for certain Na^+, K^+, and other voltage-gated ion channels.[15] This, of course, does not mean that such mutations do not exist, and it is possible that large-scale screening projects such as the Epilepsy Phenome-Genome Project will uncover them. Since only a small fraction of all epilepsies display Mendelian patterns of inheritance, if HCN channels are to be implicated in genetic epilepsy, they are more likely to be implicated as a polygenic or susceptibility trait. Several medium-scale screening projects of sporadic epilepsy have reported polymorphisms in HCN genes occurring at higher frequency in case versus control patients. One study of 84 patients with idiopathic generalized epilepsy identified a single *HCN1* polymorphism (*A881T*) that was not identified in 510 controls. There was a far higher degree of sequence variation in the *HCN2* gene; however, there were only two nonsynonymous mutations.[16] One of these, *R527Q*, was analyzed using heterologous expression; I_h generated from the mutant channels was found to have biophysical properties similar to those from wild-type channels. A three-proline deletion in *HCN2* identified in one patient in the first study was also independently observed in another study of patients with idiopathic generalized epilepsy (IGE) or febrile seizures (FS).[17] This variant was found in 3 out of 65 (2.3%) unrelated epilepsy patients, all of whom had FS, but in 0 of 72 patients with IGE and 3 of 772 controls. Analysis of expressed mutant channels suggested an increase in I_h. Again, since this particular mutation has not thus far been found to cosegregate with disease, it cannot at this point be regarded as causative of epilepsy but only as a possible susceptibility trait.

It is worth noting that several studies have identified *HCN4* mutations in association with inherited cardiac arrhythmia.[18,19] Thus, at present, the strongest association of HCN channelopathy and disease is for this subtype, which is minimally expressed in the adult brain.

Investigation of HCN channel expression in human brain tissue from patients with epilepsy has similarly been limited. A comparison of HCN channel mRNA expression from temporal lobe resections overall found no significant change in comparison to autopsy controls; however, a subgroup of patients with the greatest degree of hippocampal sclerosis appeared to have an increase in *HCN1* expression limited to the dentate gyrus (DG).[20] This finding was surprising, since DG neurons normally demonstrate very little I_h, and was interpreted as a potential "compensatory" upregulation of expression in the most severely affected patients. Other investigators found that I_h magnitude measured in neocortical neurons from brain tissue acutely removed during epilepsy surgery inversely depended on the frequency of presurgical seizures, suggesting that more severe epilepsy was associated with a loss of neocortical HCN channel function.[21] In this study, however, no control comparisons were made, a common limitation of studies involving live human tissue.

In summary, the human evidence for genetic HCN channelopathy in epilepsy is thus far anecdotal. However, a significant body of evidence obtained from animal modeling suggests that HCN channelopathy could be causative of genetic epilepsy and develops in the setting of acquired epilepsy as well.

HCN Channels in Animal Models of Genetic Epilepsy

The above human studies provide suggestive, but still anecdotal, evidence for human genetic HCN channelopathy. Studies in animal models

of genetic deletion of HCN channels advance a far more compelling case that this ion channel may be relevant to epilepsy. Constitutive knockout of the *hcn2* gene produced a phenotype consistent with the high density of the HCN2 subunit in the thalamus: a tendency of thalamocortical neurons studied in brain slices to fire bursts of action potentials, and spontaneous absence seizures, marked by generalized 5 Hz spike-wave discharges, detected in the mutant animals.[2] These mice also displayed a cardiac sinus arrhythmia, consistent with loss of HCN2 channel expression from sinoatrial node cells.

Two studies have examined *hcn1* deletion for evidence of epilepsy.[3,22] Neither of these studies detected spontaneous seizures in knockout animals. However, both studies demonstrated that *hcn1* deletion increased the severity of seizures, whether provoked by kindling or chemoconvulsants, with a high rate of death from status epilepticus (SE). In the kainic acid (KA) model of epilepsy, even after the dose of KA was halved to reduce death from SE, the latency period from SE to the occurrence of the first spontaneous seizure was shortened from 386 h to 60 h.[3] This study went one step further to examine pyramidal neuron excitability in *hcn1* knockout mice. Consistent with prior work showing an inhibitory effect of HCN channels on excitability in cortex and hippocampus (Table 7–1), pyramidal neurons lacking the principal HCN subunit mediating I_h demonstrated both increased intrinsic excitability and prolonged excitatory responses to synaptic stimulation. Both studies confirmed the role of HCN channels as exerting an inhibitory and even an anticonvulsant influence on cortical and hippocampal excitability. That *hcn1* deletion produces cortical and hippocampal hyperexcitability while not producing epilepsy is interesting and at this point not subject to easy explanation. One possible explanation is that constitutive deletion of HCN1 channels leads to compensatory upregulation of tonic $GABA_A$ receptor-mediated current that may partially suppress hyperexcitability.[23] Use of conditional knockout animals of HCN channels might help support or disprove this idea. A similar situation is reported for the K^+ channel subunit Kv4.2, a predominantly dendritic subunit that exerts a significant influence on neuronal excitability. In fact, deletion of the gene encoding for Kv4.2 also does not result in epilepsy.[24]

HCN channel dysfunction has also been identified in inbred rodent models of genetic epilepsy. One such model of absence epilepsy, the Wistar Albino Glaxo/Rij (WAG/Rij) rat, shows loss of HCN channel function. WAG/Rij rats display spontaneous spike-wave discharges associated with behavioral absence-like episodes, with seizures appearing to begin from a cortical focus, then generalizing via rapid intracortical spread.[25] The cortical origin of seizures has been found to correlate with loss of I_h in neocortical neurons, accompanied by a loss of HCN1 protein expression;[26] this loss of HCN1-mediated currents was confined to the dendrites of neocortical neurons, progressed during development, and paralleled the onset of behavioral seizures.[27] Neither of these studies addressed the question of whether the changes in HCN channel expression and function were the cause or effect of seizures in this animal model (that most likely has numerous gene mutations contributing to epilepsy); however, a subsequent study suppressed developmental seizures in the WAG/Rij rat with ETX administration for the first 5 months of life, then measured changes in HCN1 expression as well as that of two Na^+ channel proteins known to be dysregulated in this model, Nav1.1 and Nav1.6.[26] Surprisingly, epilepsy-associated changes in all three ion channels were reversed when seizures were chronically suppressed, and although spontaneous seizures recurred when ETX treatment was stopped, the time course of their development was markedly prolonged.[28] These intriguing results suggest that HCN1 channels in the WAG/Rij model of epilepsy, while not causative of epilepsy, may potentially contribute to the course of epileptogenesis by amplifying the effect of spontaneous seizures. This phenomenon in other contexts has been referred to as "seizures beget seizures" and may be relevant in acquired models of epilepsy as well, as discussed below.[29]

HCN Channel Downregulation in Animal Models of Acquired Epilepsy

It is interesting that the first studies to link HCN channels and epilepsy were landmark publications that launched much of the future investigation in the field, yet turned out not to

predict subsequent developments. This work used a newly characterized model of febrile seizures in which immature rats were exposed to high temperature, provoking SE.[30] This stimulus produced an unexpected, long-lasting increase in GABAergic inhibition in CA1 pyramidal neurons accompanied by an increase in I_h measured at the soma. It was suggested that hyperexcitability might result following IPSPs as the increased I_h triggered rebound AP firing.[31] However, follow-up work using the same model but investigating regulation of the *hcn1* gene transcription and protein production found persistent downregulation of expression; *hcn2* was transiently upregulated, then returned to baseline.[32]

Subsequent work in other animal models of acquired epilepsy has consistently found downregulation of HCN channel expression and function, changes that were opposite to the upregulation of I_h initially seen in hyperthermia model. The first study to look at I_h changes in a model of SE induced by KA used whole-cell patch clamp recordings in the dendrites of entorhinal cortical neurons.[33] This was an important advance in methodology since, as described above, the vast majority of HCN channels are localized to the dendrites of pyramidal neurons, raising the possibility that in epilepsy they are differentially regulated compared to somatic channels. (Most subsequent studies have used dendritic patch clamp recording to study changes in I_h in epilepsy.) These authors found that dendritic excitability increased in an HCN channel-dependent fashion within 24 h of KA-induced SE and remained so at 1 week post-SE, demonstrating an early change in HCN channel function that promoted hyperexcitability.

Subsequent work tracked changes in I_h during the development of epilepsy and confirmed the association of decreased I_h during epileptogenesis. When dendritic recordings were made from CA1 pyramidal neurons in animals exposed to pilocarpine-induced SE, I_h was significantly reduced at two different time points, an acute period 1 week post-SE when the animals, as verified by electroencephalographic (EEG) recordings, started to manifest spontaneous seizures, and at 1 month after SE, when the animals were chronically epileptic.[4] In both cases, there were two changes in I_h properties that reduced its overall magnitude: a reduction of dendritic I_h density that was reflected in a loss of HCN protein expression, and a hyperpolarizing shift in I_h activation that reduced the amount of current active at rest. The downregulation of I_h gating progressively worsened as seizure frequency increased from the 1 week to the 1 month time points, while the loss of I_h density was constant. Both of these changes were associated with increased excitability of CA1 pyramidal neurons.

A second study essentially replicated these findings, and further observed that loss of I_h altered the intrinsic resonance of pyramidal neurons for synaptic excitation at theta frequencies,[34] possibly underlying deficits in hippocampal-dependent memory tasks that accompany temporal lobe epilepsy.[35] Similar chronic loss of I_h was observed following KA-induced SE, although the authors also observed a transient (1–2 days post-SE) increase in I_h at the soma.[36] Loss of I_h and HCN channel expression has been observed in other animal models of epilepsy, including perinatal hypoxia[37] and cortical dysplasia.[38] This suggests that the loss of I_h seen in chemoconvulsant models is not model-specific and may be a general feature of animal models of epilepsy.

It is not entirely clear why the discordant result of increased I_h was observed in the initial hyperthermia model. It is probably not explained by recordings done exclusively at the soma in those first studies, as a subsequent report using dendritic recordings in hyperthermia-exposed animals found a similar upregulation of I_h.[39] Possibly the discrepancy results from the mild epilepsy phenotype that results from hyperthermia-provoked SE, yielding only brief electrographic seizures in a minority of animals and at later time points than those studied in the original description.[40] By contrast, the chemoconvulsant models produce a much more robust epilepsy phenotype with a rapid developmental onset.

Mechanisms of HCN Channel Downregulation in Acquired Epilepsy

The findings in the pilocarpine model revealed that HCN channelopathy in acquired epilepsy consists of two separate mechanisms of ion channel dysfunction: a loss of I_h current density manifested by reduced HCN1 protein expression,

and a downregulation of voltage-dependent gating of the remaining channels. It is important to ask whether either or both of these phenomena are the cause or the effect of epilepsy. This question was at least partially answered by controlling seizures with phenobarbital administration for the first week post-SE and then measuring I_h properties.[4] Preventing spontaneous seizures reversed the hyperpolarizing shift in I_h gating, demonstrating that this was a seizure-dependent phenomenon. The loss of I_h density and HCN1 protein expression, however, was independent of ongoing seizures. Recent evidence shows that the loss of HCN channels begins as rapidly as 1 h post-SE, well before the onset of spontaneous seizures, and thus may be a contributor to the development of the epileptic condition.[41] While gating changes in the remaining channels are caused by seizures rather than the reverse, it is conceivable that by promoting neuronal hyperexcitability, this HCN channelopathy mechanism could contribute to the gradual run-up in seizure frequency that occurs during epileptogenesis. Some support for this latter idea comes from the observation that *HCN1* knockout mice have a much more rapid development of epilepsy after chemoconvulsant-induced SE than wild-type mice.[3]

What are the molecular underpinnings of the separate processes producing HCN channelopathy in epilepsy? For the loss of HCN channel expression, it is clear that transcriptional downregulation is at least one mechanism. Several investigators have validated the loss of *HCN1* mRNA expression at time points beginning 3 days after SE and persisting into the period of chronic epilepsy.[32,34,42] In an in vitro model of epilepsy using KA administration in organotypic slice cultures, this loss of *HCN1* transcription was dependent on α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and Ca^{2+}/calmodulin-dependent protein kinase II (CAMKII) activation,[43] although in vivo involvement of these entities is unknown. Whether transcriptional downregulation is the earliest process leading to loss of HCN channel expression is unclear. HCN channels, like other ion channels, are subject to dynamic regulation of their membrane localization and stability. The best-described mechanism involves an accessory protein, tetratricopeptide-repeat containing Rab8b interacting protein (TRIP8b). This protein, expressed as a multitude of alternatively spliced isoforms, interacts with HCN1 channels and stabilizes their somatodendritic expression.[44–46] It appears that the interaction between Trip8B and HCN1 channels is reduced in epilepsy, but this process does not appear to begin prior to the onset of transcriptional downregulation.[36]

More is known about the processes underlying the downregulation of HCN channel gating in epilepsy. It is well known that although cAMP upregulates the gating of HCN2 and HCN4 channels, the HCN1 isoform is largely insensitive.[47] However, the gating of HCN1 channels is modulated by phosphorylation, notably by p38 mitogen-activated kinase (p38 MAPK), with kinase activation producing a depolarizing (upregulating) shift in gating and kinase inhibition producing the opposite effect.[48] Dephosphorylation by the serine-threonine phosphatase calcineurin (CaN) produces concordant effects on HCN1 gating, with increased phosphorylation upregulating gating and decreased phosphorylation downregulating it.[49] Since HCN channel gating is downregulated in chronic epilepsy, it would be reasonable to ask whether these phosphorylation pathways are dysregulated as well; in fact, p38 MAPK is relatively deactivated in epileptic tissue, while CaN activity in enhanced.[49] These changes in phosphorylation activity were driven by unknown upstream signaling processes and not by changes in the protein expression of the individual entities. This suggests that the epileptic state is associated with dynamic changes in signaling processes that might be amenable to pharmacological targeting, as has been suggested for another phosphorylation pathway, the mammalian target of rapamycin.[50] Phospholipid pathways may also modulate HCN channels, but whether they are altered in epilepsy is unknown.[51,52]

Antiepileptic Drug Actions on HCN Channels

The downregulation of HCN channels in epilepsy suggests that if this process could be pharmacologically reversed, an antiepileptic benefit might be realized. Interestingly, there are several reports of existing AEDs that interact with HCN channels. The first published report showed that acetazolamide (ACZ), a carbonic anhydrase inhibitor with some efficacy in absence epilepsy, upregulated I_h in thalamocortical neurons.[53] This effect was attributed to an

alkalinization of intracellular pH, leading to a 5 mV depolarization of voltage-dependent gating. The AED lamotrigine (LTG) also upregulates I_h through a ~10 mV depolarizing shift of gating in hippocampal pyramidal neurons.[5] In the case of LTG, although its effect was demonstrated in hippocampal neurons, upregulation of I_h in neocortical or thalamic neurons might potentially explain its efficacy against generalized seizures. Application of LTG blocks spontaneous rhythmic firing in combined thalamocortical brain slices.[54] The action of LTG on thalamic neurons is dependent on HCN channels, as was shown in recordings from reticular thalamic neurons, spontaneously bursting-firing cells whose rhythmic output is dependent in part on HCN2 channels. When LTG was superfused on thalamic tissue slices, the frequency of rhythmic firing was markedly reduced; however, this action of LTG was abolished in cells from *HCN2* knockout animals.[55] A similar test of the specificity of LTG action in hippocampus or neocortex using *HCN1* knockout animals has not yet been reported. And although LTG also acts to reduce Na^+ currents in a manner similar to that of the AEDs phenytoin (PHT) and carbamazepine (CBZ),[56] this mechanism of action is unlikely to explain its efficacy in generalized epilepsy, as PHT and CBZ are poorly effective in these syndromes.[57]

Another angle on the action of LTG is seen in its effects in interneurons residing in the stratum oriens that project to pyramidal neuron dendrites.[58,59] In these spontaneously active interneurons, HCN channels are presumably localized perisomatically such that upregulation of I_h depolarizes the resting membrane potential and increases the firing rate; this had the concordant effect of decreasing pyramidal neuron excitability by virtue of an increased frequency of spontaneous inhibitory postsynaptic currents. This result was notable because the actions of AEDs are often considered only from the perspective of inhibition of principal neurons, whereas the same action on interneurons might be expected to be counterproductive on overall brain excitability. This study demonstrated a potentially complementary action of LTG on interneurons compared to their pyramidal counterparts that arose from differing contributions of HCN channels to excitability in the two neuron types.

Aside from LTG and ACZ, the conventional AED gabapentin has also been shown to upregulate I_h.[60] It would seem straightforward to ask whether HCN channel inhibition by a drug such as ZD 7288 might have a proconvulsant effect. Some studies using in vitro models of seizures to address this question have reported a paradoxical anticonvulsant action of HCN channel inhibition.[61] Other studies have reported that ZD 7288 inhibits glutamatergic transmission; therefore, it cannot be considered a selective antagonist for HCN channels when synaptic transmission is studied.[62] Because *hcn1* deletion lowers the threshold for provoked seizures and SE, and *hcn2* deletion results in generalized epilepsy, it seems reasonable to conclude that HCN channels exert an anticonvulsant effect on the brain as a whole. This would suggest that discovery of novel specific HCN channel agonists might be a productive avenue for future AED development.

CONCLUSIONS

The HCN channel has emerged as a compelling new candidate channelopathy in epilepsy. It plays a powerful inhibitory role in cortical and hippocampal excitability, both at single-neuron and network levels, and it influences the development of thalamocortical rhythms as a result of its high expression in thalamic nuclei. In animal models of acquired epilepsy, HCN channel expression is downregulated, contributing to pathological hyperexcitability. Conversely, several AEDs upregulate the function of HCN channels, offering the potential of a novel target for further AED development.

Evidence of human HCN channelopathy is thus far anecdotal. However, given the substantial support from animal models for a pathological role of this channel in acquired epilepsy in particular, understanding the mechanisms by which HCN channels are dysregulated may provide insights applicable to the larger number of epileptic ion channelopathies that are continually being characterized.

Chapter 8

Phasic $GABA_A$-Mediated Inhibition

Enrico Cherubini

γ-Aminobutiric acid (GABA) is the main inhibitory neurotransmitter in the adult mammalian central nervous system (CNS). It inhibits neuronal firing by activating two different classes of receptors, $GABA_A$ and $GABA_B$. Unlike $GABA_A$ receptors, which form integral ion channels, $GABA_B$ receptors are coupled to ion channels via guanine nucleotide-binding proteins and second messengers. $GABA_A$ receptors mediate two distinct forms of inhibition, phasic and tonic. The first consists of fast inhibitory postsynaptic potentials (IPSPs) regulating point-to-point communication between neurons. The second consists of a persistent inhibitory conductance that plays a crucial role in regulating membrane potential and network excitability.[1] In the case of phasic inhibition, synaptic $GABA_A$ receptors, facing presynaptic release sites, are activated by brief exposure to a high concentration of GABA released by exocytosis of presynaptic vesicles. Once released, GABA diffuses throughout the neuropil before being taken up by selective plasma membrane transporters, which contribute to the clearance of the neurotransmitter.[2] In the case of tonic inhibition, extrasynaptic $GABA_A$ receptors, localized away from the synapses, are persistently exposed to low concentration of "ambient" GABA.

This review will focus on $GABA_A$-mediated phasic inhibition which, in physiological conditions, exerts a powerful control on cell excitability and network oscillations thought to be associated with higher cognitive functions.[3] An impairment of fast GABAergic signaling is involved in various psychiatric and neurological disorders including epilepsy.[4]

$GABA_A$-MEDIATED IPSCS: PRESYNAPTIC REGULATION

Source of GABA

GABA is released from GABAergic interneurons which comprise ~15% of the total neuronal population. It is synthesized from glutamate by the enzyme glutamic acid decarboxylase (GAD65 and GAD67) and, in particular, by GAD65, which is preferentially localized at GABAergic nerve terminals. GABAergic interneurons constitute a heterogeneous group of cells that have been characterized on the basis of their firing patterns, molecular expression profiles, and selective innervation of different domains of principal cells.[5] They provide feedback and feedforward inhibition.[6,7] In addition, the spatiotemporal dynamics between the activity of interneurons, with extensive axonal arborizations, and that of pyramidal cells leads to coherent network oscillations crucial for information processing.[5,8]

In the majority of cases, the release of GABA from GABAergic interneurons occurs via vesicle exocytosis, the process by which a single vesicle fuses with the presynaptic plasma membrane and releases its content into the synaptic cleft. However, the release of GABA may also occur in a nonvesicular way through the reversal of GABA transporters.[9] Thus, in pathological conditions (e.g., temporal lobe epilepsy), bursting-induced membrane depolarization and an increase in intracellular $[Na^+]$ would enhance GAT-1 reversal (GAT-1 is the isoform of GABA transporters localized almost exclusively on axon terminals) and GAT-1-mediated GABA release.[10] Recently, using a heterologous expression system, Wu et al.[9] have provided evidence that the membrane potential at which the GABA transporter GAT-1 reverses is close to the normal resting potential of neurons and that the reversal can occur rapidly enough to release GABA during action potentials. This is consistent with the hypothesis that transporter-mediated GABA release can also contribute to the maintenance of phasic $GABA_A$-mediated inhibition in physiological conditions, as in the case of vesicular transmitter failure during high-frequency firing, thus acting as a brake to prevent runaway excitation.[10]

The release of GABA from presynaptic nerve terminals is influenced by the probability of release *P* and by the number of release sites *N*. Large *P* and/or large *N* can be used to distinguish strong from weak GABAergic synapses. Strong connections produce large IPSPs with few transmitter failures. Weak synapses with high failure rates exhibit paired-pulse facilitation (facilitation of a second response evoked at a short interval from the first), while strong synapses with low failures rates exhibit paired-pulse depression (depression of a second response occurring at a short interval from the first).

Regulation of GABA Release by Presynaptic Intracellular Calcium Stores

Interestingly, *P* can be affected by spontaneous calcium signals (reminiscent of "calcium sparks"),[11] such as those detected at cerebellar interneuron–Purkinje cell synapses.[12] These events (sensitive to ryanodine) depend on the release of calcium from intracellular calcium stores following an action potential-dependent increase in intracellular calcium rise.[13] Ryanodine-sensitive calcium stores are likely to mediate large-amplitude miniature inhibitory postsynaptic currents (mIPSCs) due to the synchronous release of GABA from several release sites. At the same synapses, presynaptic calcium stores also regulate the evoked release of GABA, as demonstrated by the ryanodine-induced decrease in the paired-pulse ratio and the increase in the coefficient of variation,[14] defined as the ratio between the standard deviation and the mean. *P* can also be also modified in a synapse-selective manner by receptors localized on presynaptic terminals, whose activation up- or downregulates the release of GABA. In addition, synapses can differ in the number of functional release sites, *N*, which can vary from 1 to 10s. For instance, at individual synaptic contacts among stellate cells in the cerebellum, presynaptic action potentials generate synaptic currents presumably arising from single or multiple release sites.[15] In case of multiple release sites, decreasing the probability of GABA release (by modifying the calcium/magnesium ratio) decreases the average number of release sites and shifts the amplitude distribution toward smaller values. In contrast, at single release sites, the amplitude distribution of the evoked currents whose potency

(successes without failures) is unaffected by decreasing the release probability can be fitted with a Gaussian function.[16,17] Some GABAergic synapses are also characterized by multivesicular release. This occurs when the content of several vesicles is released simultaneously by an action potential at a presynaptic active zone, leading to fluctuations of inhibitory synaptic events that vary in magnitude according to the degree of receptor saturation. For instance, at cerebellar stellate-basket cell synapses, more than one containing vesicle, released slightly asynchronously, leads to a very small increase in the peak amplitude of the synaptic currents because, at these synapses, receptor occupancy is high and close to saturation.[6,17,18] It is noteworthy that the functionally determined number of release sites is usually larger than those structurally defined at the electron microscopic level, because a single presynaptic active zone is often made by a large number of functional release sites.[19]

Regulation of GABA Release by Presynaptic $GABA_A$ and $GABA_B$ Receptors

The release of GABA is up- or downregulated by a variety of receptors localized on GABAergic terminals in proximity to the release sites. Of particular interest are $GABA_A$ and $GABA_B$ autoreceptors, which can be activated by spillover of GABA from axon terminals or by "ambient" GABA present in the extracellular medium. While high-*P* synapses more likely undergo activity-dependent depression of synaptic transmission, low-*P* synapses undergo activity-dependent facilitation. A decrease in *P* may result from the shunting effect of GABA due to the increase in conductance produced by presynaptic receptor activation. This, in turn, would produce a decrease in the amplitude of presynaptic spikes or prevent them for invading axon terminals.[20] Alternatively activation of $GABA_A$ receptors may reduce *P* via inactivation of Na^+ or Ca^{2+} channels. An increase in *P* following activation of axonal $GABA_A$ receptors may result from depolarization of presynaptic terminals (due to the high chloride concentration in the terminals and the reversal of GABA, which would be more depolarized with respect to the resting membrane potential), with consequent activation of voltage-dependent calcium channels and elevation of intracellular calcium.[21] In the immature hippocampus, activation of $GABA_A$ receptors localized on mossy fiber terminals (which in the immediate postnatal period are GABAergic)[22] by spillover of GABA from neighboring GABAergic interneurons or mossy fibers themselves has been shown to enhance mossy fibers excitability, thus contributing to activity-dependent synaptic facilitation.[23] In cerebellar interneurons, activation of $GABA_A$ autoreceptors[24] leads to an enhancement of GABA release which is developmentally regulated [25] (see Fig. 8–1).

In contrast to $GABA_A$ receptors, activation of presynaptic $GABA_B$ receptors always limits GABA release via G-protein-dependent inhibition of P/Q and N types of voltage-dependent calcium channels.[26] For instance, at GABAergic synapses between Golgi cells and granule cells in the cerebellar glomerulus, activation of presynaptic $GABA_B$ receptors leads to a reduction of *P*.[27] In the neonatal hippocampus, spillover of GABA from mossy fiber terminals downregulates its own release, leading sometimes to synapse silencing.[28]

DYNAMICS OF GABA TRANSIENTS IN THE SYNAPTIC CLEFT

Once released from presynaptic nerve terminals, GABA crosses the synaptic cleft and binds to postsynaptic receptors. Fast synaptic transmission requires that GABA be released at high concentration for a very short period of time. The time course of the agonist in the cleft is therefore a key factor in shaping synaptic currents. Allosteric modifiers of receptor gating have allowed quantitative estimation of the peak concentration of the agonist in the cleft and the time course of its clearance. Using this method, the synaptic GABA transient was estimated to be ~3 mM, while the speed of GABA clearance was estimated to follow a single exponential function of ~100 μs.[29,30] Such brief exposure of $GABA_A$ receptors to GABA indicates that activation of postsynaptic receptors occurs in nonequilibrium conditions. Similar results have been found with fast-off competitive $GABA_A$ receptor antagonists. With this approach, synaptic GABA has been proposed to peak at 3–5 mM and to be cleared out within

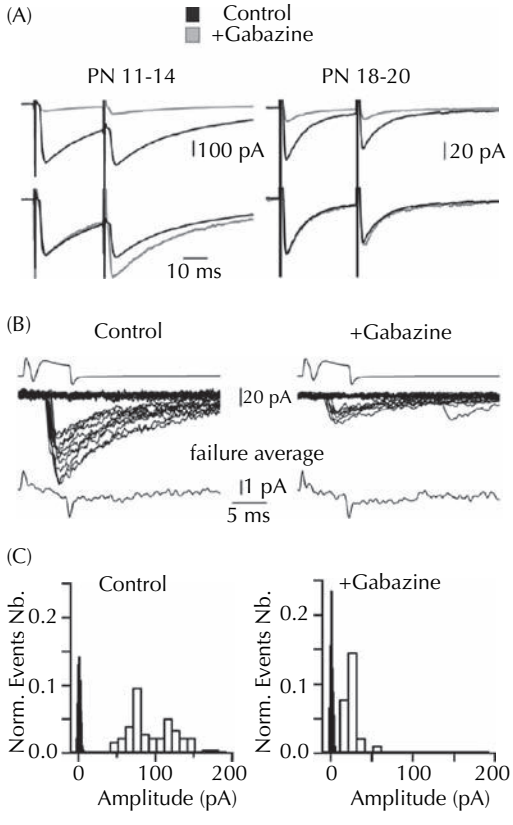

Figure 8–1. Endogenous activation of presynaptic $GABA_A$ receptors enhances GABA release from juvenile cerebellar basket cells. **A.** Gabazine (300 nM) reduced much more potently the amplitude of evoked synaptic currents in the younger than in the older age group (black traces: control; gray traces: + gabazine). However, after scaling to the amplitude of the first response, an increase in the paired-pulse ratio was apparent following gabazine application in the P11–P14 group but not in the P18–P20 group (bottom panels). **B.** Traces from two connected molecular layer interneurons showing depolarization-driven presynaptic action currents (top) and postsynaptic responses (middle traces) during control conditions (left) and in the presence of gabazine (right). Failure averages (bottom traces) fail to reveal any synaptic currents. Positive and negative current transients mark the onset and offset of the presynaptic depolarizing voltage step, reflecting capacitive coupling between presynaptic and postsynaptic pipettes. In this cell, gabazine reduced the peak current amplitude to 14% of the control level. **C.** Amplitude histograms for successful events (open bins) and for failures (closed bins), from the data in **A.** Note the increase in failure rate with gabazine. Reproduced with permission from ref. 25.

300–500 μs.[31] Although $GABA_A$ receptors are exposed to GABA for a very short period of time, synaptic currents outlast the duration of the GABA transient. This is because the activated channels have a high probability of entering into long-lived desensitized states, which precede channel reopening and agonist unbinding.[32]

GABA Transients May Regulate Synaptic Variability

It is noteworthy that, in cultured hippocampal neurons, fast-off competitive antagonists have been shown to differentially block small and large mIPSCs, suggesting that, at nonsaturated synapses, changes in the peak concentration and the speed of GABA clearance in the cleft may be important sources of presynaptic variability.[33] Interestingly, in the neocortex, slow $GABA_A$ receptor-mediated inhibitory postsynaptic currents (IPSCs), originating from neurogliaform cells, are generated by a GABA transient with unusual characteristics, as indicated by the large inhibitory effect of the low-affinity competitive $GABA_A$ receptor antagonist (1,2,5,6-tetrahydropyridin-4-yl)methylphosphinic acid (TPMPA)[34] (see Fig. 8–2).

It has been proposed that the high density of neurogliaform cell axons could counteract transmitter reuptake mechanisms and that GABA released from these terminals could act as a volume transmitter to reach receptors at synaptic and extrasynaptic sites in the tissue with which the axons intermingle.[35]

Once released into the cleft, the agonist is cleared by the combined action of diffusion and buffering systems. Diffusion is influenced by the geometry of the cleft and by the viscosity of the extracellular liquid,[36] which is composed of glycoproteins and fibrils. Buffering systems consist of membrane transporters, receptors, and other GABA binding sites.

GABA Transporters

GABA transporters not only passively bind GABA but also actively remove it from the extracellular space. High-affinity Na^+/Cl^-coupled GABA transporters are expressed on the plasma membrane in close proximity to the synapses. Of the four GABA transporters identified to date (GAT-1, GAT-2, GAT-3, and BGT-1), GAT-1 prevails at GABAergic synapses and is almost exclusively localized on axon terminals (forming symmetric synaptic contacts)

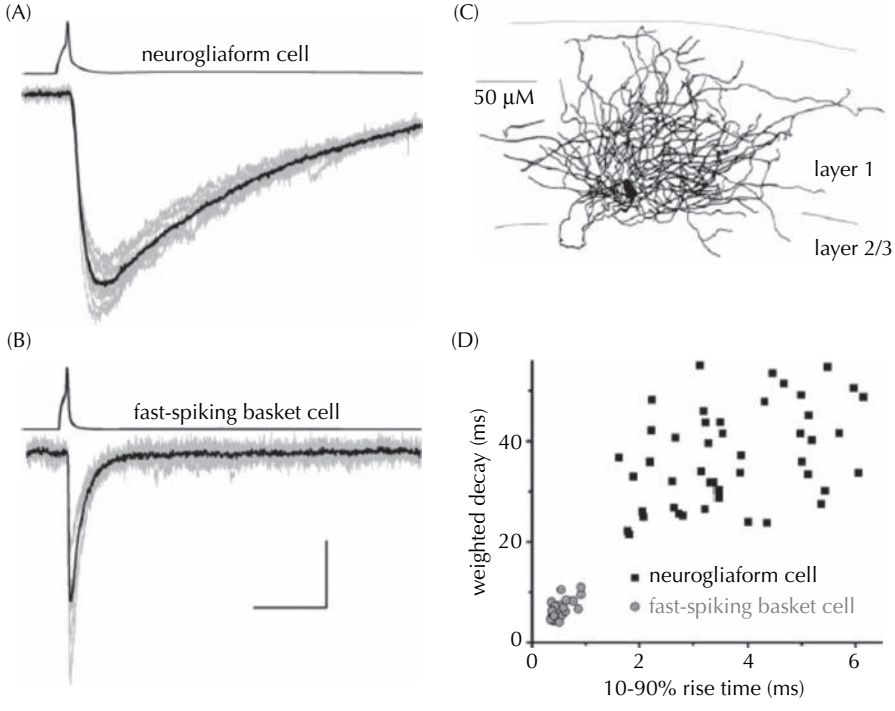

Figure 8–2. Slow $GABA_A$-mediated IPSCs originating from neurogliaform cells. **A.** Ten consecutive slow IPSCs (gray, lower trace) and their average (black) evoked in a layer 2/3 pyramidal cell after single action potentials in a layer 1 neurogliaform cell (upper trace). **B.** Inhibitory postsynaptic currents evoked by a layer 2 fast-spiking basket cell. **C.** Camera lucida reconstruction of the soma and axons of a neurogliaform cell. Gray lines indicate the borders of cortical layers. **D.** Comparison of the kinetics of postsynaptic responses evoked by neurogliaform cells (black squares) and fast-spiking basket cells (gray circles). Each point represents an individual connection. Reproduced with permission from ref. 34.

and on distal astrocytic processes.[37] The use of selective GAT-1 inhibitors has allowed investigation of the functional role of this transporter in $GABA_A$-mediated inhibition. Thus, in rat neocortex and hippocampus, blockers of GAT-1 have been shown to affect not only tonic but also phasic $GABA_A$-mediated inhibition, as indicated by the increase in the decay time of evoked IPSCs.[38–42] GAT-1 seems to play a crucial role during sustained neuronal activity such as that observed during seizures.[43]

Recent experiments with neocortical neurons in slices obtained from GAT-1 knockout (KO) mice have demonstrated that high-frequency stimulation of GABAergic terminals induces slowly developing bicuculline-sensitive inward currents that last for several seconds and are larger in GAT-1 KO than in WT mice, indicating a severe impairment of GABA clearance from the extracellular space in the former. In addition, in GAT-1 KO mice, stimuli delivered to the same fibers immediately after the high-frequency train evokes synaptic currents smaller in amplitude and exhibiting slower decay kinetics and a slower recovery process[43] (see Fig. 8–3).

Interestingly, GAT-1 KO mice exhibited increased expression of GABA-synthesizing enzymes GAD65 and GAD67 as an adaptive process for compensating for the loss of GAT-1.

$GABA_A$-MEDIATED IPSCS: POSTSYNAPTIC REGULATION

$GABA_A$ Receptors

The speed and reliability of inhibitory synaptic transmission require the presence of clustered

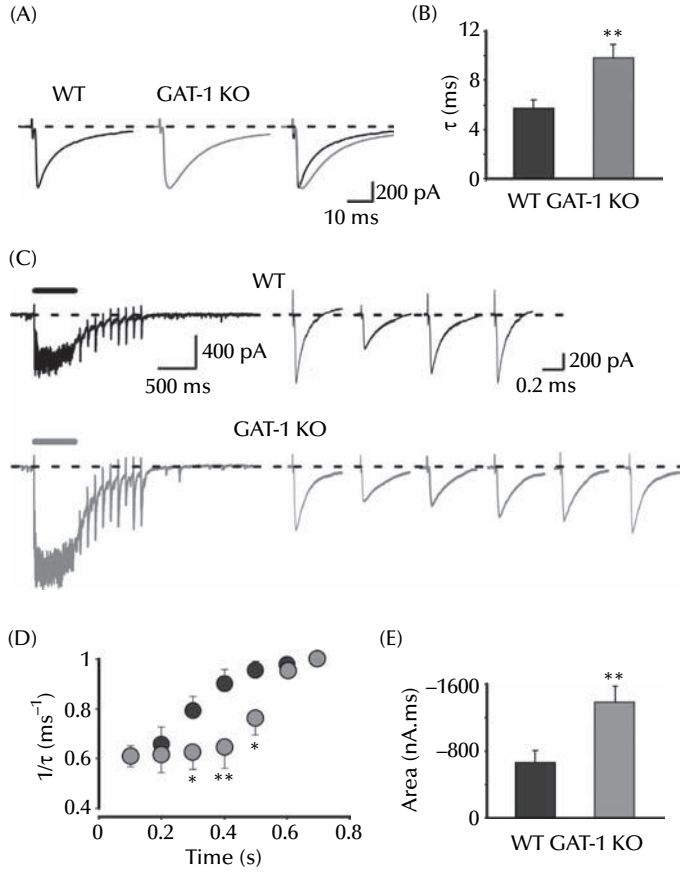

Figure 8–3. GABA transporters 1 play a crucial role during sustained synaptic activity. **A.** Prolonged decay of IPSCs evoked from layer II/III pyramidal neurons by local stimulation of GABAergic fibers (in the presence of 20 µM 6,7-dinitroquinoxaline-2,3-dione (DNQX) and 1 µM (2*S*)-3-[[(1*S*)-1-(3,4-Dichlorophenyl)ethyl]amino-2-hydroxypropyl](phenylmethyl)phosphinic acid hydrochloride (CGP 55845) in neocortical slices from GAT-1 KO mice compared to wild-type (WT) mice. **B.** Each column represents the mean decay time constant of IPSCs obtained from WT (n = 7) and GAT-1 KO mice (n = 7). $^{**}p < 0.01$. **C.** Representative traces recorded at –60 mV from WT and GAT-1 KO mice during and after repetitive stimulation of GABAergic fibers (50 stimuli at 100 Hz, horizontal bars) in WT (black) GAT-1 KO mice (gray). Note the larger inward current and the longer recovery time of individual IPSCs in GAT-1 KO mice. **D.** Recovery of the decay of individual IPSCs evoked at 200 ms intervals after the high-frequency stimulation train in WT (black) and GAT-1 KO mice (gray). Each point is the average of six experiments. **E.** Charge transfers associated with $GABA_A$-mediated slow inward currents induced by repetitive activation of presynaptic GABAergic terminals in WT (n = 6) and GAT-1 KO mice (n = 5). $^{*}p < 0.05$; $^{**}p < 0.01$. $GABA_A$ receptors at the plasma membrane in precise apposition to presynaptic releasing sites. The postsynaptic organization comprises a large number of proteins that ensure the correct targeting, clustering, and stabilization of neurotransmitter receptors. Among them, the tubulin-binding protein gephyrin plays a crucial role in the functional organization of inhibitory synapses.[44] Through its self-oligomerizing properties, gephyrin forms hexagonal lattices that trap glycine and $GABA_A$ receptors[45,46] and link them to the cytoskeleton. Disruption of gephyrin function leads to reduced $GABA_A$ receptor clustering,[47] an effect associated with loss of GABAergic innervation.[48] This observation suggests the existence of cross-talk between the post- and presynaptic sites of the synapse. The backward control of presynaptic signaling may occur via neuroligin 2, a postsynaptic cell adhesion molecule that directly binds gephyrin

through a conserved cytoplasmatic domain[49] and interacts transynaptically with neurexins.[50]

$GABA_A$ receptors belong to the Cys-loop ligand-gated ion channels family, which includes nicotine acetylcholine receptors (nAChRs), glycine receptors, and ionotropic 5-hydroxytryptamine ($5\text{-}HT_3$) receptors. Nicotine acetylcholine receptors and $5\text{-}HT_3$ receptors are cation-selective channels, while $GABA_A$ and glycine receptors are anionic-selective channels. All the subunit members of this family show 30% sequence homology but have greater similarity at the level of their secondary and tertiary structure. These receptors are organized as pentameric membrane-spanning proteins surrounding a central pore forming the ion channel. Each subunit has a large extracellular N terminus (containing a signal peptide, a cysteine bridge, and glycosylation sites), four hydrophobic transmembrane domains (M1–M4), an intracellular loop between M3 and M4 (containing protein kinase A, protein kinase C, and tyrosine kinase phosphorylation sites), and a short C terminus. M2 is crucial for receptor gating and selectivity. This region lines the channel pore and constitutes the most conserved part of the receptor. Introduction of site-direct mutagenesis of three amino acids from the M2 domain of glycine or $GABA_A$ receptors into the M2 segment of α7 nAChRs is sufficient to convert a cation-selective channel into an anion-selective channel.[51] Channel opening would result from the concerted tilting of the subunits that rotate around an axis parallel to the membrane plane.

Permeability of $GABA_A$ Receptor Channels

Activation of $GABA_A$ receptors opens channels largely permeable to Cl^-. However, a significant inwardly directed component of GABA-gated anionic current is carried by HCO_3^-.[52,53] The passive redistribution of H^+ and HCO_3^- following activation of $GABA_A$ receptors by GABA would lead to a more acidic intraneuronal pH.[54] Hence, the electrochemical equilibrium potential for HCO_3^- would be less negative (~15 mV) than the resting membrane potential, and since HCO_3^- can also act as a carrier of a depolarizing current, the GABA reversal potential (E_{GABA}) will not be identical to the equilibrium potential for Cl^- but it will shift toward more positive values.[55] Taking into account an HCO_3^- and Cl^- permeability ratio of 0.2–0.4, the quantitative influence of HCO_3^- on E_{GABA} can be estimated using the Goldman-Hodgkin-Katz equation, which shows that $[HCO_3^-]_i$ (~15 mM at a pH of 7.1–7.2) influences E_{GABA} in the same way as 3–5 mM of $[Cl^-]_i$. Thus, the depolarizing influence of HCO_3^- on E_{GABA} will be significant in neurons with low $[Cl^-]_i$, as in adults, but it will be negligible in immature neurons in which $[Cl^-]_i$ is relatively high. High $[Cl^-]_i$ in immature neurons would make the equilibrium potential for Cl^- less negative than the resting membrane potential, providing the driving force that accounts for the depolarizing and excitatory action of GABA.[56] $[Cl^-]_i$ is under the control of two main cation-chloride cotransporters, NKCC1 and KCC2, which increase and lower $[Cl^-]_i$, respectively.[55] Due to the low expression of the KCC2 extruder at birth, chloride accumulates inside the neuron via NKCC1. The developmentally upregulated expression of KCC2 toward the end of the first postnatal week results in the extrusion of chloride, causing the shift of GABA from the depolarizing to the hyperpolarizing direction.[57] KCC2 extrudes K^+ and Cl^- using the electrochemical gradient for K^+. Genetically encoded chloride probes have allowed investigators to directly monitor $[Cl^-]_i$ in a noninvasive way.[58] Using this tool, it has been clearly demonstrated that $[Cl^-]_i$ decreases during development in hippocampal neurons. It is worth mentioning that GABA-induced depolarization may still result in inhibition of cell firing if the positive shift in the membrane potential is associated with a strong "shunting inhibition."[59]

GABA may still have a depolarizing and excitatory action in mature CNS neurons when the equilibrium potential of this neurotransmitter (E_{GABA}) is more positive that the resting membrane potential.[60] Shifts of E_{GABA} have been suggested to underline modifications of $[Cl^-]_i$ observed in the suprachiasmatic nucleus during the circadian cycle of adult mammal neurons[61] (but see ref. 62). In addition, evidence has been provided that in adult animals, GABA excites layer V cortical cells through an action that critically depends on the resting membrane potential of the cell and on the temporal and spatial (dendritic and somatic) profile of GABAergic synaptic inputs of targeted neurons.[63]

Heterogeneity of $GABA_A$ Receptors

In mammals, $GABA_A$ receptors are highly heterogeneous. Twenty different subunits encoded by different genes have been cloned to date. They have a molecular weight ranging between 48,000 (γ2) and 64,000 (α4) kDa, and can be subdivided into seven structurally related subfamilies (α1–6, β1–4, γ1–3, ε, δ, θ, π, and ρ1–3) with a high degree of homology. The most common native receptor stoichiometry is two α subunits, two β subunits, and one γ/δ/ε subunit.[64] However, the θ subunit, cloned from the rat striatum, can also coassemble with α2, β1, and γ1.[65] In addition, alternative splicing further increases the diversity. Thus, the gene encoding the γ2 subunit has two splice variants, designed short (γ2S) and long (γ2L), that differ only in eight amino acids inserted into the large intracellular loop.[66] The γ2 splice variants show differential abundance in different brain regions and different age-related changes in their level of expression.[67] A recent study has demonstrated that the γ2S variant not only serves as an integral subunit of $GABA_A$ receptors but also as an accessory protein acting as an external modulator of fully formed receptors.[68] The ρ subunits, identified in the retina and possibly present also in other brain structures, initially described as $GABA_C$ receptors based on their different pharmacological properties (they are relatively insensitive to bicuculline but sensitive to the GABA analog *cis*-aminocrotonic acid), are closely related in sequence, structure, and function to other $GABA_A$ receptors, and therefore they should be fully considered $GABA_A$ receptors[69, 70] (see Fig. 8–4).

The multiplicity of subunit combinations has crucial consequences for the function of native receptors, as indicated by recombinant studies.[71] In addition, receptor heterogeneity constitutes the major determinant of receptor pharmacology. The kinetics and pharmacological diversity generated by the interaction of synaptically released GABA with different native receptors are particularly evident during development, when changes in the time course of GABA-mediated transmission are essential for synaptic integration. During the third postnatal week, in granule cells of the dentate gyrus, the acceleration of mIPSCs kinetics is related to the enhanced expression of the α1 subunit.[72] Similarly, the age-dependent decrease in deactivation kinetics of cerebellar granule cell IPSCs and their increased sensitivity to furosemide can be attributed to an enhanced expression of the α6 subunits.[73]

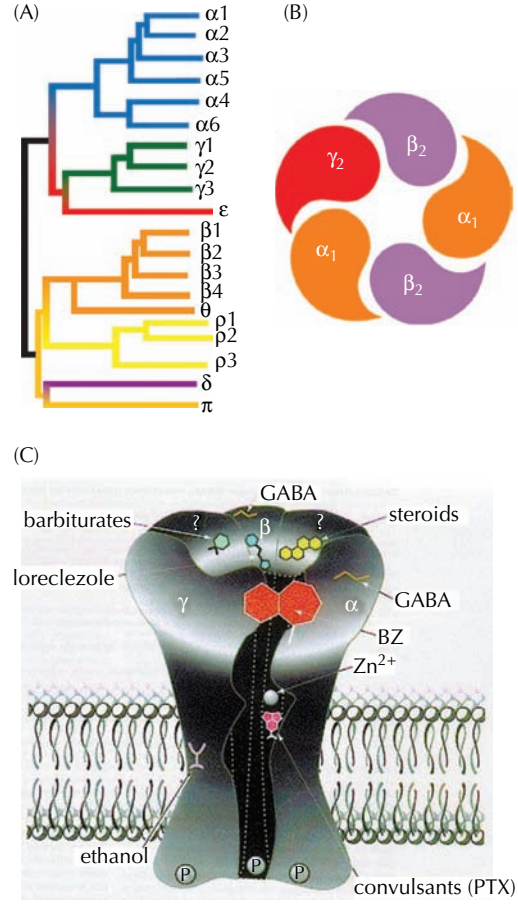

Figure 8–4. $GABA_A$ receptors. **A.** Dendrogram of the known 20 genes for $GABA_A$ receptors. The distances along each line are proportional to the degree of sequence identity between different homologous subunits. The Greek letters represent subunit families of high (>70%) identity. **B.** Schematic representation of the most common $GABA_A$ receptor assembly found in the CNS, α1β2γ2 with its appropriate stoichiometry of 2:2:1. **C.** Schematic representation of agonist binding sites and extracellular modulatory domains within the $GABA_A$ receptor. Adapted from refs. 2 and 70.

$GABA_A$ Receptor Distribution

In situ hybridization of mRNA and immunostaining experiments have revealed that the vast majority of $GABA_A$ receptors in the CNS contain the γ2 subunit.[74] Among the α subunits, α1 is the most abundant, and is often coexpressed

with the β2 and γ2 subunits. The α5 subunit is relatively rare except in the olfactory bulb, hypothalamus, and hippocampus, where it is located mainly at extrasynaptic sites. At synaptic sites, α5-containing $GABA_A$ receptors contribute to the slow decay of IPSCs evoked in the hippocampus by Schaffer collateral or stratum lacunosum-moleculare activation.[75,76] The α6 subunits, which are highly expressed in the forebrain and cerebellum, are extrasynaptic. The β subunits exist in functional receptors usually with only one type per pentamer (β2 is widespread, while β1 is less common). The δ subunit, localized at extrasynaptic dendritic and somatic membranes, is thought to be able to replace the γ subunit in the pentamer.[77] However, the α4 and α6 subunits are just as often combined with the δ subunit as with the γ2 subunit. In cerebellar granule cells the δ subunit is an obligatory partner of the α6 subunit, whereas in the forebrain it is primarily associated with the α4 subunit. Interestingly, some glutamatergic mossy fiber synapses in the cerebellum express abundant α6, γ2, and β2/3 but not δ subunits.[78] Although the functional role of these receptor subunits has not been fully elucidated, it is reasonable to assume that their activation by spillover of GABA from adjacent synapses may exert a modulatory effect on excitatory inputs. The ε subunit is rare, but in some areas, such as the hypothalamus, it can substitute for the γ or δ subunits.[79] The function of the θ and π subunits has not yet been fully characterized.

Modulation of $GABA_A$ Receptors

$GABA_A$ receptors are the targets for a variety of endogenous modulators or exogenous ligands generally used for the treatment of neurological and psychiatric disorders. Their pharmacological effect depends strictly on the subunit combinations. The use of transgenic mice in which different $GABA_A$ receptor subunits have been either deleted (due to gene ablation) or mutated has allowed better characterization of the functional properties of various receptor subunits.

MODULATION OF $GABA_A$ RECEPTORS BY ENDOGENOUS MOLECULES

$GABA_A$ receptors are substrates for phosphorylation via protein kinases. The resulting covalent modification constitutes one of the major mechanisms regulating their trafficking, cell surface expression and function.[80] Phosphorylation largely depends on subunit composition. For example, in pyramidal cells, intracellular delivery of protein kinase A (PKA), but not of protein kinase C (PKC), reduces the amplitude of mIPSCs, whereas in the dentate gyrus, PKC but not PKA enhances the peak amplitude of mIPSCs.[81] Protein kinase A–dependent phosphorylation depends strongly on the β subunits: PKA increases mIPSC amplitude in olfactory granule cells that express the β3 subunit[82] but reduces it in CA1 pyramidal cells that express the β1 subunit.[81]

$GABA_A$ receptors can also be modulated by zinc, a divalent cation highly expressed in neurons at areas associated with transmitter release.[83] In the hippocampus, zinc is stored with glutamate in synaptic vesicles present on mossy fiber terminals from which it can be released upon nerve stimulation in a calcium-dependent way to regulate synaptic excitation.[83] However, during sustained activation of mossy fibers, zinc may spill over to reach synaptic and/or extrasynaptic $GABA_A$ receptors. Zinc acts as an inhibitor of $GABA_A$ receptors lacking the γ subunits and composed mainly of αβ or αβδ subunits.[83] Therefore, it affects mainly tonic inhibition. However, at higher concentrations, zinc can also alter phasic inhibition by interfering with receptor gating.[84] Compelling evidence that endogenously released zinc can modulate IPSCs has been provided by Ruiz et al.,[85] who demonstrated that chelating zinc with either calcium-saturated EDTA or *N*,*N*,*N*′,*N*′-tetrakis (2-pyridylmethyl)ethylenediamine enhances the amplitude of IPSCs evoked by stimulation of the dentate gyrus.

Neuroactive steroids are potent endogenous modulators of $GABA_A$ receptors[86] and play a crucial role in neuronal excitability and brain function. Neuroactive steroids such as allopregnanolone and allotetrahydrodeoxycorticosterone (THDOC) at nanomolar concentrations have been shown to enhance GABA action by prolonging the channel open time, thus producing sedative-hypnotic, anxiolytic, and anticonvulsant effects.[87] Natural fluctuations in their level during the menstrual cycle and stress could affect several neuropsychiatric disorders including catamenial epilepsy, anxiety, and depression. At higher concentrations (>1 μM), neurosteroids produce a direct opening of

$GABA_A$ receptor–associated chloride channels.[88] This suggests the existence of at least two different binding sites on $GABA_A$ receptors, although their identification has remained elusive until now. Most of the behavioral effects of neurosteroids are mediated by extrasynaptic receptors containing δ and ε subunits. However, these compounds can also modulate synaptic receptors, as demonstrated by their ability to prolong IPSC decay.[89] However, the concentrations needed to produce such an effect vary considerably among different neurons.[86] Studies designed to mimic synaptic events using rapid application of saturated concentrations of GABA have suggested that neurosteroids produce the observed effect by slowing the recovery of $GABA_A$ receptor channels from the desensitized state.[90] Interestingly, modulation of synaptic α3β3γ2 $GABA_A$ receptors by neurosteroids may mediate the putative endogenous analgesic action of these compounds in the spinal cord.[91]

MODULATION OF $GABA_A$ RECEPTORS BY EXOGENOUS MOLECULES

$GABA_A$ receptors can be allosterically modulated by clinically important drugs including benzodiazepines, barbiturates, anesthetics, and so on. The pharmacological action of these compounds on $GABA_A$ receptor function has been extensively reviewed.[92–94] In this chapter, I will focus only on benzodiazepenes (BZs), which are widely used in clinical practice as anxiolytics, sedative-hypnotics, and anticonvulsants. By enhancing the apparent affinity of $GABA_A$ receptors for GABA, BZs potentiate the action of GABA via an increased probability of channel opening. Benzodiazepines bind at the interface between α and γ subunits and their pharmacology is influenced by these subunits, whereas β subunits, although necessary to construct a channel, do not affect the sensitivity of $GABA_A$ receptors to these drugs. Since most of the actions of diazepam are mediated by receptors composed of α1βγ2, α2βγ2, α3βγ2, and α5βγ2, a point mutation in the genes encoding for α subunits (a histidine to arginine substitution) is able to render these receptors insensitive to BZs.[95] Knockout mice expressing BZ-insensitive α1 subunits fail to exhibit the sedative effects of diazepam while retaining its anxiolytic response,[96] which seems to depend on α2, α3,[97] and/or γ2 subunits.[98] Interestingly, by positively modulating $GABA_A$ receptors, BZs can cause addiction in vulnerable individuals. A recent study has provided evidence that the addictive properties of these drugs depend on the increased firing of dopaminergic neurons in the ventral tegmental area following disinhibition.[99] This would rely on the potentiation of α1-containing $GABA_A$ receptors, usually absent on midbrain dopaminergic neurons, which in turn would selectively inhibit nearby GABAergic interneurons, leading to disinhibition of dopaminergic cells.

FUTURE PERSPECTIVES

The evidence reviewed here shows that $GABA_A$-mediated synaptic currents can be tuned by a variety of different factors acting at the presynaptic, cleft, and postsynaptic levels. The multitude of $GABA_A$ receptor subunits can assemble in a restricted and nonrandom way to generate distinct receptor subtypes with different physiological and pharmacological properties.

Although much remains to be learned about the mechanisms controlling GABA release and clearance, neuron–glia interaction, trafficking, and anchoring of $GABA_A$ receptors and associated proteins, a thorough assessment of $GABA_A$ receptor subtype-specific functions will provide the rational basis for developing new therapeutic tools for the treatment of neuropsychiatric disorders. In addition, using optogenetic techniques[100] to target specific neurons expressing different $GABA_A$ receptor subtypes will allow elucidation of the functional role of various subunits in network activity and animal behavior.

Finally, a better understanding of the mechanisms by which excitatory GABAergic signaling (phasic and tonic) controls adult neurogenesis and the integration of newborn neurons into existing neuronal circuits[101] will allow highlighting of the plasticity and regenerative capacities of the adult mammalian brain in response to experience.

ACKNOWLEDGMENT

I wish to thank the colleagues who contributed to some of the original work reported in this

chapter and all members of my laboratory for useful discussions.

Chapter 9

Tonic $GABA_A$ Receptor–Mediated Signaling in Epilepsy

Matthew C. Walker
Dimitri M. Kullmann

Fast inhibitory signaling in the brain has conventionally been considered to be predominantly mediated by the vesicular release of GABA from presynaptic terminals onto postsynaptic $GABA_A$ receptors.[1] Transient opening of such receptors results in a brief increase in postsynaptic permeability to Cl^-, generating an inhibitory postsynaptic potential (IPSP) that reduces the probability of firing of the neuron. However, there is abundant evidence that GABA can also act relatively far from its site of release, and this, together with several other discoveries in the last two decades, has contributed to a reappraisal of the roles of $GABA_A$ receptors in modulating neuronal and circuit excitability.[1]

Much of the new understanding of GABAergic transmission comes from in vitro brain slice experiments, which allow direct postsynaptic recording of IPSPs or, by voltage-clamping the postsynaptic neuron, inhibitory postsynaptic currents (IPSCs). Importantly, during the synchronous activation of many synapses, sufficient GABA can "spill" out of the synapse to activate extrasynaptic $GABA_A$ and also metabotropic $GABA_B$ receptors, prolonging the IPSP.[2,3] This may serve to dampen excessive network activity. More recently, a slower form of signaling has been described in which high-affinity, slowly desensitizing $GABA_A$ receptors detect low concentrations of ambient GABA in the extracellular space even in the absence of evoked release. This has been termed *tonic $GABA_A$ receptor–mediated inhibition*[1,4] (see Fig. 9–1).

Tonic $GABA_A$ receptor activity was evident in some of the first patch-clamp studies of GABAergic inhibition in the rodent hippocampus[5] and was later described in layer III cells of somatosensory cortical slices.[6] In these and other studies, application of a $GABA_A$ receptor antagonist reduced the resting membrane conductance and produced a shift in the baseline "holding" current required to clamp neurons at a given membrane potential (Fig. 9–1). Shortly afterward, $GABA_A$ receptor–mediated tonic

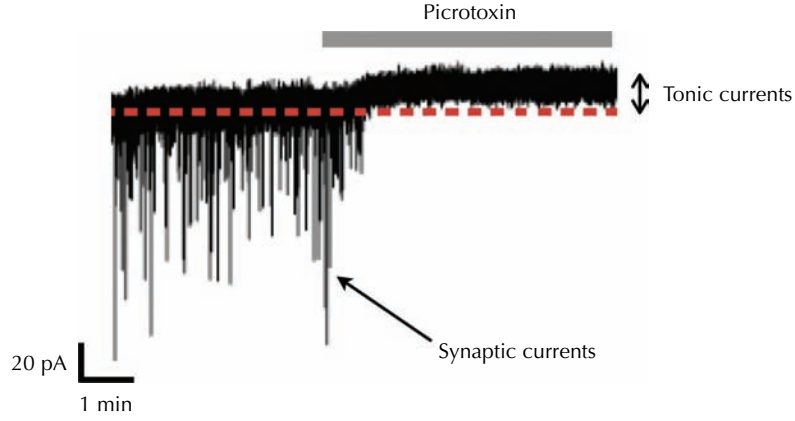

Figure 9–1. Voltage-clamp recording from a dentate gyrus granule cell in the presence of glutamate receptor blockers. Inhibitory postsynaptic currents (IPSCs) are represented by phasic inward currents (downward deflections) that are inhibited by the $GABA_A$ receptor blocker picrotoxin. Picrotoxin also blocks the tonic current, which results in an outward shift of the holding current.

currents were described in cerebellar granule cells.[7,8] Application of $GABA_A$ receptor antagonists in this preparation not only resulted in a shift in the baseline current but also decreased the background noise, consistent with a block of stochastic channel openings. These tonic currents are both developmentally regulated and cell-type specific.[1,4] Indeed, in some neurons, the tonic current represents a greater proportion of the total $GABA_A$ receptor–mediated current than that mediated by spontaneous synaptic activity.[1,4]

Although the tonic activity of $GABA_A$ receptors is often termed tonic *inhibition,* it is important to bear in mind that $GABA_A$ receptors do not always inhibit neurons. Opening of these receptors has two main effects: a membrane potential change and a decrease in membrane resistance. The membrane potential change caused by opening of $GABA_A$ receptors depends on the electrochemical gradients for Cl^- and, to a lesser extent, for $HCO3^-$ ions that also move through the open channel.[9] Irrespective of whether the receptors are activated phasically (by local presynaptic exocytosis) or tonically (by ambient GABA), these gradients determine if $GABA_A$ receptors de- or hyperpolarize the neuron. In mature neurons, $GABA_A$ receptors are generally hyperpolarizing, but early in development, they can be depolarizing because the intracellular Cl^- concentration is high.[9] These voltage changes further interact with subthreshold voltage-dependent conductances and propagate within dendrites. $GABA_A$ receptor opening also shunts excitatory inputs by decreasing the resistance of the membrane, and this provides an additional mechanism that reduces the excitability of the postsynaptic cell irrespective of whether GABAergic signaling is de- or hyperpolarizing.

$GABA_A$ RECEPTOR SUBTYPES UNDERLYING TONIC CONDUCTANCES

$GABA_A$ receptors are pentameric structures composed of 5 subunits from a possible choice of 19 subunits.[10] Other than those containing the ρ subunit (which form a separate class of $GABA_C$ receptors), $GABA_A$ receptors usually consist of two (from a repertoire of six) α subunits, two (from three) β subunits, and another subunit (usually a γ or δ subunit). There are thousands of possible subunit combinations; however, relatively few are expressed with any frequency in the mammalian central nervous system. The specific subunit combinations confer different channel conductances, affinities for GABA, and kinetics. Moreover, different subunits alter the response of the receptors to endogenous and exogenous modulators, including Zn^{2+} and neurosteroids. The subcellular location of $GABA_A$ receptors (synaptic versus extrasynaptic) is also determined

by subunit composition. As a general rule, γ subunits are required for synaptic expression; however, γ subunit–containing receptors are also found extrasynaptically.[11] δ Subunit–containing $GABA_A$ receptors, in contrast, are exclusively extrasynaptic. The β subunit may also play a role in determining the location, trafficking, and pharmacology of $GABA_A$ receptors.[12] Importantly, the receptors mediating tonic currents are different from those contributing to the peak synaptic currents and tend to have a high affinity for GABA, desensitize slowly and incompletely in the presence of the agonist, and are probably located extrasynaptically. However, as hinted above, the distinction between receptors mediating phasic and tonic inhibition is blurred because, during intense synaptic activity, exocytosed GABA can diffuse out of the synaptic cleft and overwhelm transporters to activate peri- and extrasynaptic receptors.[13,14]

Among the receptor subtypes that contribute to tonic signaling are $\alpha_4\beta_x\delta$ receptors, which have been proposed to mediate the tonic current in dentate granule cells[15–17] and thalamocortical neurons,[18–20] and $\alpha_6\beta_x\delta$ receptors that mediate the tonic current in cerebellar granule cells.[8,16,21] Other receptor subtypes may also mediate tonic currents, including $\alpha_5\beta_x\gamma_x$ receptors in CA1 pyramidal cells[22] and ε-containing receptors in hypothalamic neurons.[23] The ε-containing $GABA_A$ receptors, which occur not only in the hypothalamus but also in the amygdala and locus ceruleus, are of specific interest in this regard, as they can open spontaneously in the absence of GABA but desensitize with high concentrations of GABA.[23] This leads to the prediction that tonic $GABA_A$ receptor–mediated currents in these brain structures should be paradoxically "turned off" by increases in extracellular GABA. It is likely that other $GABA_A$ receptor subunit combinations are also expressed extrasynaptically and are able to mediate a tonic current. Some whole-cell patch-clamp data complemented by single-channel recordings support the presence of a zolpidem-sensitive $GABA_A$ receptor that can mediate a tonic current in the hippocampus, implying the presence of α_1, α_2, or α_3 with a γ subunit.[24,25] These subunit combinations are not usually associated with high-affinity extrasynaptic receptors, but rather with low-affinity synaptic receptors. The presence of receptors with unusual subunit composition, such as $\alpha_x\beta_3$ without either γ or δ, has also been inferred on the basis of sensitivity to GABA and Zn^{2+} as well as single-channel conductance.[26] These studies illustrate our lack of knowledge of the full range of $GABA_A$ receptor subtypes, a situation that is not helped by the poor availability of subtype-specific agonists and antagonists. Moreover, there is growing evidence that within one cell type (e.g., CA1 pyramidal cells, dentate gyrus granule cells and interneurons), more than one receptor subtype may contribute to the tonic current.[25,27–31] A heterogeneous population of receptors with different affinities mediating the tonic current increases the number of potential modulators and also extends the range of extracellular GABA concentrations that can modulate excitability of the neuron.

FUNCTIONS OF TONIC $GABA_A$ RECEPTOR CURRENTS

The physiological importance of tonic $GABA_A$ receptor–mediated currents is supported by the finding that genetic deletion of the α_6 subunit, resulting in the absence of tonic inhibition in cerebellar granule cells, leads to a compensatory upregulation of two-pore K^+ channels to restore the resting membrane conductance.[32] There is also considerable evidence that tonic currents mediate a qualitatively different form of inhibition from that generated by synaptic currents. Clearly, tonic currents provide a form of signaling over a different timescale than that mediated by phasic synaptic currents. Although the mechanisms that modulate tonic conductances are poorly understood, it is likely that they fluctuate relatively slowly, on a timescale of seconds to days. Among the mechanisms that have been reported to modulate tonic inhibition are alterations in receptor expression, variations in extracellular GABA concentrations, changes in endogenous neuromodulators (in particular neurosteroids), and a variety of neuroactive drugs, both therapeutic and recreational.[4] Thus, tonic $GABA_A$ receptor–mediated signaling is far more than a background leak conductance, and the developmental and computational roles of tonic signaling in different neurons are beginning to attract attention.

Tonically active $GABA_A$ receptors have been detected in embryonic neocortical cells in situ in the ventricular zone[33] prior to synapse

formation in hippocampal principal cells.[34] Currents mediated by these receptors have, therefore, been hypothesized to play a part in neuronal development. This hypothesis has received further support from the observation of tonic currents in developing dentate gyrus granule cells; these currents are depolarizing because of the high intracellular chloride concentration and have been suggested to have a trophic effect, promoting dendritic development.[35]

In neurons where the Cl^- reversal potential is close to the resting membrane potential, the major effect of tonically active $GABA_A$ receptors is to increase membrane conductance. This will reduce the membrane time constant[4] and, at the same time, attenuate rapid fluctuations in membrane voltage arising from the action of excitatory synapses. The consequences for the computational properties of individual neurons are difficult to predict. In particular, spontaneous fluctuations in membrane potential play an important role in setting the slope or gain of the input–output relationship of a neuron.[36–39] Information is encoded in very different ways in different brain circuits, and the effect of the tonic conductance on the input–output relationship is likely to depend on whether information is represented as changes in the rate of firing of individual neurons (*rate coding*) or as changes in the recruitment of neurons to firing threshold (*sparse coding*).[39] For small neurons that use rate coding (such as cerebellar granule cells), there is convincing evidence that the gain of the input–output slope is sensitive to tonic inhibition.[36,39] In contrast, tonic inhibition has less effect on the gain of the input–output function of a complex neuron that uses sparse coding (such as a hippocampal pyramidal cell) and instead has a larger effect on the offset of the input–output curve[37,39] (Fig. 9–2). Such an effect on offset is further promoted by a strong outward rectification of the tonic current in hippocampal pyramidal cells.[37] This effect on excitability may contribute to increasing the threshold for induction of long-term potentiation.[40] These considerations provide a possible explanation for the finding that genetic ablation or pharmacological reduction of tonic currents mediated by α_5 subunits, which contribute to tonic currents in hippocampal pyramidal cells, increases the rate of spatial learning.[41–43] However, this increased rate of learning may be at the expense of a general increase in the probability that a neuron will fire, loss of sparse network activity, and consequently a decrease in the ability to discriminate different input patterns.

Tonically active $GABA_A$ receptors not only shunt excitatory currents, but also affect the membrane potential. In many neurons in the adult brain $GABA_A$ receptors hyperpolarize

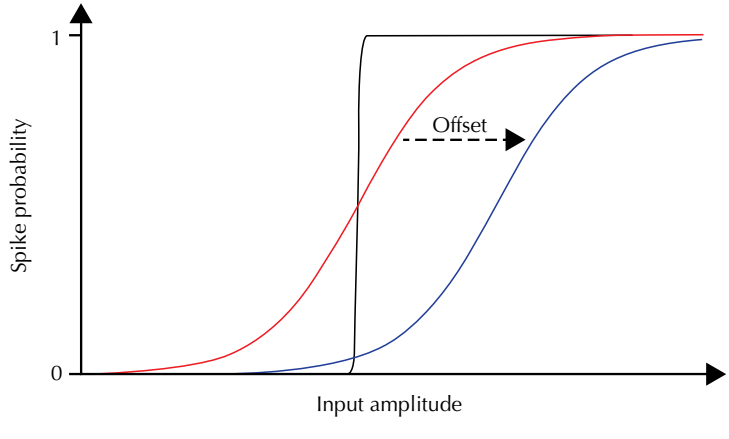

Figure 9–2. The input–output function of a pyramidal cell can be represented by the probability of neuronal firing plotted against the amplitude of the input (black curve). Synaptic noise reduces the gain (slope) of the input–output function because inputs that would otherwise be subthreshold occasionally summate with positive membrane potential fluctuations, thus reaching the firing threshold (red curve). Tonic currents, in contrast, predominantly affect offset, shifting the curve to the right (blue curve).

the membrane, and this aspect of tonic currents further reduces neuronal firing. However, in situations in which $GABA_A$ receptor–mediated currents are strongly depolarizing, tonic current can have a paradoxical excitatory effect by bringing neurons closer to the action potential threshold. Tonic activation of presynaptic $GABA_A$ receptors on mossy fiber terminals has such a depolarizing effect, promoting glutamate release and long-term potentiation.[44] Furthermore, in the thalamus, the hyperpolarizing effect of tonic currents can change the firing pattern of thalamocortical neurons from a regular firing to a burst-firing pattern,[19] which is important for the generation of sleep rhythms (such as slow waves during deep sleep) and also for absence seizures (see below).

To understand the network effects of tonic $GABA_A$ signaling, it is also necessary to consider its relative magnitude in different cell types.[4,25] Under baseline conditions in vitro, the $GABA_A$ receptor–mediated tonic current in hippocampal interneurons is considerably larger than the current mediated by spontaneous IPSCs and thus is an important determinant of interneuron excitability.[25] In keeping with this situation, a low concentration of picrotoxin that relatively selectively inhibits tonic currents significantly increases the frequency of spontaneous IPSCs in hippocampal pyramidal cells. These findings suggest that tonic conductances in interneurons act as a homeostatic regulator of synaptic inhibition of principal cells: if the ambient GABA concentration decreases, interneurons become more excitable, resulting in an increase in the frequency of GABA receptor–mediated IPSCs in pyramidal cells.[25] Conversely, an increase in ambient GABA concentration would be expected to render interneurons relatively less excitable, leading to a decrease in synaptic inhibition, while tonic inhibition of pyramidal neurons increases (Fig.9–3). What are the likely network consequences of a shift from synaptic to tonic inhibition in pyramidal cells? The decrease in synaptic inhibition would be expected to decrease membrane voltage fluctuations and therefore to increase the gain of the neuron's input amplitude-firing probability curve, and at the same time to shift it to the left (decrease offset). However, this shift due to the decrease in synaptic inhibition may be more than compensated for by the increase in tonic inhibition.[37] The net effect would therefore be to increase the neuronal gain while maintaining or increasing the offset.[37] Interestingly, extracellular GABA has been shown to increase in the hippocampus when an animal is stressed or exposed to a new environment,[45,46] and by increasing the neuronal gain, such an effect is likely to promote neuronal firing and long-term potentiation, while the increase in neuronal offset prevents indiscriminate neuronal firing.

Cell-type specificity has also been reported in the thalamus; tonic $GABA_A$ receptor–mediated currents are present in thalamocortical neurons but not in reticular thalamic neurons.[18,19] The thalamocortical neurons gate sensory input into the neocortex, while the reticular thalamic neurons are inhibitory and provide the main synaptic inhibitory drive onto thalamocortical neurons. Therefore, in contrast to the hippocampus, the synaptic inhibitory currents onto thalamocortical neurons are likely to remain unaltered by a local increase in extracellular GABA.

Tonic inhibition likely plays a role in numerous other brain functions. For example, in the striatum, tonic $GABA_A$ receptor–mediated signaling has been shown to be larger in D2

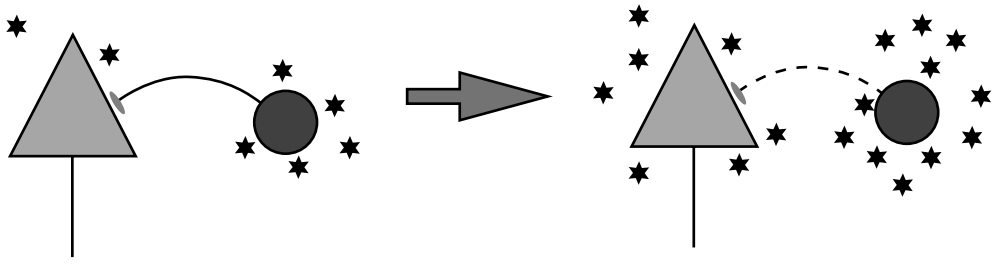

Figure 9–3. Tonic $GABA_A$ receptor–mediated currents in interneurons of the hippocampus are relatively larger and more sensitive to low ambient GABA concentrations than are currents in pyramidal cells. As the GABA concentration increases, interneurons become less excitable, so phasic inhibition of pyramidal cells is "switched off," while tonic inhibition of pyramidal cells increases.

dopamine receptor-expressing spiny stellate cells that project to the globus pallidum (the *indirect* pathway) than in D1-expressing cells in the *direct* pathway that project to the substantia nigra.[47] This difference appears to result both from a complex interplay of expression of α_5 subunits and β_3 phosphorylation by protein kinase A, which itself is activated or inhibited by D1 and D2 receptors, respectively.[48] These findings provide a mechanism for dopamine release to shift the balance of strength of signaling via the direct and indirect pathways.

TONIC INHIBITION IN THE HIPPOCAMPUS AND TEMPORAL LOBE EPILEPSY

Tonic $GABA_A$ receptor currents have been described in dentate granule cells,[15,49] hippocampal pyramidal cells,[50] and hippocampal interneurons.[25] The receptors predominantly mediating tonic current in these three cell types are different. In CA1 pyramidal cells, the receptors are predominantly those containing α_5 and γ subunits,[22] while in dentate granule cells, the tonic current is predominantly mediated by receptors containing α_4 and δ subunits.[16] δ Subunits also contribute to tonic currents in interneurons.[51]

Neurosteroids increase the efficacy of $GABA_A$ receptors containing the δ subunit[52] and thus increase tonic conductances.[16,53] Indeed, the synthetic neurosteroid ganaxolone has entered a clinical trial for the treatment of epilepsy.[54] In addition, neurosteroids alter δ and α_4 subunit expression.[55,56] This effect appears to depend upon the length of exposure, with short-term exposure to allopregnalone resulting in increased δ subunit expression and increased tonic currents in dentate granule cells,[57] while longer-term exposure can result in δ subunit and $GABA_A$ receptor downregulation.[58] Short-term increases in neurosteroids occur with acute stress and during the menstrual cycle, and it is likely that these effects contribute to changes in seizure threshold under these conditions.[56,57,59] Indeed, withdrawal of neurosteroids can result in a lowered seizure threshold,[60] and an effect on tonic inhibition provides an attractive candidate mechanism to explain the menstrual variation in seizure frequency (catamenial epilepsy).[61] In some conditions of chronic stress or during pregnancy, the effect of downregulation of receptors mediating tonic inhibition is probably compensated for by the increase in circulating neurosteroids directly enhancing the efficacy of remaining receptors.

Seizures themselves and epilepsy can also affect $GABA_A$ receptor–mediated inhibition. In particular, prolonged acute seizures alter $GABA_A$ receptor expression, and the epileptogenic process is accompanied by differential changes in subunits. During status epilepticus, there is an internalization of synaptic $GABA_A$ receptors,[62,63] providing a candidate mechanism for loss of benzodiazepine potency.[64] However, extrasynaptic δ-containing receptors are preserved.[65] The efficacy of drugs that act on tonically active $GABA_A$ receptors, such as some anesthetic agents,[66,67] may therefore be maintained during status epilepticus. With the development of chronic temporal lobe epilepsy, animal models indicate that δ subunit expression decreases in dentate granule cells[68] and α_5 subunit expression decreases in CA1 pyramidal cells.[69] Since these subunits contribute to tonic $GABA_A$ receptor currents in dentate granule cells and CA1 pyramidal cells, respectively, tonic inhibition in these cell types would be expected to decrease. Surprisingly, this is not the case: tonic currents are maintained or increased during epileptogenesis.[28,30,70] This is not secondary to a decrease in GABA uptake, but is rather the result of the substitution of one set of extrasynaptic $GABA_A$ receptors by another and/or translocation of synaptic receptors to extrasynaptic sites. Although the tonic currents are preserved, their pharmacology changes because of the subunit alterations.[28,30] What is perhaps more surprising is the maintenance of these tonic currents, even in the face of quite marked decreases in synaptic inhibition. The preservation of tonic currents is also evident in resected tissue from patients with refractory temporal lobe epilepsy.[71]

The network implications of the relative preservation of tonic, but loss of phasic, inhibition can only be speculated on but are likely be similar to the effects observed when extracellular GABA increases: an increase in neuronal gain but a maintenance or increase in the offset of the input–output curve.[37] The tonic current probably provides an adequate inhibitory restraint under conditions of low network activity, but as activity increases there may be

two consequences: first, inadequate fast compensatory changes through feedforward and feedback inhibition, and second, increased neuronal gain resulting in larger numbers of firing neurons. This may provide the ideal conditions for seizure generation. This hypothesis could also explain why seizures are rare, intermittent events in people with even severe epilepsy.

TONIC INHIBITION IN ABSENCE SEIZURES AND ABSENCE EPILEPSY

Tonic currents are expressed in thalamocortical cells but not in reticular thalamic neurons.[18,19] Such currents hyperpolarize thalamocortical neurons, and thus predispose to burst firing by deinactivating T-type Ca^{2+} channels and/or activating hyperpolarization-activated cation conductance. Tonic $GABA_A$ receptor signaling has therefore been proposed to be intimately involved in both the generation and pharmacology of absence seizures. Specifically, an increase in tonic currents in thalamocortical neurons results in neuronal hyperpolarization, and therefore a change of thalamocortical neuron firing from regular to burst patterns, promoting spike-wave generation. Several lines of evidence support this hypothesis.[72,73] First, drugs that increase tonic currents in thalamocortical neurons promote absence seizures. This has been observed in animal models treated with GABA uptake inhibitors or with 4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol (THIP), a drug that acts specifically on δ-containing receptors.[74,75] Thalamocortical seizures, or their spike-wave electroencephalographic (EEG) signature, have also been observed in humans in whom extracellular GABA concentrations have been increased by the administration of tiagabine, a GABA uptake inhibitor, or vigabatrin, a GABA transaminase inhibitor (both drugs used in the therapy of partial epilepsy).[76] Second, gamma-hydroxybutyrate (GHB), a drug that is well recognized to induce absence seizures, increases extracellular GABA in the thalamus.[72,77] Third, δ subunit knockout mice are resistant to the pro-absence effects of such drugs.[72] Fourth, increased tonic currents in thalamocortical neurons, and reduced GABA transporter activity, have been reported in animal models of spontaneous absence seizures (e.g., the Genetic Absence Epilepsy Rat from Strasbourg [GAERS], *lethargic* mice, *stargazer*).[72,73,78] Lastly, knockdown of the δ subunit in thalamocortical neurons in GAERS using antisense oligodeoxynucleotides inhibits absence seizures.[72] It is also noteworthy that polymorphisms in δ subunits in humans have been associated with familial generalized epilepsies.[79] However, interestingly, these genetic variants tend to decrease $GABA_A$ receptor function; therefore, how this change in tonic $GABA_A$ current contributes to the generation of absence seizures remains unclear.

TONIC INHIBITION AS A TARGET FOR ANTIEPILEPTIC DRUGS

Two main approaches can, in principle, be used to alter tonic inhibition: target the specific $GABA_A$ receptor subtypes that mediate tonic inhibition and increase the extracellular GABA concentration.

$\alpha_4\delta$-Containing receptors, which underlie tonic currents in dentate gyrus granule cells, are positively modulated by neurosteroids.[16,53] In addition, they are particularly sensitive to anesthetic agents (such as propofol) and to THIP.[20,66,67,80] Since these receptors are maintained in status epilepticus despite the internalization of γ-containing $GABA_A$ receptors, they could be a useful target in the later stages of status epilepticus when there is increasing benzodiazepine resistance. This may explain the usefulness of propofol as an anesthetic and anticonvulsant agent in the later stages of status epilepticus.[81] Similarly, the preservation of tonic currents in partial epilepsy argues for the use of drugs that target these receptors. Ganaxalone, a synthetic neurosteroid, is one such drug;[54] however, because the δ subunit is downregulated by chronic exposure to neurosteroids, this approach may not be effective in the long term. δ Subunit–containing receptors can also be directly activated by drugs such as THIP. A problem with this approach is lack of spatial specificity, in that such drugs target not only dentate granule cells but also thalamocortical neurons, thus inducing sleep and, at higher concentrations, anesthesia. In addition, as mentioned above, such drugs can have a pro-absence effect. Indeed, these drugs have been disappointing in animal seizure models.[82]

A further confounding factor when using $GABA_A$ receptor subtype–specific drugs is that

epileptogenesis results in subunit alterations that may decrease the efficacy of these compounds. This may be the case for the δ subunit in dentate gyrus granule cells (but see ref. 71) and also for the expression of the α_5 subunit in hippocampal pyramidal cells.[28]

As for an increase in extracellular GABA concentration, this can be achieved by inhibiting GABA transporters (tiagabine) or by decreasing GABA breakdown by GABA transaminase (vigabatrin). Another approach would be to increase GABA synthesis, and it has been argued that some presently available antiepileptic drugs (e.g., valproate) may work partly via this mechanism.[83] Decreasing GABA uptake would seem to be an ideal approach to decreasing network excitability, but this suffers from four important problems. First, although a specific inhibitor (for instance, one that targets GABA transporter 1[GAT1]) may be effective in increasing the tonic current in the hippocampus, this may not be the case in the neocortex, where GAT3 can compensate for GAT1 inhibition.[84] Second, as discussed above, increasing extracellular GABA will also have an effect on interneurons, thus decreasing synaptic inhibition and paradoxically increasing network excitability.[25] Third, increasing tonic inhibition in the thalamus can promote the generation of absence seizures.[72] Fourth, increasing extracellular GABA also activates pre- and postsynaptic $GABA_B$ receptors, and this can have complex network effects, reducing both excitability and synaptic inhibition (the latter by inhibiting vesicular GABA release).[85] Lastly, reversal of GABA transporters during neuronal activity may even be a mechanism by which extracellular GABA can be increased during excessive neuronal activity.[86] Thus, although tiagabine is an effective antiepileptic drug, it has been described to have, in some circumstances, pro-absence effects and its efficacy in humans is, overall, disappointing. Use of vigabatrin is also hampered by many of the same problems; its clinical use is also limited by concentric visual field restriction, which most likely results from GABA accumulation in the retina.[87]

CONCLUSION

Tonic currents have a profound effect on network excitability and are not lost in focal epilepsy. They therefore represent an attractive target for antiepileptic drug therapy. However, the hyperpolarization mediated by tonic currents in the thalamus may contribute to the generation of absence seizures. A promising area for future development is to target the modulation of tonic currents in principal neurons, especially if the $GABA_A$ receptors subunits mediating them differ pharmacologically in the epileptic and healthy brain.

Chapter 10

Glutamatergic Mechanisms Related to Epilepsy

Ionotropic Receptors

Raymond Dingledine

The ionotropic glutamate receptors are ligand-gated ion channels that mediate the vast majority of excitatory neurotransmission in the brain. The past 20 years have been a golden age for glutamate receptor research. Even before that time, in the early 1980s the invention of the first selective antagonists for what would come to be known as *N-methyl-D-aspartate* (*NMDA*) *receptors*[1] triggered a flood of investigations as the realization grew that NMDA receptors were critically involved in synaptic plasticity, learning, creation of the proper wiring diagram of the brain during development, excitotoxicity, and a host of neurological disorders involving aberrant circuitry organization, including epilepsy (reviewed in refs. 2 and 3). Cloning of the first glutamate receptor subunit was reported in December 1989,[4] and within the next 2 years an additional 15 subunits were cloned.[3,5] The subsequent application of molecular and gene ablation technologies has revealed a wealth of subtlety regarding control of synaptic transmission highlighted, perhaps, by a resurgence of interest in how excitatory input patterns to GABAergic interneurons regulate synchronous firing throughout the brain. Over the past decade, our understanding of how these receptors work has been brought to the structural level by successful crystallization of numerous glutamate receptor subunits (see ref. 6). The mechanisms (transcriptional, translational, and post-translational) underlying seizure-induced changes in expression of glutamate receptors have been elucidated. A wealth of new pharmacologic reagents, particularly allosteric receptor modulators, have been introduced that can facilitate study of the roles of specific glutamate receptors in epilepsy. The proposal that reactive astrocytes release glutamate, which then acts to synchronize neuron firing within local microdomains, has been developed. Here I review the functional properties of glutamate

Table 10–1 **Glutamate Receptor Nomenclature**

IUPHAR Name	HUGO Symbol	Common Names	Receptor Family
GluA1	GRIA1	GluR1, GluRA	AMPA
GluA2	GRIA2	GluR2, GluRB	AMPA
GluA3	GRIA3	GluR3, GluRC	AMPA
GluA4	GRIA4	GluR4, GluRD	AMPA
GluK1	GRIK1	GluR5	Kainate
GluK2	GRIK2	GluR6	Kainate
GluK3	GRIK3	GluR7	Kainate
GluK4	GRIK4	KA1	Kainate
GluK5	GRIK5	KA2	Kainate
GluN1	GRIN1	NMDAR1, NR1, GluRξ1	NMDA
GluN2A	GRIN2A	NMDAR2A, NR2A, GluRε1	NMDA
GluN2B	GRIN2B	NMDAR2B, NR2B, GluRε2	NMDA
GluN2C	GRIN2C	NMDAR2C, NR2C, GluRε3	NMDA
GluN2D	GRIN2D	NMDAR2D, NR2D, GluRε4	NMDA
GluN3A	GRIN3A	NR3A	NMDA
GluN3B	GRIN3B	NR3B	NMDA
GluD1	GRID1	δ1, GluRdelta-1	Delta
GluD2	GRID2	δ2, GluRdelta-2	Delta

receptors and discuss recent data pointing to their potential roles in epilepsy. But first, a word on nomenclature.

NOMENCLATURE

The rapid growth of literature on glutamate receptors throughout the 1990s predictably spawned multiple names for the same subunit in different species, or sometimes in the same species but cloned nearly simultaneously in different laboratories. The resulting confusion has abated slowly, but a strong effort has been made recently to replace the older names for glutamate receptor subunits by International Union of Basic and Clinical Pharmacology (IUPHAR) names[7] (see http://www.iuphar-db.org/LGICNomenclature.jsp). The IUPHAR nomenclature, which was designed to harmonize with the gene names and which will be used throughout this chapter, is presented in Table 10–1. Several excellent reviews have appeared in recent years that complement and extend the next three sections.[6,8–13]

GLUTAMATE RECEPTOR STRUCTURE

Ionotropic glutamate receptors are tetrameric protein complexes made up of four subunits surrounding an ion channel pore. Each protein complex draws subunits from the same receptor subfamily (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate [AMPA], kainate, NMDA), with subunit assembly between subfamilies apparently strictly prohibited. Each subunit sports three transmembrane domains and a membrane reentrant loop (M2) that results in a cytoplasmically located C terminus (Fig. 10–1A). The cytoplasmic location of the Cterminus is important because residues near this terminus interact with numerous

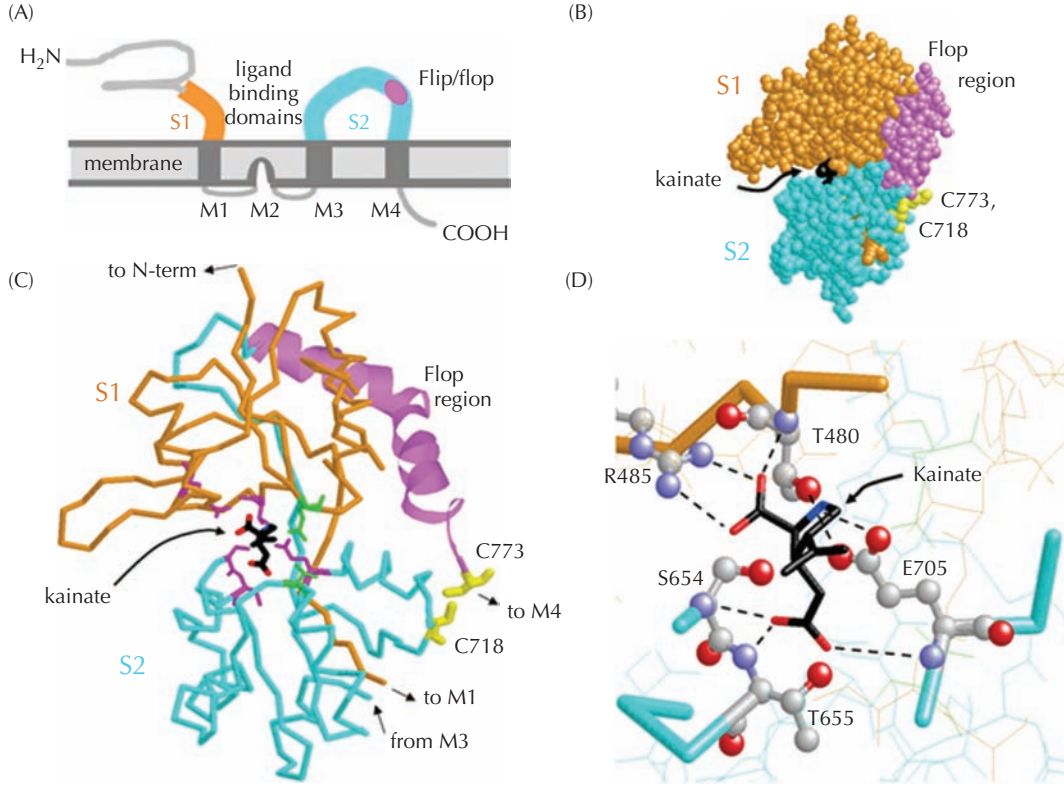

Figure 10–1. Transmembrane topology (**A**) and crystal structure of the agonist-binding domain (**B–D**) of the GluA2 subunit protein. The two domains that contain agonist-binding residues are colored in gold (S1) and turquoise (S2). The flip/flop region is indicated in violet. **B.** Space-filled representation of the kainate-bound S1 and S2 domains joined by an 11-residue linker peptide, with coloration the same as in **A**. The position of a single-kainate agonist molecule (black) within a deep gorge of the protein is indicated; the two disulfide-bonded cysteines (C718 and C773) are shown in yellow. **C.** Backbone representation of the subunit, with kainate (black) docked into its binding site. The kainate-binding residues are shown as stick figures in magenta, the two cysteines in yellow, and the flop helix structure in violet. The two green residues (E402 and T686) do not directly bind to kainate but instead interact with each other, helping to hold the clamshell in the closed conformation. **D.** Close-up view of the ligand-binding pocket. The binding residues are in space-filled representation, with atoms colored conventionally (gray carbon, cyan nitrogen, red oxygen). Modified from ref. 3.

intracellular scaffolding and trafficking proteins that regulate both insertion of the receptors into the postsynaptic membrane and activity-triggered recycling.[6]

How structure drives molecular function of the ionotropic glutamate receptors is discussed in great detail in ref. 6. For all ionotropic glutamate receptors studied, the ligand-binding domain is in the form of a hinged clamshell consisting of two lobes that close around the agonist molecule (depicted as gold and blue sections in Fig. 10–1A,B). Agonists bind deep within a gorge and make atomic contacts with both gold and blue lobes of the clamshell (Fig. 10–1C,D). Agonist binding causes partial closure of the clamshell, trapping the agonist in the receptor and putting a torque on the transmembrane segments that apparently induces a twist in the transmembrane helices, thereby opening the channel. For AMPA receptors, "full" agonists cause a more complete clamshell closure than partial agonists.[14] Each subunit in a tetrameric structure typically binds the same agonist; however, NMDA receptors are unique among all neurotransmitter receptors in requiring the binding of both glutamate (to GluN2 subunits) and glycine or D-serine (to GluN1 subunits) for channel opening.[15]

The amino-terminal domain of glutamate receptors also forms a clamshell,[16–18] but in this

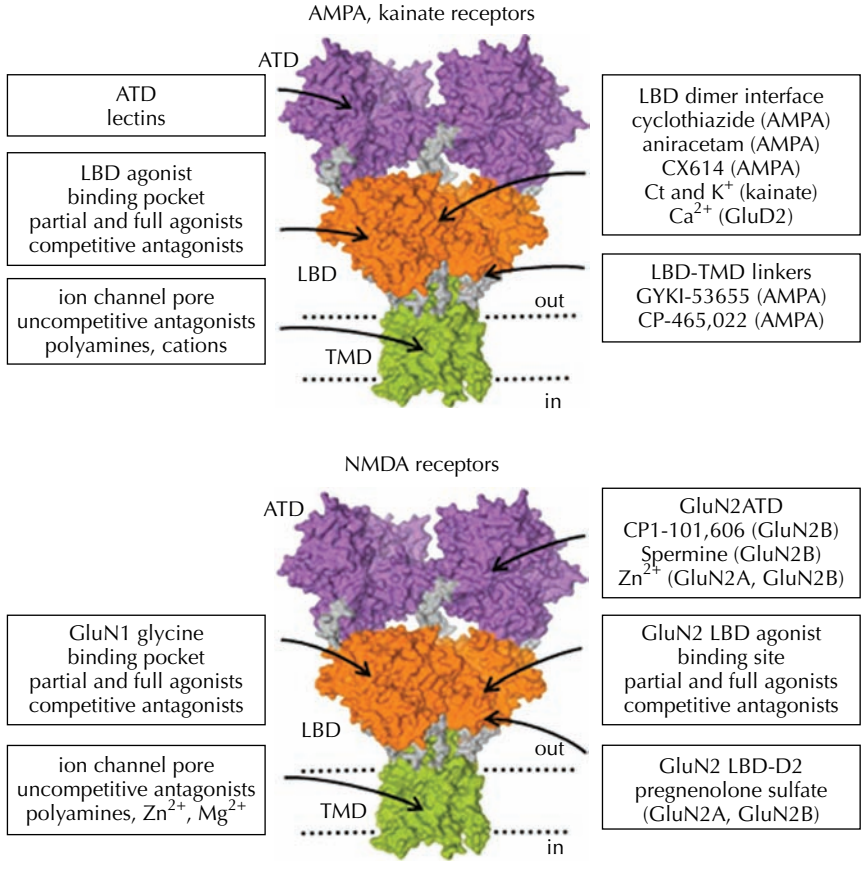

Figure 10–2. Binding sites for agonists, antagonists, and modulators in the ligand binding domain (LBD), amino terminal domain (ATD), and transmembrane domain (TMD). The receptor targets of ligands selective for one or several subunits are listed in parenthesis. "AMPA" and "kainate" indicates that the ligand selectively targets GluA or GluK receptor subunits, respectively. The ATDs, LBDs, TMDs, and linkers are shown in purple, orange, green, and gray, respectively. Modified from ref. 6.

case modulators bind at the interface between GluN1 and GluN2 rather than within the cleft (18a). The structure of the extracellular and transmembrane domains of one of the subunit dimers in a tetrameric glutamate receptor is shown in Fig. 10–2, along with the location of binding sites for agonists and allosteric modulators. The pharmacology of ionotropic glutamate receptors has become quite rich in the past decade, with the creation or discovery of numerous antagonists and allosteric modulators that are selective for particular receptors or even particular subunit combinations.[6,8] Many of the highly selective allosteric compounds target the amino-terminal domain.[10,13] For example, cyclothiazide allosterically potentiates AMPA but not kainate receptors, whereas concanavalin A potentiates kainate but not AMPA receptors; in both cases, potentiation occurs by relief from desensitization. Similarly, CP-101,606 selectively inhibits GluN2B-containing NMDA receptors, whereas zinc provides a high-affinity (10–30 nM IC50) block only of GluN2A-containing NMDA receptors.

CONTROL OF RECEPTOR PROPERTIES

Splice variants that control function or subcellular location have been identified for most of the subunits. The first example was the flip and

flop variants of each of the four AMPA receptor subunits. This cassette of 38 amino acids, which is located in an extracellular loop shown in Fig. 10–1A–C, influences desensitization rates of the receptors. C-terminal splice variants exist for most of the subunits and regulate coupling of the subunits to cytoplasmic proteins. For example, alternative exon 5 incorporation into GluN1 strongly determines responsiveness to allosteric modulation by protons and polyamines.

A very interesting regulation is determined by editing of the primary RNA transcript for AMPA GluA2 and kainateGluK1-GluK2 subunits. This editing involves enzymatic conversion of a glutamine codon to an arginine codon in the prespliced RNA,[19] which influences a wide range of functional properties including calcium permeability, single-channel conductance, voltage-dependent block by cytoplasmic polyamines, and, in the case of AMPA receptors, assembly efficiency.

The particular subunits that each neuron chooses to express are strong determinants of the synaptic phenotype, and subunit expression, in turn, is controlled both transcriptionally and translationally. The most intensively studied ionotropic glutamate receptor in this respect is GluA2, which features a neuron-restrictive silencer element (NRSE) in its promoter that is responsible for downregulation of GluA2 after status epilepticus.[20–22] Seizures cause rapid (within hours) induction of the transcriptional repressor, REST, which recruits histone deacetylases to the GluA2 promoter via the corepressor, Sin3A (Fig. 10–3A). The mechanism of repression likely involves deacetylation of histones that are physically bound to the *Gria2* gene because a histone deacetylase inhibitor prevents both deacetylation of *Gria2*-bound histones and GluA2 downregulation after status epilepticus.[22] Genes encoding GluN1 and GluN2C also have an NRSE, but less is known about the conditions under which the REST repression system is brought into play for the NMDA receptors. Currently, more than 1300 genes are known to have confirmed NRSE sequences, making the REST/NRSE system broadly seizure-responsive.

The 5′-untranslated region (UTR) of many ionotropic glutamate receptor mRNAs is unusually long. These long 5'-UTRs often exhibit high GC content and contain out-of-frame AUG codons that could act as decoys for scanning ribosomes, reducing or preventing translation initiation at the true glutamate receptor AUG. At least two major transcriptional start sites exist for the *Gria2* gene, as depicted by the pair of bent arrows in Fig. 10–3A. Interestingly, the longer transcripts contain an imperfect GU repeat that serves as a translational repressor, is conserved between rodents and humans, and is polymorphic in length in humans.[23] Additionally, GluA2 transcripts have alternative 3' UTRs that control the rate of initiation of protein synthesis. Translational suppression by the longer

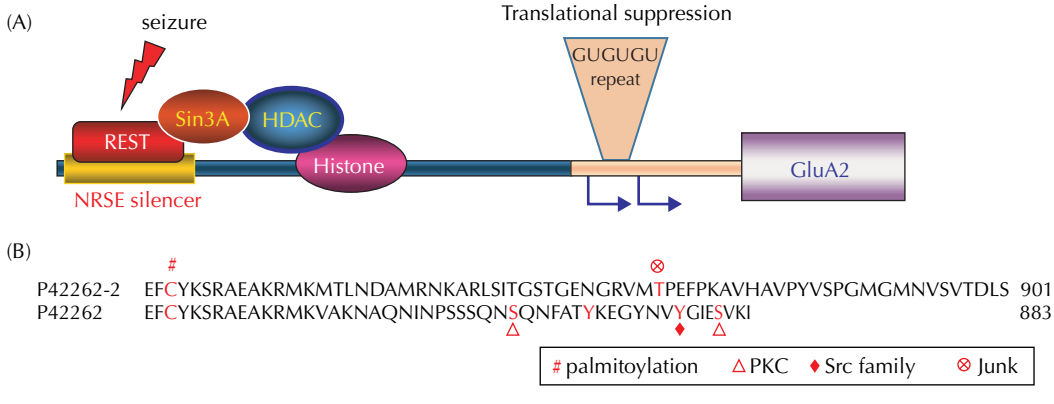

Figure 10–3. Control of GluA2 expression by transcriptional repression mediated by the REST/NRSE system (**A**), translational repression mediated by alternative 5'UTRs (**A**) and posttranslational processing on alternative C-terminal domains (**B**). To the left in **B** is the UniProt-SwissProt human accession number of the two splice variants. The length of each subunit, including the signal peptide, is shown at the right, with residue numbering beginning with the initiating methionine.

3'UTR seems to be mediated in part by binding of CPEB3[24] and in the rat hippocampus is relieved by seizures.[25,26] Thus, both transcription and translation of GluA2 are regulated by seizure-induced signaling systems. The GluN1 and GluN2A subunits are also under translational control by the 5'-UTR and 3'-UTR, respectively.[27,28]

The combination of specific phosphoprotein antibodies, site-directed mutagenesis, chromophore-tagged receptors, and, in some cases, fragmentation followed by mass spectrometry, has in the past decade led to the secure identification of phosphorylation sites on the C-terminal domains of ionotropic glutamate receptors, and in some cases to an understanding of the functional consequences of phosphorylation. The most intensively studied subunits are GluN1 and GluA1. The C-terminal domain of GluA1 exhibits four protein kinase C (PKC) targets, plus one protein kinase A (PKA) and one calmodulin kinase II (CAMKII) site. Phosphorylation at each of these sites has been shown to regulate activity-dependent receptor trafficking, open probability or conductance of the channel.[6] GluA2 has alternative C-terminal domains that are differentially regulated by phosphorylation, as shown in Fig. 10–3B. GluN1 has four C-terminal splice variants, only the longest of which appears to harbor phosphorylation sites. Status epilepticus causes rapid dephosphorylation of serines 890 and 897 on GluN1, then slowly developing hyperphosphorylation of these serines by PKCγ and PKA, respectively.[29,30] Phosphorylation of S890 disrupts surface clusters of NMDA receptors,[31] whereas phosphorylation of S897 promotes insertion of receptors into the synaptic membrane.[32]

GLUTAMATERGIC MECHANISMS IN EPILEPSY

Currently available glutamate receptor antagonists, with the possible exception of those directed toward kainate receptors, are as a rule poor anticonvulsants due to meager selectivity toward rapidly firing neurons, yet activation of glutamate receptors on neurons and probably on astrocytes contributes to the initiation and propagation of seizures. Given this conundrum, I will consider here several related topics that might be developed therapeutically.

Astrocytic Release of Glutamate

It is now clear that astrocytes in vitro can respond to chemicals (e.g., glutamate, prostaglandins, tumor necrosis factor alpha) released from surrounding cells during periods of repetitive firing or inflammatory stimuli. The astrocytic response in vitro involves generation of a cytoplasmic calcium signal and subsequent release of glutamate and/or D-serine.[33] The consequence of astrocytic glutamate release has been the subject of numerous studies. One of the most convincing was that of Jourdain et al.,[34] who showed that repetitive depolarization of an astrocyte through a patch pipette in hippocampal slices increased the frequency of spontaneous miniature excitatory postsynaptic currents (EPSCs) recorded in nearby dentate granule cells. A number of internal controls ruled out neuronal depolarization as the culprit. Following such astrocytic stimulation, GluN2B-containing receptors on presynaptic terminals of the perforant path were activated, which in turn potentiated synaptic transmission by elevating the probability of transmitter release. GluN2B activation could be prevented by direct astrocytic infusion of the calcium chelator 1,2-*b*is(o-*a*minop*h*enoxy)e*t*hane-N,N,N',N'-*t*etra*a*cetic acid (BAPTA) or a tetanus toxin protease. The precise conditions under which such strong, prolonged depolarization of astrocytes would occur was not addressed by their study, but it can be supposed that status epilepticus would serve this purpose. Moreover, the key astrocytic event—release of glutamate or a similar compound, or perhaps adjustment of the extracellular space to allow neuron-released glutamate to feed back onto presynaptic receptors—could not be definitively determined.

Although evidence is mounting for a specific role of astrocytic calcium waves in neurodegeneration during status epilepticus[35] and ischemia,[36] it is proving frustratingly difficult to determine exactly how and under what conditions the calcium wave contributes to neuropathology.[33,37] One clue comes from the studies of Bezzi et al.,[38] who showed that the tumor necrosis factor-α (TNFα) produced

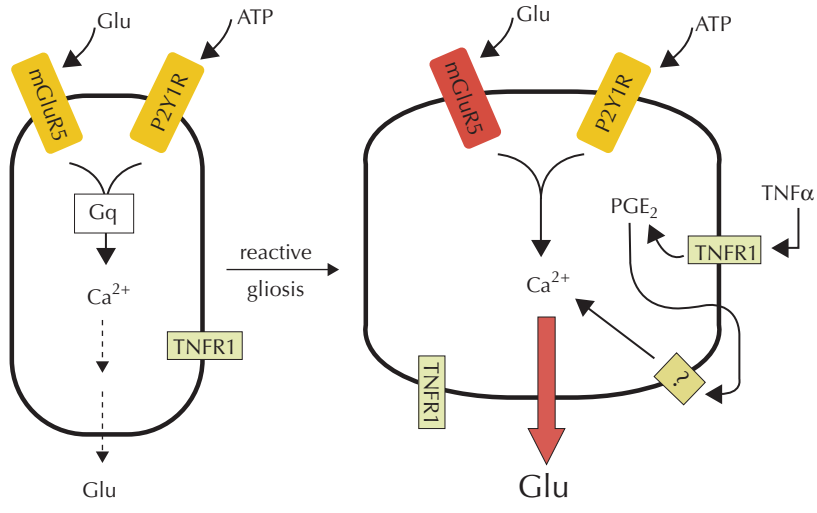

Figure 10–4. Potential mechanism by which inflammation could boost astrocytic glutamate release. *Left*: Scheme for control of astrocytic glutamate release by two G protein–coupled receptors. Right: In the epileptic brain, mGluR5 is upregulated, and activated microglia as well as reactive astrocytes release TNFα, which acts on TNFR1 receptors in a pathway that promotes prostaglandin formation. Prostaglandin, in turn, activates a Gq-coupled prostanoid receptor that boosts intraastrocyte Ca^{2+} release and thus astrocytic glutamate release. From ref. 33.

by reactive astrocytes and activated microglia boosts glutamate release from astrocytes through a cyclooxygenase-mediated pathway. Thus, it is possible that astrocytic glutamate release is minimal normally but enhanced in inflamed tissue (Fig. 10–4).

Impaired Glutamine Cycle in Sclerotic Tissue

Much of the glutamate released from excitatory nerve terminals is transported by active membrane pumps from the extrasynaptic space into surrounding astrocytes. Glutamate is then largely converted to glutamine by an enzyme, glutamine synthase, that is expressed by astrocytes and oligodendrocytes but not by neurons. Glutamine, in turn, is transported to extracellular fluid and is taken up by both inhibitory and excitatory neurons, where it is converted back to glutamate by phosphate-activated glutaminase. The movement of glutamate and glutamine between neurons and astrocytes is called the *glutamine cycle* and is an important feature of the close metabolic relationship that exists between neurons and glia in the brain. The glutamine cycle supplies this glutamate precursor to both glutamateric and GABAergic neurons. The role of the glutamine cycle in epilepsy is somewhat controversial. Inhibition of glutamine transport or glutamine synthase reduces the amplitude of GABAergic evoked or spontaneous inhibitory postsynaptic currents (IPSCs),[39,40] resulting in disinhibition and suggesting a major function of the glutamine cycle in the dynamic regulation of inhibitory synaptic strength. The notion that disruption of the glutamine cycle should promote seizures is reinforced by the observations that astrocytic glutamine synthase is downregulated in sclerotic tissue resected from epilepsy patients,[41] that selective induction of astrogliosis causes reduced GABAergic inhibition in the hippocampus that could be reversed by exogenous glutamine,[42] and that recurrent seizures develop in rats after local inhibition of glutamine synthase in the hippocampus.[43] However, when GABAergic inhibition is blocked, the resulting epileptiform activity in hippocampal[44] and cortical[45] slices maintained in vitro is dramatically attenuated by inhibition of glutamine transport or glutamine synthase. This finding suggests that a continual supply of glutamine is needed to fuel glutamate synthesis for excitatory synaptic transmission in rapidly

firing neurons. Taken together, these studies indicate that inhibition of the glutamine cycle can reduce both GABAergic inhibition and synaptic excitation mediated by glutamatergic synapses. To develop this notion further, it will be important to explore the anticonvulsant potential of potentiating residual glutamine synthase in reactive astrocytes under the more realistic conditions of chronic epilepsy. For a more thorough discussion of the potential roles for disruption of the glutamine cycle in epilepsy, see Chapter 12 in this volume.

Special Role for Kainate Receptors in Epilepsy

The year 1974 brought the first demonstration that a newly developed antihelminthic, kainic acid, caused convulsions in mice.[46]Much has been learned about the pharmacology and biology of kainate receptors in the last decade (reviewed in refs. 8 and 47). Because kainate is a powerful agonist at AMPA receptors as well as at kainate receptors, consideration of the roles of kainate receptors in epileptiform activity awaited the development of selective drugs and genetically modified mice. Genetically engineered mice lacking GluK2 showed an interesting phenotype.[48,49] First, the potency with which kainate induced an inward current in CA3 pyramidal cells from these mice was reduced about sixfold. Kainate-induced inward currents on CA3 interneurons, and kainate-induced increase in the frequency of spontaneous IPSCs on pyramidal cells, were also absent in mice lacking GluK2. Second, kainate was unable to induce gamma oscillations (38 Hz) in the CA3 region of mice lacking GluK2. Finally, mice injected with a moderate (20 mg/kg ip) but not a higher (30 mg/kg ip) dose of kainate were protected from seizure development. These results point to an important role for GluK2 in mediating epileptiform activity produced by kainic acid.

The role of GluK1 in seizure development, on the other hand, is more controversial, with superficially opposing results of pharmacological and genetic experiments. Genetic ablation of GluK1 *increased* the potency with which kainate induced gamma oscillations and epileptiform activity in CA3,[49] and yet a first-generation GluK1-selective antagonist prevented pilocarpine-induced seizures in rats as well as seizure activity produced by 6 Hz corneal stimulation.[50] This antagonist, LY377770, was 10- to 100-fold selective for GluK1 versus the four AMPA receptors in ligand binding assays, and was >40-fold selective for GluK2 or GluK2/GluK5 receptors. Kainate was still able to elicit seizure activity in GluK1 knockouts (unpublished data reported in ref. 47), but the *sensitivity* to kainate in the GluK1 nulls was not reported. It would be simple to dismiss the pharmacological results based on insufficient selectivity, but one must also consider the consequence of homeostatic adjustments in circuitry or receptor expression in the GluK2 knockouts (as shown by Christensen et al.[51]).

CHALLENGES AND OPPORTUNITIES

In the past decade, we have seen the first fruits of understanding the molecular function of ionotropic glutamate receptors based on their protein structure and posttranslational processing. In addition, roles for reactive astrocytes in the buildup of extracellular glutamate during seizures have been proposed. A major challenge for using this information to develop new anticonvulsants is the near-ubiquitous distribution of ionotropic glutamate receptors, which mediate the vast majority of excitatory neurotransmission in virtually every brain region. However, the tremendous strides made in developing subunit-selective antagonists of kainate receptors[8] represent a real opportunity to explore the potential for the use of kainate receptor antagonists in epilepsy. A related opportunity relies on the finding that activation of Gαq-coupled receptors such as M1 muscarinic receptors (by, e.g., pilocarpine) can potentiate the activation of heteromeric kainate receptors.[52] It might therefore be possible to use selective antagonists of group 1 metabotropic glutamate receptors, muscarinic receptors, or Gαq-coupled prostaglandin receptors to allosterically dampen kainate receptor activity. More gentle allosteric inhibition may be preferable to frank antagonism of the ionotropic glutamate receptors to minimize adverse effects.

Glutamine synthase represents another intriguing molecular target, even though this astrocytic enzyme supplies glutamate to both

inhibitory and excitatory neurons. A potentiator of residual glutamine synthase expressed by reactive astrocytes might restore inhibitory balance. No chemical potentiator exists yet, but the application of high-throughput screening of small molecules followed by medicinal chemistry would be the preferred route to developing an allosteric potentiator.

DISCLOSURE STATEMENT

The author is a cofounder of NeurOp, Inc., a preclinical pharmaceutical company that seeks to develop NMDA receptor antagonists for CNS indications.

Chapter 11

Glutamate Receptors in Epilepsy

Group I mGluR-Mediated Epileptogenesis

Riccardo Bianchi
Robert K. S. Wong
Lisa R. Merlin

In the early 1990s, the epileptogenic potential of metabotropic glutamate receptor (mGluR) activation in the hippocampus was first suggested by data using the then newly developed broad- spectrum mGluR agonist (1*S*,3*R*)-1-aminocyclopentane-1,3-dicarboxylic acid (ACPD).[1] These studies revealed that mGluR activation had the potent ability to recruit the hippocampal network to express robust synchronized discharges. These synchronized bursts had features suggestive of typical seizure discharges in that (1) their length was on the order of seconds and (2) they were comprised of an intrinsic oscillatory series of discharges that began at a high frequency and gradually slowed. And indeed, work in other labs confirmed that ACPD application does elicit seizures in the intact organism.[2] A hypothesis was developed proposing that the group I mGluRs, which are predominantly localized to the edges of synapses (*perisynaptic*),[3] were likely to be activated at times of intense glutamate release,

and this could result in the expression of acute seizures such as the impact seizure that occurs acutely in the setting of head trauma. However, subsequent studies using the selective group I mGluR agonist (*S*)-3,5-dihydroxyphenylglycine (DHPG) revealed a potential additional consequence of group I mGluR activation: long-lasting changes in network excitability.[4]

THE mGluR MODEL OF EPILEPTOGENESIS

The impact of selective group I mGluR activation on the in vitro hippocampal network was profound. Not only did such activation result in the expression of ictal-like discharges, but removal of the mGluR agonist was insufficient to restore baseline network excitability; instead, ictal-like discharges continued to be expressed unabated for hours following agonist exposure and removal (Fig. 11–1).[4] This network plasticity was strongly suggestive of the initiation of an epileptogenic process, one in which normal neuronal cortex is converted into a persistently hyperexcitable state with a lowered threshold for the production of seizure discharges. It was proposed that this form of epileptogenesis was likely to be clinically relevant because the instigating agent was acting at glutamate receptors, and glutamate was long recognized as the key excitatory transmitter in the central nervous system (CNS) underlying the expression of seizure discharges.

Numerous studies revealed that group I mGluR activation can induce long-lasting changes in cellular and synaptic properties (plasticity) in the CNS, including long-term potentiation and depression.[5,6] As with all metabotropic receptors, a G-protein-coupled second-messenger signaling cascade is recruited upon stimulation, and the intracellular enzymes activated can have long-lasting consequences for cellular excitability. In the case of the group I mGluRs—receptors coupled to the $G_{q/11}$ protein and phospholipase C signaling pathway—two direct effects were well characterized early on: production of diacylglycerol, which would result in protein kinase C activation, and inositol triphosphate production, which would stimulate release of calcium from intracellular stores.[7] Early studies attributed the synaptic long-lasting effects of group I mGluR activation to either or both of these intracellular pathways, and it was initially assumed that the network plasticity we observed was similarly mediated, but later studies revealed the additional involvement of a more complex set of proteins and enzymes, to be described later in this chapter.

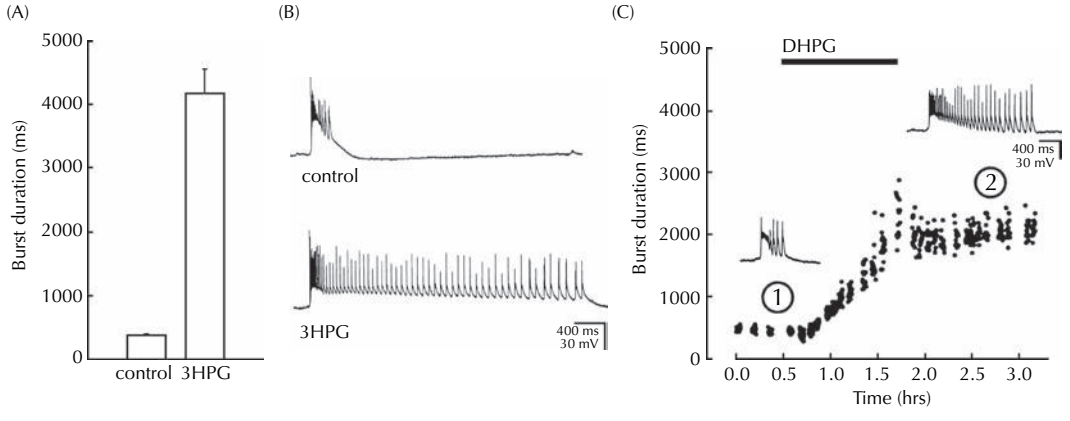

Figure 11–1. Group I metabotropic glutamate receptor (mGluR) activation induces persistent ictal-like discharges in the hippocampus. **A.** Summary histogram of mean duration of synchronized bursts elicited by picrotoxin (*control*) and maximum duration of prolonged bursts during application of the selective group I mGluR agonist (*S*)-3-hydroxyphenylglycine ((*S*)3HPG, 250–500 μM, $n = 7$ slices). Error bars: SEM. **B.** Intracellular recording from a CA3 pyramidal cell in a hippocampal slice before and during exposure to 250 μM (*S*)3HPG. **C.** Time course of synchronized burst prolongation; burst duration displayed before (*1*), during (*bar*), and after (*2*) group I mGluR stimulation with (*R,S*)-3,5-dihydroxyphenylglycine ((*R,S*)DHPG; 100 μM). Ictal-like discharges induced by (*R,S*)DHPG persisted for hours after washout of the agonist. Insets: Records before (*1*) and after (*2*) transient exposure to DHPG. Modified from ref. 4.

Plasticity of any type has two critical components: the initiating factors necessary for induction of the modification, and the downstream effectors that underlie the sustained expression of the enhanced response. Experiments described below have delved into understanding the necessary contributors to each of these components.

KEY FEATURES RELEVANT TO INDUCTION OF GROUP I mGluR-DEPENDENT EPILEPTOGENESIS

Most studies examining the in vitro model of mGluR-induced epileptogenesis have been performed on the hippocampal slice preparation. In many instances, slices were initially exposed to picrotoxin, an antagonist of $GABA_A$ receptor-mediated inhibition, to elicit baseline interictal activity in the CA3 network. While there were data to indicate that this additional agent was not necessary for the induction of persistent ictal-length activity, the picrotoxin model was useful for the following reasons: (1) It helped to confirm the baseline health of the slice by establishing the initial responsiveness of the network. (2) It reduced the interslice variability of the mGluR-induced ictaform activity. (3) It allowed easier interpretation of the site of action of the mGluR agonist: numerous studies had indicated that group I mGluRs are localized to principal neurons, interneurons, and glial cells,[8] and mGluR activation could therefore potentially have direct suppressive effects on inhibitory responses. Nevertheless, elimination of $GABA_A$ receptor-mediated inhibition from the network activity in the mature hippocampal slice never elicited ictaform discharges; only interictal-length bursts (generally <650 ms in duration) were produced. Furthermore, additional suppression of $GABA_B$ receptor-mediated responses also failed to elicit ictal-length discharges.[9]

Under conditions of suppressed GABA-mediated inhibition, exposure to selective group I mGluR agonists invariably induced ictaform discharges.[4] It was therefore suggested that group I mGluR activation participated in the interictal-to-ictal transition, eliciting ictaform discharges via a direct excitatory effect on the hippocampal network. But the persistence of the ictal discharges following transient agonist exposure was the finding of greatest interest due to its relevance to epileptogenesis. A series of experiments using coapplied antagonists indicated that the agonist was truly washing out of the chamber, suggesting that the persistence of the effect was due to a true network modification and not a pharmacological artifact.[4] But was group I mGluR activation truly necessary to induce this modification?

Silent Induction

When hippocampal slices are perfused with the $GABA_A$ antagonist picrotoxin, interictal bursts recur spontaneously and rhythmically approximately every 10 s for as long as the slice is exposed to the agent. When group I mGluR agonist is subsequently introduced, the burst frequency promptly increases to two to three times its original rate, then returns close to baseline frequency as the length of the bursts gradually increase to ictal length.[10] In light of this, it was hypothesized that perhaps the persistence of the effect was merely a kindling-like phenomenon resulting from the bombardment of recurrent bursting rather than a direct effect of the mGluR activation itself. To address this question, experiments were performed in which, after demonstration of normal interictal activity in the presence of picrotoxin, all bursting activity in the slice was suppressed via the perfusion of ionotropic glutamate receptor antagonists. Then, in the presence of this pharmacological blockade, the slice was transiently exposed to 20–40 min of group I mGluR agonist (DHPG), an experimental protocol referred to as *silent induction*.[11] Upon removal of all agents except picrotoxin, the synchronized discharges that emerged were markedly potentiated to ictal length. The data demonstrated that (1) induction of ictaform events in this model is independent of ionotropic glutamatergic activation, and (2) group I mGluR activation itself has a powerful, direct, long-lasting effect of enhancing hippocampal network responsiveness.

Group I mGluR Subtypes: mGluR1 and mGluR5

Experiments in which the group I mGluR agonist was applied in the presence of antagonist

confirmed that the epileptogenic effect was indeed driven by activation of group I mGluRs. The group I mGluR family is comprised of two receptor members, mGluR1 and mGluR5. Were both receptor subtypes necessary for induction of this epileptogenic effect? Utilizing selective antagonists against either mGluR1 or mGluR5, it was demonstrated that mGluR5 activation alone was often both necessary and sufficient to induce a persistent ictogenic effect.[12] This was evident from two sets of data: (1) If group I mGluR agonist was transiently applied in the presence of mGluR1-selective antagonist, persistent ictal-length discharges often appeared following subsequent removal of the mGluR1 antagonist, uncovering the epileptogenic effect that was induced by activation of mGluR5 alone. (2) If group I mGluR agonist was applied in the presence of mGluR5-selective antagonist, persistent ictal-length discharges were generally not elicited, revealing that mGluR5 activation was a necessary component of the induction process.

NMDA Receptors

N-methyl-D-aspartate (NMDA) receptor activation has frequently been associated with the induction of long-term potentiation and/or depression of synaptic responses.[13] It was therefore natural to consider the possibility that NMDA receptor activation may be necessary for the induction of the mGluR-driven long-lasting network effect. Nevertheless, experiments performed in the presence of NMDA receptor antagonist demonstrated that the group I mGluR agonist could still elicit its full epileptogenic effect, in regards to both enhanced burst length and persistence, following agonist removal.[14]

Protein Synthesis

Protein synthesis has been shown to play a key role in various forms of long-lasting synaptic modifications.[15] Experiments were performed to examine the protein synthesis dependence of the group I mGluR-induced epileptogenic effect. Utilizing anisomycin and cycloheximide, agents that suppress mRNA translation, it was shown that even prolonged group I mGluR agonist application failed to elicit burst prolongation in the presence of either protein synthesis inhibitor. By contrast, protein synthesis inhibitor had no effect on the expression of picrotoxin-induced interictal discharges.[10] The dependence of group I mGluR-mediated induction of ictaform events on mRNA translation would turn out to be highly relevant to understanding the pathophysiology of seizures and other clinical features of fragile X syndrome, as will be discussed later in this chapter.

Protein synthesis inhibitors had no effect on the expression of ictal-length discharges elicited with the broad-spectrum mGluR agonist ACPD, even though these discharges were shown to be group I mGluR-dependent.[16] Consistent with this finding, these ACPD-induced group I mGluR-driven but protein synthesis-independent ictal discharges were not persistent; rather, they readily disappeared upon removal of the broad-spectrum agonist.[4,16] Encouragingly, these data suggest that group I mGluR-mediated seizure discharges can be elicited without inducing an epileptogenic process, and further investigations clarifying the distinction between these two forms of mGluR activation may allow for the development of unique antiepileptogenic agents.

Phospholipase C

Group I mGluRs are coupled to intracellular signaling pathways via activation of phospholipase C (PLC);[7] this PLC activation was shown to be a critical component of the epileptogenic process. Pharmacological inhibition of PLC prevented induction of ictal-like discharges by DHPG, and similarly, in slices prepared from PLCβ1 knockout mice (mice lacking the major isoform of PLC expressed in the hippocampus), group I mGluR activation failed to elicit ictal-like discharges.[17] These data revealed that PLC activation is necessary for group I mGluR-induced epileptogenesis.

Activation of PLC stimulates two parallel signaling pathways: diacylglycerol-mediated protein kinase C (PKC) activation and inositol triphosphate–driven increases of intracellular Ca^{2+} via release from intracellular stores.[7] Although PKC is a mediator of many group I mGluR-induced effects, experiments performed in the presence of chelerythrine, a PKC inhibitor, revealed no significant suppressive effect on the induction of persistent ictaform activity by group I mGluR agonist.[18]

On the other hand, agents that interfere with Ca^{2+} release from intracellular stores did prevent the expression of ictaform activity elicited by either DHPG[19] or ACPD,[20] suggesting that mGluR-induced epileptogenesis is dependent on intracellular Ca^{2+} mobilization.

Extracellular-Signal-Regulated Kinase 1/2

Group I mGluR agonist elicits two phases of extracellular-signal-regulated kinase (ERK) 1/2 activation in hippocampal slices: an early response elicited directly by receptor activation and signaled via tyrosine kinase, and a later response driven by both neuronal firing and PKC activation. As indicated above, neither neuronal firing[11] nor PKC activation[18] is necessary for the mGluR-mediated induction of long-lasting ictaform activity. However, inhibition of either tyrosine kinase or ERK 1/2 phosphorylation prevented DHPG from inducing ictal-like discharges, suggesting that the induction process is dependent on the early receptor-mediated ERK 1/2 response.[21]

Phospholipase D

Cysteine sulfinic acid (CSA) is an amino acid endogenous to the nervous system that is released in the hippocampus during periods of high-intensity activity[22] and, among its many actions, activates phospholipase D (PLD)-coupled metabotropic receptors.[23] Cysteine sulfinic acid-mediated activation of PLD can be antagonized with the agent PCCG-13.[24] Through the use of these two agents, it was shown that PLD activation impedes the epileptogenic process induced by selective group I mGluR activation, while it has no suppressive effect on baseline interictal bursting or on fully induced persistent ictal activity.[25] Activation of PLD also had no effect on reversible ictal activity elicited with the broad-spectrum mGluR agonist ACPD.[16] As the CSA-mediated suppression of epileptogenesis was blocked by chelerythrine,[18] it was proposed that CSA's antiepileptogenic effect may be mediated by PLD-driven PKC activation, which could then feed back to inhibit group I mGluR-mediated responses.

The role of PKC in the antiepileptogenic effect of CSA was tested with experiments in which phorbol esters were used to activate PKC. Phorbol esters failed to inhibit mGluR-driven epileptogenesis; in fact, the ictal activity induced in the presence of phorbol esters was more robust than that elicited by DHPG alone. Additional experiments revealed that phorbol esters elicited a powerful epileptogenic effect of their own, accelerating the epileptogenic process and potentiating the ictal discharge duration.[26] It is possible that the PKC activation responsible for PLD-mediated suppression of epileptogenesis may need to be subtype-specific and/or localized to specific synapses on the activated neurons to evoke its suppressive effect.

WHAT SUSTAINS THE ONGOING EXPRESSION OF THE GROUP I mGluR-INDUCED ICTAL DISCHARGES?

As NMDA receptor–mediated responses can be enhanced by group I mGluR activation,[27] and as potentiated NMDA responses can sustain enhanced synchronized activity in hippocampal networks,[28] it was hypothesized that mGluR-induced NMDA potentiation may underlie the sustained expression of the ictal bursts in the hippocampus. However, experiments revealed that this was not the case; the ictal discharges continued unabated in the presence of NMDA antagonist.[1,14] What, then, was responsible for the sustained expression of the prolonged ictal discharges?

Autopotentiation

The ictal-length persistent discharges that are expressed following the transient activation of group I mGluRs proved to be quite resistant to most of the agents described above that impede induction of the discharges: neither protein synthesis inhibitor[10] nor CSA[25] could suppress the ongoing ictal activity once it had been induced. However, there was one agent that could effectively suppress the sustained expression: group I mGluR antagonist.[1,4,11] If introduced after induction had occurred and prolonged bursts were fully expressed, the group I mGluR antagonist shortened the synchronized discharges to interictal length, but ictal bursts promptly reappeared upon removal

of the antagonist. These findings suggested that group I mGluRs undergo *autopotentiation*; that is, transient agonist-mediated selective activation results in long-lasting enhanced responsiveness of group I mGluRs, allowing endogenous glutamate to sustain the activation of the receptors. Experiments utilizing selective mGluR1 and mGluR5 antagonists revealed that both receptors participate in the expression of the prolonged bursts: either antagonist alone elicited significant reversible shortening of the sustained ictal-length bursts, although the mGluR1 antagonist was more effective, almost completely restoring the discharges to their interictal length prior to agonist exposure.[12]

Although presynaptic enhancement of glutamate release remains a possible contributor to this observed potentiation of mGluR responses, it appears more likely that the primary site of modification is postsynaptic. In recent studies, postsynaptic long-lasting effects on intrinsic properties of CA3 pyramidal cells induced by group I mGluR activation have been identified.[29,30] These cellular modifications may underlie epileptogenesis by inducing persistent changes in the cell-firing pattern, thereby sustaining prolonged ictal-like discharges.

Persistent Effects of Group I mGluR Activation

There are numerous reported cellular effects mediated by group I mGluR activation. Most have not been established as long-lasting, but even those that do persist (e.g., enhancement of NMDA responses[27]) do not necessarily contribute to the enduring nature of the epileptogenic effect.[14] The following are two excitatory effects of group I mGluR activation that have been established as long-lasting and likely contribute to the ongoing expression of the persistent ictal discharges.

INDUCTION OF A VOLTAGE-DEPENDENT CATIONIC CURRENT $I_{MGLUR(V)}$

A major response to group I mGluR stimulation in CA3 pyramidal cells is the appearance of a depolarization-activated, voltage-dependent ionic current ($I_{mGluR(V)}$) that has an activation threshold at around –60 mV, and a reversal potential of about –10 mV, and shows no inactivation[17,29,31] (Fig. 11–2). $I_{mGluR(V)}$ induces plateau potentials that sustain rhythmic periods of prolonged action potential firing of 2–7 s with intervals of similar durations.[17] $I_{mGluR(V)}$ also promotes repetitive firing by eliciting spike afterdepolarizations (ADPs).[32] This intrinsic pattern of neuronal firing could drive synchronized ictaform activity via the recurrent glutamatergic collateral connections in the CA3 cell population.[33] Indeed, pharmacological blockade of $I_{mGluR(V)}$[17,29] or its abolition in transgenic preparations[17,34] prevents the expression of group I mGluR-dependent ictal-like discharges, suggesting that $I_{mGluR(V)}$ underlies this mGluR-induced synchronized activity.

SUPPRESSION OF ACTION POTENTIAL AFTERHYPERPOLARIZATIONS

DHPG-mediated activation of group I mGluRs elicits suppression of action potential afterhyperpolarizations (AHPs), an effect that enhances repetitive firing in CA3 pyramidal cells.[32,35] This AHP suppression can be long-lasting,[30] suggesting that it may contribute to the prolonged neuronal firing during synchronized group I mGluR-mediated ictal activity.

Consistent with the persistent nature of these two cellular effects, DHPG cannot elicit $I_{mGluR(V)}$ or AHP suppression in the presence of protein synthesis inhibitors,[29,30] lending support to the hypothesis that these cellular effects may underlie the sustained expression of the protein synthesis-dependent persistent ictal bursts.[10]

ENDOGENOUS REGULATION OF GROUP I mGluR-DEPENDENT EPILEPTOGENESIS

Studies on the endogenous control of group I mGluR-dependent epileptogenesis were prompted by the observation that persistent ictaform discharges are elicited by selective activation of group I mGluRs with DHPG[4,10] but not by the broad-spectrum mGluR agonist ACPD[4,16] or by synaptic stimulation of group I mGluRs,[29,36,37] suggesting that group I mGluR-mediated epileptogenesis is normally prevented. Concurrent activation of group II mGluRs does not account for the reversibility of the ACPD-induced ictogenesis.[4,16] Active protein synthesis

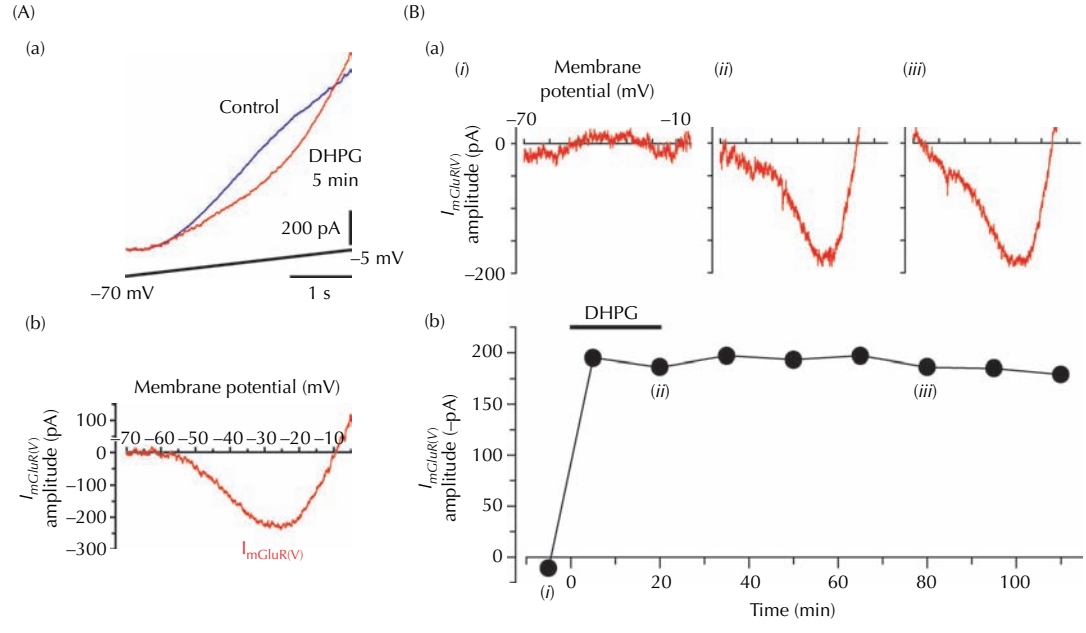

Figure 11–2. Group I mGluR activation induces a long-lasting voltage-dependent cationic current: $I_{mGluR(V)}$. **Aa.** Current response to a depolarizing ramp from –70 mV to –5 mV obtained from a CA3 pyramidal cell in a solution containing low Ca^{2+} (0.2 mM), Mn^{2+} (1 mM), TTX (1 µM), and Cs^{+} (5 mM) to suppress Ca^{2+}, Na^{+}, and K^{+} currents (*Control*) superimposed on current response in the same cell after addition of (*S*)DHPG (50 µM). **Ab.** *I–V* plot showing the current induced by DHPG, $I_{mGluR(V)}$, obtained by subtracting the control current response from the response in DHPG. **B**. *I–V* plots (***a***) of currents recorded in a CA3 pyramidal cell before (*i*), during (*ii*), and after (*iii*) DHPG application, and time course of $I_{mGluR(V)}$ development and maintenance relative to DHPG exposure (***b***). Modified from ref. 29.

is critical to the induction process underlying the mGluR-driven epileptogenic effect,[10,16,21] suggesting this to be a potential site of regulation.

Recent data reveal that there are multiple endogenous regulators of protein synthesis. Brain cytoplasmic 1 (BC1) RNA is a small non-protein-coding RNA expressed in neuronal dendrites,[38] where it inhibits activity-dependent protein synthesis.[39–41] Mice lacking BC1 RNA are susceptible to audiogenic seizures, and their hippocampal CA3 neuronal network displays synaptic hyperexcitability leading to ictal discharges.[37] These epileptogenic responses were shown to be protein synthesis dependent, and driven by enhanced activation of mGluR5 and ERK 1/2, as antagonism of either of these could suppress the epileptic effect.[37] These data suggest that, in wild-type mice, BC1 RNA is an endogenous translational repressor of group I mGluR-mediated epileptogenesis.[37,42]

The finding that group I mGluR-dependent long-term depression (LTD) is abnormal in preparations lacking functional fragile X mental retardation protein (FMRP),[43] an intracellular RNA-binding protein that represses mRNA translation,[44] pointed to this protein as another candidate for control of protein synthesis-dependent DHPG-induced epileptogenesis. Indeed, in experiments carried out on hippocampal slices from transgenic mice lacking FMRP, synaptic stimulation of group I mGluRs was able to elicit the DHPG-like persistent cellular and network excitatory effects previously seen only with DHPG application: both $I_{mGluR(V)}$ and persistent ictaform discharges were readily elicited, and these effects could be blocked with protein synthesis inhibitors.[29,36] These data are consistent with an inhibitory role of FMRP on group I mGluR-induced, protein synthesis-dependent plasticity in the normal condition, and with the hypothesis that absence of FMRP-mediated inhibition results in exaggerated group I mGluR-dependent protein synthesis-dependent responses responsible for the seizures seen in patients with fragile X syndrome[45] (Fig. 11–3).

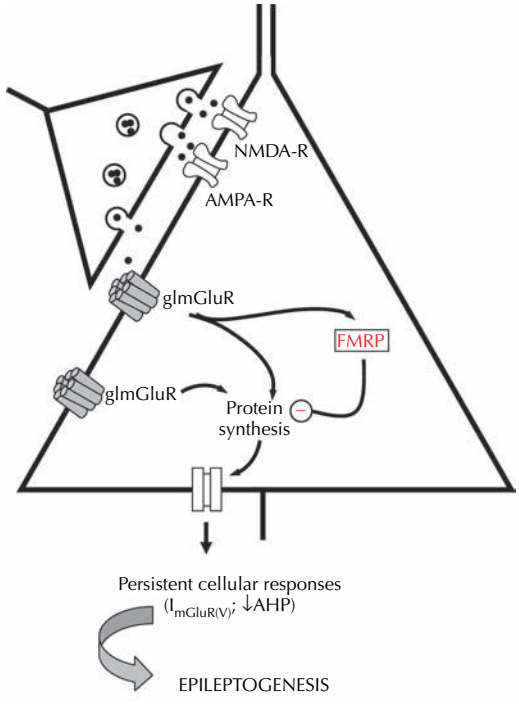

Figure 11–3. Group I mGluR model of epileptogenesis. Activation of group I mGluRs induces local translation eliciting cellular plasticity. Cellular plasticity includes long-lasting $I_{mGluR(V)}$ and AHP suppression. Integrative expression of cellular plasticity causes long-lasting ictal-like discharges. This epileptogenic process is normally controlled by a number of translation repressors, such as FMRP and BC1 RNA. Derepression of translation occurs in FXS, which is characterized by a single genetic defect resulting in loss of FMRP function. In the absence of FMRP, synaptic activation of group I mGluRs elicits exaggerated translation causing neurodevelopmental disorders and epilepsy.

FRAGILE X SYNDROME: A CLINICAL CONDITION IN WHICH HYPEREXCITABLE GROUP I mGluRS UNDERLIE A PHENOTYPE THAT INCLUDES SEIZURES

Group I mGluRs appear to play a central role in the pathophysiology of fragile X syndrome (FXS) in humans.[45] Fragile X syndrome is caused by a mutation that results in lack of expression of functional FMRP. The *Fmr1* knockout mouse expresses the full phenotype associated with FXS: memory deficits, learning disabilities, autism, epilepsy, altered body growth, and macroorchidism are features common to both the knockout mouse and the human condition, and thus this mouse has become a useful model for studying the underlying pathophysiology of the disease.[46] Studies have shown the efficacy of mGluR5 antagonist in suppressing audiogenic seizures in this model[47] (Fig. 11–3), and the results of clinical trials involving patients with FXS have been encouraging as well.[48] But even more remarkably, in *Fmr1* knockout mice crossbred to express 50% fewer mGluR5 receptors, a startling observation was made: all phenotypic anatomical and behavioral abnormalities usually seen in the fragile X mouse were normalized except for the macroorchidism.[46] The implications are profound: excessive mGluR5-driven protein synthesis is responsible for much more than just epileptogenesis; it has a broad impact on memory, behavior, and even prepubescent body growth in FXS. These data lead us to believe that the clinical importance of the group I mGluR system may be even more widespread than is currently realized.

ADDITIONAL CLINICAL CONDITIONS IN WHICH GROUP I mGluR HYPEREXCITABILITY MAY PLAY A KEY ROLE

The involvement of group I mGluR activation in epileptogenesis may well extend beyond FXS. The following are some examples of neurological conditions that are associated with enhanced susceptibility to seizures and for which recent data raise the issue of possible roles of group I mGluRs in their pathogenesis.

Alzheimer's Disease and Down Syndrome

Common features of Alzheimer's disease (AD) and Down syndrome (DS) are overexpression of amyloid precursor protein (APP) and accumulation of β-amyloid (Aβ) in brain plaques, with associated dementia.[49,50] Both AD and DS are associated with an increased incidence of seizures,[51] and recent data suggest that Aβ may be epileptogenic.[52] Studies on AD and DS mouse models reveal increased susceptibility to audiogenic seizures[53,54] and remarkably, mGluR5 antagonists reduce both Aβ production and the expression of seizures.[54,55] These

data suggest that mGluR5 activation may underlie epileptogenesis in AD and DS, and one may speculate that mGluR5 hyperexcitability contributes to the cognitive deficits and growth abnormalities as well. Interestingly, it appears that FMRP normally inhibits mGluR5-stimulated translation of APP and that Aβ is overexpressed in FXS,[56] indicating exaggerated mGluR5-mediated translation as a common pathogenic initiator in these distinct neurological diseases.

Posttraumatic and Poststroke Epilepsy

In patients who have sustained head trauma or stroke, there is an increased risk of developing epilepsy over the ensuing years.[57] Although the mechanisms for this epileptogenic process have not been fully elucidated and are likely multifactorial, the earliest inciting factor in both trauma and stroke is acute massive glutamate release, which may initiate an injurious process similar to kindling and culminating in the expression of recurrent unprovoked seizures. During the latent period, one can envision subclinical synchronized activity percolating in the network, contributing to a kindling-like phenomenon. The glutamate that instigates this cascade likely activates perisynaptic group I mGluRs, which may be key contributors to the epileptogenic process.

Traumatic brain injury (TBI) has been reproduced with animal models to study the mechanisms of epileptogenesis.[58] Chronic cellular modifications induced by TBI include loss of inhibitory interneurons, sprouting of excitatory connections, and increased excitability of pyramidal neurons.[59,60] Interestingly, at least some of these changes are activity-dependent because they are prevented by tetrodotoxin.[61] Contribution of group I mGluRs to posttraumatic neuronal injury is suggested by the findings in rat models that their activation exacerbates neuronal death in vitro, while their pharmacological blockade decreases the neuronal loss produced by TBI in vivo.[62,63] However, whether group I mGluR-dependent neuronal injury or activation of these receptors takes any part in epileptogenic processes following TBI is unknown. To assess the therapeutic potential of group I mGluR antagonists in this context is of particular interest since most of the classical antiepileptic drugs tested so far are rather ineffective against posttraumatic epilepsy.[64]

It is clinically recognized that only a subpopulation of patients with strokes or head trauma develop epilepsy, and at present we do not have the means to predict accurately which patients will have this outcome. We can speculate, however, that any patient with hyperexcitable group I mGluRs, either due to direct mutations or lack of sufficient endogenous repression, will be more prone to the epileptogenic process and may benefit from treatments targeting this pathway during the latent period, before their first clinical seizure is experienced. Advances in genetic testing may someday allow us to identify these patients. It is interesting to note that animals deficient in the expression of group I mGluRs have been shown to be particularly resistant to developing epilepsy following an episode of status epilepticus.[65] Although we are a long way from fully understanding the complex role of group I mGluRs in seizure expression and epileptogenesis, there are clear indications that such studies may have broad implications for the development of new therapeutic strategies for a wide variety of neurological conditions associated with epilepsy.

Chapter 12

Plasticity of Glutamate Synaptic Mechanisms

J. Victor Nadler

Epilepsy may be defined as a disorder of brain function characterized by the repeated and unpredictable occurrence of seizures. Seizures involve the disordered, rhythmic, and synchronous firing of central nervous system (CNS) neuron populations. Seizures originate in neuronal populations capable of bursting, develop because of an imbalance between neuronal excitation and inhibition, and are characterized by high-frequency firing associated with membrane depolarization. Neuronal excitation and inhibition may become unbalanced in many different ways. This chapter focuses on the contribution to seizures of glutamate synaptic plasticity, both anatomical plasticity that creates new excitatory synapses and functional plasticity that enhances the efficacy either of excitatory synapses or of glutamate itself. Observations made with human tissue are emphasized.

Glutamate is the principal excitatory neurotransmitter in mammals. About 60%–70% of all synapses in the CNS appear to be glutamate synapses (see Fig. 12–1). Glutamate also serves as the principal neurotransmitter utilized by sensory neurons. Autonomic neurons and motoneurons are about the only excitatory neurons in mammals that utilize a transmitter other than glutamate. Thus, the formation of enhanced or novel glutamate circuits, enhanced excitatory transmission, and/or an excess of glutamate itself could disrupt the balance of excitation and inhibition leading to the occurrence of seizures.

STRENGTHENING OF RECURRENT EXCITATION

Many cases of epilepsy arise from lesions of the brain. The consequences of brain injury depend not only on the degeneration of neurons and their axonal projections but also on reactive growth triggered by the injury. Degeneration of axonal projections stimulates the growth of collateral fibers from uninjured axons followed by a

process termed *reactive synaptogenesis*.[1] In many instances, axon sprouting and synaptogenesis appear to serve as mechanisms of repair. That is, the degenerated axons are replaced by new projections of the same type. The end result may be the restoration of at least some normal function. In contrast, the focal lesions often associated with epileptogenesis initiate the strengthening of recurrent excitatory circuitry. In humans with epilepsy, this phenomenon is most clearly observed in the dentate gyrus. Reorganization of the dentate gyrus is of particular interest because this region normally imposes high resistance to the propagation of seizures from the highly excitable entorhinal cortex to the equally excitable CA3 area of the hippocampus. The principal neurons of the dentate gyrus, the granule cells, are normally difficult to activate, both individually and as a population. The difficulty of activating synchronous population discharge can be explained, in part, by the scarcity of recurrent excitatory connections among dentate granule cells. The relative independence of granule cell activity is required to support the function of these cells in mediating pattern separation during the formation of new memories. Most persons with temporal lobe epilepsy exhibit a type of CNS pathology known as *hippocampal sclerosis*. Within the hippocampus, the most consistent region of neuronal loss is the hilus of the dentate gyrus. Loss of the hilar mossy cells opens synaptic territory on the proximal part of the granule cell apical dendrite. For reasons that remain unclear, denervation of this dendritic region attracts neoinnervation primarily from the axons of other granule cells. Granule cell

axons, the mossy fibers, sprout new collaterals and form recurrent excitatory connections. Because mossy fiber terminals contain numerous densely packed synaptic vesicles that contain zinc, mossy fiber sprouting can be detected by the Timm stain, which visualizes vesicle-bound zinc. Several investigators used this approach to demonstrate mossy fiber sprouting in hippocampal tissue resected for medically intractable temporal lobe epilepsy.[2–5] In addition, the new mossy fiber terminals were visualized with an antibody to dynorphin, a neuropeptide contained in those terminals.[6] Formation of recurrent excitatory circuitry in the human dentate gyrus is associated with a reduced threshold for granule cell synchronization.[7,8] The formation or strengthening of recurrent excitatory circuitry is one mechanism that could synchronize neuronal firing and thus support the initiation or propagation of seizures.

Robust mossy fiber sprouting has been observed in all animal models of epilepsy characterized by the loss of hilar mossy cells.[9,10] Studies of these models have generally confirmed the role of recurrent mossy fibers in synchronizing granule cell firing and supporting population bursts. Dentate granule cells are unusual in that they continue to be born and differentiate throughout life. Strong seizures increase the rate of granule cell neurogenesis markedly, and postseizure-generated granule cells possess properties distinct from those of preexisting granule cells. Many retain the hilar basal dendrite and burst potential characteristic of immature granule cells, and they serve as prominent sources and recipients of recurrent mossy fiber innervation. Granule cell basal dendrites provide a target for recurrent mossy fiber synapses in addition to the proximal apical dendrite. In humans, unlike rodents, about 25% of dentate granule cells normally have a basal dendrite. Thus, recurrent excitation of granule cells may be a normal feature of human brain, which is then enhanced by mossy fiber sprouting during epileptogenesis. About 95% of recurrent mossy fiber synapses are made with other granule cells and only 5% with inhibitory neurons. Frequency facilitation at mossy fiber–granule cell synapses operates over a rather narrow dynamic range (0.8–2 Hz), but even small changes in excitatory transmission could substantially increase synchronized granule cell discharge, especially if some granule cells generate a burst of action potentials. Thus, the normally rather quiescent dentate gyrus may be driven into reverberating epileptiform activity under conditions that strongly engage the novel recurrent dentate gyrus circuitry.

Recurrent axon sprouting is not confined to the dentate gyrus. In animal models of epilepsy, the number of monosynaptic recurrent excitatory synapses also increases dramatically in area CA1 of the hippocampus and the neocortex. Some seizures appear to propagate directly from the entorhinal cortex to area CA1, bypassing the dentate gyrus.[11] In these instances, the enhancement of recurrent excitation in area CA1 would appear to be of greater importance than changes in the dentate gyrus. Further studies are needed to determine how widespread the strengthening of recurrent excitation is in different regions of the brain, how large a role this type of plasticity plays compared to other changes that take place in the epileptic brain, and, importantly, the extent to which this type of plasticity outside the dentate gyrus occurs in the brain of humans with epilepsy.

EXTRACELLULAR GLUTAMATE CONCENTRATION

Measurements of extracellular glutamate concentration by microdialysis have revealed, as expected, an increase immediately before and during seizures in humans with epilepsy.[12,13] Perhaps less expected is the finding that the extracellular glutamate concentration is also elevated during the interictal period. This occurs despite neuronal loss and glial proliferation. Normally, the extracellular glutamate concentration is maintained in the low micromolar range. In one study, the extracellular glutamate concentration of the hippocampus was found to be four- to fivefold greater in patients with temporal lobe epilepsy than in controls.[14] This difference was only observed in brain regions from which seizures are thought to originate. A high ambient extracellular glutamate concentration could, among other actions, evoke a tonic *N*-methyl-D-aspartate (NMDA) current in neurons nearby, chronically depolarize those neurons, enhance neuronal excitability by activating Type I metabotropic receptors, and in extreme situations initiate an apoptotic/necrotic cascade. Mechanisms potentially responsible

for increasing the extracellular glutamate concentration include enhanced biosynthesis, enhanced release, impaired metabolic inactivation, and impaired clearance from the extracellular space.

Glutamate Biosynthesis

Glutamate can be synthesized by at least six different metabolic routes. However, perhaps 80% of the glutamate used as a transmitter by CNS neurons is synthesized from glutamine by phosphate-activated glutaminase. The mitochondria of glutamate terminals express this enzyme in abundance. Glutamine produced within astrocytes diffuses into the extracellular space and is taken up by nerve terminals. It is then hydrolyzed to glutamate by phosphate-activated glutaminase. Cytoplasmic glutamate is then made available for release through transport into synaptic vesicles by a specific vesicular transporter.

One study of human hippocampi resected for medically intractable temporal lobe epilepsy indicated enhanced expression and activity of phosphate-activated glutaminase per neuron in some regions.[15] Hippocampal enzyme activity was greater in the damaged hippocampus of lesional temporal lobe epilepsy than in the intact hippocampus of other forms of temporal lobe epilepsy. Thus enhanced production of glutamate may contribute to the increase in its ambient extracellular concentration.

Glutamate Release

Glutamate produced by intraterminal mitochondria is taken up into a population of synaptic vesicles that is specialized for this purpose. The expression of vesicular glutamate transport determines that a particular synaptic terminal will release glutamate.[16] Four vesicular transporters have been identified. Two of these, designated VGLUT1 and VGLUT2, are expressed by synaptic vesicles of glutamate pathways. VGLUT1 is the type most frequently expressed in forebrain regions. A third vesicular transporter, VGLUT3, is expressed by synaptic vesicles of some nonglutamate pathways, including pathways that release serotonin or dopamine. Synaptic terminals of these pathways contain largely or completely separate populations of glutamate and nonglutamate vesicles. Expression of VGLUT3 in some synaptic vesicles endows these pathways with the ability to release some glutamate along with their predominant transmitter. The physiological role of glutamate corelease is unclear. Finally, sialin, a lysosomal H^+/sialic acid cotransporter, accumulates glutamate and aspartate in synaptic vesicles by a mechanism independent of sialic acid transport.[17] Sialin is the only vesicular transporter identified thus far that can transport aspartate; the other excitatory amino acid vesicular transporters are highly specific for glutamate. Transport is driven by an inside-positive vesicular membrane potential that is created by an electrogenic proton pump. Glutamate is then released upon nerve terminal depolarization by Ca^{2+}-dependent exocytosis. In most instances, when the action potential invades the synaptic terminal, Ca^{2+} entry releases the contents of either one or zero glutamate vesicles, and the quantity of glutamate released is normally sufficient to saturate the postsynaptic receptors. However, both multiquantal release and lack of receptor saturation have been reported at some glutamate synapses. Glutamate regulates its further release by feeding back onto terminal autoreceptors. Glutamate release is also regulated by the previous activity of that terminal, other transmitters present locally in the extracellular fluid, and products of cell metabolism, most notably adenosine and arachidonic acid.

No studies of synaptic glutamate release from epileptic human tissue have been reported. However, three studies that utilized either an electrophysiological approach[18] or depolarization by elevated K^+[19,20] in animal models of temporal lobe epilepsy indicated an enhancement of glutamate release. Both approaches evoked predominantly the exocytotic release of glutamate from nerve terminals. Astrocytes can also release glutamate by both exocytotic and nonexocytotic mechanisms. Indirect evidence suggests that epileptogenesis may increase the capacity of astrocytes to release glutamate.[21] Enhanced expression of the flip splice variants of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors by astrocytes has been reported in lesional temporal lobe epilepsy.[22] Activation of these receptors by extracellular glutamate, in conjunction with the activation of Type I metabotropic receptors, would be expected to evoke intracellular Ca^{2+} oscillations that could potentially drive astrocytic glutamate release. However, enhanced astrocytic release has not been demonstrated in either human

tissue or animal models. Although enhanced neuronal release clearly could account, at least partly, for the increased ambient extracellular glutamate concentration in epileptic brain, it is not clear to what extent glial release of glutamate contributes to the extracellular pool.

Conversion to Glutamine

As described above, glutamine is the primary substrate for the biosynthesis of the glutamate transmitter pool. The biosynthesis of glutamine involves cooperativity between glutamate nerve terminals and the adjacent astrocytes. Glutamate released from nerve terminals is transported into astrocytes and converted to glutamine by glutamine synthetase, an enzyme expressed by astrocytes but not by neurons. The glutamine synthetase reaction requires adenosine triphosphate (ATP). Astrocytic end-feet, enriched in glucose transporters, cover virtually all capillary walls in the brain. Glutamate transport into astrocytes stimulates glucose uptake by these cells. Glutamine produced by the astrocytes diffuses into the extracellular space, where it is available for uptake by glutamate terminals and subsequent conversion to glutamate. This cooperative metabolic pathway involving two distinct cell types is referred to as the *glutamate-glutamine cycle*. The glutamate-glutamine cycle provides a mechanism for coupling glutamate transmission with glucose utilization, one of the signals detected by positron emission tomography (PET) imaging. The energy demands of this cycle account for ~85% of total brain glucose utilization.[23]

Glial proliferation (gliosis) is a prominent feature of damaged brain regions in lesional epilepsies. Reactive astrocytes have a reduced expression of glutamine synthetase. Thus, the immunoreactivity and total enzymatic activity of glutamine synthetase are reduced markedly in regions of neuronal loss, despite glial proliferation.[24–26] Similar results have been reported in animal models.[27–31] Congenital loss of glutamine synthetase results in seizures and death within days after birth.[32] Moreover, reducing the expression or activity of glutamine synthetase in animals either causes seizures or increases seizure susceptibility.[26,33,34] Thus, the conversion of glutamate to glutamine may be viewed as a neuroprotective measure intended, in part, to prevent the hyperactivation of glutamate receptors by extracellular glutamate. Failure of this mechanism in lesional epilepsies may contribute to the increase in extracellular glutamate concentration, leading in turn to seizure generation and excitotoxic cell death.

Plasma Membrane Transport

High-affinity (1–10 μM K_T) excitatory amino acid transporters expressed on the cell surface bind glutamate after its synaptic release, thus clearing the synaptic cleft in preparation for the next presynaptic action potential and limiting the spillover of glutamate from the cleft. The latter effect inhibits glutamate from activating extrasynaptic receptors or receptors located at nearby synapses. Because NMDA receptors bind glutamate with high affinity, distant NMDA receptors would be activated inappropriately if much glutamate were to escape the synaptic cleft routinely. In addition, transporters limit activation of the postsynaptic Group I and presynaptic Group II metabotropic glutamate receptors that lie in proximity to, but outside, the synaptic cleft. Maintenance of a low extracellular glutamate concentration is also necessary to prevent excitotoxicity. Indeed, knockout or knockdown of excitatory amino acid transporters in animals results in seizures and neurodegeneration.[35–37] In addition to limiting the extracellular concentration of glutamate, presynaptic excitatory amino acid transporters recover transmitter for reuse and astrocyte transporters accumulate glutamate for use as the metabolic precursor for glutamine. Transport activity requires energy, and both the direction and rate of transport depend on the extracellular Na^+ and intracellular K^+ concentrations.

Cloning studies identified five excitatory amino acid transporters (EAATs), two mainly glial and three neuronal. EAAT1 (GLAST) and EAAT2 (GLT-1) are expressed mainly by astrocytes, with EAAT2 predominating. In fact, EAAT2 accounts for 1% of total astrocyte protein and for ~90% of glutamate removal from the extracellular space. EAAT2 is also expressed to some degree by most glutamate neurons and has been localized to the plasma membrane of the synaptic terminal. Synaptic terminal expression of EAAT2 presumably explains the robust glutamate transport found in synaptosome preparations. EAAT3 (EAAC1) is expressed on the postsynaptic surface at glutamate synapses. EAAT4 is expressed largely

Table 12–1 **Localization of Excitatory Amino Acid Transporters**

EAAT1 (GLAST)	Astrocytes, Bergmann glia, Muller cells	
EAAT2 (GLT-1)	Astrocytes, glutamate nerve terminals	Accounts for ~90% of glutamate removal from the extracellular space
EAAT3 (EAAC1)	Postsynaptic membrane of glutamate synapses	
EAAT4	Cerebellar neurons (perisynaptic region)	
EAAT5	Retinal photoreceptors and bipolar cells	

by cerebellar neurons and EAAT5 by photoreceptors and bipolar cells of the retina (see Table 12–1).

In lesional epilepsies, one might expect increased expression of glial excitatory amino acid transporters because of the increase in glial membrane surface. In contrast, most reports have indicated reduced EAAT2 immunoreactivity and protein in regions of neuronal loss.[38–42] Similar to glutamine synthetase, expression of EAAT2 may be downregulated in reactive astrocytes. Alternative splicing of EAAT2 mRNA in patients with temporal lobe epilepsy may lead to reduced protein levels.[43] Because glutamate is cleared from the extracellular space predominantly by the action of EAAT2, downregulation of this transporter might well account for the high ambient extracellular glutamate concentration observed in the same brain regions. In addition, a chronic deficiency in glutamate transport might raise the extracellular glutamate concentration sufficiently to promote additional neuronal injury and death. However, two studies found no change in the expression of EAAT2.[44,45] The reason for this discrepancy is unclear. Aside from possible differences in technique, it is also possible that the different laboratories studied patients having different seizure etiologies, with a different treatment history, and/or having suffered brain damage at different times before the tissue was excised. None of the human studies included measurement of transport activity, only transporter protein. Therefore, the functional status of EAAT2 in human epilepsy remains uncertain. Studies of animal models are similarly conflicted; both reduced[20,46,47] and unchanged[48,49] expression of EAAT2 have been reported.

In contrast to EAAT2 expression, studies of both excised human tissue[38–40,44] and animal models[20,48,50,51] revealed the enhanced expression of EAAT3 by surviving neurons in damaged regions of epileptic brain. Upregulation of EAAT3 at postsynaptic sites may represent an attempt by surviving neurons to protect themselves from the deleterious effects of an increased extracellular glutamate concentration. However, the functional significance of this change has not been investigated.

GLUTAMATE RECEPTORS

Glutamate acts upon several structurally and pharmacologically different types of membrane receptor. The *ionotropic receptors* are themselves cation channels composed of multiple subunits, whereas the *metabotropic receptors* operate through G-protein coupling. For historical reasons, the ionotropic glutamate receptors are named for structural analogues of glutamate that activate receptors of that particular class selectively.

The vast majority of glutamate synapses operate through postsynaptic AMPA and NMDA receptors. Kainate receptors are expressed prominently on the presynaptic membrane, the postsynaptic membrane, or both at some glutamate synapses. AMPA receptors are expressed by astrocytes as well as neurons. Cloning studies justified the original separation of ionotropic glutamate receptors into classes based on agonist pharmacology. Glycopolypeptide subunits that participate in receptor assembly within one class exhibit much greater sequence homology than subunits that contribute to receptors of the other two classes (see Table 12–2).

The metabotropic glutamate receptors have been subdivided into three groups based on their agonist affinities and their preferred signal transduction pathways. Group I metabotropic glutamate receptors signal mainly through the activation of phospholipase C (mGluR1, mGluR5). Group I receptors are located postsynaptically but outside the synaptic cleft. They are also expressed by astrocytes. Neuronal

Table 12–2 **Ionotropic Glutamate Receptor Subunit Composition**

AMPA[a]	NMDA[b]	Kainate[c]
GluR1 (GluA1, GluRA)	NR1 (GluN1)	GluR5 (GluK1)
GluR2 (GluA2, GluRB)	NR2A (GluN2A)	GluR6 (GluK2)
GluR3 (GluA3, GluRC)	NR2B (GluN2B)	GluR7 (GluK3)
GluR4 (GluA4, GluRD)	NR2C (GluN2C)	KA1 (GluK4)
	NR2D (GluN2D)	KA2 (GluK5)
	NR3A (GluN3A)	
	NR3B (GluN3B)	

[a]AMPA receptor subunits can form a functional channel either by themselves or combined with other subunits. The channel is permeable to Na^+, K^+, and Ca^{2+} when a GluR2 subunit is absent, but only to Na^+ and K^+ when GluR2 is present.
[b]All NMDA receptors contain two glycine-binding NR1 subunits, and the channel is permeable to Na^+, K^+, and Ca^{2+}. Incorporation of two glutamate-binding NR2 subunits allows channel opening upon the binding of glutamate. NR3 subunits bind glycine and, if combined with NR1, may create a novel type of glycine receptor. NR1/NR2/NR3 combinations are also possible. The role of NR3 subunits in glutamate synaptic function is unclear.
[c]GluR5, GluR6, or GluR7 subunits or any combination of the three can form a functional channel with low agonist affinity. Incorporation of KA1 or KA2 into the complex forms a channel with high agonist affinity. Neither KA1 nor KA2 can form a homomeric channel.

postsynaptic Group I receptors are activated mainly during high-frequency activity when glutamate overflows the synapse. Group I receptors on astrocytes respond to changes in the ambient extracellular glutamate concentration. Receptor activation enhances excitability and causes release of Ca^{2+} from intracellular stores. One type of Group II metabotropic glutamate receptor, mGluR2, is located typically on the preterminal portion of the axon. This receptor is activated only when glutamate overflows the synapse. Activation of these receptors reduces subsequent glutamate release. The other type of Group II metabotropic glutamate receptor, mGluR3, appears to be expressed predominantly by glial cells. Group III metabotropic glutamate receptors are particularly sensitive to the glutamate analogue L-AP4. There are four receptors in this class, designated mGluR4, mGluR6, mGluR7, and mGluR8. mGluR6 serves as the postsynaptic receptor for glutamate at the synapse in the retina between the photoreceptor cell and the bipolar cell. mGluR4, mGluR7, and mGluR8 are expressed in a largely nonoverlapping pattern on terminals of glutamate pathways in the brain. They are located at the release sites; receptor activation reduces subsequent glutamate release. It appears that Group III receptors regulate glutamate release regardless of presynaptic action potential frequency, whereas mGluR2 functions in this way only when a high presynaptic firing frequency results in overflow of glutamate from the synaptic cleft. Firing frequencies as low as 3 Hz have been associated with glutamate overflow onto mGluR2 receptors (see Table 12–3).

AMPA Receptors

Nearly all glutamate-activated fast excitatory postsynaptic potentials (EPSPs) depend on the activation of AMPA receptors. For AMPA receptors in particular and ionotropic glutamate receptors in general, the receptor is composed of four glycopolypeptide chains (subunits) arranged like the staves of a barrel with a channel in the middle through which cations can flow. AMPA receptors bind glutamate with low affinity (K_D ~100 μM) and in most instances desensitize rapidly. All AMPA channels are permeable to both Na^+ and K^+. Because the inward Na^+ flux exceeds the outward K^+ flux ($E_{Na,K} \approx 0$ mV), the net effect is a depolarization: the fast EPSP. The underlying synaptic current is the fast excitatory postsynaptic current (EPSC).

Table 12–3 **Metabotropic Glutamate Receptors**

	Group I	Group II	Group III
Members	mGluR1 (mGlu1) mGluR5 (mGlu5)	mGluR2 (mGlu2) mGluR3 (mGlu3)	mGluR4 (mGlu4)[a] mGluR6 (mGlu6)[c] mGluR7 (mGlu7)[b] mGluR8 (mGlu8)[a]
Selective agonist	3,5-DHPG	DCG-IV	L-AP4
Signal transduction	Activation of PLC	Inhibition of adenylate cyclase K^+ channel opening Ca^{2+} channel inactivation	Inhibition of adenylate cyclase K^+ channel opening Ca^{2+} channel inactivation Phosphodiesterase activation (mGluR6)

[a]High agonist affinity.
[b]Low agonist affinity.
[c]Localized to retina.

Four subunits, designated GluR1–GluR4 (or GluA1–GluA4 or GluRA–GluRD), contribute to AMPA receptors. Each of these subunits can exist in *flip* and *flop* versions dependent on alternative splicing. The involvement of the flip versus flop version of the subunit in channel formation affects the extent of receptor desensitization, with flip subunits promoting less desensitization and thus more prolonged channel opening. Flip subunits are more commonly expressed during ontogenic development than in the adult brain. AMPA receptor subunits can form a channel either by themselves (homomeric channels) or with other subunits (heteromeric channels). The great majority of AMPA receptors expressed by excitatory neurons and many AMPA receptors expressed by inhibitory neurons include one or two GluR2 subunits. In this instance, the channel lacks permeability to Ca^{2+}. However, AMPA receptors expressed by astrocytes and many other inhibitory neurons lack a GluR2 subunit. Therefore, the channel is permeable to Ca^{2+}, in addition to Na^+ and K^+. Finally, the subunit composition of postsynaptic AMPA receptors is influenced by previous synaptic activity at that site. For example, in the basal state, postsynaptic AMPA receptors expressed by excitatory neurons are composed mainly of GluR2 and GluR3 subunits. Calcium/calmodulin-dependent (CaM) kinase II becomes activated during high-frequency activity as a result of NMDA channel opening (see below). CaM kinase II phosphorylates cytoplasmic GluR1 subunits, causing GluR1-GluR2 receptors to be inserted into the postsynaptic membrane. There is thus a net increase in the number of synaptic AMPA receptors, and the new receptors differ in subunit composition from the preexisting receptors. This is part of the molecular basis for the important biological process known as *NMDA receptor-dependent long-term potentiation* (LTP). Long-term potentiation is thought to be the elemental process that underlies declarative memory and types of learning that depend on formation of these memories.

Studies of excised tissue from epileptic human brain have indicated upregulation of neuronal AMPA receptors in certain brain regions. AMPA receptor binding associated with the dendrites of dentate granule cells was increased in persons with lesional temporal lobe epilepsy,[52] as was GluR1 immunoreactivity of CA3 hippocampal cells and hilar mossy cells.[53] These results are consistent with hyperexcitability driven by enhanced AMPA receptor activation. In some animal models, expression of GluR2 mRNA and protein is reportedly downregulated.[40,54,55] This change would be expected to increase the proportion of Ca^{2+}-permeable AMPA receptors and thus total Ca^{2+} influx in postsynaptic neurons. It has also been reported in animals that seizure-induced neuronal degeneration is preceded by downregulated expression of GluR2.[56] Thus, loss of GluR2 may lead to excitotoxic cell death.

Reactive astrocytes in sclerotic hippocampi of persons with temporal lobe epilepsy exhibit enhanced expression of flip splice variants, which may cause prolonged astrocyte depolarization and Ca^{2+} influx.[22] No such change was found in the undamaged hippocampi of persons with

nonlesional temporal lobe epilepsy. Increased cytoplasmic Ca^{2+} in astrocytes could lead to astrocytic Ca^{2+} waves that trigger glutamate release from those cells. Thus, AMPA receptor plasticity in astrocytes may contribute to the increased extracellular glutamate concentration in lesional forms of temporal lobe epilepsy.

NMDA Receptors

NMDA receptors normally coexist with AMPA receptors in the postsynaptic membrane. The extent to which NMDA receptor activation contributes to the EPSP depends on the resting membrane potential of the postsynaptic cell. Its contribution increases as the membrane potential becomes less negative. At most synapses, the NMDA receptor plays a negligible role in the EPSP evoked by a single impulse because the channel is blocked by Mg^{2+} ions. The binding of Mg^{2+} to the open channel is voltage-dependent; Mg^{2+} binds much less strongly when the membrane is depolarized. Thus, NMDA receptors are activated significantly only when glutamate release is paired with postsynaptic depolarization. In response to a single impulse, glutamate released from the synaptic terminal produces a depolarization by activating AMPA receptors. However, this EPSP is too short-lived to relieve much of the Mg^{2+} block. The EPSP is short-lived because (1) the AMPA receptor desensitizes rapidly when activated by glutamate, (2) the AMPA receptor has a low affinity for glutamate, causing bound glutamate to dissociate from the receptor rapidly, and (3) the following inhibitory postsynaptic potential (IPSP) returns the membrane potential toward the resting value. During repetitive activity, however, the postsynaptic depolarization is more prolonged and the Mg^{2+} block is effectively relieved. In addition, repetitive activity reduces GABA inhibition. Under these conditions, the NMDA receptor contributes substantially to the EPSP. In comparison to the AMPA receptor-mediated component, the NMDA component is of longer duration and exhibits slow kinetics. In general, the NMDA receptor serves as a mechanism by which experience alters synaptic transmission and properties of the postsynaptic cell for a period of hours to years. High-frequency activity is associated with experiences that result in memory and learning. High-frequency activity can also be pathological, as in seizures.

Both the long-lasting changes in synaptic function and NMDA receptor-induced pathology depend on the permeability of NMDA channels to Ca^{2+}. Like the AMPA receptor, it is the large fluxes of Na^+ and K^+ through the open channel that account for the NMDA component of the EPSC and EPSP. In contrast, the smaller Ca^{2+} influx is responsible for altering the properties of the synapse and the postsynaptic cell. Because the intracellular Ca^{2+} concentration at rest is very low, even a small influx of Ca^{2+} can increase the local intracellular concentration substantially. At this higher concentration, Ca^{2+} activates a number of key enzymes and transcription factors whose concerted action leads to a long-lasting enhancement of the EPSP and, in the extreme, to cell death.

Forebrain NMDA receptors are composed primarily of three subunits designated NR1, NR2A, and NR2B. Each receptor consists of two NR1 subunits and two NR2 subunits. Glutamate binds to the NR2 subunit, whereas the NR1 subunit binds the essential coactivator glycine. NR1-NR2B receptors exhibit much slower decay kinetics than NR1-NR2A receptors. Thus, the charge transferred per channel opening is much greater. Glutamate synapses in developing forebrain utilize predominantly NR1-NR2B receptors. During the maturation of the forebrain, NR1-NR2A receptors are inserted into the postsynaptic membrane and NR1-NR2B receptors are relegated largely to extrasynaptic sites. However, both NR1-NR2A and NR1-NR2B receptors can be found in both locations.

With respect to NMDA receptors, the most interesting finding reported in studies of resected human tissue is the often increased expression of NR2B mRNA and the increased function of NR1-NR2B receptors in damaged regions of epileptic brain,[57–59] even though total NMDA receptor expression may be downregulated.[52] Because responses mediated by NR1-NR2B receptors decay more slowly than those mediated by NR1-NR2A receptors, the associated Ca^{2+} influx would be enhanced. A large influx of Ca^{2+} through NMDA channels may facilitate seizure generation, and influx through extrasynaptic NR1-NR2B receptors can precipitate excitoxicity.[60] Of particular interest is the finding of increased NR2A and NR2B mRNA expression in dentate granule cells of persons with lesional temporal lobe epilepsy.[57] Studies of animal models suggest enhanced NMDA receptor function at perforant path

synapses on these cells.[18,61] In addition, NMDA receptors are expressed on some populations of glutamate synaptic terminals. In this location, tonic activation of these receptors by extracellular glutamate facilitates glutamate release. In an animal model of temporal lobe epilepsy, presynaptic NMDA receptors of the entorhinal cortex were found to be upregulated.[62] Because the entorhinal cortex is thought to be essential for the propagation of limbic seizures and of neocortical seizures into the limbic system, NMDA receptor-induced potentiation of glutamate release in that region may be significant.

Kainate Receptors

The kainate receptor resembles the AMPA receptor with respect to structure, regulation, and ionic selectivity. Kainate activates both AMPA and kainate receptors; there is considerable overlap in agonist action on the two receptors. Kainate receptors tend to be most abundant in those brain regions where NMDA receptors are least abundant. Their kinetic properties are intermediate between those of AMPA and NMDA receptors. Thus, simultaneous activation of postsynaptic AMPA and kainate receptors prolongs the response to glutamate and may result in repetitive firing of the postsynaptic cell. Kainate receptors are present on some glutamate preterminal axons and on portions of the synaptic terminal outside the synaptic cleft. Some glutamate terminals, including the mossy fiber terminals of the hippocampus, express both high- and low-affinity kainate receptors. They are activated when glutamate overflows the synaptic cleft during repetitive activation of the presynaptic neuron. Activation of low-affinity presynaptic kainate receptors depolarizes the terminal, reducing subsequent glutamate release by limiting action potential-evoked Ca^{2+} influx. Activation of high-affinity presynaptic kainate receptors prolongs the action potential-induced depolarization and enhances Ca^{2+} entry into the terminal. Thus, Ca^{2+} influx may be enhanced or reduced by kainate receptor activation, depending on the magnitude and duration of presynaptic depolarization and on the local extracellular glutamate concentration. By enhancing Ca^{2+} influx, kainate receptor activation mediates the dramatic frequency facilitation observed at mossy fiber synapses on CA3 hippocampal pyramidal cells. Kainate receptors are also expressed by inhibitory neurons, where their activation can both stimulate and depress GABA release.

Three subunits that bind agonist with low affinity (GluR5–7) and two subunits that bind agonist with high affinity (KA1–2) contribute to kainate receptors. Native receptors are composed of either a combination of low- and high-affinity subunits or exclusively of low-affinity subunits. Kainate receptors normally form a channel permeable just to Na^+ and K^+. However, some kainate receptors that contain GluR5 or GluR6 subunits are also permeable to Ca^{2+} (due to lack of RNA editing).

Compared to AMPA and NMDA receptors, the status of kainate receptors in epileptic brain has been little studied. Expression of GluR5 and GluR6 mRNA was reportedly decreased per CA2/CA3 pyramidal cell in the hippocampus of persons with temporal lobe epilepsy, whether or not the hippocampus was damaged.[63] In contrast, KA2 and GluR5 mRNAs were upregulated in dentate granule cells of patients with sclerotic hippocampi. The latter finding suggests the production of additional pre- and postsynaptic kainate receptors needed to regulate and mediate, respectively, transmission at newly formed recurrent mossy fiber synapses. In the temporal neocortex and hippocampus of humans with epilepsy, the editing efficiency of GluR5 and GluR6 subunits is reportedly enhanced.[64,65] This may be regarded as a compensatory response to seizures, reducing Ca^{2+} influx through kainate channels. Studies of animal models have not yielded consistent changes in kainate receptor expression, and possible changes in kainate receptor function have not been assessed.

Metabotropic Glutamate Receptors

Because metabotropic glutamate receptors are quite heterogeneous with respect to signal transduction and localization, their activation may alter seizure generation and propagation in diverse ways. Stimulation of Group I metabotropic receptors in the hippocampus transforms normal neuronal activity into a prolonged epileptiform discharge. This may come about through the metabotropic receptor-related activation of a voltage-gated cation current expressed in CA3 pyramidal cells.[66] In addition, the liberation of Ca^{2+} from intracellular stores that is driven by activation of Group I metabotropic receptors in

astrocytes, combined with Ca^{2+} influx through AMPA channels, triggers Ca^{2+} waves and subsequent astroglial glutamate release. Strong coactivation of AMPA and Group I metabotropic glutamate receptors in neurons can raise the intracellular Ca^{2+} concentration by enough to provoke long-lasting potentiation of the EPSP. Activation of Group II or Group III metabotropic glutamate receptors reduces transmitter release. The effect on seizures depends on whether the receptor is expressed by excitatory or inhibitory presynaptic elements and on the role of those particular synapses in circuit excitability. However, the overall effect of activating these receptors is likely to be inhibitory toward seizure generation and propagation.

Little is known about the role of metabotropic glutamate receptors in human epilepsy, although excessive activation of Group I receptors may account for seizures in persons with fragile X syndrome.[67] Studies of animal models, however, suggest downregulation of Group II and Group III metabotropic receptors.[68–72] In pilocarpine-treated mice, for example, feedback regulation of glutamate release from medial perforant path terminals in the dentate gyrus was found to be compromised.[69] Regulation of lateral perforant path transmission by feedback activation of mGluR8 was unchanged. In pilocarpine-treated rats, however, autoregulation through mGluR8 was reduced.[68] In reactive astrocytes of the hippocampus, the immunostaining of mGluR3 and mGluR5 was reportedly increased in an electrical stimulation model of temporal lobe epilepsy.[73] The combination of enhanced AMPA (see above) and Group I metabotropic receptor expression by astrocytes would be expected to increase the cytoplasmic Ca^{2+} concentration in the presence of glutamate. Although much work on human tissue remains to be done, studies of animal models suggest that both enhanced activation of Group I metabotropic glutamate receptors and reduced autoregulation of glutamate release by Group II and Group III metabotropic receptors could facilitate spontaneous recurrent seizures.

SUMMARY AND FUTURE DIRECTIONS

Studies of glutamate pathways and synaptic mechanisms in human epilepsy have been limited by the restricted availability of tissue. This is especially true of biochemical and electrophysiological functions whose evaluation require fresh tissue. Nevertheless, studies to date suggest that epileptogenesis involves substantial plasticity of both glutamate circuitry and glutamate synaptic mechanisms, at least in regions of neuronal loss. These changes are predominantly in a direction that would be expected to promote hyperexcitability. An increased density of recurrent excitatory pathways may promote the synchronous discharge of principal neuron populations. A high ambient extracellular glutamate concentration may depolarize nearby neurons, evoke a tonic Ca^{2+} current by activation of extrasynaptic NMDA receptors, enhance neuronal excitability by activating Type I metabotropic glutamate receptors, and possibly initiate excitotoxicity. Several changes in glutamate mechanisms may act in concert to raise extracellular glutamate: enhanced biosynthesis from glutamine in nerve terminals, reduced conversion to glutamine by astrocytes, and downregulation of the glial plasma membrane transporter EAAT2. Studies of animal models suggest that enhanced glutamate release from both nerve terminals and astrocytes may also contribute. Glutamate receptor plasticity may also enhance neuronal excitability. Some evidence suggests enhanced AMPA receptor activation in both neurons and astrocytes, as well as enhanced expression and function of NR1-NR2B NMDA receptors. Although little is known about the status of glutamate metabotropic receptors in humans with epilepsy, studies of animal models suggest downregulation of inhibitory metabotropic receptors. Thus, coincident sprouting of recurrent excitatory connections and altered pre- and postsynaptic glutamate mechanisms could potentially promote circuit hyperexcitability.

Given the exuberant sprouting of glutamate axons and apparently upregulated glutamate synaptic function in lesional epilepsy, there would appear to be great potential for the development of drugs that interfere with glutamate transmission to prevent seizures and drugs that interfere with glutamate plasticity to prevent the development of epilepsy after neuronal loss. However, the epileptogenic potential of these changes depends on where the change is expressed —excitatory versus inhibitory circuits, excitatory versus inhibitory neurons, and neurons versus glia. Although studies of animal

models generally favor promotion of hyperexcitability, there has been no confirmation of this from human studies, apart from a few that focused on recurrent excitatory circuitry in the dentate gyrus. A major drawback to the development of glutamate-based drugs is that glutamate serves as the predominant excitatory transmitter throughout the CNS. Thus, it is difficult to target therapy to hyperexcitable brain tissue without causing adverse effects, even disturbing vital functions. Although mechanisms that regulate glutamate transmission differ in different excitatory pathways, nearly every form of regulation is repeated at many sites in the brain. The best way around this dilemma would be the development of agents that target glutamate circuits or mechanisms when they are overexpressed or overactive, but not when they are functioning normally. Conditional negative receptor modulators would be one example of such agents. The utility of memantine, a blocker of overactivated NMDA channels, as a treatment for Alzheimer's disease serves as a precedent for the type of agent that might be clinically useful.

Chapter 13

Neuronal Synchronization and Thalamocortical Rhythms during Sleep, Wake, and Epilepsy

Igor Timofeev
Maxim Bazhenov
Josée Seigneur
Terrence Sejnowski

Neuronal synchronization can be divided into long-range and local synchrony. *Long-range synchrony* is usually detected with two or more electrodes placed some distance apart. It leads to brain activity that is correlated at long distances and may be seen using both local field potential (LFP) and electroencephalogram (EEG) recordings. The first tool (i.e., the LFP) provides a microscopic measure of brain activity summarizing electrical activities of possibly thousands of neurons [1–4]. The second type of recording (i.e., the EEG) is a result of changes in electrical activity of multiple sources and ultimately represents activity patterns of large populations of neurons and glial cells in the brain. *Local or short-range synchrony* can be detected either with one relatively large field potential electrode or with two or more small [intracellular or extracellular unit (action potential) recording] electrodes located at short (less than 1 mm) distances from each other. Synchronous activity of a few neurons does not necessarily lead to measurable EEG signals, but this can be seen using LFP recordings. Because of the low-pass filtering properties of the extracellular media,[5] high-frequency electric fields associated with action potentials steeply attenuate and large-amplitude slow

LFP and EEG potentials are mainly generated from nearly simultaneously occurring de- and hyperpolarizing events in a large number of neighboring cells with a major contribution from large pyramidal neurons.[6]

In general, synchronization of electrical activity in the brain occurs as the result of interaction among sets of neurons. The following major types of interaction between brain cells (neurons and glia) are possible: (1) chemical synaptic transmission, which takes place when an action potential that is fired by the presynaptic neuron invades the nerve terminals, allowing Ca^{2+} entry, triggering neurotransmitter release, and finally causing de- or hyperpolarization of the postsynaptic neuron[7,8]; (2) interactions between electrically coupled cells via *gap junctions*[9]; these interactions are bidirectional and work as a low-pass filter, that is, fast processes (e.g., action potentials) are filtered out, but slow processes (e.g., slow synaptic potentials) are transmitted with minor attenuation[10]; (3) ephaptic interactions, which are mediated by large extracellular currents and field potentials generated by cortical structures in the absence of specialized contacts[11,12] (it should be noted that some researchers separate ephaptic transmission from field effect interactions[13]); (4) nonspecific interactions, commonly achieved by alteration in the extracellular ionic balance caused by the activity of brain cells.[14–17]

MECHANISMS OF NEURONAL SYNCHRONIZATION

Neuronal synchronization is defined as the correlated appearance in time of two or more events associated with various aspects of neuronal activity at different levels, from single cell to the whole brain.

A common scenario involves adjustment or phase locking of the rhythms of two or more neurons leading to the stable phase differenceof membrane voltage oscillations (periodic or not)—for example, coincidence of action potentials. Such coincidence of electrical activities of many neurons would lead to coordinated changes in extracellular ionic currents in close proximity to these neurons, which can then be detected as changes of the LFP, which are reflected on the scalp EEG. If individual neurons fire action potentials periodically and these events are synchronized among many cells, periodic LFP oscillations would be observed. Finally, if long-range synchronization takes place among distinct brain areas, it would lead to global changes in electrical activity usually associated with EEG rhythms.

Chemical Synaptic Mechanisms of Synchronization

Synaptic interaction is a common mechanism of communication between neurons. Transmitter release by presynaptic terminal leads to receptor activation on the postsynaptic cell and the generation of inward or outward currents, which depolarize or hyperpolarize the postsynaptic cell. Summation of activities from synchronized inputs enhances transmission of information more effectively than raising discharge rates.[18] Generally, both excitatory and inhibitory synaptic interaction may contribute to synchronization of neuronal activity. For example, in a minimal circuit including synaptic connection from cell A to cell B, the action potential in cell A would trigger an excitatory postsynaptic potential (EPSP) in cell B. If this potential is ample enough, it can trigger an action potential in cell B**,** which may occur nearly simultaneously (after a small delay) with the action potential in cell A.

This process is more complex in real cortical networks. The amplitude of single-axon EPSPs is small and variable. In vitro, it ranges from 0.1 to 2 mV (but sometimes up to 9 mV), with a mean of about 1 mV.[19–23] In vivo, due to multiple factors associated with network activities (e.g., shunting or frequency-dependent attenuation), the amplitude of successful single-axon EPSPs is about 0.5 mV.[15] Given the fact that the EPSP amplitude depends linearly on the number of synaptic contacts formed by all the presynaptic neurons,[21,23] only 40 to 50 synaptic contacts are needed to bring the postsynaptic neuron membrane potential from a resting level of –75 mV to –80 mV to a firing threshold of about –55 mV in vivo. On the other hand, the actual rate of EPSPs received by a neocortical neuron in vivo may be much higher. Indeed, spontaneous firing rates in vivo are on the order of 10 Hz.[24,25] Large neocortical neurons possess between 10,000 and 50,000 synapses.[26] Assuming 25,000 synapses on average and considering that 80% of these synapses are excitatory,[27] about 200,000

synapses may be activated each second, or 200 synapses each millisecond (80% from 25,000 synapses × 10 Hz = 200,000 per s or 200 per ms). The half-width of EPSPs in vivo is about 10 ms, and this time might be assumed as a period for efficient integration of presynaptic inputs. Thus, a neocortical neuron can receive up to 2000 inputs during a 10 ms period for efficient integration. Because failure rates in vivo are very high (70%–80%),[15] the neuron receives about 400–800 EPSPs within the integrating period. This is still 10–20 times more than the needed number of simultaneously firing presynaptic neurons to fire postsynaptic neuron (40–50 synapses [see above]). Therefore, the mechanisms of cortical synchronization based exclusively on excitatory intracortical connectivity would lead to overexcitation of the network and cannot be considered as an efficient mechanism of cortical synchronization.

An efficient way to synchronize a population of excitatory cells involves inhibition. Imagine a group of excitatory neurons $A_1, \ldots, A_n$ that generate action potentials, which are not synchronized across cells. Imagine now that all these neurons receive common inhibitory input from inhibitory cell B. The action potential in cell B would provide synchronous inhibitory postsynaptic potentials (IPSPs) in neurons $A_1, \ldots, A_n$, so, when the IPSP terminates, all these neurons $A_1, \ldots, A_n$ can spike synchronously. If some of these excitatory cells now project back to inhibitory neuron B, synchronous spiking between $A_1, \ldots, A_n$ would trigger a new spike in cell B, starting a new cycle of oscillation (Fig. 13–1). This mechanism of synchronization, commonly referred to as *feedback inhibition* (see ref. 28 for a review of this topic), is involved in many brain rhythms in different brain systems including, for example, some types of gamma oscillations,[29,30] thalamic spindles,[1,31] and others.

Gap Junctions and Synchronization

Gap junctions (i.e., electrical synapses) allow direct flux of ions between connected cells, providing a mechanism of communication that is action potential independent.[32,33] If few cells are connected through electrical synapses, any change of membrane voltage in one neuron would trigger current flow between coupled neurons leading to corresponding changes of membrane voltage in the latter cells, providing a synchronizing effect. Because of the relatively high resistance of electrical synapses, they act as low-pass filters.[10] In cortical networks, groups of GABA-releasing interneurons[34,35] and glial cells[36] are interconnected via gap junctions. There is a set of indirect evidence suggesting that electrical coupling may occur between axons of pyramidal neurons.[37,38] The role of axonal gap junctions in the generation of electrical activities is unclear. Intraaxonal recordings did not reveal the presence of afterhyperpolarizing potentials (AHPs)

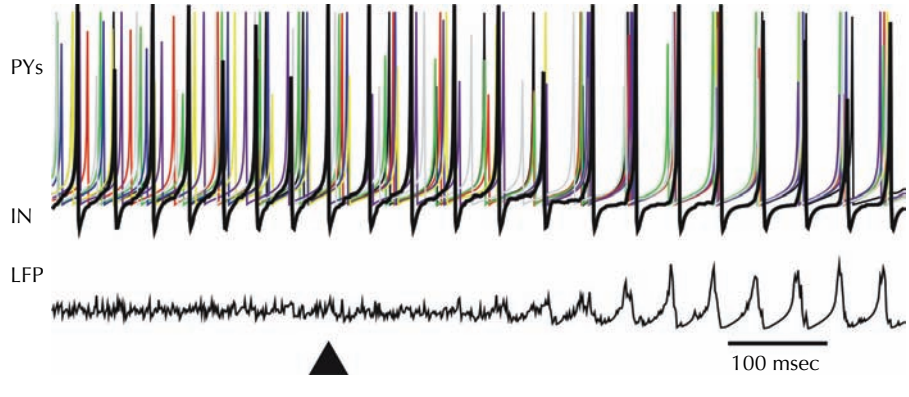

Figure 13–1. Effect of feedback inhibition in spike synchronization**.** Top: eight pyramidal neurons (PYs, thin lines of different color) oscillate asynchronously in the 20–25 Hz frequency range with no inhibitory feedback. About 200 ms after an inhibitory GABAergic synapse from the interneuron (IN, black thick line) to PYs was activated (arrowhead), spikes in the pyramidal neurons became synchronized by IN-mediated IPSPs. Bottom: increase of PY synchronization was reflected in large-amplitude LFP oscillations (M Bazhenov, I Timofeev, unpublished observation).

in axons.[39,40] Low-pass filter properties of gap junctions prevent efficient transmission of fast spikes to coupled neurons, and absence of AHPs prevents slower synchronization. Because of this and because of the extremely short range of electrical coupling, while axo-axonal gap junctions may enhance already existing synchronization manifested by slow membrane voltage oscillations, it is unlikely that they play a primary role in establishing neocortical synchronization.

Ephaptic Interactions

Extracellular currents produced by electrical activity of neurons and constituting local field potentials may directly influence electrical properties of neurons.[13] This effect may include depolarization or hyperpolarization of the cell membrane and therefore a change in excitability. Although they are relatively weak, these effects have a global influence and may provide a significant impact when neuronal activity is already synchronized by means of other mechanisms. Examples include slow-wave sleep oscillations or epileptic activity when a certain degree of synchrony of electrical activity between neurons is already achieved through chemical or electrical interactions. In that case, the weak but global effect of ephaptic interaction further enhances the synchrony. Not only internally generated fields can affect neuronal excitability. The application of an external electric field with an amplitude within the range of in vivo endogenous fields modulates cortical slow oscillation[12,41] and potentiates memory.[41]

Changes in Extracellular Ionic Concentrations

Electrical activity of neurons is associated with opening and closing of different ionic channels and therefore may lead to changes in extracellular ion concentrations. These effects include primarily ions whose extracellular concentrations are low, such as K^+ and Ca^{2+}. Opening of K^+ channels (such as delayed rectifier voltage-gated channels mediating the hyperpolarizing phase of the action potential) or Ca^{2+} channels increases the extracellular K^+ concentration and decreases the extracellular Ca^{2+} concentration. While these local changes are normally compensated for by ionic pumps and interaction with glia, significant alternations in extracellular ion concentrations triggered by electrical activity in one cell may diffuse to neighboring neurons, leading to changes in their excitability and, therefore, contributing to synchronization of electrical activity between neighboring cells. Experimental evidence suggests that a variety of ions undergo activity-dependent changes in concentration.[14,16] During active states of cortical slow oscillation, due to activation of synaptic currents (primarily mediated by the *N*-methyl-D-aspartate [NMDA] receptor) and Ca^{2+}-gated intrinsic channels, the extracellular concentration of Ca^{2+} decreases from 1.2 mM to 1.0 mM.[15,42] This leads to a dramatic increase in synaptic failure rates (up to 80%).[15] Therefore, chemical synaptic interactions contributing to synchronization become largely impaired. On the other hand, lower concentrations of extracellular Ca^{2+} promote opening of hemichannels,[43] which increases the effectiveness of gap junctions and, therefore, electrical coupling. The most dramatic changes in extracellular concentrations of K^+ and Ca^{2+} occur during paroxysmal discharges. The extracellular K^+ concentration reaches 7–18 mM during spontaneous electrographic seizures in neocortex[44–46] and the extracellular Ca^{2+} concentration decreases to 0.4–0.7 mM.[44,47,48] These changes dramatically reduce synaptic excitability, basically abolishing synaptic responses.[49] Changes in ionic concentrations affect the reversal potential of a variety of intrinsic currents that contribute to neuronal excitability, synchronization, and generation of oscillatory activities, potentially promoting synchronized oscillations during epileptic seizures.[17,50] For example, hyperpolarization-activated depolarizing current (I_h) in neocortical neurons is relatively weak, and in normal conditions it is unlikely to play any significant role in the generation of cortical oscillations. However, during seizure activity, when the extracellular K^+ concentration increases, the I_h reversal potential shifts to a more depolarized value, allowing this current to depolarize a set of cortical neurons to the firing threshold, thus leading to the generation of spikes and onset of the next cycles of spike-wave discharges.[51]

THALAMOCORTICAL OSCILLATIONS

Periodic oscillatory activity is a common result of neuronal synchronization and it is an emerging property of the thalamocortical system. Neuronal oscillations enable selective and dynamic control of distributed functional cell assemblies.[52] The patterns and the dominant frequencies of these oscillations are defined by the specific mechanisms involved and depend on the functional state of the brain. Normal oscillatory activities include slow (0.1–15 Hz, present mainly during slow-wave sleep or anesthesia) and fast (20–600 Hz) activities. The fast activities may be present in various states of vigilance and frequently coexist with slower rhythms. Each type of oscillation is generated by a particular set of intrinsic neuronal currents, synaptic interactions, and extracellular factors. Spontaneous brain rhythms during different states of vigilance may lead to increased responsiveness and plastic changes in the strength of connections among neurons, thus affecting information flow in the thalamocortical system.

The various oscillatory rhythms generated in the thalamocortical system may be divided into two main classes: intrinsic**,** generated by a single neuron as a result of an interplay between specific intrinsic currents (e.g., thalamic delta oscillation), and extrinsic, or network oscillations, which require the interaction of excitatory and inhibitory cells within a neuronal population (e.g., spindle oscillation, reviewed in ref. 53). Intrinsic neuronal currents contribute to the generation of network oscillations. Oscillations may also be generated in a population of nonpacemaker neurons coupled through gap junctions**.**

Near-Steady or Infra-Slow Oscillation (<0.1 Hz)

This type of oscillatory activity has a period ranging from tens of seconds to 1 min.[54] Prolonged metabolic disturbance, irritation of brain structures, or afferent stimulation intensifies these activities, and phenobarbital or diethyl ether anesthesia as well as strong electrical stimulation of cerebral cortex dramatically decreases or abolishes this brain activity.[54] Very little is known about the underlying mechanisms of these oscillations. Hypercapnia induced a negative scalp direct current (DC) shifts (~–0.3 mV/CO_2%) and hypocapnia induced a positive scalp DC shifts (~0.3 mV/CO_2%)[55] Infra-slow activities likely have a cortical origin given that they can be recorded from neocortical slabs.[56] Indirect evidence suggests that infra-slow oscillations (0.02–0.2 Hz) synchronize faster activities, modulate cortical excitability and contribute to the increase of epileptic activity during sleep.[57]

Slow Oscillation

During slow-wave sleep and some types of anesthesia, the dominant activity pattern is a slow oscillation occurring with a low frequency (0.3–1 Hz).[1,25,58–60] During slow oscillation the entire cortical network alternates between silent (hyperpolarizing, or Down) and active (depolarizing, or Up) states, each lasting for 0.2–1 s (Fig. 13–2). Silent periods are periods of disfacilitation, that is, periods of absence of synaptic activity, while active periods are periods of intensive synaptic activity leading to the generation of fast oscillations within the thalamocortical system.[25,59,61–64] The survival of slow oscillations after extensive thalamic lesions in vivo[65] and in cortical in vitro preparations,[66] and the absence of slow oscillation in the thalamus of decorticated cats,[67] point to an intracortical origin of this rhythm.

A particular feature of slow oscillation is that each cortical slow wave originates in a particular location and propagates to involve other cortical regions. According to Massimini et al.,[68] in young adult human males (20–25 years old) the preferential sites of origin of slow waves are in frontal cortical regions. However, in this high-density EEG study, it was unclear whether it was active or silent states that propagated. Multisite intracellular experiments on cats demonstrated that it was the onset of the active state that propagated, but the onset of silent states occurred more synchronously.[69] In contrast to the previous study, the active states in cats more commonly start at the border between areas 5 and 7 of parietal cortex.[69] A very recent study[70] demonstrates that propagation of slow activity in the human brain undergoes progressive age-dependent changes. In preschool-age children (2–3 years old), the propagating waves start from the occipital cortex. From early

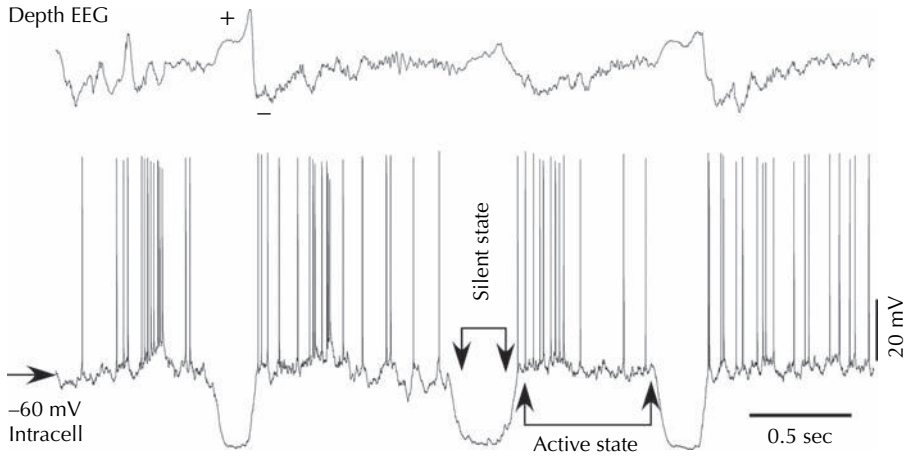

Figure 13–2. Cortical sleep slow oscillation**.** At the EEG level, the slow oscillation appears as periodic alterations of positive and negative waves (indicated by + and – signs). During EEG depth-positivity, cortical neurons remain in the hyperpolarized silent state. During EEG depth-negativity, cortical neurons move to active states, reveal barrages of synaptic events, and fire action potentials. Modified from ref. 53.

childhood to late adolescence, the location on the scalp showing maximal slow wave activity undergoes a shift from posterior to anterior regions. This suggests a progressive change in excitability of various cortical areas and that slow oscillation in the brain of adult cat is generated in areas homotypical to the human adolescent brain. Propagation of activity suggests (1) the presence of cortical regions with different levels of excitability that start the active states and (2) the presence of synaptic chains that mediates slow oscillation with some delays.

At least three distinct mechanisms for the origin of slow cortical oscillations were proposed. The first depends on spontaneous miniature synaptic activities (miniature postsynaptic potentials, mPSP)[71] caused by the action potential-independent release of transmitter vesicles and regulated at the level of single synapses.[72,73] Occasional summation of miniature EPSPs during the hyperpolarized (silent) phase of slow-sleep oscillations activates the persistent sodium current and depolarizes the membrane of cortical pyramidal cells, which is sufficient for spike generation.[74–76] This triggers the active phase of the slow oscillation, which is maintained by synaptic activities and the persistent sodium current. Modeling experiments suggest that short-term synaptic depression and activation of the Ca^{2+}-dependent K^+ current were sufficient to terminate the active state.[75] More recent electrophysiological experiments demonstrated that the active states terminate with high levels of synchrony.[69] Because the short-term synaptic plasticity and activity of intrinsic currents are very specific for each synapse or neuron, the occurrence of nearly simultaneous termination of the active widespread states over large distances suggests the presence of an active (inhibitory) mechanism for the termination of active states. Indeed, about 40% of inhibitory fast-spiking interneurons increase their firing rates at the end of spontaneous active states during slow oscillation.[77] These cells can contribute to the synchronous termination of active states.

Another possible mechanism accounting for the generation of active states during slow-sleep oscillation may be the generation of spontaneous activity by layer V cortical neurons.[66,78] Using a cortical slice preparation, it was shown that oscillatory activity in the frequency range of slow-sleep oscillation could be generated at an extracellular K^+ concentration of 3.5 mM, which is slightly higher than that in vivo (i.e., 3.2 mM).[66] This activity was usually initiated in layer V and propagated over the whole slice.

The third hypothesis attributes transitions from silent to active states to the selective synchronization of spatially structured neuronal ensembles involving a small number of cells.[79] The *selective synchronization* hypothesis predicts that even during silent states, some neurons of the network still generate irregular spontaneous firing.

A group of recent in vitro studies suggests that thalamocortical neurons encompass an

intrinsic mechanism that may act as a secondary oscillator supporting slow rhythm.[80] Cortical activity can recruit, through corticothalamic synapses, intrinsic oscillatory mechanisms in thalamocortical neurons,[81] which could then increase synchrony among cortical inhibitory interneurons. Our current studies indicate that thalamic mechanisms may be responsible for the maintenance of active states with properties observed in vivo.[82,83]

A recent in vivo study on anesthetized or sleeping cats demonstrated that spontaneous active states can originate from any cortical layer, but most often they start from deep layers and propagate toward more superficial layers.[76] It was shown that numerous spontaneous spike-independent synaptic events detected during network silent states summate prior to the onset of active states in all recorded neurons. The pyramidal layer V neurons are the biggest cortical neurons[26]; they possess the largest number of synapses, making it most likely that these neurons will summate spontaneous synaptic events to a threshold level for action potential generation and initiate the active network states. During silent network states, the levels of extracellular Ca^{2+} are increased and contribute to the increase in synaptic release of neurotransmitter,[15] facilitating the onset of the active network states.

Regardless of the specific mechanisms involved in sleep slow oscillation generation, long-range excitatory and inhibitory synaptic connectivity likely plays a major role in synchronization of transitions between active and silent states of slow oscillation leading to the periodic LFP and EEG oscillations observed in animals and humans during deep sleep.

Delta Oscillation

Field potential recordings from neocortex in human and animal models during sleep reveal the presence of delta oscillations (1–4 Hz). The delta oscillation likely has two different components, one of which originates in the neocortex and the other in the thalamus. Neocortical delta activity was significantly enhanced after surgical removal of thalamus[84] and in chronically isolated neocortical slabs.[85] Little is known about the cellular mechanisms mediating cortical delta oscillation. One hypothesis suggests that cortical delta activity could be driven by the discharge of intrinsically bursting neurons.[86] On the other hand, the thalamic delta rhythm is a well-known example of rhythmic activity generated intrinsically by thalamic relay neurons as a result of an interplay between low-threshold Ca^{2+} current (I_T) and hyperpolarization-activated cation current (I_h).[86a] As such, the delta oscillation may be observed during deep sleep when thalamic relay neurons are hyperpolarized sufficiently to deinactivate I_T.[87–90] It was also shown that at a certain level of leak current (I_{leak}), the "window" component of I_T in thalamocortical neurons may create oscillations similar in frequency to the intrinsic thalamic delta oscillation.[91] While specific intrinsic mechanisms are responsible for the generation of oscillatory activity in individual thalamic neurons, these oscillations would not be synchronized and would not lead to the observed LFP and EEG rhythms unless the spiking/bursting activity of individual neurons becomes synchronized by chemical and electrical synapses, as described earlier in this chapter.

Slow-wave sleep may be essential for memory consolidation and memory formation.[92–95] It has been proposed that synaptic plasticity associated with slow and delta oscillations could contribute to the consolidation of memory traces acquired during wakefulness.[96]

Sleep Spindle Oscillations

Sleep spindle oscillations consist of waxing-and-waning field potentials at 7–14 Hz, which last for 1–3 s and recur every 5–15 s. In vivo, spindle oscillations are typically observed during the early stages of sleep or during active phases of sleep slow oscillation. In vivo, in vitro, and in silico studies suggest that the minimal substrate accounting for spindle oscillations consists of the interaction between thalamic reticular and relay cells[31,97–100] (Fig. 13–3). Burst firing of reticular thalamic neurons induces IPSPs in thalamocortical neurons. This deinactivates I_T, inducing rebound burst firing in thalamocortical neurons, which, in turn, excite reticular thalamic neurons, allowing the cycle to start again. During the early phase of spindles, the reticular nucleus singlehandedly drives spindle oscillation via intrinsic mechanisms.[100–103] The second component of spindles, on the other hand, develops primarily as a result of interactions between reticular

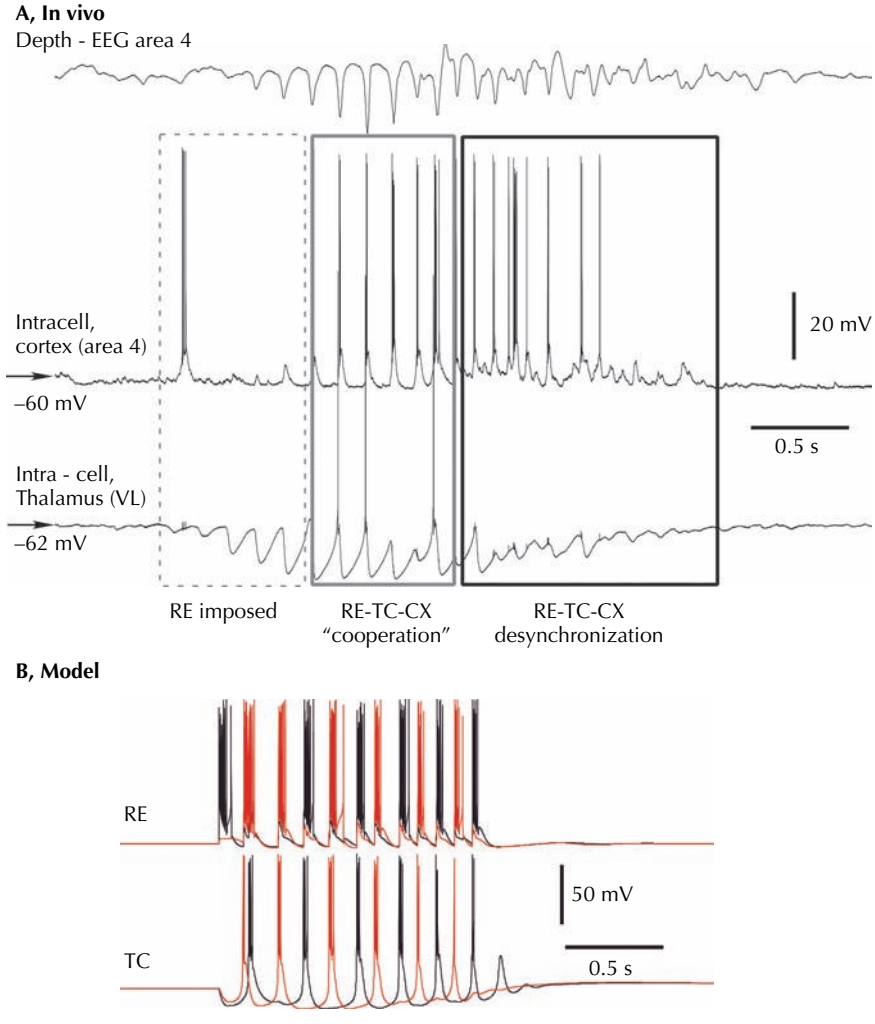

Figure 13–3. Cellular basis of spindle activity**. A.** In vivo recordings. Three phases of a spindle sequence. and relay neurons.[104,105] Additionally, cortical firing contributes to spindle synchronization through corticothalamic feedback connections, thereby producing simultaneous excitation of reticular and relay neurons.[106,107] The waning phase of spindles occurs as a result of network desynchronization[103,107a] and Ca^{2+}-induced, cyclic adenosine monophosphate (cAMP)-dependent upregulation of the hyperpolarization-activated cation current, I_h, in relay cells.[108–110] It is important to mention that reticular thalamic neurons are interconnected via gap junctions, which aid in synchronizing spindles.[111,112]

While spindle oscillations propagate in thalamic slices,[113] thalamocortical synaptic interactions promote large-scale synchrony of spindle oscillations in vivo.[114] Human sleep spindles are highly synchronous across the scalp when measured by EEG but not when measured simultaneously with a magnetoencephalogram (MEG)[115]. The signals obtained with MEG technique show low correlation and low coherence with each other or with EEG signals. Principal components analysis shows that the MEG field pattern is more complex than the EEG pattern, implying that MEG signals are produced from

multiple partially independent cortical generators, whereas EEG signals may instead be dominated by a weak but widespread spindle generator. It was proposed that the differential activity patterns in the core (thalamocortical neurons forming specific, focused projections to cortical layers IV and VI) and matrix (thalamocortical neurons forming diffuse projections to layer I) subsystems may explain the discrepancies between the temporal patterns of spindles simultaneously observed in EEG and MEG recordings.[116]

Recent studies show that sleep-related spindle oscillations are essential for memory formation[92] and demonstrate short- and middle-term synaptic plasticity (reviewed in ref. 96). Spindling may activate the protein kinase A molecular "gate," thus opening the door for gene expression[117] and allowing long-term changes to take place following subsequent inputs.

Beta-Gamma Oscillation

The waking state of the brain is characterized by the predominance of frequencies in the beta (15–30 Hz) and gamma (30–80 Hz) ranges.[118,119] These fast rhythms are also synchronized between neighboring cortical sites during some forms of anesthesia, natural slow-wave sleep, and rapid-eye-movement (REM) sleep,[62,120a] when consciousness is suspended and thoughts are either absent or bizarre. During slow-wave sleep the fast rhythms follow the onset of depth-negative EEG waves (Fig. 13–4). In vitro experiments and computational models demonstrated that gamma activity generation depends on the activity of inhibitory interneurons.[121–126] Gamma activity can exist in transient and persistent forms. Experimentally, transient (hundreds of milliseconds) gamma oscillations can be induced by

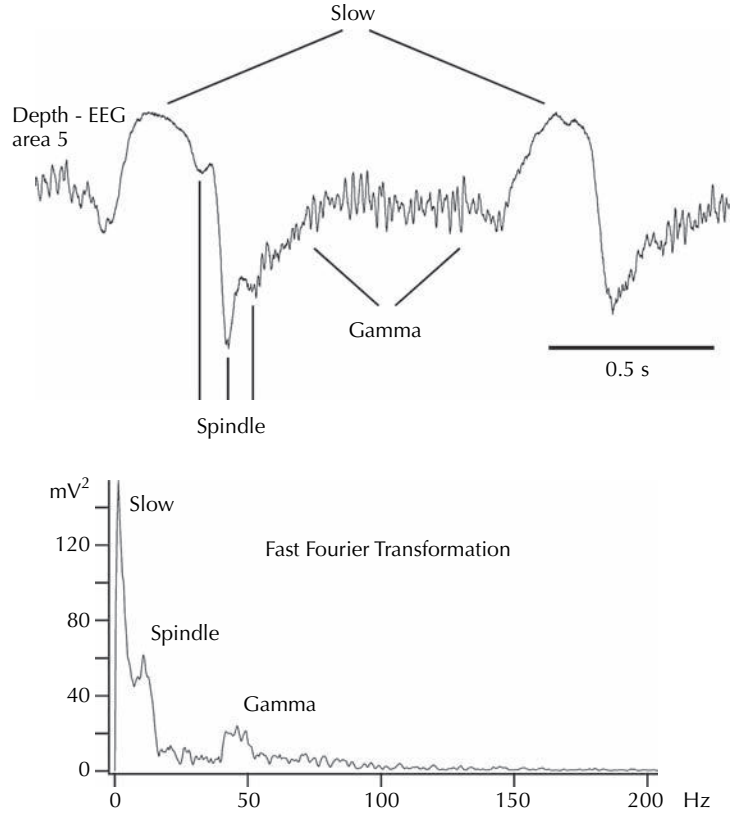

Figure 13–4. Gamma oscillation is an important component of slow oscillation of sleep. Depth- EEG recoding from area 5. Slow oscillation, spindles, and gamma activities are indicated. Below, fast Fourier transformation of the recoding shown above. Modified from ref. 53.

tetanic stimulation of the hippocampus.[124,127] Persistent gamma activity is found in CA3[128] and neocortex[129]; this form of gamma oscillation can be induced by bath application of carbachol or kainate, and it can last for minutes to hours. During persistent gamma activity, the interneurons fire on every cycle or every two cycles and pyramidal cells fire at much lower frequencies, suggesting that active inhibition is involved in the generation of this particular rhythm. Finally, it was found that GABAergic interaction in isolated interneuron networks may lead to network oscillation in the gamma frequency range.[130,131] In both computational models and in vitro experiments, it was shown that the frequency of these oscillations depends on the conductance and decay time of $GABA_A$ currents.[130] Large-scale network simulations revealed that coherent gamma range oscillations may appear through occasional increases in spiking synchrony within local groups of cortical neurons.[132] It was shown that even local synaptic connectivity may explain long-range synchrony of gamma oscillations.[133]

During waking, gamma activity is associated with attentiveness,[134,135] focused arousal,[136] sensory perception,[137] movement,[138,139] and prediction.[140] It has been proposed that synchronization in the gamma frequency range is related to cognitive processing and is important for temporal binding of sensory stimuli.[18,141,142] Gamma activity with low levels of coherence is present within active phases of slow-wave sleep.[62,64,143,144] However, the role of this activity is unknown. During REM sleep, highly coherent gamma activity[143] may contribute to the generation of dreams.

Ripples

Fast oscillations (>100 Hz), termed *ripples*, were initially described in the CA1 hippocampal area and in the perirhinal cortex, where they were associated with bursts of sharp potentials during anesthesia, behavioral immobility, and natural sleep.[145–149] In the neocortex, fast oscillations (>200 Hz, up to 600 Hz) have been found in sensory-evoked potentials in the rat barrel cortex[150,151] during high-voltage spike-and-wave patterns.[152] The neocortical network seems to be sufficient for the generation of ripples, as demonstrated using isolated cortical slab preparations.[153] In addition to active inhibition,[149,153] the electrical coupling mediated by gap junctions contributes to ripple synchronization.[154–156] The electrical coupling may occur between axons of principal cells[157] as well as via a network of inhibitory interneurons.[10,34,35,158,159] Since ripples are also recorded in glial cells, the electrical coupling between gial cells could also play a role in the synchronization of ripples.[155] The field potentials increase neuronal excitability, and by a positive feedback loop they could also be involved in the generation of neocortical ripples.[160] In nonanesthetized brain, the highest amplitude of ripples in neocortex occurs during active phases of slow-wave sleep, it is lower during both REM sleep and the waking state, and it reaches the lowest values during the silent phases of slow-wave sleep.[153]

Neocortical ripples are generated during large-amplitude spontaneous or evoked field potential deflections. These ample changes in the field potential are associated with synchronous activity of many neurons. This suggests that ripples may "alert" the brain network to the presence of a large firing neuronal constellation. The danger of such a focal synchronous excitation of a neuronal pool is that it may overcome a certain threshold of excitability, leading to the onset of seizures.[155,160]

Short- and Long-Range Synchrony during Experimental Epilepsy

Cortically generated electrographic seizures arise without discontinuity from sleep oscillations.[161] These seizures are accompanied by the generation of large-amplitude field potentials, suggesting the presence of enhanced local synchrony,[161] and are characterized by spike-wave (SW) or spike-wave/polyspike-wave (SW/PSW) complexes at 1–2.5 Hz, intermingled with episodes of fast runs at ~7–16 Hz.[162–165] The evolvement of these seizures from the cortically generated slow oscillations may be shaped by the thalamus.[81,163,166–169] The electrographic pattern of SW/PSW seizures, as well as their occurrence during slow-wave sleep, resembles the seizures accompanying the Lennox-Gastaut syndrome in humans.[170–173]

These seizures could be classified as primarily focal and secondarily generalized (see Fig. 3

in ref. 174); visual inspection suggests that on most occasions they start and stop almost simultaneously in all recorded areas. Precise measurements of synchrony during SW/PSW seizures suggest that long-range synchrony recorded on a wave-by-wave basis is rather loose.[161,168,174,175] The coefficient of correlation of field potentials recorded during SW complexes fluctuates between 0.3 and 0.8.[176] However, the field potentials recorded during these seizures are of large amplitude, often exceeding the amplitude of slow waves recorded during natural slow-wave sleep[176] or during anesthesia-induced slow oscillation,[161, 163] suggesting the existence of high local synchrony. Within the fast runs, the patterns of synchronization recorded in different electrodes are as follows: (1) synchronous, in phase, (2) synchronous, with phase shift, (3) patchy, repeated in phase/phase shift transitions and (4) nonsynchronous, with slightly different frequencies in different recording sites or absence of oscillatory activity in one of the recording sites; the synchronous patterns (in phase or with phase shifts) are most common.[174] All these patterns could be recorded in the same pair of electrodes during different seizures or even during different periods of fast runs within the same seizure. An example of such recording is shown in Fig. 13–5. Here, during the first period of fast runs, which started and terminated almost simultaneously at both the intracellular and EEG levels, the field potential and the neuron recorded 2 mm apart oscillated with different frequencies, and thus there was no synchronization. During the next period of fast runs, both the neuron and the field potential signals oscillated in perfect synchrony, and the neuron fired constantly during the descending phase of the field potential deflection.

Why is the local synchrony during seizures enhanced, as indicated by large-amplitude field potentials, and why is the long-range synchrony impaired, as shown by a variety of synchrony patterns (Fig. 13–5)? We propose the following scenario that explains both enhanced local and decreased long-range synchrony. Seizures are associated with activation of a large variety of neuronal currents.[161,177] During seizures, the extracellular levels of K^+ increase and the extracellular levels of Ca^{2+} decrease. While diffusion potentially reduces ion gradients in the extracellular space, a limited diffusion rate, further reduced by cell swelling during a seizure, allows formation of local areas of abnormal ion concentrations. These changes are commonly found in different structures, including neocortex and hippocampus, and in both in vivo and in vitro recordings.[44,47,178,179] The changes in extracellular concentration of K^+ and Ca^{2+} occur simultaneously.[47,180,181] Low levels of extracellular Ca^{2+} significantly dampen synaptic transmission.[8,182] Thus, chemical synaptic transmission cannot play a leading role in synaptic interactions during seizures. In addition, our recent data show that in high (12 mM) extracellular K^+ conditions, action potential generation is impaired and action potentials fail to propagate via axons (Fig. 13–6), probably due to a depolarizing block and decreased input resistance.[49] Therefore, action potentials do not reach target structures. All these factors lead to an impairment of long-range synchronization during seizures because the neurotransmitter mediating these interactions is not released. On the other hand, low Ca^{2+} conditions could favor local synchronization via gap junctions. Indeed, when extracellular levels of Ca^{2+} drop to 1 mM or lower, as it is observed during seizures, the hemichannels that form gap junctions remain open,[43] while they are half closed in physiological Ca^{2+} conditions (1.2 mM). This strengthens the electrical coupling between the glial cells[183] and cortical interneurons[34,35] that mediate local synchrony. Furthermore, elevated extracellular levels of K^+ enhance cell excitability and promote bursting activity[17,50,184] that is transmitted better through gap junctions than through single-action potentials. Potentially, electrical coupling between axons of pyramidal cells[37] could also contribute to local synchronization, although the major types of activities recorded in axons are action potentials, which cannot be efficiently transferred via gap junctions because they constitute a low-pass filter. The use of halothane, a gap junction blocker, effectively blocks seizure generation.[155]

Hence, the decrease in extracellular levels of Ca^{2+} and the increase in extracellular levels of K^+ to those levels that occur during seizures significantly impair long-range neuronal synchronization due to a decrease in neuronal firing ability and a diminution of transmitter release. However, the same changes may increase local synchrony, mediated via gap junctions and possibly by ephaptic interactions.

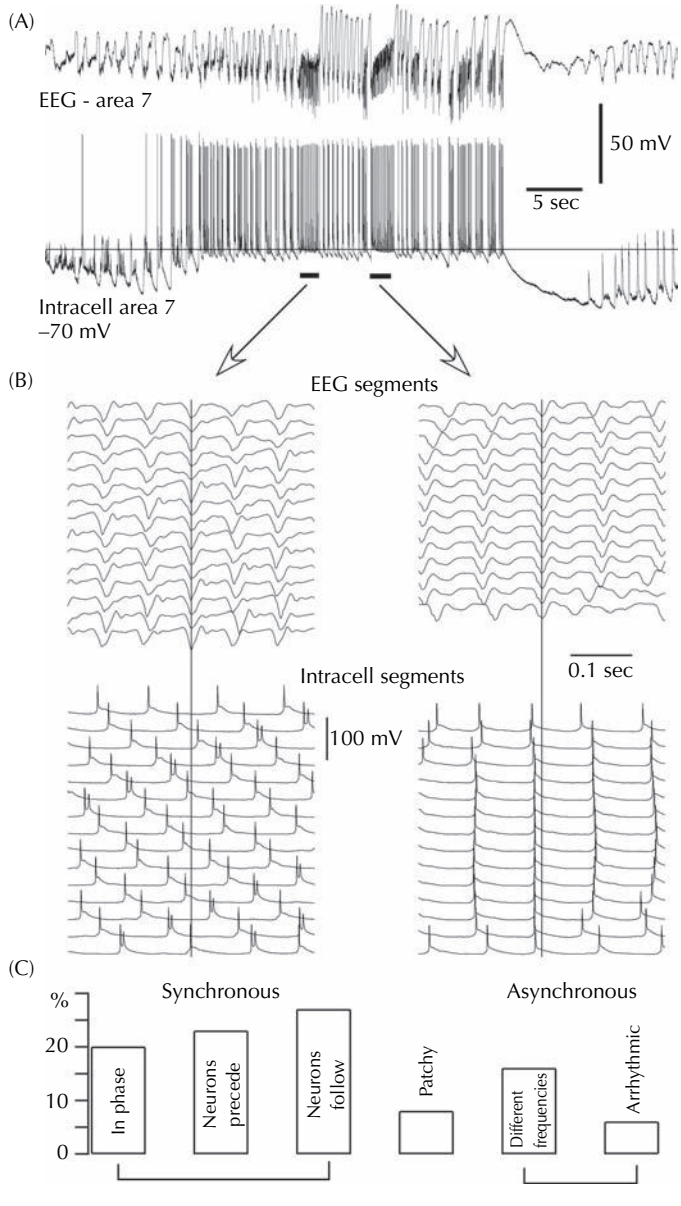

Figure 13–5. Variability in neuron–field synchronization during fast runs. **A.** Depth-EEG and simultaneous intracellular recordings during an electrographic seizure. The distance between the field potential electrode and the intracellularly recorded neuron was 2 mm. **B.** A superposition of field potential (upper panels) and intracellular recordings (lower panels) during fast runs for the two consecutive periods of fast runs. Note the different frequencies of oscillations in the EEG and intracellularly recorded neuron during the first period and in phase synchronization during the second period. **C.** The distribution of patterns of synchronization for 312 periods of fast runs. The coherent patterns (zero time lag or with phase shift) constituted 70% of the cases. "Arrhythmic" stands for periods of fast runs recorded at one electrode, while the activity in another electrode was not rhythmic. Adapted from ref. 174.

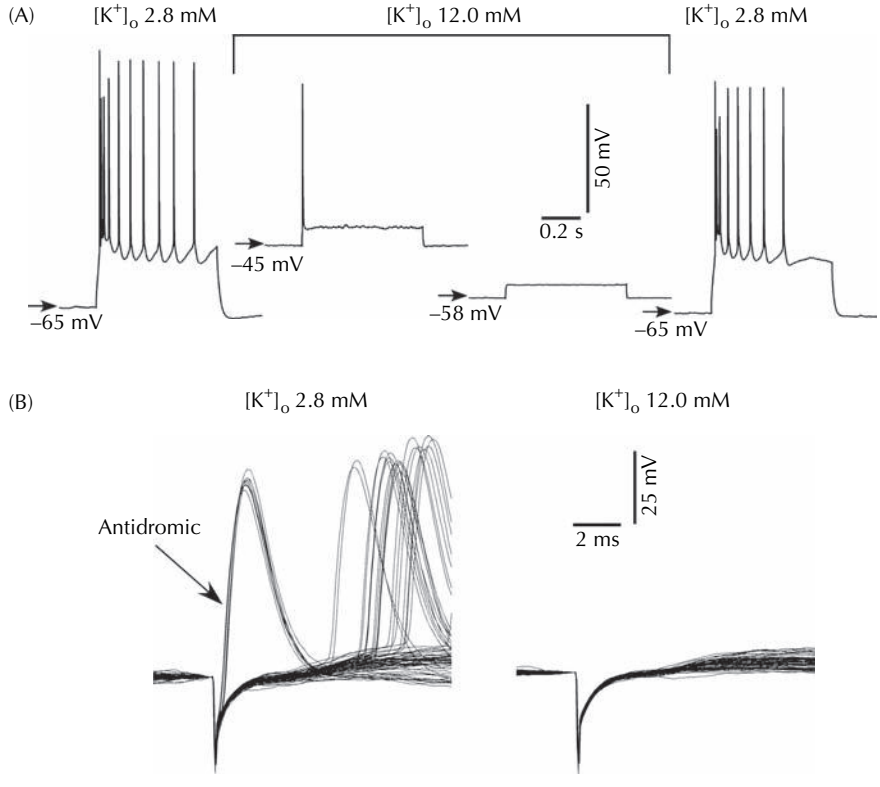

Figure 13–6. High K^+ concentration impairs generation of action potentials in neocortical neurons. **A.** Responses of a cortical neuron to depolarizing current pulses in control (2.8 mM) and "paroxysmal" (12 mM) K^+ conditions. When 12 mM K^+ was used, the neuron became depolarized and generated a maximum one spike in response to an intracellularly applied current pulse. When the membrane potential was returned to near-control values (–58 mV) by injection of a negative holding current, action potentials were not generated. **B.** Electrical stimulation of neighboring cortical tissue induced antidromic and orthodromic responses in recorded neurons. Both anti- and orthodromic spikes were abolished when 12 mM K^+ was used. J Seigneur, I Timofeev, unpublished observations.

CONCLUSIONS

We propose that neocortical synchronization can be achieved via intracortical and thalamocortical mechanisms. Four leading mechanisms of synchronization play a distinct and important role: (1) chemical synaptic transmission, (2) electrical coupling, (3) ephaptic interactions, and (4) activity-dependent changes in ionic concentrations. Major types of cortical rhythmic activities (slow oscillation, delta, spindles, beta-gamma, ripples, paroxysmal spike waves, and fast runs) are generated using these mechanisms. It is difficult, however, to identify the exact contribution of each mechanism to a specific type of oscillation. It is clear that long-range synchronization is achieved using chemical synaptic interactions. Due to the low-pass filtering properties of gap junctions, electrical coupling should play a smaller role in synchronization of fast rhythmic activities compared to slower activities. Nevertheless, the gamma rhythm depends on the activity of interneurons, which are known to be interconnected via gap junctions; therefore, gap junctions should play a critical role in the generation of these oscillations. Weak electrical fields in the EEG range effectively synchronize cortical activities at low but not at high frequencies. Finally, activity-dependent ionic changes may influence local synchronization by modulating neuronal excitability; however, since ionic changes also affect synaptic transmitter release, this could result in impairment of long-range synchrony.

Chapter 14

Limbic Network Synchronization and Temporal Lobe Epilepsy

John G.R. Jefferys
Premysl Jiruska
Marco de Curtis
Massimo Avoli

Cognitive function, including perception and the formation and recall of memories, depends on the integrated, often synchronous, activity of many neurons. The limbic system in general, and the hippocampal formation in particular, have well-developed anatomical and physiological mechanisms that promote neuronal synchronization. Examples of physiological synchronization include the theta rhythm, beta and gamma oscillations, and sharp-wave ripples. In general, the mechanisms of these synchronous activities depend on intrinsic neuronal properties and the interplay between populations of principal cells and interneurons.

Excessive neuronal synchronization is, however, the hallmark of epileptic discharges as well. Synchronization in epilepsy occurs at different levels: between cells, within local networks, and between limbic structures. It also occurs at different time scales, from milliseconds upward, using a range of modalities. In this chapter, we will discuss pathological synchronizing mechanisms involved in epilepsy of limbic origin, with an emphasis on seizures and epileptic high-frequency activity. We will also discuss potential methods of disrupting synchrony with a view to developing novel therapeutic approaches.

Limbic seizures typically last for a few tens of seconds to several minutes. However, they are not the only electroencephalographic (EEG) anomaly found in the epileptic brain. Interictal discharges are brief events, stopping within a couple of hundred milliseconds to a few seconds. They are discussed in detail in this book in Chapter 17 (see also ref. 1), but here we need to mention them briefly because they provide crucial clues to synchronizing mechanisms that

may also play a role in seizures. A large part of this early work relied on the hippocampal slice in vitro exposed to convulsant treatments. Under these conditions, the CA3 region usually generates interictal discharges and not seizures (although there are exceptions[2–4]). However, discharges lasting as long as seizures have been recorded in juvenile CA3 networks[3] or adult CA1[5–7] and/or entorhinal cortex[8,9] in rodents.

MECHANISMS OF SYNCHRONIZATION DURING LIMBIC SEIZURES

Perhaps the first detailed understanding of epileptic synchronization came from experiments on the actions of convulsants on normal brain tissue, and particularly on normal rodent hippocampus both in vivo and in brain slices in vitro. Many of these convulsants block GABAergic inhibition[10] (e.g., penicillin, picrotoxin, bicuculline), but some boost glutamatergic excitation[11] (e.g., low Mg^{2+}, which also compromises inhibition, albeit slowly), or intrinsic excitability[5,12] (high K^+, which also has some impact on inhibition, and low Ca^{2+}), while 4-aminopyridine has the unusual property of enhancing both excitatory and inhibitory synapses as a result of its blocking K^+ channels.[13] It is important to realize that these kinds of acute models really reflect symptomatic epileptiform activity in normal brain, with the convulsant treatment subverting normal physiological synchronizing mechanisms to produce abnormal hypersynchronous epileptiform discharges. In contrast, chronic epileptic foci depend on (usually multiple) changes in neuronal intrinsic and synaptic properties, connectivity, changes in glial cell properties, and in many cases neuronal death (see the section "Neurobiology of Temporal Lobe Epilepsy" below).

Several mechanisms have been implicated in the initiation and persistence of seizures. Failure of inhibition, loss of afterhyperpolarization, increase in $[K^+]_o$, enhanced excitatory synaptic transmission, paradoxical enhancement of inhibitory network activity, and depolarizing GABA all have been proposed, and all of these mechanisms may contribute, to varying degrees in different situations, to epileptiform synchronization. Synaptic transmission mediated by ligand-gated ion channels synchronizes over milliseconds to tens of milliseconds. Faster synchronization depends on electrical mechanisms, gap junctions, and ephaptic or field interactions, which can operate over fractions of a millisecond to a few milliseconds. Slower synchronization, hundreds of milliseconds upward, can depend on several mechanisms: G-protein coupled receptors (neuropeptides, amines, and other neuromodulators), fluctuations in the extracellular concentration of ions (most notably K^+), interactions between neurons and glia, and the dynamics of interaction between coupled hyperexcitable regions.

Synaptic Mechanisms

Early work with acute convulsants showed that the CA3 region of the hippocampus was particularly good at generating interictal discharges, which were soon related to abrupt "paroxysmal" depolarization shifts (PDSs) in pyramidal cells.[14,15] The PDS produced by most acute convulsants proved to be caused by a chain reaction of excitation.[10,16] The anatomical substrate for this chain reaction is the extensive axon collateral network of CA3 pyramidal cells, which connect with many other CA3 pyramidal cells (and even with themselves in *autapses*) in addition to their longer-range projections to CA1, septum, and contralateral CA3. These synaptic networks can play a role in the synchronization occurring during both seizures and interictal discharges, and indeed may be strengthened by sprouting of new connections and other synaptic changes in chronic epileptic foci.

Divergent connections of CA3 pyramidal cells to other local pyramidal cells allows for the expansion of the synchronous population discharge that is necessary for the chain reaction (Fig. 14–1). Physiologically, the unitary potentials at these synapses are relatively strong (~1 mV)[17] for excitatory synapses in the mammalian brain. The effect of these strong synapses is amplified by the presence of voltage-dependent inward currents, mainly through Ca^{2+} channels, which make CA3 pyramidal cells fire bursts of action potentials under appropriate conditions.[10] Of course, these anatomical and physiological properties play crucial roles; under normal condition, the sharp-wave ripple of consumatory behaviors and memory consolidation[18] resembles, and may be a more controlled version of, the interictal discharge. However, under

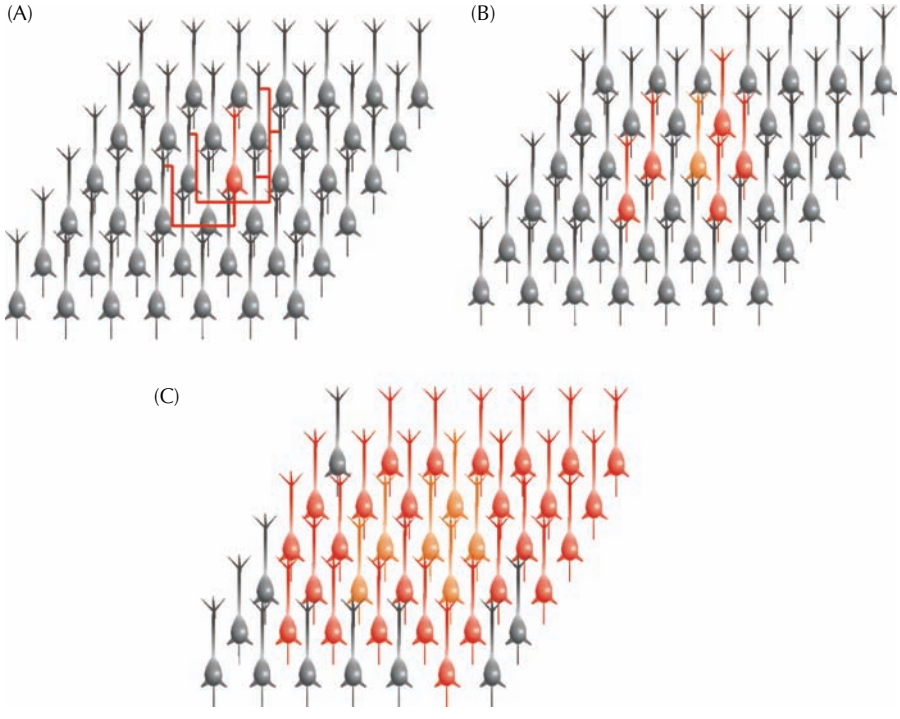

Figure 14–1. Chain reaction. **A.** CA3 pyramidal neuron has divergent connections with (in this case) five other pyramidal cells. **B.** Firing of the CA3 neuron will result in postsynaptic activation of the five pyramidal cells. **C.** Each of the five pyramidal cells then recruits its divergent postsynaptic targets, resulting in the recruitment of a large population of CA3 pyramidal neurons into synchronous firing within a small number of synaptic steps.

convulsant treatments, physiological mechanisms of synchronization get out of hand and produce the hypersynchronous depolarizations with burst firing that result in the large-amplitude field potential transient of the epileptic interictal discharge.

The chain reaction mechanism needs a critical mass or minimum aggregate to produce a hypersynchronous epileptic discharge: essentially, the population needs to be large enough to allow the majority of neurons to be recruited successfully. The concept of a minimum aggregate has had practical implications for the surgical treatment of refractory epilepsy in the development of multiple subpial transection,[19] which can be useful for seizures originating in eloquent cortex. This surgical procedure uses a series of cuts through the cortical thickness to disrupt horizontal axons that propagate and synchronize epileptic activity across the cortex. Cutting these associational fibers and leaving relatively small islands of cortical circuits can result in the disappearance of seizures and interictal discharges, both of which require critical numbers of neurons. The key point here is that the neocortex, where this procedure is applied, differs from the hippocampus in making its afferent and efferent connections vertically down through the underlying white matter. This means that the vertical longer range and extracortical connections are preserved and can sustain physiological function, while the horizontal intracortical connections necessary for horizontal spread and synchronization of neuronal activity during epileptic discharges are interrupted.

Inhibitory neurons also form interconnected networks, which play roles in physiological oscillations.[20–23] If the local neuronal population is tonically depolarized, then networks of particular classes of interneuron can sculpt coherent oscillations from the otherwise disorganized firing of the population. Feedback excitation from pyramidal cells onto inhibitory neurons is also capable of eliciting coherent oscillations because of the divergence of the

synaptic connections.[24] Inhibitory networks can play several distinct roles in epilepsy. Inhibitory networks can drive oscillations, for instance in the run-up to seizure onset, when in some situations they have the effect of entraining the excitatory population in ways that promotes hypersynchrony.[25] The dynamics of these networks can produce high-frequency activity (HFA) at frequencies seen preceding seizure onsets (see the section "High Frequency Oscillations" below).

Inhibitory networks can also lead to excessive inhibitory currents that can overload the ability of the adult neuronal Cl^- transporter (KCC2) to maintain a low intracellular Cl^- and thus allow HCO_3^- to dominate the postsynaptic current, resulting in depolarization and potentially excitation. Efflux of HCO_3^- is not the only mechanism by which excessive GABA release causes depolarization: GABAergic synchronous events are associated with increases in extracellular K^+, probably due to the activity of transporters responsible for reuptake of GABA and extrusion of Cl^-. This synchronizing mechanism is well typified when limbic cortical networks are treated with the K^+ channel blocker 4-aminopyridine.[8,26] As illustrated in Fig. 14–2A, slow interictal discharges continue to occur spontaneously, and to spread to other limbic structures during pharmacological blockade of ionotropic glutamatergic transmission. It should be emphasized that these

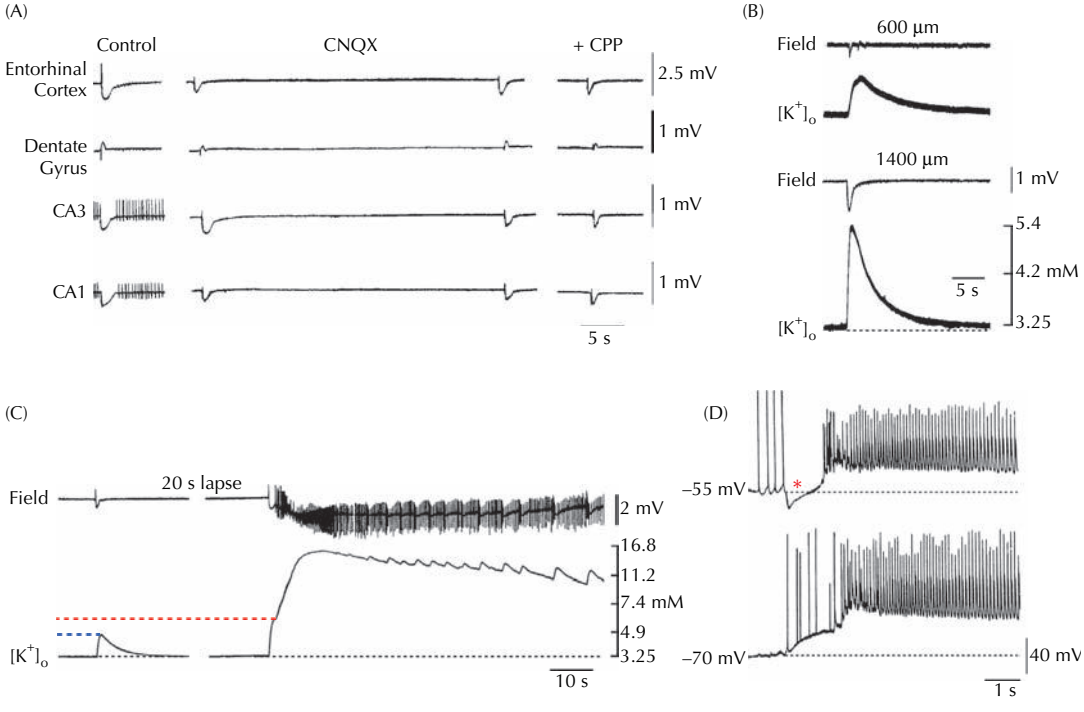

Figure 14–2. Epileptiform activity recorded in a rodent combined hippocampus-entorhinal cortex slice during continuous application of 4-aminopyridine. **A.** Field potential recordings from different hippocampal areas and the entorhinal cortex demonstrate the occurrence of fast CA3-driven interictal activity in the hippocampus proper and slow interictal events that are present in all recorded structures. Note that the latter type of activity continues to occur during application of glutamatergic receptor antagonists (CPP [(*RS*)-3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid] and CNQX [6-cyano-7-nitroquinoxaline-2,3-dione]). **B.** Slow interictal discharges analyzed with simultaneous field potential and $[K^+]_o$ recordings at two different depths of the entorhinal cortex. Note the transient elevations in $[K^+]_o$ that accompany the interictal discharges. **C.** Simultaneous field potential and $[K^+]_o$ recordings during interictal and ictal activity in the entorhinal cortex; note that the slow interictal event (left) is associated with a $[K^+]_o$ increase up to around 4 mM, while that seen at ictal discharge onset is accompanied by an increase up to 7 mM. **D.** Intracellular recording (sharp microelectrode filled with K-acetate) of the ictal discharge onset from an entorhinal cortex cell. Note that when the neuronal membrane is depolarized by intracellular injection of steady positive current (–55 mV), the amplitude of the sustained ictal depolarization decreases while the initial long-lasting depolarization becomes hyperpolarizing compared with the recording obtained at resting membrane potential (resting membrane potential = –70 mV). Panels A to C are modified from ref. 8; panel D is modified from ref. 27.

glutamatergic-independent events depend upon the activation of $GABA_A$ receptors since they disappear during application of picrotoxin or bicuculline (not illustrated). They are associated with transient increases in $[K^+]_o$ (Fig. 14–2B). Events of this sort can initiate seizures (Fig. 14–2C), and intracellular current injection shows reversal at membrane potentials consistent with predominant roles for $GABA_A$ receptors, and not with predominant roles for glutamate receptors (Fig. 14–2D).[8,27] Under some circumstances, $GABA_A$ receptor–mediated activity can be the sole synaptic mechanism in the generation of seizure-like events.[28]

Depolarizing GABA mechanisms have been implicated in the transition to seizure in several experimental models of epileptiform discharge.[7,29,30] Depolarizing GABAergic mechanisms may also play roles in clinical epilepsy: (1) at least one antiepileptic drug (AED), topiramate, has been shown to inhibit carbonic anhydrase,[31] thus reducing the driving force of the HCO_3^-, and (2) synchronous, predominantly depolarizing, GABAergic events occur in brain slices of resected epileptic foci.[32–35]

Interneurons can contribute to the transition to seizure through mechanisms other than GABA-mediated depolarization.[36] Intense and prolonged GABAergic activity preceding seizures has been associated with an increase in extracellular potassium, which may then depolarize principal cells and recruit them for seizure activity[7,37,38] characterized by fast oscillatory activity at 30–100 Hz, defined as beta-gamma activity.[39] Prolonged interneuronal depolarization may result in depolarization block of their action potential firing, which decreases the strength of inhibition onto principal cells, thus contributing to the transition to seizure.[37] Furthermore, interneurons can have a synchronizing role through conventional inhibitory, hyperpolarizing postsynaptic potentials.[25]

As we mentioned above, interneuronal networks play crucial roles in generating physiological rhythms,[23] and it has been suggested that interneurons may play similar functions in early stages of seizures with prominent activity in the beta, gamma, and slower ripple bands. In these cases, it is likely that synchronous activity of interneuronal networks connected by gap junctions and inhibitory synapses can constrain the firing of large populations of principal cells into specific time windows between synchronized inhibitory postsynaptic potentials (IPSPs), potentially strengthening their collective impact on convergent postsynaptic targets. Recovery from strong hyperpolarizing inhibition can cause rebound excitation by activating low-threshold currents, including the T-type calcium and I_h currents.[40] Single interneurons exert a widespread control over hundreds of synaptically connected neurons that is particularly remarkable in the hippocampus.[41] Therefore, rebound excitation of principal cells driven by interneuron network activity may result in strong synchronization of excitation[21] that can generate epileptiform discharges under pathological conditions.

Nonsynaptic Mechanisms

Nonsynaptic coupling has probably been underrecognized in the neuroscience literature. The ability of hippocampal slices to generate seizure-like events in the presence of low or zero extracellular Ca^{2+},[5,42] and in the presence of drugs blocking synaptic transmission,[43] shows that synaptic transmission is not necessary for epileptiform synchronization.[5,44] The fast population spikes that can initiate these *field bursts*, and that can occur throughout the discharge, appear to depend on electrical interactions, most likely field effects but possibly also gap junctions.[44] The prolonged duration of the field bursts can be attributed to the accumulation of extracellular K^+, which has a relatively slow clearance and is able to sustain depolarization over tens of seconds.[44] While the in vitro low-Ca^{2+} condition is distinctly artificial, these observations are relevant to epilepsy in vivo: low levels of extracellular Ca^{2+} do occur during seizures,[45,46] and similar nonsynaptic mechanisms operate under conditions of intact synaptic transmission and normal extracellular Ca^{2+} concentration.[47,48] In practice, synaptic and nonsynaptic mechanisms interact intimately both in promoting and in controlling epileptiform synchronization (see Fig. 14–3).

GAP JUNCTIONS

Gap junctions are sites of direct electrical communication between cells. Proteins known as *connexins* assemble into pores aligned in the two communicating cells. The pore allows relatively large molecules to pass, including dyes

and intracellular signaling molecules. Gap junctions switch between open and closed states and can be modulated by a range of intracellular signals, including pH, cyclic adenosine monophosphate (cAMP), and Ca^{2+}.[44]

Glia, especially astrocytes, are coupled by gap junctions and show prominent dye coupling, at least in cortical gray matter,[49] where they mediate the propagation of intracellular Ca^{2+} waves through the syncytium they form. These gap junctions are powerful enough to contribute ~30% of the input conductance of individual glia.[50] Astrocyte gap junctions play a role in promoting the clearance of extracellular K^+ following its accumulation. Hippocampal slices from mice lacking astrocyte gap junctions have lower seizure thresholds, supporting the idea that this mechanism helps control seizures.[50] Gap junctions between astrocytes are upregulated in patients with temporal lobe epilepsy (TLE), which could be seen as a protective response, but glutamatergic signaling between astrocytes and neurons may mean that this upregulation could be pro-epileptic.[51]

Interneurons have well-documented gap junctions both in hippocampus[52] and in neocortex.[53,54] These gap junctions are capable of synchronizing pairs of interneurons of the same subtype (e.g., fast spiking or low-threshold spiking) and promoting synchronous firing of interneuronal populations,[55] and of enhancing coherent oscillations emerging from their GABAergic synaptic network.[56] Seizure-like activity mediated by $GABA_A$ receptors with glutamatergic receptors blocked also depends on gap junctions, implicating gap junction coupling of interneurons in seizure generation.[28]

Pyramidal cells may have gap junctions too. Indirect evidence implicated electrotonic coupling between hippocampal pyramidal cells, and in particular between pyramidal cell axons,[57] but direct evidence for these gap junctions has proved elusive, suggesting that they are rather rare;[58,59] thus, only 10 out of 2000 pairs of neocortical pyramidal neurons were found to be electrotonically coupled in a recent study.[60]

EPHAPTIC (FIELD EFFECT) INTERACTIONS

Neuronal activity generates electric fields, which, of course, are responsible for the EEG. Neuronal excitability also can be modulated by electric fields; essentially, if a voltage gradient in the extracellular space produces a negative potential just outside the neuron, then its membrane will experience a *transmembrane* depolarization and it will become more excitable.[44] The details differ, depending on the neuron's membrane resistance and length constant, but the link between extracellular negativity and transmembrane depolarization is consistent.

A central question is whether the endogenous fields are strong enough to modulate neuronal activity. In hippocampal slices, exogenous fields of a few millivolts per millimeter DC can modulate evoked responses in vitro[61] and AC fields of a few hundred microvolts per millimeter can entrain activity when neurons are close to threshold so that small perturbations in transmembrane potential have significant effects.[62,63,63a] Stronger fields of up to 10–20 mV/mm occur during seizures, suggesting that they may participate in synchronization during the seizure itself.[44] Relatively strong fields can also occur during physiological activity, on the order of 1 mV/mm, in both hippocampus[44] and neocortex,[64] suggesting that they could play a (probably modest) role in normal brain function. The situation we have outlined here is for electric fields generated by populations of neurons. The fields generated by individual neurons or small groups of neurons are smaller and more complex. Such interactions depend on the proximity of the potentially coupled neurons and align more closely with the original use of the term *ephaptic*. Computer simulations suggest that they are strong enough to have a significant effect.[65]

EXTRACELLULAR POTASSIUM AND OTHER ION FLUCTUATIONS

The long duration (up to many tens of seconds) of the low-Ca^{2+} field bursts may be attributed to elevations in extracellular K^+ concentrations that should increase neuronal excitability. K^+ increases during seizures in models with intact synaptic transmission in vitro (e.g., Figs. 14–2C, 14–3) and in vivo, resulting in slow negative shifts of the extracellular potential, which have also been detected in humans.[66] In some situations, the extracellular K^+ concentration needs to reach a threshold value to trigger a seizure.[2,8] The clearance of extracellular K^+ occurs over many seconds and is slow enough to contribute significantly to the prolongation of

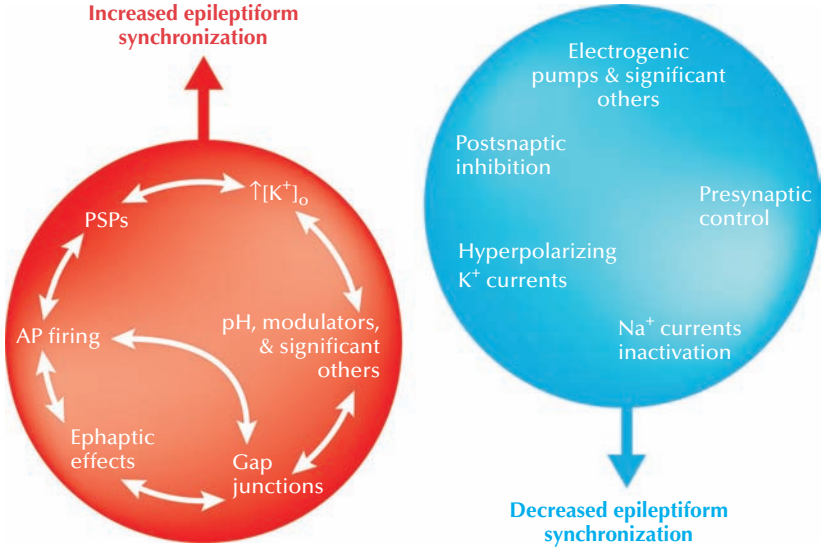

Figure 14–3. Schematic diagrams illustrating mechanisms that promote epileptiform synchronization and their broad relationships (left panel in red) and those that reduce epileptiform synchronization (right panel in blue).

seizures. Intense neuronal firing is superficially the most obvious source of extracellular K^+, but as mentioned above, inhibitory synaptic transmission is a particularly potent source because the transporters for GABA reuptake and Cl^- extrusion,[67] like many other ion and neurotransmitter transporters, depend in part on the efflux of K^+ down its concentration gradient. These increases in K^+, probably with contributions from changes in other ions,[45] tend to increase excitation synchronously for all the neurons exposed to the ionic change.

K^+ buffering is impaired in chronic epileptic foci with hippocampal sclerosis,[51] apparently because of decreased expression of astrocyte Kir channels. This loss of function will exacerbate the impact of K^+ transients on promoting and sustaining epileptic activity. The resulting impairment of glutamate uptake, along with the downregulation of glutamine synthetase found in both clinical and chronic experimental foci, will further promote epileptic activity.[51]

Glial cells play active roles in neuronal function beyond regulating extracellular K^+ and taking up neurotransmitters. It has become increasingly clear that glia can release glutamate and other neurotransmitters in response to elevations of intracellular Ca^{2+}, which may involve Ca^{2+}-dependent exocytosis. This can be triggered by activation of receptors on the glial surface, notably mGluRs, or by depolarization from increased extracellular K^+.[51] It is likely that they will contribute to seizure activity by providing pathways for the propagation of excitation that are not limited to classical synaptic pathways and by providing relatively slow forms of neuronal depolarization[51] (Fig. 14–3).

SEIZURE ONSET

Temporal lobe seizures, both clinical and experimental, have been divided into two groups on the basis of their onset: low-voltage fast (LVF) and hypersynchronous (HYP).[68,69] The clinical evidence argues that cases with LVF onsets may have more diffuse seizure onset zones that include extrahippocampal areas.[68] However, if the LVF onset reflects recording of a seizure onset at site/s remote from where the seizure initiates, then the mechanism of onset could be similar to that of HYP.[69] This issue is still controversial, because human data support the notion that LVF in the beta-gamma frequency range have a high localizing value for the identification of the seizure-onset zone[70–72] (for a review, see ref. 36). The advent of faster sample rates in clinical electrophysiology showed the presence of high-frequency activity (HFA) at seizure onset.[70,71] In conventional EEG this activity

appears as an electrodecremental pattern.[36,70,71] The presence of beta-gamma oscillations at seizure onset is also supported by the characterization of seizure patterns in chronic animal models of partial epilepsy.[73] Moreover, in an in vitro model of seizures induced by transient disinhibition of the whole guinea pig brain, LVF sustained by inhibitory postsynaptic activity coupled with interneuronal bursting were found in the entorhinal cortex at the very onset of limbic seizures.[39] A role for GABAergic reinforcement to either initiate or precede an ictal discharge was also reported in hippocampal slices treated with low $[Mg^{2+}]_o$ with[37] or without 4-aminopyridine.[74]

The existence of a preictal state has been postulated and may provide opportunities for seizure prediction[75] as well as providing clues on the mechanisms of the transition to seizure. Experimental investigations of the preseizure period in acute experimental epilepsy in brain slices revealed low-amplitude HFA at ~200 Hz some tens of seconds before seizure onset.[48,76,77] No individual neuron fired at this rate: each cycle of HFA was generated by synchronous activity of a small aggregate of neurons (within ~5 ms), with each neuron firing on a minority of cycles.[48] This synchronization was most likely due to ephaptic interactions[44] and not gap junctions.[48] Under other circumstances, HFA of up to 200 Hz (known as the *ripple band*) was associated with, and most likely entrained by, firing of fast-spiking interneurons.[78] Preictal HFA in models in vitro changed dynamically in the run-up to the next seizure, with progressive increase in power, expansion in the spatial extent of synchronization, and decrease in mean frequency.[48] This hypothesis seems to be supported by recent human findings[79] that demonstrate the coalescence of microseizures recorded with microelectrodes just ahead of a large-scale clinical seizure observed during diagnostic presurgical assessment in pharmacoresistant patients.

The role of preictal HFA in humans with epilepsy remains an open question. Some reports showed increased power in high-frequency bands up to 20 min preceding the seizures,[80] but others found no preictal HFA.[81] Where it has been reported, it tends to be highly localized,[70,82] which means that failure to record it could mean either that it is not present or that the electrodes are not in the right place.

SEIZURE TERMINATION

In most cases, limbic seizures stop within tens of seconds to a few minutes. Identifying what mechanisms make seizures stop would have a major impact on the treatment of epilepsy. Seizure termination is as complicated a process as seizure initiation (Fig. 14–3). Several mechanisms of seizure termination have been described, including: synaptic inhibition, afterhyperpolarizations due to K^+ channels, neuromodulators (adenosine, endogenous opioids, endocannibinoids), depletion of the readily releasable pools of synaptic vesicles, sodium channel inactivation, changes in extracellular ions (notably Ca^{2+}, K^+, and H^+), and activation of sodium-potassium pumps. Such mechanisms may well play roles, alone or in combination, in seizure termination. Intracellular acidification arising from seizure activity would tend to close gap junctions,[83] which may reduce electrotonic synchrony between neurons, particularly between classes of interneurons where gap junctions are well documented, although gap junctions between glia may also be important, particularly in light of the roles they play in neuronal activity. Acidosis can impact on seizures by other mechanisms, such as acid-sensing ion channels (ASIC): work on genetically modified mice revealed that ASIC1a has a major effect on seizure severity, contributing to seizure termination and being responsible for the modulation of seizures by modifications of extracellular pH.[83a]

While seizures are generally considered to be hypersynchronous events, recent work suggests that spatial synchrony may increase to a maximum towards the termination of the seizures, raising the possibility that increased synchrony may play role in terminating epileptic seizures, both clinical[84] and experimental.[47] One idea that is gaining ground is that seizures stop when cycles of activity become too synchronous throughout the seizure-generation zone at the same time that the frequency of the activity drops.[47,73] The end result is that the prolonged and synchronous hyperpolarization of the seizure-generation zone prevents excitation from resuming anywhere in the circuit.[47,84] One specific idea is that the slow afterhyperpolarization due to Ca^{2+}- activated K^+ channels builds progressively, as a result of intracellular accumulation of Ca^{2+} and Na^+, to such a degree that the hyperpolarization becomes so

prolonged that it blocks reexcitation by I_h[47] or by synaptic activation from asynchronously active regions.

ROLES AND INTERACTIONS OF SPECIFIC LIMBIC AREAS IN SEIZURES

Where limbic seizures originate may vary both between and within cases, whether patients or experimental animals. It has been shown experimentally in vitro and in vivo, and in human patients, that several limbic structures can initiate seizures: hippocampus, entorhinal cortex, perirhinal cortex, amygdala. In some cases one structure can dominate, while in other cases onset can be multifocal. During the course of individual seizures, activity propagates widely along synaptic pathways, and can become highly synchronized between limbic and other regions in both hemispheres.

Early theories argued that propagation through *reentrant loops* in the limbic system played a key role in sustaining and prolonging seizures beyond the few seconds of the interictal discharge.[85] However, more detailed measurements of the cycles of activity within each seizure show near-zero mean phase lags between the various limbic structures,[86,87] suggesting that they perhaps have more in common with coupled oscillators than with reentrant loops. In line with this view, left and right hippocampi in the intrahippocampal tetanus toxin model had a near-zero phase lag, due to the lead swapping sides repeatedly during each seizure, while on each side CA3 consistently led CA1, reflecting the predominantly unidirectional transmission through the Shaffer collaterals.[88] The long-range networks may be crucial for the persistence of seizures in vivo through the reexcitation of each region by others that are active as it recovers from periods of inhibition.

Some parts of the limbic system may make specific contributions to seizures. A classic example is the dentate gyrus, which has been considered a "gate" that controls the spread of seizures through the network. As mentioned above, evidence obtained from in vitro models of epileptiform synchronization indicates that the CA3 region is particularly effective at generating interictal discharges, and the entorhinal cortex is especially effective at generating prolonged seizure-like events. The relatively frequent and brief interictal discharges may control seizure generation, as shown in Fig. 14–4A, where lesioning slices between the hippocampus and entorhinal cortex revealed seizures in the latter. Moreover, stimulation at 0.5–1.0 Hz can block seizure initiation (Fig. 14–4B), providing further support for the idea that repetitive activity of the kind produced by interictal discharges can be anticonvulsant.[9,43,89] In the intact brain the circuitry is even more complex; for instance, midline thalamic nuclei, which are part of the limbic system, may play a key role in synchronizing limbic seizures through their diffuse and widespread connections.

NEUROBIOLOGY OF TEMPORAL LOBE EPILEPSY

Hippocampal Sclerosis and Other Pathologies

Hippocampal sclerosis is found in about two-thirds of cases of TLE. Prolonged status epilepticus does lead to neuronal death, so experimental models of TLE induced by an episode of status epilepticus are associated with substantial neuronal loss and gliosis. In cases without an initial status epilepticus, whether hippocampal sclerosis is a consequence of repeated seizures or of some initial precipitating injury remains an open question. More subtle and selective losses of neurons, particularly inhibitory interneurons, have been reported and may have functional consequences.[90,91]

Principal neuron damage associated with hippocampal sclerosis has been implicated in the mechanism for fast ripples[92] but now seems not to be necessary for them.[93] Damage of large numbers of principal neurons will have a major impact on their synaptic targets, notably by the loss of their synaptic drive, but also potentially by causing plastic changes in both connectivity and neuronal excitability. This is a process in which loss of function of the hippocampus proper could produce gain of function in parahippocampal structures, such as the entorhinal and perirhinal cortices or amygdala, thus leading to a

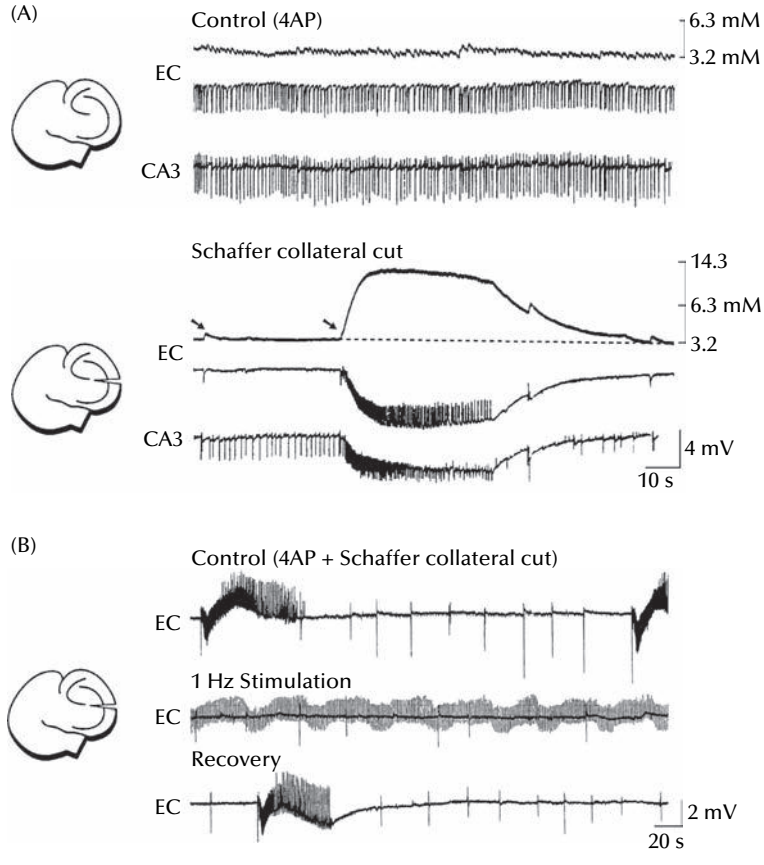

Figure 14–4. A. Effects induced by cutting the Schaffer collaterals on the epileptiform activity recorded from a rodent combined hippocampus–entorhinal cortex slice during continuous application of 4-aminopyridine (4AP). Note that under control conditions the pattern is characterized by fast CA3-driven interictal discharges, while after Schaffer collateral cut, ictal discharges are disclosed. (EC: entorhinal cortex.) **B.** Effect induced by extracellular stimuli delivered in the CA1-subiculum area subfield at 1 Hz on the ictal activity recorded after Schaffer collateral cut. Note that the low-frequency stimulation prevents the occurrence of ictal discharges and that ictal activity reappears after termination of the repetitive stimulation protocol.

chronic condition of poorly controlled seizures in epileptic animals and perhaps in TLE patients.

High-Frequency Oscillations

High-frequency oscillations (HFOs) associated with the epileptic state can be found during interictal periods, often, but not always, superimposed on interictal discharges. High-frequency oscillations in the band between 100 and 250 Hz, known as *ripples*, also occur during normal physiological activity, most notably in *sharp-wave ripples*, which may play key roles in memory formation and consolidation.[94] More promising in terms of pathophysiology are HFOs faster than 250 Hz, known as *fast ripples*, which appear to be selective for epileptic foci and have been proposed as biomarkers for the epileptogenic zone.[18,81,95,96] (The precise demarcation frequency between ripples and fast ripples varies among publications.)

The mechanisms of HFOs are starting to be clarified. Ripples may well be paced by fast rhythmic IPSPs[97] controlling the activity of pyramidal neurons induced by synchronous excitation, which produces the *sharp-wave* and is due to something akin to the glutamatergic chain reaction of the interictal discharge described above. The mechanisms of

fast ripples are more controversial. They are correlated with the presence and extent of hippocampal sclerosis.[92,98,99] This led to the hypothesis that the loss of neurons was a necessary requirement for the higher frequency of fast ripples, because it fragmented the ephaptic coupling of pyramidal cells.[92] Our work on the hippocampal tetanus toxin model of nonlesional TLE argues that neuronal loss is not a necessary requirement for the production of fast ripples.[93] The selective production of fast ripples by the hippocampus injected with tetanus toxin argues that they are good markers for the primary epileptogenic zone even in the absence of neuronal loss, and that they are better than interictal discharges or ripples, both of which occurred equally often in injected and contralateral hippocampi.[93]

TARGETING SYNCHRONY AS AN APPROACH TO THERAPY

As outlined above, epileptic seizures are essentially a form of neuronal hypersynchrony. Conventional AEDs generally target excitability rather than synchrony, although they may impact on it indirectly, for instance by retarding the chain reaction of excitation described above. In contrast, electrical stimulation of the epileptic focus can directly impact on neuronal synchrony. Strong depolarizing direct and high-frequency sinusoidal currents can block seizure activity in vitro, most likely because excessive depolarization results in inactivation of Na^+ channels so that neurons are no longer able to fire action potentials.[100,101] The depolarization will decay electrotonically along the axons, so that at some distance from the soma it will drive repetitive firing. While this may appear unhelpful, the resulting action potentials will be asynchronous between axons and may contribute to desynchronization of postsynaptic targets. Stimulation may also have the effect of releasing enough neurotransmitter to deplete the readily releasable pool of neurotransmitter vesicles, perhaps mimicking the effects of some classes of interictal activity.[9,43,89]

The termination of seizures by slow, repetitive, hypersynchronous activity (see the section "Seizure Termination" above)[47,73] suggests that stimulation at low frequencies could block seizures. In line with this view, low-frequency stimulation at ~1 Hz (Fig. 14–4B) reduces ictal-like discharges generated by the rodent brain in an in vitro slice preparation,[9,43,89] as well as in at least one model in vivo.[102]

CONCLUSIONS

Neuronal hypersynchronization is a key aspect of limbic seizures and interictal activity. In the case of symptomatic seizures or acute models of epilepsy, this hypersynchronization depends on the aberrant engagement of mechanisms normally responsible for physiological synchronization, which is prominent in the hippocampus and other limbic areas. In chronic epileptic foci, aberrant synchronizing mechanisms may contribute substantially to the generation of spontaneous epileptic discharges.

Neuronal synchronization depends in large part on the operation of synaptic networks, both excitatory and inhibitory. However, other mechanisms play significant roles, notably relatively slow fluctuations in $[K^+]_o$ and other ions and the faster actions of ephaptic and gap junction coupling. Evidence is accumulating for important roles for glia, both in $[K^+]_o$ and neurotransmitter buffering, and their ability to release glutamate and other neuroactive substances. The long-range connectivity of the limbic system is also important, both because interactions between its components appear to sustain and propagate seizures and because certain areas exert control over the epileptiform activity generated by others, such as the hippocampus controlling seizures in the entorhinal cortex. We conclude that investigating epileptic synchronization in the limbic system will help us understand the generation of epileptic discharges and may provide leads on more selective treatments to prevent or ameliorate epileptic seizures.

Chapter 15

Imaging of Hippocampal Circuits in Epilepsy

Hajime Takano
Douglas A. Coulter

Temporal lobe epilepsy (TLE) is the most common variant of adult human epilepsy. Although many brain regions are affected by TLE, the hippocampus and associated parahippocampal cortices are critically implicated. Clinical evidence supporting this contention includes a characteristic TLE-associated hippocampal pathology, termed *mesial temporal sclerosis*, and the efficacy of amygdalahippocampectomy in the treatment of TLE, in which removal of the affected hippocampus and amygdala eliminates seizures in many patients with mesial TLE. Temporal lobe epilepsy is an acquired seizure disorder, usually developing with a prolonged latency following some form of brain injury in the patient's past, such as a central nervous function (CNS) infection, head trauma, or a prolonged seizure episode such as status epilepticus (SE) or complex febrile seizures. Advancing our knowledge of the mechanisms underlying epilepsy necessarily involves studying the dynamic properties of neurons in situ, as they function in their physiological circuit, with all of the emergent complexities involved in the generation of the integrated output of brain regions.

Several animal models of TLE exist. A majority involve experimental induction of a brain injury through administration of a chemoconvulsant or electrical stimulation, both of which induce an episode of SE. Following resolution of SE, a high proportion of animals go on to develop spontaneous seizures with hippocampal involvement within weeks to months. One such model, involving pilocarpine administration as the chemoconvulsant, is one of the major models used to study TLE. The development of epilepsy after pilocarpine treatment follows three distinct stages.[1–3] (1) After administration of pilocarpine, the hippocampus begins to exhibit high-frequency spiking, which develops into electroencephalographic (EEG) seizures, repeating every 3–5 min and eventually leading to continuous seizures that can last for several hours (SE) unless they are terminated by administration of drugs such as diazepam

alone, diazepam with pentobarbital, or phenytoin. (2) Following termination of SE, there is a subsequent latent period during which animals exhibit a relatively normal EEG and behavior; this period may last for days to weeks. (3) Signaling the end of the latent period is the emergence of spontaneous recurring seizures, which persist for the life of the animal. Seizure frequencies vary from several daily to sporadic seizures two or three times per week or occurring as clusters every 5 to 8 days.[3]

How might an epileptogenic injury (e.g., SE) trigger the subsequent delayed emergence of spontaneous seizures in TLE? The characteristic hippocampal pathology found in human TLE patients, including patterned segmental neuronal loss, sclerosis, and mossy fiber sprouting, can be reproduced in animal models of TLE.[4] Damage caused by SE includes CA3 and CA1 pyramidal cells, hilar mossy cells, and specific types of interneurons; dentate granule cells and CA2 pyramidal neurons tend to be preserved. Neuronal damage induced by SE is not limited to cell death. Altered cell morphology has also been described as a result of SE in neurons that survive this brain injury. This injury-induced anatomical plasticity includes the appearance of mossy fiber sprouting.[5] In addition, SE triggers other biological responses, including an increased rate of neurogenesis in the dentate gyrus,[6] increased activity of microglia, and induction of reactivity in astrocytes.[7]

In addition to the cell death and anatomical changes in neurons and glia described above, SE induces significant functional plasticity in surviving hippocampal neurons. This plasticity is triggered by alterations in transcriptional, translational, and posttranslational regulation of the function of transcription factors, ion channels, neurotransmitter receptors, ion and neurotransmitter transporters, and kinases in many different neuron types in the hippocampus. Notable examples of this type of functional plasticity include alterations in ion channel function, such as calcium currents,[8] hyperpolarization-activated mixed cationic channels[9,10] and potassium channels,[11] and changes in neurotransmitter receptors, including $GABA_A$ receptors[12,13] and glutamate receptors,[14] as well as in chloride transporters[15] and excitatory amino acid transporters.[16–18]

Although important, the role that these anatomical, morphological, pathological, and functional plasticity changes play in hippocampal circuit activity alterations in epileptic brains remains an open question. We simply do not know how the hippocampus becomes hyperexcitable. We also do not know how hyperexcitable cells integrate into a pathologically functioning circuit, contributing to induction of spontaneous recurrent seizures. These critical questions cannot be easily addressed by conventional EEG or single-cell recording techniques. Advancing our knowledge of the mechanisms underlying epilepsy necessarily involves studying the dynamic properties of neurons in situ, as they function in their physiological circuit, with all of the emergent complexities involved in generation of the integrated output of brain regions. In recent years, optical imaging technologies, collectively termed *functional imaging*, have developed rapidly, have provided us with the ability to conduct detailed neuronal circuit characterizations, and constitute perhaps the most powerful tools available to begin to address emergent function in both normal and pathological neuronal circuits. In this chapter, we will describe the basic tools and mechanisms of functional imaging and their application to in vitro hippocampal circuit characterization in naive and epileptic animals.

FUNCTIONAL IMAGING

Why Functional Imaging?

In order to understand network dysfunction in epileptic brain, it is necessary to characterize circuit dynamics comparing naive and epileptic brain. In conventional electrophysiological recording, cellular properties can be characterized in detail for a single cell and cellular interactions can be studied among at most two or three cells. Functional imaging, on the other hand, provides the ability to characterize dynamic properties of multiple cells (>100 cells) simultaneously. Activity can be monitored in individual hippocampal subregions and/or the entire hippocampal circuit. Using functional imaging, differences in signal propagation patterns can be distinguished in naive tissue and tissue from epileptic brain. Multicellular functional imaging also provides the ability to isolate unusual cell behavior in epileptic brain that may not be detected by single-cell recording techniques

simply because the population of such abnormal cells may be small and the chances of targeting the particular population of rare cells for electrophysiological recording may be correspondingly small. In another example, one can map the dynamic connectivity of multiple neurons by sequentially stimulating subsets of neurons optically using either photolysis of caged neurotransmitters or optogenetic approaches. One can then ask whether epileptic brains exhibit different patterns or prevalence of neuronal connectivity compared to naive animals.

Spatial and Temporal Resolution

The results obtained with various functional imaging approaches have the potential to be tremendously informative. However, dynamic imaging of neuronal circuit function is challenging, with achievement of the necessary spatial and temporal resolution required to resolve neuronal responses constituting the most difficult aspect of optical recording. For example, neurons and their processes are small, with a spatial extent measured in micrometers. In contrast, the circuits within which neurons function may extend millimeters to 1 cm or more. Studies examining circuit function must retain cellular resolution while probing areas spanning regions orders of magnitude larger in size (Fig. 15–1). The difficulty of achieving spatial resolution is compounded by the demanding temporal requirements of circuit recordings. The fundamental neuronal activities are action potential (AP) firing and synaptic transmission, with an AP lasting for 0.5–2 ms and a synaptic response lasting for 10–50 ms. To capture these events, any imaging method should have a temporal resolution of 1 kHz or better. To date, no single microscopic imaging approach can fulfill the requirements described above. However, integration of a combination of multiple imaging approaches can begin to accomplish this goal.

Various Types of Functional Imaging

VOLTAGE-SENSITIVE DYE IMAGING

Voltage-sensitive dye imaging (VSDI) monitors neuronal activity though the use of voltage-sensitive fluorescent or nonfluorescent dye molecules that are inserted into the cell membrane.[19,20] Changes in membrane potential are in essence changes in the electrical environment in which the voltage-sensitive dye (VSD) resides (the membrane), and elicit voltage-dependent shifts in the absorption spectra and/or shifts in the fluorescence emission spectra of a VSD. One can monitor AP firing and synaptic transmission using this technique. Optical acquisition systems in VSDI frequently have high temporal resolution exceeding 1 kHz frame rates, a significant strength of this form of imaging. The most commonly used VSD imaging method is wide-field microscopy combined with image acquisition using a fast charge-coupled device (CCD) camera (Table 15–1). Due to this high temporal resolution, the CCD camera must be sensitive enough to detect low light levels since the amount of light captured

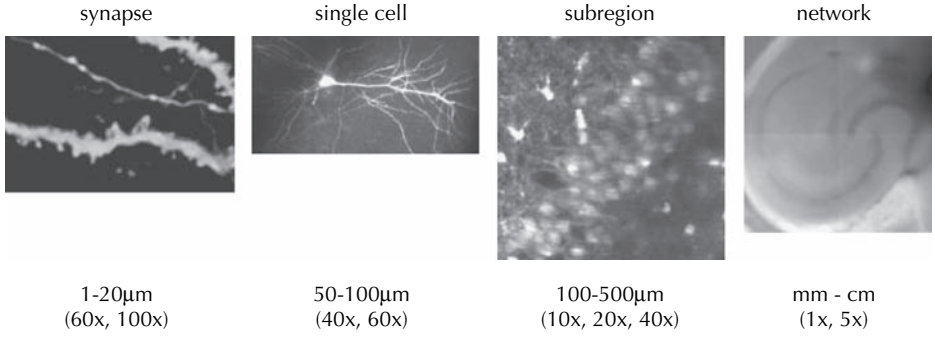

Figure 15–1. Spatial constraints of brain imaging studies. Image examples, typical image size, and microscopy objective lens to be used to study the dynamic function of these components. From left to right: (1) three-dimensional reconstruction of neuronal processes expressing the GFP molecule; (2) CA1 pyramidal cells in a slice filled with a dye; (3) CA3 pyramidal cells in a slice loaded with a calcium indicator dye; (4) hippocampus slice loaded with a VSD.

Table 15–1 **Various Forms of Functional Imaging**

	Experiment Scale	Probes, Loading Method	Microscopy
VSD imaging	Network	Bulk-loading VSD Genetic probe	Wide-field microscopy with fast CCD camera
	Single-cell	Internally injecting by patch pipette Genetic probe	
Calcium imaging	Multicellular	Bulk-loading AM-ester form of dyes Genetic probe	Confocal or two-photon microscopy Fast confocal microscopy with fast CCD camera
	Single-cell, synapse	Internally loading salt form of dyes Genetic probe	
Chloride imaging	Multicellular	Bulk-loading dye Genetic probe	Two-photon microscopy with point scan or line scan
	Single-cell	Internally injecting dyes Transgenic, viral infection	
Uncaging	Network multicellular single-cell synapse	Bath application Internally by patch pipette	Point-scanning device attached to wide-field microscopy, confocal microscopy, or two-photon microscopy UV or two-photon excitation
Channelrhodopsin	Network multicellular single-cell	Genetic	Blue light source (light-emitting diode, laser, display device) attached to a wide-field microscope, confocal microscope, or two-photon microscope

during a 1 ms or shorter epoch (one frame) is limited. The CCD camera also has to have a high readout speed, low dark noise, and low readout noise. In VSD experiments in our laboratory, we use a low-noise back-thinned CCD camera that has a smaller number of pixels (80x80 pixels), achieving an image acquisition rate of 2 kHz.[21] Conventional laser scanning confocal microscopy and multiphoton microscopy are not suitable for VSD imaging of neuronal circuit function due to their slow image acquisition rate (typically 1–10 Hz). Alternatively, multibeam scanning devices such as a spinning disk microscope, a swept-field microscope, and a multibeam multiphoton microscope are, in principle, sufficiently fast to allow VSD imaging.

Most VSDs are lipophilic, and so can be bulk-loaded by applying a dye solution to the tissue. The bulk-loading method is suitable for monitoring network activity with a low-magnification objective lens. However, in this form of recording, it is hard to identify single-cell morphology or dendrites of a particular cell in bulk-loaded slice tissue. Many VSDs also suffer from a low signal-to-noise ratio. Because changes in VSD signal responses to neuronal activity can be as small as 0.1%–1%, event averaging is often utilized to enhance the signal-to-noise ratio. Event averaging usually must be accompanied by triggered stimulation, such as an electrical pulse train of a certain frequency, although in some cases, spontaneous events can be averaged post hoc following an experiment based on event detection algorithms.

In addition, VSDs can be internally loaded into neurons through a patch pipette in a conventional electrophysiology setup. With this loading method, one can study dynamic properties of synaptic transmission within a single neuron. In some cases, neuronal connectivity can be studied using only optical approaches by combining VSD imaging with a photolytic uncaging system.[22] Recently, successful genetically encoded voltage-sensitive probes have been developed.[23] With this new technology,

Table 15–2 **Temporal Characteristics of Various Forms of Imaging**

	Image Size	Temporal Resolution
Wide-field microscopy with a fast CCD camera	80 × 80 pixels	2 kHz
Confocal microscopy and two-photon microscopy	512 × w512 pixels	1–10 Hz
	Line scan	200–500 Hz
Fast confocal microscopy with a fast CCD camera	512 × 512 pixels	25 Hz
Multibeam two-photon microscopy	128 × 128 pixels	500 Hz

one can characterize the activity of a specific neuron at a high magnification and the activity of an entire network at a low magnification within the same system.

CALCIUM IMAGING

Calcium imaging (Cal·I) of hippocampal tissue slices has been ongoing for decades, with the use of multiphoton microscopy in these studies reported since the 1990s.[24,25] Conventional Cal·I uses a calcium indicator dye loaded into cells. Calcium imaging is based on a change in fluorescence emission spectra (e.g., OGB-1 and fluo3) or a change in absorption spectra (e.g., fura-2) of calcium indicator dyes upon calcium ion binding. This process is reversible and follows the chemical equilibrium between cytosolic free Ca^{2+}, the ion free form, and the ion bound form of the calcium indicator dye. There are three major routes of calcium influx into the cytosol in neurons. One is through voltage-gated calcium channels, which, due to the high depolarization threshold of these channels, usually only occurs when neurons fire APs. Another route is through *N*-methyl-D-aspartate (NMDA) receptor-mediated synaptic transmission, in which activated receptors conduct large amounts of calcium. Lastly, activation of certain G-protein-coupled receptors may trigger the activation of phospholipase C and the release of inositol trisphosphate (IP3), followed by activation of IP3 receptors in endoplasmic reticulum, causing Ca^{2+} release from internal calcium stores. Due to the high affinity of the calcium indicator for calcium, once Ca^{2+} binds to a calcium indicator dye, even though Ca^{2+} is pumped out of cells and sequestered in intracellular stores continuously, it takes several tens to several hundreds of milliseconds to unbind from the dye and restore dye fluorescence to basal levels. Thus, due to the long-duration response of calcium indicators, Cal·I equipment normally does not require millisecond temporal resolution and conventional research CCD cameras, scanning confocal microscopy, and two-photon microscopy can be used in Cal·I experiments (Table 15–1).

Monitoring neuronal activity from multiple neurons (multicellular imaging) can be accomplished by bulk-loading the acetoxymethyl (AM)-ester form of calcium indicator dyes. Fura-2 AM and OGB-1 AM are widely used. With this loading method, due to the relatively low cytoplasmic dye concentrations achieved (10 μM or less), it is difficult to identify the dendrites and axon of a particular neuron, especially in pyramidal cells in CA regions or granule cells in the dentate gyrus of hippocampal slices. Instead, one can monitor signal changes from the soma of multiple neurons. While the temporal response of Cal·I is slower than that of VSDI, changes in signal corresponding to cellular activity are very high, often 5%–100% in fluorescence during a response. This facilitates monitoring of cellular activity without event averaging. Since fluorescence emission from bulk-loaded slices is weak, we typically use high numerical aperture water-immersion objective lenses with modest magnifications (16x, 20x, and 40x). With these magnifications, it is possible to monitor individual cellular behaviors of entire hippocampal subregions (CA1, CA3, DG, etc.). For reference, a 40x confocal image field could contain 100–300 cells, while a 16x image field could contain 500–1000 neurons, all of which are accessible for imaging responses (Fig. 15–1). Confocal microscopy or two-photon microscopy is preferable for imaging slices at moderate to high spatial resolution since wide-field epifluorescence microscopy with a CCD camera collects fluorescence from the entire slice depth, confounding interpretation of the resulting responses. However, conventional confocal microscopy or two-photon microscopy still suffers from slow image

acquisition speeds (poor temporal resolution) because excitation spots must be scanned pixel by pixel, reducing the typical imaging speed to 1 to 10 Hz frame rates (Table 15–2). In our laboratory, we use an advanced form of confocal microscopy, known as *swept-field microscopy*, which incorporates multibeam scanning to speed acquisition rates, coupled with an electron multiplying CCD (EM-CCD) camera capable of recording at frame rates exceeding 1 kHz. Using this combination of technologies, one can achieve a real experimental acquisition rate of 25 Hz for images with 512x512 pixels or 300 Hz at 128x128 pixels (Table 15–2).

Calcium indicators can also be internally loaded into neurons through patch pipettes using a conventional electrophysiology setup.[26] With this loading method, one can study dynamic properties of fine processes or even activity in individual synaptic spines (Table 15–1). In addition, there are many genetically encoded calcium indicator probes available that can be used to study single-cell activity, multicellular activity, and even network properties.

CHLORIDE ION IMAGING

$GABA_A$ receptor-mediated inhibition depends on maintenance of the intracellular chloride concentration at low levels, 2–10 mM.[27] This is accomplished through the activity of two chloride transporters expressed in neurons: a chloride extruder, potassium chloride cotransporter 2 (KCC2), and a chloride accumulator, sodium-potassium chloride cotransporter 1 (NKCC1). The activity of NKCC1 predominates in the developing central nervous system, and as a consequence, the intracellular chloride concentration is elevated to 10–40 mM[28] and GABA consequently is excitatory. As development progresses, KCC2 transporter function increases, intracellular chloride concentrations decrease, and GABA channel activation therefore elicits hyperpolarization. Chloride transporter expression and function are activity dependent and change during the development of epilepsy.[15] As a consequence, depolarizing GABAergic synaptic responses may be recapitulated in epilepsy. To characterize this phenomenon at the cellular and circuit levels, it is crucial to understand the variation in the intracellular chloride level of individual cells and how this may change in epileptic brains. Monitoring cytosolic chloride levels can be accomplished using chloride ion indicators, including quinoline dyes such as *N*-(ethoxycarbonylmethyl)-6-methoxyquinolinium bromide (MQAE).[27] MQAE displays fluorescence quenching when dye molecules collide with chloride ions. Thus, at higher chloride concentrations, MQAE exhibits lower fluorescence emission and vice versa. The apparent dissociation constant for MQAE is 40 mM in neuronal cells. As in the case of Cal·I, circuit studies utilizing chloride imaging are most powerful when conducted using moderate magnification. Since the peak absorption wavelength of MQAE is in the ultraviolet (UV) range, imaging tissue continuously causes phototoxicity. Thus, two-photon excitation, with its reduced photodamage, is a preferable way of conducting imaging studies utilizing this dye. Genetic probes have also been developed for chloride imaging and provide a powerful way to characterize both static cytosolic chloride concentrations and variations in these levels during dynamic activity.[28,29]

Various Stimulation Methods in Imaging Studies

ELECTRICAL STIMULATION

The most simple and direct way of characterizing the input-output relationship of hippocampal circuits is to electrically stimulate a specific pathway and image the response from a specific subregion. One can control stimulus frequency and magnitude and conduct repeated trials to obtain averaged responses. For example, electrical stimulation in the direct entorhinal cortical afferent to area CA1, the temporoammonic pathway, induces neuronal activity in the dendrites of CA1 pyramidal neurons.[21]

SPONTANEOUS AND DRUG-INDUCED NETWORK ACTIVITY

Another way of characterizing network circuitry is to use a model that exhibits spontaneous network activity. For example, developing brains exhibit spontaneous network activity called *early network oscillations* (ENOs) and *giant depolarizing potentials* (GDPs). These network oscillations differ from an epileptic form of activity yet share many of its characteristics. For example, CA1 and CA3 neurons

exhibit synchronous network oscillations that are driven or governed by GABAergic neuronal activity. Drug-induced epileptiform activity (e.g., 4-AP and/or bicuculline-induced activity) can also be monitored using Cal·I approaches.[30]

PHOTOLYSIS OF CAGED COMPOUNDS

Synaptic input can be mimicked by using so-called caged neurotransmitters. Caged compounds usually contain a UV light-sensitive chemical group that, upon irradiation with UV light, breaks and releases a neurotransmitter (or other messenger molecules) as a product of the photo reaction. Caged compounds can be applied in the extracellular (imaging) solution during an experiment and then released with UV light being applied to small area, producing an uncaged neurotransmitter.[31] When this method is combined with two-photon excitation instead of UV irradiation, neurotransmitter is released in a three-dimensionally focused volume, exactly mimicking the spatial dynamics of synaptic neurotransmitter release at a spine (Table 15–1). If this technology is combined with high-resolution two-photon microscopy, the functional mapping of synaptic activity can be obtained. When it is combined with lower- to moderate-magnification objective lenses and Cal·I or VSD imaging, one can study cellular connectivity among multiple cells.

CHANNELRHODOPSIN/OPTOGENETIC APPROACHES

Channelrhodopsin (CR) is a light-sensitive cationic channel isolated from alga that can be introduced into neurons either by viral transfection or by construction of transgenic mice.[32] Because its expression is genetically encoded, CR can be expressed in restricted cell types when under the control of cell-specific promoters. Channelrhodopsin is activated by irradiating blue light, which, when sufficiently strong, can induce AP firing. Unlike extracellular electrode stimulation, CR stimulation is performed remotely by light and causes no physical damage to the tissue (Table 15–1). By appropriately designing the optical system, one could activate multiple targets within a tissue without significant delay.[33] Combining the CR stimulation method with functional imaging requires careful consideration of the absorption spectra and emission spectra of each element (CR, VSD, calcium indicator, etc.), as well as the use of appropriate optical filters.

IMAGING THE EPILEPTIC BRAIN: REPRESENTATIVE EXAMPLES

Dentate Gyrus Gating Function

In normal brain, the hippocampus receives input from the neocortex via the entorhinal cortex (EC; Fig. 15–2). In the main canonical trisynaptic excitatory hippocampal network, signals propagate from layer II of the EC to the dentate gyrus (DG) through the *perforant* pathway, then from the granule cells of the DG to CA3 via the output axons of these neurons, the mossy fibers. Area CA3 pyramidal neurons interconnect reciprocally via recurrent axon collaterals and, in addition to sending output to the contralateral hippocampus, project to

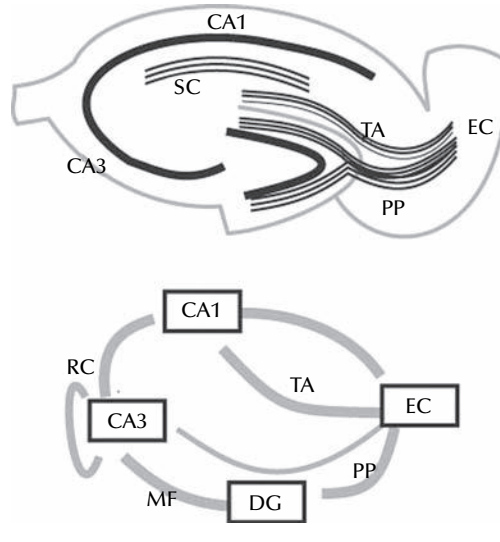

Figure 15–2. Schematic illustration of hippocampus structure in a horizontal slice and corresponding major excitatory pathways. In the trisynaptic pathway (TSP), the signal propagates from layer II of the entorhinal cortex (EC) to the dentate gyrus (DG) through the perforant path (PP), then from the DG to CA3 via mossy fibers (MF). CA3 neurons interconnect via a recurrent network (RC) and to CA1 through the Schaffer collaterals (SC). CA1 output to layer 5 of the EC occurs both directly and indirectly via the subiculum. The hippocampus contains another excitatory input, called the *temporoammonic* (TA) pathway, in which signal propagates from layer 3 of the EC to directly to CA1 distal dendrites.

pyramidal neurons in area CA1 through an axon collateral termed the *Schaffer* collateral pathway. CA1 outputs to layer 5 of the EC directly or indirectly via the subiculum. This signal transduction loop is referred to as the *trisynaptic pathway* (TSP; Fig. 15–2), although there are actually four to five synapses in a more comprehensive excitatory limbic loop. This type of excitatory interconnectivity is inherently unstable and prone to uncontrolled activation, so intrinsic regulators of unchecked activity are also present in the hippocampus. As an example of one such regulator, in the normal hippocampus, the DG → CA3 excitatory relay is limited (gated or filtered) by complex inhibitory mechanisms as well as by the low intrinsic excitability of dentate granule cells. These inhibitory mechanisms include feedforward GABA synaptic inhibition, feedback inhibition, and tonic GABAergic currents.[34]

How can the properties of this EC → DG → CA3 circuit be visualized with functional imaging? Previous work in our laboratory used fluorescence VSD (RH795 and/or JPW 3031) to characterize hippocampal circuit function in brain slices prepared from normal adult rats.[35,36] The VSD was bulk-loaded and imaged with a 4x objective lens using a fast CCD camera at a frame rate of 2 kHz. The VSD response to perforant path stimulation (100 Hz, four pulses) was imaged in the DG/CA3 area. Upon stimulation, the inner molecular layer of the DG showed a strong excitatory response. This excitatory response spread to the dentate granule neuron cell body layer and also to the proximal hilus, but only minimally activated the CA3 pyramidal cell layer (Fig. 15–3A). This indicates that dentate granule cells did not fire APs, and the response to perforant path activation was predominantly a subthreshold postsynaptic response. If granule cells did fire synchronous APs, the excitatory response to perforant path activation should have propagated through the mossy fibers and subsequently excited CA3 cells. The lack of dentate granule cell firing in response to perforant path activation was verified using Cal·I (Fig. 15–3B). Calcium transients in bulk-loaded neuronal somata only occur following AP firing, and are not seen with subthreshold depolarization such as an excitatory postsynaptic potential (EPSP). Under normal control conditions, only a small proportion of dentate granule cells exhibit calcium transients following perforant path activation (3%–5% on average). However, if inhibition is blocked with the $GABA_A$ antagonist picrotoxin, this proportional activation of dentate granule cells increases to 60%–65% following perforant path activation (Fig. 15–3B, middle panel). Despite the strong electrical stimulation, dentate granule cells are regulated by strong inhibitory mechanisms. These experiments demonstrate the inhibition-dependent "gating" aspect of DG function.

Breakdown of the dentate gate has been hypothesized to be a primary contributor to seizure generation in epilepsy. In animals with fully developed epilepsy, we have investigated whether the dentate gating function was disrupted. Surprisingly, the gating function was intact in these chronically affected animals.[35] This finding is consistent with several TLE studies[37,38] that indicated that inhibition within the dentate remains operative and suppresses seizure propagation from the entorhinal cortex. In contrast, recent studies from our laboratory, examining DG function in animals in the latent period preceding epilepsy onset, 1 week after pilocarpine-induced SE, showed markedly disrupted dentate gating functions[15] (Fig. 15–3B, bottom panel), with 60% of cells activating in response to perforant path stimulation, comparable to the results of control studies in the presence of a GABA antagonist (Fig. 15–3B, middle panel). This suggests that the gating function is corrupted by SE-induced processes and remains corrupted during the latent period (7 days after SE), only recovering at the point of development of chronic epilepsy (1 month or longer after SE).

Calcium Imaging of Epileptiform Activity

Network oscillations are associated with synchronous activity of large numbers of neurons and occur as a component of both normal and pathological circuit function. Investigation of individual cell behavior during network activity is critical in understanding the mechanisms regulating the generation of these types of responses. Voltage-sensitive dye imaging can capture network activity; however, it is not widely used in this context due to the necessity of event averaging and difficulty in identifying individual cell morphology, both constraints

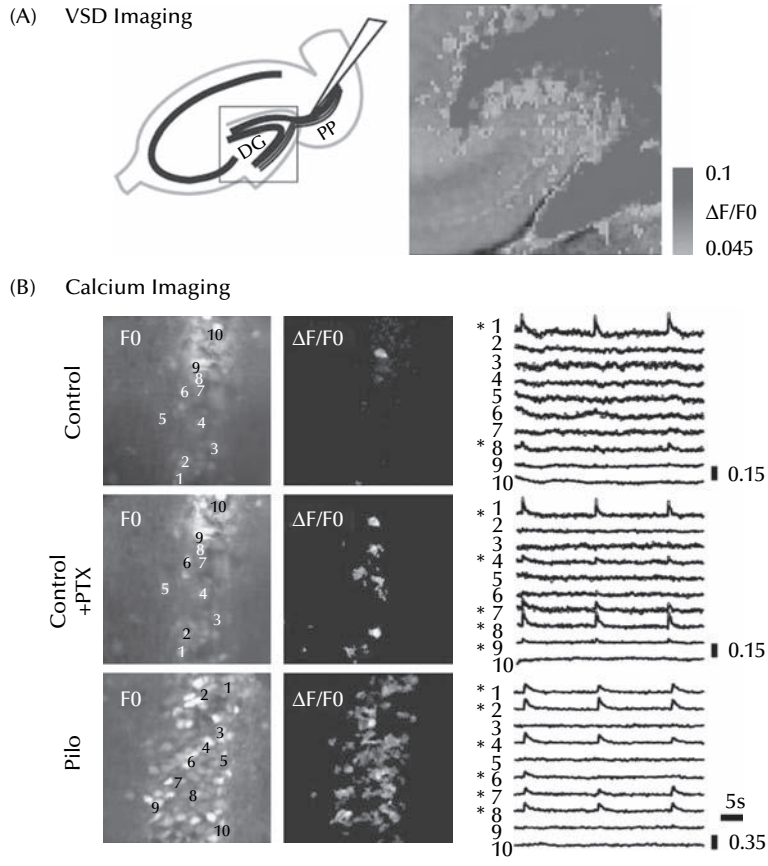

Figure 15–3. Dentate gyrus (DG) gate function. **A.** A schematic of the hippocampus illustrates the major afferent pathways to the hippocampus and the position of the stimulation electrode used to activate the perforant path (PP). A VSD image of a hippocampal slice from a control animal, containing most of each dentate blade and CA3. A snapshot at 25 ms after a burst stimulus applied to the PP generates a strong voltage response (dark color) in the DG that is minimally transmitted as excitation in CA3. **B.** Upper panels: Calcium imaging of the DG from a control animal and an experimental animal 7 days after injection with pilocarpine. The PP pathway was stimulated while imaging the response from calcium indicator–loaded tissues. Images on the left show baseline fluorescence, and second images show normalized fluorescence changes after electrical stimulation. Traces show normalized fluorescence changes on a randomly selected population of 10 cells from the images. Asterisks (*) indicate cells that responded to the electrical stimulation. Despite strong electrical stimulation, the majority of dentate granule cells did not have a response in control animal. Middle panels: In the presence of 100 μM picrotoxin in the imaging solution, the same electrical stimulation recruited more responsive cells, demonstrating disruption of inhibitory mechanisms. Lower panel: In a slice prepared from an animal 1 week after pilocarpine injection (during the latent period), there was a significant increase in dentate granule cell activation following PP stimulation. (Image courtesy of Dr. Cho.)

imposed by the low signal-to-noise ratios inherent in this mode of imaging. Calcium imaging, on the other hand, has proven to be useful in monitoring individual cell activity in cortical and hippocampal structures during synchronous circuit activity.[39–47] The hippocampus and cortex of young rodents (P3–5) generate recurrent spontaneous network oscillations, which are hypothesized to contribute to the consolidation of circuit connectivity. Some of these events are driven by GDPs[48] and other variants of network oscillation also occur, usually at a developmentally earlier stage.[41,42] Cell firing during these synchronous network bursts occurs at low frequencies (0.5 Hz or less). As was observed in previous work,[41,42] Cal·I can capture this network activity in simultaneous recordings of hundreds of individual cells. Figure 15–4 show an example of spontaneous synchronous network bursting captured

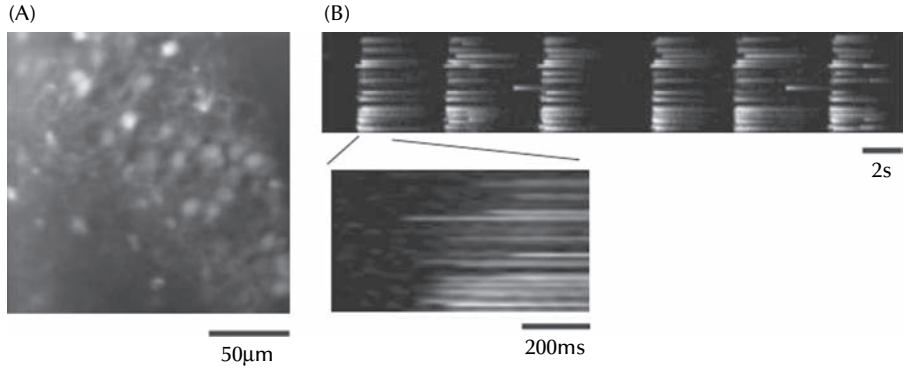

Figure 15–4. Calcium imaging of synchronous network activity captured in area CA3b from a slice prepared from a mouse aged P4. **A.** Snapshot of a calcium dye–loaded slice. **B.** The change in fluorescence was measured for multiple cells and shown as a raster plot. The insert shows a zoomed image of the onset of a synchronous network burst. The images were captured at 100 Hz by a fast confocal microscope equipped with an EM-CCD camera (128x128 pixels). Note the stereotypic activation order for individual cells in multiple bursts.

in the CA3b area from a slice prepared from P4 mouse (a raster plot depicts the responses of multiple cells). The images were captured at a 100 Hz frame rate using a fast confocal microscope equipped with an EM-CCD camera (128x128 pixel images). The spontaneous synchronous network events occurred repeatedly, that is, six times in 30 sec traces. These calcium transients arise from neurons firing APs, triggering the opening of voltage-gated calcium channels. The inset shows a raster plot zoomed on the rising phase of the signal change for the first network burst. The fast acquisition speed (100 Hz) was necessary to resolve differences in onset time of individual cell responses during synchronous network events. By analyzing the onset time of calcium transients for multiple cells for multiple network bursts, we determined that activation was not a random stochastic event. In contrast, bursts had a stereotypic, deterministic firing order, with individual neurons playing defined, repeated roles in burst generation. This can be visualized by sorting the raster plot by the activated order in the first network burst and determining how this trend was maintained in subsequent network bursts. This example illustrates that some cells are always activated earlier than others and some cells are always activated later than others. We hypothesize that intrinsic cellular properties and/or intrinsic connectivity determine these differing roles for individual neurons. In future studies, it will be interesting to determine if there is any association between onset time and type of cell, that is, between interneurons or principal cells. Given the resemblance of these early synchronous network bursts in the developing brain to interictal bursts characteristic of epilepsy, information gleaned from these studies may inform additional efforts to dissect the burst structure of epileptiform events in slices prepared from epileptic animals.

CONCLUSIONS

Development and application of integrated dynamic imaging approaches examining neuronal circuit function shows significant promise in furthering our understanding of the mechanisms underlying epileptogenesis, epilepsy, and seizure generation.

Chapter 16

Normal and Pathological High-Frequency Oscillations

Richard J. Staba

During natural waking and sleep behavior, the occurrence of spontaneous rhythmic field potentials, for example theta (3–8 Hz), gamma (30–80 Hz), and high-frequency oscillations (HFOs; 80–600 Hz), correspond with an increase in the rate and synchrony of neuronal firing. Compared to theta and gamma oscillations, networks supporting the generation of HFOs can be smaller in size and events shorter in duration, but the increase in neuronal firing and synchrony of discharges that occurs on a temporal scale of a few milliseconds or less can be much greater. Because HFOs can facilitate synaptic transmission through local networks, these events are implicated in information processing and consolidation of memory. Alterations to neuronal networks associated with epilepsy can also generate abnormal or pathological HFOs (pHFOs) that are believed to reflect fundamental neuronal disturbances associated with brain areas capable of generating spontaneous epileptic seizures. However, distinguishing normal HFOs from pHFOs is not always simple, particularly in studies involving intracranial brain recordings in presurgical patients with medically refractory epilepsy. This chapter will describe some of the spatial and temporal properties of HFOs observed in normal and epileptic mammalian brain and roles HFOs could play in normal brain function and epilepsy. Important to any description of HFOs are the putative mechanisms that support the generation of normal HFOs and pHFOs, and how pHFOs could be clinically useful in the treatment of epilepsy.

NORMAL HIGH-FREQUENCY OSCILLATORY NETWORK ACTIVITY

Spontaneous HFOs

In limbic structures of several mammalian species, including rodents, bats, nonhuman primates, and humans, spontaneous HFOs termed *ripples* contain spectral power between 80 and 200 Hz and have a duration of tens to hundreds of milliseconds.[1–4] The largest-amplitude ripples are found within the pyramidal cell layer of hippocampal subfield CA1 (Fig. 16–1A) and are also present in CA3, subiculum, entorhinal cortex, and amygdala.[5,6] In vivo studies in rodents have not observed normal ripples in the granule cell layer of dentate gyrus, although a study in cats observed ripple-frequency "minispindles" that occurred in CA1 but were also present in the hilus of the dentate gyrus.[7]

Hippocampal ripples occur more frequently during awake immobility and slow wave sleep (SWS) than in states characterized in animals by prominent theta rhythms such as exploratory behavior and rapid eye movement (REM) sleep. During episodes of SWS, hippocampal ripples can occur bilaterally and are often associated with large-amplitude slow waves called *sharp waves* (SPWs) generated in hippocampal CA3 (Fig. 16–1A).[8] Multielectrode studies show that there is strong coherence between ripples recorded in CA1 over distances of 4 or 5 mm suggesting that neuronal activity coordinated on a temporal scale of several milliseconds can occur across large areas of hippocampus.[5,9,10]

Neocortical HFOs

Spontaneous ripple-frequency HFOs are also present in neocortex. In cats, neocortical HFOs occur most frequently during episodes of SWS and states of ketamine anesthesia, and their appearance in isolated cortical tissue suggests that intracortical circuits can support the generation of HFOs.[11] Neocortical HFOs are often associated with the electroencephalogram (EEG) depth-negative component of the

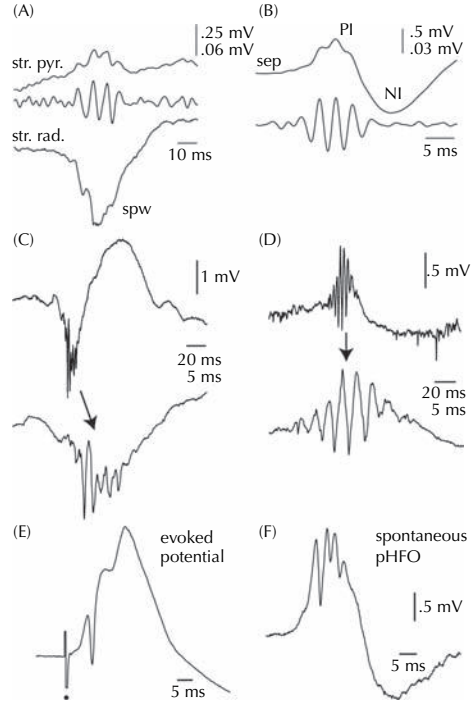

Figure 16–1. Examples of normal HFO and pHFOs. **A.** Spontaneous ripple recorded in CA1 of normal rat. The ripple is present in the wide bandwidth (0.1 Hz–1 kHz; top) and the corresponding bandpass filter (80–200 Hz; middle) traces recorded just above the pyramidal cell layer (str. pyr.). A sharp wave (spw) is shown in the wide-bandwidth trace recorded below the pyramidal cell layer within the stratum radiatum (str. rad.; bottom). **B.** Averaged somatosensory evoked potential (sep; 1 Hz–2 kHz; top trace) recorded in rat barrel cortex during contralateral whisker stimulation. The bandpass filter trace (200–600 Hz; bottom) more clearly shows the fast ripple-frequency HFO superimposed on the earliest component of the biphasic positive-negative (P1-N1) slow wave. **C.** Wide-bandwidth (1 Hz–3 kHz; top trace) EEG interictal spike associated with a pHFO recorded in entorhinal cortex ipsilateral to seizure onset in a patient with MTLE. The pHFO occurs on the descending limb of the depth-negative component of the interictal spike. The bottom trace more clearly shows the pHFO on a shorter time scale. **D.** Spontaneous pHFO in the absence of an EEG interictal spike. The pHFO was recorded in subiculum ipsilateral to seizure onset in a patient with bilateral MTLE. **E.** Averaged evoked potential recorded in human epileptic hippocampus during electrical stimulation of the ipsilateral entorhinal cortex. The evoked response consists of a short-latency population spike superimposed on a large-amplitude population postsynaptic potential. A stimulation artifact (denoted by the black circle) precedes the onset of the evoked potential by ~5 ms. **F.** Wide-bandwidth (1 Hz–3 kHz) spontaneous pHFO recorded from the same patient and microelectrode as in panel E. Superimposed on the EEG interictal spike is a pHFO that strongly resembles a burst of population spikes.

neocortical slow wave oscillation (0.5–1 Hz). Coherence among neocortical HFOs is strong over distances up to 10 mm within individual gyri, while the coherence weakens between HFOs in different gyri.[11]

In rat and human neocortex, somatosensory evoked potentials (SEPs) are associated with HFOs that contain spectral frequencies between 200 and 600 Hz (Fig. 16–1B). In rats, rapid mechanical stimulation of the vibrissae or electrical stimulation of the thalamic ventrobasal nuclei can evoke HFOs in somatosensory barrel cortex.[12–14] In humans, peripheral nerve stimulation elicits SEPs that contain HFOs with different components of the HFO arising from thalamic and cortical circuits.[15–20]

Sensory-evoked neocortical HFOs are typically superimposed on the earliest components of the biphasic positive-negative SEP (Fig. 16–1B) that can propagate in phase over several millimeters in rat barrel cortex.[13] Simultaneous stimulation of individual vibrissae evokes HFOs that propagate across barrel cortex and can constructively interact in a fashion that results in a supralinear summation of HFOs within sites of interaction.[21,22] These latter studies suggest that the locally facilitated HFO response could reflect a recruitment of additional neurons that discharge due to the in-phase interactions between propagating HFOs.

Neuronal Correlates of HFOs in Normal Mammalian Brain

Much of what is known regarding the neuronal activity associated with ripples derives from in vivo wide-bandwidth recordings in rat hippocampus. In CA1 of behaving rats, the SPW-ripple complex is associated with a significant increase in firing from pyramidal cells and several types of interneurons. Pyramidal cells discharge during the trough of the extracellular ripple oscillation but do not fire during each cycle of the ripple.[23] Interneurons such as basket cells that provide perisomatic inhibition to pyramidal cells can fire at ripple frequencies, and the timing of their discharges coincides closely with those from pyramidal cells.[24] Furthermore, recording from pyramidal cells reveals the presence of an intracellular oscillatory potential that corresponds with extracellular ripple oscillation and is likely mediated by chloride ions due to the activation of $GABA_A$ receptors from discharging basket cells.[9] These latter data suggest that hippocampal ripples reflect fast inhibitory postsynaptic potentials (IPSPs) that can powerfully regulate the firing and timing of pyramidal cell discharges.

Excitatory and inhibitory neurons are also involved in the generation of neocortical HFOs. Fast-spiking cells, presumably GABA-containing neurons, discharge bursts of action potentials at intraburst intervals that correspond with the frequency of the extracellular HFO.[11] Fast-spiking cell discharges can precede those from regular spiking cells, which occur during the trough of the extracellular HFO.[25] Similar to the coordinated pattern of firing between pyramidal cells and interneurons during hippocampal ripples, neocortical HFOs could reflect IPSPs from fast-spiking cells that regulate the timing and firing of regular spiking cells.

Mechanisms Generating Normal HFOs

The single-neuron studies discussed in the preceding section indicate that inhibitory networks could play an important role during hippocampal ripples and neocortical HFOs. Inhibitory interneurons can entrain pyramidal cells or other interneurons into a rhythmic pattern of firing,[26] and it is possible that phasic activation of hippocampal interneurons by external input could produce rhythmic IPSPs that regulate the timing of pyramidal cell discharges.[9] In contrast, some studies have shown that blocking $GABA_A$ receptor activation does not abolish spontaneous hippocampal ripples or evoked neocortical HFOs.[27,28] However, under conditions of reduced inhibition, ripples contain higher spectral frequencies and significantly longer durations, and can be associated with epileptiform discharges, all of which raises the question of whether ripples under these conditions in vitro are the same as those in vivo. Furthermore, blocking $GABA_A$-mediated inhibition in a hippocampal slice can generate ripple-frequency HFOs in the isolated dentate gyrus that reflect synchronously bursting granule cells.[29] While there is no direct evidence for ripples in the normal dentate gyrus, studies show that abnormal ripple-frequency HFOs do

occur in the epileptogenic dentate gyrus of epileptic rats.[30,31]

Electrotonic coupling mediated through gap junctions is another mechanism that could support the generation of HFOs. In vitro studies show that chemical agents that interfere with gap junction communication between hippocampal neurons suppress ripples, while manipulations intended to increase gap junction conductance are associated with an increase in ripples.[32] Furthermore, SPW-ripple complexes occur less frequently in hippocampal slices from mice deficient in a gene encoding a neuronal gap junction subunit than in tissue slices from littermate controls.[33] These in vitro data are consistent with the suppression of CA1 ripples in vivo in rats administered halothane anesthesia, which can reduce electronic coupling.[9] In addition, computer simulations predict the generation of ripples in hippocampal networks that contains axon-to-axon gap junctions between pyramidal cells.[34] These data suggest that electrical signaling through gap junctions may contribute to the synchronous neuronal discharges associated with ripples.

Nonsynaptic mechanisms such as ephaptic or field effects could also be involved with the generation of HFOs.[35,36] Ephaptic interactions arise when depolarizing currents associated with neuronal action potentials generate an electric field in the extracellular space that depolarizes adjacent neurons.[37] The probability that ephaptic interactions could trigger action potentials in nearby neurons increases if neurons are in close proximity to each other and neighboring neurons are already close to firing threshold. Field effects occur on a larger spatial scale and can arise when local populations of neurons generate large-amplitude field potentials, such as SPWs, that depolarize nearby inactive neurons.[38] Given the organized parallel arrangement of principal neurons in hippocampus and neocortex, the summation of extracellular currents across local principal cell networks could be sufficient to depolarize and coordinate the firing during hippocampal ripples and neocortical HFOs.

Physiological Role of HFOs

Spontaneous ripples have been implicated in information transfer between hippocampal and neocortical structures during sleep.[39] During SWS, the large-scale neuronal activation associated with SPWs and the increase in precisely timed discharges of pyramidal cells during ripples provide ideal conditions for synaptic transmission to extrahippocampal sites. In vitro evidence indicates that SPW-like stimulation is effective in inducing long-term potentiation in deep layers of entorhinal cortex,[40] which are cellular layers that receive hippocampal output and project to neocortical sites. In addition, there is evidence that ripples are temporally coupled with forebrain spindle oscillations that occur regularly during episodes of SWS.[41] Coordinated discharges along hippocampal and neocortical pathways could be related to processes associated with memory consolidation when short-term hippocampal memory traces are transferred to neocortical networks for long-term storage. A recent study in patients with medically refractory epilepsy found a significant correlation between ripples in hippocampus and rhinal cortex,[42] similar to the coherence of ripples between hippocampus and parahippocampal structures in rats.[5] In this patient study, rates of ripples in rhinal cortex measured after a brief daytime nap correlated with the number of successfully recalled items learned during a prior cognitive task. While these latter data are consistent with the possible role of normal ripples in memory consolidation, not all HFOs in the epileptic brain are normal.

ABNORMAL HFOS IN EPILEPSY

Spatiotemporal Properties of Pathological HFOs

In animal models of chronic limbic epilepsy, HFOs with spectral frequencies between 250 and 600 Hz, termed *fast ripples*, occur in dentate gyrus, subfields CA1 and CA3, subiculum, and entorhinal cortex (Figs. 16–1C, 16–1D). Fast ripples are found in rats that exhibit recurrent spontaneous seizures, but not in rats that have been subjected to an epileptogenic insult, such as status epilepticus, that do not exhibit spontaneous epileptic seizures.[43] These findings and the unique association between interictal fast ripples and sites of seizure onset indicate that fast ripples are pathological.[44]

In the intrahippocampal kainate model of mesial temporal lobe epilepsy (MTLE), in addition to fast ripples, interictal ripple-frequency HFOs can be found in the epileptogenic dentate gyrus, an area where normal ripples do not occur in normal rats (Fig. 16–2).[30] Similar to fast ripples, ripple-frequency HFOs appeared within days to weeks after kainate injection, but only in rats that later exhibit spontaneous seizures. In addition, shorter latencies to the first appearance of fast ripples or ripple-frequency HFOs in dentate gyrus correlated with shorter latencies to the first spontaneous seizure.[30] These data indicate that spectral frequency alone is not sufficient for distinguishing normal ripples from ripple-frequency pHFOs, but like fast ripples, ripple-frequency oscillations in epileptogenic dentate gyrus are also pathological. Importantly, these finding indicate that the occurrence and location of pHFOs can predict, although are not required for, the development of seizures after an epileptogenic insult and thereby provide a biomarker for epileptogenesis.

It has been proposed that pHFO-generating neuronal clusters represent a basic mechanism underlying limbic epilepsy.[44] Support for this hypothesis derives from studies that show that the size and location of pHFO-generating sites in dentate gyrus become stable over time,[45] but application of bicuculline, an antagonist to inhibitory $GABA_A$ receptors, causes these areas to increase in size.[46] In addition, the number of pHFO-generating clusters in dentate gyrus correlates with seizure frequency, and the spectral power of these oscillations increases during the transition to hippocampal hypersynchronous seizures.[45,47] These findings suggest that spontaneous seizures arise when reduction in tonic inhibitory influences results in the coalescence and synchronization of pHFO-generating sites.

Differences between Normal and Pathological HFOs

Studies in the rat hippocampus have identified several important differences between normal ripples and pHFOs.[48] Normal ripples arise from a relatively large area of tissue that involves the controlled firing of pyramidal cells and interneurons, and the extracellular ripple largely reflects summated IPSPs from precisely timed interneuron discharges. In contrast, pHFO-generating sites can be localized to small, discrete neuronal clusters often embedded in tissue that does not generate pHFOs,[46] although HFOs observed in scalp EEG recordings suggest that neocortical sites could be larger than those found in epileptogenic hippocampus.[49] Figure 16–2 shows an example of the local generation of spontaneous pHFOs in epileptic dentate gyrus. The pHFO recorded on electrode contact 2, positioned within the granule cell layer, does not appear on contact 1, located 200 μm from contact 1, and the voltage of the pHFO reverses in polarity in the depth beginning on contact 3. During pHFOs, there is no consistent firing pattern between interneurons and pHFOs, although principal cell discharges occur during the trough of the extracellular pHFO.[43,50] It is believed that pHFOs reflect bursts of population spikes arising from synchronized discharges of abnormally bursting principal cells and possibly interneurons (compared to Figs. 16–1E and 16–1F).[31]

It is not clear how abnormal synchrony is generated during pHFOs, but recording in CA3 of normal hippocampal slices bathed in high-potassium medium showed that blockade of ionotropic glutamatergic signaling reduces synchronous discharges between pyramidal cells and attenuates pHFO-like field events.[51] The same study demonstrated that increasing the fidelity of pyramidal cell discharges increases pHFO amplitude, whereas disrupting intrinsic action potential–generating mechanisms decreases pHFO amplitude. These data suggest that increased chemical transmission through recurrent excitatory synapses between pyramidal cells can generate pHFOs. However, another study recording in CA3 of hippocampal slices from epileptic rats offers an alternative explanation.[52] In this study, a reduction in neuronal spike timing was associated with a decrease in ripple power and an increase in fast ripple power, although the amplitude of fast ripples was much *lower,* not *higher*,[31] compared to that of ripples. Furthermore, increasing spike timing in epileptic CA3 restored ripples and decreased fast ripples, suggesting that in vitro, fast ripples emerge from an abnormal reduction in neuronal synchrony, not an *increase* in synchrony. It could be argued that ripples and

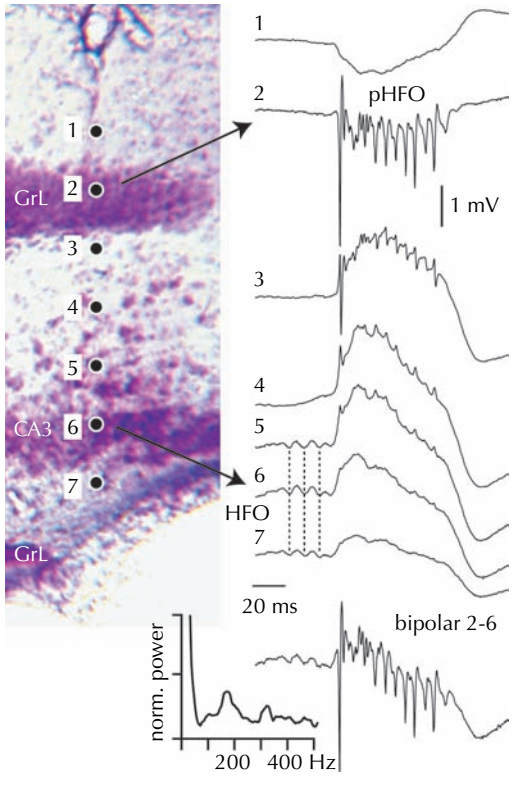

Figure 16–2. Multicontact electrode array recording spontaneous pHFOs in the dentate gyrus of an epileptic rat. A local fast ripple and a ripple-frequency HFO occur on electrode contacts numbered 2 and 6 in the granule cell layer (GrL) and area CA3, respectively. There is no evidence for a pHFO on contact 1, and the pHFO on contact 2 reverses in polarity in the depth starting on contact 3. Note that there is no reversal in potential associated with the ripple-frequency HFO recorded between contacts 5 and 7. A bipolar recording between contacts 2 and 6 (bottom trace) shows the occurrence of both HFOs, and the corresponding normalized power spectral histogram (left) shows the different spectral frequencies associated with each HFO. The bipolar recording does contain the spatial information to distinguish between the two local networks, each supporting the generation of pHFOs. Circles and numbers on the histological section (left) denote the approximate position of electrode contacts that was based on histological analysis and the voltage-depth profile of evoked potentials. Electrode contact spacing is 200 µm. Adapted from ref. 48.

fast ripples from the epileptogenic CA3 in this latter study were both pathological and that each HFO reflects bursts of population spikes with differing degrees of neuronal synchrony.[48] Clearly, there is a need for additional studies that will differentiate normal from pathological HFOs in vitro and in vivo.

HFOs in Patients with Epilepsy

The first human studies on interictal HFOs were carried out using microelectrodes positioned in the hippocampus and entorhinal cortex of patients with medically refractory MTLE.[2,43] Several of the properties of fast ripples recorded in patients resemble those of fast ripples in epileptic rats, including spectral frequency, duration, association with the seizure-onset zone,[43,53] and generation in cellular layers of entorhinal cortex that support evoked population spike discharge and abnormal synchrony of burst firing.[54] Microelectrode studies in patients also demonstrated that rates of fast ripples are highest during SWS and remain elevated during REM sleep.[55] With respect to pathological substrates and the hippocampal sclerosis often observed in patients with MTLE, higher rates of fast ripples in hippocampus correlate with severity of local atrophy,[56] and higher rates of fast ripples and lower rates of ripples correlate with lower neuron densities in Ammon's horn and dentate gyrus.[57] These data suggest that rates of fast ripple and ripple discharge reflect the severity of epileptogenicity and thus have clinical value in determining the treatment for patients with MTLE. In addition, morphological abnormalities associated with hippocampal sclerosis could promote the generation of fast ripples, although a recent study showed that fast ripples are present in a nonlesional animal model of temporal lobe epilepsy (TLE).[58]

It is not yet possible to distinguish normal from pathological ripple-frequency HFOs in human mesial temporal lobe limbic structures, but presumably normal hippocampal ripples share several important characteristics with normal ripples found in the nonprimate hippocampus. Human ripples have similar spectral frequencies; occur bilaterally, with the highest rate during SWS and the lowest during REM sleep[2,53,55]; and arise from broad areas of tissue supporting generation and synchrony of neuronal discharges.[54] Single-neuron studies in humans show that putative interneurons reach their highest rate of firing during the onset of the ripple, whereas pyramidal rates peak during the maximum amplitude of the ripple event[59] (Figs. 16–3A–C). During individual cycles of the ripple, human pyramidal cells fire during the trough of the ripple, while interneurons discharge between 0.0 and 1.0 ms

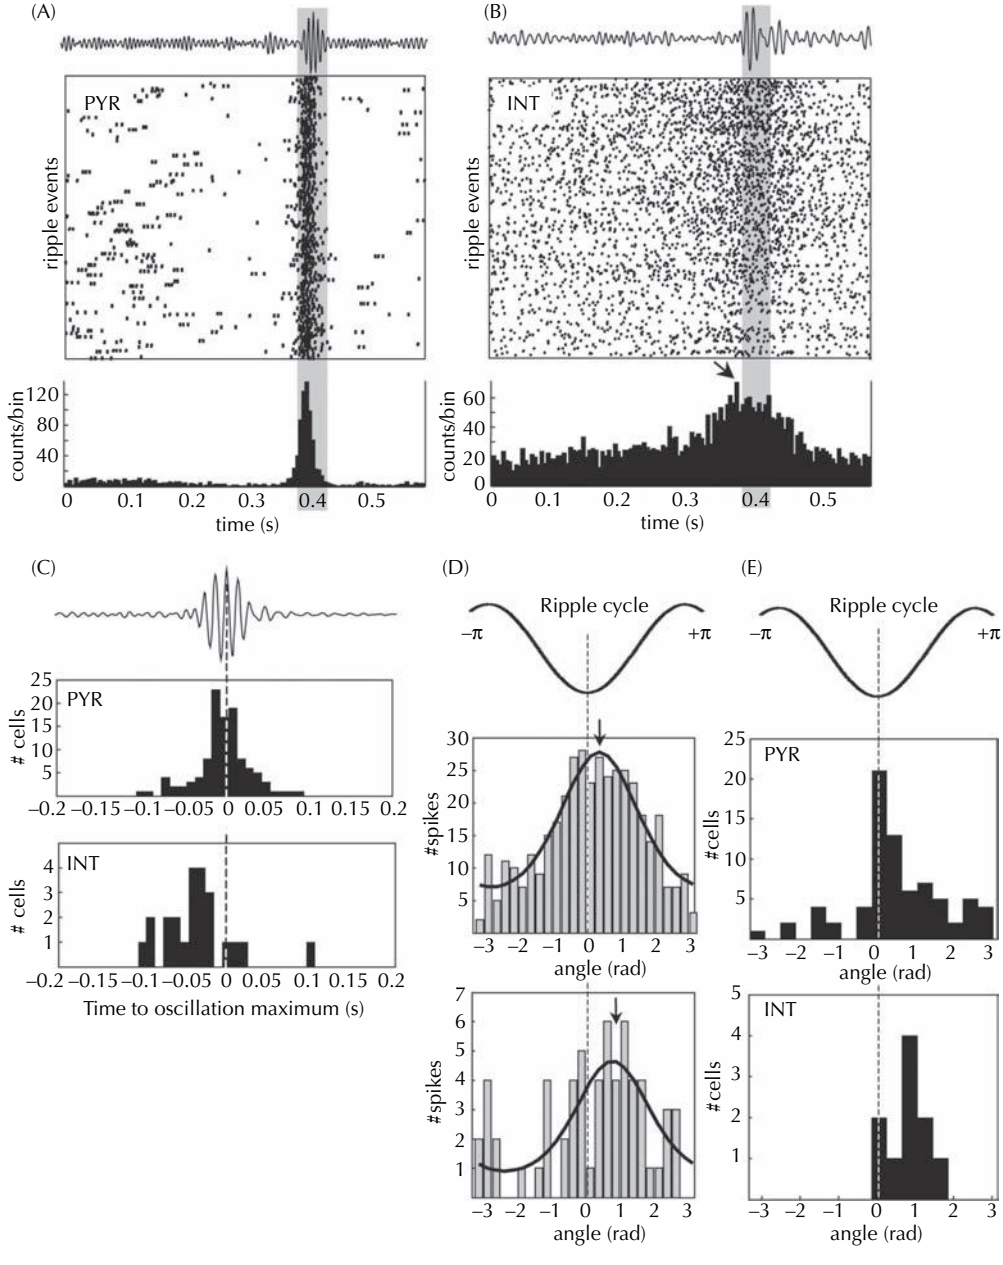

Figure 16–3. Single-neuron correlates of human hippocampal ripples. **A.** Raster plot of putative pyramidal cell (PYR) firing (horizontal axis) during individual ripple events (vertical axis). The trace at the top shows an example of a ripple oscillation. The cumulative histogram on the bottom shows that maximum PYR firing occurs during the ripple. **B.** Same as in panel A, but for a putative interneuron (INT). Maximum INT firing occurs before the peak amplitude of ripple oscillation (denoted by the arrow in the histogram at the bottom). **C.** Cumulative histograms show that maximum firing rates of most PYR cells occur near the peak amplitude of the ripple, indicated by the dashed line. In contrast, the highest firing rates of INT occurred ~50 ms before the ripple. **D.** Phase histogram of spike firing from a single PYR (top) and INT (bottom) in relation to the phase angle of the ripple shown atop the histograms. The trough of the ripple cycle is a zero phase angle (dashed line). A von Mises function fitted to each phase histogram (continuous solid line) shows that the mean firing phase for the PYR cell was 0.5 (± 0.9) radians and for the INT it was 0.8 (± 0.7) radians (denoted by arrows). The difference in firing phase between PYR and INT (~0.3) corresponds to an average 0.5 ms delay for a 100 Hz ripple oscillation. **E.** Cumulative histograms summarizing PYR and INT firing in relation to the phase of the ripple cycle. Most PYR cells and the INT discharged during the trough of the ripple (0 radians; denoted by the dashed line). Adapted from ref. 59.

of pyramidal cells, which is similar to the well-timed firing between pyramidal cells and some interneurons during rat hippocampal ripples (Figs. 16–3D and 16–3E).

Interest in pHFOs as markers of epileptogenic areas in presurgical patients has driven the development of many clinical electrophysiology systems used with standard clinical depth and subdural grid electrodes to support higher sampling rates and provide greater bandwidth. Studies using these systems confirm the strong association between pHFOs and epileptogenic regions, particularly fast ripples compared to ripple-frequency HFOs.[60–63] In addition, a patient study found pHFOs associated with epileptogenic lesions that included focal cortical dysplasia and nodular heterotopia, but rates of pHFOs were more strongly linked to areas of seizure onset than to anatomical lesion.[64] These latter data suggest that pHFOs are not limited to a specific type of epilepsy, but could be a fundamental property of epileptogenicity common to many types of epilepsy. Moreover, these results suggest that in some types of epilepsy, electrophysiological disturbances can be remote from anatomical abnormalities.

Interictal Spikes and HFOs

Recording of EEG interictal spikes can be useful for delineating the epileptogenic region, but the spatial extent of interictal spikes is usually more widespread than the seizure onset zone. Studies demonstrate a significant spatial and temporal association between interictal spikes and HFOs, although 40% to 50% of HFOs occur independently of interictal spikes.[61] Thus, abnormal HFOs may occur on the rising component, peak or the descending component of an interictal spike or may not be associated with a spike at all. [60,65–67] One study found that the occurrence of interictal spikes containing abnormal HFOs along with HFOs alone was more sensitive in predicting the seizure-onset area than the occurrence of interictal spikes alone, with no HFOs.[61] Furthermore, in a separate study that used surgical outcome to verify the boundaries of the epileptogenic region, patients with a good surgical outcome had a significantly larger proportion of abnormal HFO-generating sites removed than patients with a poor surgical outcome.[68] In contrast, there was no difference in the number of interictal spike (with no HFOs) or seizure onset sites removed between good and poor surgical outcome groups. The results from these latter studies need to be confirmed with studies using a greater number of patients. Nevertheless, the results suggest that pHFOs not only delineate the epileptogenic region better than interictal spikes with no pHFOs, but also better than EEG identification of the site of seizure onset.

Seizure Generation and pHFOs

In animals and human patients with epilepsy, the power of HFOs can increase several seconds to tens of minutes before seizure onset.[30,69–76] Focal cortical seizures that secondarily generalize are characterized by a relatively small area of pHFO generation at seizure onset that can move along the cortex and increase in size as the seizure progresses.[77] It is hypothesized that an increase in size and synchrony among pHFO-generating sites can trigger seizures,[30,44] but not all seizures are associated with an increase in HFO power and some seizures can be accompanied by a reduction in HFO power during onset.[78] It is possible that a preictal increase in HFO power that reflects bursts of population spikes could indicate enhanced synchronization of principal cell networks that reach a threshold supporting the spread of ictal discharges. In contrast, a preictal increase in HFOs that reflect IPSPs could be an indication of interneuronal network activation to suppress propagation of epileptiform discharges, whereas a reduction in these latter-type HFOs might fail to prevent the spread of ictal discharges. A more thorough understanding of the neuronal mechanisms during the ictal transition will help clarify the role of pHFOs during seizure genesis.

CONCLUSIONS

Basic research studies on HFOs indicate that these local oscillatory field potentials correspond with an increase in the rate and synchrony of neuronal discharges. There is compelling evidence supporting the view that normal hippocampal ripples and neocortical HFOs in the normal brain reflect IPSPs of interneurons that regulate the firing and timing of postsynaptic

principal cells. In contrast, substantial evidence suggests that pHFOs in the epileptic brain reflect bursts of population spikes that arise from local clusters of abnormal synchronously firing principal cells. Studies in animals and human patients with epilepsy demonstrate a strong association between interictal pHFOs and sites of seizure onset, and during some hippocampal and neocortical seizures, an increase in pHFOs preceding seizure onset. Furthermore, in animals, the early appearance of pHFOs after an epileptogenic insult correctly predicts the occurrence of spontaneous epileptic seizures. These results suggest that pHFOs can accurately identify the epileptogenic region, that is, brain areas necessary and sufficient for generating spontaneous seizures, and a unique biological marker of epileptogenicity and epileptogenesis. Future studies are needed to improve the criteria for differentiating normal HFOs from pHFOs in clinical recordings and develop noninvasive means for recording spontaneous HFOs. By successfully addressing these issues, it is anticipated that pHFOs could be used in clinical studies to optimize surgical treatment of medically refractory epilepsy, as well as in studies that seek to develop new therapies for treatment and possible prevention of epilepsy.

Chapter 17

Interictal Epileptiform Discharges in Partial Epilepsy

Complex Neurobiological Mechanisms Based on Experimental and Clinical Evidence

Marco de Curtis
John G.R. Jefferys
Massimo Avoli

Seizures (also termed *ictal discharges*) represent the critical events and the primary clinical burden of an active epileptic condition. Between seizures, however, the brain of patients with epilepsy generates pathological patterns of activity, called *interictal epileptiform discharges* (IEDs), that are clearly distinguished from the activity observed during the seizure itself. The correlation between IEDs and ictal discharges in intractable partial epilepsies has been the subject of several studies (for review see refs. 1–4), yet no conclusion regarding the reciprocal relationship and interdependence of IEDs and ictal discharges has been reached to date. Indeed, the existing data findings have led to two opposite views that assign to IEDs either a preventive or a precipitating role in seizure occurrence.

Interest in the mechanisms underlying IEDs has been revived during the last decade by presurgical diagnostic studies that utilized prolonged video-electroencephalography (EEG) along with intracranial EEG monitoring over periods of several days. Analysis of IEDs recorded from the scalp and with intracranial electrodes in patients with partial epilepsy have focused on the relation between IED topographic distribution and seizure patterns, and on their occurrence during the preictal state.[5–10] The methods used to localize the electric source(s) within the brain volume that generate IEDs recorded using scalp EEG electrodes have been extensively reviewed and will not be considered in this chapter.[8,11–13] Intracranial recordings either with cortical surface grids/strips or with intracerebral electrodes have

been more useful to identify different IED patterns, since electrodes are positioned in closer proximity to the physiological IED generators. These studies, along with experimental evidence obtained from animal models of partial epilepsy, have demonstrated the existence of diverse IED electrical patterns. Focal IEDs show large pattern variability (including spikes, sharp waves, bursts of fast spikes, sequences of fast oscillation, etc.) even in the same patient/model (Fig. 17–1). Given this diversity, it is reasonable to assume that different types of IEDs may be mediated by distinct neurobiological mechanisms and play divergent functional roles with respect to ictogenesis. In this chapter, we will review the clinical and experimental evidence that demonstrates the multiplicity of IED patterns based on data obtained from humans and from experimental models of partial epilepsy and seizures. The neurobiological mechanisms responsible for the generation of different IEDs will also be considered.

DIFFERENT IED PATTERNS IN EPILEPTIC PATIENTS: SPIKES, SPIKE BURSTS, SHARP WAVES

As mentioned above, interictal patterns are diverse and variable in partial epilepsies. Fast events defined as interictal spikes are characterized by a large-amplitude, rapid component lasting 50–100 ms that is usually followed by a slow wave 200–500 ms in duration[14,15] (Fig. 17–1A). Highly reproducible interictal spikes are typical of cryptogenic and benign forms of epilepsy, such as epileptic disorders with Rolandic or occipital paroxysms.[16,17] In these clinical conditions, interictal spikes show a selective and specific regional distribution. In contrast, partial epilepsies secondary to brain lesions show more irregular interictal spikes, often associated with IED patterns that include sharp waves (characterized by a rapid component that lasts for 100–300 ms), bursts of spikes, fast oscillations, and repetitive, paroxysmal slow waves (Fig. 17–1B–E; but see ref. 18).

Interictal epileptiform discharges in partial pharmacoresistant epilepsies have been well characterized. In humans, simultaneous unit recordings and laminar field potential profiles obtained with intracortical multielectrodes during acute (surgical) corticography[19] or chronic presurgical monitoring[20,21] have revealed that interictal spikes are initiated by large potential deflections, consistent with paroxysmal depolarization shifts similar to those recorded experimentally.[22–25] Moreover, the cortical layers where these depolarizations occur differ according to whether the spike is locally generated or propagates from a distant area.[19,21] Finally, characterization of unit firing during

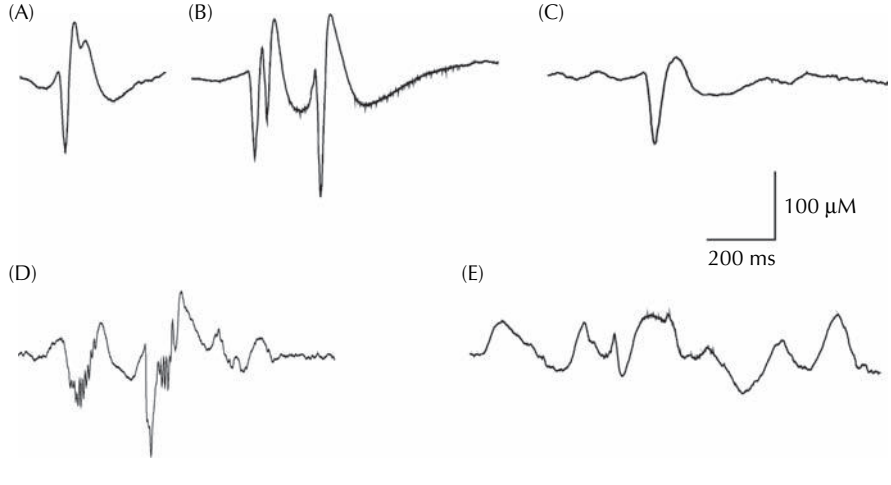

Figure 17–1. Interictal epileptic discharge patterns recorded in human partial epilepsies with intracranial electrodes. **A.** Interictal spike. **B.** Group of interictal spikes from neocortical dysplasia. **C. S**harp wave from a lesional partial epilepsy. **D.** Fast activity (brushes) riding on a spike recorded from a Taylor type II FCD. **E.** Paroxysmal slow activity superimposed on slow spikes recorded in a lesional partial epilepsy.

interictal spikes has demonstrated heterogeneity inside and outside the seizure onset zone, suggesting that IEDs are not a simple paroxysm of hypersynchronous excitatory activity, but rather represent the interplay of multiple distinct neuronal types within extended neuronal networks.[26]

Certain forms of human lesional partial epilepsies and cortical dysplasias show distinctive patterns that have specific diagnostic value.[27–29] One such condition is the Taylor-type II focal cortical dysplasia (FCD) that features IEDs characterized by high-frequency spikes and polyspikes, defined as *brushes*[30–32], that last for 100–200 ms, recur with a periodicity of 1–2 s and is enhanced during slow-wave sleep. Electrical stimulation has demonstrated that brushes in Taylor-type II focal dysplasias are followed by a desynchronization/depression of activity that lasts for 0.5–1 s and are associated with a higher threshold for the generation of further IEDs.[33] Interictal epileptiform discharges in temporal lobe epilepsy (TLE) with hippocampal sclerosis are less frequent than in focal dysplasias and consist of either spikes or sharp waves that are often undetectable on the scalp EEG.[34,35] In patients with severe hippocampal atrophy, large-amplitude spikes shorter than 100 ms with small-amplitude postspike slow activity have been reported. These IEDs increased in frequency and became rhythmic before and after ictal events.[36]

INTERICTAL SPIKES IN ACUTE AND CHRONIC ANIMAL MODELS IN VIVO

The temporal correlation between IEDs and ictal discharges has been analyzed in vivo in animal models mimicking both acute seizures and chronic epilepsy. Pioneering intracellular recordings obtained from neurons located in the *epileptic focus* induced by application of convulsants (e.g., penicillin) have demonstrated that interictal spikes correlate with paroxysmal depolarizing shifts of membrane potential leading to sustained action potential firing and at times followed by a robust hyperpolarization.[22,23,37] These studies have also shown that the transition to seizure is characterized by IED acceleration along with a decrease or disappearance of the postburst hyperpolarizing potential, a phenomenon that was proposed to result from the progressive accumulation of extracellular potassium.[38,39]

This transition pattern, however, has not been reproduced in chronic models of TLE. Thus, in both kindling and drug-induced status epilepticus (SE) models, the IED frequency either did not change or it decreased before the onset of an ictal event[40–43] (for review see ref. 2). Interictal spiking has also been analyzed in animals injected with kainic acid in one hippocampus; this represents a widely used chronic model that faithfully reproduces TLE. As in TLE patients, unilateral IEDs were reproducibly observed in this model in rats,[44,45] mice,[46] and guinea pigs (Carriero, Arcieri, and de Curtis, unpublished observations). More recently, video-EEG monitoring of the epileptic activity recorded during the latent and chronic periods in rats undergoing pilocarpine-induced SE has revealed that following the appearance of seizures, IEDs diminish in duration in the CA3 region and occur at higher rates in the amygdala.[47] Therefore, these findings suggest that IEDs undergo structure-specific changes following the appearance of spontaneous seizure activity. Little information about IEDs is available for other chronic models of partial epilepsy, such as posttraumatic models or models of cortical dysplasia studied in vivo.

IEDs IN ACUTE ANIMAL MODELS IN VITRO

Interictal epileptiform discharges can be studied in brain slices that are maintained in vitro following experimental procedures that favor epileptiform synchronization. Several reports have shown that IEDs are initiated by gradual enhancement and progressive recruitment of synaptic excitation that reaches the threshold for regenerative calcium currents.[48–50] This process further sustains recurrent excitation and promotes the synchronous firing of a large number of neurons that contribute to the buildup of a population event recognizable as a population spike/sharp wave. Excitatory postsynaptic potentials associated with these IEDs[25,51,52] are mediated by glutamate receptors of the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and *N*-methyl-D-aspartate

(NMDA) subtypes.[53–57] Similar mechanisms of IED generation have also been identified in slices of the neocortex,[58–60] piriform cortex,[50,61] and entorhinal cortex (EC)[62] following a variety of pharmacological manipulations. Regenerative potentials sustained by high-voltage calcium spikes[61,63–66] and by a persistent fraction of the voltage-gated sodium current[67–69] also contribute to paroxysmal depolarizing shifts. Finally, interictal synchronization is further facilitated by nonsynaptic interactions mediated either by extracellular electric fields (ephaptic interactions) or by intercellular gap junctions[70,71] that exist between principal neurons or interneurons.[72–74]

Interictal epileptiform discharges and the associated glutamatergic paroxysmal shifts are typically observed during prolonged application of (1) drugs that interfere with GABAergic inhibition such as bicuculline, penicillin, and picrotoxin (Fig.17– 2A, B), (2) agonists of glutamatergic transmission such as kainic acid, or (3) solutions with an ionic composition that enhances neuronal excitability. However, epileptiform discharges can also be induced by drugs that boost both glutamatergic and GABAergic synaptic transmission, such as the potassium blocker 4-aminopiridine (4AP). Early studies have shown that 4AP induces two types of IEDs within the hippocampal formation. The first type is characterized by fast IEDs that are driven by the CA3 network and are abolished by AMPA receptor antagonists. The second type consists of slow IEDs that were spared by glutamatergic receptor blockers, but were abolished by GABAergic antagonists.[75] It was subsequently shown that these slow IEDs can be recorded from any limbic cortical area as well as from the neocortex in brain slices obtained from rats or mice (as well as in the human neocortex; see below). This evidence has recently been confirmed in several areas of the in vitro isolated guinea pig brain[76] (Fig. 17–2C).

Intracellular recordings in brain slices have demonstrated that the slow IEDs induced by 4AP are coupled to a complex intracellular potential consisting of hyperpolarizing and depolarizing components. Recently, similar GABAergic IEDs—which correlated in EC neurons with inhibitory postsynaptic potentials—have been reported in the isolated guinea pig brain maintained in vitro during glutamatergic receptor blockade[76,77]; under these pharmacological conditions, the slow IEDs continued to propagate within the hippocampal-entorhinal region and from one EC to the EC of the contralateral hemisphere (Fig. 17–2). These slow IEDs are abolished by $GABA_A$ receptor antagonists as well as by a mu-receptor agonist both in the brain slice and in the isolated guinea pig in vitro preparation, thus confirming that they reflect the synchronous activity of local GABAergic networks. It is unclear how the slow IEDs propagate during glutamatergic receptor blockade, but data obtained in brain slices suggest the involvement of nonsynaptic mechanisms such as transient increases in extracellular potassium and subsequent redistribution of this ion (see below). However, the involvement of long-range GABAergic pathways or syncytia-like connections among interneurons cannot be ruled out.[78,79]

Experiments performed in the in vitro isolated guinea pig brain, in which inhibition was reduced about 50% by short-lasting bicuculline systemic perfusions, have demonstrated the existence of IEDs sustained by bursting of inhibitory interneurons that precede by about 1 min the generation of a seizure-like discharge.[80] These IEDs were associated with inhibitory postsynaptic potentials in EC principal neurons of both superficial and deep layers. In addition, glutamatergic IEDs and GABAergic IEDs could be simultaneously induced by this short-lasting bicuculline application in the piriform cortex and in the EC, respectively. Hence, this evidence suggests that an epileptic brain can generate interictal activity sustained by both glutamatergic and GABAergic networks, and is in line with the occurrence of GABA-dependent IEDs, as reported in human cortical slices obtained from postsurgical specimens.[81–83] Interictal epileptiform discharges that correlate with synchronous inhibitory postsynaptic potentials in large groups of neurons are often associated with seizure onset.[80,84] It is therefore tempting to speculate that GABA-mediated interictal events may contribute to the enhancement of synchronization of local epileptic networks through a mechanisms of post-inhibition resetting of neuronal firing.[85,86]

Interictal epileptiform discharges have recently been analyzed by coupling electrophysiological recordings with imaging of activity-depended intracellular changes in calcium

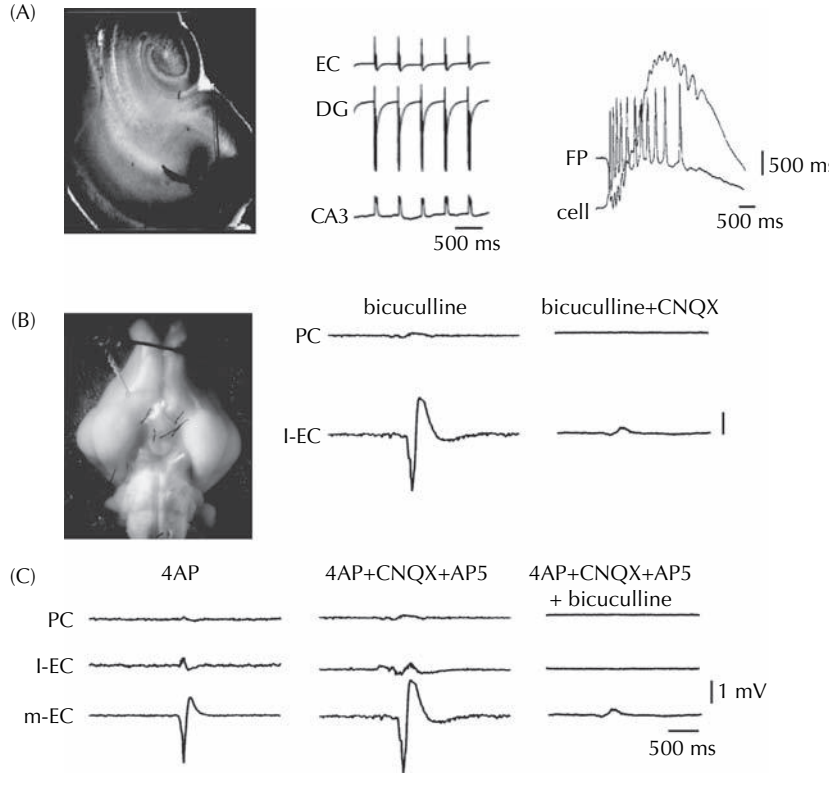

Figure 17–2. Interictal epileptic discharges analyzed in in vitro models of epileptiform synchronization. **A**. Glutamatergic interictal spikes induced in hippocampal slices (left panel) by application of 20 μM bicuculline. Field potentials recorded in the entorhinal cortex (EC), in the dentate gyrus (DG), and in the CA3 region are illustrated by the middle panel, while simultaneous intra- and extracellular recordings during an interictal spike in the DG are shown in the right panel. **B.** Glutamatergic interictal spikes induced in the in vitro isolated guinea pig brain (left panel) by arterial perfusion of bicuculline (50 μM). These IEDs are reduced by application of the glutamatergic receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). **C**. GABA-mediated interictal spikes. generated in the limbic cortices of the in vitro isolated guinea pig brain by arterial perfusion of 4AP (50 μM; left panel). Recordings were performed in the piriform cortex (PC), in the lateral and medial entorhinal cortices (l-EC and m-EC), and in the CA1 region of the hippocampus. These IEDs persisted after blockade of glutamatergic synaptic transmission with 10 μM CNQX and 100 μM AP5 (middle panel). Additional perfusion with the GABAa receptor antagonist bicuculline (50 μM) abolished the interictal spike (right panel).

concentration (for review see ref. 87). Increases in calcium signals have been identified during IEDs and ictal discharges in neurons, presumably as a correlate of neuronal firing.[88–90] In one of these studies, both IEDs and seizures appeared to be associated with calcium increases in astrocytes and these increases were independent of neuronal activation, thus suggesting that ictogenesis could be sustained exclusively by astrocyte activation and by the associated release of glutamate.[90] However, even though the contribution of glutamatergic glio-transmission to ictogenesis has been confirmed by other authors, the unique role of astrocyte in seizure initiation has not been replicated.[91] One recent report analyzed this issue in different experimental models of seizures and IEDs; these experiments showed that astrocyte calcium signaling contributes to sustained ictal activity, but is not involved in the generation of IEDs.[92]

HIGH-FREQUENCY OSCILLATIONS AS INTERICTAL EVENTS

High-frequency oscillations (HFOs) at >100 Hz have been recorded from cortical structures in humans and animal models, both under physiological conditions and in partial epilepsies (for review see ref. 93). Cortical HFOs at

100–200 Hz occur under physiological conditions, during the interictal state in patients presenting with partial epilepsy, and in animal models.[93–96] Intracranial EEG recordings obtained from pharmacoresistant patients suffering from mesial TLE have shown that HFOs are observed in coincidence with an interictal spike and in isolation. Further studies have confirmed these observations in TLE patients[97,98] and also in the epileptogenic region of patients with neocortical partial epilepsy.[99–101] Physiological HFOs (also termed *ripples*) are implicated in the process of memory consolidation[102] and represent population inhibitory postsynaptic potentials generated by principal neurons entrained by synchronously active interneuron networks.[103,104] Juxtacellular recordings obtained with microelectrodes in the human hippocampus during physiological ripples demonstrated that pyramidal cells fired preferentially at the highest amplitude of the ripple, while interneurons discharged earlier than pyramidal cells.[105] Pathological fast ripples that express very-high-rate oscillations (250–600 Hz) were recorded exclusively from epileptic tissue of epileptic patients and in animal models of TLE.[96,106,107] Fast ripples can be observed in the interictal state, while components in the beta-gamma frequency range are usually associated with ictal discharges.[108] Moreover, pathological fast ripples recorded in vivo, unlike ripples, are supported by synchronous burst firing of abnormally active principal neurons and are assumed to be independent on inhibitory neurotransmission.[93]

More recently, a different pattern of very-low-amplitude HFOs with high intrinsic rhythmicity (>250 Hz) has been identified in the seizure onset region in mesial TLE patients during the preictal period.[98,109,110] This activity—which is concealed in the intracranial recordings and can only be extracted by amplifying the appropriately filtered signal—occurs in coincidence with IEDs and sharp waves but also in the absence of any detectable IED.[98,111] In summary, HFOs may be interpreted as typical IEDs in partial epilepsies, and their association with other types of IEDs is not the rule.

The cellular and network mechanisms responsible for interictal HFOs have been analyzed in detail in in vitro brain slices exposed to pro-epileptic drugs. Physiological fast oscillations, either pharmacologically induced[85,112–114] or occurring spontaneously during up-down states,[115,116] were proposed to be supported by synchronization of inhibitory GABAergic networks via gap junctions with or without the contribution of glutamatergic networks. Faster oscillations, such as ripples, were also found to be supported by both excitatory and inhibitory transmission and gap junctions.[117,118] It is not clear whether the HFOs seen during interictal discharges in epileptic tissue are the same as physiological fast activities. Dzhala and Staley[106] and Behrens et al.[119] proposed that epileptic HFOs are initiated and synchronized by excitatory interactions between pyramidal cells in the hippocampus. More recent reports have proposed that HFOs generated at the onset of an ictal hippocampal discharge[120,121] correlate with transient GABAergic input,[122] indicating that GABAergic mechanisms are the source of epileptic HFOs at least in this case.

THE SLOW COMPONENT AFTER THE INTERICTAL DISCHARGES

Interictal epileptiform discharges recorded from the epileptogenic zone are assumed to be generated by synchronous neuronal firing. In line with experimental evidence,[23,24,123] presurgical intracranial studies in patients with partial epilepsy have demonstrated that the sharp component of a neocortical IED is followed by a depression of neuronal excitability. This phenomenon has been reported in mesial TLE patients analyzed with unit activity recordings[124–126] as well as by using the paired pulse stimulation paradigm. Thus, these studies provide evidence for the existence of inhibitory phenomena during the postspike slow wave.[127] Moreover, in Taylor type II focal dysplasia, a refractory period of 0.5–1 s has been identified after the interictal spike.[33] In this study, an enhanced threshold for spike generation was seen in brain regions that surround the epileptogenic zone during single-shock stimulations at 1 Hz that were performed to identify eloquent and symptomatogenic areas. Interestingly, no refractory period was observed after IEDs that were generated within the seizure-onset zone.

Early experimental studies[123] and more recent reports[128] have shown that glutamatergic IEDs are followed by a period of depression in excitability that may result from several mechanisms. Cortical surface IEDs

are usually larger then 1 mV, and they are associated with the simultaneous activation of large ensembles of neurons and possibly astrocytes. This synchronous activation generates massive neuronal firing that boosts recurrent synaptic activation and nonsynaptic field and direct interactions. Since GABAergic inhibitory interneurons are presumably preserved in the area of IED generation,[129–131] the activation of recurrent inhibitory networks during IED may be responsible for dampening neuronal excitability. Recurrent inhibition mediated by $GABA_A$ receptors lasts for 100 ms and could be reinforced and prolonged up to about 1 s by the activation of "slow" $GABA_B$ receptors. Since post-IED depression lasts longer than 1 s,[123] other mechanisms should be implicated in its generation. In line with this view, it has been shown in the piriform cortex that intra/extracellular pH changes associated with IEDs contribute to this depression by decoupling gap junctions.[132,133]

Intracranial studies in TLE patients have demonstrated that background activity and HFO are reduced in amplitude during the slow wave that follows an IED, suggesting post-IED depression.[100] Preliminary findings obtained at the Claudio Munari Epilepsy Surgery Center in Milan suggest that fast activity is reduced after an IED generated in the *irritative zone* surrounding the area of seizure onset,[134] whereas it is preserved and even enhanced after IEDs generated within the seizure-onset zone (Fig. 17–3). Thus, IEDs characterized by spikes or sharp waves generate a long-lasting period of inhibition/depression that dampens the fast,

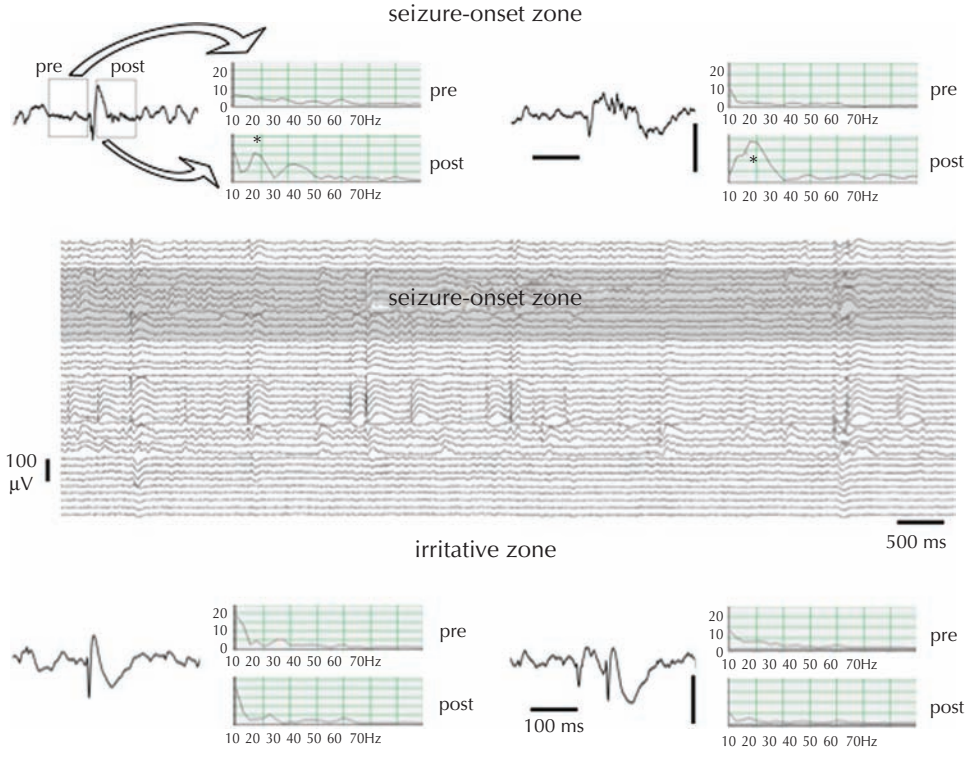

Figure 17–3. Intracranial recordings performed in a patient with cryptogenic partial epilepsy during presurgical evaluation of the epileptogenic region. The area of seizure onset is shaded in light gray in the central panel, which illustrates 10 s of continuous recording. Interictal spikes were observed in the seizure-onset zone (enlarged in the upper part of the figure) and in the surrounding irritative zone (lower part of the figure). Power spectra analysis was performed 500 ms before and after the spike component in the frequency range between 10 and 80 Hz. The frequency plots demonstrate the presence of fast activity at 20–40 Hz after the spikes recorded within the seizure-onset region (upper panels), whereas no fast activity was observed after spikes recorded in the irritative zone. Stereo-EEG recordings were kindly provided by Dr. S. Francione of the Caudio Munari Epilepsy Surgery Center.

transient increase in excitability that occurs during the spike/sharp wave. Postspike depression is typical of the tissue that borders the seizure-onset zone; hence, these findings may support the idea that some IEDs control brain hyperexcitability within the epileptic network and protect the region against seizure entrainment.

IN VITRO RECORDINGS OF IEDS FROM POSTSURGICAL BRAIN TISSUE

The fundamental mechanisms of IEDs have also been analyzed in postsurgical cortical slices of human brain tissue incubated in vitro for electrophysiological analysis. Human cortical slices in vitro do not generate spontaneous ictal discharges in standard saline bath solutions unless excitability is enhanced with various experimental procedures.[135] Yet, spontaneous IEDs can be recorded in postsurgical slices (that included the subiculum and the CA2 region) obtained from hippocampi of patients suffering from mesial TLE with Ammon horn sclerosis[82,136] as well as neocortical partial epilepsies.[81] As detailed in Chapter 14 in this book, interictal spikes in these studies were blocked by antagonists of either glutamate or $GABA_A$ synaptic transmission.[82,83] Hence, spontaneous IEDs in human cortical tissue in vitro are generated by both $GABA_A$ergic and glutamatergic synaptic conductances.

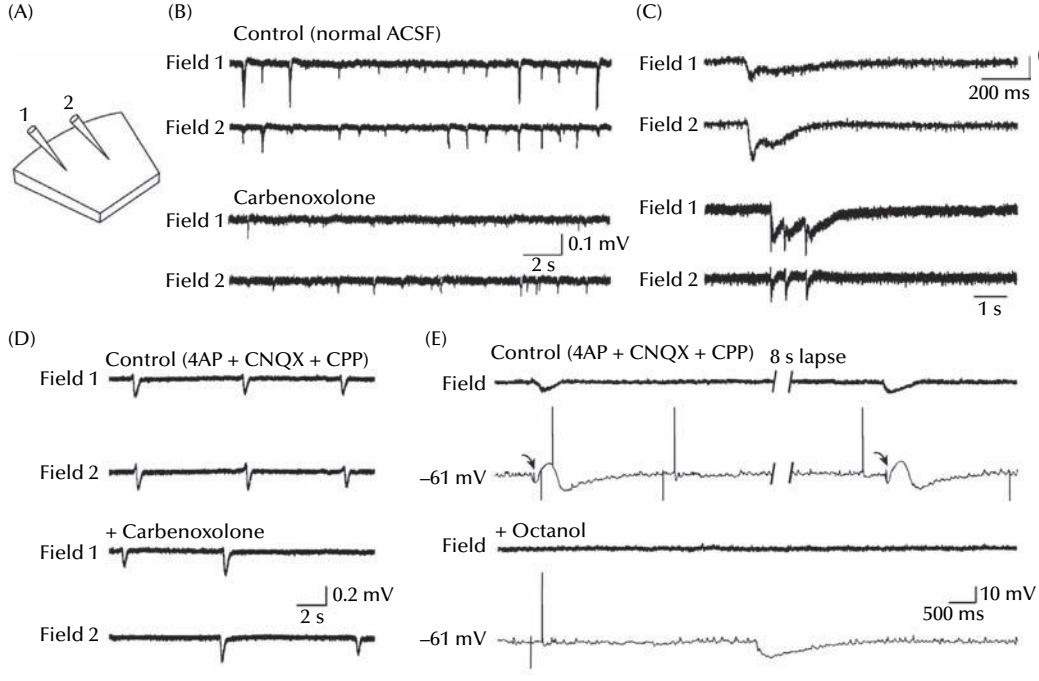

Figure 17–4. Effects of gap-junction decouplers on the synchronous activity generated by human neocortical slices in vitro. **A.** Schematic drawing of the location of the two recording extracellular microelectrodes used in the experiments shown in **B–D**; the interelectrode distance was approx. 2 mm. **B**. Carbenoxolone (0.3 mM) reduces the rate of occurrence and the amplitude of the spontaneous activity recorded in normal medium from an FCD slice. ACSF = artificial cerebro-spinal fluid; CPP = 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid. **C**. Expanded samples of this spontaneous activity; note that it consists of one (upper panel) to three (lower panel) fast transients riding on a slow negative shift. **D**. Carbenoxolone (0.3 mM) decreases the rate of occurrence and disrupts the synchronization of the spontaneous activity recorded during application of 4AP+glutamatergic receptor antagonists in a neocortical slice obtained from a TLE patient. **E**. Effects of octanol (1 mM) on the synchronous activity recorded with extracellular (Field) and sharp intracellular (K-acetate-filled; –61 mV) microelectrodes from a TLE neocortical slice treated with 4AP+glutamatergic receptor antagonists; note in the control sample that the field events were intracellularly mirrored by early hyperpolarization, followed by long-lasting depolarization (LLD) and terminated by prolonged hyperpolarization. Bath application of octanol abolishes the field events and the associated intracellular potentials, while long-lasting hyperpolarizing potentials continue to occur; note also the action potentials of small amplitude that occur during the early hyperpolarizing component (curved arrows) in the Control sample.

High-frequency oscillations characterized by very fast frequencies at 80–400 Hz have been reported to occur in postsurgical neocortical slices obtained from patients with drug-resistant TLE.[137] In this study, HFOs associated with interictal spikes did not require synaptic transmission, as they continued to occur in the presence of glutamatergic and GABAergic receptor antagonists; they were, however, abolished by application of drugs that are known to decouple gap junctions, such as carbanoxolone. The effects induced by gap junction decouplers have also been documented in human neocortical slices obtained from patients with FCD as well as from TLE patients.[138] This study showed that spontaneous IEDs recorded in the presence of normal medium from FCD tissue were reduced and, even more importantly, were no longer synchronized during carbenoxolone application (Fig. 17–4B); moreover, similar effects were seen when IEDs were elicited by 4AP in neocortical slices that had no obvious structural abnormality (Fig. 17–4D). These IEDs, when recorded in the presence of glutamatergic receptor antagonists, correspond intracellularly to a complex sequence of potentials that are dominated by a long-lasting depolarization (Fig. 17–4E) and are accompanied by transient increases in extracellular potassium.[139]

Electrophysiological analysis of slices of human FCD tissue has shown that during 4AP

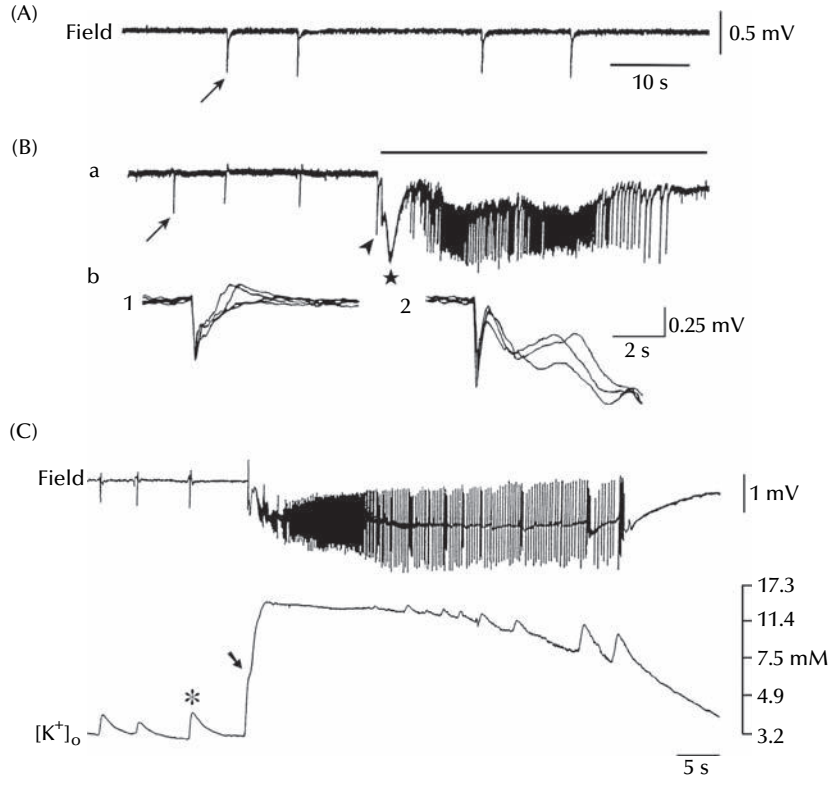

Figure 17–5. Synchronous activity induced by bath application of 4AP in neocortical slices obtained from TLE (i.e., presenting with no architectural anomaly) and FCD patients. **A.** Isolated field potentials (arrow) occur spontaneously in a TLE slice analyzed with field potential recording. **B.** Spontaneous field potential discharges recorded in an FCD slice; note that in this experiment, both isolated interictal field potentials (arrow) and an ictal discharge are shown in a. Note also that the onset of the ictal event is associated with the occurrence of a negative field potential (arrowhead) that is followed by a slow negative event (asterisk) leading to ictal discharge oscillations. In b, superimposed interictal discharges (1) and ictal discharge onsets (2) are illustrated. C. Field potential activity and concomitant changes in $[K^+]_o$ induced by 4AP in FCD tissue. Note that $[K^+]_o$ increases up to 4.5 mM during the isolated negative field events (asterisk), reaches values of approx. 6.4 mM during the negative-going field potential leading to the ictal discharge onset (arrow), and levels off to values of 12–14 mM during the ictal event.

application, IEDs that are mainly dependent on GABA receptor-mediated conductances may be instrumental in eliciting NMDA receptor-mediated ictal discharges.[140–142] As illustrated in Figure 17–5B, ictal discharges recorded from FCD slices were preceded by negative-going events resembling those seen in isolation during the interictal period; however, the field potentials leading to ictal discharge onset were always of larger amplitude and were followed by a secondary, slow negative field event from which ictal oscillations emerged. The ability of IEDs to initiate ictal synchronization in the human FCD tissue depends on the presence of a $GABA_A$ receptor–mediated mechanism that leads to sizable increases in extracellular potassium. As illustrated in Fig. 17–5C, the transient elevations in extracellular potassium associated with the IEDs that shortly preceded the ictal discharge onset were characterized by rises in extracellular potassium larger than those seen in association with similar field potentials occurring during the interictal period. A similar association of large elevations in extracellular potassium and ictal discharge onset has been observed in the deep layers of the EC[143] as well as in isolated hippocampal slices obtained from young rats.[144,145] Indeed, elevating extracellular potassium can disclose seizure activity both in vivo[146] and in vitro.[147,148] It should be emphasized that a similar 4AP treatment in human neocortical tissue without obvious structural abnormality induces only periodic, synchronous, interictal-like GABA receptor-mediated potentials[149] (Fig. 17–5A). Therefore, these in vitro data support the view that epileptogenicity is a functional feature of FCD tissue.

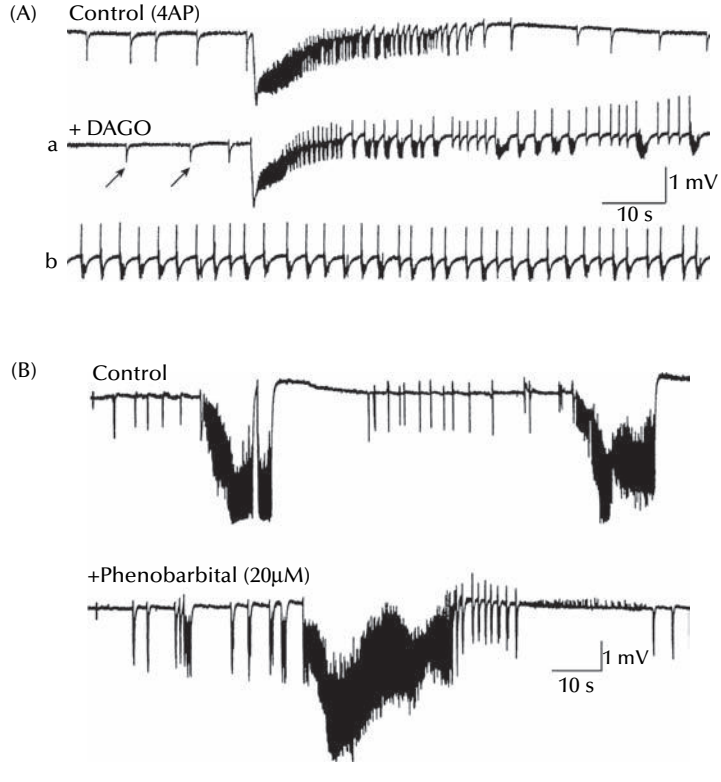

Figure 17–6. $GABA_A$ receptor function modulates ictal discharges in brain FCD slices.

A. Bath application of the μ-opioid receptor agonist [D-Ala^2, NMe-Phe^4, Gly-ol^5]-enkephalin (DAGO; 10 μM) reduces the amplitude of the isolated negative field events (arrows in a) and transforms ictal activity into regular, robust interictal discharges (b). a and b are a continuous recording that was started 2 min after the onset of DAGO application. **B.** Bath application of phenobarbital (20 μM) increases the duration of the interictal events and of the ictal discharges induced by 4AP in an FCD slice.

The role of GABA receptor–mediated synchronization in initiating ictal activity in FCD tissue is further supported by pharmacological manipulations aimed at decreasing or enhancing the function of $GABA_A$ receptors. $GABA_A$ receptor antagonists or activation of μ-opioid receptors (which blocks the release of GABA from interneuron terminals) made ictal discharges and GABA receptor-mediated interictal events disappear (Fig. 17–6A). Under both conditions, FCD slices generated recurrent epileptiform activity that lacked the features of an electrographic ictal event. Conversely, potentiating $GABA_A$ receptor function with minimal concentrations of phenobarbital[150,151] caused a prolongation of the ictal discharges along with potentiation of the slow interictal events (Fig. 17–6B).

CONCLUSIONS

Evidence reviewed in this chapter indicates that IEDs are heterogeneous in terms of both pattern and underlying mechanisms. It has been proposed that the core region in which focal seizures are generated is surrounded by an area that generates hypersynchronous activity (the irritative region) interposed between the seizure-onset area and the surrounding normal tissue.[134] Interictal epileptiform discharges are generated both in the epileptogenic zone and in the irritative region and can spread to (and thus be recorded from) adjacent healthy brain structures. Therefore, it is reasonable to conclude that interictal events are sustained by cellular and pharmacological mechanisms that vary according to the site of generation. Different IEDs sustained by GABAergic and glutamatergic networks could have opposite functions with respect to seizure generation, either precipitating it or preventing it, depending on the site where they originate within the epileptogenic tissue. According to this view, post-IED depression could be a selective feature of IEDs that occur in brain regions (such as the irritative region) in which neuronal homeostasis and synaptic networks are not drastically altered by the epileptogenic process. In seizure-onset regions, tissue damage could be more intense and post-IED depression may not be present or may be insufficient to dampen excitability, allowing IEDs to effectively trigger seizures.

Chapter 18

$GABA_A$ Receptor Function in Typical Absence Seizures

Vincenzo Crunelli
Nathalie Leresche
David W. Cope

A typical absence is a nonconvulsive epileptic seizure that is characterized by a sudden and relatively brief impairment of consciousness, occurring concomitantly with a generalized, bilaterally synchronous *spike* (or *polyspike*) and *slow wave discharge* (SWD) at 2.5–4 Hz in the electroencephalogram (EEG).[1,2] Typical absence seizures are part of the multifaceted clinical and EEG presentation of many idiopathic generalized epilepsies (IGEs), but in childhood absence epilepsy (CAE) these seizures are the only neurological symptom and are not accompanied by either metabolic, neuropathological, or other neurological deficits.[1,2] The human studies reviewed in this chapter, therefore, will be those that relate to CAE, since this is the only IGE in which a putative causal link can be made between a typical absence seizure and the underlying genetic variants or pathophysiological mechanisms without the confounding effects of other epileptic and nonepileptic neurological phenotypes.

Typical absence seizures are genetically determined, and the classical 2.5–4 Hz SWD trait has been shown to be inherited in an autosomal dominant manner.[1,2] Indeed, there is a strong consensus in describing the occurrence of (typical) absence seizures as a familial disease with a complex multifactorial genetic background. There is also a general consensus, based on some old invasive studies and modern noninvasive imaging investigations, that typical absence seizures originate from abnormal electrical activities in reciprocally connected

thalamic and cortical territories—that is, in what is generally referred to as *thalamocortical networks*—with little or no involvement of other brain areas, including hippocampus, cerebellum, and limbic regions.[3–7] Key cellular elements of thalamocortical networks include pyramidal cells and interneurons of different cortical layers, the thalamocortical (TC) neurons of sensory thalamic nuclei and their main inhibitory input, that is, the GABAergic neurons of the nucleus reticularis thalami (NRT). Importantly, the notion that a typical absence seizure is "generalized" from the very start of the SWD has been recently challenged by the observation that the onset of an absence seizure in humans is associated with paroxysmal activation of discrete, often frontal and parietal cortical regions, spreading then to other cortical regions and to the thalamus.[3,5] The presence of a putative cortical *initiation site* had previously been shown in genetic rat models of typical absence seizures in which, differently from human absences, it is localized in the perioral region of the primary somatosensory cortex.[8,9] Indeed, direct application of the antiabsence drug ethosuximide at this putative initiation site, but not 1 mm away from it, readily abolishes absence seizures in freely moving rats.[10]

It is now well established that $GABA_A$ receptor ($GABA_AR$)–mediated inhibition consists of a phasic component (i.e., the classical inhibitory postsynaptic potentials [IPSPs]), which is generated by GABA interacting with synaptic $GABA_ARs$, and a tonic component (i.e., a persistent membrane hyperpolarization with increased conductance) that is due to GABA activation of perisynaptic or extrasynaptic $GABA_ARs$.[11] Abnormalities in both synaptic and extrasynaptic $GABA_ARs$ have undoubtedly been of primary significance among the various human molecular genetic alterations[12–15] that have in recent years provided support for the idea that IGEs, and in particular absence seizures, are channelopathies.[16] In this chapter, we first summarize recent evidence demonstrating that enhanced tonic $GABA_A$ inhibition is a common feature of both pharmacological and genetic models of absence epilepsy. In particular, enhanced tonic $GABA_A$ inhibition in TC neurons is both necessary and sufficient for the expression of typical absence seizures, and in genetic models it is not due to a neuronal abnormality but to a malfunction of the astrocytic GABA transporter GAT-1. The available data on phasic $GABA_A$ inhibition, on the other hand, suggest that the changes in this type of GABAergic function observed in animals and humans affected by typical absence seizures are both brain region and neuronal type specific. We will then discuss how all these findings concerning phasic and tonic $GABA_A$ inhibition fit within our current understanding of the pathophysiological mechanisms of typical absence seizures, and propose that the currently prevailing view of an overall GABAergic loss of function in typical absence seizures and CAE is no longer tenable.

TONIC $GABA_A$ INHIBITION

Enhanced Tonic $GABA_A$ Inhibition in Genetic Models of Typical Absence Seizures

The tonic $GABA_A$ current measured in vitro in TC neurons of the somatosensory ventrobasal thalamus in different genetic models of absence seizures is enhanced compared to the current in their respective control animals.[17] This is true for a polygenic rat model, that is, the Genetic Absence Epilepsy Rat from Strasbourg (GAERS)[18] (Fig. 18–1A1–2) and for various mouse models with known spontaneous monogenic mutations, including stargazer and lethargic mice[19] (Fig. 18–1A3). In particular, there is a clear developmental profile of this increased GABAergic function since in GAERS up to postnatal day 16, the current is similar to that in the nonepileptic control (NEC) strain but almost doubles in amplitude at postnatal day 17 (Fig. 18–1A2) and remains elevated well past the time of seizure onset[17] (around postnatal day 30 in this strain[18]). In contrast, no tonic $GABA_A$ current is detected in the GABAergic NRT neurons of GAERS and their respective nonepileptic control strain (unpublished observation), as it is indeed the case in normal Wistar rats.[20]

GAT-1 Malfunction Underlies Increased Tonic $GABA_A$ Inhibition

The enhanced tonic $GABA_A$ current of TC neurons in genetic absence models is not due

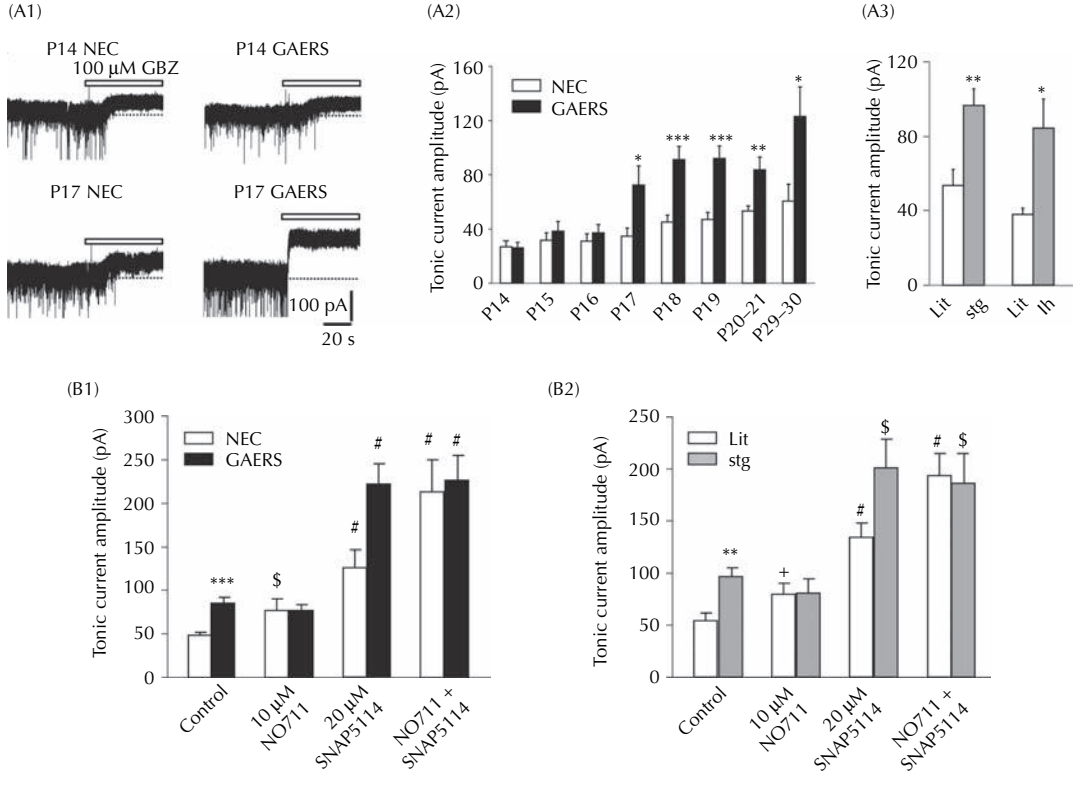

Figure 18–1. The enhanced tonic $GABA_A$ current in TC neurons of rat and mouse genetic models of typical absence seizures results from a malfunction in the GABA transporter GAT-1.

A1. Current traces from TC neurons of postnatal day (P) 14 and 17 nonepileptic control (NEC) and GAERS rats indicate the presence of a tonic $GABA_A$ current that is revealed as a shift in baseline current following the focal application of 100 µM gabazine (GBZ, white bars). The amplitude of the tonic current is about twofold larger in GAERS compared to NEC at P17. **A2**. Tonic current in NEC and GAERS at the indicated postnatal days. **A3**. Tonic $GABA_A$ current in stargazer (*stg*) (P19–21) and lethargic (*lh*) (P27–30) mice and respective control age-matched littermates (Lit). **B**. Comparison in P18–21 NEC and GAERS (**1**) and in P19–21 stargazer (*stg*) mice and littermates (Lit) (**2**) of the effects of blocking GAT-1 alone (by 10 µM NO711), GAT-3 alone (by 20 µM SNAP5114), and GAT-1 and GAT-3 together (NO + SNAP) on tonic $GABA_A$ current amplitude of TC neurons. **A2** and **A3**: $^*p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$, mutant versus nonmutant animals. **B1** and **B2**: $^*p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$, mutant versus nonmutant animals under control conditions; $+ p < 0.05$, $\$ p < 0.01$, and $\# p < 0.001$, drug versus nondrug for each strain. From ref. 17.

to increased vesicular GABA release, overexpression of extrasynaptic $GABA_A$Rs, or misexpression of synaptic $GABA_A$Rs, but results from a malfunction of the GABA transporter GAT-1,[17] despite its being far less abundant in the thalamus than GAT-3.[21] As shown in Fig. 18–1B1–2, in fact, (1) block of GAT-1 (by the selective blocker NO711) in GAERS and stargazer has no effect on the tonic current amplitude of TC neurons, (2) block of GAT-1 in the respective nonepileptic rats and mice increases tonic current amplitude to values similar to those seen in GAERS and stargazer mice, and (3) the compensatory increase in uptake by GAT-1 that is seen following block of GAT-3 (by the selective blocker SNAP5114) in nonepileptic animals is lost in both GAERS and stargazer mice.[17] A malfunction in GAT-1 also underlies the increased tonic $GABA_A$ current in TC neurons of lethargic mice.[17] These data support and enlarge previous observations that had shown reduced GABA uptake by GAT-1[22] and an increased level of extracellular GABA[23] in the ventrobasal thalamus of GAERS compared to NEC. In contrast to GAERS and stargazer mice, however, GABA transport by GAT-1 is reversed in lethargic mice, with this transporter being a source of ambient GABA.

Interestingly, NO711 increases tonic $GABA_A$ current by a similar amount in dentate gyrus granule cells of GAERS and NEC,[17] indicating that GAT-1 activity is not compromised in a brain area that does not participate in the generation of typical absence seizures[18] and where the distribution of this transporter is primarily neuronal.[24] Indeed, the tonic current of dentate gyrus granule cells is not different between GAERS and NEC.[17]

In summary, therefore, genetic models of typical absence seizures (i.e., in GAERS, stargazer, and lethargic mice) show a brain region–specific enhancement of tonic $GABA_A$ current, which in TC neurons is due to the increased extracellular GABA level resulting from a malfunction in GABA uptake by astrocytic GAT-1.

Enhanced Tonic $GABA_A$ Inhibition in the GHB Model: Role of $GABA_B$Rs

Systemic (or intrathalamic) injection of γ-hydroxybutyric acid (GHB) is undoubtedly the best-established pharmacological model of typical absence seizures,[25,26] and systemic administration of 4,5,6,7-tetrahydroisoxazolo[5,4-c] pyridin-3-ol) (THIP), a selective agonist at δ subunit-containing extrasynaptic $GABA_A$Rs,[27] has been shown to elicit SWDs in normal animals.[28] Therefore, whereas it is not surprising that THIP dose-dependently enhances the tonic $GABA_A$ current in TC neurons of normal Wistar rats,[17] one would not expect GHB, which does not bind to $GABA_A$Rs and is believed to elicit absence seizures by activation of $GABA_B$Rs,[26] to have an effect on the tonic $GABA_A$ current. However, GHB dose-dependently enhances the tonic $GABA_A$ current in TC neurons of normal Wistar rats[17] (Fig. 18–2A,B) at concentrations that are similar to the brain concentrations that elicit absence seizures in vivo.[29] This effect of GHB is not due to some aspecific action since it is abolished by the $GABA_B$R antagonist CGP55845 (Fig. 18–2B). Interestingly, application of CGP55845 alone significantly reduces the tonic $GABA_A$ current amplitude in TC neurons of Wistar rats to 74% of control values[17] (Fig. 18–2B), indicating that facilitation of extrasynaptic $GABA_A$Rs by $GABA_B$Rs contributes approximately one-quarter of the tonic $GABA_A$ current in normal rats. Importantly, CGP55845 also reduces the tonic current in GAERS, stargazer, and lethargic mice to about 55%, 65%, and 57%, respectively[17] (Fig. 18–2C), suggesting that facilitation of extrasynaptic $GABA_A$R function by $GABA_B$R activation contributes up to half of the tonic current in these genetic models.

In summary, therefore, a GAT-1 malfunction in thalamic astrocytes of mouse and rat genetic models leads to an increase in ambient GABA in the sensory thalamus, which in turn elicits an enhancement in tonic $GABA_A$ inhibition through both direct activation of extrasynaptic $GABA_A$Rs and indirect facilitation of extrasynaptic $GABA_A$Rs via activation of $GABA_B$Rs.

Enhanced Tonic $GABA_A$ Inhibition of TC Neurons Is Necessary and Sufficient for Typical Absence Seizure Generation

Assessing the impact of enhanced tonic $GABA_A$ current of TC neurons on the expression of absence seizures requires experiments in freely moving animals, in which both the behavioral and EEG components of the seizures can be studied without bias introduced by the concomitant use of anesthetics and/or analgesics. In fact, unrestrained and undrugged GAT-1 knockout (KO) mice, which have an enhanced tonic $GABA_A$ current in TC neurons, express ethosuximide-sensitive typical absence seizures[17] (Fig. 18–3A,F). Similarly, direct injection of the selective GAT-1 blocker NO711 into the ventrobasal thalamus by reverse microdialysis in normal Wistar rats triggers ethosuximide-sensitive typical absence seizures[17] (Fig. 18–3D,F). Moreover, in δ–$GABA_A$R KO mice, which exhibit markedly reduced $GABA_A$ inhibition in TC neurons, systemic administration of GHB fails to induce absence seizures[17] (Fig. 18–3F). Similarly, the intrathalamic injection of a δ subunit-specific antisense oligodeoxynucleotide in GAERS strongly decreases both the tonic $GABA_A$ current and spontaneous seizures 1–2 days after injection, whereas a missense oligodeoxynucleotide has no effect[17] (Fig. 18–3E). Finally, intrathalamic administration of the δ subunit-specific agonist THIP in normal Wistar rats elicits absence seizures in a concentration-dependent manner, an effect that is reversed by systemic administration of

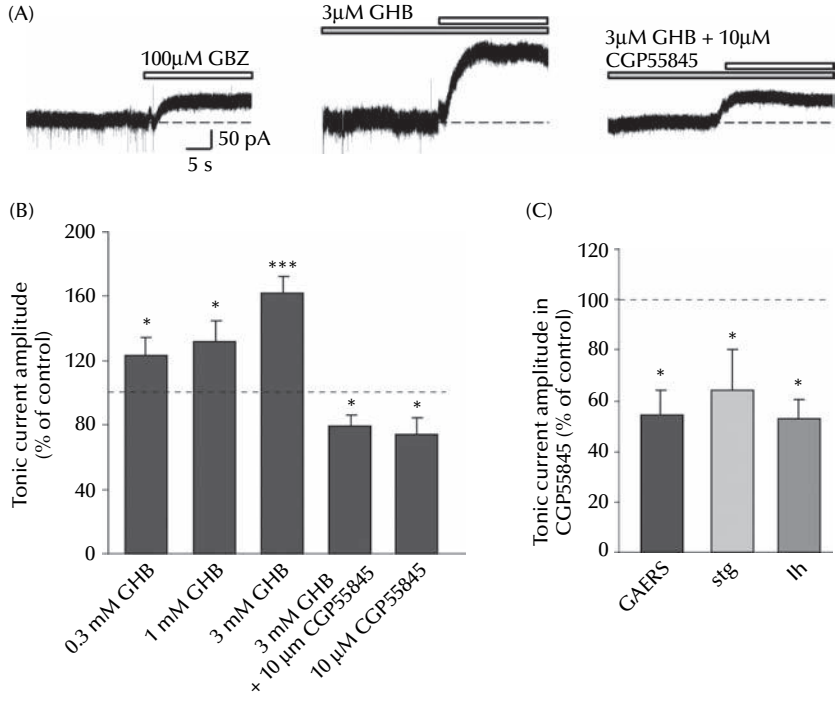

Figure 18–2. $GABA_B$Rs involvement in the tonic $GABA_A$ current of TC neurons in genetic and pharmacological models of typical absence seizures. **A**. Current traces from TC neurons of normal Wistar rats showing the GHB-elicited increase in tonic $GABA_A$ current and its block by the $GABA_B$ antagonist CGP55845 (10 μM). **B**. Comparison of the effects of different concentrations of GHB on tonic $GABA_A$ current amplitude in normal Wistar rats and its block by CGP55845 (10 μM). Note how CGP55845 alone decreases tonic current amplitude compared to control conditions. Values are normalized to the average tonic current in the absence of GHB or CGP55845. **C**. Effect of bath application of 10 μM CGP55845 on tonic $GABA_A$ current in GAERS, stargazer (*stg*) and lethargic (*lh*) mice. Values are normalized to the average tonic current amplitude in the absence of CGP55845. **B** and **C**: $^*p < 0.05$ and $^{***}p < 0.001$. From ref. 17.

ethosuximide[17] (Fig. 18–3C,F). Taken together, these data show that enhanced tonic $GABA_A$ inhibition in TC neurons is both necessary and sufficient for the generation of typical absence seizures. In addition, they provide a mechanistic explanation for the aggravation of absence seizures that is observed in humans and experimental models following systemic and intrathalamic administration of drugs that increase GABA levels, including tiagabine, a GABA uptake blocker, and vigabatrine, a GABA transaminase blocker.[18,30–32]

Significance of Tonic $GABA_A$ Inhibition in Typical Absence Epilepsy

The discovery of an increased tonic $GABA_A$ current in TC neurons represents the first abnormality that (1) is common to both well-established pharmacological and genetic models of typical absence seizures, irrespective of species and known upstream mutations, (2) is manifested both before and after the developmental onset of seizures, (3) contributes to the exquisite sensitivity of experimental absence seizures to selective $GABA_B$R agonists and antagonists, and (4) explains the aggravating effects of GABAergic drugs in both human and experimental absence seizures. Importantly, these results, together with the presence of powerful $GABA_A$ IPSPs in the majority of TC neurons during absence seizures in vivo[33,34] (Fig. 18–4A1–2; see below), lead to another significant conclusion, that is, that studies aiming at reproducing typical absence seizures by indiscriminately blocking $GABA_A$Rs of TC neurons[35–38] are inherently flawed.

The finding that the increased tonic $GABA_A$ inhibition in TC neurons of genetic models

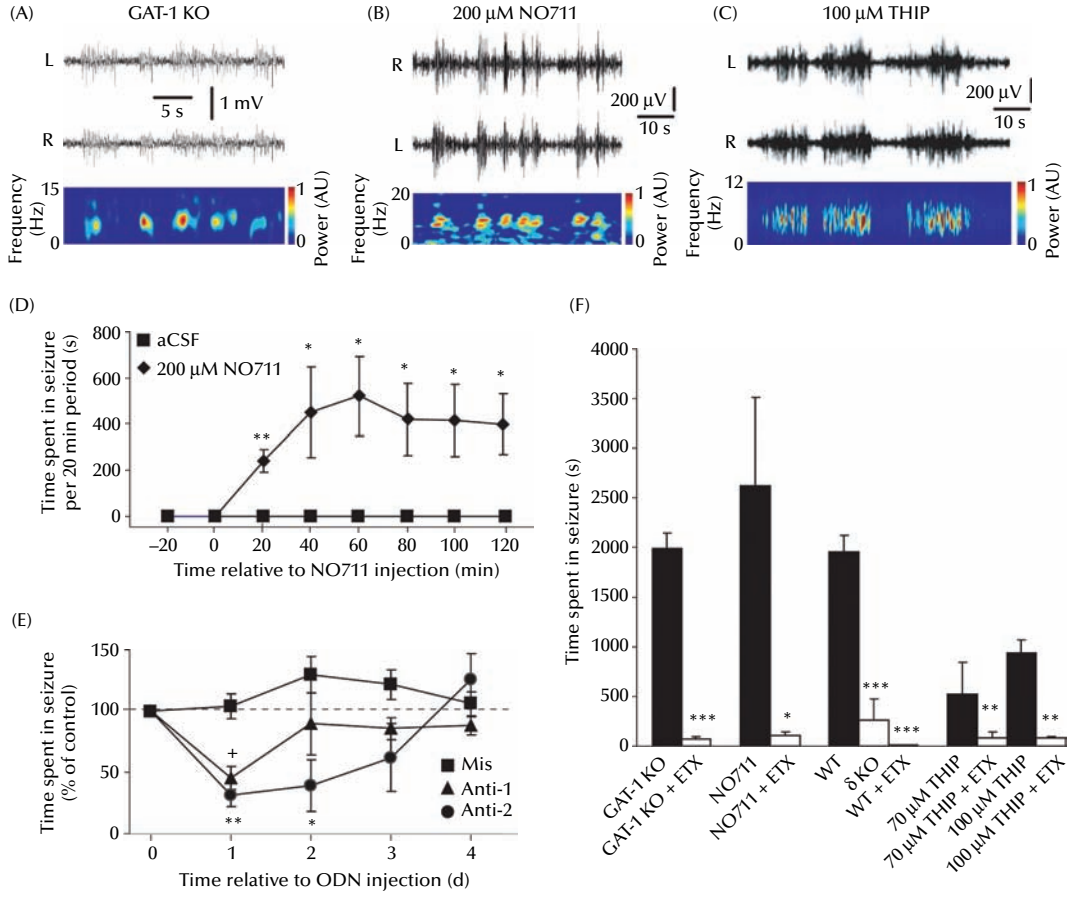

Figure 18–3. The tonic GABA$_A$ inhibition in TC neurons is both necessary and sufficient for typical absence seizure generation. **A**. Bilateral EEG traces from a normal Wistar rat following intrathalamic administration by reverse microdialysis of 200 µM of the selective GAT-1 blocker NO711 (spectrogram of the L trace is illustrated below). **C**. Bilateral EEG traces from a normal Wistar rat following intrathalamic administration by reverse microdialysis of 100 µM THIP (spectrogram of the R trace is illustrated below). **D**. Time course of the induction of SWDs by intrathalamic administration of NO711. **E**. Spike-and-wave discharges are substantially reduced in GAERS 1 and 2 days following a single intrathalamic injection of a small and large dose of a δ-subunit antisense oligodeoxynucleotide (Anti-1 and Anti-2, respectively) but not of a missense oligo (Mis). **F**. Summary histograms showing the cumulative (over 1–2 h) time spent in seizures for different transgenic and pharmacological mice and rat models and the abolition of their SWDs by systemic administration of ethosuximide (100 or 200 mg/kg/ip). $^*p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$. From ref. 17.

is due to a malfunction of GAT-1 shifts the emphasis from a neuronal to an astrocytic etiology of absence epilepsy. The impaired GAT-1 activity in GAERS is not caused by decreased expression of GAT-1 mRNA or protein levels in either thalamus or cortex.[17] Also, GAT-1 cDNA from GAERS, stargazer, and lethargic mice presents no genetic variants, whereas the mutations responsible for absence seizures in stargazer and lethargic mice are not present in GAERS.[17] Potential abnormalities that may lead to reduced GAT-1 function, but have not yet been tested, include the inability of this protein to reach the outer astrocytic membrane, an alteration in its subcellular location, and/or abnormalities in its phosphorylation. Similarly, we are aware of no study that has investigated GAT-1 (or GAT-3) genetic variants in human CAE.

Experimental typical absence seizures can be elicited or aggravated by selective GABA$_B$R agonists and can be blocked by selective

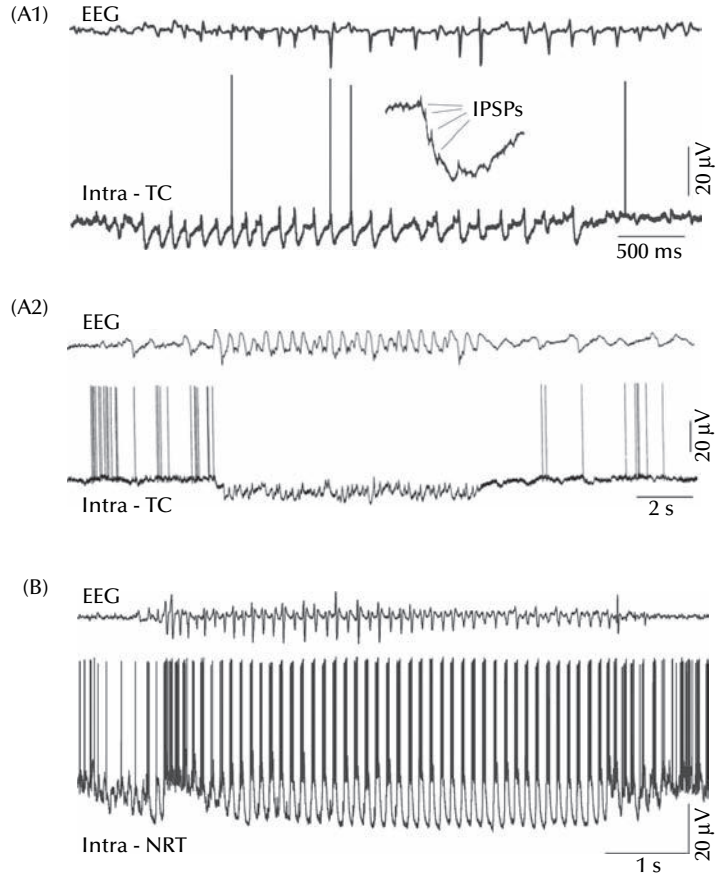

Figure 18–4. Intracellular correlates of TC and NRT neuron activity during spontaneous SWDs in vivo. **A1**. Intracellular recording (bottom trace) from a TC neurons in GAERS in vivo during a spontaneous SWD (top trace) shows the presence of bursts of IPSPs occurring in synchrony with each spike and wave complex. Note the individual IPSPs in the enlarged burst in the inset. **A2**. Intracellular recording (bottom trace) from cat TC neurons in vivo during an SWD (top trace) shows the presence of IPSPs superimposed on a long-lasting hyperpolarization that lasts for the entire duration of the SWD. **B**. Intracellular recording (bottom trace) from an NRT neurons in GAERS in vivo during a spontaneous SWD (top trace) shows the presence of a large low-threshold Ca^{2+} potential in synchrony with each spike-and-wave complex. $GABA_B$R antagonists, applied either systemically or intrathalamically.[39–41] Because about 50% of the tonic $GABA_A$ current observed in TC neurons of GAERS, stargazer, and lethargic mice is abolished by a $GABA_B$R antagonist[17] (Fig. 18–2C), the behavioral and EEG effects of $GABA_B$R-selective drugs on typical absence seizures can no longer be explained simply by the ability of these drugs to affect $GABA_B$-mediated IPSPs and/or presynaptic $GABA_B$Rs, but should also take into account the positive modulation by $GABA_B$Rs of the tonic $GABA_A$ inhibition in TC neurons.

PHASIC $GABA_A$ INHIBITION

The picture concerning phasic $GABA_A$ inhibition in typical absence seizures is much more complex than that of tonic $GABA_A$ inhibition, since contradictory results have emerged from studies in various experimental models. For the sake of clarity, therefore, the analysis of available evidence on phasic $GABA_A$ inhibition will be presented separately for each main neuronal type of the thalamocortical network, that is, cortical neurons, TC neurons, and the GABAergic neurons of the NRT.

Phasic $GABA_A$ Inhibition in Cortex

Among the various mutations in $GABA_A$R subunits, those that have been identified in related or unrelated CAE patients are α1(S326fs328X), β3(P11S), β3(S15F), β3(G32R), γ2(R43Q), γ2(R139G), and γ2(IVS6+2T→G).[12–15,42] Functional analysis of these mutant proteins expressed in heterologous systems has shown that all of them bring about a marked decrease in GABA responses.[12] Importantly, humans carrying the γ2(R43Q) mutation have been shown to have a decreased short-interval intracortical inhibition assessed with transcranial magnetic stimulation, leading to cortical facilitation.[43] γ2(R43Q) mutant mice constructed by homologous recombination express spontaneous ethosuximide-sensitive absence seizures.[44] Moreover, despite the fact that the γ2 subunit has an almost ubiquitous expression and is apparently required for functional synaptic $GABA_A$Rs, these mice exhibit a brain region–specific alteration in phasic $GABA_A$ inhibition, since cortical layer 2/3 pyramidal cells but not TC or NRT neurons show a reduction in miniature IPSCs (mIPSCs) compared to age-matched wild-type littermates.[44] Whether the region specificity of this malfunction is also present in humans with the γ2(R43Q) mutation, or only occurs in mice because of some species-specific promoters or silencers, is not known at present. Nevertheless, together with showing the physiological effect of a human genetic variant in a "true" physiological system as opposed to heterologous expression systems, the key significance of this finding is that it is the first clear evidence that the downstream abnormalities of a human genetic variant in CAE can be brain region specific. Importantly, the cortex-specific abnormality in phasic $GABA_A$ inhibition that results from the human γ2(R43Q) mutation exquisitely complements previous experimental data showing that (1) in felines in vivo the localized block of $GABA_A$Rs by cortical application of bicuculline, which leaves intact phasic $GABA_A$ inhibition in the thalamus, does elicit SWDs,[33] and (2) in rat and mouse genetic models, phasic $GABA_A$ inhibition in TC neurons is either unaffected or increased compared to their respective non-epileptic controls[17,44–47] (see below).

On the basis of indirect evidence, decreased cortical GABAergic inhibition has also been suggested to occur in layer 2/3 regular spiking neurons[48] as well as in layer 5 pyramidal neurons[49] of adult Wistar Albino Glaxo/Rij (WAG) rats, another well-established polygenic model of typical absence seizures.[50] However, no change is observed in mIPSCs in pyramidal cell and interneurons of cortical layers 2–3 of young preseizure GAERS,[45] and cortical GABAergic inhibition is intact in the feline generalized penicillin epilepsy model.[51]

In summary, the evidence from a human mutation indicates that decreased phasic $GABA_A$ inhibition in cortex characterizes typical absence seizures, though further studies are needed to clarify the extent of this decrease in terms of different cortical regions, layers, and neuronal types: this additional work might shed light on the existing discrepancies concerning changes in phasic $GABA_A$ inhibition among experimental models.

Phasic $GABA_A$ Inhibition in TC Neurons

Reduced or absent phasic $GABA_A$R function in the thalamus also characterizes the current view of the pathophysiology of typical absence seizures. While this may be partly true for intra-NRT inhibition, it certainly does not hold for TC neurons. Thus, both in felines that show spontaneous or cortical bicuculline-induced SWDs[33] and in the well-established GAERS model,[34] the vast majority (60% and 94%, respectively) of TC neurons recorded in vivo during SWDs exhibit bursts of $GABA_A$ IPSPs, each tightly synchronized with the EEG spike and wave complex (Fig. 18–4A1–2). Indeed, the rise time, amplitude, frequency, and decay time constant of mIPSCs and spontaneous IPSCs (sIPSCs) measured in TC neurons in vitro do not differ between GAERS and NEC both prior to[45] and after spontaneous seizure manifestation[17] (i.e., postnatal days 12–25 and postnatal day 30, respectively), and paired pulse depression of evoked IPSCs is similar between the two strains[45] (Fig. 18–5B3). As mentioned earlier, no change in TC neuron IPSCs occurs in mice carrying the human γ2(R43Q) mutation,[44] and no change in IPSC properties has been detected in TC neurons of β3 KO mice[52] that show absence seizures as part of a much more complex neurological phenotype. Also, in lethargic, stargazer, and tottering mice,

sIPSCs in TC neurons are similar to those in their respective littermates,[17] and no difference has been found in evoked IPSCs in lethargic and tottering mice compared to control mice.[47] Finally, an increase in mIPSCs frequency, potentially leading to enhanced phasic inhibition, is observed in TC neurons of the absence seizure-prone DAB/2J mouse strain.[46]

In a manner similar to that of the genetic models, in the best-established pharmacological model of absence seizure, that is, the GHB model, a net increase in phasic $GABA_A$ inhibition is observed in TC neurons of the ventrobasal thalamus.[53] This is because whereas GHB reversibly and dose-dependently decreases the amplitude of all sensory[54] and corticothalamic EPSCs[53] (Fig. 18–5A1), the two main excitatory drives to TC neurons, at low concentrations (250 μM–1 mM) it only affects the $GABA_A$ IPSCs in some but not all TC neurons[53] (Fig. 18–5A2–3). In particular, 250 μM GHB produces an effect in <10% of tested TC neurons, whereas at 0.5–1 mM it decreases only half of the recorded IPSCs (Fig. 18–5A4–5). Thus, at brain concentrations (250 μM–1 mM) similar to those that elicit absence seizures in vivo,[29] GHB brings about not only the previously described $GABA_B$R- and K^+-dependent hyperpolarization[26,55] and an increase in tonic $GABA_A$ inhibition[17] (see above), but also an imbalance between the excitatory and inhibitory drives to TC neurons, leading to a net increase in their phasic $GABA_A$ inhibition. This, in turn, helps to impose the periodic phasic inhibition that sculptures the electrical behavior of TC neurons during SWDs, as observed in vivo in feline[56] and rat[57] models (Fig. 18–4A1–2).

On the basis of all this evidence from both genetic and pharmacological models, as well as from mice expressing the human γ2(R43Q) mutation, it is therefore surprising that the data in support of the presence of an enhanced or unchanged phasic GABAergic function in TC neurons have been selectively dismissed over the last 15 years, such that textbooks and topical reviews[58–62] still present the pathophysiological mechanisms of TC neuron activity during typical absence seizures as the one that is observed in vitro during application of a $GABA_A$R antagonist.[35,36,38] It is also surprising that the in vivo evidence that is often used to support this view is the ability of bicuculline (or other $GABA_A$R antagonists) to generate, in ketamine-xylazine anesthetized rats, strong field potentials at 3 Hz,[37] which are claimed to represent SWDs even if their sensitivity to ethosuximide or other antiabsence drugs was not tested. Indeed, it is highly unlikely that these field potentials represent SWDs, since the ketamine-xylazine combination, like other general anaesthetic, is known to abolish the SWDs of any well-established in vivo model of absence epilepsy.[18,51,63]

In summary, therefore, the presence of these serious issues of interpretation, together with the evidence showing an increased tonic and an unchanged/increased phasic $GABA_A$ inhibition in TC neurons of genetic and pharmacological models, strongly support the conclusion that the block of thalamic $GABA_A$Rs that continues to be used in many in vitro and some in vivo studies does at best elict some form of thalamic hyperexcitability of as yet unknown pathophysiological relevance, but it is definitely not the activity that is present during typical absence seizures.

Phasic $GABA_A$ Inhibition in NRT Neurons

The existance of contradictory data makes it difficult at present to draw a unifying picture of the changes in the phasic $GABA_A$ inhibition of NRT neurons that are associated with an absence seizure phenotype. Starting from inbred genetic models, mIPSCs recorded from NRT neurons of preseizure GAERS show a 67% higher frequency, a 25% larger amplitude, and a 40% faster decay than those in age-matched NECs.[45] Moreover, paired-pulse depression of evoked $GABA_A$ IPSCs is significantly smaller (46%) in NRT neurons of GAERS than in NECs[45] (Fig. 18–5B1–2). This smaller paired-pulse depression of IPSCs in GAERS would undoubtedly ensure a consistent hyperpolarizing drive to help promote the expression of the strong low-threshold Ca^{2+} potential-mediated bursts of action potentials that are the hallmark of NRT neuron firing at each spike and wave complex in vivo[56,57] (Fig. 18–4B). Moreover, an increase in mIPSC frequency, potentially leading to enhanced phasic $GABA_A$ inhibition, is observed in NRT neurons of the absence seizure-prone DAB/2J mouse strain.[46] Finally, an almost complete disappearance of the

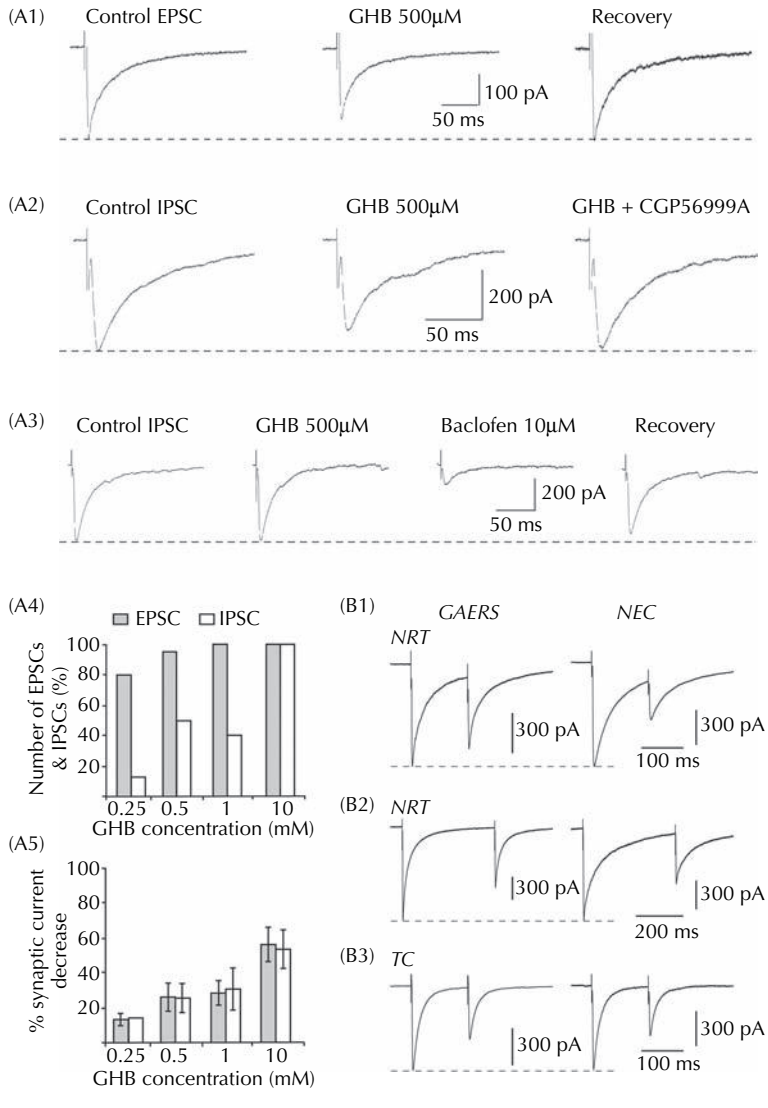

Figure 18–5. Phasic $GABA_A$ inhibition in TC and NRT neurons of genetic and pharmacological models of typical absence seizures. **A1**. γ-Hydroxybutyric acid reversibly decreases the amplitude of a cortical EPSC recorded in TC neurons. **A2**. Example of an NRT-derived IPSC (recorded in a TC neuron) that is decreased by GHB. The effect is blocked by the $GABA_B$ antagonist CGP56999A (100 nM). **A3**. Example of an NRT-derived IPSC (recorded in a TC neuron) that is unaffected by GHB (500 µM). Following washout of GHB, the IPSC is reversibly reduced by the selective $GABA_B$ agonist baclofen (10 µM). **A4**. All cortical EPSCs are decreased by GHB, while only a number of NRT-derived IPSCs are sensitive to low concentrations of this drug. **A5**. Plot showing the similar potency of GHB on cortical EPSCs and NRT-derived IPSCs. **B**. Paired-pulse depression of IPSCs in NRT neurons of GAERS is much smaller than in NEC than in GAERS for interstimulus interval similar (B**1**) but not longer (B**2**) than that of the SWDs. **B3**. Paired-pulse depression of IPSCs recorded in TC neurons is similar between GAERS and NEC. A from ref. 53. B from ref. 45.

α3 subunit, which in the thalamus is selectively expressed in NRT neurons,[64] has been reported in these GABAergic neurons from WAG rats,[65] suggesting a potential loss of function.

Surprisingly, however, α3 KO mice do not show spontaneous absence seizures and indeed exhibit a small reduction in GHB-elicited seizures compared to wild-type littermates, a result that has been interpreted as resulting from a powerful compensatory gain in phasic $GABA_A$ inhibition in NRT neurons.[66] On the other hand, since unknown mechanisms lead

to this unexpected compensatory increase in NRT $GABA_A$ inhibition following deletion of the α3 subunit, the lack of spontaneous absence seizures and the relative resistance to pharmacologically induced absence seizures may also be due to additional compensatory changes in phasic (or tonic?) $GABA_A$ inhibition in cortex, or tonic inhibition in thalamus, all of which were not investigated in that study.[66] Further evidence for a pro-absence role of a decreased phasic $GABA_AR$ function in NRT neurons has also come from the observation of an increase in high-frequency discharges at 3 Hz in β3 subunit KO mice, which show a massive reduction in sIPSP frequency and amplitude in NRT but no change in TC neurons.[52] Since these β3 KO mice exhibit a large variety of neurological deficits and are considered a model of Angelman's syndrome, it is difficult to unequivocally assign a causative role for this decreased intra-NRT inhibition in typical absence seizures.

In summary, whereas in inbred models and models with spontaneous mutations there is either an increase or no change in intra-NRT phasic $GABA_A$ inhibition, data from two transgenic mice suggest that a decrease in this NRT synaptic function has a pro-absence effect. Thus, it may be tempting to conclude that abnormalities in intra-NRT phasic $GABA_A$ inhibition are not a necessary condition for the expression of typical absence seizures, a view supported by the lack of changes in NRT IPSCs of mice carrying the human γ2(R43Q) mutation.[44] In this respect, it is worth noting that the antiabsence effect of clonazepam in humans and experimental models[67,68] may not be solely due to its ability to increase phasic $GABA_A$ inhibition in NRT,[69] since α3 subunit–containing $GABA_ARs$ that are the target of this benzodiazepine are also present in neocortical neurons.[70]

ROLE FOR PHASIC AND TONIC $GABA_A$ INHIBITION IN THE GENESIS OF ABSENCE SEIZURES

The evidence reviewed in this chaper suggests the following scenario concerning the cellular contribution of phasic and tonic $GABA_A$ inhibition to typical absence seizures. Decreased phasic $GABA_A$ inhibition in the neocortex leads or contributes to a paroxysmal development of normal 5–9 Hz oscillations in a discrete somatosensory cortical *initiation site.* This strong and highly synchronous cortical output powerfully excites the GABAergic neurons of the NRT, which respond by generating low-threshold Ca^{2+} potential-mediated bursts of action potentials at every spike-and-wave complex of the SWD. This rhythmic burst firing, in turn, results in bursts of IPSPs in TC neurons that override cortical excitation. Concomitantly, ambient GABA levels around TC neurons abnormally increase due to reduced GABA uptake by GAT-1, enhancing extrasynaptic $GABA_AR$ function directly, and indirectly by a $GABA_BR$-dependent facilitation. Enhanced tonic inhibition persistently hyperpolarizes the TC neurons and increases their membrane conductance, reducing their action potential output, with low-threshold Ca^{2+} potential-mediated bursts of action potentials rarely occurring. Furthermore, the responsiveness of TC neurons to excitatory sensory synaptic inputs is reduced, "gating" information flow through the thalamus, abolishing responsiveness to external stimuli, and causing behavioral arrest. Importantly, the rhythmic IPSP bursts entrain TC neuron output to each cycle of a SWD, providing sparse but synchronized input to the cortex and maintaining paroxysmal activity in thalamocortical networks.

CONCLUDING REMARKS

Despite the long-standing notion of an overall decrease in $GABA_AR$ function in typical absence seizures, a critical appraisal of the human and experimental evidence strongly supports the view of different, brain region-specific changes in both phasic and tonic $GABA_AR$-mediated inhibition in this nonconvulsive epileptic phenotype. In particular, decreased phasic $GABA_A$ inhibition characterizes cortical activity, though more studies are needed to disclose any neuronal type- and layer-specific abnormalities. Enhanced tonic inhibition, which results from a malfunction of the astrocytic GAT-1 transporters, together with unchanged or increased phasic inhibition, is present in TC neurons of both genetic and pharmacological models of typical absence seizures. Contradictory results in different species and transgenic animals and the reliance on unsuitable in vitro model systems

still do not provide a clear view of the changes in phasic $GABA_A$ inhibition that accompany the typical absence seizure in NRT neurons. Thus, thalamic and cortical model systems in which $GABA_A$Rs are indiscriminately blocked do not reproduce the complex pattern of alterations in these neurotransmitter receptors that is observed in human and experimental absence seizures, and are therefore of no value for understanding the cellular mechanisms operating in thalamocortical networks during typical absence seizures.

Chapter 19

$GABA_B$ Receptor and Absence Epilepsy

Hua A. Han
Miguel A. Cortez
O. Carter Snead III

BACKGROUND ON $GABA_B$ RECEPTORS

The type B receptor for gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain, is a 7-transmembrane-domain G-protein coupled receptor. $GABA_B$ receptors ($GABA_BRs$), upon binding with their endogenous ligand GABA, mediate slow and sustained inhibitory responses via downstream Ca^{2+}/K^+ channels. Ligand activation of $GABA_BRs$ also initiates G-protein-dependent cell signaling pathways leading to long-term alterations in cellular functions within the central and peripheral nervous systems. Perturbations of the $GABA_B$ system during development may shift the excitatory/inhibitory balance, culminating in various

neurological conditions, including typical and atypical absence seizures. The acute administration of baclofen (a $GABA_BR$ agonist) to wild-type rodents is sufficient to induce an absence seizure phenotype. Exacerbation of absence seizures occurs when baclofen is administered in pharmacological and genetic rodent models of typical absence seizures, while $GABA_BR$ antagonists suppress the seizures. A similar GABAergic pharmacological response is observed in the AY-9944 model of chronic atypical absence seizures, characteristic of Lennox- Gastaut syndrome. AY-9944, a cholesterol synthesis inhibitor, is also known to increase the expression levels of $GABA_BRs$ within the rodent forebrain regions and alters $GABA_BR$ trafficking during development. The severity of atypical absence seizures in the $GABA_BR$-overexpressing transgenic mouse model is $GABA_BRs$ subunit specific. A more pronounced atypical absence seizure phenotype results from the overexpression of the R1a $GABA_BR$ subunit as opposed to R1b. The absence seizure phenotype is circuitry dependent, with exclusive thalamocortical involvement in typical absence seizures as opposed to thalamocortical-hippocampal recruitment in atypical absence seizures. The pathophysiology of typical absence seizures with normal cognitive development and atypical absence seizures associated with severe impairment in cognition involves $GABA_BR$-mediated neurotransmission and is circuitry dependent. The implications of these fundamental findings for the circuitry dependency and $GABA_BR$ subtype specificity for seizure severity are discussed in terms of clinical perspectives in the chapter, including the potential for new therapeutic interventions and future research directions.

A Novel GABA Receptor

GABA is the main inhibitory neurotransmitter in the brain and can activate both ligand-gated ion channels ($GABA_AR$ and $GABA_CR$) and metabotropic G-protein-coupled receptors ($GABA_BRs$). Activation of $GABA_AR$ and $GABA_CR$ results in the influx of chloride ions and the generation of a fast inhibitory postsynaptic potential (IPSP). For many years, $GABA_AR$ was thought to be the sole GABA-activated receptor in the brain. However, in 1979, Bowery et al. demonstrated in rat myocardial tissue the presence of a baclofen-activated GABA receptor, which was insensitive to the GABA agonist 3-aminopropane sulfonic acid (3-APS) and to the GABA antagonists bicuculline, picrotoxin, and penicillin.[1] This phenomenon was replicated in rat cerebellar, striatal, and cortical slices in which the K^+-evoked release of radiolabeled neurotransmitters could be reduced by GABA or baclofen but not by bicuculline or 3-APS, supporting the conclusion that bicuculline-insensitive receptors were present in the central nervous system.[2] These bicuculline-insensitive receptors were designated as $GABA_BRs$ to differentiate them from the bicuculline-sensitive $GABA_ARs$.[3]

Cloning and Characterization of the $GABA_BR$

The $GABA_BR$ was successfully cloned in 1997.[4] The first positive clone with a molecular weight of M_r of 106K was labeled as R1a $GABA_BR$, and the second protein with a molecular weight of M_r of 92K was identified as R1b $GABA_BR$. The R1b protein differed from the R1a protein in that the first 147 N-terminal residues are replaced by 18 other residues. Hence, the R1b protein probably had arisen from an alternative transcription start site.

Subsequently, the R2 $GABA_BR$ protein was cloned.[5–9] Since the cloning of the R1 and R2 isoforms of the $GABA_BR$, oligodimerization of the R1 and R2 subunits has been considered to be essential for the cell surface expression of the receptor and G-protein activation.[7,8] However, recent studies utilizing functional proteomics have demonstrated that the $GABA_BR$ actually is a heteromultimer of high-molecular-mass complex of R1, R2, and potassium channel tetramerization domain-containing (KCTD) proteins, in which different KCTD isoforms serve as auxiliary subunits to modulate the pharmacology and kinetics of the receptor response.[10]

Distribution of $GABA_BR$ in the Central Nervous System

The $GABA_BR$ is ubiquitously expressed throughout the mammalian central nervous system (CNS). R1a and R1b $GABA_BR$ subunits

are abundantly expressed in the cerebral cortex, especially in layer VIb, the pyramidal cell layer of the CA3–CA1 regions of the hippocampus, the granular layer of the dentate gyrus, medial habenula, basal ganglia, ventral tegmental area, olfactory bulb, thalamus, amygdala, and hypothalamus, as well as in cerebellar Purkinje and granule cells.[4,11,12] By contrast, $GABA_BR$ R2 mRNA is highly expressed in Purkinje cells of the cerebellum, and in the cerebral cortex, thalamus, and hippocampal pyramidal cells, while showing a low level of expression in the caudate/putamen and hypothalamus.[5,13] The R1a subunit is predominantly expressed in presynaptic terminals of glutamatergic neurons, in which it probably contributes to the inhibition of glutamate release, while the R1b subunit is thought to influence postsynaptic inhibition.[14–18] $GABA_BRs$ can also act as autoreceptors, inhibiting GABA release within presynaptic terminals.[19–21] As extrasynaptic/perisynaptic receptors, $GABA_BRs$ are thought to regulate GABA spillover from the synaptic cleft.[12,22] Although the $GABA_BR$ is primarily located on neuronal cell populations, it can also be found on astrocytes, implicated in reinforcing inhibitory or disinhibitory circuits through the release of glutamate or the uptake of GABA spillover.[23,24] The $GABA_BR$ has also been reported to be expressed on cultured activated microglia but not in myelin-containing oligodendrocytes[25]; in view of these findings, a role for $GABA_BR$ in modulating the release of interleukin-6[26] has been postulated, but the exact function of the microglial $GABA_BRs$ remains unclear.

Developmental Profile of $GABA_BRs$ in the CNS

The $GABA_BR$ subunits R1a and R1b protein levels decrease between postnatal day (P) 7 and adulthood in the rat cerebral cortex, the cerebellum, and, most drastically, the spinal cord.[27] Between P21 and P28 and during adulthood, no differences in R1a and R1b expression levels have been found in the brainstem, striatum, and hippocampus. However, in the cerebral cortex, R1a levels are higher than R1b levels between P2 and P14. The downregulation of R1a levels coincides with the upregulation of R1b levels as the animal matures. Finally, in the adult brain, there is twice as much R1b as R1a. Additionally, binding affinities for L-baclofen do not differ between the R1a and R1b isoforms. However, the R1 subunit of the $GABA_BR$ in adult animals have a higher (10-fold) binding affinity for L-baclofen than P1 animals. Levels of R2 in the cortical regions increase from P2 to P28, then gradually decreases as the animal approaches adulthood.[7] Interestingly, in the cerebellum and spinal cord, R2 levels peak during early postnatal stages and then decline with maturation, presenting with a sharper reduction in the spinal cord.[28]

PHYSIOLOGY OF THE $GABA_BR$

Intracellular Signal Transduction

The $GABA_BR$ regulates intracellular signaling via an adenylyl cyclase–cyclic adenosine monophosphate (cAMP)–dependent pathway.[29] Stimulation of the $GABA_BR$ with (–) baclofen can inhibit both basal and forskolin-stimulated adenylyl cyclase,[30] which in turn can be blocked by the addition of pertussis toxin, indicating the involvement of the $G_{1\alpha}$- and $G_{0\alpha}$- subunits of the G protein.[31,32] Interestingly, when both $GABA_B$ and other metabotropic neurotransmitter systems (noradrenergic, histaminergic, etc.) are stimulated simultaneously, adenylyl cyclase activity is significantly increased.[32–34] It is conceivable that this synergistic phenomenon is due to the interactions and cross-talk between various subtypes/subunits of the G-protein and the adenylyl cyclase complex from the many signaling pathways within the cell.[35–37] Therefore, this synergistic activation of the adenylyl cyclase pathway might affect neuronal activity on a more permanent basis.

Coupling of $GABA_BR$ to Ion Channels

The P/Q and N subtypes of Ca^{2+} channels[38–42] are inhibited through the binding of $\beta\gamma$ subunits released by G-proteins coupled to activated $GABA_BRs$.[43] In this way, $GABA_BRs$ function presynaptically as auto- or heteroreceptors,

respectively inhibiting the release of GABA or glutamate. At postsynaptic sites, activation of GABA$_B$Rs leads to release of the βγ complex from the G-protein, which then interacts with inwardly rectifying K^+ channels,[7,44] leading to a net increase in conductance and, thus, to an efflux of K^+ ions (Fig. 19–1). There is evidence that this process underlies the mechanism involved in the generation of slow inhibitory postsynaptic currents (IPSCs) and long-lasting hyperpolarization at the postsynaptic level.[45] Specifically, the Kir3 subtype of the K^+ channels appears to be involved in long-lasting hyperpolarization.[44,46]

TYPICAL VERSUS ATYPICAL ABSENCE SEIZURES

Two very different types of absence seizures are observed both clinically in children[47] and experimentally in rodents (Table 19–1).[48] Typical absence seizures (TASs) are generally considered to be benign because the seizures are characterized by ictal spike-wave discharges (SWDs) associated with only brief momentary behavioral and motor arrest. The seizures are easily controlled with antiepileptic drugs and are not associated with cognitive impairment[49,50]; lastly, they disappear during

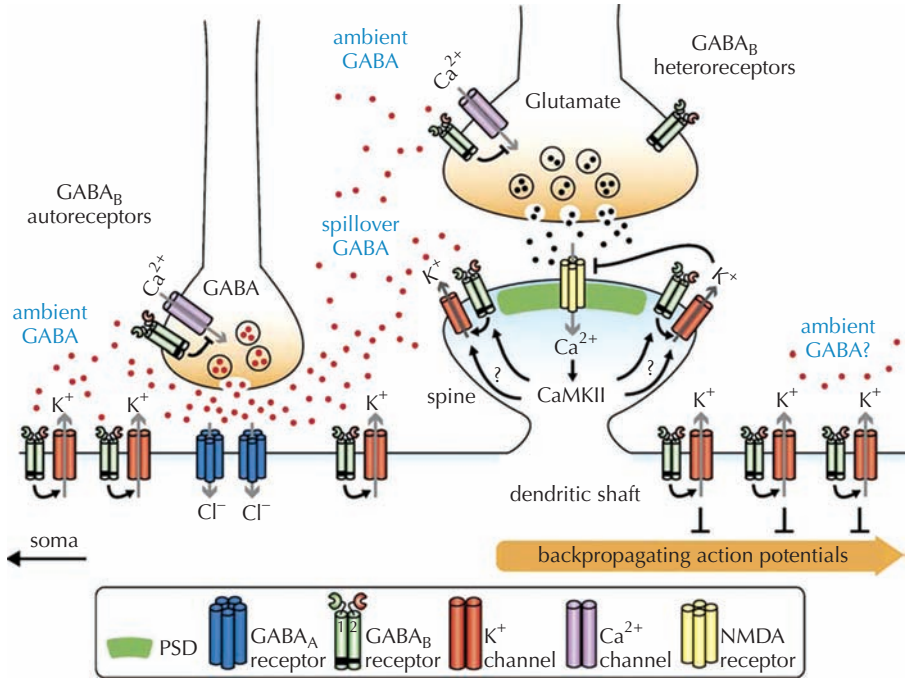

Figure 19–1. Localization and physiological roles of GABA$_B$ receptors. GABA$_B$ receptors are located presynaptically, postsynaptically, and on extrasynaptic membranes. Presynaptic GABA$_B$ receptors prevent neurotransmitter release by downregulating the activity of voltage-sensitive Ca^{2+} channels or by direct inhibition of the release machinery. GABA$_B$ autoreceptors inhibit the release of GABA, whereas GABA$_B$ heteroreceptors inhibit the release of glutamate and several other neurotransmitters. Some GABA$_B$ heteroreceptors are activated by ambient GABA, others probably by GABA spillover from inhibitory terminals. Postsynaptic GABA$_B$ receptors induce sIPSCs by activating Kir3-type K^+ channels, which hyperpolarizes the membrane, favors voltage-sensitive Mg^{2+} block of NMDA receptors, and shunts excitatory currents. GABA$_B$ receptors in spines and dendritic shafts are activated by spillover of GABA from adjacent terminals during population oscillations or during epileptiform activity, which may serve to regulate the excitability of the network and to counteract excess excitation. Dendritic GABA$_B$ receptors inhibit backpropagating action potentials through activation of K^+ channels, which may influence synaptic plasticity processes and action potential generation at the axon hillock. During high-frequency transmission, GABA depresses its own release by an action on GABA$_B$ autoreceptors, which permits sufficient NMDA receptor activation for the induction of LTP. In turn, activation of NMDA receptors and calcium/calmodulin-dependent protein kinase II (CaMKII) in dendritic spines enhances the sIPSC mediated by GABA$_B$ receptors and K^+ channels, which is proposed to influence the temporal resolution of synapses. From ref. 16.

Table 19–1 **Comparison of Features of TAS and AAS in Rodent Models and Humans**

	GAERS (TAS)	GABABR1bR2 Transgenic Hybrid Mouse (AAS)	Human (AAS)
EEG

Exacerbated by $GABA_AR$ and $GABA_BR$ agonists	+	+	+
Blocked by $GABA_BR$ antagonists	+	+	No data

*Characteristics that separate AASs from TASs. ETO ethosuximide; VPA valproic acid; TMD trimethadione; SWD spike-and-wave discharge; the $GABA_BR1bR2$ transgenic hybrid mouse is a mutant mouse overexpressing $GABA_B$ receptor subunits R1b and R2 in forebrain neurons; GAERS, Genetic Absence Epilepsy Rat from Strasbourg.

adolescence. In stark contrast, atypical absence seizures (AASs) are malignant[51,52] because they are progressive. The seizures are severe and characterized by ictal slow spike-wave discharges (SSWDs) associated with a prolonged ictal behavioral twilight state, during which semipurposeful movement is observed, and comorbid impairment in cognition is usually observed.[53–56] The impairment in cognition in AAS is thought to be caused by the involvement of limbic circuits,[54,57] which are spared in TAS.[58–60] The differences between typical and atypical absence seizures are summarized in Table 19–1.

ANIMAL MODELS OF TYPICAL ABSENCE SEIZURES

Genetic Absence Epilepsy Rat from Strasbourg (GAERS)

This rodent model is characterized by spontaneous SWDs at 7–11 Hz that start and end abruptly on a normal background electroencephalogram (EEG). The ictal events that are time locked with these discharges are staring and cessation of movement. GABAergic agonists and γ-hydroxybutyric acid (GHB) prolong the duration of SWDs in the GAERs, and the SWDs in this model are also exacerbated by pentylenetetrazole (PTZ), 4,5,6,7-tetrahydroisoxazolo(5,4-c)pyridin-3-ol (THIP), and penicillin.[61] The SWDs in the GAERS have been shown to originate from the facial somatosensory cortex, from which they spread to both hemispheres.[62] The seizures have a classic pharmacological profile, being enhanced by $GABA_AR$ and $GABA_BR$ agonists as well as by phenytoin and carbamazepine, and they are blocked by ethosuximide, benzodiazepines, and $GABA_BR$ antagonists. Enhancement of cognitive performance in GAERS was sustained in rats treated with $GABA_BR$ antagonists.[63]

WAG/Rij Rat

This is another commonly investigated genetic model of TAS, which presents the characteristics outlined in Table 19–1, as the GAERS do. Although the SWDs in the WAG/Rij have been shown to originate from the somatosensory cortex,[64] there is dissociation between the SWDs and sleep spindles in this model.[65] Within the thalamus, the bilateral 7–11 Hz SWD originates from the rostral pole of the nucleus reticularis (RTN) compared to the involvement of the entire RTN in sleep spindle

generation.[65] Levels of mRNA for most R1 GABA$_B$R subunits are diminished in the neocortex of WAG/Rij, whereas R2 mRNA levels are unchanged. R1 subunits fail to localize in the distal dendrites of WAG/Rij neocortical pyramidal cells, which may contribute to neocortical hyperexcitability.[66] The RTN and ventroposteromedial thalamic nucleus are coupled prior to the onset of SWDs in the WAG/Rij, suggesting that SWDs may derive from an intermixed delta-theta activity and that the seizure onset may require a reinforcement of intracortical and corticothalamic associations.[67] Higher doses of baclofen are required to depress pharmacologically isolated, stimulus-induced IPSPs generated by WAG/Rij neurons. Decreased function of presynaptic GABA$_B$Rs in the neocortex may contribute to neocortical hyperexcitability in this model.[68]

GHB-Treated Rodent

The bilateral 7–9 Hz SWD in this model originates from the thalamocortical circuitry, and G-protein-mediated mechanisms are involved in the pathogenesis of SWDs.[69] Intracortical perfusion of the GABA$_B$R antagonists, CGP 35348 and phaclofen, and the GHB receptor antagonist NCS 382, attenuated GHB-mediated changes in the basal and K^+-evoked release of GABA, which supports the idea that GHB induces a selective decrease in the basal and depolarization-induced release of GABA in cerebral cortex.[70] GHB most likely acts at the presynaptic GABA$_B$R.[60, 71] Similar to other animal models of typical absence, the hippocampus does not show SWDs in the GHB-treated rat (Fig. 19–2). There is some evidence that the GluR2 subunit may be involved in the initiation and maintenance of absence seizures induced by GHB.[72] Although neurogenesis appears to occur in convulsive seizures and in the kindling model, there is no evidence of this phenomenon in the GHB model.[73]

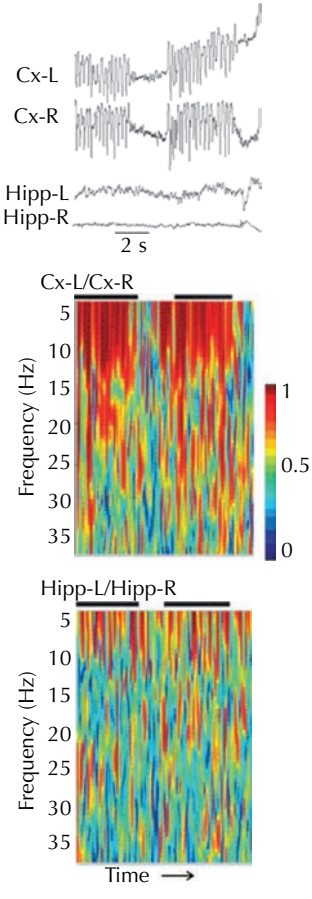

Figure 19–2. Temporal phase synchrony during absence seizures. Upper traces depict four simultaneous recordings in a rat injected with γ-butyrolactone (GBL), displaying two typical SWDs in the cortex (Cx-L and Cx-R, left and right cortical electrodes, respectively) and no apparent paroxysms in the hippocampi (Hipp-L and Hipp-R, left and right hippocampal electrodes, respectively). Lower color panels show the phase synchrony (color-coded, with red indicating the highest level of phase synchrony and blue the lowest) between the cortical recordings (upper panel) and between the two hippocampal recordings (lower panel). The black horizontal bars signal the two SWDs occurring in the cortex; the time axis is indicated (the synchrony plots correspond to the same length in time as the original traces above, ~12 s. Note the enhanced synchronization during the SWD between the cortical sites at almost all frequency ranges (from 5 to 35 Hz, *y*-axis), while the synchrony between the hippocampal electrodes shows many more fluctuations. From ref. 60.

lh/lh Mouse

In the lethargic (*lh/lh*) model, GABA$_B$R antagonists suppressed and GABA$_B$R agonists exacerbated absence seizures. GABA$_B$R activation may produce disinhibition, which is a possible role for GABA$_B$R in the expression of absence seizures in *lh/lh* mice.[74] Enhanced nuclear cyclic AMP–responsive element (CRE)- and activator protein 1 (AP-1) DNA-binding activities were found in the thalamocortical regions and have been implicated in the generation

and/or propagation of absence seizures in this model.[75] The repeated administration of the $GABA_BR$ antagonist CGP 46381 (60 mg/kg) attenuated seizure activity and the increased DNA-binding activities.[76] As well, $GABA_BR$ binding and synaptically evoked $GABA_BR$-mediated inhibition of *N*-methyl-D-aspartate (NMDA) responses were selectively increased, which suggested that enhanced $GABA_BR$-mediated synaptic responses may underlie absence seizures in *lh/lh* mice.[77]

ANIMAL MODELS OF ATYPICAL ABSENCE SEIZURES (AAS)

AY-9944-Treated Rodents

The administration of AY-9944, a cholesterol biosynthesis inhibitor at delta 7-reductase, to rodents produces a seizure phenotype that mimics AAS. The phenotype consists of slow SWD (SSWD), 4–5 Hz, during which the animal is able to move, and unlike TAS, there is no strict on-off relationship between the SSWD and the ictal event. In addition, also in contrast to the animal models of TAS, in the AY-9944 model the SSWD can be recorded from the hippocampus[78] (Fig. 19–3). A final difference is that in this model of AAS there is cognitive impairment, a characteristic not found in animal models of TAS.[79] As well, the AY-9944 model shows the characteristic pharmacology described above for the GAERS and detailed in Table 19–1. The AASs in the AY-9944 model are spontaneous, recurrent, and lifelong. AY-9944 is a cholesterol synthesis inhibitor that increases the expression levels and trafficking of the $GABA_BR$ in forebrain regions specifically during brain development, and lipid rafts participate in this process.[80] AY-9944 leads to prepubescent atypical absence onset[81] and to a maximum peak in adulthood.[82] There are no changes in histology[78,83] or neurogenesis[73] in this model.

Transgenic Mouse Models of Atypical Absence Seizures

Transgenic mice that overexpress the R1a $GABA_BR$ subtype show a phenotype characterized by atypical absence seizures associated with spontaneous, recurrent, bilaterally synchronous, 3–6 Hz SSWDs that are blocked by ethosuximide and exacerbated by baclofen. The discharges occur coincident with absence-like behaviors such as staring, facial myoclonus, and whisker twitching. However, similarly to the AY model described above, and in contrast to typical absence epilepsy models, these mice move during the ictal event, display SSWDs in both thalamocortical and limbic circuitry, exhibit impaired hippocampal synaptic plasticity, and display significantly impaired learning abilities (Fig. 19–4). A similar but less pronounced AAS phenotype results from the overexpression of the R1b subtype. The severity of AAS in the

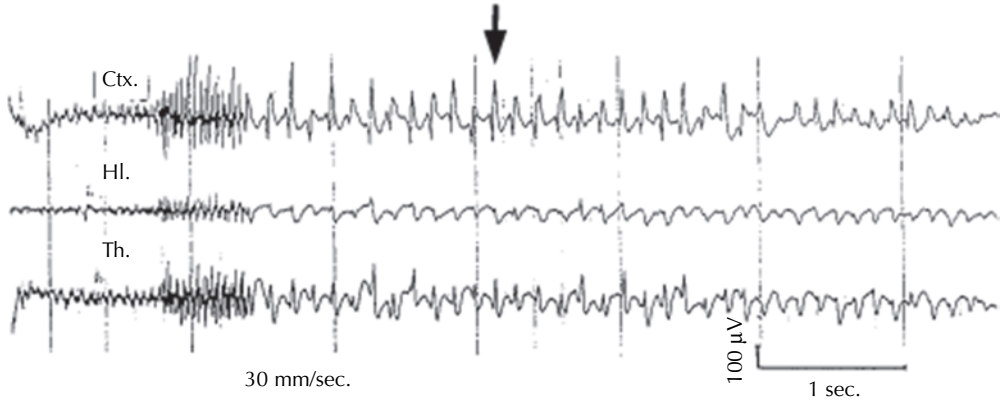

Figure 19–3. Baseline bipolar depth recording at P55 in the AY-9944 model. The figure illustrates the spontaneously recurrent 5 Hz spike-and-wave burst recorded from cortex (CTX.), hippocampus (Hi.), and thalamus (Th.) in a rat treated postnatally with AY-9944, better seen at 30 mm/s (arrow). The epileptiform activity was recorded from the hippocampus in all AY-9944-treated animals that had depth electrodes implanted ($n = 8$). From ref. 78.

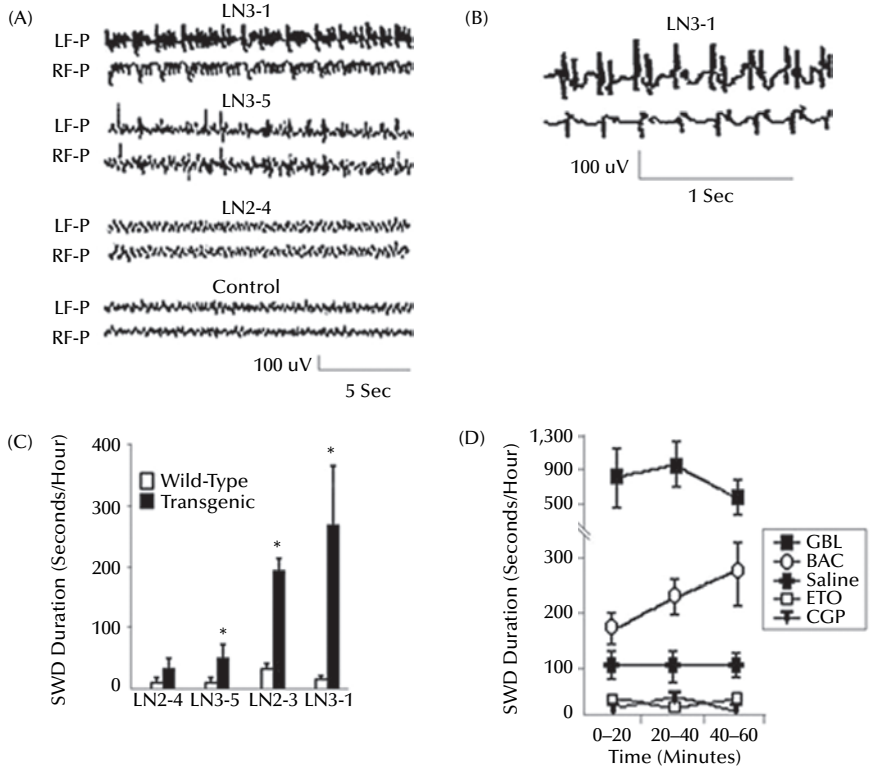

Figure 19–4. A. Baseline electrocorticography (ECoG) recording from the electrodes placed in cerebral cortex of a wild-type mouse and from the cortex of LN3–1, LN2–4, and LN3–5 transgenic mice. The traces denote differential signals between either the left frontal parietal electrodes (LF-P) or the right frontal parietal electrodes (RF-P). Note that the frequency of the seizure is 3–6 Hz. All subjects were 2 months of age or older at the time of the recordings. **B.** Higher-resolution tracing illustrating the spike-and-wave components of the ictal event from the cortex of an LN3–1 transgenic mouse. **C.** Comparison of the spontaneous SWD activity of the different transgenic mouse lines. Although the frequency of the seizure was consistent among the different lines, the amount of seizure activity per hour differed significantly among them. Note that the amount of seizure activity present in each line correlates with the amount of immunoreactive transgene expressed within each line (see Fig. 19–1). Data are presented as the mean and standard error of the seizure duration per hour of recording from $n = 10$ (LN2–4), $n = 11$ (LN3–5), $n = 10$ (LN2–3), and $n = 12$ (LN3–1) transgenic mice. **D.** The pharmacological responsiveness of the spontaneous SWD in the GABA$_B$R1a transgenic mice is consistent with absence epilepsy. The cumulative SWD duration in transgenic line LN3–1 was measured for 1 h either following saline injection or following the administration of the pro-absence drug γ-butyrolactone (GBL), the GABA$_B$R agonist (–)baclofen (BAC), the GABA$_B$R antagonist CGP 35348 (CGP), or the antiabsence drug ethosuximide (ETO). As shown in the figure, the duration of the SWD was significantly ($p < .01$, $n = 8$–10) reduced by pretreatment with either ETO or CGP and exacerbated by GBL or BAC. Note that the injection of the control saline was sufficient to reduce the SWD duration (compare panels C and D). Asterisks denote significant differences from their wild-type littermate ($p < .05$ Student's unpaired t-test). From ref. 84.

GABA$_B$R-overexpressing transgenic mouse model is GABA$_B$R subunit specific.[84,85]

GABA$_B$R-MEDIATED MECHANISMS IN TYPICAL AND ATYPICAL ABSENCE SEIZURES

The GABA$_B$R pharmacology in AAS and TAS is the same: GABA$_B$R agonists exacerbate and GABA$_B$R antagonists block both types of seizures.[48] GABA$_B$R agonists and antagonists act in this regard upon the thalamic circuitry involved in the bilateral synchronous SWDs in TAS[65,86] and SSWDs in AAS.[57] Intrathalamic neural networks serve as an intrinsic oscillatory unit within thalamocortical circuitry that drives the bilaterally synchronous SWDs, but their function depends upon reciprocal synaptic connectivity between excitatory thalamocortical relay neurons, excitatory corticothalamic

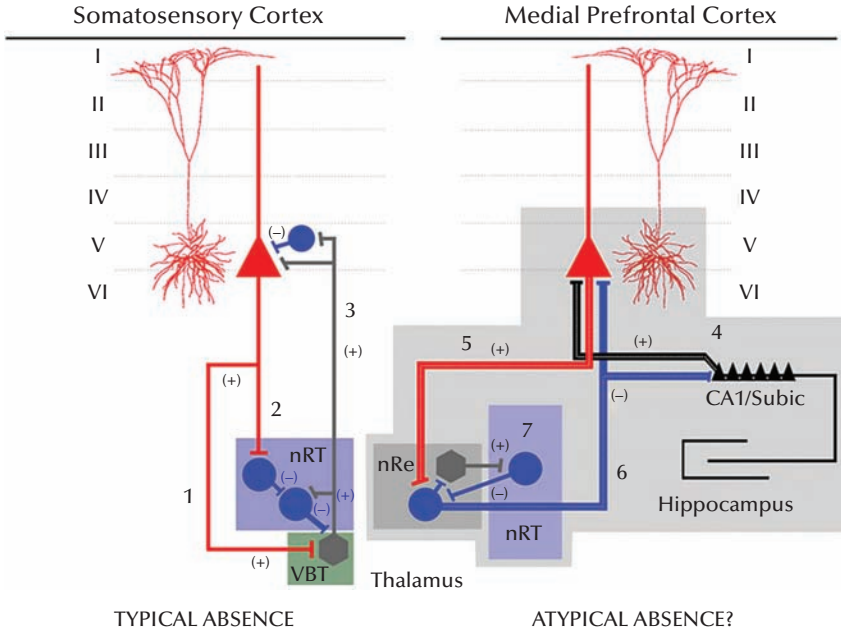

Figure 19–5. The well-established neuronal circuitry of TASs involves reciprocal connections between layer 5/6 of the perioral region of somatosensory cortex where the seizures are initiated, the ventrobasal thalamus (VBT; 1 and 3), and the caudal reticular nucleus of the thalamus (nRT; 2). The hypothesized circuitry of AASs (right), whereby the initiating epileptiform event for an AAS is postulated to occur in layer 5/6 of the medial prefrontal cortex (mPFC) and then project to the nucleus reunions of the thalamus (nRE; 5), which projects back to the mPFC and monosynaptically to the CA1 (6), which in turn projects to the mPFC (4). This reverberating circuit is modulated and driven by reciprocal intrathalamic connections between the nRE and the rostral nRT (7). Blue = GABAergic neurons; red = glutamatergic neurons. (–) indicates inhibition; (+) indicates excitation. Modified from ref. 57.

neurons, and inhibitory GABAergic neurons in the RTN and cortical interneurons.[87, 88] The $GABA_BR$ link[89] in this thalamocortical system that creates and promulgates the abnormal neuronal oscillatory activity within the circuitry, which manifests itself as either TAS or AAS, involves the low-voltage activated (LVA) Ca^{2+} channels. The LVA Ca^{2+} channel is found in both thalamus[90] and frontal cortex[91–93] and has the property of exquisite voltage sensitivity that allows regulation of oscillatory behavior within neuronal networks.[90,94] In the corticothalamic circuitry described in Fig. 19–5, powerful $GABA_BR$-mediated inhibition results in deinactivation of LVA Ca^{2+} channels with a resultant LVA Ca^{2+} current, rebound burst firing, and recurrent excitation of the RTN. In TAS this leads to recurrent excitation of the cerebral cortex, but in AAS, where the circuitry differs, midline thalamocortical neurons, most likely the nucleus reuniens (nRe) of the thalamus,[57] are activated and lead to oscillations within the cortical-thalamo-hippocampal circuitry. Thus, burst firing within either TAS or AAS circuitry depends upon LVA Ca^{2+} current, which is coupled to $GABA_BR$-mediated inhibition.

TYPICAL AND ATYPICAL ABSENCE SEIZURES ARE CIRCUITRY DEPENDENT

The absence seizure phenotype is circuitry dependent. Typical absence seizures (TAS) are generated from thalamocortical connections, and AASs are generated from cortical-thalamo-hippocampal circuitry[57,60] (Fig. 19–5). Recent data[57] suggest that the SSWDs in the R1a $GABA_BR$ transgenic model of AAS emanate from the cerebral cortex, midline thalamus, RTN, and the CA1 region of the hippocampus. A highly significant finding in those experiments was the noninvolvement of the ventrobasal nucleus of the thalamus (VB) in the SSWDs that characterize the AAS phenotype because VB is the major thalamocortical relay nucleus involved in TAS[58,64,95] (see Fig. 19–5).

Rather, the data showing the projection of the SSWDs to the CA1 in the R1a $GABA_B$R transgenic model of AAS[57] strongly suggest that the midline thalamic nucleus most likely involved in this genetic model of AAS is the nRe, since this is the midline thalamic nucleus that has direct projections to the CA1.[96–98] Because the nRe links CA1 and medial prefrontal cortex (mPFC),[97,98] the cortical component of the cortico-thalamo-hippocampal circuitry in AAS may well be the mPFC (Fig. 19–5).

The rationale for postulating a cortical focus for AAS is that TASs have been reported to arise from a cortical focus in humans[86] and animals.[64,95] Given the reciprocal projections of nRe to the mPFC[98,99] and RTN,[96] and given the pronounced direct monosynaptic projections from CA1/subiculum to the mPFC,[99] whether the initiating epileptiform event for an AAS within the proposed circuitry (Fig. 19–5) could take place in layer 5/6 of the mPFC requires further confirmation. Our postulation is conceivable because there are reciprocal projections from nRe to the mPFC[98,99] and RTN[96] and pronounced direct monosynaptic projections from CA1/subiculum to the mPFC.[99] However, there are no direct mPFC-to-CA1 projections, so it appears that the nRe serves as a critical relay from the mPFC to CA1—that is, as a reverberating loop that is modulated by reciprocal intrathalamic connections between the nRe and the RTN.[98,100,101] Taken together, all these data suggest that the EEG, behavioral, and cognitive phenotypes of the R1a $GABA_B$R transgenic model of AAS are dependent upon a reverberating neuronal circuitry that involves the mPFC, nRe, and the CA1 region of the hippocampus.

IMPAIRMENT OF LEARNING AND MEMORY IN ATYPICAL ABSENCE SEIZURES

$GABA_B$R Modulation of Learning and Memory

Several lines of evidence indicate that $GABA_B$R agonists impair learning and memory, whereas $GABA_B$R antagonists improve the cognitive processes. Administration of baclofen to patients resulted in memory loss reported in three different case studies.[102] In experimental models, posttraining intraperitoneal injection or intra-amygdala infusion of baclofen resulted in the impairment of retention on an inhibitory avoidance task.[103–105] Baclofen has also been shown to potentiate the amnesic effect of scopolamine on the performance of rats in the radial arm maze test, even though baclofen was unable to alter the performance when given separately.[106] However, intraseptal administration of baclofen reduced the correct choices and thus increased the errors in the radial maze test.[107] Other studies utilizing different learning paradigms demonstrated an impairing effect of baclofen on the performance of rats in the Y-maze[108] and the Morris water maze tests.[109] More recently, $GABA_B$R activation in the entorhinal cortex by direct infusion of baclofen inhibited spatial learning in the Morris water maze test.[110] This finding was dependent on a protein kinase A (PKA)-dependent pathway able to activate the two-pore, weakly inwardly rectifying K^+ (TWIK)-related potassium type 2 (TREK-2 K^+) channels in entorhinal neurons. Increased $GABA_B$R activity also has been shown to disrupt reconsolidation of a conditioned reward memory by facilitating the extinction of the normally resilient memory trace.[111] However, it has to be mentioned that one study has reported positive effects of baclofen on recognition memory in mice pretreated with methamphetamine.[112]

Conversely, $GABA_B$R antagonists have been demonstrated to improve cognitive performance and/or to reverse amnesia in animals,[50,104, 113–117] to enhance the cognitive performance in experimental TAS,[63,118] and to reverse the deficits in both cognition and long-term potentiation (LTP) in a pharmacological model of AAS.[79] There is recent clinical evidence that $GABA_B$R antagonists may improve cognition in human.[119,120] Although the majority of published data support the general thesis that $GABA_B$R agonists decrease and $GABA_B$R antagonists enhance the cognitive performance, mutant mice lacking R1a or R1b subunits appear to have impaired memory, which indicates that the R1a subunit is involved in familiar and novel object recognition and that, on the other hand, the R1b subunit is involved in acquisition and extinction of aversive memories.[121,122]

The mechanism of the cognition-enhancing effects of $GABA_B$R antagonists is thought to involve the inhibition of CREB2/CRE pathways by the reduction of CRE protein binding.[114] Alternatively, the behavioral effects

of $GABA_BR$ blockade also can be mediated by an increase in the levels of phosphorylated PKA[123] and synapsin Ia and IIa proteins,[124] and previously heightened release of somatostatin into the extracellular regions of the hippocampus was found in vitro.[125]

$GABA_BR$-Mediated Mechanisms in Impairment of Learning and Memory in Experimental Atypical Absence Seizures

As mentioned above, administration of AY-9944 to rats or mice early in development results in recurrent AAS similar to human atypical absence epilepsy in EEG, pharmacology, ictal behavior and developmental profile.[54,79] In addition, this model of AAS exhibits cognitive deficits that mirror those observed clinically in AAS, an invariable component of the Lennox-Gastaut syndrome. In vitro tests of synaptic plasticity in the AY-9944 model of AAS demonstrated impairments in CA1- LTP, paired-pulse facilitation (PPF), and presynaptic depression (PD). Furthermore, AY-9944 animals in the radial arm maze test showed fewer perfect entries, a greater number of errors, and a requirement for more training days to learn the task than saline-treated controls. The antiabsence drug ethosuximide significantly attenuated AAS in the AY model but failed to rescue the spatial learning abilities and working memory in AY animals.[79] However, a specific high-affinity $GABA_BR$ antagonist, CGP 35348, not only blocked the AAS, but also restored the LTP to baseline and reversed the cognitive deficit in the AY-9944 model. Importantly, dose-response studies showed that doses of CGP 35348 that failed to influence AAS activity in AY-9944-treated rats completely reversed the spatial working memory deficit in these animals. Thus, $GABA_BR$ antagonists are antiepileptic, reverse the learning deficit, and rescue the impaired CA1-LTP in experimental atypical absence epilepsy.[79] These data suggest that the cognitive dysfunction in the AY-9944 model of AAS is $GABA_BR$ dependent and that it is not influenced by AAS activity. In line with this hypothesis, transgenic mice overexpressing the R1a or R1b $GABA_BR$ subtype in forebrain[84,85] present with characteristic AAS, reduced hippocampal LTP and significantly impaired hippocampal learning functions.

CONCLUSION

$GABA_BR$-mediated mechanisms have been known for many years to be involved in the genesis and propagation of both TASs[126–129] and AASs,[78,84] as well as in the associated cognitive impairments.[54,79] Moreover, the data reviewed in this chapter indicate that TAS and AAS share the same pharmacological profile, because they share common thalamic circuitry perturbations, notably nRT involvement. However, TAS and AAS phenotypes differ in seizure severity, SWD characteristics, and impairment in learning abilities, mainly because they differ in the other parts of the circuitry involved. In TAS, cognition is not affected because the SWD is constrained within thalamocortical circuits and does not involve limbic circuits. In AAS, on the other hand, cognition is impaired because of the SWD involvement of limbic circuitry that is recruited through cortico-thalamo-hippocampal pathways,[130] hence the difference in seizure semiology and cognitive involvement.

Because of the demonstrated efficacy of $GABA_BR$ antagonists in preventing SWDs, the potential of $GABA_BR$ antagonists as powerful antiabsence drugs has been long proposed,[61] yet clinical trials of $GABA_BR$ are lacking both in TAS and AAS. Frequent refractory seizures and severe impairment in cognition represent the most disabling aspects of pediatric epilepsy and are the major contributors to the burden of illness in children affected by epilepsy.[131] Because of data suggesting that atypical absence seizures are independent of their comorbid cognitive deficits, yet both are $GABA_BR$ dependent,[79] there is a clinical imperative to initiate clinical trials of a $GABA_BR$ antagonist in the AASs observed in Lennox-Gastaut syndrome.[119,120]

Chapter 20

Brainstem Networks

Reticulocortical Synchronization in Generalized Convulsive Seizures

Carl L. Faingold

Penfield and Jasper[1] proposed that generalized seizures involve the brainstem reticular formation (BRF) and other brain sites that are extensively connected to most other brain regions as a centrencephalic system. Considerable subsequent research has confirmed a major role for the BRF in the neuronal networks that subserve generalized convulsive seizure

generation. The BRF has been defined to include the core of the brainstem in the medulla, pons, and midbrain. The projections between brainstem nuclei, as well as those to and from the BRF, are massive, including all levels of the central nervous system (CNS) from spinal cord to cerebral cortex. Recent research on the anatomical and neurochemical diversity of nuclei within the BRF has been extensive, leading to a more complex view of the functions of the brainstem. However, these observations have not invalidated the original concept that the BRF has the potential to act as an extremely large network (reticulum) capable of "mass action" under certain circumstances, such as arousal or generalized convulsive seizure.[2–4] Depression of BRF neurons was originally and is still implicated as a major mechanism of action for depressant and anesthetic drugs.[2,5]

Direct brainstem or spinal cord stimulation can induce tonic muscular activity resembling the tonic convulsive component of generalized tonic-clonic seizures (GTCS).[6] In addition, the stereotypical and coordinated four limb generalized tonic and clonic motor movements seen during GTCS are proposed to be due to excessive activation of the normal locomotor network[7] that lies primarily in brainstem and spinal cord.[8] Thus, it has been proposed that generalized convulsive movements involve the recruitment of the normal locomotion network into the epilepsy network, which mediates GTCS. The concept of network interaction in epilepsy is an important advance in understanding how convulsions and other major alterations of brain organization occur, as discussed below.

The mechanisms that mediate convulsive seizures have been widely studied in a variety of animal models, involving chemical or electrical stimulation in normal animals, and these studies have yielded important insights into convulsive mechanisms. It has become clear that there is an important genetic component to human epilepsy susceptibility.[9] Thus, many specific genetic abnormalities occur in epileptic patients and their families, and genetically based animal models of epilepsy have also been discovered. The *two-hit* hypothesis (nature plus nurture) is proposed to be the most common cause of human epileptic syndromes.[9] Thus, a genetic predisposition is the first hit, and an inducing event such as a brain injury or infection is the second hit that triggers the onset of the epileptic syndrome.

AUDIOGENIC SEIZURES AS GENERALIZED CONVULSIVE EPILEPSY MODELS

The severe seizure strain of genetically epilepsy-prone rats (GEPR-9s) is a well-studied genetic model of generalized convulsive epilepsy.[10,11] These rats exhibit greater than normal susceptibility to seizures induced by convulsant drugs, hyperthermia, hyperbaric conditions, and electrical kindling, and GEPR-9s are also susceptible to sound-induced or audiogenic seizures (AGS). The AGS in GEPR-9s begin with wild running and proceed to tonic convulsions, ending in tonic hind limb extension, which is followed by postictal depression of consciousness. Susceptibility to AGS occurs in many other rodent strains, including the moderate-severity seizure strain of GEPR-3s, and AGS mechanisms have been studied in different rodent models worldwide.[11–15] In DBA mice, AGS have recently been shown to be an important model of human sudden, unexpected death in epilepsy, as discussed below.[16,17] Models of AGS have also been widely used to test anticonvulsant drugs, and drugs that are effective in human epilepsy are effective against AGS in the various models. Spontaneous seizures are seen rarely in AGS models, and their susceptibility to seizures is also associated with the two-hit hypothesis of genetic predisposition plus an environmental insult to the brain, as proposed for human epilepsy.[9] In GEPR-9s the first hit is a genetic defect in GABA-mediated inhibition,[11] and the second hit is an intense acoustic stimulus, which initiates the AGS.

NEURONAL NETWORK FOR AGS

The neuronal network required for AGS in GEPR-9s is confined exclusively to the brainstem,[6,10] including the lower brainstem primary auditory nuclei (Fig. 20–1A), but forebrain structures are not required for AGS.[10,18]

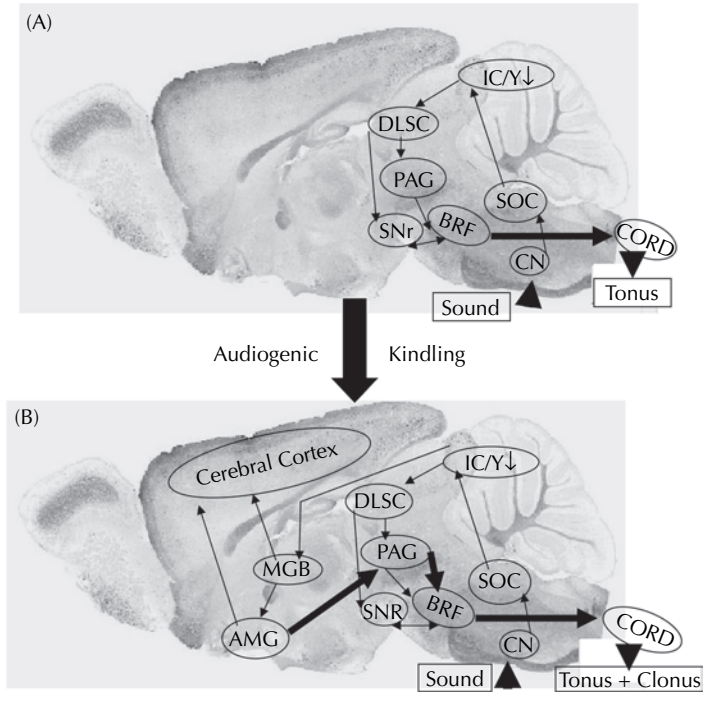

Figure 20–1. These diagrams show the neuronal network for audiogenic seizures (AGS) in genetically epilepsy-prone rats (GEPR-9s) and changes after AGS kindling. **A.** The AGS network (prior to AGS kindling) involves progression of the seizure via the brainstem primary auditory nuclei, including the cochlear nucleus (CN) and superior olivary complex (SOC) up to the inferior colliculus (IC). A deficit of GABA-mediated inhibition ($\gamma\downarrow$) in IC results in excessive auditory-evoked IC neuronal firing that initiates AGS. This involves projections to the normal locomotor pathway (deep layers of superior colliculus (DLSC) to periaqueductal gray (PAG), substantia nigra reticulata (SNr), and (pontine) brainstem reticular formation (BRF), which project to the spinal cord, mediating the convulsion. No forebrain structures are required. **B.** After periodic frequent repetitive AGS (audiogenic kindling) in GEPR-9s, the seizure network expands to include the medial geniculate body (MGB), amygdala (AMG), and cortex, which now exhibits epileptiform cortical EEG activity. The AMG is the most critical structure for generating the additional convulsive post-tonic clonus that is induced by AGS kindling.

Inferior Colliculus as the AGS Initiation Site—GABA Mechanisms

The inferior colliculus (IC) is the consensus initiation site for all AGS models, including GEPR-9s, GEPR-3s, and acoustically primed, thyroid-deficient and ethanol-withdrawn rats based on blockade, stimulation, and neuronal recording studies.[11] GABA is the major inhibitory neurotransmitter in the IC, mediating several different normal forms of acoustically evoked inhibition in the IC, including firing reductions normally induced by high-intensity acoustic stimuli.[11] Several forms of GABA-mediated inhibition are significantly reduced in GEPR-9s, leading to greatly increased IC neuronal firing (Fig. 20–2A,B), which acts as the triggering mechanism for AGS.[11] Direct stimulation of IC produces AGS susceptibility in normal rats.[19,20] Increased excitability, due to deficits of GABA-mediated inhibition, in IC neurons is also seen in the IC slice, and in other parts of the brain where it is associated with an 80% reduction of $\gamma 2$ subunit levels of $GABA_A$ receptors.[21–23]

Superior Colliculus in the AGS Network

Neurons in the deep layers of the superior colliculus (DLSC) are a major nonprimary auditory recipient of IC output and are strongly implicated in the AGS network, since blockade of DLSC blocks AGS.[19,24,25] The DLSC neurons are strongly implicated in triggering

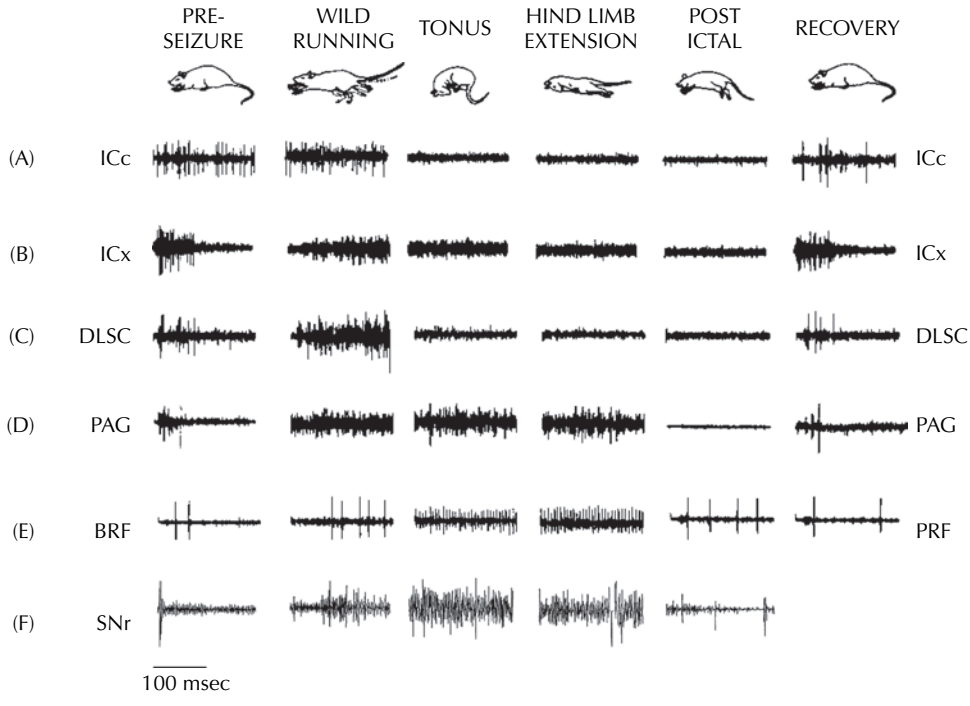

Figure 20–2. Composite behavioral activity in GEPR-9s and concurrent neuronal firing in the major network nuclei for AGS seen during each seizure behavior in the awake animal. The structures include (**A**) the inferior colliculus central (ICc) and (**B**) inferior colliculus external (ICx) nuclei; (**C**) the deep layers of superior colliculus (DLSC); (**D**) periaqueductal gray (PAG); (**E**) pontine brainstem reticular formation (BRF); and (**F**) substantia nigra reticulata (SNr). Thus, ICc and ICx firing is greatest during AGS initiation, while the greatest increase in DLSC neuronal firing occurs at the onset of wild running. The greatest increases in PAG, SNr, and BRF neuronal firing occur during the tonic and clonic phase(s) of AGS. The BRF and SNr are the only areas active during postictal depression of consciousness. Note: Recovery of SNr firing occurred but was not recorded in the example in F. (Acoustic stimulus parameters: 12 kHz tone burst, 100 ms duration, 5 ms rise-fall, 100 dB SPL, 2–4 Hz repetition rate. Each row is from the same rat.) Drawings according to ref. 45.

the wild running phase of AGS.[26,27] An abrupt onset of acoustically evoked firing at relatively high acoustic intensities was observed in DLSC neurons of GEPR-9s, which was significantly above the normal threshold. The DLSC neurons began to exhibit rapid tonic burst firing 1–2 s prior to the onset of the wild running behavior at the beginning of AGS (Fig. 20–2C).[26] The DLSC project to the spinal cord directly and via the pontine BRF and periaqueductal gray (PAG), and DLSC also project to the substantia nigra reticulata (SNr).[27–29]

PAG in the AGS Network

The PAG is a brainstem site that is extremely important in the neuronal network for AGS, since blockade of PAG blocks AGS, and PAG neurons are implicated in initiation of the tonic and clonic phases of AGS in GEPR-9s.[28,30] The PAG receives input from the DLSC and projects directly and indirectly to the spinal cord.[31–33] Acoustically evoked PAG neuronal responses in GEPR-9s are elevated compared to those in normal rats. The PAG neurons displayed tonic neuronal firing patterns during the wild running and tonic hind-limb extension phases of AGS (Fig. 20–2D).[28] In vitro studies indicate that the properties of PAG neurons exhibit abnormal membrane and synaptic properties in animals that are susceptible to AGS.[34]

Substantia Nigra in the AGS Network

The SNr is also implicated in control of seizures, including AGS in GEPR-9s, since blockade of SNr blocks AGS.[29] Acoustically evoked

SNr neuronal firing in awake normal rats was not detectable except at very high intensities, but the threshold for acoustically evoked neuronal firing in GEPR-9s was considerably lower (Fig. 20–3). The responsiveness of SNr neurons in GEPR-9s was also significantly greater than that in normal rats. During AGS in GEPR-9s, SNr neurons showed enhanced rapid firing (Fig. 20–2F). The SNr neurons showed occasional action potentials during postictal depression.

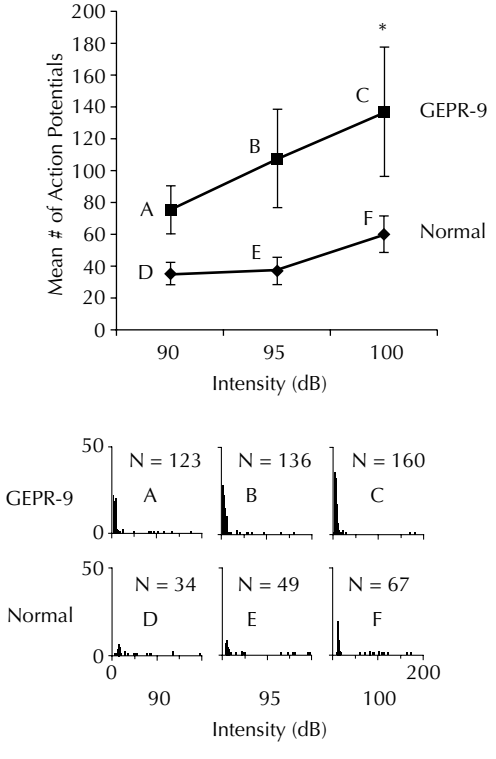

Figure 20–3. Comparison of acoustically-induced firing changes in the substantia nigra reticulata (SNr) in GEPR-9s compared to normal Sprague-Dawley rats. Acoustically evoked SNr neuronal firing in awake normal rats was not detectable except at very high intensities (≥90 dB SPL re; 0.0002 dyn/cm^2), but the threshold for acoustically-evoked neuronal firing in GEPR-9s was considerably lower. The upper graph shows the mean (n = 5 rats/group) number of acoustically-evoked action potentials/poststimulus-time histogram (PSTH) in GEPR-9s (**A–C**) compared to normal rats (**D–F**). There was a significantly greater response at C ($p < 0.05$, ANOVA) compared to control. The PSTHs below show typical examples from the graph above, presenting the number of action potentials (N) for each example. Each row is from the same rat. N = number of action potentials in the PSTH. (Acoustic stimulus parameters: 12 kHz tone burst, 100 ms duration, 5 ms rise-fall, 100 dB SPL, 0.5 Hz rate, 50 presentations.)

BRF in the AGS Network

Blockade within the pontine region of BRF blocks AGS susceptibility.[26] Neurons in the pontine BRF are implicated in triggering the tonic phase of AGS in GEPR-9s and GEPR-3s.[35,36] The BRF neurons in GEPR-9s exhibit precipitous intensity-evoked increases at a significantly lower intensity than normal rats. At the onset of AGS (wild running), the firing rate of BRF neurons increased and the rate of BRF firing increased dramatically as the tonic phase of the seizure began. During postictal depression BRF neuronal firing slowed, gradually returning to normal, but the BRF is one of two network nuclei active during this behavior[26,35] (Fig. 20–2E).

Changes in Nuclear Dominance during AGS

The neuronal recording data mentioned above indicate that changes occur in the dominance (greatest firing change) in each specific site within the requisite nuclei in the neuronal network for AGS during each sequential phase in a hierarchical manner during the behavioral phases of the convulsion[26] (Fig. 20–2). Thus, IC firing is greatest during AGS initiation, while the greatest increase in DLSC neuronal firing occurs just prior to the appearance of wild running. The greatest increases in PAG, SNr, and BRF neuronal firing occur during the tonic and clonic phase(s) of AGS (Fig. 20–2). The BRF is the major area active during postictal depression of consciousness, and may be indicative of the critical role of the BRF in maintaining "vegetative" cardiac and respiratory functions, which maintain the life of the animal when much of the rest of the brain is depressed.

RETICULAR FORMATION IN CONVULSANT-INDUCED GENERALIZED SEIZURE INITIATION

Brainstem reticular formation neuronal response changes are also implicated in other epilepsy models, including seizures induced by convulsant drugs.[37,38] Thus, the elevated

BRF neuronal response to sensory stimuli are induced by subconvulsant doses of convulsant drugs and is proposed to be a major mechanism involved in sensory initiation of seizures in this reflex epilepsy model. This model represents another example of the two-hit hypothesis of epilepsy. In this case, the first hit is the subconvulsant dose of bicuculline, pentylenetetrazol, or other convulsant drug. When the second hit—sensory stimulation—is presented, this triggers a generalized convulsive seizure in which BRF neurons appear to play a major role.[37] Normally, BRF neuronal responsiveness is very restrained, leading to minimal conduction of repetitive stimuli along the extensive ascending and descending BRF pathways. The BRF neuronal responses to sensory and other stimuli exhibit pervasive repetition-induced response habituation characterized by major declines in responsiveness with succeeding presentations of the stimulus and/or increases in the stimulus presentation rate.[37,38] When animals are given a subconvulsant dose of the $GABA_A$ receptor antagonist, bicuculline, or a number of other convulsant drugs and then subjected to sensory or electrical stimuli in one of several modalities, the sensory second hit can trigger convulsive seizures.[37] However, before seizure is induced, BRF neurons undergo a major increase in responsiveness to these various stimuli.[37,38] Extensive increases in BRF neuronal responsiveness seen in this epilepsy model would greatly enhance the output along the numerous pathways from the BRF. This intense output would tend to recruit and synchronize the firing of the large numbers of neurons in the multitude of CNS regions that receive BRF input, including the spinal cord, where the central program generators for the convulsive behaviors are localized.[39] Such a simultaneous and massive synchronization of neuronal firing is likely to play a key role in the establishment of the neuronal network subserving these generalized convulsive seizures. When the number and distribution of affected neurons reach a critical mass, the neuronal network for seizure is assembled, and the emergent properties of this network are expressed in triggering a generalized seizure by the sensory stimulus. This process could explain how the enhanced seizure susceptibility brought about genetically or by convulsant drug treatment would allow a sensory stimulus that was a modality-specific communicative signal to become the initiating factor in the pervasive cascading activation of the neuronal networks that ultimately produces the emergence of a generalized convulsive seizure. Similar mechanisms may also be operative in other forms of epilepsy, since the ability of sensory stimuli to trigger convulsions (reflex epilepsy) is also seen in many experimental epilepsy models and in human epilepsy.[11,13,40–42]

RETICULAR FORMATION PLASTICITY—CONDITIONAL MULTIRECEPTIVE NEURONS

The BRF is a nonprimary (sensory or motor) brain region, and this region contains a high proportion of cells that have been termed *conditional multireceptive* (CMR) neurons; other sites with high percentages of CMR neurons include the amygdala and certain regions of the cerebral cortex.[38] Unlike most primary neurons, CMR neurons exhibit extremely inconsistent responses to stimuli in the behaving animal, depending on the conditions affecting the organism, including vigilance states, drug treatment, and learning paradigms. The degree of CMR neuronal responsiveness is highly unpredictable, since these neurons are capable of exhibiting a major degree of response enhancement or diminution, depending on the external and internal milieu that the behaving organism is experiencing. This response plasticity can be either short-term or long-term in duration. Conditional multireceptive brain regions also have extensive connections to numerous brain areas, and the participation of CMR regions in any neuronal network can be highly variable. The mechanisms that allow BRF and other CMR neurons to undergo such a great increase in responsiveness are related to the physiological functions of these structures. Thus, most BRF neurons normally respond poorly to repetitive stimuli, and these declines in BRF neuronal responsiveness are associated with progressive reductions in excitatory postsynaptic potential (EPSP) amplitude, which can result in subthreshold EPSPs as stimuli are repeated.[37,38] These subthreshold EPSPs can be brought to threshold by blocking inhibition or enhancing excitation, which can be induced by pharmacological treatments. Thus, systemic or iontophoretic treatment with antagonists (bicuculline

or strychnine) of inhibitory neurotransmitter receptors can cause CMR neurons to become consistently responsive to external inputs (e.g., peripheral nerve, sensory, or electrical stimuli in the brain) to which these neurons did not previously appear to respond.[37,38] Conversely, agents that enhance GABA-mediated inhibition (e.g., barbiturates or benzodiazepines) or antagonize glutamate-mediated excitation (e.g., ketamine) can cause CMR neurons to become temporarily unresponsive to inputs that they responded to previously.[37,43]

SEIZURE REPETITION INDUCES NEURONAL NETWORK CHANGES

Audiogenic Kindling in GEPR-9s as a Model of Generalized Tonic-Clonic Seizures

The AGS models of epilepsy do not show epileptiform electroencephalographic (EEG) activity in the cortex during seizure, which is often considered the hallmark of human epilepsy (R. Naquet, personal communication). However, periodic AGS repetition (AGS kindling) in several strains of AGS-susceptible rats does result in the appearance of an epileptiform cortical EEG.[44–46] After AGS kindling in GEPR-9s, the tonic hind limb extension is followed by another convulsive behavior, post-tonic generalized clonus (PTC), and this sequence of convulsive behaviors closely mimics human GTCS, including the cortical epileptiform EEG. After AGS kindling in GEPR-9s, the seizure network undergoes permanent expansion from the brainstem and recruits forebrain structures, including the amygdala and cerebral cortex, as discussed below. This has led to the idea that unkindled AGS of GEPR-9s are a "larval" form of GTCS similar to human infantile spasms. After AGS kindling, the larval form develops into full-blown GTCS.[6]

IC Changes in Audiogenic Kindling

During AGS kindling (typically, 14 seizures over 7–14 days) in GEPR-9s,[45] IC neuronal firing in GEPR-9s showed significant increases in the number of acoustically-evoked action potentials by the second AGS repetition, which peaked at the 4th seizure, remaining elevated to about the same degree through the 14th seizure.[47] The increased IC neuronal firing was observed prior to the appearance of PTC. Although IC neuronal firing increases may subserve, at least, the initial increase in AGS severity, changes in neuronal firing in nuclei of the neuronal network for AGS efferent to the IC are likely to be responsible for the increased AGS severity that occurs after the fourth AGS repetition.

Reticular Formation Neuronal Firing Changes in Audiogenic Kindling

Although the BRF neuronal firing changes induced by AGS kindling in GEPR-9s have not been evaluated, the changes in BRF firing induced by AGS kindling in GEPR-3s have been studied.[36,48] The pontine BRF also plays a critical part in the neuronal network for AGS in GEPR-3s.[36] AGS in unkindled GEPR-3s culminate in generalized clonus, but AGS kindling in GEPR-3s results in a different additional seizure behavior, facial and forelimb (F & F) clonus, not seen prior to kindling, and which is also seen after AGS kindling in other AGS models.[44–46] After AGS kindling in GEPR-3s, BRF neuronal firing was greatly increased. Tonic BRF neuronal firing occurred during generalized clonus, which changed to burst firing after AGS kindling. Burst firing in BRF neurons also occurred during F & F clonus.[48] Increased neuronal firing and the change from tonic to burst firing suggest that AGS kindling involves increased BRF excitability. These data support an important role for BRF neurons in the generation of both the increase in generalized clonus and the F & F clonus induced by AGS kindling in GEPR-3s. Similar changes may also be induced in BRF neurons in GEPR-9s by AGS kindling.

Medial Geniculate Body Changes in Audiogenic Kindling

The medial geniculate body (MGB), which is the next major primary auditory nucleus efferent to the AGS-initiating site in IC, is not required for AGS induction prior to AGS

kindling. However, the MGB is strongly implicated in the kindled AGS network in GEPR-9s.[49] Blockade of the MGB blocks the PTC component of kindled AGS, causing the seizure to revert, reversibly, to the unkindled behavior pattern.[49] Audiogenic seizure kindling in GEPR-9s also results in changes in neuronal firing patterns in the MGB.[49] Acoustically-evoked MGB neuronal responses after AGS kindling in GEPR-9s were elevated, with an increased incidence of sustained firing associated with a loss of habituation. The MGB neurons exhibited rapid tonic firing during tonic seizures in GEPR-9s, suggesting that the MGB may be involved in the propagation of seizure activity. But MGB neuronal firing was silent during PTC, suggesting that MGB does not play a direct role in this behavior.

Amygdala Changes in Audiogenic Kindling

The amygdala appears to be the most critical site in seizure network expansion in AGS kindling in GEPR-9s, since focal blockade of this structure can block PTC, causing the AGS behaviors to revert temporarily to the unkindled pattern.[50] In addition, chemical stimulation of the amygdala in unkindled GEPR-9s results in susceptibility to AGS that closely mimics the AGS behavior pattern seen in kindled GEPR-9s.[51] Extensive increases in lateral amygdala neuronal firing are induced by AGS kindling in GEPR-9s.[43] These changes include significant increases in onset-only patterns and increases in acoustic responsiveness to over five times that of normal neurons. Amygdala neurons also fired tonically during tonic convulsions and exhibited burst firing during PTC. Greater acoustically-induced synchronization of lateral amygdala firing, as indicated by elevated responsiveness and increased concentration of firing near the stimulus onset, may be critical for mediating the behavioral and EEG changes induced by AGS kindling in GEPR-9s.

As noted above, GEPR-3s also undergo AGS kindling, and changes in amygdala firing also occur in this model.[52] Audiogenic seizure kindling in GEPR-3s results in F & F clonus, and this behavior is blocked by bilateral blockade of amygdala, causing the seizure behavior to revert to the unkindled generalized clonus pattern temporarily. Lateral amygdala neuronal responses to high-intensity acoustic stimuli are significantly increased after AGS kindling compared to unkindled GEPR-3s. Rapid firing occurred during wild running and generalized clonic behaviors before and after AGS kindling in GEPR-3s. Burst firing occurred during F & F clonus in GEPR-3s after AGS kindling, which was not seen in unkindled GEPR-3s. These findings indicate that amygdala neurons play a critical role in AGS kindling in GEPR-3s as well.[52]

Changes in the MGB-to-Amygdala Pathway in Audiogenic Kindling

Both the MGB and amygdala are implicated in the network expansion induced by AGS kindling, as described above. Lateral amygdala neuronal responses to MGB electrical stimulation in GEPR-9s are greatly increased by AGS kindling, compared to unkindled GEPR-9s, and a threshold reduction in amygdala neuronal responsiveness to MGB stimuli was also seen in AGS kindled GEPR-9s.[53] These findings indicate that AGS kindling increases the efficacy of the MGB-amygdala pathway in GEPR-9s, suggesting that synaptic plasticity in this pathway within the expanded seizure network is an important pathophysiological mechanism subserving AGS kindling.

Molecular Mechanisms of Audiogenic Kindling in Amygdala

Increased amygdala neuronal firing induced by AGS kindling may initiate permanent pathophysiological alterations in the amygdala, in part, by enhanced glutamate receptor-mediated excitation, since focal microinjection of *N*-methyl-D-aspartate (NMDA) into amygdala of unkindled GEPR-9s or GEPR-3s induces susceptibility to PTC in GEPR-9s or F & F clonus in GEPR-3s, which mimic AGS kindling in both AGS models temporarily.[51] When a cyclic adenosine monophosphate (cAMP) activator was microinjected into amygdala of unkindled GEPR-9s, seizures that mimic AGS kindling were also evocable, but this effect lasted indefinitely.[54] Conversely, when an NMDA antagonist or inhibitor of cAMP synthesis was

microinjected into the amygdala, the effects of AGS kindling were reversed, and the seizure pattern temporarily reverted to that seen prior to AGS kindling.[51,55,56] These data suggest that AGS kindling-induced repetitive NMDA receptor activation in the amygdala triggers a molecular cascade that critically involves activation of cAMP, which leads to the permanent expansion of the seizure neuronal network that is induced by AGS kindling.

PAG Changes in Audiogenic Kindling

Audiogenic seizure kindling in GEPR-9s also induces changes in PAG neuronal firing.[57] As noted above, the PAG is implicated in generalized clonus initiation in unkindled GEPR-9s. A pathway from the amygdala to PAG is well known.[58] The PAG neurons in kindled GEPR-9s showed significantly elevated responses to acoustic stimuli compared to unkindled GEPR-9s. During the wild running and tonic hind-limb extension, PAG neurons display tonic firing. Burst firing was seen in PAG during PTC that coincided temporally with expression of the PTC behavior in kindled GEPR-9s, which was never seen in unkindled GEPR-9s.[57] The burst pattern of neuronal activity is known to be associated with neuroplasticity, which suggests that neuroplastic changes are occurring in the PAG of GEPR-9s that may contribute importantly to AGS kindling-associated epileptic network expansion and emergence of PTC.

Plasticity in the Amygdala-to-PAG Pathway in Audiogenic Kindling

As noted above, pathways from the amygdala to PAG are well documented, and the PTC behavior induced by AGS kindling may involve a reentry of AGS activity from the amygdala to PAG, as shown by a recent study inGEPR-9s.[59] Electrical stimulation in amygdala evokes neuronal responses in PAG in unkindled GEPR-9s, but PAG responsiveness to these stimuli is significantly increased in AGS-kindled GEPR-9s compared to unkindled GEPR-9s. These findings suggest that AGS kindling involves plastic changes in the amygdala-to-PAG pathway, which may be an important epileptogenic mechanism, mediating the emergence of the PTC behavior that is induced by AGS kindling.

Cerebral Cortical Neuronal Firing in Audiogenic Kindling

Cortical epileptiform activity is induced during AGS kindling in GEPR-9s and in GEPR-3s, which is absent prior to AGS kindling.[45] Neuronal changes in the cortex induced by AGS kindling have not been evaluated in GEPR-9s, but perirhinal cortex neuronal firing changes induced by AGS kindling in GEPR-3s were examined.[60] As noted above, AGS kindling in GEPR-3s induces an additional behavior, F & F clonus, immediately following generalized clonus.[45] Focal bilateral blockade of the perirhinal cortex resulted in complete and reversible blockade of only the F & F clonic seizure behavior in AGS-kindled GEPR-3s but did not affect generalized clonus before or after AGS kindling.[60] Significant increases in perirhinal cortex neuronal responses to acoustic stimuli were also induced by AGS kindling in GEPR-3s.[60] During F & F clonus in GEPR-3s, burst firing appeared in these cortical neurons. These findings support a critical role for the perirhinal cortex in the neuronal network for AGS kindling in GEPR-3s associated with the emergence of epileptiform cortical EEG activity and suggest that the epileptiform EEG activity seen in the cortex in GEPR-9s may involve neuronal firing changes similar to those seen in GEPR-3s.

Cerebral Cortex Neuronal Firing in Convulsant Drug-Induced Seizures

Convulsant drugs, such as bicuculline, induce major response increases in the CMR neurons in BRF, as noted above, and cerebral cortex neuronal responses are also increased in this model.[61] Neuronal responses to sensory stimuli in BRF and pericruciate cortex were recorded simultaneously in awake animals, and the neuronal responses to sensory stimuli in both structures were greatly enhanced following administration of subconvulsant doses of bicuculline (Fig. 20–4). The degree of enhancement in BRF neurons is somewhat greater in

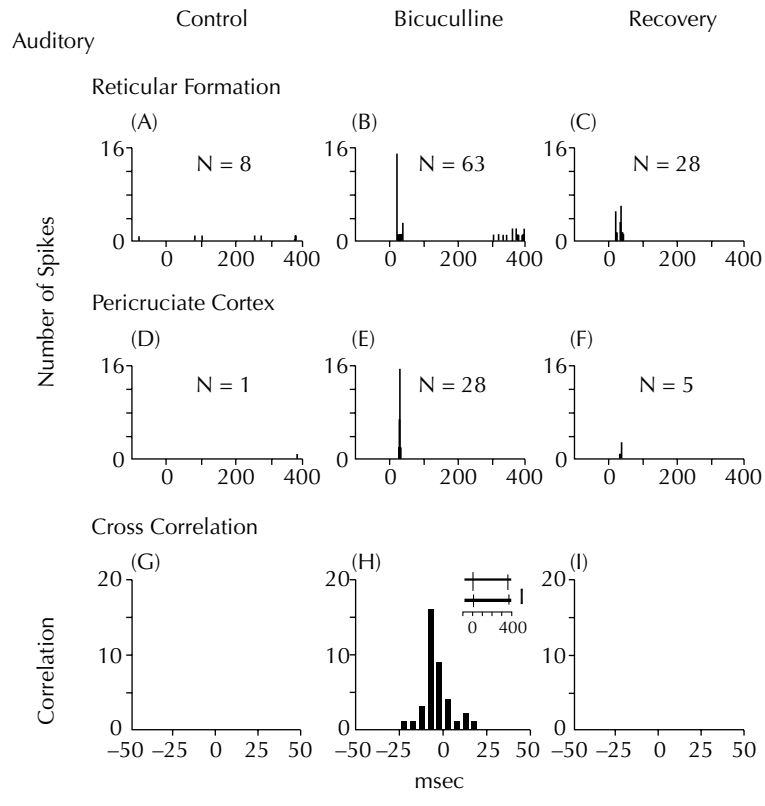

Figure 20–4. Typical example of the effect of a subconvulsant dose of bicuculline (0.08 mg/kg, i.v.) on neuronal firing in a midbrain BRF neuron (**A–C**) and simultaneously in a pericruciate cortex neuron (**D–F**), and the cross-correlogram (8 ms bin width) between these activities (**G–I**) in the awake cat. Few responses to the auditory stimulus were observed prior to bicuculline administration (**A,D**), with no detectable activity in the correlogram (**G**). Within 3 min of the drug's administration, both neurons became responsive to the stimulus (**B,E**), as illustrated by the peak in the peristimulus time histograms (PrSTHs). There was a major peak in the correlogram, with the midbrain BRF neurons firing consistently 15 ms prior to the cortical neuron, as shown by the negative values in the correlogram (**H**). (By convention, a negative value indicates that the BRF neurons fired first.) The neuronal responses gradually reverted to being minimally responsive 26 min after drug administration (**C,F**). No peak in the correlogram was present at this time (**I**). The inset in part H shows the three superimposed oscilloscope tracings for the raw data for both neurons (BRF in top trace) (calibration, 1 mV. *N* = number of action potentials in the PrSTHs. (Acoustic stimulus parameters: 1 ms duration click, 75 dB SPL, 0.5 Hz rate, 25 presentations, 400 ms duration, 1 ms bin width.) From ref. 61.

magnitude and occurs in a greater percentage of BRF neurons.[37,38] The latency of the responses to the stimuli is shorter in the BRF than in the cortex in 70% of cases. A large percentage of simultaneously recorded BRF and cortical neurons, which became responsive to the same stimulus, exhibited consistent convulsant-induced cross-correlations of firing, which were not present before drug treatment.[61] The latency and correlation data are consistent with the possibility that the BRF mediates the cortical enhancement. The bicuculline-induced correlation of firing of BRF and pericruciate neurons may be involved in the mechanism of initiation of convulsant-mediated seizure generalization induced by sensory stimuli. These findings may illuminate an important mechanism of reticulocortical synchronization.

INTERACTIONS BETWEEN NEURONAL NETWORKS

The CNS neuronal networks that mediate specific single physiological functions, such as hearing, can interact with other networks to produce many normal brain functions (e.g., acoustically-evoked startle), and such network interactions can also result in CNS disorders

(e.g., epilepsy). Such network interactions may also be important to the therapy of these disorders.[38] Network interactions often involve brain regions with high proportions of CMR neurons because of their extensive neuroplasticity, as noted above. Such network interactions are proposed to be a major mechanism for the induction of functional brain changes in positive directions, as in learning, or in negative directions, as in certain brain diseases. Network-mediated emergent properties of neurons can also be prominent targets for the action of CNS drugs in the intact brain.[7] The interactions between different networks can be competitive or cooperative as well as acute or chronic. Interactions between networks may involve sequential and/or simultaneous network activation. A critical nexus of network interaction in the production of generalized seizures is postulated to involve CMR brain regions, particularly the BRF. An example of sequential network interaction is the interaction of the normal auditory network and the normal locomotion network that occurs in AGS discussed above and illustrated in Fig. 20–1.

Epilepsy Network–Respiratory Network Interaction

Network interactions can also result in negative effects that have been observed in certain types of epileptic seizures, including that seen in sudden unexpected death in epilepsy (SUDEP). Human SUDEP is associated with respiratory difficulties in many human cases.[62] Many inbred and gene knockout mouse strains exhibit susceptibility to AGS, and in many of these mouse strains the seizure can be fatal.[11,16,17] DBA/1 and DBA/2 inbred strains of mice exhibit generalized convulsive seizures leading to respiratory arrest. These mice often die after AGS due to respiratory failure, and the incidence of death can be reduced or prevented by respiratory support, enhanced oxygen, or drugs that enhance respiration.[63] The DBA/2 and DBA/1 mouse animal models of SUDEP have been proposed to involve a negative sequential network interaction. This interaction is thought to involve activation of the sound-induced generalized convulsive seizure network that causes disruption of the normal respiratory network, with possible effects on cardiovascular networks. This network interaction leads directly to respiratory arrest immediately following the seizure (Fig. 20–5), which results in sudden death associated with subsequent cardiac failure, mechanisms proposed to be a major cause for human SUDEP.[16,17,62,63]

Pain Network–Epilepsy Network Interaction

Competition between networks can also exert positive effects. The neuronal network subserving analgesia is proposed to activate structures of the descending antinociceptive pathway that include the PAG,[64] which is implicated in epilepsy, as noted above. Periaqueductal gray neurons, unlike BRF neurons, are quiescent during postictal depression in GEPR-9s.[28] However, the PAG plays an important role during a significant period following postictal depression, during which the rats are less responsive to nociceptive stimuli. Thus, a reduction of pain responsiveness is noted in GEPR-9s, lasting for nearly 2 h after AGS.[65] Focal blockade of the PAG will prevent this form of analgesia.[65]

RETICULOCORTICAL SYNCHRONIZATION MECHANISMS

The CMR nature of BRF neurons may be a key mechanism in reticulocortical synchronization, since normally inactive BRF neurons can become highly active participants in neuronal networks that mediate seizures. Thus, in GEPR-9s, response habituation of BRF neurons to acoustic stimuli is significantly diminished[35] and may be a key element in the seizure network that mediates reticulocortical synchronization after AGS kindling.[11,26] Reticulospinal projections also become critical in epilepsy networks induced by convulsant drug interaction with stimulus-induced seizures, as discussed above.[37,38] The functional basis for the involvement of reticulospinal projections in motor convulsions may lie in the role that these projections are known to play in the normal neuronal network for locomotion.[8] The immense interconnectivity of BRF neurons provides extensive potential opportunities for

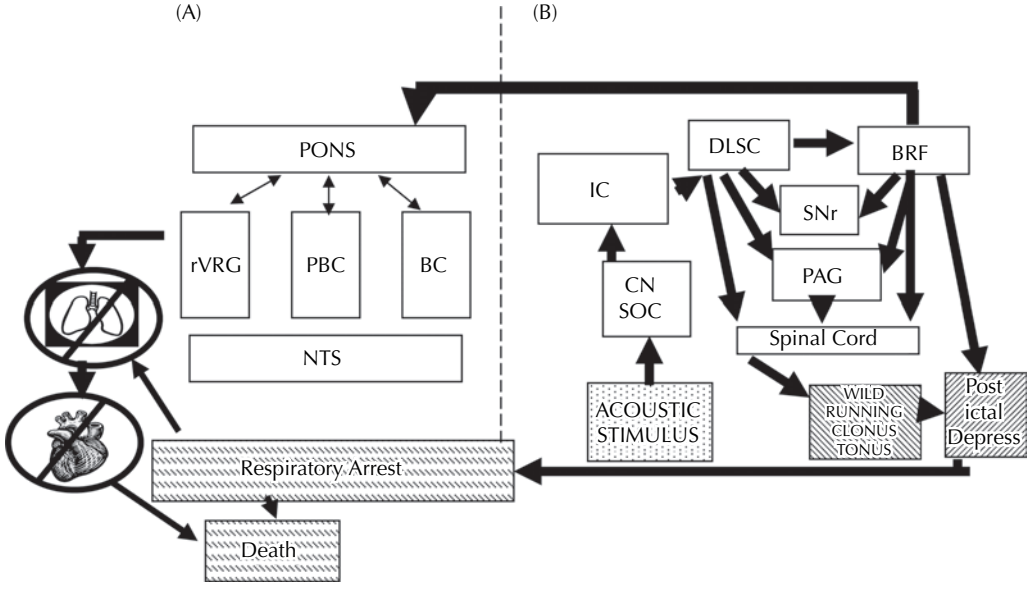

Figure 20–5. Diagram of network interactions involved in AGS that are postulated to occur in the DBA mouse models of human SUDEP, which exhibit AGS, leading to death due to respiratory depression. The diagram of elements of the normal network for respiration is shown in panel **A**. The diagram of the AGS network is shown in panel **B**. High-intensity acoustic stimuli activate the AGS network, which is postulated to involve a network interaction (based on that of GEPR-9s) between the normal brainstem primary auditory network nuclei cochlear nucleus (CN) and superior olivary complex (SOC) up to the level of the inferior colliculus (IC) and elements of the normal locomotion network, beginning in the deep layers of the superior colliculus (DLSC) and proceeding to the periaqueductal gray (PAG), substantia nigra reticulata (SNr), and brainstem (pontine) reticular formation (BRF), which project to the spinal cord. DBA mice that exhibit severe AGS (tonic hind limb extension) have postictal (seizure) depression of consciousness. The depression of consciousness is postulated to lead to BRF suppression, which produces a negative electrophysiological and neurochemical network interaction between the seizure network and the respiratory network. This leads to respiratory arrest and SUDEP, associated with subsequent cardiac failure. The latter events are believed to model a major cause of human SUDEP. Abbreviations: rVRG = rostral ventral respiratory group, PBC = pre-Bötzinger complex, BC = Bötzinger complex, NTS = nucleus tractus solitarius.

participation in various types of reticulocortical seizure networks, as originally suggested by Penfield and Jasper.[1]

The BRF neurons are known to be a key element in the neuronal network for the acoustic startle response.[66] High-intensity acoustic stimuli in an appropriate behavioral situation will evoke a major motor reaction (startle response) in humans and animals, but similar stimuli of lower intensities or in different behavioral situations do not evoke this motor response. In AGS-susceptible animals, the excessive output from IC neurons evoked by the high-intensity acoustic stimulus is projected to the hyperresponsive BRF neurons, and this results in intense output of BRF neurons along the reticulospinal pathway, which is critical in triggering the motor convulsions seen in AGS.[35] Thus, BRF neuronal hyperresponsiveness to sensory stimuli may lead to generalized seizures due to pathological intensification of the normal brain network that mediates the acoustic startle response. Since startle reactions can also be triggered by visual or somatosensory stimuli, the hyperresponsiveness of BRF neurons to these stimuli, which is induced by convulsant drugs, such as bicuculline, may also contribute to the generalized convulsions that are inducible by these stimuli in animals treated with otherwise subconvulsant doses of these convulsants.[37,38]

CONCLUSIONS

Penfield and Jasper[1] proposed that generalized seizures involve the BRF. Considerable research has confirmed a major role of the BRF in GTCS. Direct stimulation of the brainstem or spinal cord alone induces tonic muscular activity resembling the tonic convulsions of GTCS. Genetically epilepsy-prone rats

(GEPR-9s) are an epilepsy model that exhibits a genetically-based abnormally high sensitivity to seizure induction by a number of modalities, including high-intensity acoustic stimuli, which lead to convulsive AGS. The AGS in GEPR-9s end in tonic convulsions, and the neuronal network for these seizures requires only brainstem nuclei, including the BRF.[6] After periodic AGS repetition (AGS kindling) in GEPR-9s, the tonic seizures are followed by an additional behavior, PTC, and the resulting convulsive pattern closely mimics human GTCS, including cortical epileptiform EEG not seen prior to AGS kindling. After AGS kindling, the seizure network permanently expands from the brainstem to include the forebrain, leading to the idea that unkindled seizures of GEPR-9s are a "larval" form of GTCS similar to infantile spasms. After AGS kindling, the larval form develops into full-blown GTCS.[6]

The amygdala is a critical site in the seizure network expansion in AGS kindling, and extensive increases in amygdala neuronal firing are induced by AGS kindling. Focal blockade of amygdala blocks PTC, causing the seizures in kindled GEPR-9s to revert temporarily to the prekindled convulsive behavior. Microinjection of NMDA into amygdala of unkindled GEPR-9s induces PTC susceptibility, mimicking AGS kindling temporarily. However, when a cAMP activator (forskolin derivative) is microinjected into the amygdala of unkindled GEPR-9s, seizures, behaviorally identical to AGS kindling, are evocable indefinitely. These data suggest that AGS kindling-induced repetitive NMDA receptor activation in the amygdala triggers a molecular cascade, leading to the permanence of AGS kindling, in which activation of cAMP is critical, since pharmacological enhancement of cAMP levels in the amygdala leads to instant AGS kindling behavior after 2 AGS, which normally requires 14 AGS. This instant AGS kindling effect is also very long-lasting, similar to AGS kindling. Blockade of cAMP formation in amygdala of AGS-kindled GEPR-9s also reverses the effects of AGS kindling. Major amygdala projections to the brainstem, PAG, appear to be involved in PTC mechanisms, since extensive neuronal firing changes in PAG are also induced by AGS kindling. These findings suggest pathways and molecular mechanisms that may be important to epileptogenesis in human generalized tonic-clonic seizures.

Chapter 21

On the Basic Mechanisms of Infantile Spasms

John W. Swann
Solomon L. Moshe

The epileptic encephalopathies of early childhood are a challenge for both clinicians and basic scientists. For the clinician, these disorders are difficult to manage and most often respond inadequately to available therapies—particularly commonly used anticonvulsants. Indeed, disorders such as infantile spasms, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy (EIEE or Otahara's syndrome), and severe myoclonic epilepsy of infancy (Dravet's syndrome) commonly lead to persistent drug-resistant seizures and very poor neurodevelopmental outcomes including intellectual disabilities. Thus, there has long been a need for research scientists to address the underlying cause of these disorders so that they can be understood and rational treatments can be developed based on an understanding of the basic mechanisms. Indeed, in 2007, the National Institute of Neurological Diseases and Stroke (NINDS) at the National Institutes of Health (NIH-USA) included the creation of animal models of these disorders in their Epilepsy Research Benchmarks to encourage study of their basic mechanisms (http://www.ninds.nih.gov/research/epilepsyweb/2007_benchmarks.htm).

INFANTILE SPASMS: THE CHALLENGES

From the perspective of basic scientists, numerous barriers have hampered the study of these catastrophic epilepsies of childhood. Of the early epileptic encephalopathies, infantile spasms is the most common and occurs in approximately 1 in every 3225 live births. Numerous reviews have described the clinical

features of this syndrome.[1–6] However, these clinical descriptions provide few direct clues as to how the seizures are produced. The spasms do not arise immediately at birth but usually begin between 3 and 12 months of age—with a peak incidence at 6 months. The spasms themselves almost always disappear with time but are replaced by other types of refractory epilepsy—such as focal seizures or Lennox-Gastaut syndrome. This observation has led to the notion that the spasms may be an age-dependent manifestation of an underlying abnormality and that, as the brain matures, the neuronal substrate for the seizures changes and the behavioral and electrographic manifestations of the abnormality change as well. As the name *infantile spasms* implies, the seizures that characterize this disorder are unusual and typically consist of very brief (a few seconds) bilaterally symmetric contractions of muscles of the extremities, neck, and/or trunk, which result in brief flexion and/or extension jerking movements—leading originally to the use of the term *spasm*. The spasms can vary in their intensity from jerking movements that are very dramatic to very subtle ones that at times are hardly noticeable. Within a child, the intensity of the jerks can also wax and wan in their intensity. While the spasms can occur as single isolated events, they are observed more commonly in clusters, which can number more than 100 over a few minutes. In addition, these seizures commonly occur during periods of sleep-wake transitions.

The electroencephalographic (EEG) correlates of the behavioral spasms are equally unique and distinguish this syndrome from all other forms of epilepsy. Similar to the accompanying behaviors, the ictal complex of spasms is only a few seconds in duration. Figure 21–1 shows an example of an ictal complex. Typically, it begins as a generalized slow wave that is followed by an electrodecremental response (temporary flattening of the EEG) and a subsequent run of fast spiking activity.[7] However, there are often variations on this theme in which each of the components of an ictal event can be absent. Such variations can occur between patients and can occur from time to time in the same patient.[7] Electroencephalographic recordings during the interictal period show equally unusual electrographic events. Indeed, a defining and diagnostic feature of infantile spasms is a neurophysiological event called *hypsarrhythmia*.[8] Figure 21–2 shows an example of this highly abnormal EEG activity. This electrographic pattern is most often recorded during non–rapid eye movement (non-REM) sleep and consists of a seemingly chaotic mixture of asynchronous very-high-voltage slow waves intermixed with frequent large multifocal spikes. Classically, hypsarrhythmia has been described as random high-voltage slow waves and spikes that occur asynchronously in all cortical areas and change from one instant to the next. However as with the ictal complexes, variations in this pattern have been described.[9]

To study the basic mechanisms of infantile spasms, a very significant challenge is reproducing the distinct clinical features of this syndrome—that is, brief behavioral flexor/extensor spasms—and the signature ictal complexes and hypsarrhythmia in experimental systems. However, since the features of the syndrome are unique, if researchers were able to reproduce the features of infantile spasms in the laboratory, this would provide significant opportunities for advances in the understanding of its pathophysiology.

Another challenge in approaching infantile spasms is its highly variable etiology. Unlike temporal lobe epilepsy, in which status epilepticus is thought to be a primary cause, and which can be modeled in animals both in vivo and in experimentally simpler in vitro models, infantile spasms are associated with a very large number (over 200) of clinically distinct conditions.[3,10,11] Approximately 80% of patients are classified as having symptomatic infantile spasms, since they have a clearly identified underlying cause or are developmentally delayed. The remaining 20% have no identifiable cause and are referred to as *cryptogenic.* However, with advances in genetic, imaging, and other diagnostic testing, this percentage is likely to decrease in the coming years. Some of the broad categories associated with symptomatic infantile spasms are (1) central nervous system (CNS) infections such as meningitis, (2) developmental brain abnormalities or malformations such as cortical dysplasia, (3) hypoxic-ischemic encephalopathy, and (4) genetic syndromes such as Down syndrome and tuberous sclerosis complex. In terms of genetic causes, numerous single-gene mutations, deletions, or duplications have been linked to infantile spasms. These genes include *Arx*, *CDKL5*, and *MAG12*.[12–14] Interestingly, these have quite different functions in the

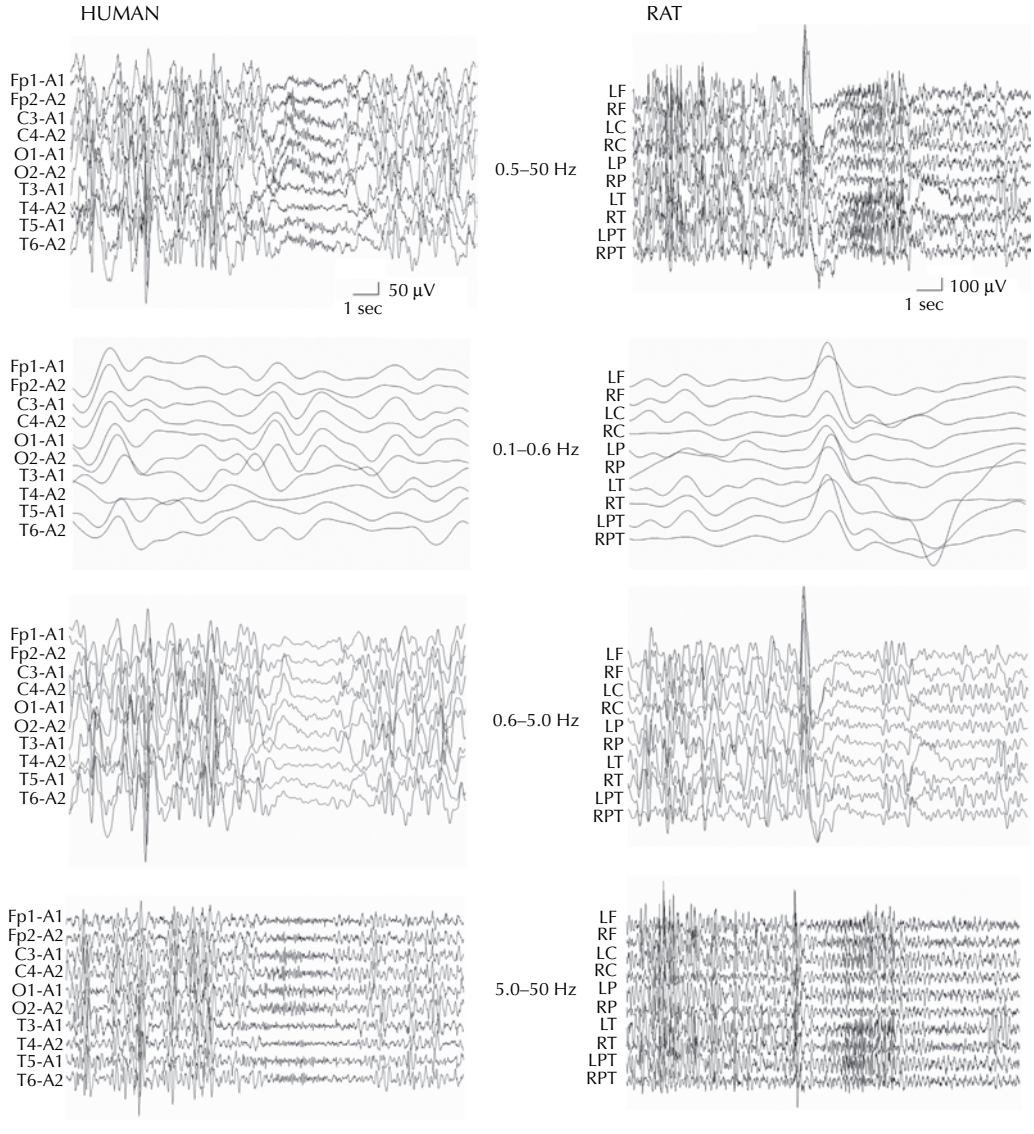

Figure 21–1. Ictal EEG discharges recorded in a human infant with infantile spasms and a rat that was infused in neocortex with tetrodotoxin (TTX). Infusion was initiated in infancy and persisted for 28 days. The top two panels show the original recordings. In the lower panels, selective bandpass filters (0.1–0.6 Hz, 0.6–5 Hz, and 5–50 Hz) were applied. In the recordings from the human, the ictal event consisted primarily of an electrodecremental response. For the rat, the ictal event consisted of an initial slow wave followed by an electrodecrement with superimposed fast activity. The electrodecremental response is clearly evident at frequencies of 0.6–5.0 Hz in both the human and the rat. The high-frequency fast activity predominates at frequencies of 5–50 Hz. The montage for the rat had electrodes positioned in: LF, RF—left and right frontal cortex; LC, RC—left and right central cortex; LP, RP—left and right posterior cortex; LT, RT—left and right temporal cortex; LPT, RPT—left and right posterior temporal cortex. The montage for the human corresponds to the International System of electrode placement. From ref. 60.

brain, which further amplifies the highly variable origins of infantile spasms.

The variable etiology of infantile spasms has led to speculation on the existence of a common mechanism(s) shared by all patients even though the associated and presumed causative conditions are so different.[3,15–18] Undoubtedly, it is quite remarkable that conditions as different as Down syndrome and meningitis can result in a seizure disorder with the same unique

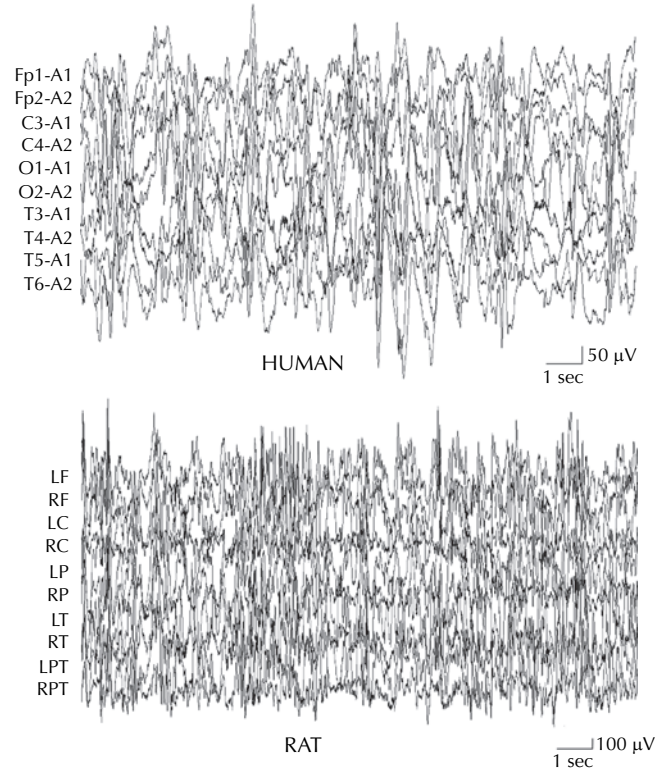

Figure 21–2. Comparison of interictal hypsarrhythmic patterns recorded in a human with infantile spasms and a rat whose neocortex was infused with TTX. The montages for the rat and human are the same as in Fig. 21–1. From ref. 60.

stereotyped clinical and electrographic features. How could a hypoxic-ischemic episode at birth, a mutation of a single gene such as *TSC1*, or a tumor all produce hypsarrhythmia and the ictal events of infantile spasms? Given that the product of more than 200 highly varied clinical conditions is the same (i.e., spasms), there must be a common final path that all these conditions converge on that produces this seizure disorder. There have been several suggestions as to what the shared mechanism might be, and these will be discussed later in this chapter in concert with potential new animal models of infantile spasms.

Another challenge in understanding the origins of infantile spasms is identifying where in the brain these seizures are generated. The EEG abnormalities are recognized as being generalized events. However, similar to the generalized spike-and-wave discharges of absence seizures, in which thalamic nuclei are thought to play key synchronizing roles, if researchers could identify the site(s) of spasm generation, this would greatly accelerate the discovery of the underlying mechanisms. Based on clinical observations, a general consensus has emerged in recent years that spasms likely result from abnormal interactions between cortical and brainstem neural networks.[5,10,16,19] Observations favoring a cortical contribution are that some children with infantile spasms have cortical malformations or injuries and that seizures in children can be eliminated by removing cortical abnormalities during epilepsy surgery. Moreover, positron emission tomography (PET) imaging studies have reported regional hypometabolism in the cortex of a majority of children with this disorder.[20–22] Hypsarrhythmia, since it is generalized across cortex, also suggests significant abnormalities there. On the other hand, altered brainstem function is suggested by the occurrence of abnormal sleep patterns and the common occurrence of spasms during sleep-wake transitions.[23] However, it is obvious even from this brief summary that there is a paucity

of data directly implicating specific neural networks of the brainstem or cortex in seizure generation.

Finally, potential clues to the mechanisms underlying infantile spasms come from its unique profile of pharmacological responsiveness. As mentioned earlier, spasms in infants are usually unresponsive to conventional anticonvulsants. However, in 1958, spasms were reported to respond to treatment with adrenocorticotropic hormone (ACTH).[24] The rationale behind the initiation of this therapeutic strategy is unclear. However, since that time, a number of clinical trials have been completed and it has been shown that, while not all children respond to ACTH, between 42% and 87% (depending on the study) of patients do respond by achieving complete cessation of clinical spasms (both behavioral and EEG) and elimination of hypsarrhythmia on prolonged EEG recordings.[25–28] The effects of ACTH are considered to be all-or-none and are in this respect unique in epilepsy therapeutics. Many have considered the complete elimination of hypsarrhythmia to be critical in order to prevent the continued progression of the disorder to other forms of epilepsy and impairments in cognition. Thus, an all-or-none effect has been considered an important endpoint in clinical trails—at least in the United States.

The site and the mechanism of action of ACTH remain an enigma. In fact, the blood-brain barrier is thought to be quite impermeable to ACTH, so its action in the CNS has been questioned. However, high doses of ACTH are often used therapeutically, and some think that enough ACTH gets into the CNS to be effective.[27] Alternatively, ACTH could be acting on the adrenal to stimulate the release of steroids, which in turn could act on the brain to suppress spasms. There is evidence that steroids can be effective in suppressing spasms, but in a head-to- head trial, prednisone was found to be less effective than high-dose ACTH.[27] This has led some to conclude that ACTH may be acting centrally to suppress seizures. Yet, questions linger since prednisone or prednisolone is effective in some patients, as the United Kingdom Infantile Spasms Study (UKISS) has emphasized.[28,29] Currently in the United States, ACTH therapy is considered "probably effective" in the treatment of infantile spasms by a joint commission of the American Academy of Neurology and the Child Neurology Society (AAN/CNS).[30] Nonetheless, it is clear that current therapies are not ideal. ACTH, the recommended treatment, can have significant side effects in some patients, especially when high doses are used.

It also remains a possibility that other treatments will be effective for subtypes of spasms, depending on their etiology. For instance, vigabatrin appears to be quite effective in suppressing spasms in children with tuberous sclerosis complex (TSC); it has been used in Europe for well over a decade and was approved in the United States in 2009 for this purpose.[31] However, it appears to be less effective in patients with spasms of other etiologies. In this regard, results of a UKISS study suggest that vigabatrin may be less effective than steroids.[28] Much interest has been engendered by a recent report suggesting that treatment of TSC patients with vigabatrin before the onset of seizures can be preventive.[32]

In this regard, some reports have emphasized the importance of treating children not necessarily before but as soon as possible after the onset of spasms, since results suggest that early treatment can lead to better long-term outcomes, including a reduction in the proportion of patients with epilepsy and impaired cognition.[33,34] It is thought that later treatment may still suppress spasms, but it may not be as effective in ameliorating their long-term sequelae. While these ideas remain controversial, they are in keeping with the notion that infantile spasms is a progressive disorder—akin to some other forms of epilepsy—and that the spasms themselves have consequences for normal brain development. However, it is important to note that even if the spasms are controlled by currently used therapies, many infants will still develop epilepsy and/or cognitive deficits, including autistic features, regardless of the etiology of the condition (with the caveat that cryptogenic cases, i.e., those without a clear pathology, usually have better outcomes). Whether this is because the child was treated too late in the course of the syndrome or because the therapies were simply ineffective in blunting the progression of this disorder is unclear. However, until very recently, the lack of animal models of infantile spasms has prevented a detailed examination of whether the syndrome can be progressive and the possible mechanisms underlying epileptogenesis.

INFANTILE SPASMS: THE QUESTIONS

Based on this review of some of the challenges associated with treating and understanding the pathophysiology of infantile spasms, there are many questions that need to be answered if we are to begin to understand the cellular and molecular mechanisms responsible for this seizure disorder and develop new and hopefully rational therapies for these children. The following list summarizes some of the questions.

1. How can one interpret the natural course of this seizure disorder in terms of its underlying mechanisms? Why do spasms occur in clusters during infancy? Is the disorder progressive? And if so, what are the mechanisms underlying the dramatic changes that occur over time? Are there underlying mechanisms of epileptogenesis? Or is the precipitating mechanism(s) unchanging and the alterations (e.g., in seizure phenotype, from infantile spasms to Lennox-Gastaut syndrome or subsequent focal seizures) that occur with time a reflection of a relatively static mechanism(s) interacting with the ongoing development of the brain, its neurons, and maturing networks? Or is it a combination of interactions between a progressive epileptogenesis and brain development?
2. If there is a shared final common path between the 200 conditions associated with the disorder and the products—the behavioral spasms, associated EEG abnormalities, and impaired cognition—what is it? If there are unique treatments for subtypes of infantile spasms (e.g., based on different etiologies: i.e., vigabatrin for TSC), does this mean that there are parallel paths for generating infantile spasms? Or, in this instance, is vigabatrin acting upstream before convergence on the final pathway?
3. Why do some but not all infants with the same underlying condition (e.g., perinatal asphyxia or TSC) develop spasms? Are there additional contributing factors? Is there a genetic predisposition?
4. Where in the brain do the spasms originate? Do they arise from cortex and/or brainstem, as some suggest, or somewhere else? And if so, where in cortex and which brainstem nuclei are responsible? And importantly, what neuronal subtypes in each area not only participate in spasm generation but also initiate the seizures? For instance, are principal neurons the key participants and initiators, and do different subpopulations of interneurons (some possibly dysfunctional) contribute in unique ways to spasms or hypsarrhythmia?
5. What is the basic mechanism underlying hypsarrhythmia? Where is it generated, and which neuronal subtypes participate in its generation? Do hypsarrhythmia and the ictal complexes of spasms share common mechanisms or are they independent electrophysiological phenomenon? What is more detrimental for long-term outcomes, hypsarrhythmia or the spasms themselves?
6. Why do spasms wax and wane in their intensity? What does this say about the underlying mechanisms? How well does behavioral spasm intensity correlate with alterations in ictal complexes recorded simultaneously? If they correlate or not, can this provide clues to underlying mechanisms?
7. Why do children with infantile spasms become cognitively impaired—many severely so? Do the spasms themselves contribute in any way to cognitive decline? What is the role of hypsarrhythmia in these developmental disabilities?
8. What is the mechanism of action of ACTH therapy? And what can this tell us about the mechanisms responsible for spasm generation?
9. How will new therapies be developed not only to control the spasms but also to prevent the development of other epileptic phenotypes and improve the cognitive outcome? Will one drug type be sufficient or is a cocktail of drugs required to target different processes?
10. As many as 50% of children with infantile spasms are currently refractory to all available therapies—including ACTH. Does this suggest that there are different mechanisms for spasm generation in these children, and will they require different types of treatment?

INFANTILE SPASMS: THE OPPORTUNITIES

It has long been thought that an understanding of the basic mechanisms of infantile spasms would be accelerated by the creation of animal models that would permit a detailed examination of the underlying cellular and molecular causes. However, until recently, this has proved to be a difficult undertaking for several reasons. The rational approach for the creation of animal models would be to reproduce one of the clinical conditions most commonly associated with the disorder in immature laboratory animals with the hope that these animals would develop a disorder mimicking what is seen in humans. For example, there are numerous animal models of neonatal hypoxic-ischemic encephalopathy, which have been studied for many years, but there are no reports of these animals having a condition like infantile spasms—although some can develop seizures later in life.[35] Perhaps this result, although disappointing, may not be unanticipated since not every child who suffers a hypoxic-ischemic episode will develop infantile spasms. Perhaps a more considered approach would be to choose a disorder in which the frequency of spasms is very high. The genetic disorder TSC is a good example since the frequency of infantile spasms in these children can be as high as 40%–50%.[36] Considering the advances made in human and mouse molecular genetics over the past decade, creating mutant mouse models that reproduce genetic disorders in children has become commonplace. And indeed, several mouse models of TSC have been created. Yet, while some of these mice develop severe epilepsy, a condition similar to infantile spasms has never been reported despite extensive experimental investigations of these mice.[37,38] Such findings have led some investigators to speculate that perhaps the rodent brain is simply not sufficiently advanced in evolutionary terms to reproduce the highly stereotyped neurological abnormalities that characterize the more complex human infant brain. However, this does not appear to be the case because in the last few years, seven different laboratories have reported models of infantile spasms either in mice or in rats. Although these are very early days in the characterization and study of all of these animal models, there is every reason to hope that one or more of them will provide unparalleled opportunities to study the basic mechanisms of this disorder.

Before reviewing the features of the animal models, it is important to discuss the criteria a model needs to meet in order to be considered a valid model of this syndrome. Unfortunately, at this early stage in model characterization, there appears to be little consensus on what features of the human condition an animal model must possess for it to be consider a valid model. In 2006 a report from a NIH/NINDS workshop on animal models of pediatric epilepsy was published. Based on the discussions at the workshop by leaders in the field, a list of criteria for an "ideal" model of infantile spasms was developed.[39] These included:

1. Unprovoked spasms early in postnatal development that occur in clusters
2. EEG correlates of the ictal complex (including the electrodecremental response)
3. Abnormal interictal EEG—hypsarrhythmia
4. Response to clinically relevant treatments (e.g., ACTH and/or vigabatrine)
5. Behavioral/cognitive sequelae

In this regard, the use of the term "*ideal*" needs to be emphasized. In numerous reviews and discussions of models, it is often noted that it is unlikely that any one animal model will meet all of these criteria but that this does not prevent it from advancing our understanding of the mechanisms of infantile spasms.[40] Perhaps a more useful list needs to be agreed upon by the scientific community that includes the *minimal* criteria required to model this disorder. And if these criteria are not met, it would not be considered a model of infantile spasms. Of course, this would not mean that the model is not important in the study of the basic mechanisms of epilepsy—if the animals had other types of seizures—or in the study of the consequences of gene mutations in a genetically engineered mouse that mimics gene mutations associated with human spasms. It would just mean that the model would not be useful in answering questions like those listed earlier concerning this syndrome. Recently, one review mentioned minimum criteria consisting of (1) an abnormal EEG, (2) spontaneous seizures that begin in the postnatal period but not necessarily spasms, and (3) cognitive deficits.[41] Another review considered (1) seizures in infancy and (2) ACTH

responsiveness as minimal criteria.[42] Clearly, significant debate and discussion will be necessary to resolve such differences of opinion. However, ultimately, the utility of any animal model will depend on its ability to answer basic questions concerning the pathophysiological mechanisms of this disorder. It is hard to envision how an animal model would be useful in studying infantile spasms if it does not at least include behavioral spasms and the EEG correlate of ictal complexes observed clinically. It would also be preferable if the spasms were initiated in infancy. It may also be necessary to construct models of infantile spasms refractory to the current clinically used treatments in order to identify new approaches. In the reviews that follow, we will attempt to highlight the features of the proposed animal models and their advantages in terms of addressing pressing questions concerning the pathophysiology of this disorder.

INFANTILE SPASMS: PROPOSED ANIMAL MODELS

The Conditional Deletion of the Aristaless-related-homeobox Gene (*Arx*) Mouse Model

The X-linked *Arx* gene encodes a transcription factor that is likely involved in early cortical development.[43] Mutations of this gene can be associated with a variety of clinical phenotypes including mental retardation, epilepsy, and the infantile spasm syndrome, X-linked lissencephaly with abnormal genitalia (XLAG) [41]. *Arx* appears to be critical in neurodevelopmental processes such as progenitor cell proliferation and neuronal migration. Based on observations that patients with XLAG and mice with similar mutations of *Arc* have deficits in interneuron migration from the basal ganglion,[43,44] Kato and Dobyns hypothesized that infantile spasms—at least in XLAG—could be due to deficits in cortical interneuron function and thus coined the term *interneuronopathy* as the basis for infantile spasms in these patients.[18] Indeed, the loss of interneurons from cortex could be a mechanism that many conditions converge on to produce infantile spasm. Thus, interneuronopathies could be critical component of a final common path to the production of spasms.

To test the interneuronopathy hypothesis, Marsh and colleagues selectively eliminated *Arx* from interneurons arising from the basal ganglion by crossing mice carrying a floxed *Arx* allele with Dlx5/6^{CIG} mice.[45] Neuroanatomical studies have confirmed deficits in subpopulations of interneurons in the cortex. Importantly, EEG recordings have shown that male mice carrying this mutation have epilepsy. Hypsarrhythmia was not observed, However, spasm-like behaviors were observed in adulthood, and these were reported to be correlated with a spike and slow-wave complex followed by an electrodecrement on EEG recordings. Surprisingly, video-EEG recordings from younger mice did not show similar spasms but instead limbic seizures. There is no easy explanation for the late onset of spasm-like events in this animal model. Electroencephalographic recordings from infant mice can be challenging, and the authors were only able to record for 24 h in three mutant male mice. Perhaps more prolonged recordings would reveal the presence of earlier spasms in these mice. Nonetheless, the direct link between human genetic abnormalities and the creation of relevant mutant mice is a powerful approach. Discoveries made with this model and the development of experimental tools to study interneuron deficits could lead to testing of the interneuronopathy hypothesis in other animal models of infantile spasms. The development of new technologies that allow routine video-EEG recordings over extended periods from infant mice would accelerate progress in characterizing such mouse models.

The Triple Repeat Expansion Model of *Arx*

This mouse model is based on the discovered link between mutations in the *Arx* gene and infantile spasms reviewed above. Since knockout of *Arx* in mice results in perinatal lethality,[43,44] Price and colleagues used a knockin strategy to engineer a targeted expansion of the first polyalanine tract in *Arx*.[46] This is the mutation very commonly associated with infantile spasms in humans.[47] Multiple neurobehavioral phenotypes were discovered in the resultant mice. As anticipated, based on *Arx* expression in the precursors of neocortical interneurons, the loss of subpopulations of interneurons was

observed. Behavioral spasms were observed in both control and mutant mice between postnatal days 7 and 11. Two types were described: low- and high-amplitude spasm-like movements. There were no differences between the frequency of the low-amplitude myoclonic events in mutant mice compared to controls. However, there were twice as many high-amplitude movements in the mutant mice. While EEG recordings on postnatal days 7 –11 were not possible, it was reported that EEG recordings on postnatal days 16–20 showed a high-amplitude slow wave followed by attenuation of the background EEG activity concurrent with brief myoclonic jerks. In older mice (24 to 70 days of age), spasms were not observed; instead, limbic motor seizures as well as 6s spike wave bursts—accompanied by behavioral arrest—were seen. Hypsarrhythmia was not reported in this mouse model. However, cognitive impairment and abnormal social interactions suggestive of an autism phenotype were observed.

Thus, this animal model has several desirable features for a model of infantile spasms. Again, the lack of quality EEG recordings from infant mice are a significant barrier to a full description of the spasm phenotype in infant mice. It would be interesting to know what the EEG correlates are of the high-amplitude spasm-like movements in control mice. Study of this mouse model in concert with the *Arx* conditional knockout described above should lead to a better understanding of the role interneuron loss may play in the pathophysiology of seizures and, in particular, infantile spasms. Study of the origins of the neurobehavioral abnormalities in these mice could address the roles of interneuron loss and/or seizures in these cognitive and autistic phenotypes that are often seen in patients with a history of infantile spasms.

The NMDA Model

Intraperitoneal injections of *N*-methyl-D-aspartate (NMDA), a glutamate receptor agonist, in rats on postnatal days 12 to 18 produce hyperflexion and tonic spasms of the body.[48,49] These have been reported to be concurrent with a slow wave and a subsequent electrodecrement on EEG recordings from cortex, although other neurophysiological discharges can occur.[50] Recently, this model has been modified by prenatal treatment with betamethasone on gestational day 15.[50] Although the rationale underlying this experimental strategy has not been fully articulated, it appears that it is an attempt to mimic prenatal stress. This treatment sensitized rats to NMDA since they responded at lower doses of the drug. In addition, rats became responsive to ACTH in that the latency to onset of NMDA-induced spasms was increased. Since the seizures were not blocked, this is not fully in keeping with the all-or-none effects of ACTH seen clinically. Additionally, ACTH usually takes days to become effective in children and commonly does not act immediately, as reported for this model. The drawback of this model is that the spasms are evoked by NMDA and do not occur spontaneously. However, as with other models described below, it could be useful in rapidly screening drugs for efficacy against spasms—assuming that the scientific community as a whole concludes that the spasms evoked by NMDA are relevant to those that occur clinically.

The Down Syndrome–Ts65Dn Mouse Model

The incidence of epilepsy in Down syndrome is significant; approximately 8% of patients have epilepsy and a third of these have infantile spasms. The Ts65Dn mouse, which is segmentally trisomic for the distal end of chromosome 16, is an accepted model of Down syndrome.[51] While spontaneous seizures have never been reported in these mice (with the caveat that audiogenic seizures can be triggered in these animals by intense noise), these mice have increased gamma-aminobutyric acid B ($GABA_B$) receptor-mediated currents, which likely result from overexpression of the GIRK2 channel due to the extra copy of this gene on chromosome 16. Since $GABA_B$ receptor agonists have convulsant properties in rodents, Cortez and colleagues thought that it is possible that treatment with these drugs might induce seizures and possibly even spasms in this mouse model.[52] Results showed that such treatments produced absence seizures in control mice but clusters of extensor spasms in the Ts65Dn mouse. Each spasm in a cluster appeared to be associated with burst discharges on EEG recordings that were separated by a marked attenuation in cortical

activity. This type of activity was observed from 1 week to 2 months postnatally. Mice were also used to screen the effectiveness of a number of anticonvulsants. Valproic acid, ACTH, ethosuximide, and vigabatrin were all reported to be effective in suppressing spasms. Like the clinically reported effectiveness of vigabatrin in TSC patients, results from this mouse model suggest that infantile spasms in Down syndrome patients may have a unique pharmacological responsiveness—which could include more conventional anticonvulsants. However, it would be important to know if the enhanced $GABA_B$ receptor function also occurs in Down syndrome patients. The advantage of this mouse model is its ease of use in drug screening. A drawback is that seizures are not spontaneous and are evoked by drug treatment. The consequences of the spasms in terms of epilepsy or neurobehavioral deficits have not yet been reported.

The CRH Hypothesis

Since ACTH is effective in suppressing infantile spasms, Baram and colleagues have pursued the molecular mechanisms by which it acts.[53] It is known from neuroendocrinology studies that systemic ACTH treatment can act through classic negative feedback systems to downregulate the expression of corticotropin releasing hormone (CRH) in the CNS.[54] This can be mediated in part by steroids that are released from the adrenal or by ACTH itself. Importantly, CRH has been shown to be a potent convulsant drug and is particularly effective in infant rats.[55] Thus, a reasonable hypothesis has been proposed that ACTH acts in infantile spasms to suppress CRH expression and thereby decrease neuronal excitability. This hypothesis has been extended to suggest that prenatal or perinatal stress may be a common factor in the etiology of infantile spasms and may be an important part of a final common path that leads to the generation of spasms.[17] It is likely that many infants with spasms have undergone some form of stress earlier in their lives. Stress is thought to increase CRH levels in the brain, and ACTH treatment may act to normalize CRH levels. While investigators continue to actively pursue these ideas, there are several shortcomings that limit enthusiasm for them at this time. It is well known that CRH produces severe limbic motor seizures in infant rats and has never been reported to produce spasm-like behaviors. Moreover, EEG recordings during CRH-induced seizures show rhythmic sharp activity consistent with seizures arising from the limbic system.[56] Neither ictal complexes nor hypsarrhythmia have been reported in recordings from CRH-treated mice. Thus, despite the strength of the rationale underlying the CRH/stress hypothesis, the link between infantile spasms and CRH remains strictly hypothetical at this time. However, it is possible that treatment of the brain with exogenous CRH is unable to mimic the effects of its release locally from neurons. And if a more physiological condition could be produced in which the effects of endogenous CRH were evoked, spasm-type seizures and EEG correlates might be seen.

The Multiple-Hit Model

Based on the notion reviewed earlier that infantile spasms results from abnormal interactions between cortical and subcortical networks—particularly those in the brainstem—Scantlebury and colleagues developed a multiple-hit model of infantile spasms.[57] In this model, investigators have simultaneously produced pathological abnormalities in cortical and subcortical brain areas of infant rats. To accomplish this on postnatal day 3, doxorubicin is injected intraventricularly and lipopolysaccharide is injected into the right cerebral cortex. Doxorubicin is an anthracycline chemotherapeutic agent that injures and kills neurons through oxidative stress, while lipopolysaccharide is a toxin released from gram-negative bacteria that is able to damage white matter and activate inflammatory cells. Two days after these treatments, rats are injected intraperiotoneally with *p*-chlorophenylalanine to deplete serotonin in the brain by blocking the synthesizing enzyme, tryptophan hydroxylase. This is used in an attempt to increase neuronal excitability. Rats display clusters of flexor or extensor spasms from postnatal day 4 to postnatal day 13, and other seizure types begin to emerge after postnatal day 9 that resemble limbic motor seizures. The EEG correlates of spasms are complex. Similar to humans, spasms have electrographic correlates in only 49% of events. Electrodecremental responses (i.e., attenuation of background activity) were

observed in 27% of spasms that had electrographic correlates. The remaining 73% of spasms with electrographic correlates coincided with spike and sharp-wave discharges and/or fast rhythmic activity. The interictal EEG was also abnormal and consisted of high-amplitude spikes and slow waves. Treatment with ACTH was found to be ineffective in this model, and vigabatrine suppressed seizures but only transiently on postnatal day 5. The rats also displayed numerous neurobehavioral deficits including learning and memory deficits, stereotypes, and impaired socialization suggesting a possible autism-like phenotype. As would be expected from the treatments used, neuroanatomical examination of the brains of these rats showed marked neuropathologies including a reduction in the thickness of the right cortex and diffuse damage to the corpus callosum, striatum, hippocampus, and thalamus, among other structures. The advantage of this model is that it may reproduce the drug-resistant symptomatic refractory spasms that are encountered clinically and therefore could be useful in screening for new treatments for this patient population.

The TTX Model of Focal Neocortical Inactivation

In contrast to many of the models of infantile spasms, the rationale behind using local infusion of tetrodotoxin (TTX) in the brain to induce infantile spasms in rat pups is not immediately apparent. Indeed, this experimental strategy was initially employed to examine the role of neuronal activity in postnatal development of the hippocampus, not to develop a model of childhood epilepsy.[58,59] Unexpectedly, however, rats treated in this way developed very brief seizures, and later it was discovered that these seizures closely resembled infantile spasms.[60] In this model, TTX (10 μM) is chronically (for 28 days) infused by an osmotic minipump into either the hippocampus or the neocortex of rats beginning on postnatal days 10–12. Identical infusions a few days later do not produce spasms or seizures. 2-Deoxyglucose studies showed that the treatment produces a region of neuronal inactivation approximately 2.5 cm in diameter centered on the tip of the infusion cannula. Thus, this treatment may mimic the regional neocortical hypometabolism reported from PET studies of patients with infantile spasms.[20–22] Initial behavioral observations showed that seizures begin sometime before postnatal day 21 and consist of brief (1–2 s) flexions or extensions of the trunk and/or forelimbs. Multichannel video-EEG recordings show that behavioral spasms are concurrent with a generalized ictal complex that is virtually identical to that seen in humans. Figure 21–1 compares an ictal complex from a rat to that recorded from a patient. The complex begins with a large slow wave followed by an electrodecremental response on which runs of spikes are subsequently superimposed. The spasms frequently occur in clusters of as many as 50 spasms, and most often occur during sleep-wake transitions. Interictally, patterns of hypsarrhythmia are recorded in the majority of animals having spasms, and these have a frequency spectrum very similar to that recorded in human infants. Figure 21–2 shows an example of hypsarrhythmia from a rat in comparison to that from a human. The spasms usually persist for 2 months, but eventually rats develop severe limbic motor seizures by 6 months of age. The pharmacological responsiveness to ACTH and vigabatrin has not been evaluated, nor have learning and memory deficits been fully characterized in these animals. The advantage of this model is the robust nature of the EEG recordings and how closely they mimic those of humans. Thus, the model could be exploited to study the cellular neurophysiology of infantile spasms. Indeed, a recent study using high digital sampling rates followed by compressed spectral array analysis and bandpass filtering showed that high-frequency EEG activity occurs throughout ictal events in these animals and prominently during the electrodecrement that is recorded using conventional EEG filter settings.[61] Studies are needed to determine the age of onset of spasms in the animals and to characterize their evolution to the condition seen on postnatal day 21—a process possibly akin to epileptogenesis.

Recently, Frost and Hrachovy[3] proposed the developmental desynchronization model for infantile spasms. Like the interneuropathy and CRH/stress models discussed above, this model is an attempt to describe a common pathophysiological mechanism that could result from the myriad etiologies associated with this disorder. Put simply, this model suggests that infantile spasms result from a

temporal desynchronization of two or more ongoing neurodevelopmental processes. The desynchronization could be caused by injury to the brain or a mutation in a gene important for neuronal development, among the many other etiologies for this disorder. At the systems, cellular, and molecular levels, normal brain development is thought to be dependent on reinforcing interactions between networks of cells and networks of molecules. It is hypothesized that when one developing system is delayed or accelerated relative to its maturational partners, a developmental desychronization results that produces infantile spasms. Features of the TTX model are consistent with the concept of developmental desynchronization since it is well known that neuronal activity plays an important role in the normal course of neuron and network maturation.[62] By suppressing neuronal activity with TTX in a portion of the neocortex, one would expect that the maturation of neurons in that region would be altered and possibly delayed compared to their synaptic partners at distant sites. Thus, the development of TTX-exposed cells should be out of sync with that of unexposed cells that continue developing at a normal pace. At this time, it is unclear how such maturational desynchronization could lead to infantile spasms, but different types of desynchonization resulting from different etiologies would have to converge on a *critical system* that would initiate the pathophysiological mechanisms in a shared or common pathway leading to spasms in children. Validated animal models could be important tools used to support or refute such theoretical models of pathogenesis and should help identify hypothesized critical systems and common pathways—if they exist.

CONCLUSIONS

We are at a very early stage in studying the basic mechanisms of infantile spasms. However, features of several promising animal models have been described, and more may be forthcoming in the near future. Technical challenges are substantial in studying seizures in infant rodents, but they are not insurmountable. The basic science and clinical communities need to evaluate each of the proposed animal models and develop minimal criteria for what they consider to be a valid animal model of this disorder. Once validated, models should provide an unprecedented opportunity to study the mechanisms responsible for this catastrophic epilepsy and hopefully provide new avenues for effective therapies.

Chapter 22

Fast Oscillations and Synchronization Examined with In Vitro Models of Epileptogenesis

Roger D. Traub
Miles A. Whittington
Mark O. Cunningham

For many years, interictal spikes, recorded in a patient's electroencephalogram (EEG), were considered to be a primary indicator that the patient might indeed have epilepsy and that the patient's seizures (when they occurred) were likely to begin in the vicinity of the interictal spike generator. That interictal spikes could often be recorded at the scalp, without the necessity of invasive recording procedures, contributed to their clinical usefulness. A question of continuing importance to basic epilepsy research was naturally this: what factors determine whether "epileptogenic tissue" will produce interictal spikes,[1] unequivocal seizure activity, or something intermediate?

It now appears, however, that very fast oscillations (VFO, >70–80 Hz), in electrocorticographic (ECoG) or depth electrode recordings, may have more localizing significance than do interictal spikes.[2–5] Furthermore, recent in vitro studies of human epileptogenic tissue indicate that VFO is the primary event during an interictal field transient—meaning that such field transients always contain VFO, possibly

riding upon slower fields produced by synaptic currents. Conversely, however, VFO can also occur alone, without the synaptic components; in contrast, the slower synaptic components do not occur without VFO[6] (see the later discussion). Numerous reports, as well, have documented that localized VFO (typically lasting for seconds) precedes electrographic seizures.[7–12] It remains to be determined whether such VFO causes the seizures or is rather the first manifestation of a pathological tissue state (awaiting more precise characterization) that is prone to generate both VFO and also seizure activity.

Unfortunately, VFO detection requires, in general, invasive recording techniques and is therefore not available for the clinical evaluation of most epilepsy patients. Nevertheless, understanding the pathogenesis of epilepsy clearly requires learning more about VFO mechanisms. In this chapter, we shall review relevant ultrastructural, in vitro slice, and computer modeling data. We shall also review evidence that proposed in vitro VFO mechanisms are applicable to the in situ brains of actual epilepsy patients. The gist of the chapter is that VFO requires the presence of sufficient gap junctional coupling between principal neurons and that VFO does not require chemical synapses—and indeed may even be facilitated by the blockade of chemical synapses.

DATA INDICATING THE EXISTENCE OF GAP JUNCTIONS BETWEEN PRINCIPAL CORTICAL NEURONS

Before considering very fast network oscillations, let us first discuss their proposed structural underpinnings: electrical coupling between the axons of principal neurons. This discussion is essential, especially given that the subject remains controversial. Our treatment here is compressed; the subject is analyzed in more depth in our recent monograph.[13] The issues are controversial because more data are required, because gap junction pharmacology is difficult, and perhaps because the ideas are novel.

That principal cortical neurons are electrically coupled was shown first, with dual intracellular recordings, by MacVicar and Dudek[14] and was recently confirmed by Mercer et al.[15] An essential issue, however, is to determine *what parts* of the neurons are coupled together: axons, somata, dendrites, or some combination. This issue is important, because the functional properties of gap junctional coupling—in particular, whether action potentials pass from one cell to another—strongly depend on the electrophysiological behavior of the membranes at, and close to, the site of coupling. There is no evidence (of which we are aware) for somatic coupling in mature tissue. There *is* evidence for axonal coupling of two basic types: structural and functional. The structural evidence can, in turn, be broken down into (1) dye coupling and (2) ultrastructure. It has long been known that pyramidal neurons can be dye-coupled and that alkaline pH increases the extent of coupling.[16,17] (The conductance of at least some sorts of gap junctions is pH-sensitive.) In addition, however, Schmitz et al.[18] demonstrated with confocal imaging of CA1 pyramidal neurons that it was "kissing" *axons* that allowed for the passage of fluorescent dye from one neuron to another (by light microscopic criteria). So far as ultrastructure goes, putative gap junctions between hippocampal mossy fibers have been shown by transmission electron microscopy, and a connexin36-containing gap junction has been visualized with freeze-fracture immunogold replica labeling (FRIL) on a mossy fiber axon (Fig. 22–1 and ref. 19).

So far as *functional* evidence goes, Schmitz et al.[18] demonstrated the existence of spikelets in CA1 pyramidal neurons, in media blocking synaptic transmission, and following stimulation of stratum oriens (which contains CA1 pyramidal cell axon collaterals). Such spikelets had a number of relevant properties: (1) they followed stimulation at hundreds of Hertz without failures; (2) they were voltage-dependent; (3) they were suppressed by intracellular acidification and by the gap junction blocker carbenoxolone (which, in control experiments, was shown not to alter intrinsic axonal membrane properties); and (4) they actually propagated along axons. The most parsimonious explanation of these findings, especially in view of the dye coupling, was that the spikelets represented decrementally conducted axonal action potentials induced in one neuron by electrical coupling with one or more axons of other neuron(s).

An alternative means of electrical coupling—dendrite to dendrite—is potentially available to

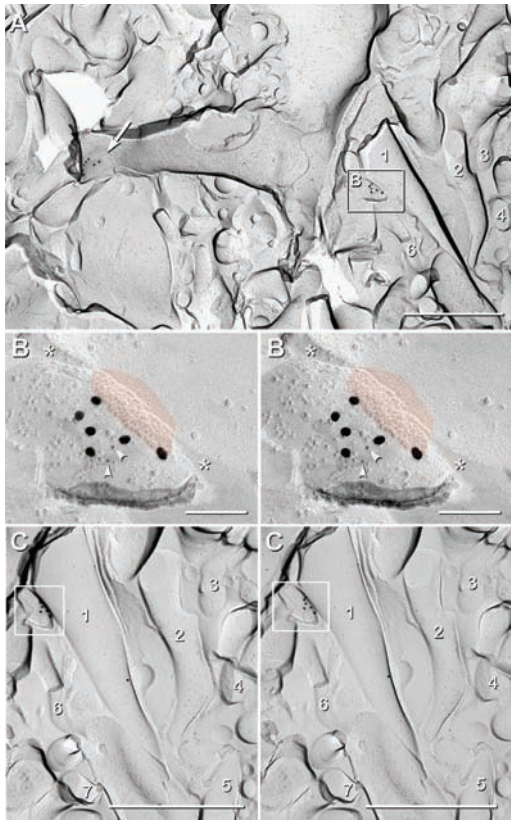

Figure 22–1. Freeze-fracture immunogold replica labeling image of a gap junction on a hippocampal mossy fiber axon (CA3c stratum lucidum, 150 g rat). **A.** Freeze-fracture replica showing two gap junctions labeled with two different gold bead-complexed antibodies identifying connexin36; the beads are 18 nm and 6 nm. The left gap junction (arrow) lies on a dendrite. The right one (box B) lies on mossy fiber axon 1 (other axons in the image are also numbered). Scale bar, 1 μm. **B.** Dual stereoscopic images of the gap junction in box B above. Arrowheads mark the 6 nm gold beads. The gap junction plaque, containing about 100 connexons, has been shaded in red. Asterisks mark the extracellular space, which is ~3 nm at the gap junction site. Scale bar, 100 nm. **C.** Stereoscopic view with the replica tilted. Scale bar, 1 μm. From ref. 19.

CA3 pyramidal neurons. It turns out that in the rat (but not necessarily in the mouse), at least some mossy fiber synapses are mixed, that is, they contain both chemical and gap junctional components.[20] Thus, it is possible that one pyramidal cell dendrite could be coupled indirectly to another dendrite through a common mossy fiber. It is not known if this mechanism is available to other types of principal neurons.

The dye coupling data of Church and Baimbridge[16] provide a clue as to *how many* other pyramidal cells any one pyramidal cell might be coupled to: even under optimal pH conditions (i.e., during alkalinization), any one cell is likely to couple to only a few (fewer than four or five, averaging about three) other cells. Additionally, the dye-coupling data in Schmitz et al.[18] indicate that, at least in CA1, any two pyramidal neurons that are coupled are likely to have somata within about 300 μm of each other.

IN VITRO MODELS OF VFO SUGGEST THAT CHEMICAL SYNAPSES ARE NOT REQUIRED FOR THEIR GENERATION

While in vitro hippocampal VFO can occur in conditions of normal neurotransmission,[21,22] it is important to note that VFO also occurs in vitro with low-calcium media (blocking synaptic transmission entirely), in the presence of cocktails of synaptic blockers, and with either gamma-aminobutyric acid A ($GABA_A$) or alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA)/kainate receptors selectively blocked[8,21,23,24] (see the later discussion). An example is shown in Fig. 22–2. These data imply that interneurons cannot be critical for VFO generation, at least in vitro, even if phasic inhibitory postsynaptic potentials (IPSPs) occur in vivo during ripples[25]: the latter IPSPs are plausibly explained as an epiphenomenon of a primary VFO generator involving the plexus of pyramidal cell axons.[26,27] The data also provide support for the notion that gap junctional coupling is the primary between-neuron interaction necessary for population VFO: chemical synapses are not necessary, and no other type of known between-neuron interaction can plausibly explain the phenomenon.

BRIEF VFO, GENERATED BY NONSYNAPTIC MECHANISMS, OCCURS DURING INTERICTAL BURSTS IN HUMAN EPILEPTOGENIC TISSUE IN VITRO

During the physiologically normal in vivo hippocampal events called *sharp-wave/ripples*

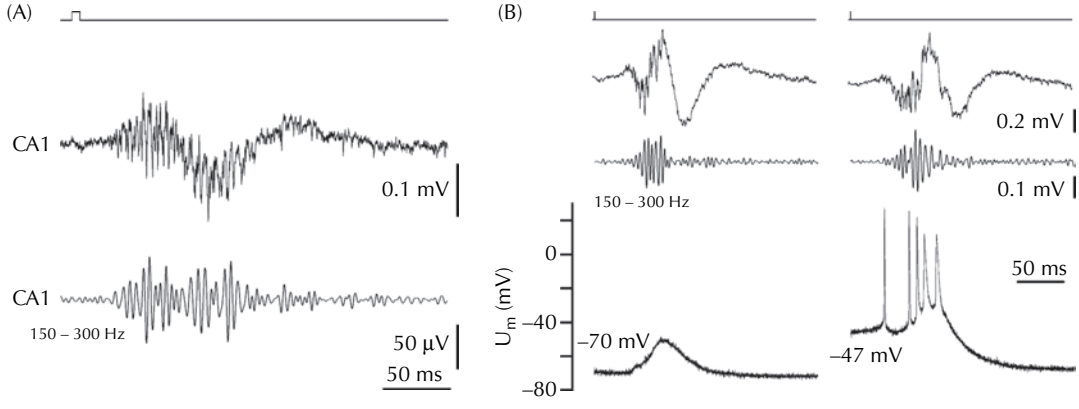

Figure 22–2. Sharp wave ripple complexes in vitro (mouse hippocampal CA1 minislice) do not require $GABA_A$ receptors. When $GABA_A$ receptors are blocked, the complexes can be evoked by pressure ejection of potassium chloride (KCl; 1 M) into stratum radiatum (upper traces), although they do not occur spontaneously. **A.** Stratum radiatum field potential of a KCl-evoked sharp wave ripple in 10 µM gabazine to block $GABA_A$ receptors. A 150–300 Hz filtered trace is shown below, highlighting the ripple. **B.** Combined extracellular (above) and intracellular (putative pyramidal cell, below) recordings during a KCl-induced sharp wave ripple with blocked $GABA_A$ receptors. The cell was held at –70 mV (left) to show the compound glutamatergic excitatory postsynaptic potential (EPSP) during the sharp wave without phasic IPSPs. (Phasic IPSPs do occur in baseline conditions in vivo[25] and in vitro.[22]) When the cell was held depolarized at –47 mV (right), it generated a burst during the sharp wave ripple, but again without evidence of phasic IPSPs. From ref. 24.

(or *physiological sharp waves*), VFO occurs superimposed on a field transient lasting for tens of milliseconds.[25,28] Analogously to this, and actually discovered first, VFO occurs superimposed on epileptiform field transients in *disinhibited* hippocampal slices,[29,30] providing additional evidence that VFO does not require phasic synaptic inhibition. A number of different instances have since been published, demonstrating VFO occurring before, during, and after interictal discharges: in vitro, in brain slices from experimental animals[31]; in vivo, in experimental animals that also have spontaneous seizures[32]; and in situ in the brains of patients with epilepsy[7,11,33] (see Fig. 22–4C for an example in a subdural grid recording from an epileptic infant who had a subcortical dysplasia).

Figure 22–3 provides an example of VFO in association with an interictal burst in human brain studied in vitro (data from ref. 6). (The patient had epilepsy secondary to mesial temporal sclerosis.) For comparison, the figure shows paroxysmal events, having quite similar morphology, in a foramen ovale recording from the same patient prior to surgery and in a network model of a cortical column. The network model contained synaptic excitation and inhibition, and paroxysmal events were simulated by a transient increase in the conductance of gap junctions between pyramidal cell axons. Both in the human tissue in vitro and in the network model, there was a poor correlation between particular synaptic conductances and the VFO; indeed, VFO persisted after blockade of chemical synapses, both in the tissue and in the model. On the other hand, blockade of gap junctions with carbenoxolone eliminated both the VFO and the paroxysmal interictal discharge; correspondingly, in the model, if gap junction conductances were too small, neither VFO nor paroxysmal discharges occurred. The effects of carbenoxolone in the experiment are unlikely to reflect nonspecific effects of the compound on chemical synapses, as the use of specific drugs known to block chemical synapses did not abolish the VFO. Similarly, carbenoxolone has been shown not to influence the time course or amplitude of axonal action potentials in hippocampal pyramidal cell axons and in dentate granule cell mossy fiber terminals.[18]

The data of Roopun et al.[6] therefore suggest that VFO is not just an epiphenomenon of epileptic discharges, but rather may have a causal relationship to such discharges—although the exact nature of this putative relationship remains to be worked out. In our opinion, the most economical hypothesis at present is this: that VFO arises from the electrically coupled

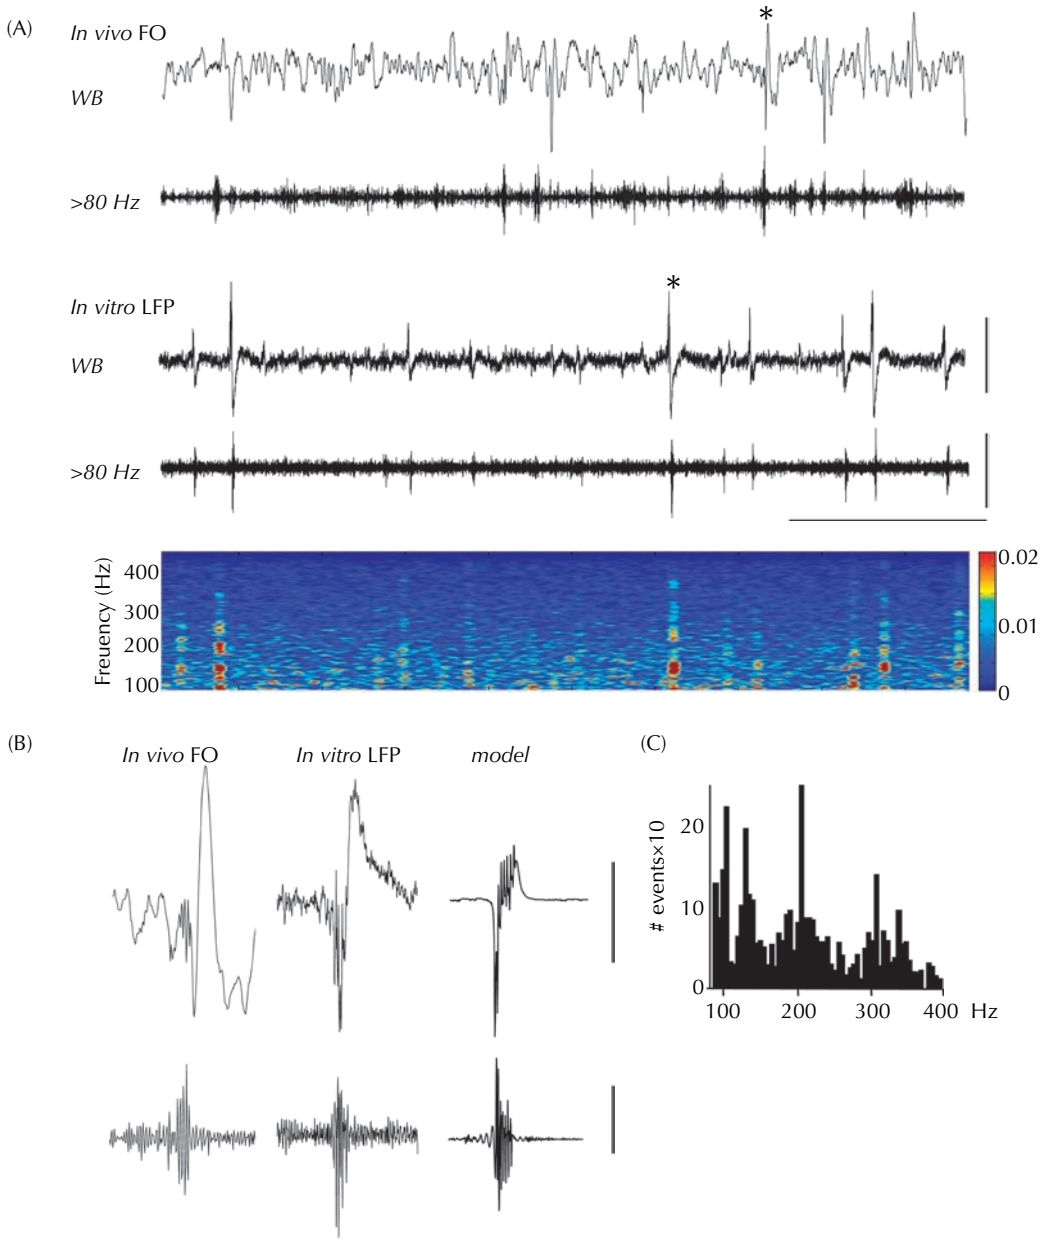

Figure 22–3. Very fast oscillations (VFOs) are spontaneously generated in human temporal neocortical slices in vitro. **A.** Foramen ovale (FO) electrodes, implanted in a patient with right medial temporal lobe sclerosis, demonstrate spike-and-wave interictal events recorded in wide bandpass (WB) mode. The bandpass filtered trace (20 s duration) illustrates that oscillatory activity above 80 Hz is observed coincidently with the sharp-wave complex. In vitro local field potential (LFP) recordings in slices of superior mediotemporal cortex (20 s duration), resected from the same patient, demonstrate spontaneous sharp-wave discharges. The bandpass filtered trace reveals VFO behavior associated with the sharp wave discharges, as can be seen in the color-coded spectrogram of the activity illustrated. **B.** Comparison of two selected (denoted by the asterisk in **A**) events from in vivo FO and in vitro LFP—inverted for reference to the far-field potential FO data—reveal a similar location of the VFO activity at the initial stage of the sharp-wave event. A cortical column model, containing synaptic (excitatory and inhibitory) and gap junctional connections, reproduced the VFO and the initial low-frequency envelope of the interictal discharge. Scale bars **(A)** 500 μV (upper), 200 μV (lower) and 5 s, **(B)** 200 μV (upper), 100 μV (lower). Scale bars for the model "field" are arbitrary. **C.** Histogram displays the total number of detected VFO events from 80 to 400 Hz ($n = 20$, epochs of data = 60 s). Bin width of histogram was 5 Hz. From ref. 6.

plexus of pyramidal cell axons, as described in Traub et al.,[27,34] and that the coherently and rapidly oscillating plexus of axons, in turn, orthodromically drives nearby downstream neurons, thereby inducing the occurrence of approximately synchronized synaptic currents.

EXAMPLE OF MORE SUSTAINED VFO PRIOR TO AN ELECTROGRAPHIC SEIZURE IN A PATIENT'S BRAIN IN SITU

Not only does VFO occur transiently during sharp wave/ripples and in association with interictal epileptiform events, but VFO can also occur stably, on a time scale of seconds, prior to an electrographic seizure.[12] Figures 22–4A and 22–4B show details of such prolonged VFO, as recorded with a subdural grid implanted over the frontal lobe of a child with intractable seizures attributed to a focal dysplasia. (See also Fig. 22–5A for the demonstration of similar phenomenology in a single ECoG electrode.) Typically in such cases, the preseizure VFO is both more localized in space and of much smaller amplitude than the succeeding electrographic seizure proper. Both the conditions permitting this type of stable VFO and the mechanisms of the VFO-seizure transition require explanation. Unfortunately, the necessary intracellular recordings and pharmacological manipulations are difficult or impossible to perform in vivo, particularly in the brains of patients. A rational plan of research will include, therefore, studies of VFO mechanisms in vitro (with human or animal tissue) and with network models, and will also include testing of model predictions with those in situ measurements that can feasibly be performed. In the next two figures, we will illustrate how this can be done.

VFO CAN BE ELICITED IN NEOCORTICAL SLICES IN NONSYNAPTIC CONDITIONS ASSOCIATED WITH SPIKELETS IN DEEP PYRAMIDAL NEURONS

Figure 22–5A illustrates approximately 0.5 s of about a 150 Hz VFO, in a subdural grid recording from an epileptic patient, that occurred prior to an electrographic seizure. Figure 22–5B shows, for comparison, field oscillations at a similar frequency (without, however, the succeeding electrographic seizure) in a rat neocortical slice. The recording conditions in Fig. 22–5B are striking. First, the tissue was "activated" by nanomolar kainate in the bath, which is likely to contribute to a sustained cortical up state.[35] Second, phasic chemical synaptic receptors were pharmacologically blocked. Finally, alkaline artificial cerebrospinal fluid (ACSF) was pressure-ejected onto the slice just prior to the VFO event. Thus, we may conclude that the VFO in Fig. 22–5B does not depend on chemical synapses and is almost certainly generated by gap junctions. In addition, it was possible to obtain an intracellular recording (from a layer 5 intrinsic bursting, "IB," presumed pyramidal neuron) simultaneously with the field recording. This neuron generated both full action potentials and spikelets (fast prepotentials)—indicative of action potential generation at a distance from the soma, and presumably in the axon—with both types of event (action potentials and spikelets) phase-locked, on average, to the population spikes in the field. Again, the occurrence of spikelets is reminiscent of VFO recorded in the hippocampus in nonsynaptic conditions,[21] wherein the spikelets are highly likely to derive from axons.[18]

An expanded view of the field/intracellular recordings is shown in the lower left part of Fig. 22–5. For comparison, the lower right part shows how these patterns are replicated in a network model of 15,000 multicompartment pyramidal neurons, interconnected only by axonal gap junctions, without chemical synapses. In this network model, it is possible to demonstrate directly that somatic spikelets arise from antidromically, and decrementally, conducted axonal action potentials. The in vitro data then provide a plausible scenario concerning how VFO could be generated in local regions of cortex in situ; stated another way, the in vitro data provide a plausible explanation for temporal aspects of VFO, including the network frequency and the tendency of individual pyramidal neurons to generate spikelets. But what about the spatial aspects of VFO? In Fig. 22–4A, for example, VFO occurs in several subdural grid electrodes and hence involves several square centimeters of cortex.

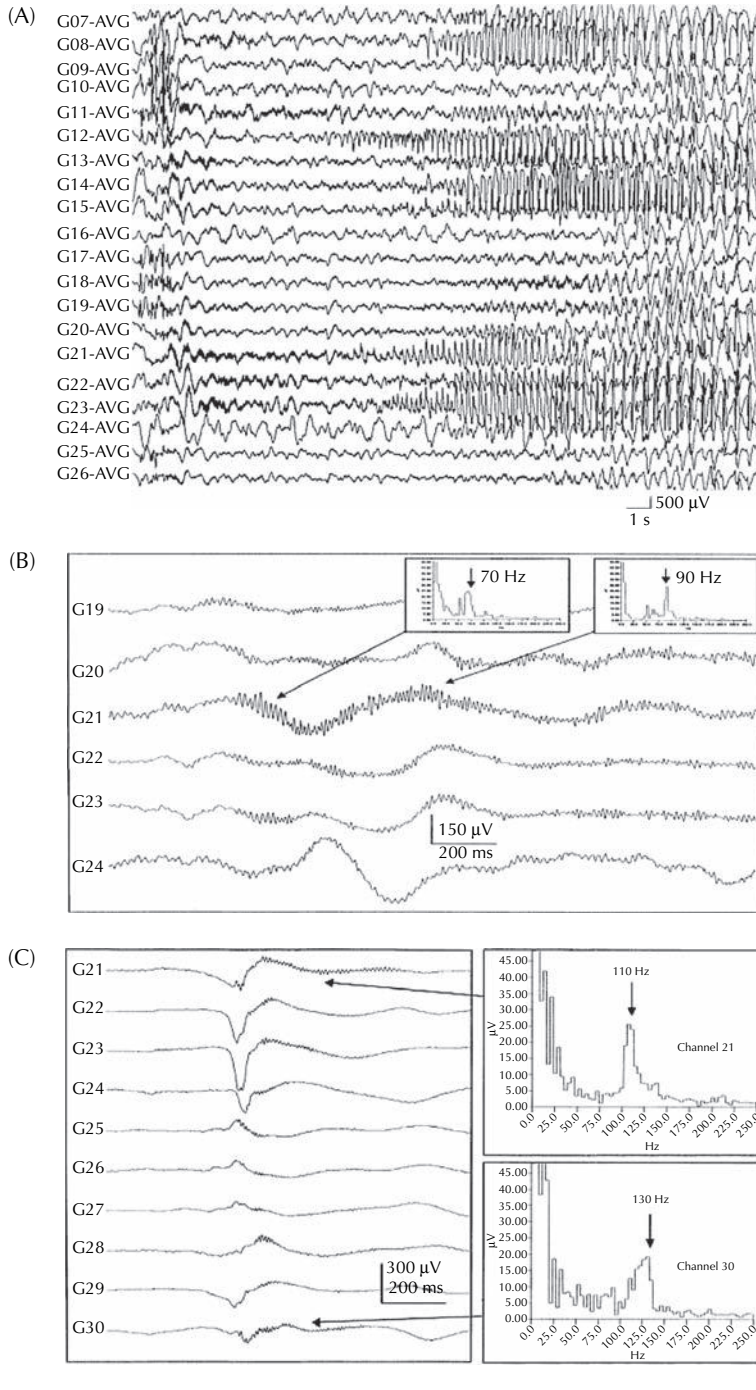

Figure 22–4. Brief, relatively localized, VFO leading to a more extensive electrographic seizure in a child with a subcortical dysplasia. A focal seizure in a child is preceded by localized very fast oscillatory activity. The patient, age 13 months, had a right frontal subcortical dysplasia, subsequently removed surgically. The EEG activity was recorded with a subdural grid of electrodes. **A.** Electrographic seizure preceded by low-amplitude very fast activity restricted to a few recording sites (including G11, G13, and G21–G23). **B.** Using a different recording technique, to give a better signal:noise ratio, shows that the very fast activity (preceding a seizure) contains frequency components of 70–90 Hz. **C.** An interictal burst recorded from the same patient contains superimposed VFO at 110–130 Hz; compare it with the in vitro and in vivo interictal spikes in Fig. 22–3. Signals recorded and analyzed by T. Baldeweg, H. Cross, and S. Boyd. From Ref. 7.

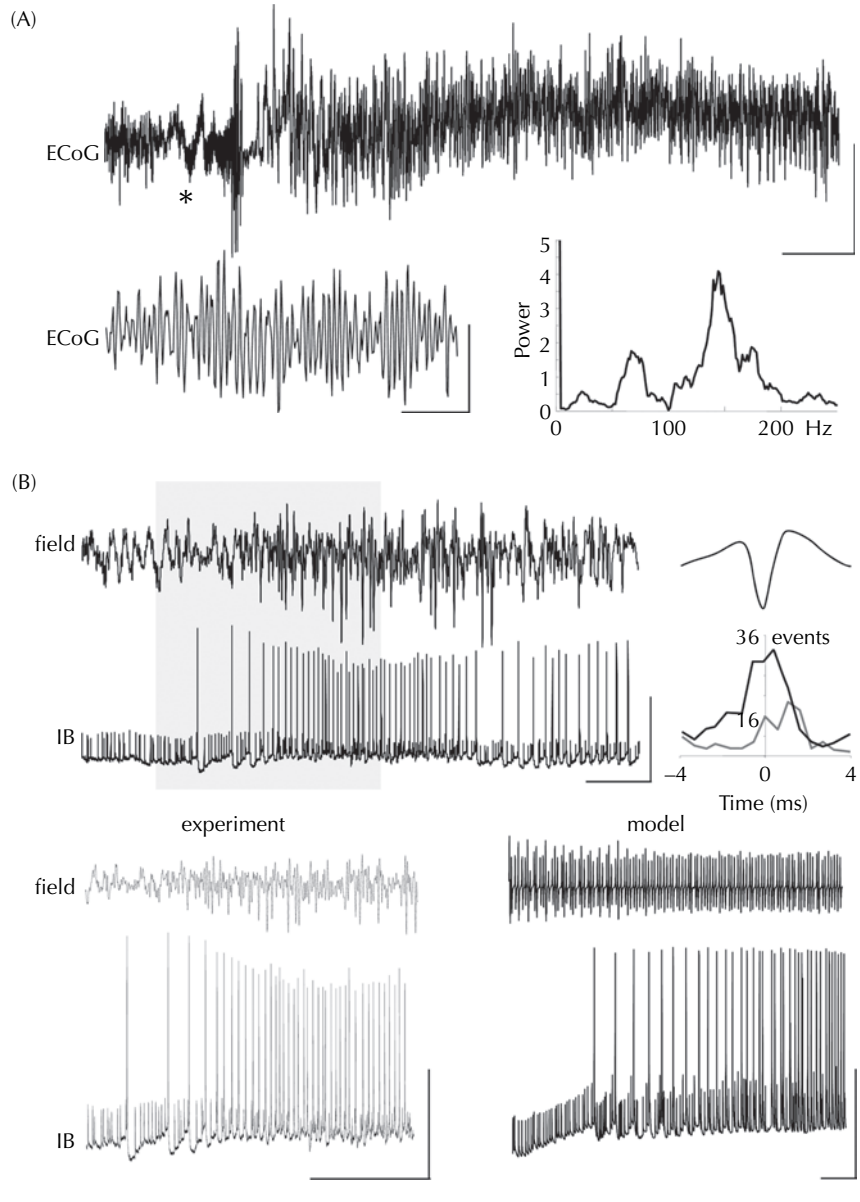

Figure 22–5. Very fast oscillations (VFO) occur at the surface of human epileptic brain; in layer 5 of rat neocortex, in vitro, with chemical synapses blocked; and in a detailed network model of neurons coupled by gap junctions without chemical synapses. **A.** An ECoG recording from epileptic frontal neocortex (patient B of ref. 38). The portion marked by * is expanded below. The power spectrum is from 1 s of data. Scale bars: 100 μV, 11 s; 10 μV, 100 ms. **B.** Upper traces are field and intracellular recordings (IB, or intrinsic bursting cell) showing VFO in layer 5 of rat temporal neocortex in nonsynaptic conditions: AMPA, NMDA, and $GABA_A$ receptors were blocked with SYM2206, AP5, and gabazine, respectively. The bath contained kainate, and alkaline artificial cerebrospinal fluid (ACSF) was pressure ejected onto the slice just before the trace begins. Scale bars; 0.1 mV (field), 50 mV (cell), 500 ms. The graph (right) shows a pooled incidence plot (bin width 0.5 ms) for 500 field VFO periods with full spike data plotted as the gray line and spikelet data as the black line.

The data in the gray box were expanded at the lower left: scale bars 0.2 mV, 40 mV, and 400 ms. Simulation data are shown at the lower right: field potential of very fast network oscillation (above, spectral peak at 112 Hz) and simultaneous "intracellular recording" (below). Scale bars 50 mV (cell), 100 ms. Note the mixture of full action potentials and spikelets, as in the experiment. The model consisted of 15,000 multicompartment IB pyramidal cells, with gap junctions between axons. A ramping bias current (–0.5 to 0.5 nA) was applied to the illustrated cell to show that spikelets are more common at hyperpolarized somatic membrane potentials and full spikes at depolarized membrane potentials. From ref. 8.

Could there be a spatial structure to this VFO, which might provide clues concerning the cellular mechanisms by which VFO is generated in situ? We consider this question next.

SPATIAL PATTERNS OF VFO IN HUMAN EPILEPTIC BRAIN ARE REPLICATED WITH A SIMPLE MODEL BASED ON LOCALIZED ELECTRICAL COUPLING BETWEEN PYRAMIDAL NEURONS

Neocortical slices contain thousands of neurons, as do our "detailed" multicompartment network models. On the other hand, cortical surfaces of many square centimeters contain millions of neurons. In vitro slices on this scale are difficult to prepare, and it is difficult to perform computer simulations of highly detailed network models on this scale as well. One approach for modeling, however, is to abstract the key physical principles for VFO that have been reasonably established from in vitro slices and detailed models, as in Fig. 22–5. Thus, the in vitro recordings and the simulation in Fig. 22–5 are similar enough that we may ask: what is it that really makes the model "tick"? In the model, VFO is generated by "percolation" of spikes from axon to axon under conditions in which (1) there is a low rate of spontaneous axonal firing and (2) each axon is coupled to a small number of other axons (on average)—but to more than *one* other axon (on average). (If each axon connects to less than one other axon, on average, then collective network behavior is impossible.) These physical ideas can be captured in an extremely reduced type of model called a *cellular automaton* with locally random connectivity.[8] In such a model, each element represents an axon that is either at rest, is firing, or is refractory. The model behavior is determined by a small number of parameters, each of which has physical meaning: (1) the time scale, determined by how long it takes for an action potential to cross from one axon to another (estimated to be about 0.25 ms); (2) a spatial scale, corresponding to the maximum separation of two neuronal somata that is compatible with a gap junction forming between them (estimated to be hundreds of microns, extrapolating from the data of Schmitz et al.[18]); (3) the mean number of axons that any one axon couples to, which must be more than one and is probably less than about three (from dye coupling data); and (4) the mean rate of spontaneous activity, which is, at present, difficult to determine experimentally.

Such a model predicts that VFO will not be spatially uniform, provided that neurons are only allowed to couple to other neurons not too far away. In these latter conditions, VFO waves start as small "blobs" that then propagate and destructively interfere with other propagating

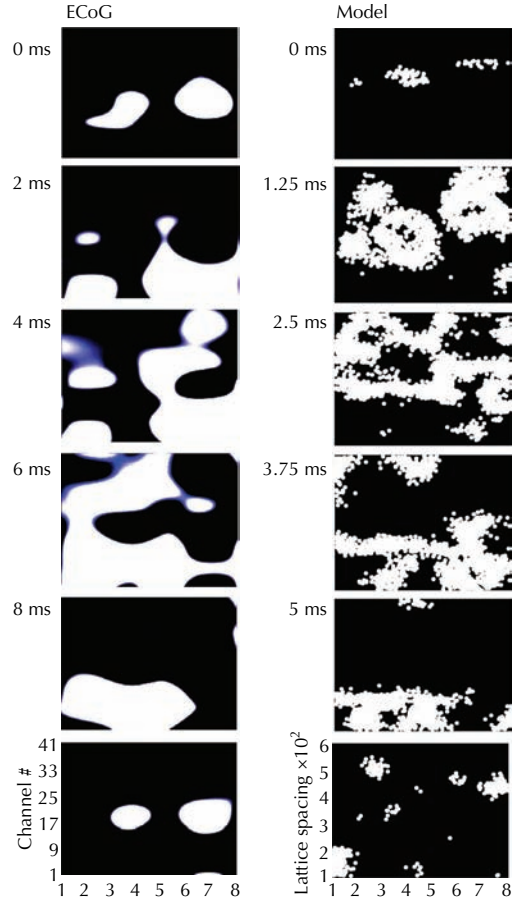

Figure 22–6. Comparison of spatiotemporal patterns in ECoG data and in cellular automaton model data. The left side shows successive frames of activity, every 2 ms, from an 8 × 6 subdural array of electrodes (with 1 cm spacing) in patient B of ref. 38. The right side shows frames of activity every 1.25 ms from a cellular automaton model with 480,000 "cells" in an 800 × 600 array with sparse, localized gap junctional connectivity (mean index <i> = 1.33, connectivity footprint = 25 lattice spacings) and rare spontaneous action potentials. From ref. 8.

blobs. The result is a statistical structure to the spatial activity that, qualitatively, resembles the spatial structure in human ECoG data (in a small number of patients so far; Fig. 22–6). Videos of the comparison between model prediction and ECoG data are to be found in the supplementary data of ref. 8.

In summary, then, the spatial patterns of VFO, predicted by a model based on gap junctional coupling and not using chemical synapses, are qualitatively similar to VFO patterns observed in situ in the human brain. This provides indirect support for the notion that VFO in situ, at least of the sort that precedes epileptic events, is indeed generated by electrical coupling between principal neurons. In the Discussion, we shall consider the clinical implications of our postulated mechanism for epilepsy-related VFO.

DISCUSSION: CLINICAL IMPLICATIONS

The evidence that in vitro VFO is generated by nonsynaptic mechanisms is, we believe, compelling[6,8,21,34]:

1. Very fast oscillation occurs in slices bathed in a low-calcium medium or in a medium in which one or multiple types of phasic synaptic transmission are blocked with specific receptor blockers.
2. In vitro VFO is affected by pH and gap junction blockers in a manner consistent with a requirement for gap junctions.
3. Network models (and a more abstract cellular automaton theory), based on the postulate of gap junctional coupling between principal neurons, account for the frequency of VFO and also for the firing patterns of individual pyramidal neurons, including frequent spikelets. The models also account for the increase in frequency with alkalinization (which presumably increases gap junction conductances).

The clinically relevant question here, however, concerns the extent to which one can reasonably extrapolate the in vitro data to the in situ epileptic brain. Bathing in situ human brain in a low- calcium medium, or with cocktails that block synaptic transmission, is, of course, not possible; nor are we aware of pH measurements in human epileptic tissue in situ (although such measurements might be feasible and would be especially useful if combined with simultaneous ECoG recording). Spikelets have been recorded intracellularly in vivo from the hippocampus of cats[36] and mice,[37] but gap junctional dependence has not been proven, and the technology does not yet exist for safe intracellular recording in human tissue in situ.

The direct resemblances between in vitro and in vivo (epileptic) VFO consist of two main elements: a common frequency range and—in a small number of patients—spatial patterns that are predicted by a gap junction model. In addition, the same human tissue that is epileptogenic in situ is capable of producing nonsynaptic VFO when studied in vitro.[6] The remainder of the evidence that in vivo epileptic VFO is gap junction-dependent is negative and consists of the following: so far as we are aware, there is no cortical preparation that has been shown to generate VFO by synaptic mechanisms. The gap junction dependence of in vivo epileptic VFO is therefore, in our opinion, the most reasonable available hypothesis.

If it is indeed true that VFO in epilepsy is generated by gap junctional coupling between principal neurons, it would matter in a number of ways, both in terms of basic epilepsy mechanisms and in terms of treatment approaches:

1. First, it would provide clues concerning epileptogenesis, the process by which previously normal brain tissue becomes capable of initiating seizures. Thus, it may be that gap junctions appear in abnormal places, in excessively great numbers, or with abnormal physiological properties. In order to pursue these important questions, it is first necessary to identify what gap junction proteins are responsible for electrical coupling between principal neurons.
2. Second, it would provide clues to the events responsible for initiating individual seizures. Specifically, VFO is favored to occur (in vitro, at least) by alkalinization—presumably opening gap junctions—and by relative blockade of synaptic transmission. Such effects could arise in tissue as a result of glial dysfunction or of abnormalities in one or more transporter systems.

3. Given the association between VFO and the initiation of seizures, it makes sense to attempt to target VFO as a possible strategy for seizure prevention. Such attempts might be directed against gap junctions per se, although with a possibility of undesirable side effects, given the normal widespread distribution of gap junctions in the brain (e.g., inferior olive, nucleus reticularis thalami, cortical and cerebellar interneurons), in the retina, and, of course, elsewhere in the body. Alternatively, other tissue factors—yet to be identified experimentally—that predispose to VFO might be targeted.

Chapter 23

Computer Modeling of Epilepsy

Marianne J. Case
Robert J. Morgan
Calvin J. Schneider
Ivan Soltesz

There are 50 million people worldwide afflicted with epilepsy, and for roughly 15 million of them, existing epilepsy treatments are not sufficient.[1] Such stark facts spur clinicians and researchers to consider dramatically different approaches to treatment, such as an implantable device that could characterize electrical activity in real time, immediately detect when the brain reaches a preictal state, and apply a counteracting current waveform, averting the seizure before it starts (see the next section),[2] or an individualized, detailed model of the patient's brain—complete with patient-specific details such as genetic mutations or head trauma—to which doctors could administer virtual drugs to determine the best treatment regimen for that person. Such a tool would complement existing therapies by reducing the likelihood of patients being subjected to treatments to which they are unresponsive.

Notably, both the implantable device and the individualized brain model use computer modeling. The device employs computer modeling in its development and in the algorithms it uses to detect the seizure and formulate an appropriate response, whereas the individualized model would use an interactive, large-scale, biologically realistic computational model.

And then there are the 2.4 million people worldwide who will develop epilepsy over the next year due to a variety of causes.[1] Ideally, we could prevent epileptogenesis in these people entirely, and computer modeling can help us achieve this goal. For example, in people who have experienced head trauma, an ideal therapy might be a drug that could be administered to prevent the development of epileptogenic alterations without disrupting the brain further. Computational models could help us determine which of the alterations are most

clinically significant and also help characterize the therapeutic effects and side effects of any proposed treatment. In patients with gene mutations, a method to induce expression of a "therapeutic" ion channel could counteract the epileptic effects of a mutated ion channel.[3] Again, an individualized computational model of the brain could help by predicting the likelihood of epileptogenesis (and therefore the need for treatment) in a person exposed to a particular environmental or genetic factor.

Such ideas may sound impractical, even outlandish, given the current state of epilepsy therapy. However, work has already begun on projects using ideas similar to those described above. For example, the Blue Brain Project has created a detailed 10,000-neuron model of a rat neocortical column[4] and aims to build a detailed, biologically realistic model of the human brain.[5] Also impressive are several implantable devices undergoing clinical trials, some of which use algorithms that can be individually tuned for each subject by his or her doctor to detect and respond to seizures.[2]

Clearly, there is a role for computer modeling in the development and operation of epilepsy therapies. Not only can it be applied directly to therapies, as in the examples above, but it can also guide researchers in choosing and designing experiments and can provide a framework for organizing experimental results. In fact, computational models have already advanced our understanding of disorders such as schizophrenia,[6] Parkinson's disease,[7] stroke,[8] and, of course, epilepsy.[9] Within the field of computational epilepsy modeling, approaches include single-cell[10–12] models (simple or detailed) and network models ranging from mean-field[13,14] to large-scale, detailed models[15–19] (Fig. 23–1).

This range of approaches is not surprising, given that epilepsy is a dynamic disorder that can be characterized at multiple levels of detail.[20] Though there exists a wealth of data

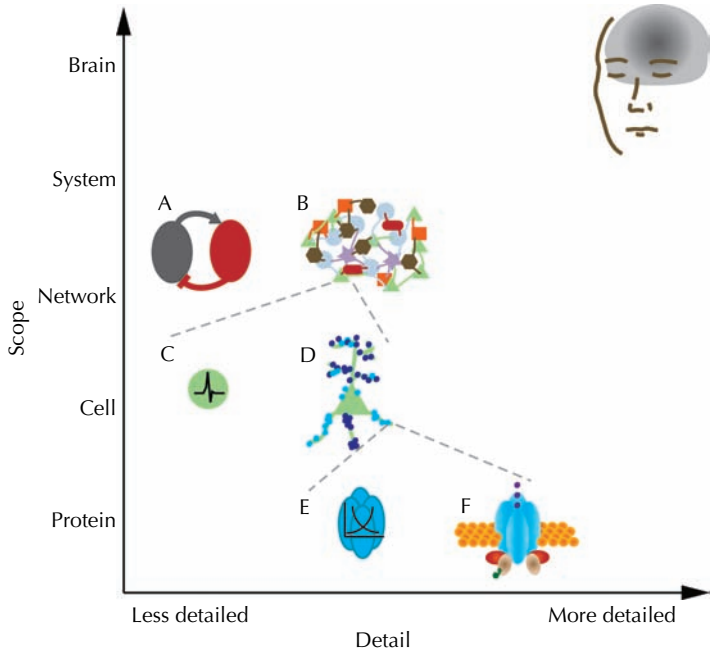

Figure 23–1. Functional computational models can be partially organized by their scope and detail. The icons above represent a few possible modeling approaches mentioned in this chapter. **A.** Macroscopic, mean-field network models, which usually incorporate at least an excitatory and an inhibitory neuronal population. **B.** Detailed network models, which include individual cells modeled at variable levels of detail. Note that both **A** and **B** can describe networks or even systems that can perform higher-level functions. **C, D.** Model cells at variable levels of detail, from integrate-and-fire models (**C**) to cells with simple morphology and mechanisms representing ion channels, receptors, and gap junctions (**D**). **E, F.** Ion channels and other subcellular mechanisms can also be represented at variable levels of detail, from their conductances in each state (**E**) to detailed protein structures that capture conformational changes and binding sites (**F**).

at each of these levels, the challenge of drawing connections across levels stands in the way of developing greater understanding and new treatments for the disorder. For example, it is difficult to understand how high-level dynamics such as aggregate electrical activity during a seizure could be predicted from low-level structural and functional factors like altered connectivity between cells or mutated ion channels. Furthermore, the many causes of epilepsy and its variable manifestations limit our ability to apply knowledge about one epilepsy model to other models. The challenges of integrating experimental research about epilepsy through multiple levels of detail and across multiple subcategories of the disorder can be addressed with computer modeling.

While a thorough survey of modeling techniques in the epilepsy field requires an entire book,[9] much can be learned from a tour of recently developed models. Here, we first discuss computer modeling to benefit patients who already have epilepsy and those at risk for developing epilepsy. Then we illustrate how computer modeling can complement experimental research. After the reader has been introduced to several models, we describe the various approaches one may take for computer modeling of epilepsy. We conclude by assessing the future of computer modeling in epilepsy and suggest resources available to those interested in using computers to model epilepsy.

COMPUTER MODELING TO PREVENT SEIZURES

Computational modeling is not just useful for clinical applications indirectly via research; it is already directly applicable to clinical practice. Aside from the well-known application of computer modeling to the discovery and development of pharmaceutical agents,[21,22] it has also been instrumental in designing therapies to prevent or reduce seizures, some of which have already been used successfully in human patients. For the purpose of this chapter, such therapies can be broadly classified as dynamic, which exert their effects only in response to seizures, and static, which exert their effects continuously (or continually, in some cases).

Dynamic Therapies

There have been promising developments in devices capable of online analysis of epileptic patients for the detection of and response to seizures. At least one device, the RNS™ device designed by NeuroPace, has shown a significant reduction in seizure frequency during clinical trials, with an acceptable level of side effects.[2] An application for premarket approval (PMA) for the RNS™ device was recently submitted to the Food and Drug Administration (FDA).[23] Though the seizure detection and response algorithm used in the NeuroPace RNS™ device is proprietary, we can review other computational models to highlight some of the computational issues inherent in seizure detection and response.

Detection of seizures requires a reliable method of characterizing seizure and even preseizure activity, one that is robust enough to detect each seizure that occurs, despite known variability in individual seizure dynamics. A variety of neural properties have been proposed as suitable for monitoring to detect seizures, including electroencephalographic (EEG) traces[24] and localized glutamate transmission.[25] One such method of characterization is matching pursuit, in which a signal (such as an EEG) is broken down into *atoms,* smaller and simpler signal elements.[26] Using this analysis, researchers were able to show considerable similarity among onset of seizures originating from the same foci in the same patient.[26]

Once a seizure has been detected, a variety of approaches can be used to correct the abnormal activity. In one approach, Lopour and Szeri[14] produced a mean-field model that showed how a control system could analyze the electrode signals from a seizing patient and apply a charge-balanced potential to nearby electrodes to terminate the seizure activity. Using a charge-balanced correction signal, where the net charge over time approaches 0, is thought to be less harmful to cortical tissue and is an important step toward the eventual goal of using such a controller therapeutically.[14]

With online detection of seizures, much emphasis is placed on how quickly the seizure can be detected; the earlier the stereotyped seizure pattern can be recognized, the more useful such information becomes. Ideally, the events leading to the clinical onset of the seizure could also be characterized well enough

to predict the onset of the seizure within a clinically meaningful time window. Seizure prediction cannot be covered in sufficient detail here, but other publications provide insight and discuss the controversies associated with computational modeling for prediction.[27,28]

Even if seizure dynamics could be characterized well enough that detection theoretically could be reliably performed early in the seizure, analysis speed is a challenge. We note that the Lopour-Szari model[14] required 5 min of computation time to analyze seizure dynamics and then compute and deliver a charge-balanced correction signal to end the seizure. However, most seizures self-terminate well within 5 min of onset.[29] For such an approach to be helpful, the detection and analysis should finish in just a few seconds, a speed increase of two orders of magnitude. The speed could be increased by running the analysis at a lower resolution[14] and more computational resources could be devoted to the task, but some technical innovation will be required for this algorithm to be incorporated in a portable seizure detection device.

Even with a therapeutic device in the FDA approval process, novel approaches to seizure detection and intervention are still relevant. Not all patients respond to the RNS™ device,[30] and for those who do, the therapeutic effects are not immediate. Tuning these devices to properly detect seizures currently takes many months, even for patients with relatively frequent seizures (i.e., at least three per month).[31] For patients with less frequent seizures, it is possible that the detection tuning process could take over a year.

Because seizure dynamics vary so widely among patients, it seems that a calibration period will be unavoidable for any detection device. However, as the field of seizure detection advances, calibrating the detection algorithm will likely require fewer seizures and fewer hours of physicians' time. Ideally, devices would be able to calibrate themselves. Current devices are already monitoring the patient's response continuously, even when the patient is receiving the therapeutic correction signal produced by the device in response to a seizure. As we develop a better understanding of seizure dynamics, that knowledge can be translated into intelligent devices capable of analyzing and correcting their own performance.

Static Therapies

In contrast to devices that detect and respond to seizures, there are also devices that deliver scheduled pulses, that is, their activity is defined by a preset pattern (periodic pacing), independently of when the patient seizes. Such devices have also shown a promising reduction in seizure frequency and do not require an extended calibration period, as they do not need to detect seizures.[2]

Other therapies that exert their effects independently of the patient's state include pharmacological treatments.[21,22] These agents affect subcellular mechanisms, such as ion channels, transporters, pumps, and receptors. Computational models that incorporate these subcellular mechanisms can help identify therapeutic targets and show how their modulation may influence dynamics at the cellular and network levels.

Here, we will introduce a computational model used by Dyhrfjeld-Johnsen et al.[38] to illustrate the effect of a channelopathy on cellular excitability. Channelopathies—pathological changes in the expression or function of ion channels—are of great interest in the field of epilepsy because they have been linked to both inherited and acquired epilepsies. For those inherited epilepsies whose mutations have been discovered, the mutations have been predominantly channelopathies.[32]

One common channelopathy occurring in epileptic animal models affects the hyperpolarization-activated, cyclic nucleotide-gated (HCN) channel responsible for an inward, mixed-cation current (I_h). Most experimental paradigms report that seizures reduce I_h,[33–37] a reduction thought to increase hyperexcitability[33] because it lessens the shunting effect associated with I_h. However, in an experimental febrile seizure model, the hyperexcitable dendrites of CA1 pyramidal cells show a marked increase in I_h.[38] Computer modeling provided an explanation for these seemingly contradictory results.

Using a computational model, Dyhrfjeld-Johnsen et al.[38] altered the h-current and examined the effects on the excitability of three detailed pyramidal cell models (Fig. 23–2). The models indicated that an increased I_h can contribute to hyperexcitability (Fig. 23–2A). Analysis of the mechanism by which I_h enhanced excitability showed that the upregulated I_h

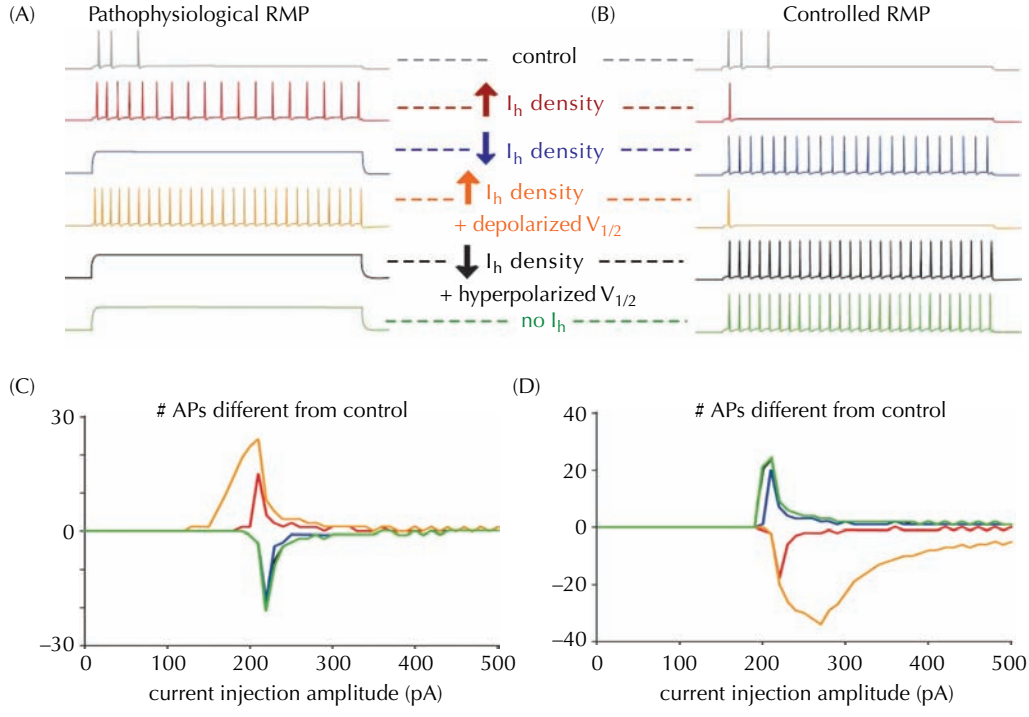

Figure 23–2. Altered h-current changes neuronal excitability. Both the modified control CA1 pyramidal neuron model[38,68] and models with altered I_h are subjected to a 1000 ms depolarizing current injection, with the membrane potential allowed to vary from control resting membrane potential (left column) or clamped at control resting membrane potential (right column). **A, B.** Example traces of simulated neuronal behaviors in response to depolarizing current injection (+210 pA) in the cases of pathologically depolarized (**A**) and controlled (**B**) resting membrane potential (RMP). **C, D.** For each amplitude of current injection, the activity of the models with altered I_h is contrasted with that of control models by comparing the number of action potentials fired. A positive difference means that the pathophysiological model has become more excitable than the control model; a negative difference indicates that the pathophysiological model is less excitable. The resting membrane potential of the pathophysiological model is set to either the pathophysiological, depolarized resting potential (**C**) or the controlled resting potential (**D**). Adapted from ref. 69.

depolarized the dendritic resting membrane potential, shifting it closer to threshold. When cells with increased I_h were held at the control resting membrane potential, no increase in excitability was observed (Fig. 23–2B). These results highlight the complex relationship between I_h and neuronal excitability; perhaps functional effects cannot be predicted by looking at only the direction of changes in I_h.

Knowing that the hyperexcitability seen in increased I_h is related to the more positive resting membrane potential, we can then propose possible therapeutic interventions. For example, a pharmacological agent that can counteract the more depolarized membrane potential[38] with minimal disturbance to physiological functions, perhaps mediated by the M-current,[38–40] should be sufficient to reduce the I_h-associated network hyperexcitability seen in the above-mentioned febrile seizure model.[38]

COMPUTER MODELING TO PREVENT EPILEPTOGENESIS

Understanding how the healthy brain becomes capable of seizing requires knowledge of the detailed changes associated with epileptogenesis. These alterations include cell loss, changes in network connectivity, mutated ion channels, and altered gene expression profiles. Quite often, multiple changes occur together, obscuring each factor's contribution to the seizure-prone brain. In this scenario, untangling the role of each factor may

be far easier in computational models than in experimental ones.

Head trauma is one model of epilepsy in which multiple changes are known to occur. These alterations affect, among other brain regions, the dentate gyrus, an area of the hippocampal formation thought to gate network activity in the healthy brain. Epileptogenic changes seen in the dentate gyrus after head trauma include mossy fiber sprouting and hilar cell loss. Mossy fiber sprouting, that is, the development of new axonal branches by granule cells, accounts for recurrent excitation among granule cells, consequent to the establishment of reciprocal synaptic contacts that are not normally present in the healthy dentate gyrus. Hilar cell loss not only affects inhibitory interneurons, but also reduces the number of excitatory mossy cells. The effect of reducing the number of excitatory mossy cell synapses onto the granule cells is not well understood.

It is quite challenging to separate these alterations in experimental models of epilepsy, but computer modeling provides a flexible way to study the changes in isolation. Santhakumar et al.[19], Dyhrfjeld-Johnsen et al.,[17] Morgan and Soltesz,[18] studied, in progressively more detail, the effects of structural changes in the dentate circuitry on hyperexcitability. The first of these studies, by Santhakumar et al.,[19] played a major role in demonstrating the promise of large-scale, data-driven models in epilepsy research, as it detailed the construction of the dentate gyrus model, containing four biophysically realistic cell types, each connected via realistic synapses using connection probabilities derived from in vivo and in vitro experiments. Using the 500-cell model that was thus constructed, Santhakumar et al.[19] were able to show that structural changes alone can predispose the dentate network to hyperexcitability.

Dyhrfjeld-Johnsen et al.[17] expanded the functional model of Santhakumar et al.[19] to over 50,000 cells, a scale of 1:20 compared to the full-size rat dentate gyrus. Their experiments also used a complete 1:1 scale structural model of the dentate gyrus to determine the graph-theoretical characteristics of the dentate network. The results of the structural model showed that the dentate gyrus is a small-world network. In a small-world network, cells make many connections to their close neighbors, yet the number of cells along a path from a given cell to any distant cell remains quite small due to the presence of a few long-distance connections. By combining the structural model results with those of the functional model at varying levels of dentate injury, Dyhrfjeld-Johnsen et al.[17] showed that head injury causes substantial alterations to the small-world structure of the dentate gyrus, resulting in a hyperexcitability profile closely correlated with structural alterations.

Because the specific pattern of new granule cell connections that occurs with mossy fiber sprouting is not known, Morgan and Soltesz[18] studied the pathological alterations in the dentate gyrus circuitry in even more detail. They questioned whether the hyperexcitability of the sprouted network depends on the specific pattern of new connections. To answer the question, Morgan and Soltesz compared nonrandom patterns of connectivity to a control network in which the granule cells were connected together randomly (Fig. 23–3A). In each case, the model had the same number of connections among granule cells, but the connections were distributed differently among the cells.

Morgan and Soltesz found that simply rewiring the granule cell network in certain ways could markedly increase excitability (Fig. 23–4). In particular, if the connections were redistributed so that most granule cells had few granule cell connections but some rare granule cells (*hubs*) had many connections (Fig. 23–3B), network activity increased greatly. These highly connected cells made the dentate network significantly more excitable without changing the total excitatory drive of the network, demonstrating the potential importance of hub cells in seizures (compare Fig. 23–4A and 23–4B). Experimental work has supported the presence of hub cells in the dentate gyrus after injury, thus beginning to validate the model's prediction and pointing to the importance of understanding the microcircuit connectivity in seizure-prone networks.[41] This work suggests that therapeutic efforts to prevent mossy fiber sprouting could reduce epileptogenesis in people who have experienced head trauma.

Epileptogenic changes are not limited to neurons and their connections. Glia dysfunction has been implicated in epileptogenesis, and therefore deserves consideration as a possible therapeutic target.[42–44] Its significance arises

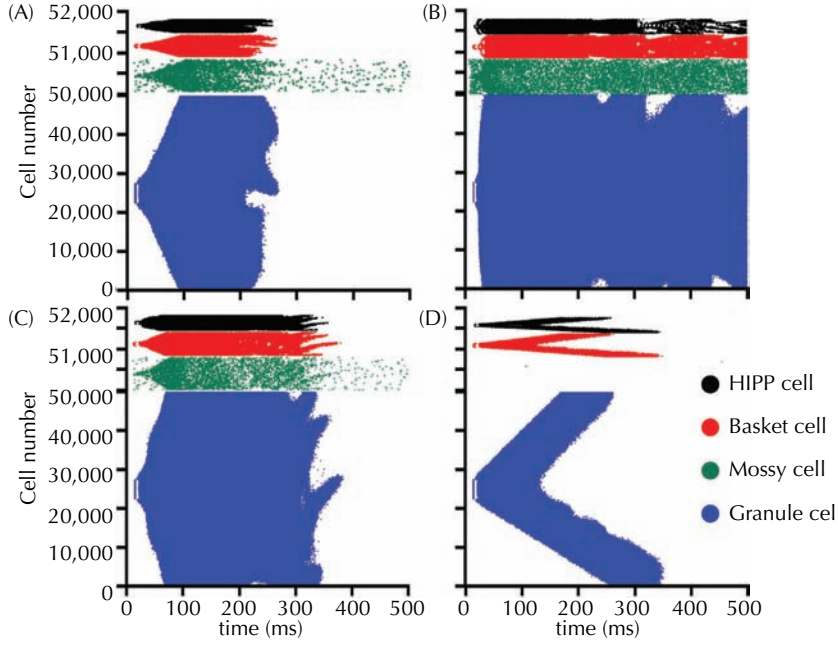

Figure 23–3. Reconnecting the granule cell network. In temporal lobe epilepsy, granule cells in the dentate gyrus sprout axon collaterals that synapse onto other granule cells, creating a recurrent excitatory circuit. **A.** In the control network, connections were modeled as random, constrained only by the extent of the granule cells' axonal arbors.[17] **B.** In the fluid percussion injury (FPI) network model, the same total number of connections are introduced, but the connectivity is different. A few cells are highly connected, while the rest remain sparsely connected. Note that the experimental network depicted here is only a visual guide to understanding the general connectivity of the network.

especially because of the glial role in regulating the concentration of extracellular potassium and because of the ability of glial cells to interfere with inhibition,[45] to release adenosine triphosphate (ATP),[39] and to affect the glutamate concentration at nearby synapses.[11,44,46] Cressman et al. and Ullah et al. investigated the role of ion concentrations and glia in epileptic networks using a model of a single cell[11] and a network.[44]

In this work, Cressman et al. first examined the effects of intracellular and extracellular ion concentrations on neuronal excitability and seizure frequency with a mathematical model of a neuron and its extracellular space, including the glia surrounding it.[11] Using the model, they showed that this single cell was capable of producing abnormal bursts of action potentials, as may be seen during seizures. The model also illustrated how increased extracellular potassium could lead to depolarization block, during which the cell is depolarized but unable to spike. Some studies have implicated depolarization block in inhibitory interneurons during seizure-like events in brain slices, which could free excitatory cells to spike excessively in bursts.[11,47]

Then, to examine the role of glia directly, Ullah et al. extended the single-cell model to a 200-cell network model consisting of pyramidal and inhibitory cells and accounting for glial function, ion pumps, and diffusion. Their model illustrated how glial dysfunction could cause neural networks to be less resilient to small perturbations such that a network exhibiting the normal persistent activity associated with higher-level functions could suddenly transition to seizure-like activity.[44] For example, they showed that the rearrangement of astrocytes associated with epileptogenesis leads to an increased extracellular potassium concentration and a reduced ability to buffer the extracellular potassium, as well as increased strength of excitatory synapses.[44] The behavior of their model was consistent with several experimental results,[44] and it underscores the potential of glia as therapeutic targets.

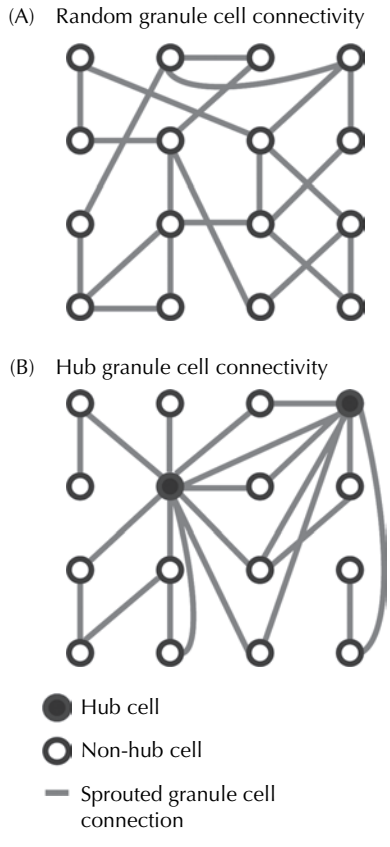

Figure 23–4. Highly interconnected granule cell hubs greatly augment network excitability. Both **A** and **B** represent raster plots of granule cell firing in a network with 50% of maximal granule cell-to-granule cell connections, where stimulation was delivered via the perforant path to 1% of the granule cells. Both networks have the same number of added connections, just distributed differently. Representative firing patterns of cells in the network are shown on the right of the raster plots. **A.** The sprouted connections are randomly distributed throughout the network. **B.** The sprouted connections are distributed such that 5% of granule cells make 210 more connections than the average granule cell and thus serve as hubs. Adapted from ref. 18.

COMPUTER MODELING TO ASSIST RESEARCHERS

Computer modeling and experimentation are complementary in research and the development of therapeutics. Each approach provides unique benefits and is improved by contributions of the other. Though definitive confirmation of scientific fact requires experimental results, modeling serves the field by enabling a flexibility and efficiency not always possible in experiments, and it can help researchers design more focused experiments.[39]

One example of a scenario in which computer modeling allowed researchers to extend their experimental observations occurred during an electrophysiological study of hippocampal mossy cells (see also above) after head injury. These excitatory neurons, located in the dentate hilus, are among the most vulnerable neurons in the entire mammalian brain[48]; factors including strong excitatory inputs, a sustained response to excitatory input, and a high level of spontaneous activity render them particularly susceptible to excitotoxicity.[49] Significant mossy cell loss is observed in human epileptic tissue and in animal models after experimental head trauma.[50–52] However, several lines of evidence suggest that some mossy cells survive trauma[49,50,52] and that these surviving mossy cells may spread or amplify dentate network hyperexcitability.

Howard et al.[53] used a rat fluid percussion injury model to study the changes in surviving mossy cells after head trauma, comparing their *I-F* (current versus spike frequency) and *I-V* (current versus membrane potential) curves before and after trauma. Surprisingly, they found no significant difference. Yet, on closer inspection, extensive, opposing alterations were found in various membrane currents and properties that together resulted in the unchanged *I-F* and *I-V* relationships observed in mossy cells after head trauma. The resting membrane potential was depolarized, the tetraethylammonium (TEA)-sensitive potassium current was decreased, and the voltage-dependent sodium channel required more depolarized potentials to activate.

Howard et al.[53] then used computer modeling to understand whether each one of these changes would affect the dentate network when considered separately. Notably, when modeled alone, each of these alterations dramatically affected network excitability (Fig. 23–5), despite canceling each other when occurring together. In this case, the computational model complemented the experimental observations by vividly demonstrating the importance of potentially homeostatic mechanisms[54] in regulating overall levels of neuronal activity in large networks.

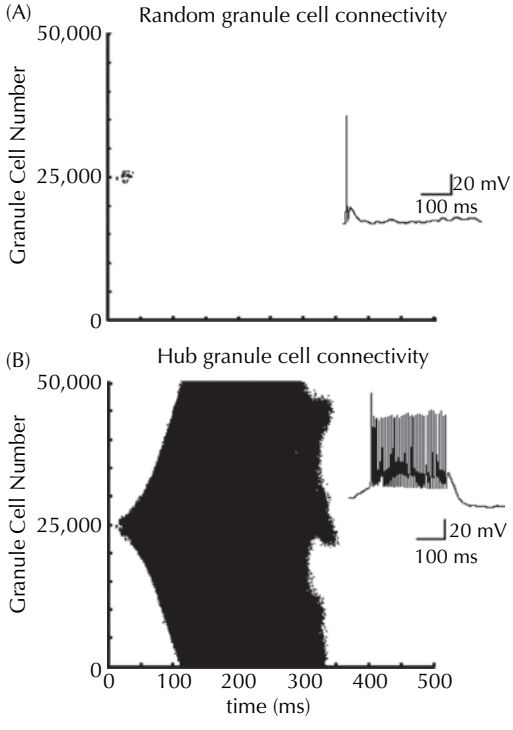

Figure 23–5. Individual posttraumatic changes to intrinsic properties of mossy cells have robust effects on dentate gyrus network hyperexcitability. Dentate gyrus network activity in response to a single simulated perforant path stimulation at $t = 5$ ms is plotted as cell number versus time. Each dot represents an action potential in one cell (blue: granule cell; green: mossy cell; red: basket cell; black: hilar-perforant path associated (HIPP) cell). Note that the scale for granule cell numbers is smaller than that for other cells. **A.** Network activity of the dentate gyrus in the FPI model with biologically realistic levels of mossy fiber sprouting and hilar cell loss. All subsequent simulations were performed with these anatomical changes in place. **B.** Network hyperexcitability is increased when mossy cell V_m is depolarized by 3 mV in the FPI model. **C.** Hyperexcitability of the network is also increased when the model is implemented with an increased mossy cell-to-granule cell synaptic conductance, representing the effect of the increased mossy cell action potential width due to change in tetraethylammonium (TEA)-sensitive potassium current. **D** Network hyperexcitability is decreased significantly when the activation curve of I_{Na} in mossy cells is shifted by 5 mV. Note that only 2 of the 750 mossy cells fire during the 500 ms simulation. Figure adapted from ref. 53.

SUMMARY OF APPROACHES TO MODELING EPILEPSY

The models described above vary in their level of detail and scope (see Fig. 23–1), and there are valid reasons for the different approaches. Researchers seeking an overall description of seizure dynamics would not necessarily want it to be in terms of the activity of thousands of neurons. For them, a higher-level approach, based on the assumption that the neural network can be characterized in aggregate terms, would be more appropriate. These aggregate, macroscopic models, such as the Lopour-Szeri model described above,[14] are often called *mean-field models* (Fig. 23–1A), indicating that their base components are entire populations of neurons similar enough to be grouped together and described in terms of average properties. Most such approaches are based on a computational model developed by Wilson and Cowan[55] that had two interconnected neuronal populations, one excitatory and one inhibitory. Though the cells are described as populations, using an average rather than individually, the average properties are still informed by physiological data. The models often produce results in the form of EEG traces, directly comparable to patient data.

Such models may also make predictions about the role of a cell population in seizure dynamics, such as one model that split the inhibitory population into separate fast and slow components while maintaining a single excitatory population.[13] The model was fit to real patient EEG data taken from preictal, preonset, and ictal time periods, and it could produce realistic EEG waveforms. The model made several experimentally verifiable predictions about the role of excitatory and inhibitory populations in seizures, including—paradoxically—that slow inhibition increases prior to seizure onset but contributes to overall excitation by inhibiting mainly the fast inhibition component.[13]

These macroscopic models have an advantage in describing seizure dynamics because they require relatively few computational resources. Their smaller computational requirements enable them to simulate the longer time periods required to model transitions into and out of the seizure state. Understanding what prompts the transition from nonepileptiform activity to the seizure state is crucial for seizure detection and intervention, and high-level models are well suited to describe such system-level dynamics.[56]

In contrast, there are questions that call for much lower-level, detailed computational models. For example, researchers interested in how a particular ion channel mutation

affects network hyperexcitability would need a highly detailed, biologically realistic model that could incorporate well-characterized ion channel properties and output precise spike times for each cell in the network (Fig. 23–1B). Such computational models are also useful for exploring the altered connectivity and cell loss seen in most models of epilepsy.[19] The various models from the Soltesz lab described above are examples of large-scale, highly detailed, biologically realistic network models.[17–19,38,53]

Even within network models that include multiple distinct cells, there is a wide variety of approaches. Neurons can be modeled at various levels of detail, ranging from morphologically detailed models with over 1000 compartments or morphologically simplified cells with detailed subcellular mechanisms (Fig. 23–1D) to integrate-and-fire neurons (Fig. 23–1C) and even simpler representations.[34] The level of sophistication at which a neuron should be modeled depends on the complexity of the computation it is expected to perform. While integrate-and-fire neurons may be sufficient to produce expected spiking patterns in some cases,[19] specific distributions of ion channels and synapses along dendrites may be necessary to model more complicated functions performed by neurons, such as coincidence detection.[34] The Cressman et al. and Ullah et al. models described above[11,44] employed mathematical neurons with subcellular and extracellular mechanisms described by a few equations. This level of detail was sufficient to answer the questions they posed in the model and enabled them to run the longer simulations necessary to characterize the dynamics in the ion concentrations. To model the astrocytic rearrangement more concretely, as they propose for future work, a more detailed model that incorporated three-dimensional cell positions would probably be necessary.[44]

As mentioned in passing above, computer modeling is limited by time and resource availability. If a model contains very detailed components (such as numerous ion channel types or detailed cell morphology), it may be necessary to remove complexity from another area of the model, either the scope (number of cells) or the length of simulation time (whether the model simulates activity occurring over a few milliseconds or several days). For this reason, often the more detailed a model is, the smaller its scope and simulation time.

Because of the above limits, computational models used in epilepsy generally describe only part of the disorder,[20] such as aggregate electrical dynamics during seizures[13] or altered neural connectivity found in the affected areas of the epileptic brain.[19] While partial models can provide much insight, there is significantly more explanatory power in a model that answers questions covering multiple levels simultaneously, such as: how do the altered firing patterns of cell type A influence the EEG signal after seizure onset?

THE FUTURE OF COMPUTER MODELING OF EPILEPSY

Given the rapid rate at which technology is developed, it is easy to imagine that computers will soon be fast enough to support a detailed, biologically realistic model of the entire human brain that could answer questions such as the one above.[5] Today modelers must choose between modeling seizure dynamics and transitions (which require lengthy simulation times) or detailed biological structures and mechanisms; in the future, it will be possible to do both at once. Such a powerful model would represent a significant tool for understanding overall seizure and transition dynamics in terms of network and cell-level activity, an area of epilepsy research that needs significant development.[47]

Already, advances in neural simulation tools allow them to run simulations in parallel (on multiple computers at once) in a fraction of the time it would take to run the same simulation on a single processor. These parallel models can support far more neurons and detail so that, for example, network models focusing on altered connectivity in epilepsy can be scaled up to full size to enable a more realistic picture of neural connectivity. Additionally, detailed network models of particular brain regions could be made bilateral. Both computational models and in vitro experiments generally approach epilepsy "unilaterally," without regard to which side of the brain is being observed or any effects of the contralateral hemisphere. However, the two sides of the brain vary remarkably in ways relevant to epilepsy. For example, there is known to be significant asymmetry between the bilateral connections of the hippocampal

formation.[57] Bilateral models could address the effects of contralateral connections and asymmetry[57] on seizures and seizure generalization.

The computational models all described so far have been simulations, in which software is configured to produce the model. However, as we create models with increasing numbers of cells, it is worth noting that a model of the whole human brain would be quite resource-intensive. For example, the Blue Brain project mentioned above uses 8192 processors to model 10,000 highly detailed multicompartmental neurons with 100 million synapses.[5,58] A model of the whole human brain would need to include 100 billion neurons and 10 quadrillion synapses, an expensive endeavor that is projected to require millions of processors and roughly 100 megawatts of power.[58]

To overcome these limitations, another approach to modeling has been developed. Rather than configure software, some modelers are configuring hardware to emulate neural networks, such as the recent Neurogrid project.[58] The resulting neuromorphic chips can be combined to produce a device capable of emulating 1 million neurons and 6 billion synapses in real time. Though these neurons are less detailed than those on the Blue Brain computer, they still contain multiple compartments and realistic ion channels. Highly detailed neurons can be modeled as well if the overall number of neurons is decreased; models with hundreds of compartments and any number of distinct ion channel types are not unfeasible.[58]

One of the main arguments against hardware modeling is its lack of flexibility. However, significant improvements have been made to address this limitation. The current Neurogrid device can support 16 different cell types, each having its own combination of ion channels.[58] The connections between cells are programmed using random access memory (RAM) and can be changed on demand. The results of the neuromorphic simulations can be viewed on an interactive display in real time at various levels, from the spike patterns of a single cell to the activity of a whole cortical layer. The applications of such a tool to epilepsy research are apparent: the ability to quickly model such a large number of neurons over a long simulation time is just what we need to characterize seizure dynamics in terms of cell and ion channel activity.

COMPUTER MODELING RESOURCES

Computer modeling is a useful research tool available to almost everyone. The monetary investment in computer modeling can be small, requiring resources available to anyone with a computer and Internet access or, for more intensive modeling, resources readily accessible at research institutions or through multipurpose shared resources such as the National Science Foundation's TeraGrid.[59]

Researchers and clinicians interested in computer modeling are urged to explore the many computational models freely available online at the ModelDB Web site.[60] In most cases, the software used to create such models is also freely available online (e.g., the neural simulators NEURON[61] and GENESIS[62]) or through network licenses at academic institutions (MATLAB[63]). The time required to learn these programs is comparable to the time required to learn various experimental techniques, and results can be obtained quickly. Importantly, the researcher has far more control over the factors important to obtaining results from models than is possible with experiments.

The large-scale, detailed, biologically realistic models referenced above employed NEURON, but many successful models have employed GENESIS as well. For example, van Drongelen et al.[64] produced a detailed, 656 cell neocortical network with GENESIS. The model included two types of pyramidal cells, basket cells, and chandelier cells, with small-world connectivity. The cells contained realistic ion channels and gap junctions. The authors used this model to explore the effect of synapse weights on the ability of the cortical network to form and sustain seizure-like oscillations and to observe the activity displayed by subpopulations of neurons during these oscillations. Surprisingly, among other results, they found that a weakening of excitatory connections in the neocortex may enable the propagation of seizure-like activity, and they concluded that strong excitatory connections are not always necessary for a network to produce seizures.[64]

Both NEURON and GENESIS can be run in parallel, which allows for a near-linear speed increase in modeling time; to run a model for the same simulation on two processors will take roughly half the time taken to run the model on

one processor. The authors recently ran a 1000 ms simulation of over 1 million detailed cells in less than 2 hour, using parallel NEURON on 608 processors.[65] MATLAB can be run in parallel as well, using its Parallel Computing Toolbox.

All three of these software programs have extensive online documentation, tutorials, and user forums supported by the software developers. Both NEURON and MATLAB regularly hold in-person workshops as well. While both NEURON and GENESIS have graphical user interfaces (GUIs), these GUIs are generally most useful when building single-cell models. For network models, there is a simulation software-independent tool called NeuroConstruct, which provides an interface to NEURON, GENESIS, and other programs for those who prefer not to work with code directly.[66]

In addition to software-specific resources, there are some excellent books on computational neuroscience in general[67] and computational modeling of epilepsy in particular.[9] They are useful for the potential modeler or for anyone wanting a deeper understanding of computer modeling in neuroscience and epilepsy.

CONCLUSION

A detailed model of the entire human brain, which could be accessed at any level of detail and be personalized for individualized patient treatment analysis, no longer seems outlandish. Likewise, it appears that an implantable seizure detection and intervention device will be available as a standard treatment option before long. Such exciting advances made possible through computer modeling should inspire researchers and clinicians to be even more creative in their approaches to epilepsy therapies. We look forward to the advances the next decade will bring in computer modeling of epilepsy.

Chapter 24

Traumatic Brain Injury and Posttraumatic Epilepsy

David A. Prince
Isabel Parada
Kevin D. Graber

The epidemiology of posttraumatic epilepsy (PTE) has been extensively analyzed and reviewed in a number of studies of both civilian and military brain injuries[1,2] (reviewed in ref. 3). Several conclusions from this research are relevant to considerations of the potential mechanisms and prophylaxis of PTE. Results clearly show that the incidence of PTE is related to the severity of injury, and is therefore significantly higher in the military during wartime than in the civilian population, ranging up to 53% with penetrating wounds[1,2] (reviewed in ref. 3). Both the increased incidence at older ages and the potential development of PTE by the large number of individuals who have survived severe concussive injury during recent conflicts suggest that the size of the affected population will increase in coming years, emphasizing the need for understanding the underlying pathophysiological processes and the development of prophylactic strategies.[4,5] Although initial seizures in those who develop epilepsy most commonly have a focal origin in neocortex, both partial neocortical and temporal lobe epilepsy can follow traumatic brain injury (TBI) in humans.[6] One remarkable feature of PTE is the variable, often very prolonged latency from injury to epilepsy, which can range from weeks to years.[1,2,6] This provides a possible window for prophylactic intervention once more information regarding the underlying pathophysiological processes

and strategies for modifying them is available. However, the long latency also represents a potential therapeutic problem, particularly in the absence of reliable biomarkers of epileptogenesis in progress. This chapter will focus on examples of aberrant excitatory and inhibitory processes in injured epileptogenic cortex and potential approaches to prevention of epileptogenesis that are focused on these pathophysiological mechanisms. Some of the challenges for the development of prophylactic therapies are also discussed. Readers are referred to a number of reviews and papers published very recently that deal with various aspects of the basic mechanisms, pathogenesis, and potential prophylaxis of PTE and complement the areas covered in this chapter.[6–18]

SPECTRUM OF POTENTIAL EPILEPTOGENIC MECHANISMS INDUCED BY TBI

A large number of alterations in gene expression[19] and a variety of pathophysiological processes occur in parallel following a brain injury[20–22] (reviewed in refs. 7 and 23), making it unlikely that an intervention focused on any one of these, in isolation, will emerge as a prophylactic "silver bullet." The situation is further complicated by the likelihood that variables such as the level of brain maturation, site and distribution of injury (focal vs. multifocal vs. diffuse), type of trauma (e.g., concussive vs. penetrating), presence or absence of significant bleeding, and other factors may affect the underlying type and sequence of epileptogenic events and the optimal timing of a potentially successful intervention in a given individual. Do different combinations of pathophysiological mechanisms underlie human epileptogenesis that follows different types of cortical injuries, such as those due to stroke with cortical infarction, penetrating versus closed concussive head injuries, focal infections, or other etiologies? The same question is relevant to potential similarities or differences in events underlying chronic epileptogenesis in various models of TBI, such as fluid percussion injury (FPI)[24] versus controlled cortical impact (CCI)[25] versus neocortical partial isolation or "undercut."[26] Are underlying mechanisms in these models in neocortex the same as those in posttraumatic temporal lobe epilepsy models, or when hippocampal damage is induced by status epilepticus rather than direct trauma? These are critical questions because they bear on potential prophylactic therapies and, unfortunately, the detailed data required for answers are incomplete.

A survey of the limited cellular results from neocortical injury models, and from animals whose temporal lobes are injured in the course of experimental status epilepticus, as well as from available human material, indicates that two pathophysiological processes are prominent in focal epileptogenesis, namely, enhanced excitatory connectivity[10,27–34,] and alterations in GABAergic inhibitory mechanisms.[33,35–40] But even within these broad categories, different types of abnormalities may be present that will require different prophylactic or therapeutic approaches. For example, disinhibition might involve alterations in gama-aminobutyric acid A ($GABA_A$) receptor subunits,[41,42] decreases in voltage-dependent calcium channels[40] or Na^+/K^+ adenosine triphosphatase (ATPase) at inhibitory terminals,[43,44] shifts in the chloride gradient due to changes in expression of chloride transporters KCC2 or NKCC,[45–47] loss of inhibitory connectivity due to structural changes in interneurons,[16,48] or actual loss of interneurons of various subtypes.[36,38]

Subsets of abnormalities can also affect the mechanisms controlling excitation, such as alterations in the probability of release (Pr) at terminals,[49] burst firing in axons[50] (reviewed in ref. 51), receptor efficacy or number,[52–56] and dysfunction of ion or transmitter transport.[57–62] In addition to alterations in inhibitory efficacy and enhanced excitation, many other potentially epileptogenic changes are present following injury, such as alterations in voltage-dependent ion channels,[63–67] blood-brain barrier disturbances,[68] inflammatory responses and release of cytokines,[21,69] alterations in glia,[70,71] and so on. In terms of evaluation of therapeutic trials of potential prophylactic agents, this plethora of abnormalities raises a difficult issue: a single agent may fail to prevent PTE even though it is effective at its intended target, that is, a false-negative result may be obtained due to the presence of other epileptogenic mechanisms acting in parallel.

CHOICE OF MODELS FOR RESEARCH ON PTE

There is no perfect model of human PTE. The advantages and disadvantages of acute and chronic models of epilepsy have recently been reviewed in detail.[72] Fluid percussion injury, CCI, and undercut models each have their place in advancing our understanding of PTE. Valuable information has also been obtained from status epilepticus temporal lobe injury models, although direct traumatic injury is not present and the resulting epileptogenesis represents a different epilepsy syndrome that may involve a somewhat different spectrum of underlying mechanisms. Discussions about the merits of one model versus another thus are only useful in the context of the particular pathophysiological process or event to be investigated. Obviously, to determine whether a drug will be prophylactic against seizures in vivo, a model in which there might be extensive injury and an expected high incidence of electrographic and behavioral posttraumatic seizures at relatively short latency after injury (i.e., high throughput) would be most practical and desirable.[73–75] However, this might not be the model of choice for investigation of the details of functional or structural alterations in neocortical GABAergic interneurons or pyramidal cells that occur at a site of stereotyped restricted epileptogenic focal injury and the potential prophylactic effects induced by the same drug on these alterations. Such a question would be better addressed with a more reductionistic approach using a model that would facilitate detailed cellular in vitro experiments and avoid the complications of widespread damage and variability.[30,32,76] Both kinds of experiments are critical for progress, and fitting the preparation used to the question posed is certainly not a new concept in neurobiological research. There is no one best approach to unraveling the mechanisms underlying the pathogenesis and prophylaxis of PTE.

PARTIAL NEOCORTICAL ISOLATION (UNDERCUT) MODEL

The authors' familiarity with this model, the significant amount of anatomical and cellular electrophysiological data available (references below and in ref. 77), and the fact that this is the first case in which prophylaxis of epileptogenesis after local cortical injury has been demonstrated (discussion below), has led us to focus on the undercut model in this review. The advantages of this model have been detailed elsewhere.[77] Most important is the relatively short interval between injury and epileptiform activity that is present in a high proportion of neocortical slices cut through the damaged area and maintained in vitro[78–80] (Fig.24–1C,D). This has allowed the detailed examination of epileptogenic cellular structural and functional alterations in pyramidal (Pyr) cells and GABAergic interneurons detailed below. We have also obtained in vivo video/electroencephalographic (EEG) recordings that show electrographic and behavioral seizures beginning with a focal discharge in the undercut cortex, spreading across the cortex on the injured side, and propagating contralaterally (Fig. 2 in ref. 77).

Partially isolated neocortical islands with intact pial circulation (*undercuts*, discussed below) are an established in vivo and in vitro model for development of chronic posttraumatic hyperexcitability and epileptogenesis,[32,78,79,81,82] and partially isolated neocortex is also epileptogenic in humans[83] (Fig. 24–1A). The undercut cortex retains normal laminations (Fig. 24–1B), although it becomes thinner with modest cell loss and obvious structural alterations in deep-lying Pyr cells[78,84] (K Graber and DA Prince, unpublished findings). Disinhibition, increases in neuronal membrane excitability, and increases in excitatory synaptic coupling have been suggested as potential mechanisms in this chronic epilepsy model.[32,78,85–87] The undercut cortex becomes progressively more epileptogenic over several weeks,[82,88] and spontaneous interictal discharges can persist for at least 1 year in the monkey.[26] The time of onset of epileptogenesis, or the "critical period" in rats, occurs during the first 3 days after injury,[89] and recent data suggest that epileptogenic activity is already present 3 days after the undercut (DK Takahashi and DA Prince, unpublished results). Isolated islands of neocortical gray matter, with neuropathological evidence of substantial axonal reorganization, are also present in postmortem specimens from epileptic children who developed extensive underlying

white matter lesions as infants.[90] Interictal epileptiform activity can be recorded within partially isolated cortex of anesthetized rats, and c-*fos* immunoreactivity (IR) is increased for weeks in the injured cortex, suggesting ongoing abnormal activity.[91] Behavioral and electrographic seizures occur in in vivo experiments on monkeys, cats, and rodents in this model (see above and references in ref. 77). Areas of partially isolated cortex with underlying loss of white matter are also present in the cortical contusion (Fig. 2 in ref. 25 and FPI models (Fig.1D in ref. 23), although it is not clear whether seizure activity originates from the cortex above these sites. Of interest are reports of chronic electrographic and clinical seizures in humans as a complication of psychosurgery in which connections from portions of frontal lobes were severed, essentially producing large, partially isolated neocortical slabs[92,93] (Fig. 24–1A).

Abnormalities in Excitatory Mechanisms in Undercut Cortex

The capacity of injured brain to make new connections has been known since the groundbreaking anatomical studies of Cajal,[94] who described sprouting of injured Pyr cell axons

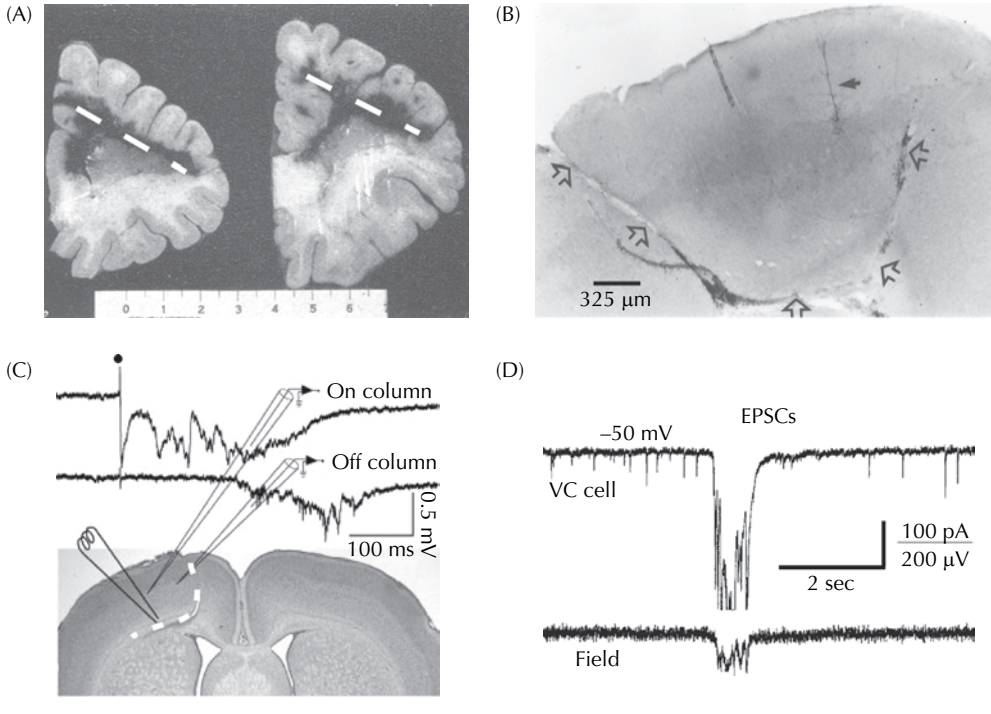

Figure 24–1. Undercut cortex in rats and humans. **A.** Coronal section of human brain in a patient who underwent undercutting surgery of the right frontal lobe for intractable pain. Dashed white lines are drawn through the undercut here and in **C**. **B.** Fixed coronal section cut through rat sensorimotor cortex containing a partial cortical isolation made 3 weeks earlier. The black arrow points to a layer V pyr cell filled with biocytin. Open arrows mark the edge of the undercut that extends from the pial surface to the white matter. **C.** Upper: Evoked epileptiform field potentials recorded simultaneously by two electrodes (On column, Off column) in layer V of an in vitro slice 3 weeks after partial isolation. Lower: Nissl-stained section from the same slice showing the approximate site of the undercut lesion and electrode positions. Stim: stimulation electrode. All-or-none prolonged polyphasic epileptiform activity was evoked by a stimulus in layer VI/white matter just above the undercut margin. An epileptiform burst was initiated by On-column stimulation and propagated across cortex to the Off-column electrode. **D.** Representative voltage clamp recording (upper trace) from layer V pyr cell in the undercut during a spontaneous epileptiform event. Vhold: –50 mV close to E_{Cl}; inward current downward. Random EPSCs were followed by a large, spontaneous epileptiform event consisting of summed polysynaptic EPSCs coincident with the epileptiform field potential burst in the bottom trace. Field: negativity down; current peak clipped). The evoked epileptiform field potential and the cell recording were similar to those evoked by extracellular stimuli (not shown). Slice perfused with standard artificial cerebralspinal fluid (ACSF). **A** modified from ref 92. **C** from ref. 89. **D** from ref. 32.

in neocortex. Maladaptive axonal sprouting and establishment of new excitatory connections occur in mature undercut neocortex[32] and as early as 2 days after injury in isolated immature neocortex.[95] Excitatory sprouting also occurs following injury to the hippocampus in other animal models of epileptogenesis[27,28,96–102] and in epileptic human temporal lobes.[103–107] The ubiquitous nature of this phenomenon is shown by its occurrence in other models of cortical trauma such as stroke,[108,109] theromoischemic lesions,[110] and FPI,[111] where it may begin hours after the trauma.[112] The onset of an axonal reaction and sprouting, as signaled by increases in immunoreactivity for growth-associated protein (GAP) 43, may begin as early as 12 h after lesions in culture, and these alterations are well established by 3 days after injury.[30,113] Sprouting occurs 3–4 days after injury to dissociated neocortical neurons in culture.[114] Hyperexcitability due to synaptic innervation by sprouted axons has been shown in experiments in hippocampus[29,30,76] and neocortex.[34] Activation of brain-derived neurotrophic factor (BDNF) may be an important mechanism underlying injury-induced sprouting and hyperactivity in hippocampus.[115,116]

Results from whole cell recordings of layer V Pyr neurons done 2–3 weeks after injury in the undercut cortex model support the conclusion that there is enhanced synaptic excitatory connectivity by showing (1) an increased frequency of miniature (m) excitatory postsynaptic currents (EPSCs); (2) a steeper input–output relationship for evoked EPSCs; and (3) an increased probability of release of glutamate from excitatory terminals.[33,49] The last finding suggests intrinsic abnormalities in the terminals of Pyr cells. In addition, anatomical studies of biocytin-filled layer V Pyr cell axons showed evidence of significant sprouting, mainly in layer V,[32] where the epileptogenic field potentials were initiated.[78,79] These functional and structural abnormalities presumably contribute to the large polysynaptic excitatory currents in Pyr cells that occur synchronously with field potential epileptiform bursts (Fig. 24–1D) and propagate across the cortex (Fig. 24–1C).

More recently, laser scanning photostimulation of caged glutamate in epileptogenic slices from undercuts allowed detailed mapping of excitatory and inhibitory connectivity.[34,48] Results showed that the excitatory "map" was significantly expanded, particularly in layer V, and that both Pyr cells and fast-spiking inhibitory interneurons were targets of presumed sprouted axons and terminals from other nearby Pyr neurons.[32] These alterations in excitatory synaptic connectivity and strength, together with abnormalities in inhibitory circuits discussed below, may contribute to the development and increased conduction of epileptiform activity across cortex in the in vivo undercut model in cat[117] (reviewed in ref. 118).

It is interesting that hyperexcitability closely resembling that recorded in layer V of undercut cortex has also been shown in neocortical slices from the FPI model. Rats from both models have epileptiform seizures in vivo,[77,119] and there is also a similarity in the morphology of field potentials that are evoked or occur spontaneously in slices versus those in in vivo EEG recordings in these two models. Also, recent recordings from another TBI model studied in vitro clearly show repetitive bursts of EPSCs that coincide with epileptiform field potentials that would be termed *ictal* EEG discharges if they occurred in vivo.[10]

Abnormalities in GABAergic Inhibitory Mechanisms in Undercut Cortex

A variety of structural and electrophysiological evidence shows that GABAergic inhibition is compromised in undercut cortex. Recent experiments in the cat suggest that glutamic acid decarboxylase (GAD)- or gamma-aminobutyric acid (GABA)- positive neocortical interneurons are selectively and progressively reduced in density in cat undercut cortex.[84] Although our initial cell counts in undercut rat cortex have not shown a selective decrease in the density of parvalbumin (PV)-immunoreactive interneurons,[120] we have found significant structural changes in biocytin-filled fast-spiking PV-containing cells, including marked decreases in axonal lengths and dendritic volume (Fig. 24–2), giving them an appearance similar to that seen in immature PV interneurons (compare Fig. 3A of ref. 121 with Fig. 24–2B). Further, the axons of these interneurons in the undercut cortex have a significant increase in the proportion of small (<1 μm in diameter) boutons and a decrease in the number of larger (>1 μm in diameter)

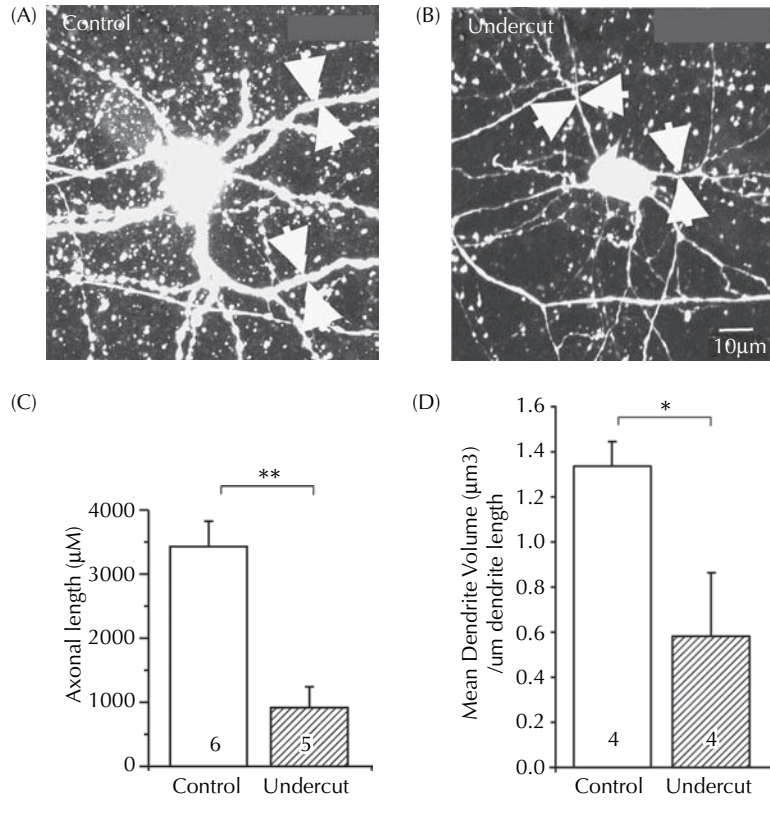

Figure 24–2. Structural alterations in fast-spiking interneurons in undercut cortex. **A,B.** Images of single layer V fast-spiking interneurons filled with biocytin and processed in control (**A**) and undercut slices (**B**). The cell from the undercut slice has thinner dendrites (arrowheads) and a less dense axonal arbor. Calibration in **B**: 10 μm for **A,B**. **C,D.** Graphs show significant decreases in axonal length (**C**) and mean dendritic volume (**D**) in undercut (hatched bars) versus control cells (white bars). The number of cells analyzed is shown in each column. Measurements were obtained from stacks of confocal images. Mean ± SD axonal length for control: 3429.8 ± 968.1 μm and for undercut: 726.9 ± 325.1 μm. $^{**}p < .001$; $^{*}p < .01$. **A,B,D** from I Parada, DA Prince, unpublished. **C** modified from ref. 16.

boutons (see Fig. 5 in ref. 16), changes that would be associated with altered pre- and postsynaptic structures at GABAergic synapses and with less effective inhibitory transmission.[122,123]

Results of several electrophysiological experiments confirm the decreased efficacy of GABAergic inhibitory transmission in the undercut cortex. Whole cell recordings in rat undercut slices showed a decreased frequency of mIPSCs in Pyr cells,[33] and quantitative electron microscopic experiments confirmed a decreased density of symmetrical (inhibitory) synapses on somata of layer V Pyr cells (J Wenzel, PA Schwartzkroin, and DA Prince, unpublished results) as one potential mechanism for decreased miniature inhibitory postsynaptic current (mIPSC) frequency. More recently, we have also shown that the axonal terminals of layer V interneurons in undercuts are abnormal in that they have a decreased probability of GABA release and an increased failure rate[40] due in part to a downregulation of N-type calcium channels in terminals (LC Faria and DA Prince, unpublished results). Dual recordings from synaptically coupled FS-Pyr or FS-spiny stellate pairs in layer IV of undercuts showed a decrease in Pr, a large reduction in the amplitude of unitary IPSCs, increased coefficient of variation and increased failures, indicating alterations in presynaptic terminals of the largest subgroup of GABAergic neurons in cortex, FS cells (J. Ma and DA Prince, unpublished results). Neuronal injury can also decrease the efficacy of postsynaptic inhibition by decreasing expression of KCC2 and impairing outward chloride transport.[124,125] In the undercut, there are also decreases in KCC2 and in the outward transport of chloride in postsynaptic Pyr cells

that would make GABAergic inhibition less effective at times of high-frequency activity.[126] Recent results, obtained with laser scanning photostimulation of caged glutamate in combination with whole cell recordings, have shown that the net effect of some of the above-mentioned anatomical and electrophysiological abnormalities is to reduce the spatial extent of inhibitory inputs onto both Pyr cells and FS interneurons in the chronic undercut.[127]

Fast-spiking interneurons in neocortex normally have a high density of Na^+-K^+ ATPase (*sodium pump*) in their membranes[44] and particularly in their axonal terminals surrounding Pyr cell somata[43,128] (Fig. 24–3A). Sodium pump activation would be important in fast-firing neurons to prevent excessive increases in $[Na^+]_i$ that might depolarize terminals and decrease GABA release. There is a significant loss of Na pump immunoreactivity in undercut cortex surrounding Pyr cells (Fig. 24–3B), similar to that previously found in the freeze-microgyrus model of epileptogenesis,[43] suggesting another potential mechanism that would lead to terminal dysfunction and decreased GABA release.

WHEN DOES POSTTRAUMATIC EPILEPTOGENESIS BEGIN?

Answers to this critical question would influence decisions about the timing of potential antiepileptogenic treatment. From the available data, it appears likely that processes eventually leading to hyperexcitability in cortical networks and to seizures may be set in motion at the time of the TBI, although the latency to the first behavioral spontaneous seizure is highly variable. Seizures in the first week after injury are usually not followed by epilepsy in humans; however, they are associated with an increased statistical risk of subsequent epilepsy,[3] indicating that, at least in some individuals, an epileptogenic process is initiated early. Epileptiform activity may be initially undetectable by surface EEG, making this an unreliable marker of the onset of epileptogenesis.[129] There is evidence for early emergence of epileptogenesis in a variety of experimental data. In models of acute neocortical trauma, epileptiform activity may develop within minutes or hours after injury in vitro,[130,131] and results from acute partial isolation experiments done under ketamine anesthesia in cats do show that acute epileptiform discharges are generated in cortex near the isolation.[132] However, the underlying mechanisms in these early seizures may be different from those in more chronic models in that they might involve acute alterations such as release of excitatory amino acids,[131] spreading depression, large increases in $[K^+]_o$, and blood-brain barrier disruption.

Recently, we recorded in vitro from undercut slices obtained 3 days after the injury and found that they generate robust, prolonged, spontaneous and evoked epileptiform field potentials associated with large-amplitude EPSCs. Confocal images obtained after immunocytochemical processing for GAP43, vesicular glutamate transporter 1 (vGLUT1), and postsynaptic density (PSD) 95 suggest

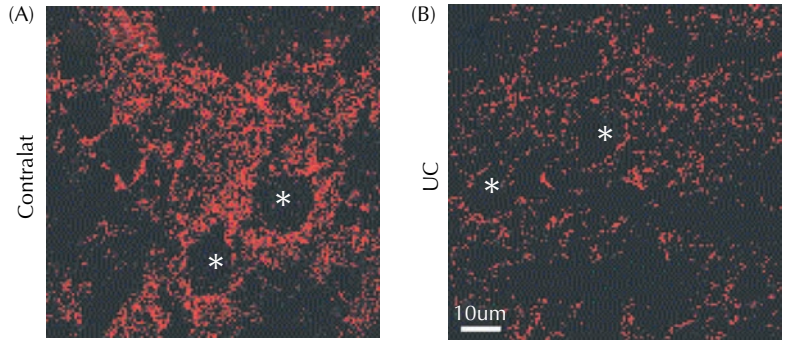

Figure 24–3. Loss of perisomatic α3Na^+K^+ ATPase in undercut cortex. **A.** Immunoreactivity (IR) for α3Na^+K^+ATPase in layer V of control cortex contralateral and homotopic to the undercut on a rat 21 days after lesioning. The IR is localized around the somata of pyr cells (asterisks in **A,B**), suggesting that it is in terminals of FS interneurons that target somata. Dual staining with GAD65 (not shown) confirmed this conclusion.[43] **B.** Undercut side from the rat in **A** shows significant downregulation of α3Na^+K^+ATPase-IR. From ref. 128.

that there is significant sprouting of excitatory axons onto Pyr somata within days after the undercut is placed. Other electrophysiological data suggest that these sprouted terminals are functional and contribute to epileptogenesis (DK Takahashi and DA Prince, unpublished results).

Axonal sprouting and excitatory synapse formation occur in parallel with a number of other pathophysiological events following TBI (e.g., alterations in GABAergic inhibition discussed above, intrinsic changes in membrane excitability[78]), so it is difficult to determine whether hyperconnectivity alone would be sufficient to induce posttraumatic epileptogenesis. A potential answer to this question comes from recent results in C1q knockout mice that have behavioral and electrographic seizures resulting from failure to prune excitatory cortical synapses during development.[133] In vitro slices from these animals are epileptogenic due to increased excitatory connectivity without apparent alterations in inhibitory events.

In experiments using CCI, epileptiform activity and electrographic seizures are present in vitro the first week after injury[10] and appear to progress, with generation of ictal discharges lasting for many seconds by the second week. In other experiments, such as those involving kainate kindling, epileptogenic activity is present early in hippocampus but goes undetected in in vivo recordings from the usual skull electrodes.[134] Our previous results using the undercut model provided the first proof in principle that posttraumatic epileptogenesis, as gauged by the occurrence of epileptiform activity in in vitro slices, begins shortly after injury and can be prevented.[80] However, this prophylaxis was effective only if the treatment, namely, topical exposure of the injured cortex to tetrodotoxin (TTX) in a slow-release resin, was administered for the first 3 days after injury. Later applications were ineffective in limiting the proportion of slices that were epileptogenic.[89] Thus, the results revealed a brief critical period of a few days beginning after the partial isolation when the seeds for subsequent epileptogenesis are sown in the undercut cortex model. Tetrodotoxin has also been effective in decreasing axonal sprouting and rhythmic neocortical burst discharges that begin by the second day after development of thermocoagulation lesions in rat neocortex, although the relationship to later epileptogenesis is unclear.[110]

These results with TTX appear contrary to the hypothesis that the enhanced excitability and epileptogenesis in the undercut may be due to activation of homeostatic increases in excitatory neurotransmission due to deafferentation.[118,135] It is possible that homeostatic compensatory increases in alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors do occur, but they are offset by decreases in innervation of postsynaptic targets induced by the TTX treatment. Immunocytochemical analysis of undercut cortex shows that TTX blockade of activity downregulates anatomical markers of the axonal and terminal sprouting response that are evident as early as 3 days after injury (Fig. 24–4A–C) and are long-lasting (Fig. 24–4D–F). Other as yet unexplored results of silencing injured cortex may account for the blockade of hyperexcitability in the undercut that outlasts the TTX treatment by many months (KD Graber and DA Prince, unpublished results). It is important to note that TTX may produce quite different (opposite) effects on epileptogenesis when given during early development in hippocampus,[136] a result that emphasizes the difficulty of generalizing results from one model to another in terms of potential prophylactic approaches.

PROPHYLAXIS OF POSTTRAUMATIC EPILEPTOGENESIS

Potential approaches to modification of the increased excitatory sprouting and synapse formation and the decreased GABAergic interneuronal structure/function are suggested by results of experiments dealing with normal development of excitatory synapses and interneurons.

Limiting Excitatory Connectivity

Reactive astrogliosis is a ubiquitous pathological finding following TBI and is present in all of the models discussed above, including the undercut. Release of thrombospondins (TSPs) by astrocytes provides an important signal for excitatory synapse formation early in development[137,138] and following injury to the mature central nervous system (CNS).[139,140]

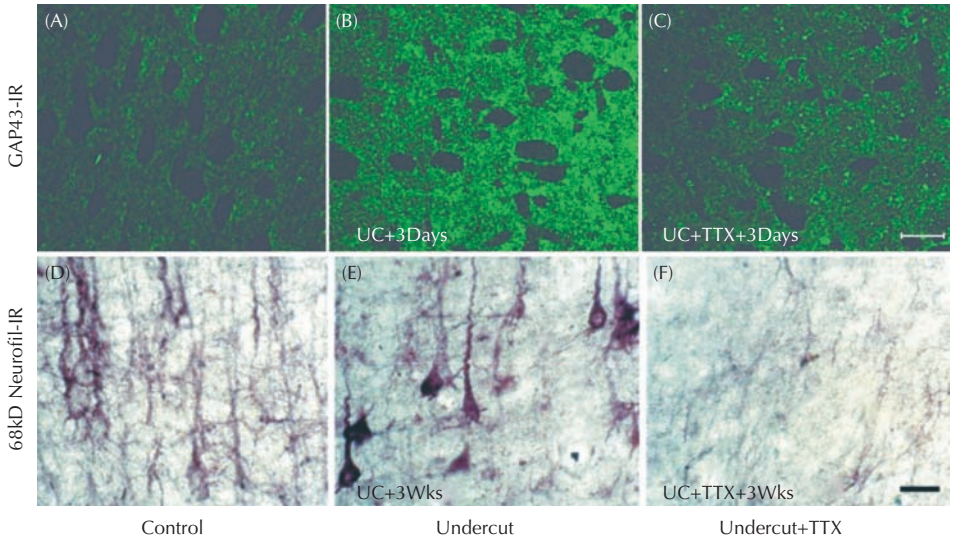

Figure 24–4. Immunoreactivity (IR) of axons and terminals in partially isolated neocortex.
A–C. Sections through layer V of rat sensorimotor cortex reacted with growth-associated protein (GAP) 43 antibody. **D–F.** Comparable sections from rats reacted with antibody for 68 kDa neurofilaments. A,D. Control from layer V of hemisphere contralateral to the undercut. B,E. GAP43-IR (B) and 68 kDa neurofilament-IR (E) in layer V of undercuts made 3 days earlier, contralateral to A and D, respectively. C,F. Representative sections from undercuts of two other rats in which Elvax impregnated with TTX was placed subdurally over the undercut area at the time of surgery. Immunocytochemistry was done after 3 days in **A–C** and after 3 weeks in **D–F**. The TTX treatment reduced IR for both GAP43 and neurofilament in the undercuts. Calibrations in C and F: 50 μm for **A–C** and **D–F**, respectively. From ref. 16.

The α2δ-1 voltage-gated calcium channel subunit, which is upregulated in peripheral pain models and after brain injury, is the receptor for the antiallodynic/antiepileptic drug gabapentin (GBP)[141,142] (reviewed in refs. 143 and 144) and is also the receptor for TSPs.[137] Gabapentin can block excitatory synapse formation in the developing retinogeniculate pathway by interfering with TSP actions.[137] The increased axonal sprouting and synapse formation are reduced in TSP knockout animals in a stroke model, leading to the hypothesis that GBP would have similar actions and might be an antiepileptogenic agent in the undercut model. In recent experiments, GBP, given by subcutaneous infusion or intraperitoneally for 2–3 days up to 14 days following the day of the undercut, decreased the proportion of slices that subsequently generated evoked epileptiform activity (Fig. 24–5A–C; H Li, KD Graber, and DA Prince, unpublished results). In addition, dual immunocytochemical processing of sections from the animals treated with GBP showed significantly fewer presumptive excitatory synapses (i.e., close appositions between pre- [vGLUT1] and postsynaptic markers [PSD95] (Fig. 24–5D–F)). Gabapentin also reduced expression of 200 kD neurofilament-IR and the number of neurons stained with fluorojade C (not shown), suggesting potential neuroprotective effects.

Preventing Structural/Functional Alterations in GABAergic Interneurons

The above structural changes in FS interneurons gave them an appearance that resembled, in some respects, that seen in immature GABAergic cells,[121] prompting us to assess expression of BDNF in neurons of the undercut, as this trophic factor is a key molecule in regulating the development and maintenance of both interneuronal and Pyr cell structure and function[121,135,145–147] (reviewed in ref. 145). Immunoreactivity for BDNF in Pyr cells and its TrkB receptor on PV-containing interneurons and the associated mRNAs were significantly downregulated as early as 3 days after the undercut, suggesting that supplying this or another trophic factor after injury

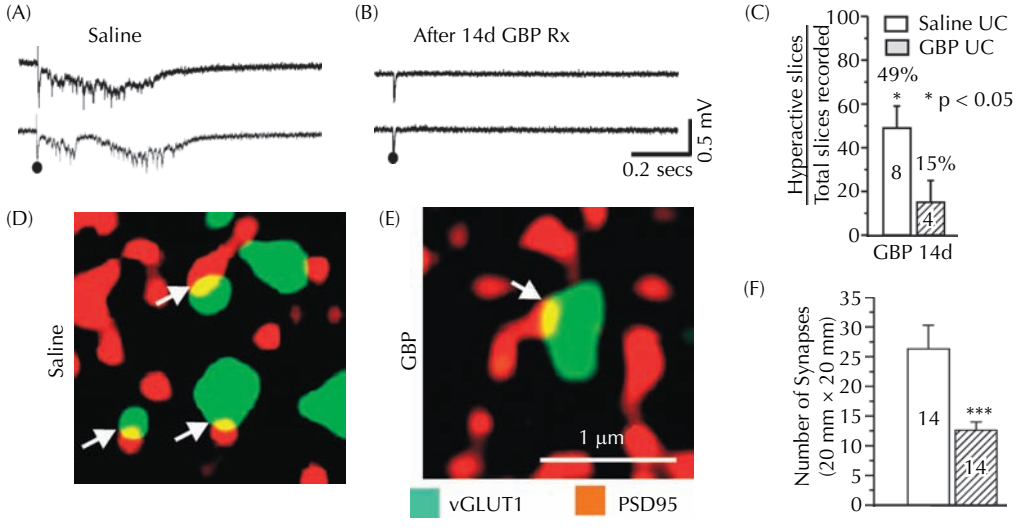

Figure 24–5. Gabapentin (GBP) in vivo reduces epileptogenesis and excitatory synapse density in undercut slices. **A,B.** Field potentials evoked in layer V of an undercut slice by stimuli in partial cortical isolations 14 days after injury. **A.** A rat was treated with an intraperitoneal (ip) infusion of saline for 14 days, followed by a slice experiment. Single stimuli within isolation evoke typical epileptiform discharges consisting of slow potentials lasting for ~400–500 ms with superimposed extracellular unit bursts. **B.** Representative nonepileptiform responses to stimulation of a slice from a rat treated for 14 days with an ip infusion of ~8 mg/day GBP via Alzet pump. Recordings were done 1 day after termination of GBP infusion. **C.** Group data showing the percentage of epileptogenic slices 14 days after undercuts in GBP- versus saline-treated animals. UC: undercut in both groups. Numbers in bars: numbers of animals. Average of 4.3 slices/rat. Gabapentin significantly reduced epileptogenesis in these experiments. **D,E.** Confocal images of neocortical layer V from undercut rats treated with ip saline (**D**) or GBP (**E**; ~8 mg/kg × 7days) after the undercut. Sections were immunoreacted with antibodies for postsynaptic (PSD95, red) and presynaptic markers (vGlut1, green). Sites of putative synapses shown by close appositions (yellow; arrows) were fewer in sections from GBP-treated rats (**E** vs. **D**). **F.** Group data from saline- (white bar) and GBP-treated animals (hatched bar). Numbers in bars: total number of sections examined. Three images were taken from each section and two to three sections were taken from each of the five rats in each group. $^{***}p < .001$. From H Li, KD Graber, DA Prince, unpublished.

(for example, ref. 148) might be an approach to prevention of trauma-induced alterations in these cells (Fig. 6 in ref. 16; see also ref. 17). Brain-derived neurotrophic factor has many potential actions[149], including both enhancement of network excitation and inhibition,[150,151] so it is unclear whether the net effect of BDNF or other TrkB receptor agonists will be anti- or pro-epileptogenic. Variables such as dose level and timing or choice of the mimetic molecule might allow differentiation of beneficial versus detrimental effects.

IMPORTANT UNRESOLVED ISSUES AFFECTING APPLICATION OF ANTIEPILEPTOGENIC THERAPIES FOR PTE

1. The question of adaptive versus maladaptive changes in connectivity following injury is a key one that must be considered in approaching potential preventive treatments that decrease epileptogenic sprouting. A number of reports implicate axonal sprouting and new connections as major adaptive plastic events in recovery of function after development of cortical lesions.[108,109] In recent experiments in a stroke model where middle cerebral artery occlusion induced expression of TSPs in astrocytes, TSP1–2 knockout mice showed significant defects in axonal sprouting and synaptic density compared to wild-type animals, together with defects in functional recovery.[140] The poststroke incidence of epilepsy was not studied in these experiments; however, the results, and those in the above references, provide a cautionary note.
2. A number of pathophysiological processes occur in parallel after a serious

epileptogenic brain injury. Although any one of these in isolation might not induce seizure activity, in combination their effects on excitability would summate and epileptogenesis could result. Thus, a single prophylactic approach might be ineffective and a "prophylactic cocktail" might be required.

3. Two key elements in developing epileptogenesis in a variety of injury models are reduction in functional GABAergic inhibition and enhanced new excitatory connectivity. Although attempts to reverse such alterations may be effective, the relationships between both excitatory and inhibitory circuit function, circuit repair, and epileptiform activity are complex. GABAergic synchronization of cortical networks occurs in epileptogenic cortical lesions[152] and in both acute[153] and genetic models of epileptiform discharge.[154] Also, depolarizing GABA responses due to altered chloride gradients occur in excitatory cells during development[155] and after injury.[125,156] These factors make the net effect of enhanced interneuronal output hard to predict. Antiepileptogenesis, through decreases in excitatory circuit activities, might also have obverse effects such as decreased activation of interneurons[157] (but see refs. 158–160) or reduced activity-dependent axonal sprouting, pathfinding, and circuit repair.[110,161,162]
4. As more becomes known about the processes controlling excitation and inhibition during cortical development or following injury, it is possible that prophylactic therapies selectively affecting maladaptive processes might be applied. One important obstacle at this time is the unavailability of a reliable biological marker that would select for individuals who will go on to develop PTE, although it is clear that the incidence increases with the severity of brain injury (reviewed in ref. 163).
5. We know little about the temporal extent of critical periods in humans when prophylactic intervention would be effective or how to identify epileptogenesis in progress. The latent period may be very long between injury and expression of behavioral seizures[1]; however, the critical period for intervention could closely follow the injury.[89,164]
6. Finally, multiple offsetting potential effects of a given intervention are possible, such as enhancement of excitatory connectivity together with "rescue" of inhibitory interneurons by TrkB receptor agonists (e.g., refs. 165, 166).

The chapters in this volume suggest that significant progress is being made in understanding the basic mechanisms leading to epilepsy, and that we may have potential prophylactic therapies available in the years to come, provided that some of the issues mentioned above are settled by detailed basic and clinical investigations.

Chapter 25

Head Trauma and Epilepsy

Asla Pitkänen
Tamuna Bolkvadze

Traumatic brain injury (TBI) refers to a brain injury caused by an external mechanical force such as a blow to the head, concussive forces, acceleration-deceleration forces, blast injury, or a projectile missile such as a bullet.[1] According to the World Health Organization, TBI will surpass many diseases as a major cause of death and disability by the year 2020.[2] With an estimated 10 million people affected annually by TBI, the burden of mortality and morbidity that this condition imposes on society makes TBI a serious public health and medical problem.

Traumatic brain injury is a heterogeneous disorder that can be classified based on the injury mechanism.[3] Depending on the characteristics of the mechanical force (amplitude, duration, velocity, acceleration), injury can be static or dynamic. Static loading occurs when the head is exposed to a heavy weight—for example, if the head is trapped underneath a car. Dynamic loading is a more common type of mechanical input causing TBI, and can be divided into two types: (1) impact loading, which occurs when a blunt object strikes the head and can initiate both contact and inertial forces, and (2) impulsive loading, which occurs during the rapid acceleration or deceleration of the head.

The 15-point Glasgow Coma Scale (GCS) is a rating commonly used to evaluate the severity of brain injury. It assesses three major parameters: verbal, motor, and eye-opening reactions to stimuli.[4] A GCS score of 13 or above indicates mild TBI, 9–12 is moderate TBI, and ≤8 is severe TBI. It is important to note that the same injury severity may represent different clinical endophenotypes that depend on the injury mechanism (e.g., static vs. dynamic) or the distribution and type of damage (e.g., gray vs. white matter).

POSTTRAUMATIC EPILEPSY IN HUMANS

Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiological,

cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one spontaneous (i.e., unprovoked) seizure.[5] After TBI, the occurrence of seizures has been categorized as immediate (<24 h), early (1–7 days), or late seizures (>1 week after TBI).[6] The immediate and early seizures are considered to reflect the severity of the injury itself, whereas the late seizures result from maturation of epileptogenic pathology. Thus, TBI associated with one unprovoked late seizure qualifies for the diagnosis of posttraumatic epilepsy (PTE).

Epidemiological studies show that a 30-year cumulative incidence of epilepsy is 2.1% for mild, 4.2% for moderate, and 16.7% for severe injuries.[7] As discussed by Herman,[8] TBI accounts for 20% of symptomatic epilepsy in the general population and 5% of all epilepsy. It can be estimated that in the United States and the European Union (EU), with a total population of about 800 million, at least 0.5 million surviving individuals live with PTE. Data on the economic burden of PTE are unavailable, but some idea is provided by the lifetime cost of TBI on average, which in the United States is about $200,000 per case when scaled to 2004 price levels.[9] Thus, in addition to the personal burden, the economic burden caused by PTE is also substantial, and treatments to prevent posttraumatic epileptogenesis would benefit the individual as well as society.

The risk factors for PTE obtained in studies of civilian or military populations include old age, penetrating injuries, injury severity (GCS <10), biparietal or multiple contusions, intracranial hemorrhage, frontal or temporal location of the lesion, brain midline shift >5 mm, duration of coma >24 h, loss of consciousness >24 h, prolonged period of posttraumatic amnesia, multiple intracranial procedures, and the occurrence of early posttraumatic seizures.[7,10–15] These data are mostly derived from epidemiological studies that were conducted before magnetic resonance imaging (MRI) became available. Apparently related to methodology, many of the identified risk factors directly or indirectly reflect the severity of brain injury, and they strengthen the view that the risk for PTE increases with the severity of TBI. However, these risk factors give little indication of the neurobiological characteristics of the injury that are most significantly associated with epileptogenesis.

A recent study investigated the civilian population with TBI using MRI analysis performed 1–360 months (median, 12 months) post-TBI; the study reported an association of PTE with contusions but not with an isolated diagnosis of diffuse axonal injury (DAI).[16] This study found no association between micro bleeds and PTE, which challenges the data from previous epidemiology studies. Further information about the endophenotypes of TBI patients that are associated with the highest risk of PTE would be of great value for attempts to model PTE in clinically relevant ways. Such information would also guide the search of mechanisms and biomarkers (or surrogate markers) for posttraumatic epileptogenesis.

Some information is available on the epileptogenic process. After the first late seizure, 86% of patients were reported to develop a second seizure within 2 years, suggesting the establishment of an epileptogenic process.[17] Further, recent magnetoencephalography (MEG) studies revealed that some patients without reported seizures after mild TBI have epileptiform spikes when assessed at 12–140 months post-TBI.[18] Some studies have also investigated the persistence of seizures after TBI. For example, Eftekhar et al.[19] reported that 75% of patients with penetrating TBI suffered during the Iraq-Iran war continue to have seizures after a 21-year follow-up, even when data were adjusted for antiepileptic drug (AED) treatment. Interestingly, no association was found between the persistence of epilepsy and lesion size.

Data on genetic risk factors for the outcome of patients with TBI are emerging, but very few studies have assessed the linkage of genes to PTE.[20] Some data are available from genes encoding ApoE or haptoglobin. The *APOE* gene, encoding for a cholesterol carrier lipoprotein, exists in three common isoforms: ε2, ε3, and ε4. One study found that the ApoE4 allele is associated with a 2.4-fold increased risk of late posttraumatic seizures after moderate to severe TBI.[21] Interestingly, an ApoE4 allele has been identified as a susceptibility gene for Alzheimer's disease, which is another condition with an increased risk for epilepsy.[22–25] Linkage of ApoE4 to an elevated risk of PTE was not, however, confirmed by another study.[26] Another gene of interest encodes haptoglobin. Previous studies have shown that serum and cerebrospinal fluid haptoglobin concentrations

are increased after TBI.[27] Sadrzadeh et al.[28] reported that the HP2–2 allele was the risk factor for PTE. However, this observation was also not verified in another study.[26]

EXPERIMENTAL MODELS OF PTE

In vivo long-term video-electroencephalographic (EEG) monitoring studies demonstrate that several models commonly used to investigate the molecular and cellular mechanisms of TBI have chronically lowered seizure thresholds or even spontaneous seizures (Table 25–1). Chronically increased seizure susceptibility to chemoconvulsants or electroshock has been demonstrated in weight-drop, fluid-percussion, controlled cortical impact, and closed skull models of TBI (Fig. 25–1). Chronic spontaneous seizures were reported after fluid-percussion- and controlled cortical impact-induced TBI in both rats and mice. Acute epileptiform activity (up to 3 days postinjury) has been reported in a rat model of penetrating ballistic injury, but whether late spontaneous seizures develop remains to be studied.[49] No data on hyperexcitability are available from blast-induced TBI in rats.[50]

The following discussion focuses on models of TBI with spontaneous late seizures.

Epilepsy in the Fluid-Percussion Model

Lateral fluid-percussion (FP)-induced TBI has become the most extensively utilized animal model of TBI, producing both focal and diffuse (mixed) brain injury.[51] It reproduces several aspects of human TBI, including focal contusion, petechial intraparenchymal and subarachnoid hemorrhages, tissue tears, and traumatic axonal injury. The sequelae include blood-brain barrier (BBB) disruption, white matter damage, neuronal loss, gliosis, altered cerebral metabolism, altered cerebral blood flow, and altered brain electrical activity. The damage appears to be most severe in the ipsilateral cortex, hippocampus, and thalamus, but milder lesions can also be detected contralaterally. More chronic network alterations include neurogenesis with axonal and dendritic plasticity. The molecular and cellular changes can continue for weeks or months, and they seem not only to underlie the acute and chronic behavioral impairments but also to contribute to the recovery process.[51]

Kharatishvili et al.[38] monitored adult Sprague-Dawley rats with lateral FP injury over a period of 12 months with periodic 24/7 video-EEG and demonstrated that 50% of the rats developed PTE (Fig. 25–2). The seizures were partial or secondarily generalized and lasted for about 60–110 s.[52] A substantial proportion of animals had lowered seizure thresholds, and it remains to be determined whether some of these animals will develop epilepsy over a longer follow-up period. Rostral parasagittal FP was also reported to trigger epileptogenesis and the occurrence of spontaneous seizures.[31] Our preliminary data show that lateral FP can trigger increased seizure susceptibility in the pentylenetetrazole (PTZ) test, as well as spontaneous seizures, in mice.[42]

Epilepsy in the Controlled Cortical Impact Model

The controlled cortical impact (CCI) injury to the lateral cortex causes a focal brain injury that is associated with a spectrum of contusion injuries including intraparenchymal petechial hemorrhages that are accompanied by epidural and subdural hematomas. Histological analysis reveals widespread cortical gray matter damage as well as axonal injury in the adjacent white matter, corpus callosum, and capsula interna. Degeneration is present not only in the cortex but also in the hippocampus and thalamus. Damage can also be observed in all of the major afferent pathways and in the visual cortex. These anatomical changes are associated with a spectrum of cognitive and motor deficits.[53] Recently, elegant studies from Hunt and colleagues[45,46] demonstrated that CCI-induced TBI in the lateral cortex triggers the development of PTE in CD-1 mice. Behavioral seizures were observed in 20% of animals with mild injury and 36% of those with severe injury when observed after 42–71 days postinjury.[45] Our preliminary observations also show increased susceptibility to PTZ-induced seizures and the occurrence of electrographic spontaneous seizures after lateral CCI injury in C57BL/6J mice.[47] Statler et al.[44] monitored rats with lateral CCI at postnatal day 17 with

Table 25–1 **Summary of *In Vivo* Recorded Changes in Excitability in Different Models of TBI (Only the Data Collected at Least 1 Week Post-Injury Are Included)**

Model	Species, Age, Strain, Preparation	Seizure Susceptibility *In Vivo*	Epilepsy					Reference
			Animals with Epilepsy (%)	Latency to Spontaneous Seizure	Seizure Frequency	Seizure Duration (s)	Epileptiform Spiking or EDs in EEG	
Weight-drop	Rat, adult	Increased susceptibility to PTZ-induced seizures 15 weeks post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Golarai et al. [29]
Central FPI	Rat, adult	No difference in PTZ kindling, started 24 h post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Hamm et al. [30]
Parasagittal FPI	Rat, P32–35	n.d.	100% (follow-up: 7 months)	~2 weeks	Up to 7 seizures/h	Ictal episodes ≤10 s (up to 99 s)	n.d.	D'Ambrosio et al. [31,32]
	Rat, adult	Increased susceptibility to PTZ-induced seizures 12 weeks post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Atkins et al. [33]
	Rat, adult	Increased susceptibility to PTZ-induced seizures 2 weeks post-TBI	No	n.d.	n.d.	n.d.	n.d.	Bao et al. [34]
Lateral FPI	Rat, adult	Granule cell hyperexcitability 1 week post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Lowenstein et al. [35]
	Rat, adult	Increased inhibition in dentate gyrus 15 days post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Reeves et al. [36]
	Rat, P19	No change in PTZ seizure threshold 20 weeks post-TBI	0% (behavioral observation)	n.d.	n.d.	n.d.	n.d.	Gurkoff et al.[37]
	Rat, adult	Increased susceptibility to PTZ-induced seizures 12 month post-TBI	50% (follow-up: 12 months)	4–11 weeks	0.3/day	104	80%	Kharatishvili et al. [38,39]
	Rat, P21–P22	Increased susceptibility to kainate-induced seizures 6 weeks post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Echegoyen et al. [40]
	Rat, adult	No change in susceptibility to fluorothyl-induced seizures 3 and 6 weeks post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Schwarztkroin et al.[41]

	Mouse, adult	Increased susceptibility to PTZ-induced seizures 6 month post-TBI	6% (follow-up: 9 months)	n.d.	0.1/d	91		Bolkvadze et al.[42]
CCI	Rat, P16–P18	Unchanged threshold for tonic hind limb extension or minimal clonic seizures in electroconvulsive seizure threshold test, testing on P34–P40 Reduced threshold for minimal clonic seizures, testing on P60–P63	n.d.	n.d.	n.d.	n.d.	n.d.	Statler et al. [43]
	Rat, P17	n.d.	1 of 8 (13%) (follow-up: 11 months)	n.d.	n.d.	45–60 s	88% had epileptiform spiking	Statler et al. [44]
	Mouse, adult	n.d.	20%(mild)–36% (severe injury)	n.d. (monitoring 42 –71 days post-TBI)	n.d	~90 s (behavioral assessment)	n.d.	Hunt et al. [45]
	Mouse, adult	n.d.	40%	6.5 ± 1.3 weeks	n.d.	n.d.	n.d.	Hunt et al. [46]
	Mouse, adult	Increased susceptibility to PTZ-induced seizures 6 months post-TBI	9% (follow-up: 9 months)	n.d.	0.2/day	50		Bolkvadze et al. [47]
Closed skull TBI	Mouse, adult	Increased seizure susceptibility to ECS-induced seizures 7 days post-TBI	n.d.	n.d.	n.d.	n.d.	n.d.	Chrzaszcz et al. [48]

Abbreviations: CCI, controlled cortical impact; ECS, electroconvulsive shock; FPI, fluid-percussion injury; n.d., no data; P, postnatal day; PTZ, pentylenetetrazol; sz, seizure; TBI, traumatic brain injury.

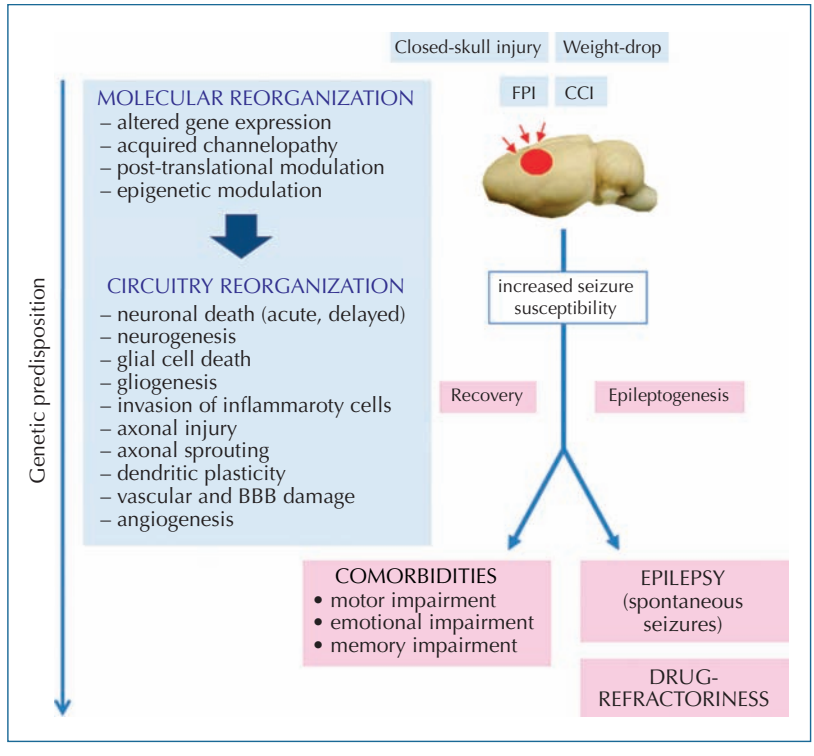

Figure 25–1. A schematic drawing of posttraumatic epileptogenesis. So far, increased seizure susceptibility in *in vivo* testing has been demonstrated in weight-drop injury, closed-skull injury, fluid percussion (FP) injury (both lateral and parasagittal), and controlled cortical impact (CCI) models of TBI. Spontaneous seizures have been shown in FP and CCI models. Traumatic brain injury triggers myriad of molecular changes at transcriptional, posttranslational, and epigenetic levels, some of which likely underlie the consequent circuitry reorganization. Recent data also demonstrate the development of acquired channelopathy after TBI that can contribute to increased excitability. Functionally, epileptogenesis and recovery progress in parallel. The outcomes can include both epilepsy and comorbidities. The epilepsy phenotype may progress and become drug-refractory. All the different aspects are under the influence of genetic factors. See text for references.

video-EEG over a period of 4–11 months post-TBI. They reported that 88% of rats developed epileptiform spiking and 13% of them (one of eight) had spontaneous recurrent seizures. Recently, Yang et al.[54] recorded spontaneous epileptiform activity in cortical slices from rats that had experienced CCI injury 14–16 days earlier at postnatal day 24.

MOLECULAR AND CELLULAR REORGANIZATION DURING POSTTRAUMATIC EPILEPTOGENESIS

The aftermath of TBI is a complex process and is considered to consist of several phases, including primary injury, evolution of the primary injury, secondary injury, and regeneration (Fig. 25–1).[55] Primary injury occurs at the moment of trauma and is accompanied by massive disturbance of cellular ion homeostasis, release of excitatory neurotransmitters, and exacerbation of excitotoxicity. The secondary injury occurs in the hours and days following the primary injury and is an indirect result of the insult. It includes a complex set of molecular changes and cellular processes, some of which may also be relevant to posttraumatic epileptogenesis. However, very few reports have specifically linked the observed postinjury molecular changes with epileptogenesis. Further, none of the studies have tried to address the question of whether the molecular cascades or network alterations contributing to epileptogenesis are separate or overlapping compared to those relevant to postinjury recovery.

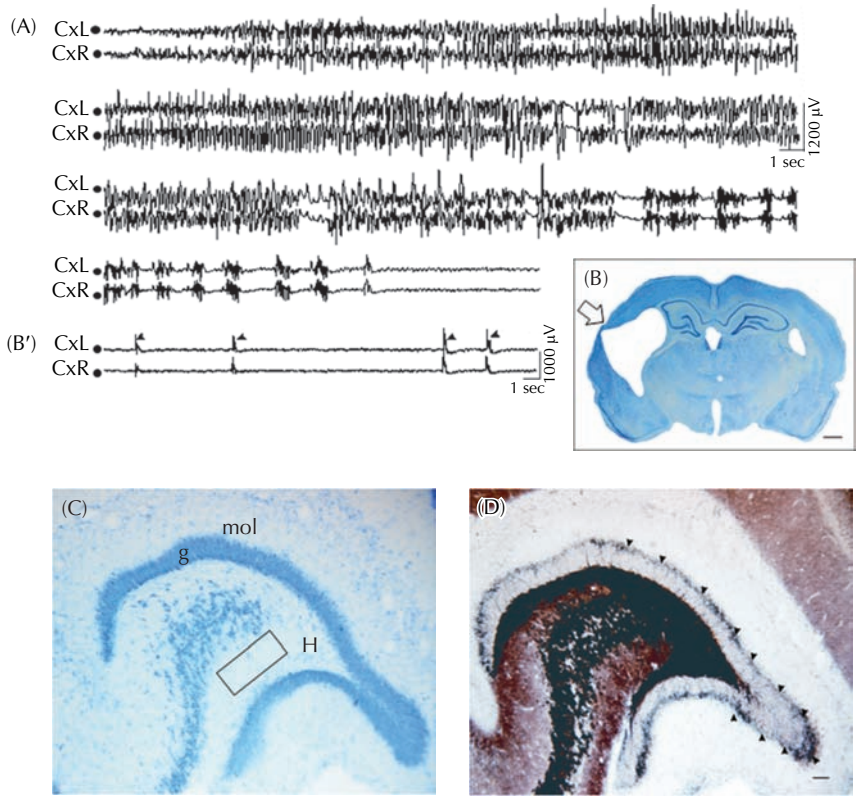

Figure 25–2. A. A representative example of a spontaneous seizure that was recorded at 6 months after lateral FP injury and was seen in both the ipsilateral and contralateral leads. The duration of the electrographic seizure was 94 s and its behavioral severity was 5 on Racine's scale.[72] **A'** shows epileptiform spiking in the same rat. **B.** A thionin-stained coronal section from the same rat subjected to lateral FP brain injury 9 months earlier. The open arrow indicates the injury site. **C.** A higher-magnification photomicrograph from a thionin-stained section of the septal end of the hippocampus of the same rat. Note the loss of hilar cells (open square). **D.** An adjacent Timm-stained section. Note the sprouting of mossy fibers into the inner molecular layer of the dentate gyrus (arrowheads). Abbreviations: C×L, left parietal cortex; C×R, right parietal cortex; g, granule cell layer; H, hilus; mol, molecular layer. The scale bar equals 1 mm in panel **B** and 100 μm in panels **C** and **D**.

Currently, *period of epileptogenesis* and *latency period* are used synonymously as operational terms referring to a time period that begins after the insult occurs (e.g., TBI or stroke) or even during the insult (prolonged febrile seizure, status epilepticus [SE], or encephalitis) and ends when the first spontaneous seizure appears. It refers to a dynamic process that progressively alters neuronal excitability, establishes critical interconnections, and perhaps requires intricate structural changes before the first spontaneous seizure appears.[56] These changes can include neurodegeneration, neurogenesis, gliosis, axonal damage or sprouting, dendritic plasticity, BBB damage, recruitment of inflammatory cells into brain tissue, reorganization of the extracellular matrix, and reorganization of the molecular architecture of individual neuronal cells.[57] Interestingly, all of these changes have been reported to occur after experimental TBI.[58] Further, they are not unique for the aftermath of TBI; they have also been described after SE, which is another common injury type used to trigger epileptogenesis in rodents.[57]

Even though data from human PTE are meager, available studies show hippocampal neurodegeneration as well as mossy fiber sprouting.[59] Approximately 53% of patients with posttraumatic temporal lobe epilepsy (TLE) have mesial temporal lobe sclerosis on MRI; in some patients, the MRI abnormalities can be bilateral and associated with multifocal injury.[60,61] Interestingly, a recent study by

Vespa et al.[62] suggests that hippocampal atrophy detected during the chronic postinjury phase could be caused by (prolonged) seizures during the acute post-TBI phase.

What are the molecular changes underlying circuitry reorganization during epileptogenesis? We recently conducted a meta-analysis of published gene array data after TBI and SE.[63] When the lists of genes regulated during post-TBI and post-SE epileptogenesis were compared, only 46 out of a total of 624 regulated genes were found to have abnormal regulation in more than one study. The commonly upregulated genes were involved in inflammatory and immune responses, response to wounding, complement activation, synaptic transmission, ion transport, regulation of apoptosis, protein phosphorylation, and proteolysis. Functions of commonly downregulated genes were related to synaptic transmission, ion transport, and calcium binding. Seventeen of 46 genes (40%) were regulated in both SE and TBI models, indicating similarity in molecular events during epileptogenesis between different etiologies. The genes regulated by both SE and TBI were *CALM3, CAMK2B, CTSB, CTSS, DBI, DNAJC3, DNAJC5, GABRD, GFAP, GRN, HPCA, IL6R, NPC2, NPTX2, PTPN6, S100B*, and *SPARC*. In addition to changes in transcription, posttranslational modifications and epigenetic changes have been described after TBI.[63, 64] One interesting subcategory of molecular reorganization is the development of various types of channelopathies, which to date have been demonstrated to affect gamma-aminobutyric acid A ($GABA_A$) receptors as well as sodium and potassium channels.[63] Further studies are needed to reveal whether any of these genes form a target to combat posttraumatic epileptogenesis.

SEARCH OF BIOMARKERS FOR POSTTRAUMATIC EPILEPTOGENESIS

Recent long-term MRI studies have provided new insight into the progression of brain damage during epileptogenesis. These studies indicate that the progression of pathology has a different temporal course in the cortex, hippocampus, and thalamus.[65] Moreover, these studies suggest that in the lateral FP model the contralateral hippocampus also undergoes changes, although to a lesser extent than the ipsilateral hippocampus. In addition to apparent neurodegeneration, long-term alterations include changes in axons/myelin as well as vasculature.[58,66] Importantly, not only epileptogenesis, but also the extent and temporal progression of neuropathological changes, vary among animals.

Little information is available concerning how each of these changes contributes to epileptogenesis and to the parallel recovery processes. So far, correlations have be found between the increased seizure susceptibility and diffusion changes or reduced cerebral blood flow (arterial spin labeling) in MRI in the hippocampus.[39,66] The development of new *in vivo* MRI techniques will hopefully enable researchers to follow specific molecular or network changes related to epileptogenesis, which in turn could advance surrogate marker identification for posttraumatic epileptogenesis. One example of this approach is the monitoring of axonal plasticity in the hippocampus by using manganese-enhanced MRI or diffusion tensor imaging (DTI).[39,65,67] It is likely that the first applications of MRI surrogate markers will soon be available for preclinical use. They will be useful for the identification of animals at risk for epilepsy after TBI as well as for the follow-up of treatment effects on epileptogenesis in individual animals.

PREVENTION OF EPILEPTOGENESIS AFTER TBI

A large number of preclinical trials have been conducted to improve motor and cognitive recovery from TBI, but none of these studies have assessed seizure susceptibility or epilepsy as an outcome measure.[68,69] Recently, however, four studies have made attempts to prevent posttraumatic epileptogenesis in experimental models (Table 25–2). The first one was the study conducted by Soltesz and colleagues, who induced epileptogenesis by lateral FP-induced TBI and administered SR141716A (Rimonabant®) as a single injection at 2 min postinjury.[40] The threshold for kainate-induced seizures was assessed at 6 weeks post-TBI. The TBI-associated reduction in the latency to kainate-induced seizures was prevented by

Table 25–2 **Effect of Treatment on Epileptogenesis after TBI in Experimental Models**

Treatment	Model	Treatment Protocol	Time of Analysis (Postinjury)	Seizure Susceptibility	Reference
Rimonabant	Lateral FP	2 or 20 min post-TBI single dose	6 weeks	⇓	Echegoyen et al.[40]
Minozac	Closed-skull midline impact	3 and 6 h post-TBI two doses	7 days	⇓	Chrzaszcz et al.[48]
Ketogenic diet	Lateral FP	3 weeks post-TBI	3 or 6 weeks	±0	Schwartzkroin et al.[41]
Hypothermia	Parasagittal FP	30 min post-TBI for 4 h	12 weeks	⇓	Atkins et al.[33]

Abbreviations: FP, fluid percussion; TBI, traumatic brain injury; ±0, no effect.

SR141716A. Also, the total time spent in seizures after kainate administration was reduced in the SR141716A group compared to the vehicle group. Importantly, no positive effect of treatment was found if SR141716A was administered 20 min post-TBI.

Another compound with favorable effects is minozac, which was discovered by using a molecular target-independent discovery paradigm.[70] The goal of this discovery program was to find a small molecule that suppressed the increased production of proinflammatory cytokines in glial cultures, as assessed using disease-relevant endpoints rather than designing a compound targeting a specific molecular pathway. This approach was combined with hierarchical biological screens for oral bioavailability, toxicity, brain penetrance, and stability before testing for efficacy in animal models of brain disorders. Chrzaszcz et al.[48] used the closed-skull midline impact model of TBI in mice and administered minozac at 3 or 6 h after injury. After 1 week post-TBI, minozac-treated mice showed less susceptibility to electroconvulsive shock-induced seizures than sham-operated rats. Whether minozac treatment prevents the long-term increase in seizure susceptibility and the occurrence of late seizures remains to be explored.

Schwartzkroin and colleagues[41] triggered lateral FP injury to 8-week-old rats and administered a ketogenic diet for 3 weeks postinjury. Seizure susceptibility to flurothyl was no different from that in rats on a standard diet when assessed 3 and 6 weeks after discontinuation of the ketogenic diet. It should be noted, however, that TBI had no effect on seizure susceptibility to flurothyl (seizure threshold, seizure duration) when injured and sham-operated animals on the standard diet were compared.

Hypothermia is considered to be a promising therapy that improves structural and functional outcome measures after experimental and clinical TBI.[71] Atkins et al.[33] induced moderate parasagittal FP injury in adult rats. Animals were kept under normothermic or moderate hypothermic temperatures for 4 h starting at 30 min postinjury. Susceptibility to PTZ-induced seizures was tested at 12 weeks post-TBI. Behavioral analysis of the data indicated a reduced number of induced seizures during the 60 min period after PTZ injection. The behavioral severity of seizures was not affected.

Taken together, there is evidence that treatments with different mechanisms of action can modulate post-TBI seizure susceptibility. Whether reduction in seizure susceptibility predicts antiepileptogenesis remains to be studied.

SUMMARY

Recent advances in model development provide a platform for studies that are aimed at understanding the post-TBI molecular

and cellular alterations leading to epilepsy. Undoubtedly, the search for surrogate markers that identify subjects with the highest risk for posttraumatic epileptogenesis will benefit from novel possibilities for following candidate epileptogenic changes in neuronal circuits *in vivo* using structural and functional imaging. Some proof-of-principle trials already suggest that post-TBI seizure susceptibility can be favourably modified.

Chapter 26

Fever, Febrile Seizures, and Epileptogenesis

Tallie Z. Baram

INTRODUCTION

Febrile seizures (FS) are the most common type of convulsions in infants and young children, occurring in 2%–6% of children.[1,2] They are defined as seizures arising during fever, not caused by an infection of the central nervous system. However, their definition does not exclude children with preexisting neurological deficits, a fact that might confound studies on the outcome of these seizures. Although there is limited evidence for adverse outcomes of simple (defined as short, with no focal motor phenomena) FS on the immature brain, complex FS, particularly long-duration FS or febrile status epilepticus (defined as seizures lasting for more than 30 min), have been associated with subsequent limbic epilepsy, as indicated by both prospective and retrospective studies as well as by recent data in animal models.[3–14] Some investigators have suspected that long-duration FS might result in cognitive defects in a subset of children.[15–17] Understanding the basic mechanisms of FS, and the potential epileptogenesis that follows them, requires animal models that enable direct examination of the causal mechanisms for the generation and consequences of these seizures. The mechanisms by which fever leads to FS, the outcome of FS measured as the risk of epilepsy, the properties

of FS associated with limbic epilepsy, and the mechanisms of epileptogenesis are discussed in the following sections.

HOW DOES FEVER CAUSE SEIZURES?

Genetic Susceptibility to FS

Febrile seizures occur sporadically and also run in families, suggesting a genetic contribution to their onset.[18] In immature rodent studies, including mice and rats of many different strains, all the animals developed hyperthermia-induced seizures, indicating that genetic susceptibility is not necessarily required for their generation.[12,19–21] Conversely, the fact that seizure-temperature thresholds (a measure of excitability)[22,23] vary among mouse strains with differing genetic makeup suggests the involvement of genotype in these seizures. Recently, increased susceptibility to FS has been found to result from mutations of several genes, including sodium channels,[24–26] gamma-aminobutyric acid A ($GABA_A$) receptors,[27–30] and hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels.[31] Other single-gene mutations, such as in the interleukin gene promoter, might predispose individuals to FS.[32] In addition, several genes might interact to promote the occurrence of these seizures in a more complex manner.

Increased Brain Temperature as a Mechanism of FS

Temperature influences neuronal properties.[33] The functions of specific ions channels (e.g., transient receptor potential vanilloid, 1 and 4) are regulated by brain temperature in the physiological and fever ranges.[34,35] Therefore, elevating the brain temperature should increase neuronal firing culminating in a seizure. Notably, hyperthermia induced by hot baths[36] or an overdose of hyperthermia-inducing medications (anticholinergics)[37] can provoke seizures in children, indicating that increased temperature itself can generate seizures. However, the exact mechanisms by which increased temperature might lead to the generation of FS have not been fully elucidated.

Fever Mediators Lead to Seizures

Fever not only increases brain temperature but also involves the release of inflammatory mediators, particularly cytokines[38,39] such as interleukin-1β (IL-1β) within the brain. Interleukin-1β contributes to neuronal hyperexcitability long term, in part by increasing the ceramide-induced Src family of tyrosine kinase function.[40] Acute changes in brain excitability might derive from the enhanced calcium permeability of glutamate receptors.[41] In addition, IL-1β exacerbates convulsant-induced seizures.[42,43] The involvement of endogenous IL-1β in the generation of FS was supported by the increased threshold temperature required to elicit experimental FS in mice lacking the IL-1β receptor type 1[22] (Fig. 26–1). Interestingly higher levels of this cytokine have been detected in individuals with FS with a mutation in the IL-1β gene promoter[32]—although the significance of this finding has been debated.[44] It is intriguing that fever of specific infectious etiologies, and specifically human herpesvirus 6, might influence the probability of FS generation.[45,46] Whether this virus, compared with other pathogens, leads to higher levels of cytokines in the child's brain has not been studied.

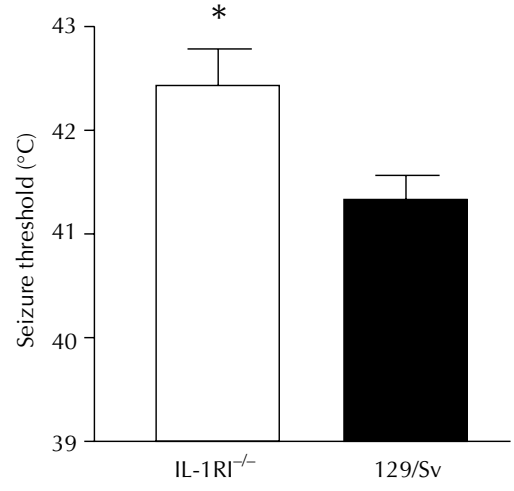

Figure 26–1. Mice lacking the IL-1 receptor type 1 ($IL\text{-}1RI^{-/-}$) are more resistant to the generation of experimental FS than wild-type controls of a similar genetic background (129/Sv). Threshold temperatures for the onset of these seizures were significantly higher in $IL\text{-}1RI^{-/-}$ mice (42.4 ± 0.3°C, $n = 26$) compared with the wild types (41.3 ± 0.2°C, $n = 21$). $^*p < .05$. From ref. 22.

Hyperthermia-Induced Hyperventilation and Alkalosis

Hyperthermia-induced hyperventilation and the consequent alkalosis have been suggested as important mechanisms for the generation of FS. Brain alkalosis has been shown to promote neuronal excitability[47,48] and may contribute to seizure pathophysiology in models with a long delay from hyperthermia to seizure onset.[49] However, it should be noted that the severe alkalosis found during prolonged crying, and that can exist for weeks in babies with pyloric stenosis, has not been correlated with a higher incidence of seizures (fever-induced or otherwise).

DO FS CAUSE EPILEPSY?

There is little evidence for an enduring adverse impact of short-duration FS on the developing brain.[4,50,51] However, prolonged or focal FS have been associated with the development of limbic (temporal lobe) epilepsy.[3,6,7,52] What is the neurobiological basis of this statistical correlation? Do long-duration FS cause temporal lobe epilepsy (TLE)? Are FS a marker of preexisting pathology? Is there a common denominator or cause that independently leads to FS and TLE or that alters the probability that FS would result in TLE?

A causal relationship between long-duration FS and the development of TLE is difficult to demonstrate or refute in humans because of the diverse genetic makeup of children and other uncontrolled preexisting factors. Single-gene (e.g., ion channel; see above) mutations, or a combination of multiple susceptibility genes, might predispose certain individuals to FS or to the development of epilepsy following FS.[25,27,28,31] In addition, the previous history of a child might render him or her more vulnerable to FS or their pro-epileptic or cognitive consequences. Controlling for these genetic and environmental/acquired factors is very difficult.

Therefore, to facilitate investigation of these seizures and their consequences, several animal models of prolonged FS[11,14,19–21,49,53,54] have been developed. In recent years, these models have led to fundamental discoveries about the mechanisms of these seizures, their effects on neuronal excitability, and their relationship to epilepsy.[8,12,55–59] We have devised and characterized a model of FS in infant rats and mice. Because fever cannot be reliably induced in suckling rodents,[60] we employed hyperthermia. Core and brain temperatures were raised to the range of 39.5 to 41.5°C for 30 min or ~60 min (re-creating febrile status epilepticus) in 10-to 11-day-old rats,[12,21] an age when hippocampal development approximates that of human infants.[61] In this model, core body measurements provide an adequate approximation of brain threshold temperature for experimental FS.[62] As described above, hyperthermia and fever utilize common mechanisms to elicit the seizures because hyperthermia leads to the release of cytokines.

Using this model, we determined if long-duration FS, induced at the stage of hippocampal development that corresponds to that of human infants,[61] leads to the development of limbic epilepsy. We demonstrated that experimental FS cause spontaneous recurrent seizures in a significant proportion of animals (35%) later in life.[57] These later seizures, resulting from an early 20 min FS, consisted of sudden freezing and typical limbic automatisms (stage 1)[63] that were coupled with polyspike/sharp-wave trains with increasing amplitude and slowing frequency on electroencephalogram (EEG). In addition, interictal epileptiform discharges were recorded in 88.2% of the experimental FS group. Interictal activity was never detected in normothermic control rats or in hyperthermic control rats (animals that sustained hyperthermia with no seizures).[57] Because, as described above, predisposing factors, both genetic and acquired, have largely been excluded in this model, these studies directly supported a causal relationship of long-duration FS and the development of TLE and set the stage for investigating the mechanisms by which these seizures promote epileptogenesis.

WHICH FS CAUSE EPILEPSY?

Febrile seizures occur in 2%–6% of children[2,64,65] and are prolonged in ~15% of this group.[1,66–68] As mentioned above, a key issue about FS is the clinical question of whether long-duration FS cause epilepsy,

and if so, why the process takes place only in some individuals. To address this question, we tested the hypothesis that seizure duration is a key parameter that governs epileptogenesis, as suggested by clinical studies.[4,7] We found that experimental FS lasting for ~20 min resulted in limbic epilepsy in ~35% of rats.[57] In contrast, when we increased the duration of seizures to ~60 min, we found that ~45% of rats developed limbic epilepsy.[13] Importantly, whereas the spontaneous seizures that resulted from FS lasting for ~20 min were mild (Racine[63] stage 1; duration average ~8 s), the duration of seizures constituting the limbic epilepsy provoked by febrile status epilepticus (FSE; 60 min FS) was much longer: 137 s on average (Fig. 26–2). The behavioral manifestations of the epileptic seizures were also more pronounced and included head bobbing, alternating or bilateral clonus, rearing, and falling (Racine stages 2–5).[63] The interictal activity recorded from cortical and hippocampal electrodes varied according to the duration of the inciting FS. Interictal activity was found in 84% of rats sustaining a ~60 min inciting FS, and individual interictal activity bouts were significantly longer and more robust than those after a ~20 min seizure.[13] However, the presence and duration of the interictal events did not predict the development of epilepsy. Thus, using an animal model enabled us to define the duration of FS as an important predictor of the severity of the TLE that develops after FS. This finding, in line with suggestive clinical literature,[69–72] carries enormous implications for the clinical management of FS.

HOW DO FS CAUSE EPILEPSY?

The mechanisms by which long-duration FS might contribute to the development of TLE are not fully resolved. Here we review several mechanisms that have been implicated in epileptogenesis and discuss their role in the epileptogenic process that follows long-duration experimental FS.

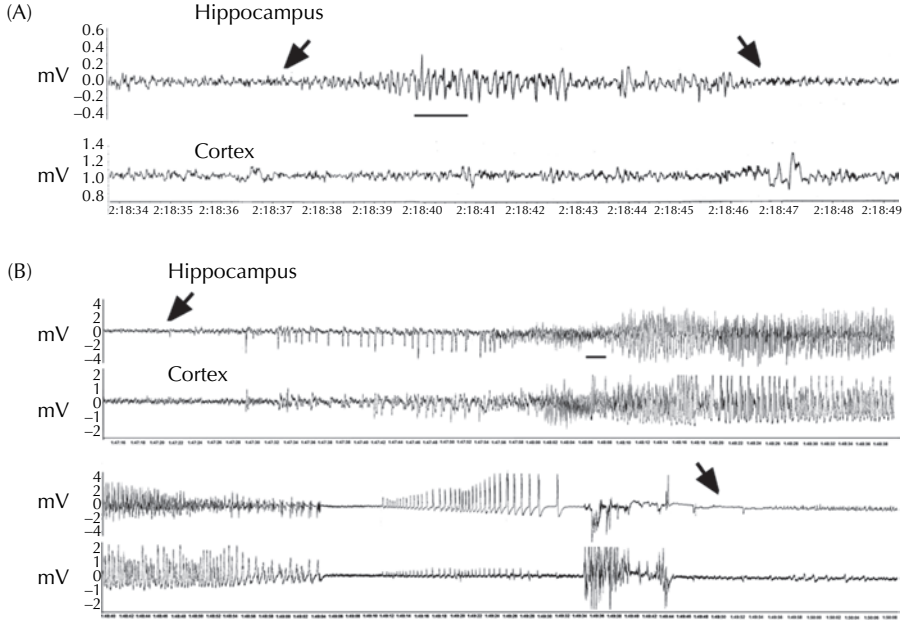

Figure 26–2. Examples of typical spontaneous electrographic seizures recorded from hippocampal and cortical bipolar electrodes in adult rats that had experienced (**A**) a 20 min or (**B**) a 60 min experimental FS. In the 60 min epilepsy model, spontaneous seizures commenced first in the hippocampus and propagated to the cortex (**B**), where epileptiform cortical discharges were apparent. In epilepsy generated by a 20 min FS (**A**), the epileptic seizure propagation to the cortex consisted of suppression. Note that the duration of the seizures was significantly longer after a 60 min FS compared to a 20 min FS (mean: 137 and 8 s, respectively; median duration: 91 and 7 s, respectively). Arrows point to the onset and end of epileptiform discharges. Calibration: 1 s. From ref. 13.

Inflammation and Cell Loss

As mentioned above, the inflammatory cytokine IL-1β contributes to the generation of experimental (and probably human) FS. However, whether or not IL-1β contributes to the epileptogenic process that is triggered by FS remains unclear. We found that IL-1β expression was induced in reactive astrocytes for at least 24 h after a ~60 min FS and returned to basal levels within 72 h.[13] Interestingly, when FS-sustaining rats that became epileptic were compared to those in which the inciting FS did not lead to spontaneous seizures, hippocampal IL-1β levels were higher only in the rats that developed epilepsy.[13]

Cytokines and other inflammatory mediators have been shown to contribute to neuronal injury and death.[73–75] In the mature brain, limbic seizures lead to the loss of vulnerable hippocampal cell populations,[76–79] and this loss is considered by many to be required for epileptogenesis.[76,78,79] In the FS model described above, a model that has been adopted by several other groups, appreciable neuronal death has not been found.[13,54,57,80] The seizures did provoke neuronal injury in the same cell distribution experiencing cell damage in human mesial temporal sclerosis (MTS); yet, the involved neurons did not seem to die.[21] Neurogenesis was also not detected after these seizures, and mossy fiber sprouting was minimal.[14,54,80,81] Therefore, such structural alterations are unlikely to account for the epileptogenic process that follows long-duration FS.

Role of Changes in the Expression of Gene Sets, Including Ion Channels, in FS-Induced Epileptogenesis

The likely mechanisms of epileptogenesis that follow experimental (and perhaps human) long-duration FS involve profound and persistent molecular changes in hippocampal neurons that induce alterations of their intrinsic excitability and network properties. Numerous molecular changes have been described after experimental FS (reviewed in ref. 82), and many are not yet known. Lasting changes in the expression of specific genes such as ion channels and endocannabinoid receptors have been explored. For example, experimental long-duration FS led to altered expression of ion channels conducting I_h, a hyperpolarization-triggered cationic current that contributes to the maintenance of neuronal membrane potential, subthreshold oscillations, and dendritic integration.[83–85] This change in I_h promoted frequency-dependent rebound depolarization in response to hyperpolarizing input; this rebound depolarization was augmented after the seizures.[8,55] At the molecular level, these changes were a result of long-lasting reduction in the expression of the HCN1 isoform, leading to an increased HCN2/HCN1 ratio and augmented heteromerization of these two isoforms.[86,87] Remarkably, reduction of HCN1 expression has since emerged as a fairly general principle in a number of models of acquired TLE.[88–92] HCN1 channel expression was found to be altered in a subset of resected hippocampi from patients with TLE and MTS, often with a history of early-life seizures.[93] As mentioned above, mutations in HCN channel genes have recently been discovered in individuals with epilepsy,[31] further supporting the role of these channels in the epileptogenic process. The precise mechanisms by which alterations in HCN channels and I_h contribute to human epileptogenesis are not fully understood.

An additional mechanism by which long-duration FS may promote hyperexcitability involves an increase in a short-term plasticity phenomenon known as *depolarization-induced suppression of inhibition* (DSI).[56] Depolarization-induced suppression of inhibition is mediated by cannabinoid receptors (CB1).[94,95] Following experimental FS, increased release of endocannabinoids upon postsynaptic depolarization of hippocampal pyramidal cells led to an increase in the number of presynaptic cannabinoid type 1 receptors, promoting increased retrograde inhibition of GABA release, which resulted in a reduction of inhibition in the hippocampal circuit.[9,56]

Activation of specific transcription factors by seizures, including experimental FS, has been recently found,[96] suggesting that rather than changes in single genes (even those governing important properties of the neuron), a coordinated change in the expression of gene clusters may be an important mechanism in the transformation of normal neurons and neuronal circuits into epileptic ones. One can only speculate that, in addition to the mechanisms described

above, many other alterations in gene expression will be found—after experimental and human prolonged FS—that will contribute to the epileptogenic process.

RELATIONSHIP BETWEEN FS, MTS, AND TLE

The absence of cell loss in rats that became epileptic following long-duration FS and FSE raises questions regarding the causal relationship of cell loss to epileptogenesis in children sustaining these seizures. One of the structural hallmarks of patients with mesial TLE with a history of long-duration FS is a specific pattern of cell loss in hippocampus, that is, MTS. It has been widely hypothesized that FS cause MTS and that the development of TLE is a consequence of MTS.[69,71,97] An alternative view is also supported by clinical data: MTS results from the recurrent seizures in individuals with TLE after FS.[98–100] The absence of cell loss in epileptic rats in our model is more consistent with the latter view.

In addition, the increased T2 relaxation time seen on magnetic resonance imaging (MRI) was reported in children with FSE and interpreted as indicating MTS.[69,71,97] In our animal model, we found abnormally elevated T2 relaxation times in the hippocampus in a subpopulation of FS-experiencing rats[13,17] (Fig. 26–3). These T2 changes on MRI were not associated with increased water content (CM Dubé, unpublished observations) and were not accompanied by neuronal loss in the hippocampus. These data suggest that acute MRI changes after long-duration FS should be interpreted with caution. Interestingly, the MRI changes observed in the hippocampus of a subset of rats following long-duration FS were predictive of hippocampal dysfunction manifesting as cognitive defects.[17]

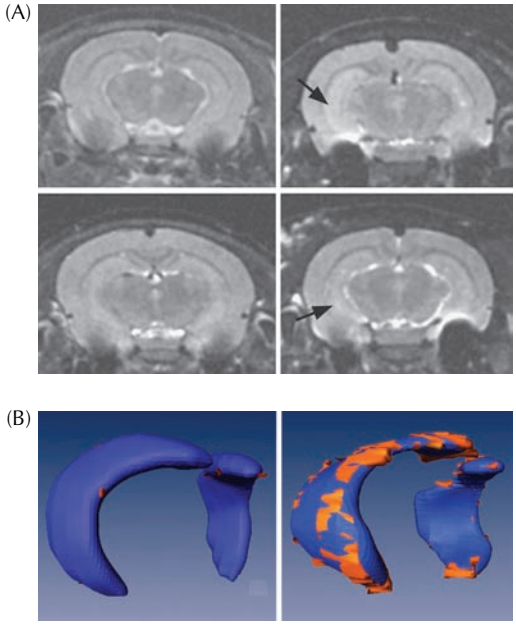

Figure 26–3. A. Examples of T2-weighted images obtained 1 month after a 60 min FS: the T2 signal (arrows) increased in the hippocampus of a subset of rats that experienced long-duration FS (right panels) compared with control rats (left panels). Absolute T2 relaxation time values (ms) were calculated on a pixel-by-pixel basis from the T2-weighted images, and T2 maps were generated. The FS rats segregated into two groups: one group with hippocampal T2 relaxation time values significantly higher compared to the mean values of the controls and a second group with T2 values similar to those of the controls. **B.** Examples of three-dimensional reconstruction of the hippocampi of two rats that sustained FS: pixels with significantly higher hippocampal T2 values compared to the pixel values (in blue) found in controls are noted in orange. **A** from ref. 13.

FUTURE DIRECTIONS

Febrile seizures are common and important, and we have only a partial understanding of their generation and consequences. Whereas short-duration (simple) FS are benign, more work is needed to tease out the neurobiological basis of the consequences of long-duration FS and FSE—both cognitive changes as well as epileptogenesis.

Among the key remaining goals in this field is the development of early and effective biomarkers that will define which child with long-duration FS is at risk for epilepsy or cognitive sequelae. Such surrogate markers of the disease process that culminate in the development of TLE and/or cognitive deficits should provide powerful tools for testing potential interventions aimed at stopping or reversing the epileptogenesis.

An additional important goal is the elucidation of the complex mechanisms underlying epileptogenesis that follows long-duration FS. Current data suggest that persistent changes

in the expression and function of gene sets that regulate neuronal and network activity (including cytokines and ions channels) might be involved. Identifying the key genes that contribute to the development of these sequelae, and delineating the mechanisms (e.g., epigenetic) that regulate these genes, may provide molecular targets for the development of novel preventive and therapeutic strategies for preventing the development of TLE after long-duration FS.[96]

Chapter 27

Role of Blood-Brain Barrier Dysfunction in Epileptogenesis

Alon Friedman
Uwe Heinemann

Focal epilepsy typically arises from neuronal tissue either within or adjacent to a cortical lesion. About 30% of epilepsies are caused by acquired etiologies such as traumatic brain injury, stroke, infection, or prolonged febrile seizures.[1] Injury-related acquired epilepsy is frequently resistant to medications and may be associated with other neurological impairments.

In most animal models of acquired epilepsy (similar to the situation in humans), a period of days to weeks is required for the development of seizures.[2,3] Typically, the initial insult is followed by a latent interval, referred to as *epileptogenesis*, in which cellular and structural reorganization occurs that ultimately leads to chronic recurrent epileptic seizures. While the molecular, anatomical, and electrophysiological activities in the epileptic focus have been described in great details (e.g., in refs. 4–8), the critical changes occurring following injury and *before* epileptic activity develops are mostly unknown. A better understanding of the molecular and physiological events during epileptogenesis is essential for the targeted development of preventive therapeutic approaches that are presently unavailable.[1]

BRAIN INSULTS AND INJURY TO THE BLOOD-BRAIN BARRIER

A plethora of data accumulating in recent years has indicated a central role for vascular integrity, specifically the permeability of the blood-brain barrier (BBB), as an important mediator of brain damage, including the delayed appearance of neuronal dysfunction and death.[9–14] Dysfunction of the BBB (which may be long-lasting,[2,15]) is frequently associated with myriad neurological pathologies and has thus attracted growing attention as a novel and important target for intervention in the setting of brain injury. Specifically, clinical and animal studies have presented evidence to support the

hypothesis that opening of the BBB triggers a chain of events leading to epilepsy.[12,13,16–23]

Both clinical data and research on animal models indicate that BBB dysfunction is a typical finding following traumatic, ischemic, or infectious brain insults, and may last for several days to weeks and even years after the acute event.[12,24,25] Opening of the BBB following experimental brain injury is usually considered to be biphasic.[26–28] The onset of the early phase is rapid, and permeability of the BBB typically reaches a maximum within a few hours, after which time it declines. The onset of the second phase is delayed, starting 3 to 7 days following injury, and is probably part of the brain's response to the injury. Clinical data suggest that for most patients, BBB permeability returns to normal within days to weeks following the insult; however, there is lack of repeated data from the same animals on BBB functions and there are no quantitative data on the extent of BBB damage in relation to the mechanism, location, and severity of the insult. The mechanisms of BBB breakdown and repair are not well understood. Breakdown of the BBB may be a direct result of the insult (trauma or ischemia to endothelial vessels—*primary BBB damage*), but it may also be secondary to the abnormal brain activity, astrocytic dysfunction, inflammation, and metabolic disturbances that typically take place as part of the brain's response to injury.

Mechanisms Underlying BBB Damage

Direct injury to endothelial cells—as occurs in traumatic shear injuries, in ischemic and metabolic insults, and in infectious and inflammatory vasculature pathologies—leads to impaired regulation of the BBB, of cerebral blood flow (CBF), and of metabolic demands, which in turn lead to metabolic imbalance and to the formation of an "ischemic" zone. The hypoxic tissue contributes locally to dysfunction of the BBB.[29] Secondary BBB damage is usually initiated within hours or days after injury; it is considered to be treatable and to have a considerable influence on the long-range clinical outcome. A number of mechanisms have been proposed for the emergence of secondary damage following BBB disruption, all of which are a consequence of either the disruption of the intricate relationship between the cellular elements of the neurovascular unit (which involves the blood vessels and particularly capillaries with astrocytic endfeet from surrounding astrocytes and—at least at larger vessels—nerve terminals impinging on blood vessels) or the impairment of the structural integrity within the tight-junction complex of the BBB (see below). Processes such as edema, inflammation, and cell death may further contribute to BBB dysfunction, independently or synergistically. Other mechanisms, such as vasospasm,[30] CBF autoregulatory failure,[31] irregularities in nitric oxide secretion[32] and coagulopathies[33] may coincide with the impairment of BBB structural integrity[34] and contribute to the resultant ischemic state and secondary loss of BBB functions. The underlying molecular changes leading to BBB dysfunction are not completely clear, but may involve vasogenic edema due to penetration of blood protein into the brain extracellular space due to increased endothelial caveolae, leading to transcytosis of plasma proteins,[35,36] decreased expression of junctional adhesion as well as tight junction proteins,[37,38] and increased expression of matrix metalloproteases.[39] Reactive cellular activity in the neurovascular junction has also been observed, including increased migratory activity of pericytes[40] and the proliferation of blood vessels due to upregulation of vascular endothelial growth factor (VEGF).[41] In addition, BBB opening itself leads to exposure of the brain tissue to serum-derived (normally nonpermeable) molecules, which serve as signaling mediators for brain repair mechanisms but which also facilitate BBB breakdown.

BBB DYSFUNCTION FOLLOWING SEIZURES AND STATUS EPILEPTICUS

While seizures and vascular changes are often found at the same time, the causal relationship between the two phenomena remains a matter of intensive research. In experimental animals, induction of seizures,[42] especially status epilepticus (SE),[13,43–48] leads to a rapid increase in BBB permeability lasting for several days to weeks. Studies in human epileptic patients are consistent with the animal data, showing evidence of a frequent increase in BBB permeability during seizures.[12,21,49–54] Ultrastructural research

on human epileptic tissue has confirmed the results of imaging studies, showing clear BBB abnormalities, including increased micropinocytosis and fewer mitochondria in endothelial cells, thickening of the basal membrane, and the presence of abnormal tight junctions[55–57] with evidence of barrier dysfunction such as markedly elevated levels of serum proteins within the epileptic tissue.[13,58] The accumulating data thus suggest that the increase in blood vessel permeability within the epileptic focus does not represent a transient seizure-related event, but rather a prominent vascular pathology within the epileptic tissue. However, the lack of a reliable quantitative method to measure BBB permeability in vivo precludes a large-scale human study to clarify this issue.

In addition to changes in BBB permeability, an increase in vessels density has been recently described in the hippocampus of patients suffering from drug-resistant temporal lobe epilepsy (TLE).[59] Notably, the vascular density, while associated with leaky vessels, is independent of seizure etiology, duration of the disease, or severity of damage or gliosis; it is, however, positively correlated with the frequency of seizures. The immature and tortuous aspect of microvessels and the loss of tight junction proteins indicate a pathological angiogenesis. This abnormality was further confirmed in the pilocarpine rat model of epilepsy (see also ref. 48), which showed progressive neovascularization during epileptogenesis, with high levels of VEGF in neurons and astrocytes and high levels of the VEGF receptor tyrosine kinase (VEGFR-2) in neurons and endothelial cells. Together, these human and animal studies strongly indicate lasting vascular and BBB damage in at least some forms of epilepsy, which calls for the understanding of the role of such vascular pathologies in epileptogenesis and seizure generation.

BBB DYSFUNCTION AND EPILEPTOGENSIS

The frequent finding of BBB dysfunction after SE, after seizures, and in epileptic patients led to the captivating hypothesis of a direct role for abnormal blood-brain communication in epileptogenesis,[20] supported by the observation of a positive correlation between the extent of BBB opening and the number of subsequent seizures in the pilocarpine model of TLE.[13] More direct evidence for the involvement of BBB dysfunction in epileptogenesis has been recently established by a series of animal studies in which a long-lasting opening of the BBB in the rat neocortex was shown to result in the delayed appearance of hypersynchronous epileptiform activity (reviewed in ref. 60; see also Fig. 27–1). Importantly, BBB dysfunction does not seem to induce epileptogenesis by provoking SE or immediate neuronal death, although under some conditions (e.g., intra-arterial mannitol) it can provoke seizures,[19] and it does reduce the seizure threshold in epileptic animals.[13] The mechanisms underlying the emergence of network hypersynchronicity under the BBB-disrupted brain are not entirely clear; however, experimental data support a role for serum proteins that normally are not found in the adult central nervous system, including albumin[17,22,23,61] and perhaps thrombin[62] via specific signaling pathways (see below). Epileptogenesis following BBB injury does not seem to be mediated by a significant loss of inhibitory interneurons,[23] but rather seems to involve early dysfunction of astrocytes (i.e., *reactive astrogliosis*) and activation of an inflammatory response (see below).

The Role of Astrocytes in Epileptogenesis Induced by BBB Dysfunction

In animal studies where BBB has been disrupted to induce a chronic epileptic focus, early dysfunction of astrocytes was observed prior to the occurrence of neuronal hypersynchronization.[17,61] These studies, as well as in vitro experiments, suggested the possible involvement of serum albumin in the regulation of astrocytic calcium signaling[63] and gene expression.[61,64] Changes in astrocytic gene expression, morphology, and function following insults to the brain are well documented,[65] and the potential role of astrocytes in seizure generation and epilepsy has been described in both experimental animals and epileptic patients.[66–69] Recent studies have indicated novel physiological roles for glial cells in the central nervous system,, such as modulation of synaptic transmission and plasticity.[70,71] It is

thus plausible that reactive (*transformed* or *activated*) glial cells play a significant role in neuronal network reorganization, hypersynchronicity, and hyperexcitability, leading to seizures.[61,72] Changes in astrocytic functions that are potentially involved in increased neuronal excitability and epileptogenesis include four alterations.

(1) *Reduced expression of potassium inward-rectifying channels* (*Kir4.1*) *and water channels* (*aquaporin 4, AQP4*): Both channels are colocalized most abundantly in astrocytic endfeet and are considered crucial for the regulation of the brain's extracellular potassium ($[K^+]_0$) and water content. Indeed, downregulation of Kir4.1 and AQP4 in genetically engineered mice results in impaired $[K^+]_0$ buffering and seizures.[73,74] Impaired $[K^+]_0$ buffering due to downregulation of Kir4.1 channels has also been reported in the hippocampus from pilocarpine-treated epileptic rats[75] and in the sclerotic hippocampus from TLE patients.[76,77] Impaired $[K^+]_0$ buffering, and specifically activity-dependent $[K^+]_0$ accumulation, will contribute to changes in the extracellular space and to neuronal excitability, resulting in a reduced firing threshold, slower neuronal repolarization, increased transmitter release, and facilitated activation of *N*-methyl-D-aspartate (NMDA) receptors, thus enhancing synchronization.[61,78]

(2) *Reduced gap junctions:* Gap junctions are functional channels between cells and consist of connexin proteins. Astrocytes are coupled via gap junctions to form large cellular networks that facilitate spatial buffering of small molecules (e.g., K^+). Connexin knockout mice show a mild decrease in the spatial buffering of $[K^+]_0$ and a decreased seizure threshold,[79] although most buffering capacity is maintained.

(3) *Impaired glutamate metabolism:* Glia cells may express glutamatergic receptors and release glutamate, and they are important for the uptake and metabolism of glutamate. In the hippocampal slice preparation from healthy mice, astrocytic glutamate release has been shown to contribute to a slow tetrodotoxin (TTX)-resistant, NMDA-sensitive neuronal inward current that may represent the typical *paroxysmal depolarization shift* (PDS) underlying the interictal burst.[80] It is not clear, however, to what extent such release contributes to epileptogenesis or to the propagating seizure activity in the epileptic brain. There is no direct evidence for increased glutamate release from astrocytes in chronic epileptic tissue, although upregulation of tumor necrosis factor alpha (TNFα; together with microglial activation) in the epileptic tissue may enhance glutamate release.[81,82] Transformed astrocytes may also affect extracellular glutamate levels by decreased uptake and metabolism. Astrocytes express two specific glutamate transporters, EAAT1 (also known as GLAST in rodents) and EAAT2 (GLT-1), which are responsible for most glutamate uptake in the brain. There is strong evidence to support the conclusion that significant impairment of astrocytic glutamate transporters is associated with the development of seizures; however, whether glutamate transporters are indeed downregulated in reactive astrocytes within the epileptic tissue is controversial, with reports demonstrating reduced, normal, and increased levels (reviewed in ref. 68). Astrocytes are also responsible for the conversion of the transported glutamate into glutamine by glutamine synthetase. Glutamine is transported back into neurons, where it is converted to glutamate by mitochondrial glutaminase and eventually to gamma-amino-butyric acid (GABA) in neurons that express the enzyme glutamate decarboxylase (GAD). Sclerotic brain tissue from TLE patients shows an approximately 40% reduction in the level of glutamine synthetase in astrocytes,[83] and glutamine synthetase inhibitors (80%–90% inhibition) cause seizures in experimental animals[84] (but see also ref. 85).

(4) *Increased release of inflammatory mediators by transformed astrocytes:* Astrocytes can produce many pro- and anti-inflammatory molecules, and these can be pro- and antiepileptogenic. Accumulating experimental evidence supports the role of interleukin 1-beta (IL-1β) in reducing the seizure threshold and in promoting epileptogenesis in the pilocarpine SE model of epilepsy.[86,87] Recent data suggest that other inflammatory mediators (e.g., cyclooxygenase-2) that are released from astrocytes may directly affect synaptic signaling,[88] plasticity,[89] and perhaps epileptogenesis.[90,91] It is still not yet clear to what extent and via which mechanisms the different inflammatory mediators contribute to alterations within the neuronal network and the generation of seizures; what

the role of inflammatory mediators might be in controlling BBB permeability; and what the role of leukocytes is in trafficking mechanisms in the inflammatory response, BBB permeability changes, and epileptogenesis.[92,93]

To summarize, experimental evidence unequivocally supports the notion that transformed (activated) astrocytes are prominent in the epileptic brain, and that these astrocytes have properties that are consistent with a reduced seizure threshold. However, it is important to distinguish between seizure generation and epileptogenicity—which involves a more complex and lasting changes in the network. To what extent do astrocytes have a direct role in such complex and long-term network changes? Hints for such a role come from experiments showing that in the SE-induced model of epilepsy, transformation of astrocytes starts within hours to days following SE, during the latent period of epileptogenesis.[94] Similarly, in the BBB disruption or albumin-exposure models, increased expression of the glial fibrillary acidic protein (GFAP), reduced expression of Kir4.1, and disturbed $[K^+]_0$ buffering precede the development of seizures,[17] strengthening the argument that transformation of astrocytes does not just reflect a hyperexcitable network, but rather contributes directly to its development. The possible involvement of BBB breakdown and albumin in the induction of astrocytic transformation is supported by studies of altered calcium signaling and DNA synthesis in cultured astrocytes exposed to serum albumin.[63] The observations that the action of serum albumin to induce astrocytic transformation is mediated via transforming growth factor beta receptor II (TGFβR2) highlight the involvement of specific signaling cascades in epileptogenesis following insult.

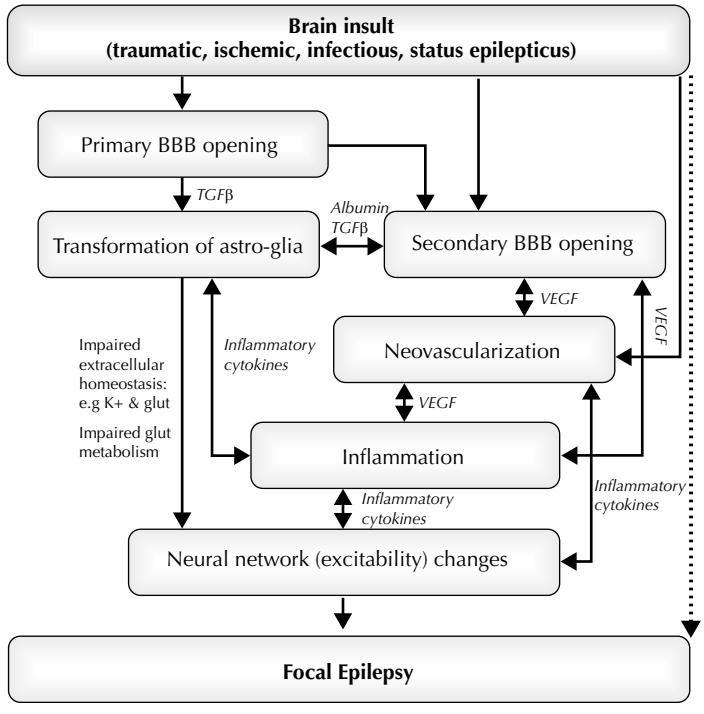

Figure 27–1. Proposed events during the development of an epileptic focus following brain injury. Prolonged seizures and ischemic, traumatic, or infectious insults induce primary and/or secondary opening of the BBB. Through serum proteins (e.g., albumin) and specific signaling cascades (e.g., TGFβ), BBB opening induces the transformation of astroglia into reactive or activated states, which initiates the release of inflammatory cytokines. In addition, vascular injury and BBB opening are associated with neovascularization with the generation of additional leaky vessels. Both the impaired buffering of extracellular potassium (K^+) and glutamate (glut) and the secreted inflammatory cytokines increase neuronal excitability and network connectivity to yield the epileptic network.

BBB Dysfunction and the Role of TGFβ Signaling in Epileptogenesis

Transforming growth factor beta (TGFβ) consists of pleiotropic cytokines that play a pivotal role in intercellular communication,[95,96] and their signaling pathways are frequently involved in cell growth, embryogenesis, differentiation, morphogenesis, wound healing, immune response, and apoptosis in a wide variety of cells.[97–99] The past decade has seen an explosion of information regarding the expression and action (sometimes contradictory) of TGFβ in the brain. Accumulating evidence unequivocally indicates that TGFβ is an injury-related cytokine that is upregulated in different forms of brain injury[100,101]; however, its exact actions are still under debate.[102] The potential involvement of TGFβ in epileptogenesis was first suggested on the basis of animal experiments documenting TGFβ upregulation in the brains of amygdala-kindled rats.[103] Aronica and colleagues showed TGFβ expression in astrocytes from the hippocampus of SE-experienced rats and suggested that it has a role in modulating glial functions in the course of epileptogenesis.[104] However, direct evidence for the role of TGFβ in cortical dysfunction and epileptogenesis is scarce. Following BBB opening, serum albumin has been shown to bind to TGFβR2, induce Smad2 phosphorylation, and activate its signaling cascades.[17,64] Indeed, BBB opening and brain exposure to albumin or TGFβ1 all induce a similar transcriptional modulation of genes, including those associated with the TGFβ pathway, astrocytic activation, inflammation, and reduced inhibitory transmission.[64] Future studies are required to confirm these promising results and the potential role of inhibition of this signaling pathway in the prevention of epileptogenesis.

In summary, data from human epileptic patients show clearly that vascular pathologies, and specifically increased BBB permeability, are a frequent finding in injury-related focal epilepsies. Studies in experimental animals are starting to reveal the mechanisms and signaling cascades leading from vascular changes to modifications of the neural network (Fig. 27–1). These studies stress the importance of interactions within different components of the neurovascular unit. Future developments in quantitative imaging of BBB permeability in human patients, together with individual and mechanism-targeted therapeutic approaches, may allow the development of new antiepileptogenic and antiepileptic treatments for specific populations.

Chapter 28

Cell Death and Survival Mechanisms after Single and Repeated Brief Seizures

David C. Henshall
Brian S. Meldrum

INTRODUCTION

While it is broadly accepted that status epilepticus can directly cause neuronal death, whether single or repeated brief seizures cause neuron loss is controversial. This is an important issue with both scientific and clinical implications. Patients may be concerned about whether their seizures are capable of causing brain damage, and clinicians make treatment decisions based

on an assumption that a few seizures are not really harmful. From a scientist's perspective, this issue is pertinent to the pathophysiology of epilepsy and the various mechanisms neurons employ to cope—or otherwise undergo cell death—in response to the repeated stress of frequent seizures. Research using animal models, and pathology and neuroimaging work in patients, show that single or repeated brief seizures under certain circumstances cause neuron loss, but they also indicate that neuron loss is not an inevitable consequence of a seizure. Recent human studies show that signaling pathways associated with apoptosis may be altered in the patient's brain, offering possible therapeutic opportunities to target seizure-induced neuronal death in different ways.

Hippocampal sclerosis is the most common pathological finding in temporal lobe epilepsy (TLE). However, there are patients with TLE with no apparent hippocampal damage and patients with hippocampal sclerosis without TLE. If hippocampal sclerosis causes TLE, then efforts to prevent this lesion's development are critical. If epileptic seizures cause neuron loss, however, therapeutic efforts to prevent all seizures from occurring become more important. This chapter describes cell death and survival mechanisms after single and repeated brief seizures in animal models and humans. What is the etiology of hippocampal and extrahippocampal cell loss in intractable TLE? Is there ongoing cell loss in refractory epilepsy? The question of whether single epileptic seizures damage the brain has been the subject of several previous reviews, to which the reader is referred.[1–3] The purpose of this chapter is to present the evidence for and against cell death after brief seizures and the molecular mechanisms that may underlie such an outcome. We omit discussion of other forms of neuronal damage (including reversible injury) that may also have significant behavioral or cognitive implications and the influence of repair mechanisms such as neurogenesis. Discussion of these issues can be found elsewhere.[4]

Evidence from Animal Models that Single or Repeated Evoked Seizures Cause Neuron Loss

Evidence that single or repeated brief seizures could cause neuronal death emerged from work in animals using electrical stimulation of various brain regions. While kindling paradigms are not ordinarily associated with permanent neuron loss,[4] papers published in the early 1990s, particularly by Sutula's laboratory, showed that kindling-induced seizures caused reductions in neuron numbers.[5] Cavazos et al. showed that repeated stimulation of the perforant path, olfactory bulb, or amygdala resulted in progressive decreases in neuronal density in multiple subfields of the hippocampus, including the hilus, CA1 and CA3, and parts of the entorhinal cortex.[6] The somatosensory cortex was unaffected, and changes were not attributable to tissue volume changes.[6]

Other studies using electrically evoked seizures have reported similar findings.[7,8] Not only is neuron loss progressive, but it may increase with secondarily generalized tonic-clonic seizures.[8] Reduced hippocampal neuron densities have also been reported after electroshock seizures,[9] and in addition to hippocampal neuron loss, a subpopulation of amygdala neurons may also be vulnerable.[10,11] Finally, recent studies by Sloviter and colleagues showed that sustained electrical stimulation of the perforant pathway leading to the hippocampus, which did not cause convulsive seizures or status epilepticus, produced extensive neuronal death and hippocampal sclerosis.[12] Thus, repeated brief seizures or subconvulsive stimulation of the hippocampus in certain models can reproduce patterns of neuron loss similar to those found in human hippocampal sclerosis (Table 28–1).

Evidence Against Single and Repeated Evoked Seizures Causing Neuron Loss

Studies in kindling models have shown that brief single seizures do not necessarily lead to cell loss. Thus, Bertram and Lothman reported reduced neuronal density after kindling but attributed this to tissue volume expansion.[13] The possible role of tissue volume changes and changes in neuronal morphology in reports of seizure-induced neuronal loss has been emphasized by numerous authors.[2,14,15] Brandt et al. also argued that neuronal density reductions after extended kindling were due to volume changes and not neuronal death.[16] Other groups also failed to detect neuronal death after

Table 28–1 **Summary of Findings on Neuron Loss after Single or Repeated Brief Seizures in Experimental Models**

Pathological Outcome	Findings
Neuron loss after repeated evoked brief seizures	Observed in many but not all models
Neuron death detected after repeated evoked brief seizures	Observed in some models
Neuron loss after seizures in spontaneously epileptic animals	Inconclusive
Neuron loss after seizures in animals with acquired epilepsy	Not currently supported by the evidence
Apoptosis-associated signaling	Modulation of Bcl-2 family genes, caspases

kindling in rats[17,18] and mice.[19] Thus, studies in which neuron counts were used as the principal measure of whether cell loss occurred are not in agreement as to whether brief seizures cause neuronal death (Table 28–1).

Detection of Acute Cell Death after Evoked Single and Repeated Brief Seizures

Direct evidence that brief seizures cause acute neuronal death has been provided by biochemical analyses. Bengzon et al. showed that a single seizure evoked by electrical stimulation of the hippocampus could cause hippocampal neurons to die, as detected by silver staining and staining of cells for irreversible DNA fragmentation using TUNEL (terminal deoxynucleotidyl transferase deoxyuridine triphsophate nick end labeling).[20] Notably, more stimulations caused proportionately more cells to die.[20] Using similar methods, other groups have also reported that repeated brief seizures cause hippocampal and extrahippocampal cell death.[11,21–23] These studies confirm that brief evoked seizures can cause neuronal death in animal models (Table 28–1).

Do Spontaneous Seizures in Epileptic Animals Cause Neuron Loss?

While brief evoked seizures in nonepileptic animals are useful models, they do not capture all aspects of the pathophysiology of spontaneous (i.e., epileptic) seizures. Is there evidence that spontaneous seizures in epileptic animals can cause neuron loss? This would be directly relevant to the etiology of progressive damage in human mesial temporal sclerosis. Two types of model have been studied in this context: animals that are spontaneously epileptic and animals that acquired epilepsy as the result of an initial precipitating injury. With the exception of certain genetically altered mice with active neurodegeneration, neuron loss does not appear to occur in spontaneously epileptic animals. For example, the hippocampus of spontaneously epileptic EL mice, which experience multiple complex partial seizures with secondary generalization on a weekly basis, shows no obvious neuron loss.[24] Evidence of subfield-specific seizure-induced hippocampal neuron loss has been reported in spontaneously epileptic rats,[25] although no acute cell death after a seizure or a biochemical marker thereof was detected.[25]

Studies in animal models of acquired epilepsy also suggest that spontaneous seizures do not cause further neuron loss. Pitkanen et al. reported that a longer duration of epilepsy was not associated with lower numbers of neurons in epileptic rats.[26] Moreover, no acutely degenerating neurons were found in any of the chronically epileptic animals, despite some of them experiencing more than 10 seizures per day.[26] Other studies appear to corroborate these data; hippocampal damage may continue for some time following status epilepticus, but neuron loss does not progress once animals are epileptic[27–29] (Table 28–1).

MOLECULAR MECHANISMS OF CELL DEATH FOLLOWING SINGLE AND REPEATED BRIEF SEIZURES

The molecular mechanisms underlying cell death following single and repeated brief

seizures are not as well researched as they have been in models of status epilepticus (reviewed in refs. 30–32). Glutamate-mediated excitotoxicity is the principal mechanism driving neuronal death after status epilepticus, whereby excessive glutamate release leads to intracellular calcium overload, oxidative stress, organelle swelling and rupture of intracellular membranes, activation of proteases, and necrosis.[33,34] Is glutamate-mediated toxicity the cause of neuron death after single or repeated brief seizures? We assume that it is, and necrosis has been detected after brief seizures,[11] but there have been no studies using appropriate pharmacological tools demonstrating that cell death can be prevented by glutamate receptor antagonists. Instead, there is biochemical and morphological evidence supporting cellular apoptosis occurring after brief seizures.[7,20,21] Notably, administration of the *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonist MK801 (which is neuroprotective in models of status epilepticus) did not prevent cell death after brief seizures.[20] The pathophysiological changes caused by brief seizures are no doubt glutamate-driven and may feature perturbed intracellular calcium homeostasis,[35] but through other pathways. These might include non-NMDA receptor-gated calcium entry and disruption of endoplasmic reticulum or mitochondrial function. Thus, apoptosis, which may have overlapping mechanisms of activation with necrosis, contributes to cell death after single or repeated brief seizures.

Molecular Control of Apoptosis

Apoptosis is a form of programmed cell death used to dispose of unwanted or damaged cells in a controlled manner. Excess neurons are removed during brain development by apoptosis, and apoptosis also occurs after the developing or mature brain is exposed to, or deprived of, certain substances. For example, ethanol exposure triggers widespread apoptosis in the developing rat brain,[36] and adrenalectomy triggers apoptosis of dentate granule neurons.[37]

Two main molecular pathways control apoptosis—extrinsic and intrinsic.[38,39] The extrinsic pathway is triggered by surface-expressed death receptors of the tumor necrosis factor (TNF) superfamily on binding of their ligands (secreted cytokines such as TNFα). The intrinsic pathway is mitochondria-mediated, and is activated by an array of intracellular stressors including DNA damage and perturbation of intracellular calcium homeostasis or organelle function.[40,41] This pathway is regulated by members of the Bcl-2 gene family at the point of initiation. Both pathways result in the downstream activation of a group of enzymes called *caspases.*

CASPASES

The caspases are a family of cysteinyl aspartate-specific proteases expressed in healthy cells in an inactive zymogen form. Caspases share a common structure comprising an N-terminal pro-domain followed by a large ~20 kD subunit and a smaller ~10 kD subunit. Caspases regulating apoptosis are typically organized into two functional groups: The upstream *initiator* caspases have long pro-domains. Activation of these requires protein-protein binding interactions between the pro-domain and scaffolding molecules activated in response to pro-apoptotic stimuli. For example, the pro-domain of caspase-8 binds to regions on signaling molecules recruited to the intracellular side of activated death receptors, whereas the pro-domain of caspase-9 associates with the apoptotic protease activating factor 1 (Apaf-1) forming the so-called apoptosome in association with released cytochrome *c* from mitochondria.[42] Activated initiator caspases then cleave and remove the short pro-domain of apoptosis effector (or *executioner*) caspases, thereby activating them.[42] Caspase-3 and other effector caspases such as caspases-6 and -7 then cleave numerous proteins within the cell, including structural proteins (a full listing can be found at http://bioinf.gen.tcd.ie/casbah/). Collectively, the caspase system results in hallmark morphological changes, DNA fragmentation (which can be detected by TUNEL), and eventual dispersal of the cell within membrane-enclosed apoptotic "bodies" to be phagocytosed by surrounding cells.

Bcl-2 Family Proteins

Bcl-2 family proteins function as critical regulators of apoptosis by controlling release of intramitochondrial apoptogenic molecules via effects on outer mitochondrial membrane permeability. The Bcl-2 family comprises both

pro- and anti-apoptotic members that share one or more Bcl-2 homology (BH) domains. Anti-apoptotic members include Bcl-2 and Bcl-xL, which possess four BH domains in common and a transmembrane anchoring domain. The multidomain pro-apoptotic members include Bax and Bak, which only possess BH domains 1–3.[43]

BH3-only proteins are a subgroup of the pro-apoptotic Bcl-2 family. These function as upstream initiators of apoptosis by binding and either inactivating anti-apoptotic Bcl-2 family proteins or directly activating pro-apoptotic Bax/Bak. BH3-only proteins are highly heterogeneous. Some reside inactively in normal cells and require posttranslational modification to be active, while others require transcriptional upregulation by cell stress or damage. Bad, for example, is expressed in many cells (including neurons) but requires dephosphorylation and disengagement from a chaperone protein called 14–3-3 to be active. In contrast, the more potently pro-apoptotic members, such as Puma, require transcriptional upregulation, for example via DNA damage-sensing proteins such as p53.[43] Once activated, Bax/Bak trigger release of cytochrome *c* from mitochondria initiating the intrinsic apoptosis pathway, culminating in caspase-dependent or -independent cell death[41] (Fig. 28–1).

OTHER SURVIVAL PATHWAYS

In addition to the anti-apoptotic arm of the Bcl-2 family, other anti-apoptotic molecules have been identified. These include protein kinase B (Akt), which is activated downstream of phosphatidylinositol 3 (PI3) kinase, which itself lies downstream of certain cytokine and surface-expressed growth and survival factor receptors.[44] Activated Akt can block apoptosis by phosphorylating and inhibiting Bad or the

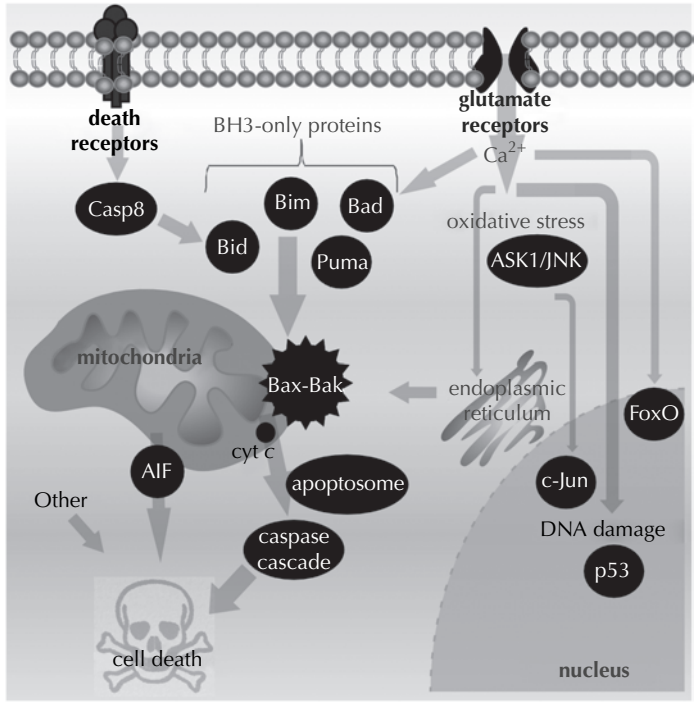

Figure 28–1. Pro-apoptotic signaling pathways. The diagram depicts major pro-apoptotic signaling pathways. BH3-only proteins function as upstream sentinels of cell stress. Bid is activated by caspase-8, which is itself activated downstream of death receptors. Bad is activated by calcium-dependent phosphatases, while Bim and Puma are upregulated by FoxO or p53, respectively. BH3-only proteins trigger Bax-Bak activation, and apoptogenic factors are released from mitochondria, including cytochrome *c* (cyt *c*), which activates the apoptosome and caspase cascade, and apoptosis-inducing factor (AIF). Ancillary pathways include induction of apoptosis via the ASK1/JNK/c-Jun pathway and other pathways, such as those downstream of endoplasmic reticulum stress.

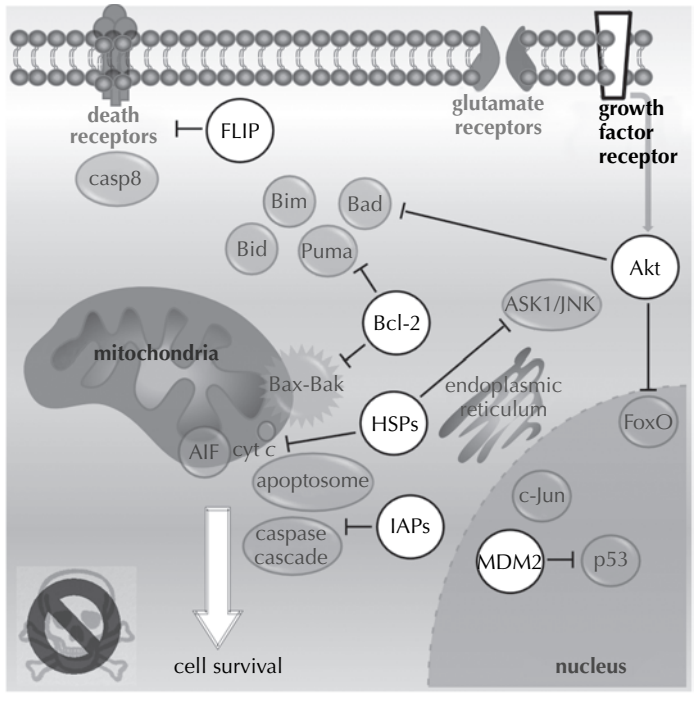

Figure 28–2. Anti-apoptotic signaling pathways. The diagram depicts key anti-apoptotic proteins that disrupt cell death at various points. FLIP (FLICE-like inhibitory protein) blocks the death receptor/caspase-8 pathway. Bcl-2 (plus the related Bcl-xL and Bcl-w) blocks pro-apoptotic Bcl-2 family proteins, Heat shock proteins (HSPs) inhibit mitochondrial apoptogenic proteins and the ASK1/JNK pathway. Akt downstream of various growth factor and other pathways inhibits the FoxO transcription factor and Bad. Inhibitor of apoptosis proteins (IAPs) function mainly by blocking caspases. Murine double minute 2 (MDM2) regulates p53 levels.

FoxO/Bim pathway.[45,46] The inhibitor of apoptosis protein (IAP) family functions mainly by direct inhibition of caspases and by targeting them for degradation by the proteasome[47] (Fig. 28–2).

Evidence of Apoptosis-Associated Signaling Pathways after Brief Seizures

Molecular evidence of apoptosis after brief seizures was first reported by Zhang et al., who detected an increase in *bax* mRNA, but unchanged *bcl-2,* expression in hilar neurons in the rat hippocampus following multiple kindling seizures.[21] Other studies have confirmed that kindling seizures cause hippocampal upregulation of *bax* as well as an increase in Bax protein.[48] Downregulation of anti-apoptotic Bcl-2 family proteins also occurs after repeated brief seizures.[48] The extrinsic apoptosis pathway may also be activated by brief seizures since kindling increases brain levels of TNFα.[49] Increased caspase-like enzyme activity and in situ staining of activated caspase-3 have been found in hippocampus after kindling seizures.[22,50]

Changes to Bcl-2 family protein expression have also been observed in models of electroshock-induced convulsions. Here, anti-apoptotic changes predominate, including downregulation of pro-apoptotic *bcl-xs* and Bim[51,52] and upregulation of anti-apoptotic Bcl-w.[53] This pattern supports protection rather than cell death.

There are no data on Bcl-2 family protein expression or function in epileptic animals. There is, however, evidence of caspase activity within the hippocampus of epileptic animals,[54,55] which may reflect ongoing cell death. The location of the active caspase signal within dendritic fields also supports caspase-mediated restructuring of neurons or other processes.[56]

It should be emphasized that the studies to date have not proven that apoptosis-associated gene changes are responsible for cell death in these models. This requires protein-protein interactions to be demonstrated and functional studies assessing, for example, damage in mice lacking specific genes. Evidence that genes associated with apoptosis can regulate seizure-induced neuronal death has been provided, however, from models of status epilepticus. Mice lacking the BH3-only proteins Bim and Puma are protected against status epilepticus-induced neuronal death,[57–59] and Bcl-2 and death receptor signaling protein complexes are formed in the hippocampus in these models.[52,60,61]

Summary: Animal Studies

Evoked brief seizures can cause neuronal death within the hippocampus and neocortex in animal models. The cell death has some of the biochemical and morphological features of apoptosis. In contrast, we do not have compelling evidence that spontaneous seizures in epileptic animals cause neuron loss. Both types of model show alterations in the expression of genes from the major families regulating apoptosis. Although we await evidence that this contributes to neuronal death after brief seizures, it has been demonstrated in models of prolonged seizures.

HUMAN CLINICOPATHOLOGICAL STUDIES: IS THERE DAMAGE PROGRESSION IN INTRACTABLE TLE?

Neuron loss, particularly within the hippocampus, is a widely observed pathological hallmark of refractory TLE in humans. Whether chronic epileptic seizures in patients cause neuron loss, however, or whether pathology arises independently of an initial precipitating injury or another (e.g., genetic) factor(s),[62] remains debated. In the next part of this chapter, we summarize various clinicopathological and neuroimaging studies that have provided evidence for and against neuron loss as a result of repeated brief seizures in humans.

Hippocampal Neuron Loss in Human TLE

There is a long history of studies identifying hippocampal neuron loss in TLE.[63–65] Most commonly, neuron loss is evident within the CA1 and endfolium or hilar region of the dentate gyrus.[66] Neuron loss and attendant gliosis are usually also evident in the CA3 subfield. While damage to the CA2 subfield and dentate gyrus tends to be less overt, neuron loss is evident in more severe cases.

A common source of evidence for seizures causing neuron loss in the human hippocampus is the association between longer seizure histories and greater neuron loss. For example, Mouritzen Dam, in a study of 20 patients with partial complex and generalized tonic-clonic seizures, found bilateral neuron loss that was most extensive in the end folium, CA3/4, and dentate granule cell layer.[67] The severity of neuron loss correlated with a longer duration of epilepsy, implying an effect of chronic seizures.[67] Similar conclusions were drawn from the large study by Mathern et al. of neuron densities in 572 hippocampal specimens from TLE patients.[68] Neuron counts decreased with longer seizure histories independent of TLE pathology or aging, implying that repeated seizures over many years (or factors linked to them) cause additional hippocampal neuron loss. However, the authors emphasized that their data showed hippocampal sclerosis to be an acquired pathology generated mainly by an initial precipitating injury, with a relatively small contribution from chronic seizures.[68] Similar conclusions were reached when hippocampal damage was examined in patients with TLE as a result of a temporal lobe mass[69] (Table 28–2).

Pathology in Nonhippocampal Regions

Extrahippocampal pathology within adjacent mesial limbic structures is present in a subset of patients with hippocampal sclerosis.[66] Affected structures include the amygdala, thalamus, and neocortex. Nevertheless, a majority of patients with TLE do not develop cortical neuron loss. A recent study reported that just 11% of surgically treated TLE cases also had neocortical neuron loss,[70] and no significant cortical neuron

Table 28–2 **Summary of Clinical Findings on Neuron Loss in Human Epilepsy**

loss was reported in another study.[71] The explanation for extrahippocampal/neocortical neuron loss in a subpopulation of patients is not yet known. It may be the result of more frequent or generalized seizures, or it may be due to an earlier initial precipitating injury[70] (Table 28–2).

Neuroimaging Evidence of Damage Progression in Intractable TLE

HIPPOCAMPUS

Many cross-sectional neuroimaging studies have reported lower hippocampal volumes in patients with epilepsy compared to controls and still lower volumes in patients with drug-resistant epilepsy.[72–84] Studies have also shown that hippocampal volume loss correlates with the number of epileptic seizures.[74,79] It should be noted, however, that not all studies explicitly state whether patients who experienced status epilepticus were excluded, and there are cross-sectional studies that failed to find an association between epileptic seizures and hippocampal volume reduction.[85] Twin studies using imaging have also contributed evidence that hippocampal sclerosis is an acquired lesion. For example, volumetric and T2 imaging of monozygotic twins by Jackson et al. determined that hippocampal sclerosis was present only in the twin with epilepsy.[86]

Longitudinal studies allow imaging of the same patients and controls over time, although they generally feature small cohorts and cover quite short periods of time.[87] Conclusions from such studies on whether epileptic seizures cause progressive hippocampal volume decline are mixed. Neuroimaging over periods of less than 4 years has detected hippocampal volume decline in relation to the number of generalized[88] and complex partial[89] seizures. However, several reports failed to detect reductions in hippocampal volume in epilepsy patients that exceeded those in controls over the same period.[83,84,90,91] Thus, current longitudinal studies have not resolved the question of progressive hippocampal atrophy in TLE (Table 28–2).

IMAGING: NONHIPPOCAMPAL REGIONS

Neuroimaging studies have reported extrahippocampal atrophy in patients with pharmacoresistant TLE. Regions affected include the entorhinal cortex and the amygdala ipsilateral to the seizure focus,[81,92–94] as well as frontal poles, lateral temporal and occipital regions,[95] and contralateral regions.[94] Some cortical decreases were found to relate to the duration of epilepsy, implying a role for repeated seizures in the changes.[95] Interestingly, extrahippocampal atrophy is more prominent in patients with left hemisphere TLE.[93]

We have few longitudinal imaging studies of nonhippocampal atrophy on which to base conclusions. Progressive atrophy involving orbitofrontal, insular, and angular regions has been reported in pharmacorefractory TLE patients.[94] Studies by Liu and colleagues, however, found that although patients with chronic epilepsy developed more neocortical volume loss compared to controls over a 3.5 year period, this was related to age and medication history rather than to an association with frequency of seizures.[96]

Summary: Imaging Evidence of Seizure-Induced Neuron Loss in Human Studies

Cross-sectional imaging studies support recurrent epileptic seizures as a cause of neuronal damage in the hippocampus of patients with TLE. There may also be seizure-induced neocortical neuron loss in some patients.

Nevertheless, major hippocampal atrophy probably results from an initial precipitating injury rather than recurring epileptic seizures. Longitudinal neuroimaging offers a better method for determining the effects of recurrent seizures in epilepsy patients, but findings to date are mixed. Taken together, neuroimaging studies suggest that structural damage is not an inevitable consequence of epileptic seizures in humans, in agreement with animal studies.

Histological Evidence of Acute Cell Death in Human TLE

Histological analyses of resected material have found evidence of acute cell death in patients with pharmacoresistant TLE. Henshall et al. detected TUNEL-positive cells in two of six neocortical resections from pharmacoresistant patients.[97] The same group, studying hippocampal sections, found TUNEL-positive cells in 9 out of 10 samples[52,98]; TUNEL-positive cells displayed features consistent with apoptosis.[98] However, the numbers were very low (ranging from zero to four per section) and did not differ statistically from those in controls.[52,98] TUNEL-positive cells were also reported to be higher in TLE sections compared to control sections in another study[99] but were not found to be elevated in three other reports[100–102] (Table 28–2). These studies suggest that there is at most very small-scale acute cell death in temporal lobe structures from pharmacoresistant epilepsy patients. Isolated dying cells may, however, be rapidly removed after seizures and difficult to detect; no study has yet undertaken an assessment of complete hippocampal resections, and counting has not been stereological.

MOLECULAR EVIDENCE OF APOPTOSIS-ASSOCIATED SIGNALING IN HUMAN TLE

The first studies to address whether programmed cell death/apoptosis signaling pathways were altered in the temporal lobe of patients experiencing frequent seizures emerged in the late 1990s. These descriptive reports noted increased Bcl-2 staining in astrocytes, although they found that Bcl-2 and Bcl-xL immunoreactivity in residual neurons of sclerotic hippocampi was similar to that in controls.[103] Glioneuronal hamartias, a form of cerebral dysgenesis, were strongly immunoreactive for Bcl-2.[103] Another early study noted that Bax immunoreactivity was stronger in TLE patients compared to control subjects and elderly drug-treated epileptics.[104]

Bcl-2 and Caspase Family Genes

The first study to apply quantitative measures of apoptosis-associated gene expression was done by Simon and colleagues at the University of Pittsburgh.[97] They reported data from 19 resected TLE patient temporal neocortex samples and 6 age- and gender-matched autopsy controls. Using Western blot analysis, they showed higher levels of Bcl-2 and Bcl-xL in patient brains (Tables 28–3 and 28–4). Immunohistochemistry showed that neurons were the main cell type expressing Bcl-2, while Bcl-xL stained mainly astrocytes.[97] The cleaved forms of caspase-1 and caspase-3 were also detected in TLE samples but not in the controls.[97] The elevated Bcl-2 and Bcl-xL levels might be molecular adaptations to inhibit cell death in surviving cells, while the activated caspases might be contributing to progressive pathology. Indeed, animal data show that overexpressing Bcl-2 or Bcl-xL is neuroprotective against excitotoxic insults,[105,106] while overexpression of caspase-3 enhances neurodegeneration after ischemia.[107] Caspase-1 knockout mice are refractory to kainic acid-induced

Table 28–3 **Expression of Pro-Apoptotic Proteins in Human TLE**

Increased

*Bcl-xL was increased in neocortex but not in hippocampus.

seizures,[108] so the presence of cleaved caspase-1 in human TLE might have pro-epileptic consequences in addition to, or instead of, a cell death-regulatory function.

Findings from Other Cohorts

Pro-apoptotic Bax expression has been reported to be moderately elevated in TLE hippocampi,[101] although this was not found in another study.[102] Several laboratories, using cohorts ranging from 12 to 24 patients, have also detected higher Bcl-2 levels in neurons and also glia in resected TLE hippocampi.[101,102,109] Levels of Bcl-w, another anti-apoptotic Bcl-2 family protein, are also elevated in resected TLE hippocampus.[53] Notably, Bcl-w expression in the hippocampus of mice is increased by exposure to repeated brief seizures.[53] This increase may protect hippocampus since overexpressing Bcl-w prevents excitotoxic (ischemic) injury in vivo,[110] while the absence of *bcl-w* increases neuron loss after status epilepticus.[53]

Another protective adaptation may be a reduction in levels of the BH3-only protein Bim in TLE hippocampus[52,111] (Table 28–3). Again, animal models of brief seizures have recapitulated this pattern,[52] which is very likely protective since the hippocampus of mice lacking *bim* are protected against status epilepticus.[59] Other BH3-only proteins may also be important; mice lacking the BH3-only protein Puma develop less hippocampal damage after status epilepticus.[57,58]

Other Caspases

Differences in the expression of many caspases have been detected in human TLE brain samples. Caspases-2, -3, -6, -7, and -9 have all been reported to be overexpressed and their active forms found,[55,102,111,112] and immunohistochemistry has localized cleaved caspases within neuron-like cells in TLE brain.[112,113] These data are evidence that caspase-mediated pro-apoptotic signaling occurs in human TLE. Caspases appear to localize within both the cell soma and dendrites,[55,111,113] supporting caspase-mediated cleavage of intracellular structural or synaptic proteins.[114]

Other Pro- and Anti-Apoptotic Proteins

Other putatively pro-apoptotic genes have been reported to be increased in human TLE tissue. There are increased nuclear levels of caspase-activated DNase, the enzyme responsible for the hallmark DNA laddering seen in apoptosis, in TLE samples.[113] Other putatively pro-apoptotic proteins showing higher expression in TLE include apoptosis signal-regulating kinase-1 (ASK1),[112,115] c-Jun,[116] Death-associated protein kinase,[98] Fas and its signaling components,[102, 115] p53,[102,117] and TNF receptor 1[115] (Table 28–3).

In addition to anti-apoptotic Bcl-2 family proteins, several other anti-apoptotic proteins are overexpressed in resected TLE tissue. These include protein kinase B (Akt),[52] heat shock protein 70,[116] endoplasmic reticulum stress-activated proteins such as glucose-regulated proteins 78/94,[111,112] and the cellular inhibitor of apoptosis protein-2 (cIAP-2)[118] (Table 28–4).

Summary: Molecular Evidence of Apoptosis in Human TLE

Alterations to apoptosis-associated signaling pathways are widely found in TLE tissue. Human findings probably reflect seizure-induced stress and the resulting adjustments to the molecular repertoire between adaptations that prevent neuron loss and, occasionally, signaling that ultimately results in cell death. Higher levels of anti-apoptotic Bcl-2 family proteins and related molecules may raise the threshold required for a seizure to cause cell death, thereby countering the influence of

pro-apoptotic molecules such as caspases. This may explain why so little acute cell death occurs in patients experiencing frequent seizures. This interpretation is consistent with animal data showing that changes to levels of apoptosis-associated genes can either prevent or exacerbate seizure-induced neuronal death.

MITOCHONDRIAL DNA DAMAGE IN EPILEPSY

Repeated seizures may result in other changes that enhance neuronal vulnerability over time. Mitochondrial function is critical for normal neuronal excitability, but mitochondria are also the primary sites in the cell for production of reactive oxygen species (ROS). Seizures increase ROS production, and studies suggest that this depletes cellular antioxidants, interferes with the function of electron transport chain enzymes, and causes DNA damage.[119] Indeed, mice overexpressing the mitochondrially localized superoxide dismutase 2 are protected against seizure-induced neuronal death.[120] Mitochondrial DNA (mtDNA) damage[121] and mtDNA copy number reductions[122,123] have also been reported in hippocampal tissue from epileptic rats, which has been suggested to contribute to reduced electron transport chain activity. Over time, neurons may become more susceptible to seizures and to their deleterious consequences, such as cationic overload.[119] Other groups, however, have not detected a reduction in electron transport chain enzymes in epileptic animals[124] or even found their expression to be increased.[125] Evidence of mitochondrial dysfunction has been reported in hippocampal tissue from TLE patients.[126,127] Together, cumulative mtDNA damage and compromised mitochondrial function may enhance neuronal vulnerability to seizures and contribute to epileptogenesis.

CHAPTER SUMMARY AND FUTURE QUESTIONS

Brief seizures can cause neuronal death in animal models. There is emerging evidence that apoptosis-associated signaling pathways are activated by these seizures, but so far we only have proof that these contribute to cell death in models of status epilepticus. There is little evidence that spontaneous seizures in epileptic animals cause acute cell death, but these animals nevertheless display alterations in apoptosis-associated pathways. In humans, there is evidence that recurrent seizures cause subtle or diffuse neuron loss in affected structures. Histopathological analyses have found a molecular signature of apoptosis-associated signaling in resected neocortical and hippocampal material from pharmocoresistant TLE patients.

Several questions remain to be answered. Is the frequency/clustering of seizures, or of particular seizure types—for example, secondarily generalized—more harmful? We await additional longitudinal neuroimaging studies specifically focused on comparing outcomes of different seizure types and severities. Future studies of pro- and anti-apoptotic signaling molecules should determine whether these occur in the same or different cells. Mouse models can make important contributions by allowing us to test which genes actually affect cell death following repeated brief seizures; in particular, they will allow us to test the influence of the particular genes in epileptic animals. This chapter has summarized the evidence for and against neuron loss after single and repeated brief seizures in animal models and human epilepsy and highlights the molecular pathways of apoptosis as a potential contributor to cell death and survival decisions.

Chapter 29

Programmed Necrosis after Status Epilepticus

Jerome Niquet
Maria-Leonor Lopez-Meraz
Claude G. Wasterlain

INTRODUCTION

In this review, we will discuss the most recent advances in the field of neuronal injury following epileptic seizures, with an emphasis on the mechanism of neuronal necrosis. The ultrastructure of cell death and the ubiquity of endogenous cell death programs were first described in the 1970s, and the two main categories of cell death, apoptosis and necrosis, were originally defined according to morphological criteria.[1] The role of glutamate and its analogues in excitotoxic cell death, and the concept of excitotoxicity—including its role in seizures—derived from the pioneering studies of John Olney and his disciples.[2–5] Multiple cell death factors and cell death programs have been identified in developmental and disease-induced neuronal apoptosis,[6–8] and there is mounting clinical and experimental evidence of their contribution to seizure-induced neuronal injury.[9–16] Because these death factors were originally identified in classic apoptosis, any form of cell death in which they are expressed is often called apoptotic, even if its morphology suggests necrosis. This has caused considerable confusion in the literature and should be discouraged.[17–20] In this chapter, we will discuss the involvement of cell death factors in morphologically defined necrosis, the main mode of status epilepticus (SE)-induced cell death in the adult and even in the developing brain. We find that necrosis is frequently an active form of neuronal death, requiring the

expression or activation of some of the same cell death factors usually identified with apoptosis. While this finding raises the hope that targeting common cell death pathways might have therapeutic benefits for both necrosis and apoptosis, the multiplicity and redundancy of cell death pathways for both modes of neuronal death also raise formidable problems when we consider the potential therapeutic applications of these mechanisms.

SEIZURE-INDUCED NEURONAL INJURY

Neuronal Injury and SE

Neuronal injury is widespread in the hippocampus and other brain regions of children or adults who died from SE,[21–24] or of patients with childhood-onset epilepsy who come to surgery for intractable seizures,[25] although epidemiological evidence of the deleterious effects of SE is lacking.[26] DeGiorgio et al. found decreased hippocampal neuronal densities in five patients who died after SE, compared to epileptic patients without SE and to controls.[27] Neuron-specific enolase, a marker of neuronal injury, is increased in the serum of patients with SE even when the seizures are nonconvulsive.[28,29] A number of anecdotal studies using magnetic resonance imaging (MRI) and other imaging techniques found cerebral edema acutely, and atrophy chronically, after nonconvulsive SE,[30–32] but other studies failed to find lesions.[33] Hippocampal atrophy has also been reported after complex or prolonged febrile seizures.[34,35] The presence of a normal brain MRI scan before nonconvulsive SE, evolving into brain atrophy after SE, has been documented,[36] and neuronal loss was found at autopsy in areas that became atrophic after nonconvulsive SE.[37] Atrophy (as seen on MRI) is strongly associated with areas of intense seizure activity in anecdotal cases,[38–40] and in one instance atrophy was shown at autopsy to correspond to neuronal necrosis and neuronal loss,[39] suggesting that neuronal loss and cerebral atrophy can result from SE in humans, although the incidence and severity of these complications after SE are not known.

Is Seizure-Associated Neuronal Injury Due to the Seizures Themselves or to Seizure-Associated Systemic Factors?

COMPLEX PARTIAL SE

As mentioned above, the limited evidence available shows elevation of cell death markers in the serum of patients after nonconvulsive complex partial SE in the absence of systemic complications. However, there is also anecdotal evidence that complex partial SE is not always followed by cerebral atrophy or behavioral deficits,[41] and there is little evidence of any type of brain damage or neurological deficit after petit mal absence SE.[42] This suggests that seizures per se can cause neuronal injury in humans, but that seizure type is a key determinant of injury.

EVIDENCE FROM ANIMAL MODELS

Meldrum and collaborators proved that seizures in paralyzed, ventilated monkeys caused neuronal loss.[43–45] The occurrence of neuronal injury in remote areas synaptically connected to the epileptic focus suggested an excitotoxic mechanism,[46] and Sloviter and Damiona showed that excessive neuronal firing by itself induced neuronal death.[47] In the immature brain, Thompson et al.[10,11] and Sankar et al.[12] demonstrated that severe, prolonged seizures cause neuronal death, although the extent of neuronal injury was highly model-dependent.[48] Recent evidence suggests that under circumstances approximating the clinical situation seen in patients with uncontrolled seizures, the mixture of the death-inducing action of severe seizures with the neuroprotective effect of seizure-associated preconditioning, in which mild seizure-associated injury mitigates the neuronal loss resulting from subsequent severe seizures, results in a neuropathological picture resembling hippocampal sclerosis.[49] Thus, the experimental evidence seems clear: systemic complications associated with seizures greatly aggravate mortality and morbidity from experimental seizures,[45,50] but in their absence, seizures per se are quite capable of causing neuronal injury and death, even in the immature brain,[10,11] and appears to do so by a variety of excitotoxic mechanisms.[16]

NECROSIS AND APOPTOSIS IN EXPERIMENTAL MODELS OF EPILEPSY

Necrosis and Apoptosis: A Morphological Definition

Necrosis and apoptosis were originally defined by morphological criteria.[1] In necrosis, early cytoplasmic changes, including severe mitochondrial and organelle swelling and rupture of the plasma membrane, precede late tigroid condensation of the nucleus with scattered, irregular, small chromatin clumps (Fig. 29–1). By contrast, in the early stage of apoptosis, chromatin condensation with loss of the nuclear membrane occurs in the presence of relatively preserved organelles and plasma/mitochondrial membranes. The advanced stages of apoptosis are characterized by the presence of multiple large, rounded chromatin masses. The picture can be complicated by the occurrence of both processes in the same cell. Following excitotoxic exposure, for example, apoptotic cells may undergo secondary necrosis, with severe swelling of the organelles and breakdown of the plasma membrane.

Following SE, Necrosis Is the Main Form of Neuronal Death in the Adult Brain…

In the adult rat brain, several models of SE show that necrosis is the dominant form of neuronal death. In models of SE induced by

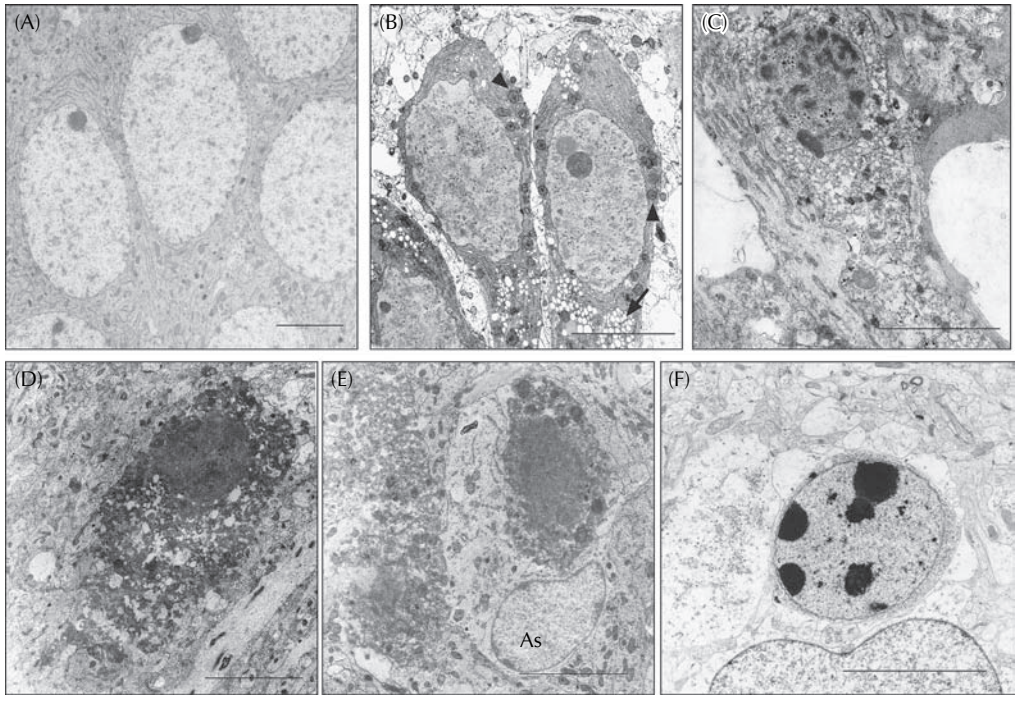

Figure 29–1. Example of necrotic and apoptotic morphologies in rat pup brain. Images **A–E** show the ultrastructure of CA1 neurons in control (**A**) and experimental animals 6 h (**B**), 24 h (**C**), and 72 h (**D,E**) following SE on day P14. Control neurons have healthy cigar-shaped mitochondria and intact nuclei (**A**). Mitochondrial swelling (arrowheads) and cytoplasmic vacuolization (arrow) are the first signs of cell damage 6 h following SE, suggesting early necrosis (**B**). Twenty-four hours following SE (**C**), this neuron displays mild, irregular chromatin fragmentation, while the cytoplasm, mitochondria, and endoplasmic reticulum show severe swelling. At 72 h (**D,E**), neurons exhibit advanced stages of necrosis, recognizable by severe organelle swelling and nuclear shrinkage (**D**), or are surrounded by astroglial cells (As, image **E**). **F**. Example of an apoptotic cell 24 h following MK-801 administration in the retrosplenial cortex from a P7 rat pup. Note the chromatin fragmentation into round clumps at a time when the cytosol is almost intact. Bars = 5 μm. From ref. 60.

lithium-pilocarpine or systemic injection of kainic acid (KA) in adult rats, Fujikawa et al.[17,18] and Tokuhara et al.[51] found necrosis in diverse areas of the brain, including the hippocampus, amygdala, and entorhinal, piriform, and frontal cortices 24 h to 7 days following SE. The apoptotic morphology could not be found even when SE duration was reduced to 60 min, suggesting that seizure severity is not a determining factor in the mode of death.[20] While necrosis is certainly the main form of seizure-associated death in the adult brain, apoptotic morphologies have been described in some models of SE, and their role cannot be disregarded.[52–54]

…And in the Developing Brain, Too

It is now well established that experimental seizures can induce neuronal injury in the developing brain.[12,55–58] Both apoptotic and necrotic morphologies have been clearly reported by light microscopy and electron microscopy (EM) in the developing brain following SE. On postnatal day 14 (P14) in rat pups, apoptosis was notably found in the inner granule cell layer of the dentate gyrus.[12,16] In the same rats, SE-induced neuronal injury was extensive in the CA1 pyramidal cell layer. Twenty-four hours after SE, EM observations showed that 47 of 50 injured CA1 neurons had a necrotic morphology (Fig. 29–1C). Seventy-two hours after SE, 50 of 50 injured neurons were necrotic[60] (Fig. 29–1D,E). In a model of lithium-pilocarpine SE in P12 rat pups, EM observations revealed that necrosis is the mode of death of injured neurons in the mediodorsal nucleus of the thalamus.[56] Altogether, these results show that necrosis is the main form of SE-induced neuronal death even in the immature brain.

Mechanisms of Seizure-Induced Neuronal Necrosis

THE TRADITIONAL VIEW OF NECROSIS AND APOPTOSIS

Traditionally, necrosis is viewed as a passive mechanism that does not require the activation of orderly cell death programs and/or synthesis of new proteins. However, many histological studies dispute this view. Following experimental SE, morphologically necrotic neurons display terminal deoxynucleotidyl deoxyuridine triphosphate nick end labeling (TUNEL) staining,[12,59,60] Bax immuoreactivity,[61] caspase expression,[16,60] or caspase-independent cell death programs.[62] Interestingly, nuclear expression of caspase-3 and nuclear translocation of Apoptosis-Inducing Factor (AIF) were found in injured neurons from patients with temporal lobe epilepsy.[63]

Are these *apoptotic* factors actively involved in the execution of necrosis? Alternatively, does their expression represent an epiphenomenon? The reduction of neuronal necrosis by caspase inhibitors in several models[16,64–66] supports the view that apoptotic factors play an important role in neuronal necrosis. Below, we will describe the experimental data suggesting the existence of active forms of necrosis.

By contrast, apoptotic neuronal death following brain insults is conceptualized as an active form of death that results from the execution of cellular programs that resemble those involved in developmentally programmed cell death. The best-characterized programs are those of the extrinsic and intrinsic pathways, which offer many alternative routes of activation of caspases, a family of cysteine proteases.[67] When the *extrinsic* pathway of programmed cell death is induced, the first step involves the activation of extracellular cell death receptors of the tumor necrosis factor (TNF) superfamily, which recruit other proteins to form a complex that activates caspase-8, which in turn activates caspase-3. This *executioner* caspase kills the cell through its widespread proteolytic effects, activating DNA breakdown, inactivating DNA repair enzymes, and attacking the cytoskeleton, among other activities. In the *intrinsic* pathway of programmed cell death, the mitochondrion plays a critical role by releasing cytochrome c from its intermembrane space to the cytosol, where, in association with apoptotic protease-activating factor-1 and deoxyadenosine triphosphate (dATP), it forms the apoptosome complex, activating caspase-9, which in turn activates caspase-3.[68] Below, we show evidence suggesting that these processes are not exclusively involved in apoptotic death but can also participate in necrotic forms of seizure-induced neuronal death.

EVIDENCE FOR CASPASE-DEPENDENT FORMS OF NEURONAL NECROSIS IN CULTURE

In primary neuronal cultures, chemical hypoxia or glutamate excitotoxicity can activate initiator caspase-9 and cell executioner caspase-3 in necrotic neurons. In the minutes to hours following the insult, cytochrome c is released from swollen mitochondria at a time when the nucleus is still intact (a sign of early stage of necrosis) and later colocalizes with active caspase-3, suggesting the activation of the intrinsic pathway. Caspase inhibitors reduce neuronal necrosis, showing that this caspase cascade is not an epiphenomenon but does contribute to neuronal necrosis. We have called this active form of necrosis *programmed necrosis*.[64–66]

Seizures and hypoxia/ischemia profoundly inhibit neuronal protein synthesis[69–72] and therefore inhibit processes requiring macromolecular synthesis (such as some forms of apoptosis). In opposition to classical apoptosis, programmed necrosis does not require protein synthesis. In primary neuronal cultures, the protein synthesis inhibitor cycloheximide reduced caspase-3 activation in staurosporine-induced apoptosis but had no effect on hypoxic neuronal necrosis.[64] Since the caspase-3 precursor is already expressed in control cultures, the execution of programmed necrosis does not require the energy-intensive process of expressing new genes, which is often necessary in classical apoptosis.

EVIDENCE FOR A CASPASE-DEPENDENT FORM OF NECROSIS INDUCED BY SE

In a lithium-pilocarpine model of SE in rat pups,[16] upregulation of initiator caspase-8

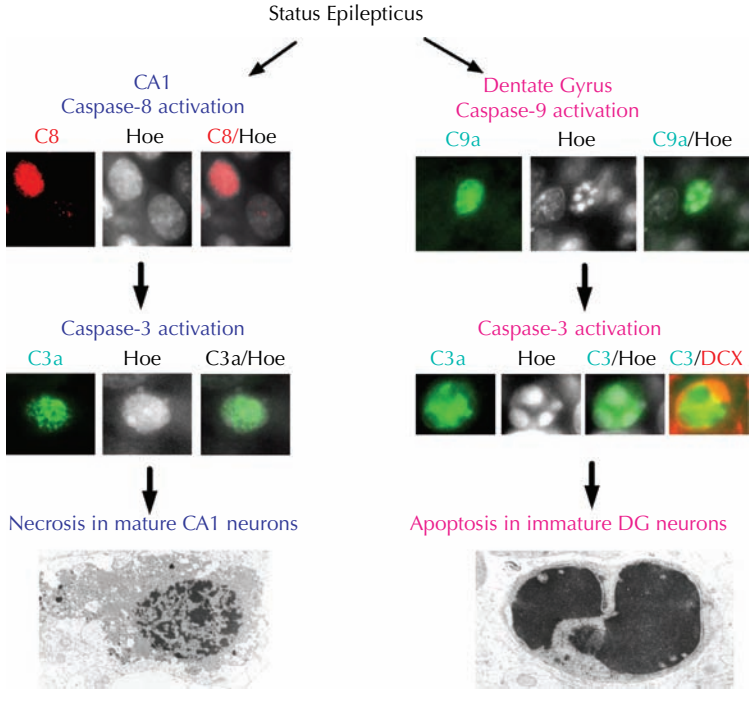

Figure 29–2. Putative neuronal death pathways induced by SE in the immature hippocampus. Fluorescent images show caspase-3a (green), caspase-8 (red), caspase-9a (green), and DCX (red) immunoreactivity and Hoechst staining (chromatin dye, white) in CA1 and the dentate gyrus following SE on P14. In CA1, images of caspase-8 and caspase-3 immunoreactivity were taken at 7 and 24 h, respectively. Images from dentate gyrus were taken 24 h following SE. At the bottom, EM micrographs obtained 24 h after SE show a CA1 necrotic neuron and a dentate gyrus apoptotic neuron. In CA1, seizures induce early and widespread activation of caspase-8, which subsequently activates the effector caspase-3 and leads to programmed necrosis. In dentate gyrus, seizures activate caspase-9 and caspase-3 and trigger apoptosis in immature neurons. From ref. 16.

precedes caspase-3 activation in CA1 (Fig. 29–2). Postembedding immunohistochemical studies show that caspase-3-immunoreactive CA1 neurons have a necrotic morphology. Pretreatment with a pan-caspase inhibitor reduces neuronal necrosis in CA1, showing that caspase activation is not an epiphenomenon but does contribute to SE-induced neuronal necrosis.[16] These results suggest that the caspase cascade of the extrinsic pathway (upregulation of initiator caspase-8 followed by caspase-3 activation) can also contribute to necrotic neuronal death.

There is indirect evidence suggesting that programmed necrosis can be found in other models of brain injury. In adult rats, KA-induced SE caused two types of pyramidal cell death in CA1: early necrosis (1 day after SE) and delayed TUNEL-positive and caspase-3-dependent programmed cell death (3–7 days after SE). Despite evidence of caspase-3 activation, apoptotic morphology could not be found at 1, 3, and 7 days following seizures, suggesting that necrosis is the main form of CA1 neuronal death.[51]

INFLUENCE OF CELL MATURITY AND INFLAMMATION ON PROGRAMMED NECROSIS

Following brain injury, apoptosis has been considered to be more likely to occur in the developing brain than in the adult one,[73] perhaps because of an age-dependent downregulation of apoptotic death factors such as caspases.[74,75] In the lithium-pilocarpine model of SE in rat pups described above, the same seizures trigger two distinct caspase pathways leading to two different modes of death: the extrinsic pathway leading to necrosis in CA1 (as described above) and the intrinsic pathway (caspase-9 and -3 activation) leading to apoptosis in the dentate gyrus (Fig. 29–2). One possible explanation for these results is the degree of cell maturity of these two neuronal populations. In the dentate gyrus, active caspase-3-immunoreactive cells had features of immature neurons: they expressed doublecortin (a marker of immature neurons[76]) and failed to express calbindin immunoreactivity (a marker of mature granule cells). Immature dentate gyrus cells may be more susceptible to death by apoptosis than CA1 pyramids, whose maturation occurs much earlier.[77–79] From these studies, we may speculate that the degree of cell maturity is more important than the level of maturation of the whole organism. Alternative explanations might involve environmental factors, that is, independent of the intrinsic properties of the neurons, such as inflammation or metabolic changes.

CASPASE-INDEPENDENT FORMS OF ACTIVE NECROSIS

Caspases are not the only apoptotic factors that may be involved in neuronal necrosis (Fig. 29–3). There is evidence that some forms of necrosis depend on the release of mitochondrial death factors, such as AIF and endonuclease G. Originally characterized for their role in apoptosis,[80–82] their release from mitochondria to cytosol and their translocation to the nucleus can induce DNA fragmentation in a caspase-independent manner. Translocation of AIF is involved in many models of neuronal injury often associated with a necrotic morphology. In cultured neurons, neurons with reduced AIF expression are more resistant to glutamate excitotoxicity or oxygen/glucose deprivation. Harlequin mice (expressing over 80% AIF expression reduction) exhibit less neuronal injury following ischemia or KA-induced seizures.[83–85] However, in the latter study,[84] seizure severity was not properly monitored and it is unclear whether Harlequin and control mice display the same susceptibility to seizures. In a model of lithium-pilocarpine SE in adult rats,[62] nuclear translocation of mitochondrial factors AIF and endonuclease G occur within 60 min of seizure onset (i..e., before signs of irreversible neuronal death), suggesting their involvement in nuclear pyknosis and DNA fragmentation. In the same study, nuclear translocation of other factors (cytochrome c, DNAse II) has been reported, suggesting the activation of various pathways leading to SE-neuronal necrosis.

The term *necroptosis* has been proposed for a kind of necrotic cell death that can be avoided by inhibiting the activity of the serine/threonine kinase RIP1, either through genetic or pharmacological methods.[86] Necrostatins, specific and potent inhibitors of RIP1, have been used as an operational definition of necroptosis.[87,88] By contrast with programmed necrosis, necroptosis involves caspase-independent pathways and other cell death factors have been implicated, including cyclophilin D, poly(ADP-ribose) polymerase 1 (PARP-1), and AIF (for review,

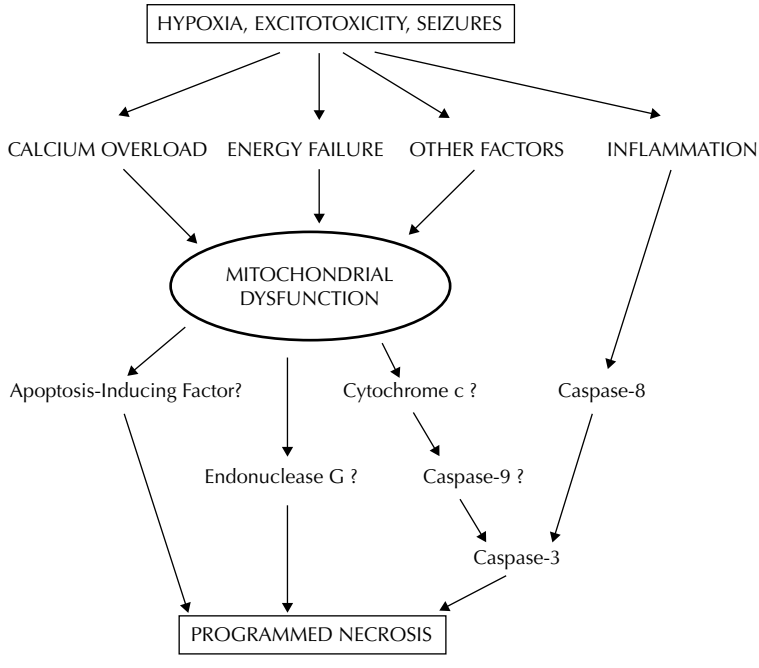

Figure 29–3. Putative mechanisms of programmed necrosis. Following hypoxia, excitotoxicity, and/or seizures, calcium entry into the mitochondria and/or energy failure contribute to mitochondrial swelling, outer membrane rupture, release of mitochondrial death factors, and activation of the intrinsic pathway. Alternatively, an inflammatory process may induce the activation of the extrinsic pathway. Adapted from ref. 6.

see ref. 89). Necroptosis has not been reported following SE, but it may contribute to *N*-methyl-D-aspartate (NMDA)-induced excitotoxicity in cultured cortical neurons.[90]

THERAPEUTIC IMPLICATION OF PROGRAMMED NECROSIS

Blocking neuronal necrosis is an important therapeutic goal. Plasma membrane rupture in the late stage of necrosis leads to release of cytoplasmic and/or nuclear material in the extracellular space, which may trigger an inflammatory response followed by secondary necrosis in neighboring neurons. The evidence of active forms of necrosis suggests the possibility of therapeutic interventions. An experimental model of SE showed that treatment with the cell-permeable, irreversible pan-caspase inhibitor Q-VD-OPH (Quinolyl-Val-Asp-Oph) can block active necrosis.[16] Intraperitoneal delivery of fusion proteins composed of an anti-apoptotic element and a transduction domain that enables the molecule to cross the blood-brain barrier has shown neuroprotective potential in models of SE.[91,92] Recent literature has also shown that cytokines, T-cells, and macrophages can add to the damage induced by seizures, and that targeting the innate and adaptive immune mechanisms may be a promising therapeutic approach.[93] However, the multiplicity of cell death pathways (caspase-dependent, caspase-independent) suggests that no magic bullet will be able to block simultaneously all forms of neuronal death.[94]

Chapter 30

Histopathology of Human Epilepsy

Nihal C. de Lanerolle
Tih-Shih Lee
Dennis D. Spencer

INTRODUCTION

Histopathological lesions that are associated with seizures are described in several neurological disease states. Such histopathological lesions are found in developmental disorders, neoplasms, microbial diseases, cerebrovascular diseases, trauma, and immune-mediated disorders, as well as in disorders primarily related to seizures such as temporal lobe epilepsy (TLE). General descriptions of these lesions have been the subject of several reviews.[1,2] Temporal lobe epilepsy, a major seizure disorder that affects over 40 million people worldwide, has received the most study in relation to its histopathology, and the histological lesion is thus best understood in relation to epilepsy. This chapter will review the state of our knowledge in the histopathology of TLE.

Pierre Gloor provides an excellent review of the historical studies of TLE.[3] However, some of the more significant of these studies bear revisiting for our current appreciation of the histopathology of TLE. The earliest systematic attempt to understand the histopathology of TLE was made by Sommer.[4] He reviewed all previously published papers on the pathology of epilepsy and examined (macroscopically) a few of his own cases; he estimated that pathology in Ammon's horn was found in about 30% of cases and that the pathology was more often unilateral. Studying the histology of only one

case, he described diffuse cell loss limited to a sector of the hippocampus, field H1 of Rose (area CA1), which subsequently became known as the *Sommer sector*. This condition, which manifests as an increased hardening of the tissue, was first noted by Bouchet and Cazauvieilh[5] and was termed *Ammon's horn sclerosis*. Bratz,[6] studying autopsied brains of epilepsy patients, confirmed the loss of neurons in Ammon's horn in about 50% of the brains and also noted that such loss was predominantly unilateral. He provided a more complete description of a sclerotic hippocampus, with accompanying woodcuts to illustrate his findings. Bratz observed the following: almost complete pyramidal cell loss in CA1 and a sharp boundary with the subiculum, which showed no cell loss; preservation of spindle-shaped cells in the stratum oriens; less complete cell loss in the hilus (end folium) and dentate gyrus; preservation of pyramidal cells in area CA2; and an abundance of blood vessels in the atrophic sector (area CA1). These detailed observations have held up as an accurate description of the gross histology of a sclerotic hippocampus.[7,8]

Whether hippocampal pathology is specially associated with TLE is still a topic of considerable discussion. To date, several lines of evidence suggest that the hippocampus does play an important role in TLE. Positron emission tomography (PET) studies demonstrate that the most significant hypometabolism is seen in the lateral temporal and medial temporal regions, with the degree of hypometabolism correlating with the severity of hippocampal pathology.[9] Hippocampal cell densities are significantly related to the amount of hypometabolism in the thalamus and basal ganglia in TLE patients.[10] Further, anteromedial temporal lobectomy, with removal of the hippocampus and amygdala, controls seizures and leads to improvement of the preoperative hypometabolism in the remaining areas of the temporolimbic network (e.g., inferior frontal temporal lobe, ipsilateral temporal neocortex, and medial thalamus).[11] Stauder[12] was the first to associate hippocampal sclerosis with TLE. He made a list of ictal symptoms and signs attributable unequivocally to temporal lobe disease (olfactory and gustatory auras, sensory aphasia and paraphasia, vertigo, auditory hallucinations or illusions and dreamy states) and correlated these with the postmortem pathology of 53 cases of "genuine epilepsy." Sixty-eight percent of the brains showed hippocampal sclerosis, of which 80% had definite and another 11% probable symptoms of genuine epilepsy, whereas none of those without hippocampal sclerosis showed symptoms. Falconer,[13] who developed the technique of en bloc resection of the temporal lobe for treatment of drug-resistant epilepsy, found a high correlation of good surgical outcome with mesial temporal sclerosis in the resected temporal lobe. Further, intracranial electroencephalographic (EEG) recordings in patients with TLE associated with hippocampal sclerosis show that seizures originate in the sclerotic hippocampus.[14] More recently, a multicenter study of seizure outcome after medial temporal resective surgery reports that hippocampal atrophy (sclerosis) and a history of absence of tonic-clonic seizures were the sole predictors of remission of seizures 2 years after surgery.[15]

Bratz[6] suggested that the hippocampal pathology in TLE cannot be assumed to be a consequence of seizures but must play a pathogenetic role. Whether hippocampal sclerosis is the cause or a consequence of seizures has remained a topic of lively debate. Several more recent observations indicate that hippocampal sclerosis is probably not a consequence of seizures. Magnetic resonance imaging (MRI) volume measurements show that the degree of hippocampal atrophy is not correlated with the duration and severity of seizures.[16] Some patients with multiple daily seizures since infancy do not have hippocampal sclerosis.[17] Likewise, a study of postmortem hippocampi from patients with poorly controlled seizures has confirmed the presence of a subgroup with no significant neuronal loss despite decades of seizures.[18] Additionally, hippocampi surgically removed from a large series of patients with TLE show that in about 15% of them (paradoxical TLE) there is no hippocampal sclerosis or evidence of extrahippocampal mass lesions, though their seizure semiology and history are indistinguishable from those of patients with hippocampal sclerosis.[7] Thus, seizures themselves do not result in hippocampal sclerosis. A more detailed and careful investigation of the histopathology of the sclerotic hippocampus and its relationship to the pathogenesis of human TLE is important, and since the 1980s there has been resurgence in investigations of the histopathology of the hippocampus in TLE. This renewed effort was ignited by a wider use

of the technique of en bloc resection of the hippocampus by neurosurgeons[19,20] and the availability of new methods for histological analysis. This chapter will attempt to summarize this considerable body of recent literature, various aspects of which have been the subject of other detailed reviews.[7,21,22]

HISTOPATHOLOGICAL VARIATIONS IN TLE HIPPOCAMPUS

In their now classic study, Margerison and Corsellis[23] examined the brains of 55 epileptic patients postmortem, in which clinical and EEG assessments of seizures during life were available. The hippocampi of this group showed varying degrees of histological change. Thirty-five percent of the hippocampi showed no evidence of neuronal loss bilaterally, while the remainder showed varying degrees of hippocampal sclerosis, ranging from classical hippocampal sclerosis (40%) to end folium sclerosis (25%). With the advent of surgery for the control of intractable epilepsy, further analyses of excised hippocampi were undertaken. Bruton[24] identified a variety of hippocampal pathologies using neuronal and myelin stains.[23] More recently, in another surgical series, the use of neuronal cell counts with immunohistochemical stains for neurotransmitters has led to the identification of several variations in the histopathology of the hippocampus in patients with medically intractable TLE.[7,25] Based on conventional histopathological criteria, hippocampi were divided into two groups—those without classical hippocampal sclerosis (compared to autopsy controls from neurologically normal subjects) and those with hippocampal sclerosis (Fig. 30–1). Those without classical hippocampal sclerosis had a small loss (<25%) of neurons throughout the hippocampus, with hippocampal volumes similar to those of autopsy controls and none of the immunohistochemical changes observed in the sclerotic hippocampi. However, these nonsclerotic hippocampi are divisible into two subgroups based on epilepsy etiology: the mass-associated TLE group (MaTLE) had an extrahippocampal temporal lobe mass lesion (low-grade gliomas, cavernomas), as opposed to a group described as having "paradoxical" temporal lobe epilepsy (PTLE), in which such mass lesions were absent and there was no history of febrile seizure or other identifiable etiological factors. Distinctive patterns correlating neuronal densities of the dentate gyrus and all areas of Ammon's horn, electrophysiological measures, and power spectral densities further differentiated these sclerotic and nonsclerotic groups.[7,25,26] The hippocampi with hippocampal

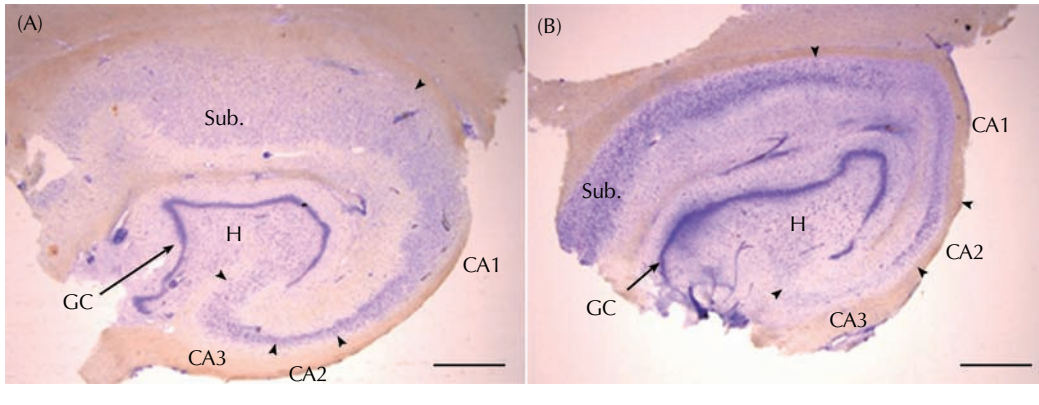

Figure 30–1. Photomicrographs of coronal sections of the hippocampus from a nonsclerotic and sclerotic (MTLE) hippocampus stained with Cresyl Violet. **A.** The nonsclerotic hippocampus is from a temporal lobe epilepsy patient with an extrahippocampal mass lesion in the temporal lobe. The hippocampus appears similar to that from a neurologically normal autopsy control, even through neuronal counts show approximately a 20% loss of neurons in all fields. **B.** This sclerotic hippocampus, also from a temporal lobe epilepsy patient, shows extensive neuronal loss in the hilus (H) and almost total neuronal loss in areas CA3 and CA1, with infiltration by glia. There is some preservation of neurons in area CA2. The neuronal density in the subiculum (Sub) is similar to that in the nonsclerotic hippocampus. The granule cell (GC) layer in **B** also shows significant neuronal loss. The arrowheads denote the limits of the respective CA fields. Bar = 50 μm.

sclerosis (mesial TLE [MTLE]) showed more extensive neuronal loss and some distinctive histopathological features. These features could be grouped into two broad categories: first, features associated with the neural reorganization of the dentate gyrus; and, second, the proliferation of astrocytes accompanying neuron loss in Ammon's horn (cornu ammonis [CA]), especially noticeable in area CA1. The details of these changes are described in the sections below.

REORGANIZATION OF THE DENTATE GYRUS IN SCLEROTIC HIPPOCAMPUS

Neuronal Changes in Dentate Gyrus

GRANULE CELLS

The principal neurons of the dentate gyrus are the granule cells, which form a densely packed C-shaped band of cells in a normal hippocampus. The granule cell has a cone-shaped tree of apical dendrites, which extend through the dentate molecular layer,[27] and in the human there are basal dendrites, which extend into the hilus as well as the molecular layer.[28] The granule cell axon, called the *mossy fiber*, extends into the hilus, where its collaterals synapse with hilar interneurons, continuing on to synapse on pyramidal neurons in area CA3.[27] Historically, the granule cells have been described as a band of cells that are relatively resistant to injury and loss in the sclerotic hippocampus. However, such resistance is visible only in a small proportion of TLE hippocampi, such as in a group of patients showing neuronal loss only in area CA1, as well as in MaTLE and PTLE groups.[7] In most of the MTLE hippocampi, there is loss of granular neurons resulting in a thinning of the layer and gaps in the cell band.[29] In other cases, there is a vertical spread or dispersion of the remaining granular neurons into the dentate molecular layer.[21] Reduced reelin mRNA levels are associated with granule cell dispersion, suggesting that the dispersion may be a developmental abnormality associated with granule cell migration.[30] Nevertheless, granule cell dispersion is not accompanied by enhanced neurogenesis in TLE patients.[31] Further, granule cell dispersion is not exclusive to hippocampi with sclerosis.[21,32] Granule cell dispersion seems more closely correlated with memory and learning changes than with seizures,[21] though some studies suggest that it is correlated with seizure frequency.[33] The surviving dentate granule cells in the sclerotic hippocampus show distinctive morphological alterations compared to those in nonsclerotic hippocampi. The apical dendrites of the granule cells in sclerotic hippocampi have a more limited spread in the longitudinal axis, a significant increase in the length of the portion of dendrites in the inner molecular layer, a decrease in the dendritic portion in the outer third, and an increase in spine density in both regions.[34] A proportion of the granule cells in sclerotic hippocampi also have axon collaterals from their mossy fibers extending into the molecular layer,[35] and these neurons have a significantly higher spine density in the proximal portion of the dendrite located in the inner molecular layer.[36]

Granule cells have a complex neurochemical profile. While glutamate is an important neurotransmitter produced by these cells, they also contain the neuropeptide dynorphin,[29] which increases in TLE hippocampi,[37] the calcium binding protein calbindin[38] and the hyperpolarization-activated cyclic nucleotide-gated cation channel 1 (HCN1), which is markedly increased when granule cell density is <50%.[39]

HILAR INTERNEURONS

The hilar region of the normal human hippocampus has many types of neurons. Among these are mossy cells, dentate pyramidal basket cells, and a variety of other interneurons characterized by their neurochemical content.[25] One of the early observations in relation to the histopathology of TLE is that interneurons mostly located in the subgranular region of the hilus and containing neuropeptide Y (NPY), somatostatin (SOM), and substance P (SP) were significantly reduced in number in the sclerotic hippocampus.[40] Many of these neurons also colocalize gamma-aminobutyric acid (GABA), and their loss may result in some loss of GABAergic inhibition. The dentate pyramidal basket cells, which are located on the hilar edge of the granule cell layer and are also GABAergic, are preserved in sclerotic hippocampi.[41]

The mossy cell is a neuron type of particular importance in TLE.[42] Large, complex spines

called *thorny excrescences*, which cover their proximal dendrites and from which the cell derives its name,[43] characterize these neurons, which are often triangular or multipolar in shape. These spines are the sites of termination of the granule cell mossy fiber axon. Mossy cells are excitatory glutamatergic neurons.[44] They can inhibit granule cells by directly exciting the pyramidal basket cells, which inhibit the granule cells.[45] In the rodent, the mossy cells are a very abundant cell type in the hilus. Mossy cells in primates (humans) and rodents show several differences. In the human, they are not the most abundant or largest cell type in the hilus, and the dendrites of most mossy cells penetrate into the dentate molecular layer and receive inputs from the perforant path.[46] In rodent models of seizures, the mossy cells are selectively vulnerable, and it is proposed that their death results in cellular reorganization favoring seizures.[42] In the human TLE hippocampus, mossy cells do not appear to be as vulnerable. Though the number of mossy cells is reduced, they have been identified in sclerotic hippocampi by increased expression of markers such as dynorphin,[47] GluR1 receptor,[48] and cocaine- and amphetamine-regulated transcript peptide.[49] In several sclerotic hippocampi, large numbers of mossy cells are observed even when most pyramidal neurons in CA1 and CA3 are lost.[47]

Plasticity of Neuronal Fibers

In addition to the loss of neurons in the TLE hippocampus, there is considerable evidence for the growth of new fiber systems, or *sprouting*. These changes are seen in the MTLE or sclerotic hippocampus. The most distinctive of these is the growth of recurrent collaterals from granule cell mossy axons into the inner molecular layer (IML). Such sprouting is recognized by the increased Timm stain, which visualizes the zinc contained in mossy fibers,[50,51] and by immunostaining for dynorphin (a peptide contained exclusively in dentate granule cells in nonsclerotic hippocampi).[40,52] These recurrent collaterals form synaptic contacts with the proximal portions of the apical dendrites of granule cells.[50,53] Enhanced immunoreactivity for dynorphin is also seen in surviving mossy cells, and their thorny excrescences are seen only in sclerotic hippocampi.[47] Four other examples of sprouting are observed in the MTLE hippocampus compared to those of other patient groups and autopsy controls.[25,40] The most striking of these examples is the increased density of NPY immunoreactive fibers throughout the dentate molecular layer. Somatostatin and SP fibers show a similar increase. Ultrastructural studies show that all of these fibers are axons, which form synaptic contacts with the granule cell soma and dendrites.[53] Acetylcholinesterase staining shows decreased staining in the IML and increased staining in the outer molecular layer (OML) of MTLE hippocampi compared to nonsclerotic hippocampi.[54]

Changes in Neurotransmitter Receptors

Associated with the reorganization of neurons and neural circuits in the dentate gyrus of the sclerotic hippocampus (MTLE) are several changes in the distribution of neurotransmitter receptors within the dentate gyrus compared to nonsclerotic surgically removed hippocampi (MaTLE and PTLE) and neurologically normal autopsy controls. These changes are summarized in Table 30–1. Several receptor subtypes that mediate glutamatergic transmission are changed. The alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) type receptor GluR 1 and GluR2/3 subunits are increased on the apical dendrites of the granule cells throughout the IML, while the GluR2/3 subunits are also increased on the granule cell bodies.[55] Such an increase in glutamate receptors may facilitate the excitation of granule cells through glutamatergic inputs such as the recurrent collaterals from mossy fibers or glutamatergic inputs from surviving hilar mossy cells (which terminate in the IML) and entorhinal inputs (which synapse on dendrites in the OML).[22] Upregulation of these AMPA-type receptor subunits on the thorny excrescences of mossy cells[56] suggests a facilitation of glutamatergic transmission from remaining granule cells through surviving mossy cells. The role of the metabotropic receptor subtypes (Table 30–1), which are also upregulated in the molecular layer and the granule cell layer,[57–59] is unclear at present; they may modulate excitatory and/or inhibitory effects.[60] Concomitant with upregulation of these glutamate receptors,

Table 30–1 **Neurotransmitter Receptor Localization in the Dentate Gyrus of the Sclerotic (MTLE) Hippocampus**

Receptor	GC	IML	OML	Hilus	Reference

+ = increased, – = decreased, 0 = no change relative to nonsclerotic and/or autopsy controls. GC, granule cell layer; IML and OML, inner and outer molecular layer, respectively.

there is also evidence of upregulation of inhibitory receptors. Thus, the $GABA_A$ receptor subtypes α1 and α2,[61] along with $GABA_B$ receptors,[62,63] are upregulated on the granule cells somata, with the $GABA_A$ α2 subtype also significantly upregulated on the proximal portion of the granule cell dendrites in the IML.[61] $GABA_A$ and $GABA_B$ receptor subtypes are also upregulated in the hilus, though their exact cellular location is unclear.[61] The receptors for SOM are upregulated in the granule cell layer and the dentate molecular layer, particularly the IML as well as the hilus,[64,65] and are consistent with the sprouting of SOM-containing axons into these regions.[40] Likewise, the NPY-Y2 receptors are upregulated in the granule cell layer and the IML as well as the hilus,[65,66] consistent with the sprouting of NPY-positive axons in these regions. The dopamine D2 receptors are upregulated in the granule cell layer and IML,[67] while vasoactive intestinal polypeptide (VIP) receptors are upregulated in the granule cell layer and hilus.[68] Several of these receptor changes—in SOM, NPY-Y2, GABA, dopamine D2, and some of the mGluR receptors—may be involved in increasing the inhibition of the excitability of surviving granule cells.[69] It thus appears that in the sclerotic hippocampus, along with processes that facilitate hyperexcitability, there are also several reorganizational changes that seem to reestablish inhibition, though perhaps inadequately.

Implications of Reorganizational Changes in the Dentate Gyrus

The implications of this wide array of histopathological changes in the dentate gyrus for epileptogenesis or the maintenance of seizures in patients with TLE associated with hippocampal sclerosis are difficult to evaluate with any certainty, though several attempts have been made (see refs. 22, 70). However, though it is commonly thought that the dentate gyrus granule cells are relatively resistant to injury and thus play a role in seizure generation, the study of a large series of sclerotic hippocampi reveals cases in which there are extremely few granule cells remaining[29]—and so are unlikely to be of functional significance. Yet, these patients had intractable epilepsy. In an intermediate state of neuronal loss, it is likely that the dentate gyrus contributes to the epileptic state. Electrophysiological recordings from granule cells in such cases indicate that these neurons are hyperexcitable.[71] A more integrated understanding of these several changes, through experimental investigation, is needed.

CHANGES IN AMMON'S HORN AND THE ROLE OF ASTROCYTES

Neurons

Ammon's horn (the hippocampus proper) is divided into three distinct fields identified as CA3, CA2, and CA1. Viewed in cross section, it is composed of a single band of pyramidal cells (the stratum pyramidale) whose apical dendrites extend into a stratum radiatum. Between the pyramidal layer and the alveus is a network of small neurons forming the stratum oriens. Ammon's horn is a region most vulnerable to neuronal loss in TLE patients.[23,72,73] The pyramidal neurons are the cell type most prominently lost. The degree of neuronal loss can vary from patient to patient, and usually ranges from greater than 50% compared to neurologically normal controls[8] to almost complete loss. In some TLE patients, neuronal loss is seen only in Ammon's horn, with the dentate gyrus being intact (CA only; see ref. 7). In a small proportion of patients, neuronal loss is confined to the dentate hilus and area CA3, a condition called *end-folium sclerosis*.[23] In the nonsclerotic patient groups with MaTLE and PTLE (see above), Ammon's horn appears intact on visual inspection, but neuronal counts show about a 20% loss of neurons, as in the dentate gyrus, and these hippocampi are qualitatively indistinguishable from those of neurologically normal subjects.[7]

In the sclerotic hippocampi, even those with extensive pyramidal cell loss, several populations of neurochemically defined interneurons remain. These neurons are especially prominent in the stratum oriens/alvear region, where they appear as characteristic horizontal neurons. In MTLE hippocampi these neurons are immunoreactive for GABA, NPY, SOM, and SP (see Fig. 6 in ref. 74) and express glutamate receptor protein subunits GluR1, GluR2/3, mGluR1, and mGluR5.[57,75] These stratum oriens neurons, which appear to form a network throughout the stratum oriens, are also more strongly immunoreactive for the enzyme phosphate-activated glutaminase.[76] Stratum oriens neurons are characterized by having soma and dendrites that extend horizontally in the stratum oriens; their axonal arbors show distinctive projections, which serve as the basis on which they are subcategorized.[77] The physiological properties of these neurons have been studied extensively in normal animals, where they have been shown to modulate the excitability of Ammon's horn pyramidal cells.[78] While these neurons have been studied in animal models of epilepsy and have been reported to be even more excitable than pyramidal cells,[79] their functions in human sclerotic hippocampi are completely unknown.

Astrocytes

The most recognized feature in the histopathology of the sclerotic hippocampus is the proliferation of astrocytes in the neuron-depleted Ammon's horn.[4] These astrocytes exhibit many unusual properties compared to astrocytes from nonepileptic brain regions and have been the subject of previous reviews.[80,81] These changes are seen in their membrane proteins (receptors, transporters, ion channels), membrane physiology, enzymes, gene expression, and neurovascular relationships.

Astrocytes from sclerotic hippocampi have increased expression of the glutamatergic receptors mGluR2/3, mGluR4, and mGluR8.[82]

Activation of these receptors is known to lead to intracellular Ca^{2+} release and Ca^{2+} wave propagation, a phenomenon demonstrated in sclerotic astrocytes.[83] It is suggested that such Ca^{2+} release leads to glutamate release from astrocytes,[84] but this conclusion remains controversial. An elevated flip-to-flop mRNA ratio of the GluR1 subunit of the AMPA-type receptor has also been reported,[85,86] suggesting an increased responsiveness to glutamate. Patch- and voltage-clamp studies demonstrate increased density of membrane sodium channels.[87–89] There is also strong upregulation of the α_{1C} subunit of the voltage-dependent calcium channel.[90] The α_{1C} subunit contributes to L-type calcium currents, suggesting a change in the current characteristic of these cells. The Kir channel on astrocytes, which normally helps astrocytes remove extracellular K^+, is also defective in astrocytes from sclerotic tissue.[91,92] A large proportion (~60%) of astrocytes in primary cultures from sclerotic seizure foci are capable of generating action potential-like responses when depolarized[89] compared to those from nonsclerotic foci. This ability to produce action potentials may be related to their more depolarized resting membrane potential (~ –55 mV) and increased Na^+ channel densities.

Astrocytes possess some key enzymes not found in neurons. Astrocytes from sclerotic foci show changes in these enzymes as well. Most prominent is the downregulation of glutamine synthetase in astrocytes in the CA fields but not in the subiculum of the sclerotic hippocampus.[93,94] Glutamine synthetase catalyzes the conversion of glutamate, removed from the extracellular space, into glutamine in a process that utilizes ammonia. Indeed, astrocytes from a sclerotic hippocampus seem to have a reduced capacity for glutamine synthesis and ammonia detoxification,[95] and cellular glutamine[96,97] is reduced in the sclerotic hippocampus. Additionally, glutamate dehydrogenase (GDH) activity is increased while aspartate aminotransferase (AAT) activity is reduced in the sclerotic hippocampus.[98] Glutamate dehydrogenase catalyzes the interconversion of glutamate to α-ketoglutarate. Lactate dehydrogenase (LDH) activity levels, normalized to citrate synthase activity levels, are also decreased in the sclerotic hippocampus.[98]

The distribution of some transporter molecules on the astrocyte plasma membrane is changed in sclerotic hippocampi. Aquaporin 4 (AQP4) is a water transporter molecule on astrocyte membranes. These molecules are more densely located on the perivascular end feet than on the rest of the cell. In sclerotic hippocampi the density on the perivascular end feet is reduced, but it is unchanged on the rest of the cell membrane.[99] The glutamate transporters EAAT1 and EAAT2 are reported as downregulated by some[100,101] but not by others.[102] The degree of change does not seems to be an adequate explanation of the high extracellular glutamate levels observed in sclerotic seizure foci.[103] The expression of the GABA transporter GAT3 is increased on astrocytes in the sclerotic hippocampus.[104] GAT3 expression is confined to cells resembling protoplasmic astrocytes, which are located in regions of relative neuronal sparing such as the dentate gyrus and hilus. The increased expression of GAT3 may contribute to the increase in removal of GABA and thus to reduced extracellular levels during the ictal state.[105]

Astrocytes and the Microvasculature

It was reported over 100 years ago that there is a proliferation of the microvasculature in the sclerotic hippocampus,[6] a finding since confirmed.[106,107] It is also reported that the blood-brain–barrier (BBB) may become leaky during a seizure, releasing substances such as albumin from the blood vessels to the brain parenchyma.[108] Such albumin may, by binding to transforming growth factor beta (TGFβ) receptors on astrocytes, trigger transcriptional activation of downstream pathways, resulting in downregulation of inward-rectifying potassium channels (Kir 4.1), increased inflammatory responses, and reduced inhibitory transmission.[109,110]

Several changes in the expression of molecules at the BBB-astrocyte interface are also observed. The erythropoietin receptor (EPO-r) shows increased expression on the capillaries and perivascular astrocytic end feet of sclerotic hippocampi, particularly in regions of neuronal loss and gliosis (CA3 and CA1).[106] Likewise, the multiple drug resistance gene (*MDR1*) mRNA expression and the protein it encodes, P-glycoprotein, show increased expression in

the capillary endothelial cells in a majority of patients with intractable TLE.[111] Among the other molecules located on the astrocytic end feet, AQP4 and dystrophin are decreased in expression, whereas CD44 and Plectin 1 expression are increased.[112] These molecular changes suggest that there are functional changes in the BBB of sclerotic hippocampi. The significance of these changes for epileptogensis is poorly understood.

Astrocyte Types

In the sclerotic areas of the seizure foci, while many cells are strongly glial fibrillary acidic protein (GFAP)-positive reactive astrocytes, accumulating evidence suggests that the astrocytes may not constitute a homogeneous population. Two subtypes of cells have been distinguished: a GluR cell that is characterized by the presence of AMPA-type GluR receptors but does not express glutamate transporters, and a GluT cell that expresses glutamate transporters but does not express glutamate receptors.[113] These cells are recognized in cultures and in slices from hippocampi and are nonoverlapping populations. The GluR cells lack gap junctions, while the GluT cells are extensively coupled.[114] GluR cells seem identical to a cell type described as the Neuron-Glial cell (NG2 cell) or polydendrocyte.[115] In the sclerotic hippocampus, several lines of evidence suggest that in addition to GFAP-positive astrocytes, there is also a population of NG2 cells.[80] These NG2 cells appear to be those that have increased calcium oscillations and calcium waves, and are also those that can be depolarized to generate action potentials.[89] It is reported that there is an almost complete loss of GluT cells in the sclerotic hippocampus, with only the GluR cells remaining, and that it is these cells that have the flip isoform of GluR1.[85,91] There is, however, a population of GFAP-positive astrocytes in the sclerotic hippocampus that show downregulation of glutamine synthetase and defective Kir channels.[95]

Probable Roles of Astrocytes in a Seizure Focus

The foregoing changes in astrocytes at the sclerotic hippocampal seizure focus may influence epileptogenesis by contributing to high extracellular glutamate levels, to high extracellular K^+ levels, and/or to the spread of excitation through the hippocampus.

The downregulation of the enzyme glutamine synthetase may produce an increase in extracellular glutamate due to inadequate clearance of the glutamate released at synapses,[93] while the increase in GDH may produce an increase in the observed cellular glutamate.[116] Further, evidence of intracellular Ca^{2+} release and Ca^{2+} oscillations in NG2-like cells in the sclerotic focus (see above), along with evidence of upregulation of the synaptic vesicle protein SNAP 23,[112] suggests the possibility that the sclerotic hippocampus may have cells capable of Ca^{2+}-dependent exocytotic glutamate release.[117] Additionally, astrocytic swelling by accumulation of water—due to inadequate clearance because of changes in the membrane distribution of AQP4—may also facilitate astrocyte release of glutamate.[118]

A diminished capacity to buffer K^+ in the sclerotic hippocampus[119] may result from impaired Kir channels.[92] Since the buffering of K^+ by the Kir channel depends on a parallel flux of water through the plasma membranes of these cells, the loss of AQP4 from the perivascular astrocytic membrane could result in diminished extrusion of water from astrocytes and thus a concentration of extracellular K^+.

The probable presence of a population of NG2-like cells in the sclerotic hippocampus, in addition to their role in Ca^{2+}-dependent glutamate release, may directly contribute to the excitability of the seizure focus. These cells may contribute to the excitability of the seizure focus because they are capable of being depolarized to generate action potentials[89] and have GluR1 receptors with elevated flip-to-flop ratios that facilitate and prolong depolarization.[85] Such cells may facilitate the generation or spread of waves of depolarization from hyperexcitabe granule cells[120] to the subiculum without synaptic pathways between the two regions.[80] Alternatively, the NG2 cell action potentials may just mediate Na^+ ion influx, to increase astrocytic $[Na^+]_i$ that stimulates the activity of Na/K adenosine triphosphatase (ATPase). An increase in Na/K ATPase in astrocytes may play a role in buffering extracellular K^+, compensating to some degree for the decreased Kir function in these astrocytes, and so may decrease

excitability. The function of NG2 cells in the sclerotic hippocampus needs further study.

GENE EXPRESSION IN SEIZURE FOCUS

In recent years, several high-throughput gene expression analyses of hippocampal tissue from TLE patients have been reported.[112,121,122] The most interesting of these studies are those that have compared the expression patterns in sclerotic hippocampi with those in nonsclerotic hippocampi. Unbiased hierarchical cluster analysis of expression data reveals that the gene expression patterns of sclerotic hippocampi from TLE patients usually cluster closely together, suggesting that they have molecular characteristics distinguishable from those of other TLE subtypes[112,122] (Fig. 30–2). While there is variability among the studies on the specific genes that are selectively expressed, there is considerable agreement on some of the functional groups of genes that are differentially expressed in the sclerotic hippocampus. In our laboratory, we compared the CA1 region from TLE patients with hippocampal sclerosis (MTLE with sclerosis) with those from two groups of patients without sclerosis (MaTLE and PTLE; see ref. 7). A comparison of this study with other studies is published elsewhere.[112] On examination of the genes selectively expressed in all MTLE hippocampi, increased expression of genes belonging to three important categories is recognized—astrocyte-associated genes, immune and inflammatory response genes, and genes associated with the endothelial cell-astrocyte interface.

Among the astrocyte-related genes upregulated in MTLE are (1) those associated with astrocyte morphology: GFAP is associated with astrocyte process extension, paladin (KIAA0992) regulates astrocyte shape, and plectin 1 (PLEC1) serves as a structural protein; the genes *ezrin*, *radixin*, and *moesin*

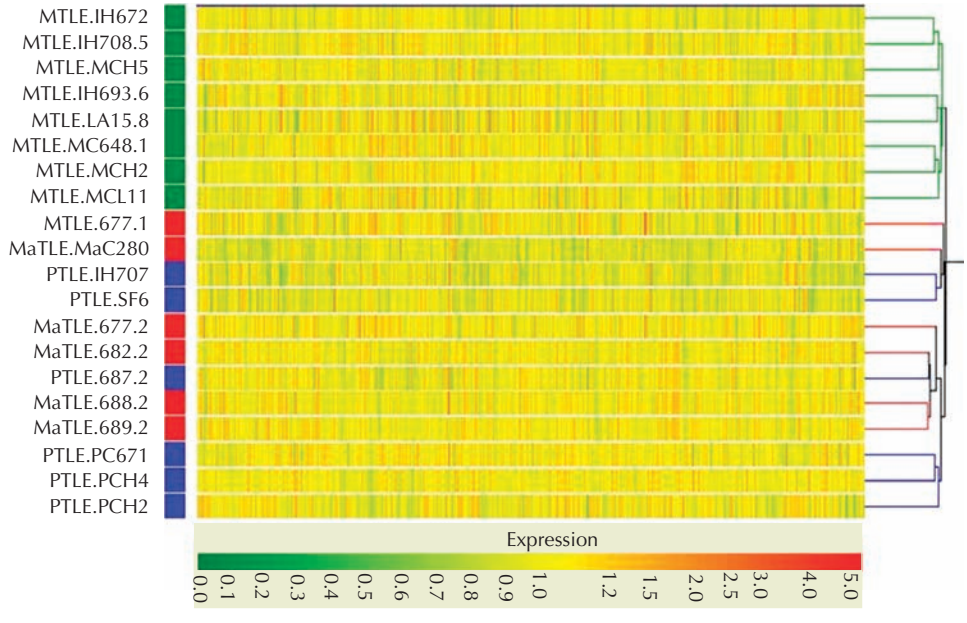

Figure 30–2. Comparison of the gene expression patterns in 20 hippocampi from patients with TLE. The dendrogram was obtained by unsupervised hierarchical cluster analysis using Gene Spring software. The analysis included all genes expressed in a microarray analysis using the Affymetrix GeneChip U133A. It shows a primary branching pattern, which separates the sclerotic MTLE (dark green) hippocampi as one cluster. The PTLE (blue) and MaTLE (red), both being nonsclerotic hippocampi, form a separate group. On the dendrogram, each horizontal color bar denotes the intensity of expression of a particular gene relative to the mean expression value of all samples. The color codes are shown in the color bar, where green represents transcript levels below the median and red represents transcript levels above it. Yellow is at the median. The more intense the color, the greater the level of trust it represents. MTLE, mesial temporal lobe epilepsy; MaTLE, mass-associated temporal lobe epilepsy; PTLE, paradoxical temporal lobe epilepsy. From ref. 112.

control three closely related proteins (ERM proteins), which constitute the machinery for association of actin filaments to the plasma membrane; (2) the CD44 family of surface glycoproteins, whose cytoplasmic domain is directly associated with the ERM proteins; (3) the extracellular matrix proteins tenascin (TNC) and chondroitin sulfate phosphoglycan 2 (CSPG2); (4) S100A6 and S100B—members of a family of proteins involved in Ca^{2+} regulation, with AHNAK being a target for S100B.

In addition to the molecules associated with the microvasculature described above (see the section "Astrocytes and the Microvasculature"), the ligands CCL3 and CCL2 for the chemokine receptors CCR1 and CCR2 found on the microvasculature[123] are increased in MTLE. CCL4 is also upregulated on astrocytes.[112,122] The binding of these ligands to their receptors on blood vessels may influence their permeability and perhaps leakage during seizures.

Several genes involved with immune and inflammatory responses are also upregulated. These include those regulating chemokines and their receptors, cytokines and their receptors, signal transduction proteins, transcription factors, transcription factor-related genes, and class II major histocompatibility complex genes. The particular genes belonging to these categories are listed in the article by Lee et al.[112] Many of these immune and inflammatory factors are probably produced by astrocytes.[124,125] Indeed, immunohistochemical localization of interleukin (IL)-1β and IL-1R in sclerotic hippocampi reveals their expression on astrocytes in areas of prominent gliosis and neuronal loss (CA1–CA3 and hilus), particularly in perivascular end feet.[126] Likewise, immunohistochemical localization of complement C1q, C3c, C3d, and C5b–C9 shows that C1q, C3c, and C3d are localized in astrocyte-like cells only in sclerotic hippocampi. C5–C9 are not localized on astrocytes. Experimental studies in animals indicate that molecules such as IL-1β and complement are closely associated with seizure generation.[127]

SUBICULUM

The subiculum is the region of the hippocampal formation from which major efferent pathways originate[128] and is involved in the spread of electrical activity from the hippocampus to other parts of the brain generating behavioral activity. Even in sclerotic hippocampi in MTLE patients, the subiculum remains largely intact, with no detectable neuron loss.[8,129,130] However, Cohen et al.[131] report that the subiculum of the sclerotic hippocampus initiates spontaneous interictal discharges that originate in a minority of subicular neurons, including interneurons and a subset of GABAergic pyramidal neurons in the subiculum and its transitional area with CA1. This paradoxical behavior of GABAergic neurons, which are normally inhibitory but behave as excitatory cells in the subiculum, has found an explanation in recent research. This switch of GABAergic neurons from inhibitory to excitatory relates to the relative expression of two Cl cotransporters—Na^+K^+, 2Cl cotransporters such as NKCC1, which accumulate Cl^- in the cell, and Cl^- extruding K^+, Cl cotransporters like KCC2. Alterations in the balance of NKCC1 and KCC2 determine the switch from hyperpolarizing to depolarizing effects of GABA. Immunohistochemical localization and quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of mRNA extracted from subiculum suggested that more than 20% of NKCC1-expressing pyramidal neurons in the sclerotic subicular/CA1 transitional zone not only lacked KCC2 but exhibited increased NKCC1. This pattern contrasts with about 95% colocalization in nonsclerotic patients.[132–134] Increased Cl^- in cells produces depolarization when GABA-mediated chloride channels are opened. Thus, it is suggested that altered Cl^- transport renders GABA neurons aberrantly excitable, contributing to the precipitation of seizures.[134] However, Wozny and coworkers[135] provide evidence, also obtained from slices of surgically removed hippocampal tissue, that interictal spontaneous activity is seen not only in sclerotic hippocampi but also in nonsclerotic hippocampi. Thus, the subiculum of the sclerotic hippocampus may not be involved in epileptogenesis only in sclerotic hippocampus. This region of the hippocampal formation may be a more generally excitable zone than other regions.

ENTORHINAL CORTEX

The entorhinal cortex (EC) is a principal source of efferents to the hippocampus, with

major projection to the dentate gyrus (perforant pathway) and CA1 (temporo-ammonic pathway). Abnormal epileptiform activity has been recorded from this region.[136,137] Histopathological studies of this region in TLE patients report neuronal loss and gliosis in layer III and, to a lesser extent, in layer II of the anterior portion of the medial EC of the sclerotic hippocampus.[138] However, other studies have reported a more variable pattern of neuronal loss[139] or no detectable loss.[140] Nevertheless, gliosis is a finding common to the EC in both sclerotic and nonsclerotic hippocampus.[140] Primary cultures from the EC (parahippocampus) of patients with a sclerotic hippocampus had increased Ca^{2+} release and Ca^{2+} oscillations in astrocytes.[83] If Ca^{2+} release is associated with glutamate release, these cells may trigger hyperexcitation of EC neurons and thus spread activity through the hippocampus. More needs to be learned about the role of these glial cells in the EC region.

PROBABLE PATHOPHYSIOLOGICAL MECHANISMS OF SEIZURE GENERATION

The probable pathophysiological mechanism of seizure generation must take into account the complex histopathological picture sketched above. Prominent features of this histopathology—a reorganized dentate gyrus, a neuronally depleted and gliotic Ammon's horn with an essentially intact and even spontaneously active subiculum—constitute the epileptogenic hippocampus.

Broadly, two sets of processes that have distinct histological substrates may be identified. The first set of processes are based in the dentate gyrus and may be important at least in the early genesis of the epileptic focus, before the loss of dentate granule cells is extensive. In this presumed early phase of pathogenesis, several cellular changes may underlie the development of hyperexcitable granule cells. These processes involve morphological remodeling of surviving granule cells, selective loss of hilar interneurons, sprouting of new axonal projections, and adaptive changes in neurotransmitter receptor distribution, representing a reorganization of the neural circuits within the dentate gyrus. An attempt to integrate these changes and hypothesize how they may result in granule cell hyperexcitability is given in de Lanerolle and Lee[22] (see Fig. 1 in ref. 22).

Despite the existence of such hyperexcitable granule cells, unanswered is the question of how such hyperexcitability passes from the granule cells to the subiculum to generate behavioral seizures, since the neural pathways connecting the two are interrupted due to extensive neuronal loss in the CA1 area early in pathogenesis. One hypothesis is that in the sclerotic region NG2-like cells, which are depolarizable and excitable, provide a substrate for the spread of waves of depolarization from the dentate gyrus to the subiculum. An alternative, though less likely, possibility is that the neural networks in the stratum oriens, which are very resistant to loss, provide a sufficient substrate for spread of neural excitation from dentate to subiculum.

It is notable that in several surgically removed hippocampi, the dentate gyrus is almost completely devoid of granule cells and Ammon's horn is very gliotic; yet, such hippocampi may take part in seizure generation in these patients. Seizures have been shown to originate from such hippocampi,[14] and in vivo dialysis studies demonstrate elevated extracelluar glutamate ictally in such foci.[105,141] In such hippocampi, the subiculum remains intact; however, the evidence, as discussed above, that the subiculum by itself is responsible for epileptic activity is weak. Alternative explanations must therefore be considered, such as astrocyte and astrocyte-related mechanisms. The unique properties of astrocytes in the hippocampal seizure focus are reviewed above, and an attempt to integrate these properties in the pathophysiology of epilepsy is provided in de Lanerolle et al.[80] Astrocytes may contribute to vascular permeability and increased extracellular glutamate and K^+ levels in the sclerotic hippocampus, which in turn may contribute to the hyperexcitability of the subiculum resulting in epileptic activity.

SPECULATION ON FUTURE CHALLENGES IN THE AREA

Our knowledge of the histopathology of TLE has advanced significantly in the recent past. However, we are still engaged largely in descriptive pathology. One of the major challenges for

the future is to understand the functional significance of the various changes observed. Of primary importance is an understanding of the functional biology of astrocytes and astrocyte-like cells in the sclerotic hippocampus. We have advanced several hypotheses regarding their role, but these need experimental testing. What are the proportions of GluR- and GluT-like astrocytes? How do they contribute to the increased extracellular glutamate and K^+ concentrations observed at the sclerotic seizure focus? Much of our information about their role in these mechanisms has come from the study of astrocytes from embryonic animal tissue and very little from the study of adult astrocytes from human foci. Do these abnormal astrocytes provide an excitable substrate for the spread of neural excitation from the dentate to the subiculum? Understanding the biology of astrocytes in TLE sclerotic foci would be very useful in providing insight into the epileptogenic mechanisms of other seizure foci such as mass lesions, tubers in tuberous sclerosis complex, and many of the neocortical epilepsies in which astrocytes may be a major constituent.

Our understanding of the functional implications of the anatomical changes in the dentate gyrus in the human also remains sketchy. Though much attention has been given to certain aspects, such as the functional significance of granule cell sprouting and glutamatergic and GABAergic mechanisms regulating granule cell function in the sclerotic hippocampus, there is far less experimental analysis of the significance of other changes, such as the new neuropeptidergic inputs to granule cells and the changed distribution of the several receptors. Studies that attempt to correlate the time course of functional changes resulting from dentate gyrus reorganization and abnormal astrocytes in the sclerotic human hippocampus are essential for a better understanding of the causative mechanisms of human TLE.

IMPACT ON FINDING CURES AND REPAIRS FOR EPILEPSIES

The current antiepileptic drugs and other repair strategies have focused attention almost exclusively on neurons as the primary cell type involved in mechanisms underlying epilepsy. The existence of a large group of patients with drug-refractory epilepsy is evidence that more effective therapeutic measures are required. The currently available antiepileptic drugs broadly target glutamatergic and GABAergic mechanisms, though they may have other effects as well. They are mediated through three main mechanisms—blockade of voltage-gated sodium and calcium channels that limit glutamate release; blockade of glutamate receptors; and the potentiation of GABAergic inhibition through increasing GABA availability or modulation of GABA receptors.[142,143] The histopathology of the epileptic hippocampus reviewed above, which shows that there is extensive *loss* of neurons in the hippocampus, suggests why current antiepileptic drugs, which focus on modulating functions of neurons, may be ineffective. New therapeutic agents should target astrocytes and astrocyte-like cells instead of neurons, as these cells are the primary constituents of the sclerotic hippocampus. Cell replacement strategies might consider transplantations of human stem cells that may develop into normal astrocytes that may restore a more normal extracellular glutamate concentration in the seizure focus and compensate for the abnormal astrocytes.

ACKNOWLEDGMENTS

We thank Ms. Ilona Kovacs, our histology associate over the past 25 years, whose outstanding expertise has contributed greatly to all of the studies from our laboratory. We also thank our many collaborators who contributed to the studies from our laboratory reported in this chapter, especially Drs. Michael Brines, Tore Eid, Jung Kim, Matthew Phillips, Sanjoy Sunderasen, John Tompkins, Subu Magge, and Edward O'Connor.

DISCLOSURE STATEMENT

The authors have no conflicts of interest to disclose.

Chapter 31

The Time Course and Circuit Mechanisms of Acquired Epileptogenesis

F. Edward Dudek
Kevin J. Staley

In order to develop and test possible therapeutic strategies for preventing or suppressing epileptogenesis, the temporal features of acquired epilepsy and its underlying mechanisms must be understood. These temporal features include the frequency, duration, and cortical extent of spontaneous seizures; this review focuses primarily on seizure frequency. Traumatic brain injury, stroke, status epilepticus, and infection/inflammation are some of the major causes of acquired epilepsy. The spontaneous recurrent epileptic seizures of acquired epilepsy usually occur after a latent period following the injury, and in at least some patients, the epilepsy is progressive (i.e., the seizures become more frequent and severe). Nearly all patients receive antiepileptic drugs (AEDs) after one or a few clinical seizures. Therefore, quantitative analyses of the temporal features of acquired epileptogenesis, independent of the effects of AEDs, cannot be studied in humans. Animal models of acquired epilepsy can circumvent this problem. The research summarized here analyzed the development of spontaneous recurrent seizures (1) in kainate-treated rats,[1] an animal model of temporal lobe epilepsy, and (2) in rats subjected to hypoxic-ischemic brain damage at postnatal day 7, a model of perinatal stroke.[2–4]

Many mechanisms have been hypothesized to account for epileptogenesis after brain injury. Numerous studies have focused on molecular and cellular changes during the latent period (the time from brain injury to the first clinical seizure), which has been thought to mark the duration of epileptogenesis; however, whether the first clinical seizure actually signals the completion of epileptogenesis or whether

epileptogenesis continues well beyond the first seizure is unknown. The frequency and pattern of spontaneous recurrent seizures as a function of time after the brain injury define the time course of epileptogenesis, and this information is fundamental to an understanding of the mechanisms of acquired epilepsy. This time course, which is essentially the natural history of acquired epilepsy, places constraints on the hypothetical mechanisms that contribute to epileptogenesis after brain injury. This chapter uses information on the time course of acquired epileptogenesis to evaluate hypotheses regarding the underlying mechanisms of epilepsy. Our focus is primarily at the level of neuronal circuits and synaptic reorganization: selective loss of specific, vulnerable GABAergic interneurons and the progressive formation of new recurrent excitatory circuits after axonal sprouting. We propose that these two mechanisms may account for—or at least contribute to—the time course of injury-induced epileptogenesis.

TWO MODELS OF ACQUIRED EPILEPSY

Most research using animal models of temporal lobe epilepsy that have spontaneous recurrent seizures is based on status epilepticus; some of the studies described in this chapter used an animal model in which status epilepticus was induced with repeated low-dose injections of kainate.[5–8] In the second animal model of acquired epilepsy, hypoxic-ischemic brain injury was induced in immature rats[2,3,9] as an animal model of perinatal stroke, which is an important cause of intractable epilepsy in children.[10,11] Use of this model allowed determination of the time course of the development of spontaneous recurrent seizures after perinatal brain injury.[4] These two animal models are quite different, but both of them show clear brain damage with neuronal death, and they both unequivocally develop epilepsy, which is manifest as readily documentable electrographic and behavioral seizures. Finally, a reduced in vitro preparation, the organotypic slice preparation, has been used to model posttraumatic epileptogenesis.[12,13] Advantages of this model are the compressed 2-week time scale over which epileptogenesis occurs and the isolation from other brain centers and systems, such as the blood-brain barrier and the immune system, which might influence epileptogenesis.

THE TIME COURSE OF ACQUIRED EPILEPTOGENESIS

The Progressive Nature of Acquired Epilepsy

The question of whether acquired epilepsy is progressive is important and long-standing. One view, as introduced above, is that acquired epilepsy (e.g., temporal lobe epilepsy) starts after a latent period, and subsequent seizure frequency and severity are variable but not necessarily progressive over time (i.e., the step-function hypothesis, Fig. 31–1A1). Another perspective is that acquired epilepsy is progressive; however, technical difficulties in measuring seizure frequency and severity (e.g., long-term, continuous recordings to account for seizure clusters) make it difficult to assess whether acquired epilepsy is progressive (i.e., the continuous-function hypothesis, Fig. 31–1A2). This issue is virtually impossible to evaluate directly in humans, because patient reporting of seizures is inaccurate and human patients are routinely treated with AEDs.[14] Human temporal lobe epilepsy often seems to be progressive, based on clinical[15–18] and magnetic resonance imaging (MRI) data.[19–21] Evidence of ongoing neuronal death in tissue resected for intractable epilepsy also supports this hypothesis.[22,23] In animal models, prolonged and virtually continuous electroencephalographic (EEG) recordings are required to determine whether the frequency and severity of spontaneous recurrent seizures increase in every animal. Bertram and Cornett,[24,25] who obtained extensive chronic recordings from rats with electrically evoked status epilepticus, found that subsequent spontaneous recurrent seizures occurred with variable frequency; however, seizure frequency generally increased over time and appeared to plateau after several months. When averaged across many kainate-treated rats, Hellier and collaborators[6] found that behavioral seizure frequency clearly increased as a function of time for nearly a year.

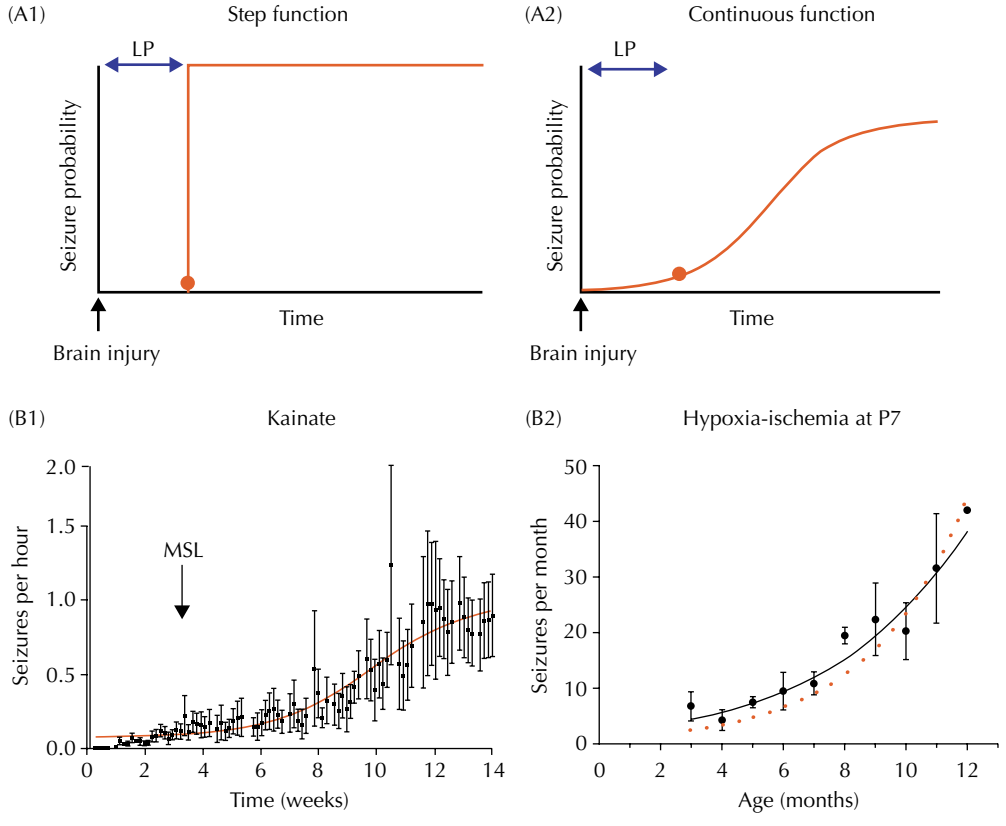

Figure 31–1. Time course of acquired epileptogenesis after brain injury. **A.** Schematic diagrams of the step-function and continuous-function hypotheses of the time course of acquired epileptogenesis. **A1.** The step-function hypothesis proposes a seizure-free period after the initial brain injury (i.e., the latent period [LP], with no epilepsy) and then the occurrence of spontaneous recurrent seizures (i.e., epileptic). The step-function hypothesis indicates that the mechanisms of seizure generation are mature when the first seizure occurs. **A2.** The continuous-function hypothesis proposes that seizure probability increases progressively after a brain injury. The hypothesis predicts an exponential increase in seizure probability or frequency followed by the development of a steady state. In the continuous-function hypothesis, the mechanisms responsible for generation of spontaneous seizures are not completely developed when the first seizure occurs, and the seizure rate continues to increase as epileptogenesis progresses. **B.** Analyses of seizure frequency as a function of time after brain injury. **B1.** Seizure frequency after kainate-induced status epilepticus. Seizure frequency increased as a function of time after kainate treatment (n = 9), which was best described by a sigmoid curve. Previous data obtained with this model suggest that most rats do not reach a steady state in seizure frequency for several months,[6] but some animals ultimately have such a high seizure frequency that they are often in status epilepticus.Note that the motor-seizure latent period (MSL) occurred after the first electrographic seizure. **B2.** Continuous video-EEG monitoring in rats subjected to hypoxia-ischemia at postnatal day 7 (P7) revealed an increase in seizure frequency and severity over time. The rats were implanted at 2 months and at ≥6 months. The data were from 10 hypoxia-ischemia-treated epileptic rats studied over an 11-month period with a best-fit exponential growth curve (dotted line) and a sigmoid curve (solid line). The sigmoid curve showed the best fit for the data. **A** modified from ref. 1. **B1** from ref. 1. **B2** from ref. 4.

After electrically induced status epilepticus (i.e., stimulation of the amygdala), video-EEG recordings every other day showed increased seizure frequency when assessed in 2-week epochs for 6 months.[26] With a similar model, but involving electrical stimulation of the angular bundle, Gorter and colleagues[27] observed a progressive increase in seizure frequency in most rats, although some rats appeared to be nonprogressive. After kainate-induced status epilepticus,[1] nearly continuous radiotelemetric recordings showed a progressive increase in seizure frequency (Fig. 31–1B1). The temporal pattern was highly variable across animals, but all animals (n = 9) showed a progressive increase in seizure frequency over the duration of the study (i.e., about 100 days) and the group data could be fit with a sigmoid curve. Based on

examination of the data from individual rats in the study of Williams and coworkers,[1] the animals from the report by Gorter and coworkers[27] that appeared to be nonprogressive might have had a progressive increase in seizure frequency if more prolonged seizure monitoring had been undertaken; on the other hand, it is possible that some animals may not show progressive worsening of the epilepsy after brain injury. In an animal model of perinatal stroke, however, every animal with a lesion developed progressive epilepsy in which seizure frequency increased over time[3,4] (Fig. 31–1B1). Notably, without virtually continuous recording for many months, seizure clusters and a low overall seizure rate would have obscured the consistent increase in seizure frequency. Thus, rats with epilepsy either after kainate-induced status epilepticus during adulthood or after a hypoxic-ischemic insult at postnatal day 7 showed a progressive increase in seizure frequency when recorded continuously over study durations lasting for at least a few months.

The Latent Period and the Duration of Epileptogenesis

The *latent period*, which is generally defined as the time from a brain insult to the first clinical seizure (Fig. 31–1A), is clearly one of the most intriguing concepts in epilepsy research. In humans, it has been reported to range from a few weeks to many years.[28] Bertram and Cornett[24,25] reported that nonconvulsive seizures always preceded the first convulsive seizure; the data in the report of Williams and coworkers[1] support this conclusion. Although the first convulsive seizures were detected roughly 2 weeks after kainate-induced status epilepticus, nonconvulsive EEG seizures first occurred at about 7 days. Furthermore, several nonconvulsive EEG seizures usually preceded the first convulsive seizure in this study.[1] The studies from these two research groups (and others) raise the possibility that in humans thought to have had latent periods of many years, unrecognized subclinical seizures may have preceded the first convulsive seizures. When examined in more quantitative detail, the longest interseizure intervals for the first 20 seizures in the work of Williams and coworkers[1] were only slightly less than the latent periods for the first electrographic nonconvulsive seizures. This result, and other data, suggest that the latent period can be viewed as the first of many long interseizure intervals (i.e., intercluster intervals), and that epileptogenesis per se involves a smooth and continuous increase in seizure probability over time after the brain injury (Figs. 31–1A2 and 31–1B). Measurements of the latent period are actually quite difficult: first, because the latent period is the time of an asymptotic departure from a baseline; and, second, because determination of the latent period requires continuous recording from the time of the brain insult to the first convulsive seizure. Thus, although the latent period is a genuine phenomenon, it may be best viewed as the initial phase of a continuous process. The continuous nature of epileptogenesis is often obscured by variable seizure frequency and the occurrence of seizure clusters. Therefore, quantitative assessments of acquired epileptogenesis may be accomplished more accurately by long-term measures of seizure frequency than by measurement of the latent period.

CIRCUIT MECHANISMS AND SYNAPTIC REORGANIZATION

Synaptic Reorganization

Acquired epilepsy may involve a wide range of mechanisms, including alterations in neurotransmitter receptors (e.g., gamma-aminobutyric acid A [$GABA_A$] receptors) and/or voltage-dependent currents (e.g., sodium channels). Although other systems may contribute to the time course of epileptogenesis, the progressive nature of this process in reduced preparations[12,13] supports the idea that local circuit alterations are sufficient to induce epilepsy. While local alterations in ligand- and voltage-gated channels may well be important, this chapter focuses on alterations in local synaptic circuits (i.e., synaptic reorganization). Two hypothetical mechanisms (also see the review by Ben-Ari and Dudek[29]) that have been studied extensively are (1) death of GABAergic interneurons and consequent decreases in GABA-mediated inhibition (Fig. 31–2A) and (2) axon sprouting with subsequent increases in recurrent excitation (Fig. 31–2B). The first

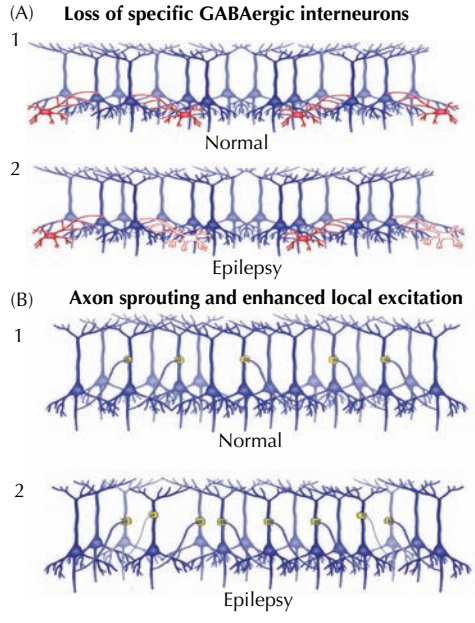

Figure 31–2. Hypothetical changes in local synaptic circuits during epileptogenesis. **A.** Loss of specific interneurons and decreased GABAergic inhibition in the hippocampus during epileptogenesis. Schematic diagram showing hippocampal pyramidal cells and interneurons under normal conditions (**A1**) and after epileptogenesis (**A2**) occurred. The diagrams illustrate the hypothesis that during epileptogenesis, some but not all interneurons are lost. **B.** Axon sprouting and increased recurrent excitation in the hippocampus during epileptogenesis. The diagrams show pyramidal cells under normal conditions (**B1**) and after axon sprouting associated with epileptogenesis (**B2**). They illustrate the hypothesis that although recurrent excitation is normally present among some pyramidal cells before epileptogenesis, it increases during epileptogenesis. From ref. 29.

mechanism involves a rapid loss of GABAergic interneurons after status epilepticus or other injuries, but interneurons may also continue to die during epileptogenesis. A mechanism that has gained considerable attention because it would be expected to require time to occur is axonal sprouting and subsequent formation of new excitatory (and inhibitory?) synaptic circuits; this time dependence could thus account for or contribute to the initial latent period and the subsequent progression of epilepsy.

Loss of GABAergic Interneurons

Experiments based on several independent morphological and physiological techniques in human tissue and animal models of acquired epilepsy support the hypothesis that a modest loss of specific GABAergic interneurons is associated with epileptogenesis (Fig. 31–2A). Immunohistochemical and in situ hybridization techniques have shown that a relatively small number of specific types of GABAergic interneurons are lost in both hippocampal and cortical areas.[5,27,30–32] Several laboratories have used whole-cell recordings of miniature inhibitory postsynaptic currents (mIPSCs) to test more specifically the hypothesis of a loss of interneuron input to granule cells[33,34] and CA1 pyramidal cells[35]; these studies have generally found that the frequency of mIPSCs is reduced (Figs. 31–3 and 31–4), which supports the hypothesis of a reduction of inhibitory GABAergic synaptic terminals (i.e., loss of GABAergic interneurons). Other interpretations of these data, such as reduced release probability, are possible but not congruent with the anatomical findings. Notably, these studies have not found reductions in the amplitude of mIPSCs (Figs. 31–3 and 31–4), thus suggesting that alterations in $GABA_A$ receptors do not contribute substantially to decreases in GABAergic inhibition during epileptogenesis, at least under these conditions. This approach has its limitations, but it uses tetrodotoxin to block action potential-mediated activity and is independent of the problems of extracellular stimulation (e.g., activation of fibers of passage, changes in action potential threshold between control and experimental groups); thus, the number of confounding variables is reduced. Therefore, the evidence from experiments on several animal models from multiple laboratories suggests that epileptogenesis is associated with a modest but significant loss of specific types of vulnerable interneurons in the dentate gyrus and the CA1 area of the hippocampus and in other areas, which in turn is manifest as a reduction of GABAergic inhibition. The reduction in GABAergic inhibition may be more robust early in the course of epileptogenesis and may at least partially resolve by the time of the first seizure.[33] For example, sprouting of GABAergic interneurons may at least partially restore inhibition.[36] Other mechanisms of disinhibition, such as reductions in the transport systems that maintain an inhibitory gradient for GABA-mediated chloride currents, may also contribute to epileptogenesis.[37–39]

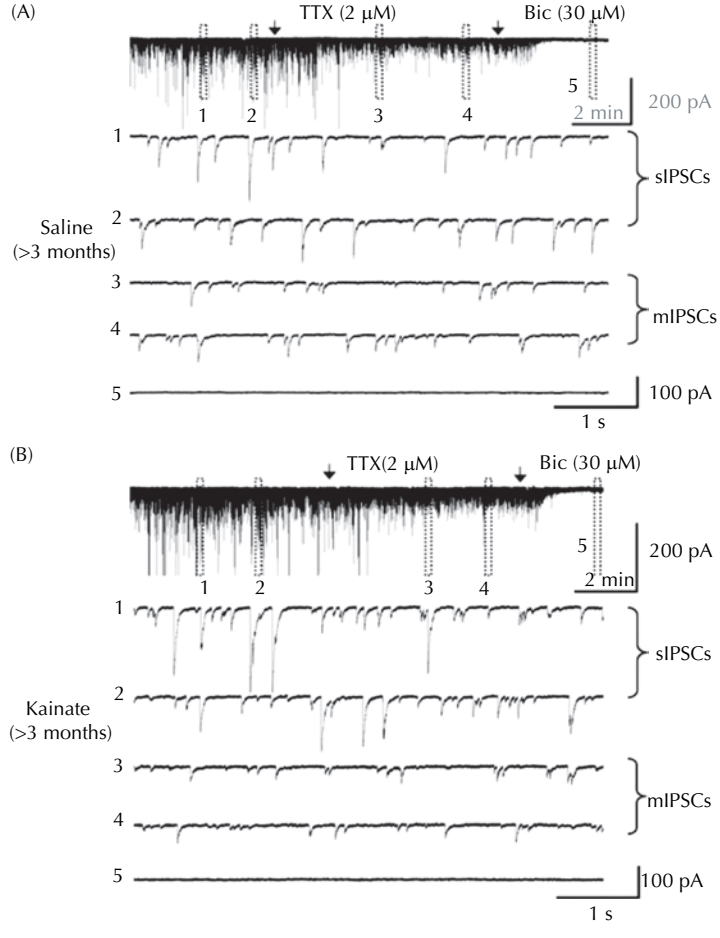

Figure 31–3. Examples of spontaneous and miniature inhibitory postsynaptic currents (sIPSCs and mIPSCs) recorded from granule cells of the dentate gyrus in rats >3 months after saline (**A**) or kainate treatment (**B**). The upper traces are recordings of sIPSCs for 18 min (**A**) and 15 min (**B**). The lower traces are expansions of the boxed parts of the recordings in the upper traces, which show sIPSCs (1 and 2) and mIPSCs (3 and 4). Bicuculline (Bic) blocked these currents, confirming that they were GABAergic. From ref. 34.

Axon Sprouting and Increased Recurrent Excitation

The concept of *synaptic reorganization* was initially based on the observation of mossy fiber sprouting and the associated hypothesis of increased recurrent excitation during acquired epileptogenesis, which has led to many studies aimed at exploring its potential role in temporal lobe epilepsy. One reason for the interest is that several laboratories had reported Timm stain in the inner molecular layer of the dentate gyrus of patients with intractable temporal lobe epilepsy.[40–43] This phenomenon is present in numerous animal models, including pilocarpine- and kainate-treated rats and the kindling model (see refs. 44 and 45 for review). Several types of electrophysiological and ultrastructural data strongly suggest that nearly all of the new mossy fiber connections are excitatory (see refs. 44 and 45 for review). For example, hilar or perforant path stimulation can evoke long-latency excitatory postsynaptic potentials (EPSPs) with prolonged spike bursts several months after status epilepticus, particularly when slices from rats with chronic epilepsy are bathed in $GABA_A$ receptor antagonists and/or high levels of potassium; in similar experiments on slices from control animals, comparable electrical stimulation only evokes an EPSP and/or a single action potential.[46–51] The rationale for performing these experiments

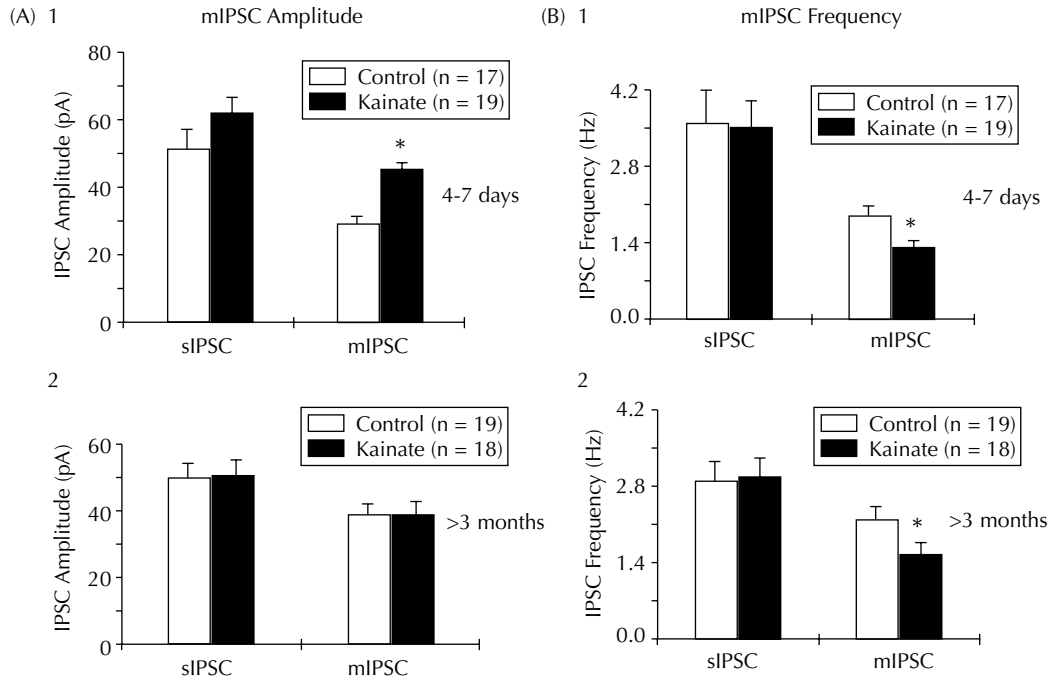

Figure 31–4. Changes in the amplitude and frequency of sIPSCs and mIPSCs during acquired epileptogenesis in kainate-treated rats. **A.** Summary of the data on mean IPSC amplitudes in rats 4–7 days versus >3 months after kainate treatment. **A1.** Although the mean sIPSC amplitude in rats 4–7 days after kainate treatment was not significantly different from that of controls, the mean mIPSC amplitude showed a significant increase. **A2.** Both sIPSC and mIPSC amplitudes in rats >3 months after kainate treatment were similar to those of controls. **B.** Summary of the data on mean mIPSC and sIPSC frequency in rats 4–7 days compared to those >3 months after kainate treatment. **B1.** The mean sIPSC frequency in rats 4–7 days after kainate treatment was similar to that from the saline groups, but the mean mIPSC frequency of the kainate-treated rats was significantly lower than that of the controls. **B2.** At >3 months after saline or kainate treatment, mean sIPSC frequencies were similar, but mean mIPSC frequencies were reduced in the kainate-treated rats. The sIPSC frequency was not significantly different in any of the four groups, and the two control groups in **B1** and **B2** had similar mIPSC frequencies. From ref. 34.

during blockade of $GABA_A$-mediated inhibition is not only that previous work showed that GABA-mediated inhibition has a masking effect on recurrent excitation,[52–55] but also that this procedure controls at least partially for epileptogenesis-associated differences in GABA-mediated inhibition (see above). Electrical stimulation, however, activates axons of passage. Experiments using glutamate microdrops[48,51] or focal photoactivation of caged glutamate,[56,57] which does not stimulate fibers of passage, have provided more direct evidence for the formation of new recurrent excitatory circuits. Dual intracellular recordings have further supported the hypothesis that mossy fiber sprouting in rats with pilocarpine-induced epilepsy is associated with an increase in monosynaptic recurrent excitatory connections among dentate granule cells.[58] Quantitative ultrastructural studies also indicate that new excitatory synapses connect primarily to dentate granule cells versus interneurons.[59,60] Newborn granule cells from seizure-induced neurogenesis in the dentate gyrus may play an important role in synaptic reorganization, at least in the dentate gyrus.[61,62]

Although mossy fiber sprouting and synaptic reorganization may be particularly important in the dentate gyrus, axon sprouting and the formation of new recurrent excitatory circuits is probably a widespread response to brain damage in many areas of the hippocampus and neocortex during epileptogenesis. Numerous studies have reported morphological and electrophysiological data that axonal sprouting (Fig. 31–5A) and enhanced recurrent excitation (Fig. 31–5B) occur in the CA1 area during epileptogenesis.[63–68] The CA1 area of the

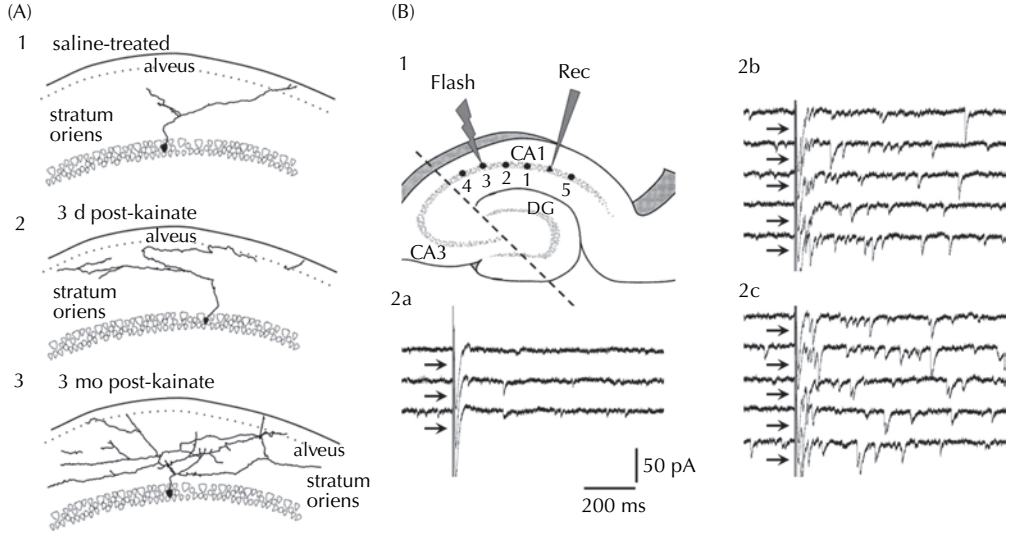

Figure 31–5. Axon sprouting and increased recurrent excitation of CA1 pyramidal cells in kainate-induced epilepsy. **A.** Examples of biocytin-filled axons from CA1 pyramidal cells during whole-cell recordings in isolated CA1 slices. **A1.** Axon from a saline-treated control rat. **A2.** The axons from kainate-treated rats 3 days after treatment were quantitatively similar to those of controls. **A3.** The axons were more highly branched in a rat >3 months after kainate treatment than in control rats or in a rat 3 days after kainate treatment. **B.** Evidence for local excitatory connections of CA1 pyramidal cells in epileptic rats was revealed by flash photolysis of caged glutamate. **B1.** Recordings were made from CA1 pyramidal cells in mini-slices, and flash stimulations were presented at different locations in the slice (circles) at 150 μm to 200 μm intervals along the cell body layer. **B2.** In a slice from a kainate-treated animal, repetitive flash stimulations (arrows, three to five flashes per site at 20 s intervals) consistently evoked a series of EPSCs in a CA1 pyramidal cell at two of five sites. **B2a.** Flashes at three sites (1, 4, and 5) evoked no EPSCs. **B2b, B2c.** Flashes at sites 2 and 3, which were 400 and 600 μm from the recorded neuron, respectively, evoked repetitive EPSCs. **A** from ref. 66. **B** from ref. 68.

hippocampus is highly vulnerable to excitotoxic neuronal death, and loss of neurons in CA1 is a classic marker of mesial temporal sclerosis. Synaptic reorganization in the CA1 area may reflect the types of morphological and functional changes that occur in many areas of the limbic system, possibly early in the epileptogenic process in humans. Many forms of acquired epilepsy in addition to temporal lobe epilepsy, including the epilepsy that occurs after perinatal and adult stroke[2,4,69] and traumatic brain injury,[70] are likely to be a network phenomenon, with at least two reorganizational mechanisms—the loss of vulnerable interneurons along with axon sprouting of principal cells followed by formation of new recurrent excitatory circuits.

POSSIBLE CONCLUSIONS

The spontaneous recurrent seizures after a brain injury, which define acquired epilepsy, typically worsen in terms of frequency and severity. Although this result has not always been seen in previous work, quantitative analyses of long-term continuous recordings are often required to detect progression. Studies of this type in the kainate model[1] and in a model of perinatal stroke[4] have provided clear evidence of progressive epilepsy in virtually all of the animals that were studied. Axonal sprouting and formation of new recurrent excitatory circuits are well known to be progressive processes, and these mechanisms could be the basis for the progressive changes that occur in these and other models. Selective interneuron loss may also be progressive and an important part of the changes that lead to progressive epileptogenesis. Considerable research has targeted the dentate gyrus, but similar mechanisms have been identified in many temporal structures and even in neocortical areas after brain injury (e.g., status epilepticus and perinatal stroke). Acquired epileptogenesis therefore appears to be a slow, time-dependent process (Figs. 31–1A2 and 31–B) rather than

a simple step function (Fig. 31–1A1) with a discrete latent period defining the boundaries of epileptogenesis[1,4]; synaptic reorganization defined by interneuron loss and the formation of sprouting-induced recurrent excitation may be an important component of acquired epilepsy that contributes to its natural history and progressive characteristics.

Chapter 32

Mossy Fiber Sprouting in the Dentate Gyrus

Paul S. Buckmaster

UNDER WHAT CIRCUMSTANCES DOES MOSSY FIBER SPROUTING OCCUR?

Granule cell axons (mossy fibers) project into the dentate hilus and stratum lucidum of CA3 in rodents[1] and other species, including humans.[2] Mossy fibers synapse with inhibitory interneurons, hilar mossy cells, and CA3 pyramidal cells[3] but very rarely with other granule cells (see below). Consequently, most granule cells normally do not display functional, monosynaptic, recurrent excitation.[4] A minor mossy fiber projection into the granule cell layer can be visualized with the Timm stain, which generates opaque silver particles specifically within zinc-rich mossy fiber boutons.[5] At all septotemporal levels of the hippocampus, occasional scattered dendrites and cell bodies of interneurons in the granule cell layer are outlined by Timm-positive punctae,[6] which electron microscopy has identified as mossy fiber synaptic boutons.[7] This pattern of Timm staining in the granule cell layer appears to increase with age.[8] At the temporal pole of the hippocampus, Timm staining reveals mossy fiber projections into the inner molecular layer that target granule cell dendrites.[5] This minor, recurrent excitatory pathway also increases with age.[9–12] The more extensive epilepsy-related recurrent mossy fiber pathway is an expansion of the normal minimal circuit already present.[13]

Aberrantly high levels of mossy fiber sprouting were first discovered during experiments investigating lesion-induced changes in neuronal connectivity. After transection of perforant path input to the dentate gyrus in young rats, black Timm staining was detected in the inner molecular layer.[14] More extensive and consistent mossy fiber sprouting developed after lesioning commissural/associational input to the inner molecular layer.[6] Electron microscopy revealed that lesion-induced sprouted mossy fibers synapse with granule cell dendrites.[6,15]

Mossy fiber sprouting was first found in patients with temporal lobe epilepsy by Scheibel et al.,[16] who reported that Golgi-stained mossy fibers project from the hilus, through the granule cell layer, and into the molecular

layer, where their boutons appose granule cell dendrites. Later, Nadler et al.[17] discovered extensive mossy fiber sprouting in rats that had been treated 1 month earlier with the excitotoxant kainic acid. Figure 32–1 shows mossy fiber sprouting in epileptic pilocarpine-treated rats. Perhaps because of the technical challenges of using the Golgi stain to follow individual granule cell axons, mossy fiber sprouting in human epileptic tissue was initially reported as rare (<1% of granule cells).[16] However, later studies used Timm staining and dynorphin immunoreactivity as markers for mossy fibers and found substantial sprouting in patients with mesial temporal lobe epilepsy.[10,18–20] Subsequently, mossy fiber sprouting was discovered in many different epilepsy-related conditions and some nonepileptic conditions (Table 32–1).

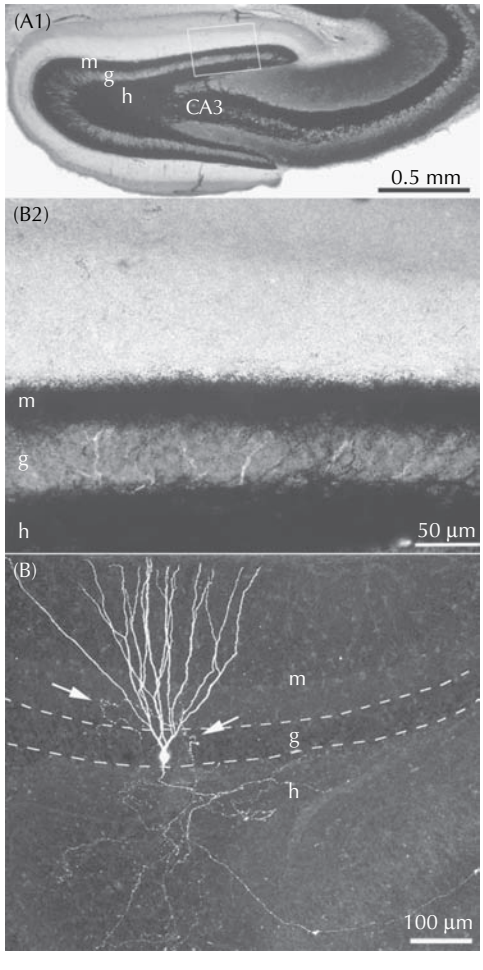

Figure 32–1. Mossy fiber sprouting in epileptic pilocarpine-treated rats. **A1.** Timm staining of the dentate gyrus (h = hilus, g = granule cell layer, m = molecular layer) and the CA3 region. **A2.** Magnified view of the boxed region in **A1** shows a dense band of black Timm staining in the inner molecular layer. **B.** Biocytin-labeled granule cell in a hippocampal slice from another epileptic rat reveals axon collaterals in the hilus and a sprouted mossy fiber (arrows) that projects from the hilus, through the granule cell layer, and into the molecular layer.

Temporal lobe epilepsy, the condition most frequently associated with mossy fiber sprouting, is the most common type of epilepsy in adults.[21] Some patients have a lesion (a hamartoma or glioma, for example) in their temporal lobe, but most have mesial temporal lobe epilepsy, which typically involves extensive neuron loss, especially in the hippocampus and, in at least some cases, a history of a precipitating injury.[22,23] Although robust mossy fiber sprouting is a common pathological finding in patients with mesial temporal lobe epilepsy,[24,25] there are exceptions.[26,27] Lynd-Balta et al.[28] proposed that young children with mesial temporal lobe epilepsy develop mossy fiber sprouting long after other changes, including neuron loss and altered expression of glutamate receptors. However, other investigators found mossy fiber sprouting similar to that of adult patients in children as young as 5.5 months old.[29] Mossy fiber sprouting does not occur exclusively in patients with mesial temporal lobe epilepsy. It also occurs in children secondary to cortical dysplasias without obvious hippocampal damage.[30] In those cases, however, the amount of sprouting is less than in children with hippocampal seizures.[29,31] On average, adult patients with mesial temporal lobe epilepsy have more mossy fiber sprouting than those with lesion-related temporal lobe epilepsy, but there is overlap between groups.[25] Mossy fiber sprouting can occur in epileptic patients without mesial temporal lobe epilepsy.[32] In addition, mild mossy fiber sprouting has been reported in patients with bipolar disorder but not epilepsy.[33] To better understand the circumstances that result in mossy fiber sprouting, it is helpful to consider the molecular and cellular mechanisms underlying its development.

HOW DOES MOSSY FIBER SPROUTING DEVELOP?

The mechanisms underlying mossy fiber sprouting remain unclear, but available evi-

Table 32–1 **Conditions in Which Mossy Fiber Sprouting Occurs in the Dentate Gyrus (Early References Indicated)**

- Patients

dence suggests likely triggers. One is seizure activity, which appears capable of causing mild mossy fiber sprouting without obvious neuron loss.[34–39] However, seizure activity alone is not always sufficient, because many seizures can propagate through the dentate gyrus without causing mossy fiber sprouting, as in Mongolian gerbils with inherited epilepsy.[7,40] Intense mossy fiber sprouting, like that found in patients with mesial temporal lobe epilepsy, appears to require deafferentation of granule cells either by transecting axons[6] or by killing presynaptic neurons.[17,41,42] Hilar mossy cells give rise to the associational pathway of the dentate gyrus (and, in rodents, the commissural pathway),[43,44] account for ~60% of all hilar neurons,[45–47] and synapse with granule cell dendrites in the inner molecular layer,[48] which also are the primary target of sprouted mossy fibers. The extent of mossy fiber sprouting correlates with hilar neuron loss in patients with mesial temporal lobe epilepsy[19,20,26] and in laboratory animal models.[49–52] More specifically, mossy cell loss correlates with mossy fiber sprouting in epileptic pilocarpine-treated rats.[47] However, fundamental questions persist. Is mossy cell loss alone sufficient to cause mossy fiber sprouting?[53] What is it about mossy cell loss that facilitates mossy fiber sprouting: granule cell deafferentation, removal of a synaptic target of mossy fibers, or both?[54] Complicating the issue, the most common experimental method used to produce mossy fiber sprouting is status epilepticus, which involves many other potential triggers in addition to mossy cell loss.

Whatever the events are that trigger mossy fiber sprouting, presumably they are transduced to granule cells as molecular cues that activate signaling pathways to coordinate mossy fiber growth and synaptogenesis. c-*Fos* expression was proposed as an early step in the process.[35] However, increased expression of c-*fos* and some other immediate early genes does not appear necessary for mossy fiber sprouting.[55,56] Increased expression of GAP-43, a membrane-bound protein concentrated at growth cones and developing presynaptic terminals, was proposed to promote mossy fiber sprouting.[24,57–60] In addition to GAP-43, tubulins[61] and microtubule-associated proteins[62] could be involved in mossy fiber sprouting. However, in regard to the molecular mechanisms underlying mossy fiber sprouting, brain-derived neurotrophic factor (BDNF)

has received the most attention. Expression of BDNF increases in the dentate gyrus after seizures.[63,64] Brain-derived neurotrophic factor promotes granule cell hypertrophy[65] and mossy fiber branching.[66] When infused in control animals, BDNF causes seizure activity and mild mossy fiber sprouting.[67] In addition, electroconvulsive seizure-induced sprouting is diminished in BDNF heterozygote knockout mice.[38] In contrast, other reports challenge the role of BDNF in mossy fiber sprouting. Mild mossy fiber sprouting develops in slice cultures from homozygote BDNF knockout mice[68] and after kindling in heterozygote BDNF knockout mice.[69] Transgenic overexpression of BDNF does not cause mossy fiber sprouting.[70] The timing of BDNF expression relative to development of mossy fiber sprouting has been questioned.[71] Vaidya et al.[38] reported that BDNF infusion does not cause mossy fiber sprouting. Nevertheless, strong evidence comes from organotypic culture experiments that induced mossy fiber sprouting by application of BDNF or a gamma-aminobutyric acid A ($GABA_A$) receptor antagonist.[72] In those experiments, an L-type calcium channel blocker, a sodium channel blocker, a TrkB inhibitor, a function-blocking anti-BDNF antibody, and transfection with dominant-negative TrkB each reduced mossy fiber sprouting. Thus, it seems likely that BDNF plays a role in mossy fiber sprouting, but the specific signaling pathways and molecular targets remain unclear.

The laminar specificity of sprouted mossy fibers is remarkable. For example, in most hippocampal slice cultures, the outer molecular layer is almost completely denervated but is relatively unstained for mossy fibers, which remain confined to the inner molecular layer.[42] Such specificity suggests strong attractant and/or repulsive extracellular signals. Although several molecular candidates have been proposed—including neural cell adhesion molecules (NCAMs),[73,74] tenascin-C,[75] Sema3A,[76] and hyaluronan[77]—none can fully account for precise targeting by sprouted mossy fibers, which remains an important area for research. In summary, there still is much to learn about the molecular mechanisms involved in transducing triggering stimuli, coordinating mossy fiber growth, and directing mossy fibers to their synaptic targets.

At the cellular level, an increasingly detailed picture of mossy fiber sprouting has emerged. After status epilepticus in rats, ~3 months are required for mossy fiber sprouting to fully develop.[12,78,79] Once fully developed, the proportion of granule cells with sprouted mossy fibers appears to be ~60% in patients with mesial temporal lobe epilepsy[80] and laboratory animal models,[81–84] but more precise estimates are needed. Recent findings suggest that only new adult-generated granule cells sprout mossy fibers into the molecular layer. Granule cell neurogenesis normally continues throughout life. For example, in young adult control rats, the number of new granule cells generated each month is 6% of the total population.[85] Granule cell neurogenesis accelerates after status epilepticus[86] or even milder seizure activity.[87] Although earlier studies questioned the role of newborn granule cells in mossy fiber sprouting,[88,89] later work showed that granule cells born up to 4 weeks before status epilepticus[90] and up to 4 days afterward can develop aberrant mossy fiber projections to the inner molecular layer, whereas older granule cells (born ≥7 weeks before status epilepticus) do not.[91] Identification of newborn granule cells as the source of aberrant mossy fibers is an important advance in our understanding of how mossy fiber sprouting develops, but questions persist. Why do newborn granule cells develop aberrant connections? Are the underlying causes attributable to intrinsic, perhaps epigenetic, changes in granule cells, to extrinsic cues in the microenvironment, or to both? Are the underlying causes transient or permanent—and if permanent, can they be reversed? Do all newborn granule cells form aberrant connections or just a subset? And how long following a precipitating injury will newborn granule cells continue to develop aberrant connections?

Human epileptic tissue displays evidence of ongoing synaptic reorganization years after precipitating injuries and the onset of spontaneous seizures.[24,74,80] Although these results might suggest that mossy fiber sprouting continually progresses and becomes increasingly severe with time, in laboratory animal models, which can be evaluated more extensively and with more temporal resolution, levels of mossy fiber sprouting appear to plateau after 3 months.[12] Together, these findings and the neurogenesis data described above suggest that older sprouted mossy fibers might be replaced by new ones. If aberrant circuits continually turn over, there may be opportunities to

interrupt the pathophysiological process even after robust mossy fiber sprouting develops. Consistent with this notion, after a 45 day delay, during which time some sprouting is likely to have developed, grafts of CA3 pyramidal neurons reduce mossy fiber sprouting following kainate infusion.[79] Furthermore, levels of mild mossy fiber sprouting after experimental electroconvulsive treatment peak and then decrease at later time points, suggesting at least partial reversal.[38] Therefore, despite evidence that mossy fiber sprouting is long-lasting or even permanent,[32,78,92] it might be worthwhile to further test its stability.

At the microcircuit level, in vivo spatial features of mossy fiber sprouting have been evaluated using axon tracers[81] and intracellular labeling.[82] Individual granule cells extend mossy fibers into the inner molecular layer over an area with an average radius of 600 μm, which is comparable to the span of hilar collateral projections in control animals. Plotting the corresponding area on a calibrated, flattened map of the rat dentate gyrus,[93] and using an estimate of 1 million granule cells per rat dentate gyrus,[94] one can predict that ~42,000 granule cells are within reach of one granule cell's sprouted mossy fibers. Integrating axon length per cell with synapse density per axon length suggests that each granule cell that sprouts mossy fibers into the molecular layer forms an average of ~500 new synapses with other granule cells.[95] If one assumes that each new synapse is with a different granule cell and that ~60% of granule cells in epileptic rats sprout mossy fibers, then the probability of finding a monosynaptically coupled granule cell within another cell's reach is 0.7%—which is consistent with experimental results.[96] In addition to mossy fiber projections into the inner molecular layer, granule cells in epileptic animals have greater axon length in the hilus,[82] increased branching of hilar collaterals,[83] and more boutons in the hilus.[81] In the hilus of epileptic animals, therefore, mossy fibers might hyperinnervate surviving neurons, consistent with recent findings from recordings of hilar somatostatin interneurons.[97] Epilepsy-related mossy fiber sprouting also occurs in stratum oriens of CA3,[98] but the present review focuses on the dentate gyrus.

In addition to their normal synaptic targets, in epileptic tissue sprouted mossy fibers form asymmetric (excitatory) synapses with ectopic granule cells in the hilus,[99,100] with granule cell basal dendrites in the hilus,[101,102] with granule cell somata in the granule cell layer,[83,103] and with granule cell apical dendrites in the granule cell layer and inner molecular layer[12,20,101,104–106] (including occasional autapses[83,101]). In the inner molecular layer, ~90% of mossy fiber synapses are with dendritic spines, the remainder with dendritic shafts. Mossy fiber synapses with granule cells are abundant, accounting for ~50% of all inner molecular synapses in epileptic pilocarpine-treated rats.[94,100] Compared to other excitatory synapses in the inner molecular layer, mossy fiber synapses appear to be larger and are more likely to be perforated,[94,105] features that suggest greater synaptic strength.[107,108] Overall, there is considerable anatomical evidence that mossy fiber sprouting creates a positive-feedback circuit among granule cells.

Sprouted mossy fibers also synapse with inhibitory interneurons but much less frequently than with granule cells.[83,105] Some have proposed that sprouted mossy fibers hyperinnervate parvalbumin-immunoreactive basket cells.[109,110] Others have countered that even in control tissue, those interneurons receive high levels of mossy fiber input.[111] If interneurons were hyperinnervated by excitatory synapses after mossy fiber sprouting, one would predict the frequency of spontaneous inhibitory postsynaptic currents in granule cells to be more sensitive to glutamatergic receptor antagonists, which was reported.[112] However, one also would expect that the miniature excitatory postsynaptic current frequency in basket cells—a more direct measure of the number of glutamatergic synapses impinging upon basket cells—would increase as mossy fiber sprouting develops; however, it does not.[113] In vivo biocytin-labeling and three-dimensional reconstruction of serial electron micrographs of sprouted mossy fibers revealed that only ~5% of synapses formed by sprouted mossy fibers in the granule cell layer and molecular layer are with GABA-immunoreactive neurons; the other ~95% are with granule cells.[95] Integrating synaptic density, synaptic target frequency, and sprouted mossy fiber length, these findings suggest that the average granule cell with sprouted mossy fiber collaterals forms 20 times more new synapses with granule cells than with interneurons.

WHAT ARE THE FUNCTIONAL CONSEQUENCES OF MOSSY FIBER SPROUTING?

As expected from the anatomical evidence reviewed above, mossy fiber sprouting creates an aberrant, recurrent, excitatory circuit. Functional positive feedback among granule cells has been demonstrated with varying experimental approaches and degrees of confidence. In animals with mossy fiber sprouting, but not in controls, in vivo perforant path stimulation evokes a delayed current sink in the inner molecular layer[114] and reverberating field potential responses, which are consistent with positive feedback among granule cells.[50,82,115] As in hippocampal slice studies,[116] reverberating responses in vivo become most apparent after inhibition is blocked. A limitation of the in vivo approach, however, is that perforant path stimulation activates many circuits in addition to sprouted mossy fibers. In hippocampal slices, especially with $GABA_A$ receptors at least partially blocked or the extracellular potassium ion concentration elevated, antidromic stimulation of mossy fibers evokes depolarizing synaptic responses in granule cells more frequently after sprouting, consistent with the formation of recurrent excitatory connections.[13,26,116–119] However, even with more focal electrical stimulation in hippocampal slice experiments compared to in vivo studies, axons other than sprouted mossy fibers could be activated, including projections from mossy cells and CA3 pyramidal cells. More specific activation of granule cells with glutamate uncaging or glutamate microdrop application evokes synaptic responses in other granule cells more frequently in slices with mossy fiber sprouting compared to controls.[120–123] Although unlikely, the possibility of polysynaptic activation through surviving mossy cells and CA3 pyramidal cells cannot be excluded completely, even with these methods. Scharfman et al.[96] provided the strongest evidence to date that mossy fiber sprouting creates a functional positive feedback circuit among granule cells. In hippocampal slices from epileptic pilocarpine-treated rats with sprouting, but not in controls, granule cells generate monosynaptic excitatory potentials in other granule cells. The probability of monosynaptic coupling between granule cells after sprouting is 0.66%,[96] which is similar to estimates based on anatomical data (see above) and a level approaching that normally found among CA3 pyramidal cells.[124] The average amplitude of granule cell-to-granule cell synaptic responses is ~2 mV, and their failure rate is 60%–70%,[96,122,125] which is not unusual for excitatory synapses in cortical areas. Granule cell-to-granule cell synapses utilize alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate/kainic acid (AMPA/KA) and to a smaller extent *N*-methyl-D-aspartate (NMDA) receptors.[13,122] Kainate receptors account for an unusually large amount of charge transfer at mossy fiber synapses with granule cells.[126] Granule cell-to-granule cell synapses can be presynaptically blocked by Type II metabotropic glutamate receptors and presynaptically facilitated by kainate receptors, and they display frequency-dependent short-term plasticity intermediate between that of normal mossy fiber synapses with interneurons and CA3 pyramidal cells.[125]

Thus, both anatomical and functional evidence confirms that after mossy fiber sprouting, granule cells receive abnormally high levels of synaptic input from other granule cells, which is minimal in control animals. The frequency of spontaneous excitatory postsynaptic currents (EPSCs) in granule cells increases with mossy fiber sprouting,[121,127] which could be attributable to more excitatory synapses. However, another possibility is increased levels of activity in slices from epileptic animals. Consistent with the latter possibility, the frequency of miniature EPSCs—which depends on the number of synapses and the probability of release but not action potentials—is similar in granule cells before and after mossy fiber sprouting,[126] not increased, as would be expected if granule cells were to receive more synapses after sprouting. A stereological electron microscopy study estimated the number of excitatory synapses with proximal dendrites per granule cell in control rats, in rats 5 days after status epilepticus, and in chronically epileptic animals.[94] Shortly after status epilepticus, which kills many hilar mossy cells, the number of synapses is reduced to <40% of control levels, but weeks later recovers to ~85% of control levels. Sprouted mossy fibers are likely to account for much, if not all, of the recovery. Together, these findings suggest that mossy fiber sprouting nearly replaces but does not exceed the original number of inner molecular layer glutamatergic synapses lost by granule cells during precipitating injuries.

The cellular electrophysiological evidence reviewed above demonstrates effects of mossy fiber sprouting at the synaptic level. However, the most important question about mossy fiber sprouting from a clinical standpoint is whether it is epileptogenic, compensatory, or neither. The extensive literature on this topic will be reviewed, beginning with relevant hypotheses. Shortly after it was discovered in kainate-treated rats, Tauck and Nadler[117] proposed that mossy fiber sprouting creates an aberrant positive feedback network among granule cells that synchronizes their activity and facilitates seizure activity. After many years of accumulating data, Nadler restated the hypothesis and added that "the recurrent mossy fiber pathway promotes seizure propagation from the entorhinal cortex to the hippocampus mainly when granule cells are driven at a frequency appropriate to promote synaptic facilitation" (≥1 Hz).[125] Buhl et al.[112] suggested that sprouted mossy fibers contribute to seizures during periods of high activity but through a different mechanism. They proposed that changes in subunit expression of $GABA_A$ receptors on granule cells in epileptic animals make them vulnerable to negative modulation by zinc. Further, they proposed that during periods of intense activity, granule cells synaptically release zinc from sprouted mossy fibers, which diffuses to GABAergic synapses and reduces inhibition when it is critically needed. Thus, two hypotheses (recurrent excitation and zinc-induced collapse of inhibition) contend that mossy fiber sprouting is epileptogenic. In contrast, Sloviter[128] proposed that sprouted mossy fibers preferentially synapse with basket cells and restore powerful recurrent inhibition lost after injuries kill hilar mossy cells. Recently, Sloviter et al.[110] restated the view that "mossy fiber sprouting may play a clinically important role in retarding seizure spread (keeping subclinical seizures subclinical)." Simmons et al.[127] proposed that the effects of mossy fiber sprouting are mixed. Some of their data support the recurrent excitation hypothesis, but they also proposed that sprouted mossy fibers release opioid peptides that have anticonvulsant effects. Other inhibitory transmitters that could be released by sprouted mossy fibers include neuropeptide Y (NPY)[129] and GABA.[130] Finally, Gloor[131] reviewed the literature on neuron loss in temporal lobe epilepsy, considered evidence of synaptic reorganization, and suggested that mossy fiber sprouting might be an epiphenomenon with neither pro- nor antiepileptic effects. Investigators have worked within the context of these diverging hypotheses. For purposes of review, reports on functional consequences of mossy fiber sprouting are summarized below in three categories: kindling studies, experiments that evaluated evoked seizure-like events, and investigations that measured frequencies of spontaneous seizures in patients with temporal lobe epilepsy and laboratory animal models.

In early kindling studies, hyperexcitability and mossy fiber sprouting were shown to develop in parallel, suggesting that sprouting might be epileptogenic.[34,92] Later studies revealed that hyperexcitability and mossy fiber sprouting can be dissociated.[132,133] But in a broader sense, the implications of kindling studies for the role of mossy fiber sprouting in temporal lobe epileptogenesis might be limited. Animals do not display spontaneous seizures unless kindled very extensively—for example, ~100 times in rats.[134] More typical kindling paradigms that involve only 10–20 stimulations generate levels of mossy fiber sprouting far below those found in many patients with mesial temporal lobe epilepsy and in other laboratory animal models.[41] Instead, kindling might more closely model the mild mossy fiber sprouting found with experimental conditions that kill few, if any, neurons and the mild mossy fiber sprouting found in some patients in whom hippocampal neurons are largely spared. This mild form of mossy fiber sprouting might be an effect, not a cause, of seizure activity.

Another set of studies tested whether evoked seizure-like responses correlate with the extent of mossy fiber sprouting. Simulations run on a computer model of dentate circuitry suggested that mossy fiber sprouting has little effect on granule cell activity and attributed the lack of effect to the granule cells' stabilizing intrinsic physiological properties.[135] However, later, more realistic computer models found that mossy fiber sprouting promotes the spread of seizure-like activity.[136] A strength of the in silico approach is the ability to specifically test individual parameters while leaving other conditions unchanged; these studies showed that mossy fiber sprouting alone is sufficient to cause hyperexcitability in the modeled dentate gyrus.[137] Furthermore, incorporating a small number of highly interconnected granule cells greatly increases network activity.[138]

Whether granule cell network hubs actually exist in epileptic tissue and generate seizures is an intriguing prediction to be tested in future experiments. In addition to computer models, actual epileptic tissue has been evaluated. In organotypic slice cultures, kainate treatment causes mossy fiber sprouting but does not affect seizure activity.[139] In contrast, in experiments with acute slices, evoked seizure-like responses by granule cells are more likely after mossy fiber sprouting develops in patients with mesial temporal lobe epilepsy[140] and in rodent models.[120,121,141,142] In summary, much, but not all, computer modeling and experimental slice data are consistent with the hypothesis that mossy fiber sprouting is epileptogenic. Compared to in vivo experiments, these studies reduced confounding influences from outside structures and more specifically evaluated the dentate gyrus region where sprouting occurs. However, caveats include the unclear relevance of computer models and hippocampal slice preparations to in vivo situations, the common requirement for pro-convulsant conditions (for example, $GABA_A$ receptor antagonists and elevated potassium ion concentrations) to unmask seizure-like responses, and dependency on provoking stimuli, which is unlike typically unprovoked seizures in patients.

Spontaneous seizures can be measured in vivo and compared with the extent of mossy fiber sprouting in laboratory animal models and when tissue is surgically resected to treat patients. Some studies found correlations between the extent of mossy fiber sprouting and seizure frequency,[41,83,143–146] but many did not.[26,28,50–52,54,78,128,147–158] Thus, although a loose association between the development of epilepsy and moderate to intense levels of mossy fiber sprouting is commonly reported (in other words, epileptic animals are more likely to display mossy fiber sprouting than nonepileptic individuals), consistently replicable, statistically significant correlations between seizure frequency and mossy fiber sprouting are lacking. Most in vivo evidence indicated above, therefore, supports the hypothesis that mossy fiber sprouting might be an epiphenomenon without major pro- or antiepileptic effects. However, the seizure monitoring methods used in many previous experiments suffered from limited sampling and might have been statistically underpowered, which increases variability in seizure frequency data, making it more difficult to detect subtle correlations. Another potential source of variability are myriad other parameters that might change independently of mossy fiber sprouting and have confounding effects on seizure frequency. Ideally, to more rigorously test its role in epileptogenesis, one would like to specifically block only the development of mossy fiber sprouting after an epileptogenic injury, carefully monitor the frequency and severity of spontaneous seizures, and compare the results to those in a similarly treated group in which mossy fiber sprouting developed.

Most efforts to block mossy fiber sprouting have been unsuccessful, despite the testing of reasonable candidate mechanisms. One prior attempt neutralized nerve growth factor with antibodies, which suppressed sprouting by cholinergic axons but not mossy fibers.[159] Treatment with the anticonvulsant vigabatrin did not block mossy fiber sprouting when administered to rats after kainate-induced status epilepticus.[160] Blocking neural activity by continuously infusing tetrodotoxin into the dentate gyrus for 1 month after status epilepticus did not suppress mossy fiber sprouting and might have made it worse.[161] It was reported that blocking protein synthesis with cycloheximide at around the time of epileptogenic injury reduced mossy fiber sprouting.[53,162,163] However, cycloheximide pretreatment reduces excitotoxic damage during status epilepticus;[87,89,164] therefore, mossy fiber sprouting may have been reduced indirectly by reducing hilar neuron loss.[165] Furthermore, when administered systemically, as in the original experiments,[166] or infused directly into the dentate gyrus,[167] cycloheximide's effect on mossy fiber sprouting could not be reproduced by other investigators. Therefore, it is doubtful that transiently blocking protein synthesis directly prevents mossy fiber sprouting.

Mossy fiber sprouting presumably begins with formation of growth cones, and previous attempts targeted growth cone function by blocking L-type calcium channels and inhibiting the calcium-activated phosphatase, calcineurin. Systemic administration of the L-type calcium channel blocker nicardipine was reported to suppress mossy fiber sprouting after pilocarpine-induced status epilepticus.[168] Also, the calcineurin inhibitor FK506 was reported to inhibit kindling[169] and block mossy fiber sprouting.[170] However, after 1 month of continuous, direct infusion into the dentate gyrus of nicardipine, FK506, or cyclosporin A

(another calcineurin inhibitor), the extent of mossy fiber sprouting was similar in infused versus noninfused hippocampi of rats that had experienced status epilepticus.[171]

The ketogenic diet was reported to reduce mossy fiber sprouting after kainate-induced status epilepticus,[172] but sample sizes in that study were small and results should be verified. Chronic treatment with oral lithium at therapeutically relevant concentrations was reported to suppress mossy fiber sprouting after pilocarpine-induced status epilepticus.[173] However, in that study, status epilepticus was curtailed early, and the level of excitotoxicity appeared insufficient to produce an adequate baseline level of mossy fiber sprouting for comparison. The NR2B-selective NMDA antagonist (Ro 25,6981) suppressed mossy fiber sprouting in organotypic cultures,[174] but it is unclear whether it would be effective in vivo. Grafting embryonic CA3 pyramidal cells into the hippocampus reduces mossy fiber sprouting after kainate-induced status epilepticus,[79] but grafted neurons sprout axons into the inner molecular layer of the dentate gyrus, suggesting that they might suppress development of one recurrent excitatory circuit (among granule cells) by establishing another aberrant positive feedback circuit in its place (a disynaptic circuit between CA3 pyramidal cells and granule cells).

Recently, a new treatment was discovered that suppresses mossy fiber sprouting. Rapamycin administered systemically[175] or directly infused into the dentate gyrus[176] reduces mossy fiber sprouting after chemoconvulsant-induced status epilepticus in rats. Rapamycin inhibits the mTOR signaling pathway that transduces extracellular signals, including BDNF, to control protein synthesis and cell growth.[177,178] Systemic treatment with rapamycin was reported to suppress both mossy fiber sprouting and seizure frequency in rats.[175] In pilocarpine-treated mice, however, systemic rapamycin suppressed mossy fiber sprouting but did not affect seizure frequency.[179] Possible explanations for the apparently contradictory results include a confounding anticonvulsant effect of rapamycin specifically in rats.[180] In conclusion, the role of mossy fiber sprouting in epileptogenesis remains unclear. As additional methods are discovered to block its development selectively, more opportunities will arise to test its functional effects. In addition to granule cells, epilepsy-related axon reorganization occurs among other excitatory neurons, including CA3 pyramidal cells,[181,182] CA1 pyramidal cells,[183] subicular neurons,[152] and neocortical neurons.[184] Therefore, future lessons learned from continued study of mossy fiber sprouting might have more general relevance for a broad range of patients with epilepsy and other brain disorders that involve synaptic reorganization.

Chapter 33

Kainate and Temporal Lobe Epilepsies

Three Decades of Progress

Yehezkel Ben-Ari

INTRODUCTION

At the end of July 2010, there were 10,168 references under "kainic acid" and 5149 references under "kainic acid AND neurons" in *PubMed*. The first reference to kainate[1] reported the structures of kainate and allokainate. In the next 20 years, attention to kainate was focused on its strong excitatory actions on crayfish muscles and other systems. The first references by the Curtis-Watkins group described the excitatory actions of this new agent that had just been purified from a seaweed known to exert an antiascaris action.[2,3] Kainate—a glutamate analogue—is a stronger excitant than other amino acids, and pharmacological

observations pointed to its unique structure/actions features that suggested the presence of a specific receptor, an observation that was rapidly confirmed. The identification of kainate-specific receptors stimulated a flurry of studies on the excitatory actions of kainate that were soon to be viewed as excitotoxic when Olney, Nadler, and colleagues discovered that kainate in fact selectively destroys various neuronal populations.[4–7] Their finding was the starting point for two parallel lines of research focused on the following questions: Why does kainate kill neurons selectively? How can this action be used as a tool to reproduce animal models of neurological disorders?

During the late 1970s and early 1980s, extensive investigation showed that kainate excites a large number of neuronal populations where receptors are present; this excitation is followed by selective neuronal loss at the site of injection, while the axons en passant are spared. Given this finding, McGeers, Schwartz and Coyle, and other investigators produced several animal models of neurological disorders, relying on the axon-sparing excitotoxic actions of kainate to model Parkinson's disease and Huntington's disease.[8–12] The technique was also used to selectively destroy cell bodies (i.e., spare axons), thus providing a method to trace neuronal connections in the brain and to determine the selective sequelae produced by neuron-specific lesions of a brain structure without altering en passant fibers. Thus, the first phase of kainate research exploited the lesioning capabilities of kainate to delete specific neuronal populations and determine the consequences of this loss on brain operation.

In 1978, during an investigation aimed at using the axon-sparing effects of kainate in the amygdala, Ben-Ari and Lagowska discovered the epileptogenic actions of amygdaloid injections of kainate.[13] Injections of low concentrations of kainic acid in the amygdala generated a status epilepticus that persisted for several hours, often until the animal died. Injections of benzodiazepine were used to interrupt the seizures, providing an animal model of limbic status epilepticus in which the mechanisms underlying the generation of a status and its effects on brain operation could be investigated.[14] This publication, in turn, led to a flurry of studies; in three decades, over 2495 references to "kainate AND epilepsies" appeared in *PubMed* (July 2010). Extensive investigations used injections of kainate parenterally and intracerebrally to test the properties of epileptogenic neurons and networks. These studies have provided a wide range of advances in our understanding of the mechanisms of seizure generation, propagation, and their sequelae, with the emergence of concepts extending from apoptotic cell death to reactive plasticity and sprouting of mossy fibres in temporal lobe epilepsy (TLE) to the selective loss of GABAergic neurons[15] (see Fig. 33–1). These concepts were subsequently confirmed with other animal models of TLE, notably pilocarpine[16] and electrical brain stimulation.[17] Parallel studies led to the discovery of kainate high-affinity receptors in the brain having a specific distribution—notably in regions that are known to play a central role in seizures, particularly in the hippocampus.[18–20] With the development of molecular biology and genetic tools, kainate receptors were cloned, and shown to belong to the glutamate receptor family, with several subunits conferring unique properties; these characterizations provided clear examples of the intricate links between biologically active natural molecules and recognition signals in the brain for these molecules.[21] This insight was further expanded by the development of relatively specific antagonists that block alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) but not kainate receptor-mediated currents (see below). Investigators were then able to identify centrally active kainatergic synapses that, when activated by glutamate, generate synaptic currents. Compelling evidence that kainate plays a role in central transmission was obtained in studies showing spontaneous kainatergic excitatory postsynaptic currents (EPSCs) and miniature kainatergic PSCs with electrical properties that differ from those of the predominant fast-acting AMPA receptor-mediated PSCs generated by glutamate. Glutamate activates a series of receptors, with kainate receptors playing a specific role different from those of *N*-methyl-D-aspartate (NMDA) and AMPA receptors. This finding, in turn, raised formidable questions: Why do certain neuronal populations use these long-lasting PSCs mediated through kainatergic receptors? Why are these receptors enriched in regions known to be highly vulnerable to seizures and to be destroyed in patients suffering from TLE? The evolution of an en passant discovery of the destructive properties

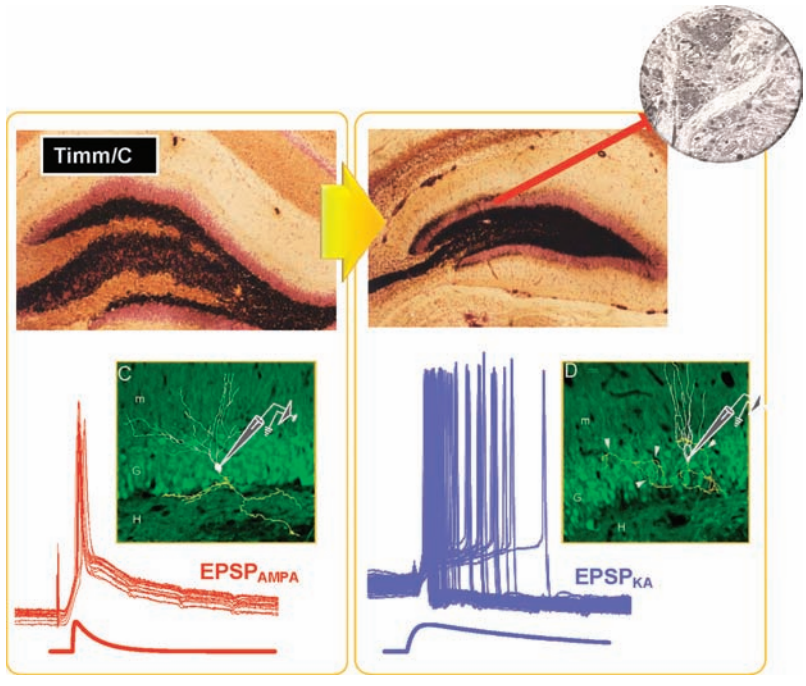

Figure 33–1. Sprouting of mossy fibers and formation of novel synapses that alter the operation of evoked synaptic currents. Sprouting of mossy fibers depicted by the typical Timm stain in the supragranular layer and the thorny excrescences of the mossy fibers in an electron micrograph. Bottom left: In a naive granule cell reconstructed to show its restricted arbor outside the granule layer, electrical stimuli evoke an EPSP mediated exclusively by AMPA receptors ($EPSP_{AMPA}$) associated with a time-locked response. Bottom right: In contrast, in a granule cell recorded from an epileptic hippocampus—induced several weeks earlier by pilocarpine—the same protocol evokes an EPSP mediated by a kainate receptor ($EPSP_{KA}$) associated with a variable-latency jitter response. Arrowhead depict the differences between naive (left) and epileptic (right) hippocampi. The microelectrodes illustrate granule cells recorded, filed with dyes and reconstructed to show the extensive sprouting of axons within the granule layer in epileptic but not in naive hippocampi. From refs. 178 and 186.

of a biologically active molecule to an endogenous selective set of synapses employing these receptors to carry out physiological functions stands at the core of present kainate research. This discovery has provided important insights into brain operation and will undoubtedly also lead to novel therapeutic strategies for TLE.

SEIZURES AND BRAIN DAMAGE PRODUCED BY KAINATE IN THE ADULT BRAIN

The Kainate Model of TLE

From the late 1970s, studies revealed that intra-amygdaloid, intrahippocampal, intracerebroventricular, or systemic injections of kainate generates a syndrome of seizures and brain damage that mimics human TLE (reviewed in refs. 15 and 22–28). Injections of kainic acid, either peripherally or centrally in various brain structures, generate seizures and brain damage syndromes in which limbic structures play key roles. Clinically, after a variable delay, animals display wet dog shakes, facial motor signs and chewing, paw tremor associated with rearing and falling, and other complex motor manifestations. Electroencephalographic (EEG) and depth recordings reveal recurrent tonic-clonic severe ictal discharges and a long-lasting status epilepticus that are reminiscent of those observed in TLE. Electroencephalographic recordings established that the seizures are initiated in regions that are highly excitable and central to TLE, notably the hippocampal CA3 region and the amygdala. The description of the propagation of seizures discharges has been repeatedly shown to include triggering zones—notably within the hippocampal CA3 region and various amygdaloid and adjacent pyriform

and entorhinal cortex regions—that appear to have among the lowest thresholds for seizure generation in the rat brain. The anatomical pathways that enable seizures to express motor manifestations are consistent with classical axonal pathways that interconnect limbic structures and their projection targets. Thus, facial signs are activated when the seizure activity in amygdala propagates to its brainstem targets, as defined by extensive human and animal investigations. Studies using 2-deoxyglucose metabolic methods, as well as a wide range of other imaging and recording techniques, have confirmed the general pattern of structures involved and the crucial role of limbic structures. In addition, following kainate-induced status epilepticus, there is a silent period followed by ongoing chronic seizure activity; although the initial status is not often observed in humans, this pattern of seizure development in animal models has been useful for dissecting out the mechanisms underlying cell death and chronic epilepsies. The kainate and pilocarpine models of TLE have been extensively used for such investigations. Other closely related models include kindling, in which daily electrical stimuli (usually of the amygdala) transforms a naive structure into one that seizes upon stimulation.[29,30] The pros and cons of these models have been reviewed and discussed extensively. The goal here is to stress that they provide, collectively, useful contexts in which to study mechanisms of epileptogenesis in limbic structures.[31–33] The clinical and pathological effects of kainate are reminiscent of those observed in partial TLEs.[15,26,30,32]

Seizure-Specific and Nonspecific Cell Loss Produced by Kainate

Administration of kainate produces a seizure and brain damage syndrome. Following recurrent seizures, there is a pattern of cell loss primarily—but not solely—in limbic structures including the hippocampus, amygdala, and pyriform cortex,[15,34] Within the hippocampus, there is a gradient of vulnerability, with CA3 pyramidal neurons being particularly vulnerable, as cell loss can be produced with low doses (that may be truly homeopathic concentrations) of kainate applied locally or at distant sites,[15,23] These observations raised considerable interest in determining the mechanisms underlying cell loss. One question was whether the damage is due to the direct actions of kainate (i.e., directly exciting the cell, increasing calcium influx, and initiating a cascade of events that have been extensively investigated in relation to neurotoxicity[4,7]). Two types of cell loss have been identified on the basis of morphological and chemical studies: apoptotic—or programmed—cell loss and necrosis (i.e., swelling followed by cell death[35,36]). It is most likely that the mechanisms underlying cell death in the kainate model (as in other models, such as ischemic cell loss[35]) depend on the severity of seizures and the concentrations of kainate injected; small doses appear to produce preferentially apoptosis, and higher doses produce necrotic cell damage. In keeping with this scheme, the regional susceptibility of hippocampal neurons in seizure models parallels the pattern of vulnerability to ischemic insults.

These observations raise yet another important question: Does kainate induce cell loss because of its direct actions or because of the seizures it generates? The following observations suggest that seizures generated by kainate can induce selective secondary damage due to seizures per se: (1) following intra-amygdaloid injections of kainate, injections of valium block seizures and prevent distal hippocampal damage but not local cell loss in the amygdala[14,37]; (2) quantitative measures of the severity of intrahippocampal electrographic seizures revealed a strong relation between the severity of paroxysmal events (including the duration of ictal events and postictal depression) and subsequent damage[38]; (3) damage in the hippocampus is prevented by lesions of mossy fiber synapses on CA3 neurons, confirming the essential role of propagated activity in these synapses in the high degree of vulnerability of target neurons to seizures[39–42]; (4) other types of limbic seizures, produced by pilocarpine or by long-lasting recurrent electrical stimulation of the fascia dentate, also trigger cell death with a similar pattern of vulnerability[16,43]; (5) direct local determination of blood flow, oxygen consumption, and partial pressure of carbon dioxide (PCO_2) showed that during recurrent seizures, the increase in blood flow overcompensates for the enhanced oxygen consumption, suggesting that the damage is not due to a metabolic failure.[44] Therefore, recurrent seizures can directly produce cell loss in vulnerable neurons.

Loss of GABAergic Interneurons and Failure of Inhibition

Because gamma-aminobutyric acid (GABA)-mediated inhibition controls the excitability of principal neurons and networks, failure of inhibition has long been favored to explain seizure generation and propagation. In keeping with this hypothesis, GABA receptor antagonists generate seizures and agents thought to specifically reinforce the GABAergic drive often reduce seizures and are used extensively as antiepileptic agents. However, there is a large variety of GABAergic populations, each of which innervates specific targets controlling highly specific cellular and network features.[45–47] By means of their cell- or domain-specific targets, activation of GABAergic synapses will differently alter neuronal and network excitability.[45–47] For example, some GABAergic neurons innervate the axon hillock of projection cells where spikes are generated; the release of GABA at these synapses alters the generation of action potentials by a large population of pyramidal neurons.[48–50] Other GABAergic neurons innervate the dendrites of pyramidal neurons; oriens lacunosum moleculare (O-LM) interneurons release GABA that would be expected to reduces the excitatory drive that impinges on pyramidal neurons[48] (see Fig. 33–2). The former synapses will entrain large ensembles of principal neurons in coordinated patterns, whereas the latter will more locally alter the responses of these neurones to inputs. GABAergic neurons also exert their inhibitory actions by a variety of different mechanisms, including a shunting action and an intracellular accumulation of chloride that tends to shift the GABA reversal potential (E_{GABA}), which results in an excitatory action of GABA (see below).

Experiments using kainate and/or pilocarpine illustrate the multiple facets of the suggested failure of inhibition and its implications in seizures and epilepsies. A decrease in the number of glutamic acid decarboxylase (GAD) mRNA-containing neurons has been observed following pilocarpine seizures primarily in interneurons labeled for somatostatin only (O-LM and bistratified cells).[17,51] Electron microscopic observations suggested that the loss of somatostatin-containing neurons

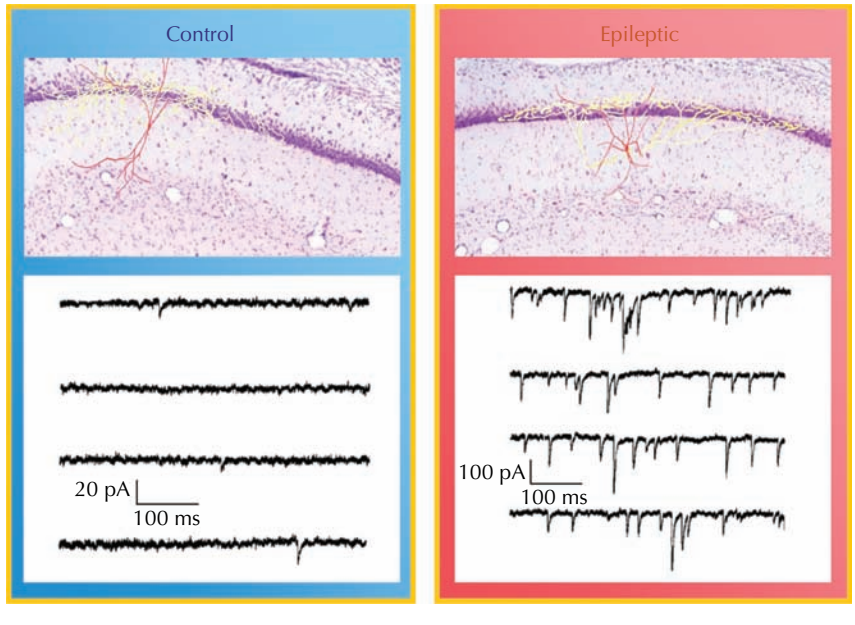

Figure 33–2. Somatic projecting GABAergic interneurons are more active in the hippocampus of epileptic animals. Recurrent seizures were generated by pilocarpine injections and weeks later, once the reactive reaction had taken place, slices were recorded from the sclerotic hippocampus. Many somatostatin-positive GABAergic neurons were lost. Surviving interneurons were patch-clamp recorded and morphologically reconstructed for identification. Interneurons in TLE had a higher frequency of ongoing synaptic currents suggesting enhanced activity in synaptic inputs. This, in turn, compensated for the loss and preserved some somatic inhibition. From ref. 186.

corresponds preferentially to the degeneration of interneurons with an axon projecting to stratum lacunosum-moleculare (O-LM cells).[51] In contrast, stratum oriens interneurons labeled for parvalbumin were preserved, suggesting that somatic inhibition is maintained, whereas dendritic inhibition is not. In keeping with this, direct recording from the somata and dendrites of principal neurons using the same model[52] revealed a marked reduction of GABAergic inhibition in the dendrites, whereas somatic inhibition was preserved.[52,53] Also, the activity of basket cells that were not destroyed by the seizures[52–54] was enhanced, thereby compensating for the loss of other interneurons. These observations collectively suggest that the glutamatergic inputs to the dendrites of principal cells will be less inhibited in epileptic neurons, whereas somatic inhibition will not. Other mechanisms affecting the strength of inhibition have been suggested, including notably (1) a reduction of miniature GABAergic postsynaptic currents (mIPSCs), suggesting decreased release of GABA from presynaptic elements,[53] and (2) postsynaptic reduction of the efficacy of zinc,[55–57] NMDA receptors, and Ca^{2+} signals,[58] and the density of GABAergic synapse subunit composition.[59,60]

The suggestion that inhibition is not reduced per se, but rather that there is a loss of the excitatory drive onto basket cells following a seizure (an induced denervation of interneurons—the so-called *dormant basket cell*[61]), has been confirmed by pair recordings from interneurons and their target pyramidal neurons in TLE hippocampi. These studies showed that GABAergic inhibition is operative.[54] It bears stressing that alterations of GABAergic inhibition are area and cell specific (but also see refs. 62 and 63). Therefore, some (but not all) facets of GABAergic actions are reduced in TLE, most likely explaining why seizures are not continuously generated by the sclerotic hippocampus.

Physiological Actions of Kainate on Hippocampal Neurons

One important question is whether kainate exerts it actions through specific kainate receptors. Direct recordings from limbic neurons have revealed that the hippocampus, and particularly CA3 neurons, are strongly excited by kainate. Submicromolar applications of kainate excite CA3 pyramidal neurons,[64–66] generating large currents and triggering action potentials. Kainate-induced currents are also observed in the presence of tetrodotoxin (TTX; refs. 64–68). At higher concentrations, kainate also activates AMPA receptors.[25] In the presence of specific AMPA and NMDA receptor blockers, kainate depolarizes rat and mouse hippocampal interneurons.[69–71]

How is this excitatory drive generated? A large repertoire of actions underlies the excitatory actions of kainate. Kainate strongly reduces evoked GABAergic PSCs,[71–74] an effect that would augment excitability. However, small submicromolar concentrations of kainate augment spontaneous inhibitory postsynaptic currents (IPSCs) in interneurons[75] as well as GABAergic mIPSPs in CAI interneurons (also see ref. 74), suggesting presynaptic regulation by kainate receptors of GABA release that increases the efficacy of GABAergic transmission between interneurons. In keeping with this, in paired recordings, low concentrations of kainate (300 nM) reduced the failures and increase the occurrence of postsynaptic responses[76] but higher concentrations (5 μM) depressed IPSCs, confirming the dose dependence of the dual actions of kainate.

Kainate also acts on voltage-gated currents. It reduces the slow hyperpolarizing K^+ current,[77,78] effects that are mediated by intracellular second messengers.[79–81] These effects can be induced with nanomolar concentrations of kainate, suggesting that they are mediated by the high-affinity receptors observed on these neurons (see below). This strong excitatory action mediated by high-affinity kainate receptors plays an important role in the epileptogenic actions of kainate (also see ref. 82).

The Yin and the Yang of Kainate Receptors: Molecular Considerations

The advent of novel genetic tools has enabled investigators to distinguish between different subtypes of glutamate receptors, including kainate receptors. Kainate receptors are

composed of various combinations of five subunits: GluR5, GluR6, GluR7, KA1, and KA2.[21,83–85] In studies of hyperexcitability and epilepsy, the GluR6 and GluR5 subtypes of kainate receptors have been of particular interest. The former has been thought to be related to limbic epilepsies because of its distribution, especially in the vulnerable CA3 pyramidal neurons.[86–88] In addition, GluR6 knockouts have greatly reduced vulnerability to seizures and to kainite-induced injury.[39,68,89] In contrast, GluR5 subunits are mostly expressed by certain types of interneurons, notably somatostatin interneurons that are enriched within stratum oriens; in these cells, the activation of kainate receptors leads to a dramatic increase in cell activity and the consequent inhibitory drive onto target pyramidal cells[69,70,90] (see Fig. 33–3). Given these data, it appears that kainate may exert a dual action: it may have pro-convulsive effects in principal neurons due to the activation of GluR6 receptor subtypes and anticonvulsive effects due to the activation of GluR5 subunits in interneurons. The strong excitation by GluR5 receptor agonists could explain the vulnerability of interneurons to seizures, as this action will dramatically excite these neurons. Additional subunit-specific actions have been reported and reviewed extensively elsewhere.[25,91,92]

SEIZURES BUT NO BRAIN DAMAGE PRODUCED BY KAINATE IN PUPS

Maturation of the Kainate System

The syndrome of seizures and brain damage produced by kainate is age dependent. Injections of kainate into immature pups generate seizures, but these seizures are not followed by cell loss.[93–97] Conspicuous damage is first seen at the end of the second postnatal week; before then, even high doses of systemic kainate (that generate seizures) fail to produce cell damage.[93–97] The clinical reflection of kainite-induced seizures is quite restricted initially—little or no facial movement or other manifestations that implicate the activation of the amygdaloid complex and its projections to the brainstem—suggesting that the critical network is not yet mature. This assumption was confirmed by direct recordings and by 2-deoxyglucose studies showing that kainate-induced seizures are initially local, with no sign of propagation to

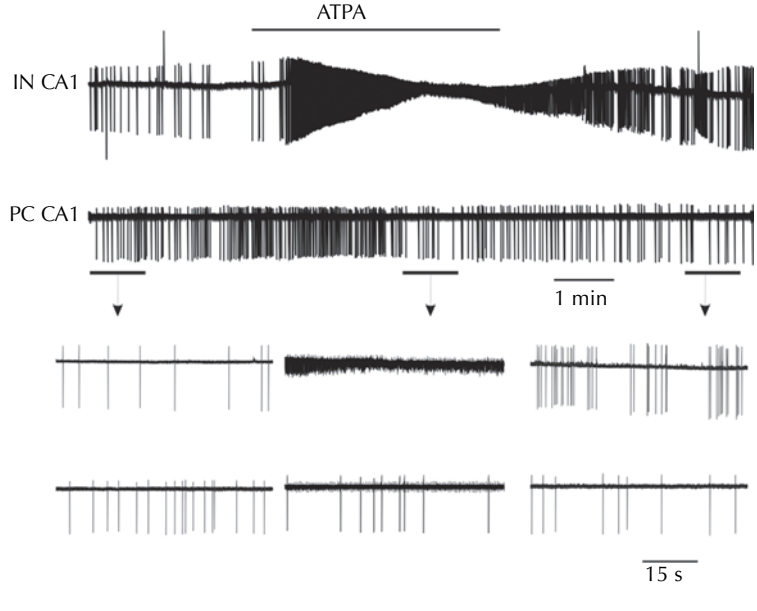

Figure 33–3. Dual actions of kainate. The GluR5 agonist (ATPA) excited interneurons, thereby inhibiting the pyramidal neurons. A pyramidal neuron and an interneuron were recorded simultaneously, and the GluR5-selective agonist was applied. Note the dramatically increased activity of the CA1 interneuron (top) and the reduced activity of the pyramidal neuron (bottom). From ref. 90.

the entire limbic system.[93–96] This time frame correlates with the progressive and protracted maturation of the fascia dentate-mossy fiber system that extends to the third week of age at least in rodents.[98] Consistent with this finding, lesions of the mossy fibers (produced by irradiation or other means) also protect CA3 pyramidal neurons from kainate-induced damage (see below). In addition to reduced hippocampal cell loss following status epilepticus, there is less mossy fiber sprouting in young animals than in adult animals, suggesting that the neuronal damage and subsequent reactive plasticity are correlated.[99,100] Interestingly, cell loss is also less readily produced in neonatal neurons in other experimental models of TLE, suggesting that the full maturation of networks and connections is indeed required for the cell loss to be produced.[101]

We do not fully comprehend why immature neurons are more resistant than those of adults to insults and epilepsies. This is likely a general phenomenon, as suggested by the observation that immature neurons are also much more resistant to anoxic insults[102,103] and have reduced pro-inflammatory cytokines associated with seizures.[104] The reduced sensitivity to glutamate[105–108] and reduced oxidative stress compared to adult seizures[109] may be pertinent in this context. Also, GABA synthesis is better preserved during status epilepticus in neonatal neurons than in those of adults.[110] Therefore, although this reduced vulnerability is not restricted to the maturation of the kainate system, it illustrates its general pertinence to epilepsies of the developing brain.

Recurrent Seizures in the Immature Brain Produce Long-Term Effects

Although seizures in pups produce a less severe syndrome and no cell loss until the end of the second week, they are not harmless. Extensive human and experimental data suggest that seizures early in life can lead to lifelong severe, intractable neurological disorders, a result of particular concern since infants and children are at high risk for seizures compared with adults.[111,112] Although most seizures in children are benign and result in no long-term consequences, experimental animal data strongly suggest that frequent or prolonged seizures in the developing brain result in long-lasting sequelae.[113–115] Behavioral effects of acute seizures or status epilepticus are also associated with the age of the animal, adult animals having substantial deficits in learning, memory, and behavior.[113–115]

Recurrent seizures in infants and children can be harmful, causing long-lasting sequel.[116,117] Similarly, recurrent seizures in pups can cause long-term behavioral and physiological alterations. Neonatal seizures induced by the inhalant fluothyl produce impairment of visual memory without any discernible cell loss.[118] This study also shows that after recurrent seizures, the number of newly formed granule cells is reduced in neonates but increased in adults. Since recurrent seizures do not readily cause cell loss and extensive damage, the long-term deficits must be due to other mechanisms.

What do these observations suggest, and how can they be reconciled and unified in a coherent theory? Can these seemingly diverse observations be related to a similar feature of developing neurons? If immature neurons are more resistant to insults in terms of cell loss but are still affected by early insults, as reflected by the long-term consequences these produce, then it is reasonable to suggest that the insults are programmatic rather than lesional and are due to alterations of developmental programs. I have recently introduced the *neuroarcheology* concept of presymptomatic electrical or morphological signatures of the developing brain that has experienced seizures or other insults.[119] The suggestion is that recurrent seizures—or other insults—produce early malformations that lead to an ensemble of misplaced and/or misconnected neurons but also alter the properties of adjacent neurons that have already reached their assigned region and developed as programmed their synaptic connections. The former remain with immature features in the adult brain, including high input resistance and a strong tendency to oscillate and generate intrinsic activities that can entrain other neurons to seizures. The latter, notably in the neocortex, are also affected and show a reexpression of immature features—notably excitatory actions of GABA.[120–127] This postinsult recapitulation of ontogenesis[119–128] has important implications, since the determination of the properties of neurons in the sclerotic hippocampus will help guide the development of suitable therapeutic agents. Although this issue deserves a great deal of description and debate,

it is important to keep in mind the major differences between immature and adult mechanisms that connect an insult and the subsequent expression of epilepsies.

ROLE OF KAINATERGIC SYNAPSES IN SEIZURE-INDUCED EPILEPTOGENESIS

One of the most salient and specific properties of neurons and synapses is their plasticity. In fact, almost all the procedures and mechanisms that take place during the operation of brain networks are altered by incoming information and depend on the magnitude of neuronal activity that impinges on its synapses. Activity-dependent alterations of synapse operation are classically observed with recurrent stimuli such as in long term potentiation (LTP), considered a cellular model of memory processes (at least with respect to cellular mechanisms and signaling pathways). Activity-dependent alterations of almost all of the steps in brain maturation have been reported, including neuronal proliferation and migration, synapse formation, network construction, and sequential development of voltage- and synapse-mediated currents.

This plasticity is not restricted to development and integration of activity in the adult brain. Following a wide range of insults—including traumatic brain injury, sensory deprivation or brain lesions, and cell loss—there is considerable synaptic reorganization, with formation of novel synapses and changes in the properties of the involved cortical regions. This plasticity has been demonstrated after visual impairments, limb deafferentation, and central insults; cortical regions are invaded by elements from adjacent structures, with neuronal sprouting and formation of novel aberrant synaptic connections in sites where they are not present normally. There is little doubt that recurrent severe seizures trigger a similar cascade of events, and the history and recurrence of seizures cannot be obliterated as if the environment is not affected. In keeping with this, seizures—notably TLE—are associated with cell loss and degeneration of a substantial part of the hippocampus and other limbic structures that are known to engage in various forms of reactive plasticity.[129,130] For over two decades, there has been direct evidence that at least in TLE in humans and in animal models, there is considerable sprouting of fibers and establishment of novel synapses that may, in turn, lead to enhanced excitability and thus contribute to the generation of further seizures. In this domain, studies using kainate have provided major breakthroughs in understanding the alterations produced by insults.

The Mossy Fibers: An Ideal Location to Look for Changes

The story starts with the mossy fibers, which are a helpful target in studies to determine the long-term changes produced by seizures. The mossy fibers constitute the main and sole output of the granule neurons of the fascia dentate—a major gate to the hippocampus through which an inflow of information that originates in the entorhinal cortex reaches Ammon's horn and modulates its operation[98,131,132] (see Fig. 33–1). Mossy fibers innervate a wide range of interneurons, but their most visible and most widely investigated targets are the giant CA3 pyramidal neurons. Mossy fibers establish their synapses with the proximal apical dendrites of pyramidal neurons—within the stratum lucidum, which, in most rodents, is located immediately above the pyramidal layer. In primates and humans, the region innervated is interspersed within the pyramidal layer, in part because the pyramidal neurons are not aligned as tightly as in rodents. Yet, in all species, the mossy fiber terminals and innervation zones are readily visible because mossy fiber terminals are very large and enriched in zinc; this property enables investigators to visualize the terminals with simple histological techniques.[133,134] Mossy fibers accumulate and release zinc in very large amounts, although the role of zinc is not fully understood.[135]

Mossy Fibers Have an Intimate Relation with Kainate Signaling

In the early period of receptor identification, autoradiographic investigations were used to determine the distribution of subtypes of receptors. Several observations have shown

that KAR-mediated synaptic transmission in hippocampus is strongly linked to the presence of mossy fiber terminals: (1) the stratum lucidum (the target zone of mossy fibers on CA3 pyramidal neurons) contains among the highest density of KARs in the brain[18]; (2) the stimulation of mossy fibers selectively generates $EPSC_{KA}$ in CA3 pyramidal cells[67,68,136,137]; (3) lesions of the mossy fibers both reduce the density of KARs[19,137] and suppress KAR-mediated synaptic transmission in CA3 pyramidal cells[137]; (4) the expression of $EPSC_{KA}$ in CA3 pyramidal cells is correlated with the postnatal development of mossy fiber synapses[138]; (5) the severity of kainate-induced seizures and brain damage is reduced in GluR6 Kos.[39,68] The $EPSC_{KA}$ evoked by mossy fiber stimulation in CA3 pyramidal neurons[67,69,136,139] has several interesting features. Stimulation of a single mossy fiber generates three types of EPSCs: (1) fast EPSCs that are mediated by AMPA receptors—the traditional ionotropic receptor-mediated currents; (2) slow EPSCs that are selectively mediated by kainate receptors; and (3) mixed EPSCs composed of both AMPA and kainate EPSCs.[137] Blocking ongoing activity with TTX revealed the presence of three comparable types of mEPSCs, indicating that kainate receptors are located at the core of synaptic terminals and act as a conventional transmitter-mediated signaling device (i.e., they are not located on extrasynaptic sites, as was initially thought),[137] $EPSC_{KA}$ are selectively restricted to some neuronal populations (i.e., they are not found on every neuron, in contrast to AMPA receptors that mediate the general fast glutamatergic ionotropic synaptic current). In particular, in the hippocampus, $EPSC_{KA}$ are enriched on CA3 pyramidal neurons and certain interneurons but not on CA1 pyramidal neurons or on granule cells. Neurons enriched with *kainatergic synapses* are also the ones that degenerate most readily in human and animal TLE—stratum oriens somatostatin-containing interneurons, CA3 pyramidal neurons, and so on—suggesting that the presence of a high density of kainatergic synapses triggers a cascade of events that is deleterious to neurons. In addition, $EPSC_{KA}$ have long-lasting slow kinetics with important implications.

A multitude of effects of kainate on synaptic transmission have been reported. Kainate inhibits mossy fiber synaptic inputs,[140] Low and high concentrations of kainite facilitate and inhibit synaptic transmission, respectively,[89,141,142] Presynaptic KARs (with GluR 7 subunits) are localized in the presynaptic active zone, close to release sites of mossy fibers, where they facilitate the release of glutamate.[143,144] Therefore, at both pre- and postsynaptic sites, kainate modulates the effects of mossy fiber synapses in a dose-dependent manner.

Mossy Fibers Sprout after Seizures: Anatomical Observations

That mossy fibers sprout after kainate injections (and consequent seizure generation) was reported over two decades ago.[19,145,146] These studies identified a novel band of mossy fiber terminals below the CA3 pyramidal neuron layer after recurrent seizures caused by the convulsive agent. This sprouting was also associated with the formation of a band of mossy fibers immediately above the granule layer, suggesting that an additional sprouting of fibers—and formation of synapses—had also occurred within the granule cells. Investigators speculated that in epileptic tissue, sprouting mossy fibers may innervate other granule cells (in contrast to the situation in the seizure-naive granule cells layer)[19,41,147–150] (see Fig. 33–1). Interestingly, this new band of mossy fiber terminals was characterized by both a high concentration of zinc (Timm stain) and high-affinity kainate receptors, suggesting that the innervations of neurons by mossy fibers entrain the postsynaptic expression of the features that normally characterize these synapses.[19,145,147,151,152] Direct demonstration that the newly formed mossy fiber terminals indeed have all the features and constituents of conventional mossy fibers was then performed using electron microscopy and kainate binding.[19,150,151] As stressed above, mossy fiber terminals have unique features (very large diameters with multiple invaginations and large numbers of vesicles). After recurrent seizures, typical mossy fiber terminals were observed in the aberrant regions above the granule layers and the infrapyramidal (CA3) zone, where they are not present in naive animals. Whether mossy fibers also sprout and increase their innervation of GABAergic interneurons has not been firmly established.

Epileptic hippocampus exhibits an aberrant mossy fiber terminal zone that is not present in naive animals. Similar observations

have been repeatedly made in a variety of animal models of TLE, including kindling and pilocarpine, providing a potential substrate for seizure-induced epileptogenesis (see below).[41,148,149,153–166] Sprouting has also been observed in human epileptic patients.[148,154,167–171] Parallel studies performed in postmortem hippocampi, first in non-TLE types of infantile seizures and then on many different types of epilepsies, suggest that this plasticity is not restricted to rodents.[148,149] If functional, this sprouting could lead to profound rearrangements in the operation of the hippocampal circuit, with increased excitation of CA3 pyramidal neurons and granule cells.

Recurrent Mossy Fiber Synapses in TLE Include Kainatergic Synapses that Are Not Observed in Naive Neurons

In spite of overwhelming anatomical evidence that mossy fibers sprout, it remained to be shown that they also are functional in their aberrant localization and that sprouting therefore contributes to enhancement of the excitability of their targets. Experimental evidence suggests that changes in voltage-gated conductances—in addition to mossy fiber sprouting—could promote the generation of epileptiform activity.[172–177] Since mossy fiber synapses are closely associated with kainate signaling, one can hypothesize that the formation of aberrant mossy fiber synapses on dentate granule cells (DGCs) would trigger the formation of functional KAR-operated synapses in chronic epileptic rats. Indeed, recordings from granule cells in an animal model of TLE—selected because they have no mossy fiber terminals in naive conditions—revealed major differences from control cells. In control granule cells, stimulation of the perforant pathway generated exclusively fast AMPA receptor-mediated EPSCs ($EPSC_{AMPA}$).[137] In contrast, in TLE DGCs, a similar stimulation paradigm generated long-lasting $EPSC_{KA}$ originating from recurrent mossy fiber synapses[178] (see Figs. 33–11 and 33–4). Therefore, epileptic DG neurons operate by means of aberrant glutamatergic synaptic currents that are not observed in naïve neurons.

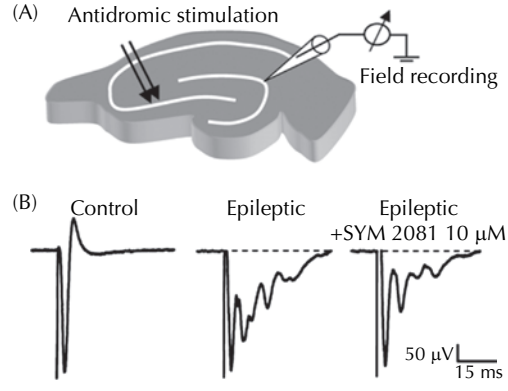

Figure 33–4. A: experimental protocol: field recordings in the granule layer and antidromic stimulation in CA3. **B**: illustration of responses evoked by the stimulation in naive and epileptic hippocampi. A kainate receptor antagonist blocked the epileptiform events generated by electrical stimulation of the perforant pathway. In a naive slice, this generated an all-or-none field EPSP. In an epileptic slice—prepared weeks after in vivo treatment with pilocarpine—the same stimulation generated an epileptiform event that was partly blocked by an antagonist of kainate receptors. From ref.178.

How do aberrant KAR-operated synapses, with their slow kinetics, impact the temporal precision of EPSP-spike coupling in DGCs of epileptic rats and generate seizures? There are indications that the loss of time-locked EPSC-evoked action potentials, and a large degree of jitter, facilitate the generation of paroxysmal synchronized activities.[179] Many studies have shown that the shape of an excitatory synaptic event, and its modulation by voltage-gated conductance, are important determinants of the temporal precision of hippocampal and neocortical cell operation.[180–185] In naive DCGs, the generation of an $EPSP_{AMPA}$ leads to a time-locked spike with a fixed latency and very little jitter. This precision is instrumental in the operation of the entorhinal cortex/perforant pathway/Ammon's horn and most likely underlies the behaviorally relevant patterns that this pathway entrains. In contrast, in TLE DGCs, there is a dramatic decrease in spike timing precision.[186] Jittery spikes are selectively evoked by $EPSP_{KA}$ (not by $EPSP_{AMPA}$, which only generate highly time-locked spikes in both control and TLE conditions).[178,186] Direct proof of the link between kainatergic synapses and reduced time-locked responses was presented in an experiment in which a simulated electrical pulse, with kainate-like kinetics, was

injected intracellularly into control DGCs—which are endowed only with fast kinetic $EPSP_{AMPA}$. The injection of a kainate-like EPSC converted the time-locked spikes to jittery responses. In other words, it is not the amplitude of the EPSC but its kinetics that is here determinant: $EPSP_{KA}$ are endowed with a long-lasting decay time constant that is ideal for the loss of these time-locked responses. Indeed, the activation by EPSPs of voltage-gated conductances near threshold is an important parameter in the modulation of the EPSP time course and of EPSP-spike coupling temporal precision.[182,187–190] We showed that $EPSP_{KA}$ but not $EPSP_{AMPA}$ activate voltage-gated currents and specifically the persistent Na^+ current (I_{NaP}), which is activated below firing threshold and amplifies EPSPs in hippocampal and neocortical neurons.[188,191,192] Using two blockers of I_{NaP}, phenytoin[180,188,193,194] and a low dose of TTX,[195,196] we found that blockade of I_{NaP} restores the temporal precision of EPSP-spike coupling in DGCs of epileptic rats. Therefore, DG epileptic but not naive neurons generate an $EPSP_{KA}$ that triggers selectively the activation of I_{NaP}, which, in turn, facilitates the generation of bursts of action potentials in a dispersed jittery pattern instead of the time-locked $EPSP_{AMPA}$ response. These observations suggest that selective interplay between an aberrant $EPSP_{KA}$ and I_{NaP} alters the temporal precision of EPSP-spike coupling in epileptic but not naive DGCs. This action is not due to an enhancement of I_{NaP} but to the unique long-lasting kinetics of kainatergic EPSCs that are needed to activate I_{NaP}. Interestingly, I_{NaP} is enhanced in neurons in both animal models and patients with temporal lobe epilepsy.[196a] These aberrant KAR-operated synapses exert a strong influence on the operation of hippocampal circuitry, given the high frequency of ongoing excitatory synaptic events in DGCs from epileptic rats.[197] It is likely that these mechanisms underlie the alterations of place cell and phase/precession patterns and the temporal organization of firing among pairs of neurons in TLE.[198,199]

The importance of sprouting and neosynapse formation in chronic epileptogenesis has been challenged by Mello and colleagues on the basis of experiments using the blocker of protein synthesis cycloheximide. In their experiments, pretreatment with cycloheximide following pilocarpine-induced status epilepticus allowed epileptogenesis but prevented aberrant mossy fiber sprouting as assessed by Timm staining. This result suggested that mossy fiber sprouting is not required for seizures to beget seizures in this model.[200,201] However, Dudek and colleagues[197,202] showed that pretreatment with cycloheximide neither altered the spontaneous motor seizure rate posttreatment (compared to that of untreated TLE animals) nor changed the pattern of Timm staining. Cycloheximide also did not prevent hilar, CA1, or CA3 neuronal loss compared to that of the untreated TLE rats. Direct evidence for functional aberrant mossy fiber synapses was obtained, suggesting that pretreatment with cycloheximide does not affect aberrant mossy fiber sprouting in epileptic rats and does not prevent the formation of recurrent excitatory circuits (also see ref. 168).

Implications of Kainatergic Pathways for the Development of Efficient Antiepileptic Agents

Several lessons can be drawn from the use of kainate and other animal models of TLE. First, to understand and eventually cure TLE, reactive plasticity must be incorporated and taken into account in the animal models used for basic and applied research. This conclusion may be valid in general for other insults and neurological disorders, since although mossy fiber synapses offer a unique opportunity to demonstrate postlesional plasticity, this is by no means restricted to mossy fibers. Axonal sprouting and innervation of aberrant targets have been observed in CA1 pyramidal neurons that are deprived of an important input by seizures,[203,204] and a wide range of lesions and insults produce fiber sprouting and formation of novel connections that impact the operation of brain networks.[205–208] These observations imply that the animal models used to mimic human neurological disorders must be chronic and must incorporate alterations. After seizures, sprouting and functional aberrant synapse operation require several weeks to take place and to express the aberrant features (including the novel aberrant kainatergic synapses); then and only then—weeks after the inaugurating status—can one investigate genuine epileptic

networks and develop suitable antiepileptic drugs. In keeping with this important point, in epileptic animals, activation of granule cell synaptic inputs generate all-or-none epileptiform bursts (instead of the normal field population spike evoked in naive neurons) that are blocked by SYM2081, a relatively specific kainate receptor antagonist,[178] This observation suggests that this aberrant synapse plays an important role in the generation of seizures by epileptic neurons, and that suitable kainate receptor antagonists could provide novel therapeutic avenues. This conclusion could not have been reached had the experimental procedures relied only on naive acutely treated animals.

SEIZURES BEGET SEIZURES IN VITRO IN THE DEVELOPING HIPPOCAMPUS

The observations that seizures induced by kainate (or other convulsive agents or procedures) do not produce cell loss and mossy fiber sprouting in immature tissue reflect an important difference between adult and infantile brain. Yet, recurrent seizures do produce long-term, often severe, neurological and behavioral sequelae. To address this puzzle, we have developed an in vitro preparation that has allowed several important observations regarding how recurrent seizures generated by kainate could lead directly to long-lasting alterations in neuronal activity.

An Experimental Protocol to Generate an Epileptogenic Mirror Focus

In spite of their essential contributions, in vivo studies do not readily provide access to the full mechanisms involved in seizure generation. Acute slice preparations also have some limitations, including the difficulties in generating ictal events similar to those observed in vivo. To circumvent these limitations, Khalilov and colleagues developed a technique for studying an intact ex vivo hippocampus preparation; the neonatal hippocampus is dissected, and the entire repertoire of recording techniques applied in vitro can be utilized,[209] This intact preparation can be used for long-lasting recordings, with excellent preservation of essential variables and physiological parameters. It is, however, limited to neonatal preparations and requires suitable relatively fast perfusion rates. Recordings from this preparation revealed larger and better network-driven signals than those observed in slices, allowing the generation and propagation of giant depolarizing potentials (GDPs)—the dominant synaptic pattern of developing cortical networks[210,211] along the entire hippocampal axis—to be described. Combined whole-cell and extracellular field recordings from the CA3 hippocampal region and the septum indicated that spontaneous GDPs are most often initiated in the septal poles of the hippocampus and propagate to the medial septum and temporal poles of both hippocampi simultaneously.[212]

This preparation was subsequently extended to a triple chamber that accommodates the two interconnected hippocampi and their connecting commissures; each hippocampus is placed in an independent chamber so that a convulsive agent can be applied exclusively to one chamber (whereas the naive contralateral hippocampus and/or the associative/commissural connections are perfused with a different solution).[213] This approach provides a unique opportunity to separate the network submitted to a convulsive agent from the naive network that experiences only recurrent seizures that propagate from the other side. Indeed, one can allow the propagation of a predetermined number of seizures before interrupting the flow of activity. Further, putative anti-epileptic drugs can be applied to either the treated or the naive network.

Using this preparation, several important observations have been made concerning the mechanisms underlying the effects of kainate-induced seizures. First, gradual developmentally dependent actions of kainate were observed. Kainate did not generate ictal seizures in postnatal day 2 (P2) tissue, but it did trigger ictal seizures at P7. The propagation of seizures is also developmentally regulated, with interictal seizures propagating to the contralateral hippocampus and septum at P2 and also to the entorhinal cortex; the latter pattern is seen only starting from P4, confirming the crucial role of the hippocampus at an early age in acting as the pacemaker of kainite-induced seizures.[214] Applications of kainate (300 nM)

to one hippocampus generate a tonic-clonic seizure pattern with ictal high-frequency oscillations (HFOs ≥ 40 Hz) similar to those observed in vivo in experimental animals and in epileptic patients.[215–219] The seizures propagate to the other hippocampus, leading to the generation of a similar electrographic event. If the connections between the two hippocampi are interrupted after one seizure, the contralateral hippocampus does not generate seizures spontaneously; that is, it does not become epileptic. In contrast, after 10–15 kainate applications to the stimulated hippocampus, the contralateral hippocampus—which has never been perfused with kainite—becomes epileptic; after disconnection from the stimulated side, it generates ongoing seizures. The networks are "chronically" epileptic; even after 2 days in vitro, ongoing seizures are generated by slices prepared from the mirror foci and artificially maintained. This preparation therefore enables investigators to directly assess the consequences of seizures on a naive network and how seizures beget seizures.

Conditions Required for Recurrent Seizures to Generate a Mirror Focus

Using this preparation, we first determined the conditions required for seizures to beget seizures and to form a mirror focus. Recurrent seizures must include HFOs (>40 Hz) to transform a naive network into an epileptic one. Seizures without HFOs do not generate a mirror focus (see Fig. 33–5). To test this, we repetitively applied kainate to one hippocampus—referred to as the *treated hippocampus*—and NMDA or GABA receptor antagonists to the other hippocampus—referred to as the *naive hippocampus*, as it did not receive kainate. The GABA or NMDA receptor antagonists did not block the propagated seizures but eliminated only their HFO components and completely prevented the formation by seizures of a mirror focus.[122,123,220] Clearly, GABA and NMDA receptors are necessary and sufficient for both the generation of HFOs *and* the formation by seizures of a mirror focus. An interesting implication of these observations is that seizures

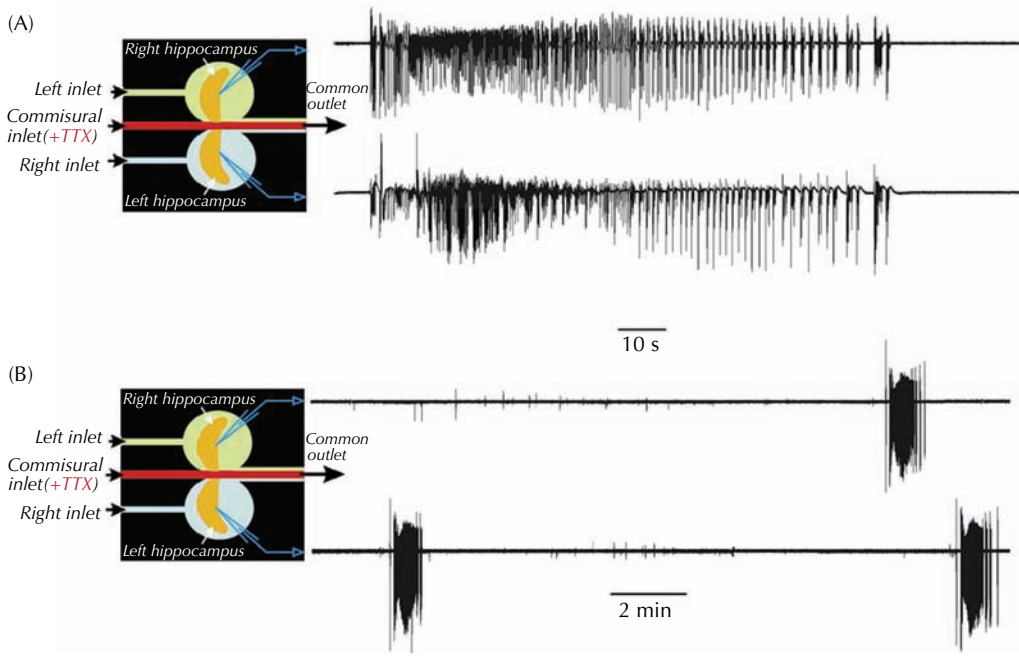

Figure 33–5. **A**: triple chamber with recordings from both hippocampi: seizures propagate from one hippocampus to the other. Recurrent seizures generated in one intact hippocampus by kainate propagated to the other hippocampus and formed an epileptogenic mirror focus. Triple chamber with the two interconnected hippocampi and their connecting commissures. **B**: formation of an epileptogenic mirror focus. After 15 kainate applications and seizures, the naive hippocampus was disconnected from the kainate-treated one by applications of TTX to the commissural chamber, thereby interrupting the flow of activity. The disconnected hippocampus generated ictal seizures for the duration of the preparation. From ref.123.

generated by GABA receptor blockers are *not* epileptogenic, as they do not lead to long-term consequences. This was directly demonstrated by applications of GABA receptor antagonists to both hippocampi that produced seizures but not epileptogenic mirror foci, as the hippocampi did not generate ongoing seizures when the drugs were washed out. Therefore, at least in the neonatal hippocampus, GABA and NMDA receptors must be operative for seizures to include HFOs, and this determines whether seizures will beget seizures. Interestingly, observations in human and animal TLE also reflect the importance of HFOs,[216–218]

This preparation was then used to determine the persistent alterations occurring in an epileptogenic mirror focus formed by the propagation or recurrent seizures from the other hippocampus. Several alterations have been reported. Gamma-aminobutyric acid strongly depolarizes and excites epileptic neurons because of a permanent shift of E_{GABA}; indeed, single-channel recordings of GABA channels showed a highly significant alteration of $[Cl^-]_I$ and the driving force of GABA (DF_{GABA}). Gamma-aminobutyric acid excites neurons in the epileptic tissue, generating action potentials.[122] The accumulation of chloride is most likely mediated by a loss of the chloride exporter KCC2, perturbing the capacity of neurons to remove chloride that accumulates during recurrent seizures[221] (but also see ref. 124). This excitatory-to-inhibitory shift of GABA actions (I to E) has been reported in several other preparations, including human TLE neurons[121]and animal models—although other underlying mechanisms (notably, increased efficacy of the chloride importer NKCC1) have been suggested.[222] This preparation also has been quite useful in testing the actions of known and novel antiepileptic drugs. For example, the NKCC1 chloride cotransporter antagonist bumetanide (which has been used for decades as a diuretic agent) also reduces seizures.[124,223,224] In the triple chamber, bumetanide applied to the naive hippocampus while kainate was repeatedly applied to the other hippocampus failed to prevent the formation by seizures of a mirror focus but efficiently reduced ongoing seizures generated by the mirror focus.[223] These actions are mediated by its potent reduction of intracellular chloride that counteracts the depolarizing and excitatory actions of GABA in the mirror focus and thereby reinforces the inhibitory actions of GABA. This modulation of GABA effects is also illustrated in a recent study in which the dynamic regulation of chloride (DCR) was determined using a perforated patch-clamp recording with focal applications of GABA and V rest selected so as to have a nil DF_{GABA}—that is, no net current at that voltage.[224] A large depolarizing step led to a chloride influx, and then the time required for chloride to return to control values was determined. In mirror focus neurons this time course was significantly augmented, and this was mimicked by specific antagonists of NKCC1/KCC2. As seizures also beget seizures in NKCC1 knockout mice and lead to a permanent rise of DF_{GABA}, it appears that NKCC1 is neither necessary nor sufficient (see a contrasting conclusion in ref. 225). We also showed that in this preparation, KCC2 is internalized—and thus is not operational—in epileptic neurons. Therefore, recurrent seizures reduce DCR, leading to more excitatory actions of GABA, at least in part because of a downregulation of KCC2 (now known to be heavily controlled by tyrosine phosphorylation and dimerization).[226] An important consequence of these effects is that phenobarbital will efficiently block seizure inauguration but aggravate established seizures.[225] Therefore, the history of seizures prior to phenobarbital administration is instrumental in determining its effects.

GENERAL CONCLUSIONS

Understanding the role of kainate signals in modulating ongoing neuronal and network-driven patterns of activity has enormously benefited from the parallel investigation of pathological and normal tissue. The past three decades have shown how kainate generates seizures and how neurons susceptible to kainate are also the ones that use it for ongoing biological functions. Clearly, the system relies on the unique capacity of kainate signals to generate biologically relevant patterns by activating a wide range of cellular mechanisms that converge to enhance neuronal excitability. Theses systems, however, "live dangerously," since insults can transform these activities into severe life-long neurological disorders. It is this link that we must better understand if we want to efficiently block pharmacoresistant TLE.

Chapter 34

Abnormal Dentate Gyrus Network Circuitry in Temporal Lobe Epilepsy

Robert S. Sloviter

Michael Frotscher

DEFINING EPILEPTOGENESIS

Significant progress has been made in understanding the causes of cryptogenic temporal lobe epilepsy when aberrant genes[1] and developmental malformations[2] are involved, but the cause of acquired temporal lobe epilepsy, in which presumably normal individuals develop epilepsy following brain injury, remains poorly understood.[3,4] Epileptogenic injuries include head trauma, infection, ischemia, and prolonged febrile seizures, although the latter insult apparently develops as a result of pre-existing abnormalities.[5] Regardless, injuries that occur in normal brains often cause both temporal lobe pathology and temporal lobe epilepsy, and therefore the possible relationship between pathology and epileptogenesis is a compelling one. However, it is not entirely clear what the term "epileptogenesis" signifies exactly, when the process of hippocampal epileptogenesis is first complete, and which mechanisms develop with a time-course that permits an inference of epileptogenic causality. For definitional purposes, we use the term "epileptogenesis" (literally the birth of epilepsy) to encompass the primary process that causes principal neurons to generate their first spontaneous, multiple

population spike-containing epileptiform discharges, whether or not they produce a clinically detected "aura" or any other behavioral manifestation. We regard the process by which spontaneous and subclinical focal seizure discharges propagate to other cell populations to produce clinically detectable behavioral signs, and changes in seizure phenotype and frequency, to be part of a separate, and often prolonged, secondary process ("epileptic maturation") that follows epileptogenesis.

WHY FOCUS ON TEMPORAL LOBE EPILEPSY AND THE DENTATE GYRUS?

There are many forms of epilepsy and many brain regions that can generate spontaneous seizures, so why focus specifically on acquired temporal lobe epilepsy and the dentate gyrus in particular? There are several reasons. Of all the epilepsies, temporal lobe epilepsy is perhaps the most amenable to study because seizures often arise from the hippocampal formation, a brain region with a highly organized structure that facilitates the assessment of often subtle structural changes. In addition, the temporal lobe is removed surgically to treat refractory epilepsy and is therefore often available for study.[6] From an experimental perspective, the similarity of hippocampal structure in rodents and humans, and the fact that epilepsy can be produced in rodents by the same insults that cause epilepsy in humans, make it feasible to relate the results of experimental studies to the human neurological disorder.

The early discovery that spontaneous epileptic seizures appeared to arise from a damaged and shrunken temporal lobe[7] focused attention on surviving hippocampal neurons as likely sources of seizure activity. The likely role of the dentate gyrus as a primary source of seizures was supported by the observation that dentate granule cells are consistently among the few surviving hippocampal neuron populations[8,9] and by the fact that the loss of neurons in the hippocampal endfolium was the single common pathology shared by all epilepsy patient brains that exhibited any detectable hippocampal cell loss.[9] The anatomical realization that the neurons of the vulnerable endfolium, previously thought to be part of the pyramidal cell layer,[10] were instead synaptically connected with the dentate gyrus[11–13] raised the possibility that the loss of dentate hilar neurons[9] might be associated with granule cell pathophysiology.[14]

Additional reasons for focusing on the dentate gyrus relate to the observation that several conspicuous secondary structural abnormalities develop after injury. In this chapter, we address selective neuron loss,[14] synaptic reorganization,[15] granule cell dispersion,[16] and the timing of their development in relation to the time of onset of spontaneous granule cell epileptiform discharges and behavioral seizures. Clearly, whether a particular pathology precedes or follows the onset of spontaneous seizures is directly relevant to whether that pathology can be causally related to the epileptogenic process.

EPILEPTOGENIC NEURON LOSS AND IMMEDIATE GRANULE CELL HYPEREXCITABILITY: IS NEURON LOSS SUFFICIENT TO CAUSE EPILEPSY?

Do dentate granule cells become hyperexcitable and also spontaneously epileptic after hippocampal injury? And if so, precisely how soon after hippocampal injury do granule cells begin to generate spontaneous epileptiform discharges? A series of experimental studies in vivo has consistently demonstrated that granule cell hyperexcitability is caused immediately by prolonged seizures or head trauma and is closely associated with extensive hilar neuron loss.[14,17–20] In our most detailed study, we found that whenever unilateral perforant pathway stimulation produced bilateral hilar neuron loss, then and only then was bilateral granule cell hyperexcitability evident.[18] Conversely, whenever granule cell hyperexcitability was restricted to the ipsilateral dentate gyrus, only extensive ipsilateral hilar neuron loss was evident. These different responses to identical stimulation controlled for the effects of seizure activity per se because although unilateral stimulation always produced bilateral seizure discharges, contralateral granule cell hyperexcitability was uniquely associated with contralateral hilar neuron loss.[18]

We attributed the immediate granule cell hyperexcitability that we observed after

prolonged perforant pathway stimulation to the extensive loss of the two main hilar neuron populations. These are the peptide-containing inhibitory interneurons that innervate the dentate outer molecular layer and the excitatory hilar mossy cells that innervate the dentate inner molecular layer.[14,18] Loss of hilar inhibitory interneurons that project to the distal dendritic region innervated by the entorhinal cortex was hypothesized to produce a direct disinhibitory effect on granule cells.[14,18] The loss of excitatory hilar mossy cells was also hypothesized to cause granule cell hyperexcitability, but to do so indirectly as a result of decreased excitation of surviving inhibitory basket cells,[14,18] which mossy cells normally innervate and excite.[21–24]

The hypothesized direct disinhibitory effect of hilar inhibitory interneuron loss[14,18] was supported by several subsequent studies.[25,26] However, the observation that extensive loss of hilar peptide-containing interneurons following ischemic insult[27] has minimal effect on granule cell excitability[28] argues against a prominent role for hilar interneuron loss in the specific injury-associated granule cell hyperexcitability that reliably follows prolonged perforant pathway stimulation.[14,18] Conversely, selective and extensive (~90%) mossy cell loss in a conditional mossy cell-knockout mouse caused immediate granule cell hyperexcitability,[29] supporting the view that extensive mossy cell loss is the primary cause of the granule cell hyperexcitability observed following kainate-, pilocarpine-, or stimulation-induced status epilepticus.[14,18,30,31]

The main obstacle to our hypothesis—that seizure-induced neuron loss alone is a sufficient and primary epileptogenic mechanism[18,32]—was stated succinctly by Wasterlain and colleagues, who noted that "this hypothesis does not tackle the problem of the 'silent period' between the initial injury and the development of spontaneous seizures. Because mossy cells are injured at the time of the original seizures and disappear within hours to days, it is hard to understand why spontaneous seizures are delayed by weeks to months, unless the loss of inhibition is permissive but not sufficient for epileptogenesis, and its role is only to permit further changes which, in turn, produce chronic epilepsy."[33]

The widely accepted notions that status epilepticus-induced brain damage in animals is reliably followed by a silent, seizure-free preepileptic state lasting for weeks to months,[33–35] and that spontaneous epileptic seizures only begin because synaptic reorganization or other secondary processes that develop during the silent period have finally matured,[15,33,34] are anecdotal and based mainly on occasional behavioral observation,[36] which inevitably risks missing early behavioral seizures and all subclinical seizures.[37] The belief in a seizure-free postinjury latent period[35] has nonetheless formed the logical basis for focusing on delayed secondary processes as likely epileptogenic mechanisms, rather than on the effects of initial neuron loss and other immediate events. However, recent studies that involved continuous monitoring of chemoconvulsant-treated rats have now consistently shown that spontaneous behavioral seizures begin almost immediately after status epilepticus-induced injury.[31,38–41] Continuous video and electrographic monitoring of electrically stimulated rats, in which residual chemoconvulsants can play no role in any early seizures that occur, have now also shown that spontaneous granule cell-onset population spikes and epileptiform discharges, as well as behavioral seizures, also begin within the first days post-status epilepticus.[41] Thus, epileptogenesis after status epilepticus is coincident with initial neuron loss (Fig. 34–1), which occurs over a period of several days,[42] indicating that neuron loss could well be the primary epileptogenic mechanism.[41]

Redefining the Term *Epileptogenesis*

Genesis literally means "birth," "coming into being," or the "beginning of something." The genesis phase in the life of a human being ends in the process of birth, not in reaching maturity. The growth and maturation of the individual is a separate and secondary process distinct from genesis. By analogy, it seems logical to define the completion of epileptogenesis as the moment when the machinery and mechanisms necessary for spontaneous abnormal epileptiform behaviors first exist. The subsequent chronic epileptic state (epileptic maturation) undoubtedly evolves and progresses, but we regard this process to be distinct from epileptogenesis. For example, a seizure focus may expand, or it may transition from a focal to a generalized process, or the frequency of seizure events may change. However, these changes would seem to be an

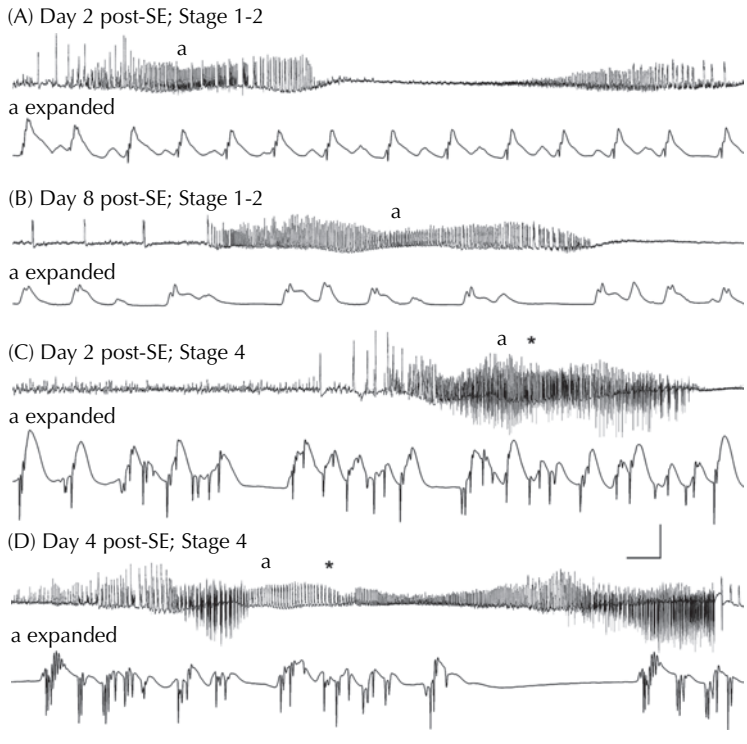

Figure 34–1. Correlation between spontaneous granule cell layer activity and behavioral seizure expression in an epileptic rat 2–8 days after 3 h of perforant pathway stimulation-induced convulsive status epilepticus (SE). Two focal (subclinical) seizures (**A,B**) on days 2 and 8 post-SE and two stage 4 behavioral seizures (**C,D**) on days 2 and 4 post-SE. **A.** On day 2 post-SE, spontaneous high-amplitude activity, consisting of field excitatory postsynaptic potentials (EPSPs) and small-amplitude population spikes, was recorded from the granule cell layer electrode. During this spontaneous event, the animal exhibited only a frozen stare, followed by stereotyped chewing movements. **B.** A similar spontaneous granule cell layer event was recorded on day 8 post-SE, which was only associated with staring and stereotyped head movements. **C,D.** On days 2 and 4 post-SE in the same animal, spontaneous granule cell layer events included larger-amplitude and downwardly deflected population spikes. These events were invariably followed by stage 3–5 behavioral seizures. Note that high-frequency spiking began prior to the first behavioral manifestation (asterisks in **C,D**) of each behavioral seizure. These events from a single rat are representative of all 72 stage 3–5 behavioral seizures recorded in 10 chronically implanted, continuously monitored rats. Calibration bars equal 1.4 s and 9 mV in **A**; 56 ms and 9 mV in **A** (expanded), **B** (expanded), **C** (expanded), **D** (expanded); 3.2 s and 9 mV in **B** and **C**; 4.5 s and 9 mV in **D**. From ref. 41.

evolving process of growth and maturation, not part of the birth process. Clearly, the conundrum quoted above, regarding "the problem of the 'silent period' between the initial injury and the development of spontaneous seizures,"[33] is the product of using the appearance of the first spontaneous generalized behavioral seizures in rats as the definitive marker of the end of epileptogenesis.[34]

Based on the results of studies in which both behavior and granule cell layer activity have been simultaneously and continuously monitored in awake animals after a highly controlled and reproducible injury,[31,41,43] we suggest that epileptogenesis is not a unitary process that ends when the first spontaneous generalized behavioral seizure is visually observed.[33–36] Rather, we regard epileptogenesis to be a process that culminates in the first spontaneous epileptiform discharge that causes a focal seizure or, at minimum, a process that ends when the brain is changed in such a way that the first spontaneous epileptiform discharge and focal seizure are imminent. We suggest that this is the process that needs to be aborted if an antiepileptogenic strategy is to be effective. However, if identified principal cell populations are not directly monitored in awake animals after injury, and if true epileptiform discharges are not clearly differentiated from high-amplitude depolarizations that contain no population spikes, but only superficially appear

to be epileptiform discharges,[31] it is doubtful that accurate inferences can be made regarding the nature, duration, or location of the process called *epileptogenesis*. Even then, important events in unmonitored cell populations may be missed, placing limits on what we should think we know about where seizures originate or where and when epileptogenesis has actually occurred.

Car manufacturing provides a useful analogy for defining epileptogenesis. Every car is assigned a "build date," which marks completion of the process that culminates in the ability of the car to operate as designed, with no additional physical changes required. It is not a date that indicates its first test drive, its first maximum speed attempt, or its first assignment of title, which are all defining characteristics of car ownership and operation. A fully built car that has not yet been driven is still a car, and giving it a build date does not preclude making additional modifications that change the car's attributes and capabilities. Thus, we regard the end of epileptogenesis as the brain's unfortunate build date when all cellular and network changes needed for the spontaneous generation of focal epileptiform discharges are first present. This altered brain state is most likely complete sometime before the first clinically detectable seizure event occurs. The chronic state that follows the initial epileptogenesis phase, which might best be called *epileptic maturation*, undoubtedly involves continuing modification and progression, but we regard epileptogenesis as the process that describes completion of the initially altered brain state, that is, the earliest time when a brain can be said to be epileptic.

Hyperexcitable Is Not Synonymous with *Spontaneously Epileptic*: Does Hippocampal Epileptogenesis Require a Second Pathology?

Although extensive and specific mossy cell loss causes immediate granule cell hyperexcitability, this hyperexcitability alone is apparently not enough to cause spontaneous granule cell epileptiform discharges or spontaneous behavioral seizures.[29] This is not surprising because granule cell hyperexcitability to afferent excitation does not require that granule cells become a spontaneously discharging population. It is therefore notable that there is a second temporal lobe pathology common to all status epilepticus models in the entorhinal cortex[41,43,44] (Fig. 34–2).

One possible explanation for the immediate development in awake animals of both granule cell hyperexcitability to afferent excitation and spontaneous granule cell-onset seizures comes from the analysis of an animal model in which extensive hilar neuron loss, entorhinal cortex damage, and extratemporal injury are consistently produced by electrical stimulation-induced status epilepticus.[41] In this model, as in animals subjected to kainate-[20,30] or pilocarpine-induced status epilepticus[31] or experimental head trauma,[19] extensive hilar neuron loss is reliably associated with immediate granule cell hyperexcitability to afferent

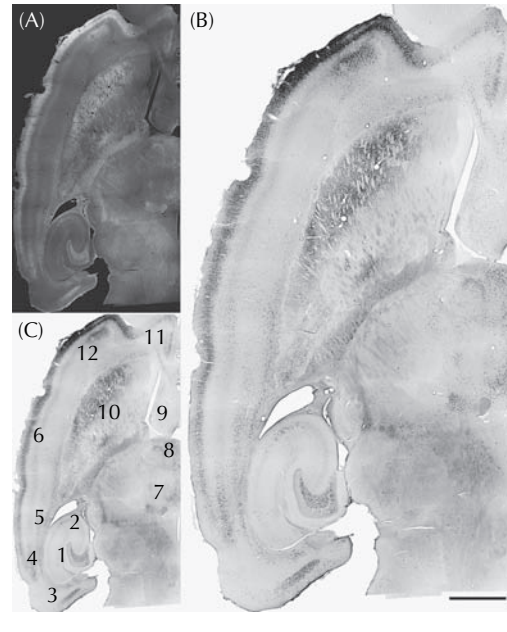

Figure 34–2. Acute Fluoro-Jade B (FJB) staining showing neurodegeneration 4 days after 3 h of perforant pathway stimulation-induced SE. **A.** Fluoro-Jade B fluorescence. **B,C.** Gray-scale inverted image of the same horizontal brain section. Note the selective degeneration of neurons in the dentate hilar region (**C1**); hippocampal area CA3a (**C2**); entorhinal cortex layer III (**C3**); perirhinal cortex (**C4,5**); layer II throughout the neocortex (**C6**); parafascicular thalamic nucleus (**C7**); intermediodorsal-, mediodorsal, paratenial, paraventricular, and central medial thalamic nuclei (**C8**); lateral septum (**C9**); lateral caudate/putamen (**C10**); infralimbic cortex (**C11**); and deep pyramidal cells of the agranular insular cortex (**C12**). excitation.[41] In the case of perforant pathway-stimulated rats, in which granule cell activity and behavior were monitored continuously, spontaneous granule cell epileptiform discharges began almost immediately and preceded each spontaneous behavioral seizure[41] (Fig. 34–1). Importantly, clinical behavioral seizures always and only occurred when granule cells generated prolonged negative-going population spikes (Fig. 34–1). Clearly, these spontaneous granule cell discharges cannot be the result of recurrent excitatory connections among granule cells[15] because the hyperexcitability, spontaneous epileptiform discharges, and behavioral seizures preceded the formation of recurrent axonal connections.[41] We suggest that although granule cells become immediately hyperexcitable[14,18–20,30] as a direct result of extensive hilar mossy cell loss,[18,29] granule cells do not generate synchronous epileptiform discharges until they receive abnormal excitatory input from the disinhibited layer II neurons of the injured entorhinal cortex.[43,45] The appearance in the granule cell layers of spontaneous large-amplitude dendritic field depolarizations virtually identical to those evoked by perforant pathway stimulation[41] (Fig. 34–1) suggests that spontaneous granule cell discharges may involve at least two principal pathologies: (1) mossy cell loss that disinhibits granule cells[29,32] and (2) entorhinal cortex damage (Fig. 34–2), which causes abnormal entorhinal layer II neuron activity that invades the dentate gyrus.[41] Future experiments will need to determine whether synchronous epileptiform activity in the entorhinal cortex precedes granule cell epileptiform discharges or whether asynchronous entorhinal activity precedes synchronous granule cell discharges. Regardless, whether spontaneous granule cell seizure discharges cause behavioral seizures immediately (Fig. 34–1) or result in a latent period before clinical seizures first occur may be a measure of the extent of injury in the entorhinal cortex, in the hilus, and in the downstream barriers to seizure spread (hippocampal pyramidal cells and synaptically linked cell populations farther down the chain). We suggest that the only network change needed for spontaneous granule cell epileptiform discharges to develop is extensive neuron loss in the hilus of the dentate gyrus and in the entorhinal cortex. We do not suggest that minor neuron loss is necessarily epileptogenic; only extensive hilar neuron loss is predicted to have a significant epileptogenic effect.[20]

MOSSY FIBER SPROUTING

Few ideas are more conceptually appealing than the hypothesis of epileptogenic mossy fiber sprouting, as formulated originally by Tauck and Nadler.[15,46] According to this scenario, normal granule cells have no recurrent excitatory connections, and therefore granule cells do not normally generate spontaneous population spikes or epileptiform discharges. Hilar mossy cell axotomy[47,48] or injury-induced mossy cell degeneration[15,49] denervates the granule cell dendrite segment normally innervated by mossy cells, and this loss of mossy cell input apparently triggers the reinnervation of granule cells by newly formed granule cell axons (mossy fibers).[50] The *mossy fiber sprouting* hypothesis posits that it is the formation of aberrant excitatory connections among normally unconnected granule cells that causes granule cells to become spontaneously epileptic.[15] Many studies have replicated and extended the original findings of Tauck and Nadler,[15,46] but several critical issues were not considered in the many studies that were designed to support the hypothesis, and other observations suggest an alternative hypothesis.

First, the mossy fiber sprouting hypothesis ignores the network effects of the initial injury-induced neuron loss and regards mossy cell loss as only a trigger for mossy fiber sprouting. However, the effects of neuron loss and reactive synaptic reorganization cannot be separated since these effects coexist, with the former apparently causing the latter.[50] Therefore, any parameters that have been correlated with mossy fiber sprouting in a multitude of studies could have been similarly correlated with hilar neuron loss, although the role of hilar neuron loss has rarely been discussed in studies that have sought to establish a causal link between mossy fiber sprouting and granule cell hyperexcitability. Second, we have found that the granule cell hyperexcitability observed in hippocampal slices from kainate-treated rats, and attributed to mossy fiber sprouting that takes weeks to develop,[15,30,31] is present in vivo immediately after kainate-induced injury, before mossy fiber sprouting develops.[30,51] Third, in

rats in which immediate postinjury granule cell hyperexcitability was confirmed in our in vivo experiments, we have shown that the growth of mossy fiber sprouting was temporally associated with gradually increasing granule cell paired-pulse inhibition and an inability to evoke granule cell epileptiform discharges rather than hyperexcitability.[30,51] Importantly, the judgment that granule cells were hyperexcitable shortly after injury, and later were powerfully inhibited, was based not only on the assessment of responses to paired-pulse stimulation,[30,51] but also on the immediate appearance of multiple population spikes in response to single-afferent stimuli and the inability to evoke granule cell epileptiform discharges during the later synaptic reorganization phase, even by high-frequency afferent excitation.[31] Fourth, direct recording from the granule cell layers in awake pilocarpine- and kainate-treated animals revealed that the granule cells do not generate epileptiform discharges before the spontaneous behavioral seizures that develop in chemoconvulsant-treated rats.[31,52] This result is in contrast to the result of identical recordings made in perforant pathway-stimulated rats, in which all spontaneous behavioral seizures were preceded by granule cell layer epileptiform discharges.[41,43] Fifth, and perhaps most definitively, in all studies in rats subjected to convulsive status epilepticus and then monitored continuously, spontaneous behavioral seizures precede mossy fiber sprouting.[38–41]

Discussion of the mossy fiber sprouting hypothesis in the literature has focused almost exclusively on the aberrant autoinnervation of granule cells, and has largely ignored the possible impact of mossy cell death and mossy fiber sprouting on inhibitory basket cells.[30,51] In fact, mossy cell loss denervates all target cell dendrites in the dentate inner molecular layer, not just granule cells, and the reinnervation of vacated synaptic sites by newly formed granule cell axons would be predicted to target both inhibitory neurons and granule cells.[30,31,51] The consistent finding that synaptic reorganization does, in fact, reinnervate both granule cells and inhibitory neurons[30,31,51,53] (Figs. 34–3 and 34–4) challenges the assumption that mossy fiber sprouting must be exclusively excitatory in nature.[15] To the contrary, we interpret the available data as indicating that mossy fiber sprouting may play a mainly compensatory or restorative role.[30,51]

Inhibitory Circuitry, Mossy Cells, and Mossy Fiber Sprouting

Elegant in vivo studies first revealed the paradoxical net inhibitory effects of the excitatory commissural projections of the dentate gyrus,[21–24] which originate from hilar mossy cells.[11,12] These studies clearly showed that although the commissural fibers were excitatory, and might be predicted to excite granule cells, activation of this pathway in vivo had a predominantly inhibitory effect on granule cells because the mossy cell-derived commissural pathway directly excited inhibitory basket cells.[21–24] Thus, although numerically superior, the excitatory input to granule cells is apparently dominated in vivo by the influence of the mossy cell-basket cell innervation. Consistent with the idea that the seizure-induced loss of mossy cells should denervate basket cells, as well as granule cells, and that mossy fiber sprouting should reinnervate both basket cells and granule cells, granule cells were found to be disinhibited and hyperexcitable immediately after hilar neuron loss, prior to mossy fiber sprouting.[30,51] Then as mossy fiber sprouting developed, the granule cells were found to become powerfully hyperinhibited in the same animals.[30,51] These and additional results are consistent with the view that (1) excitatory mossy cells normally and paradoxically produce predominantly inhibitory, rather than excitatory, effects on granule cells in vivo,[20–24] (2) mossy cell loss denervates inhibitory basket cells, possibly causing immediate granule cell hyperexcitability,[14,18,20,29] and (3) mossy fiber sprouting reinnervates basket cells as well as granule cells (Figs. 34–3 and 34–4), which correlates temporally with an apparent partial restoration of granule cell inhibition.[30,31,51,53]

Must Mossy Fiber Sprouting Be Either Entirely Excitatory or Entirely Inhibitory?

The question of whether mossy fiber sprouting is epileptogenic or restorative in nature may be simplistic regardless of how the electrophysiological and anatomical data are weighted.[51] Mossy cells and mossy fiber sprouting innervate both granule cells and inhibitory neurons and might play distinct roles in different behavioral

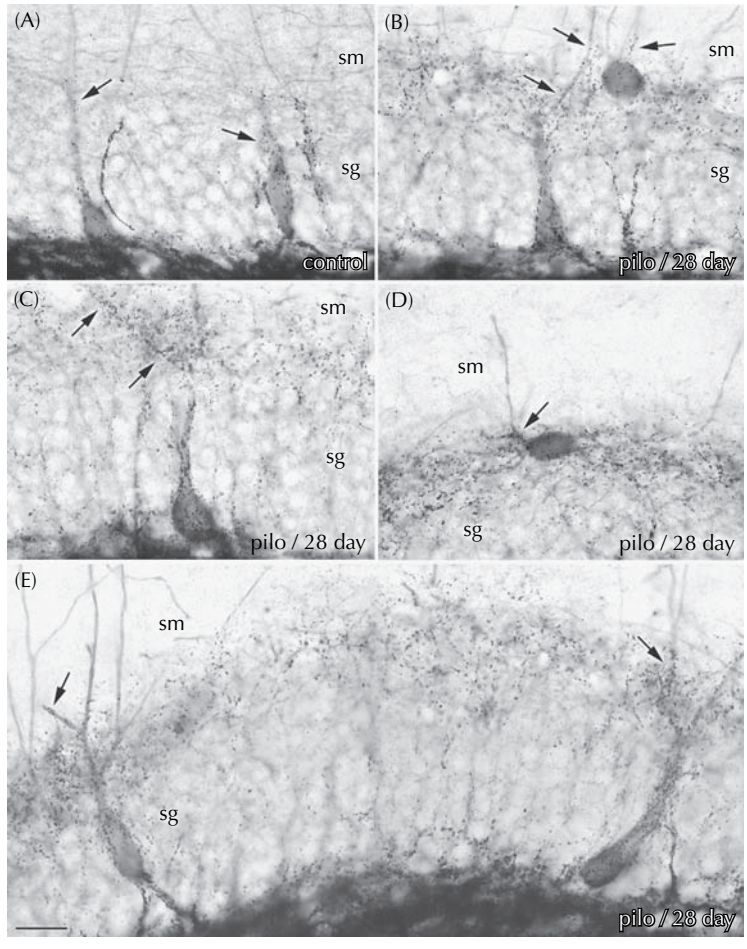

Figure 34–3. Parvalbumin-positive inhibitory interneurons are targets of aberrant mossy fiber sprouting at the time of early recovery of granule cell paired-pulse inhibition. **A.** Timm staining in a control rat. Note that Timm-positive terminals surround and outline the somata and proximal dendrites of normal granule cell layer interneurons (arrows). **B–E.** Timm-stained sections from an animal perfusion-fixed 28 days post-SE, the recovery period when 1 Hz afferent stimulation first failed to evoke epileptiform discharges (i.e., the epileptiform discharge threshold was increased). Note that aberrant mossy fiber terminals targeted the somata and dendrites of identified inhibitory interneurons of the granule cell and inner molecular layers (arrows). sg, stratum granulosum; sm, stratum moleculare. Scale bar: 26 μm in **E**; 25 μm in **A–D**. From ref. 31.

states. It is conceivable that mossy fiber sprouting could be predominantly inhibitory interictally, regulating seizure frequency, but could then play an excitatory role when inhibition is overcome and seizures occur. Although we do not know the net effect of mossy fiber sprouting under all conditions, we contend that the notion that mossy fiber sprouting must be purely epileptogenic in nature because granule cell interconnections are formed is not supported by either the time course of postinjury granule cell excitability in vivo or the relationship between mossy fiber sprouting and the latency to the first spontaneous epileptic seizures.[30,54] Understanding the role of mossy cell loss and reactive mossy fiber sprouting clearly requires (1) an unbiased consideration of the effects of both neuron loss and synaptic reorganization on dentate gyrus function and (2) testing the mossy fiber sprouting hypothesis in animals that exhibit confirmed granule cell-onset epilepsy.[41,43] The latter consideration probably excludes testing in chemoconvulsant-treated rats, which exhibit frequent generalized seizures that appear to minimally involve the hippocampus.[31,52]

The subject of cell loss and synaptic reorganization is made even more complex by the

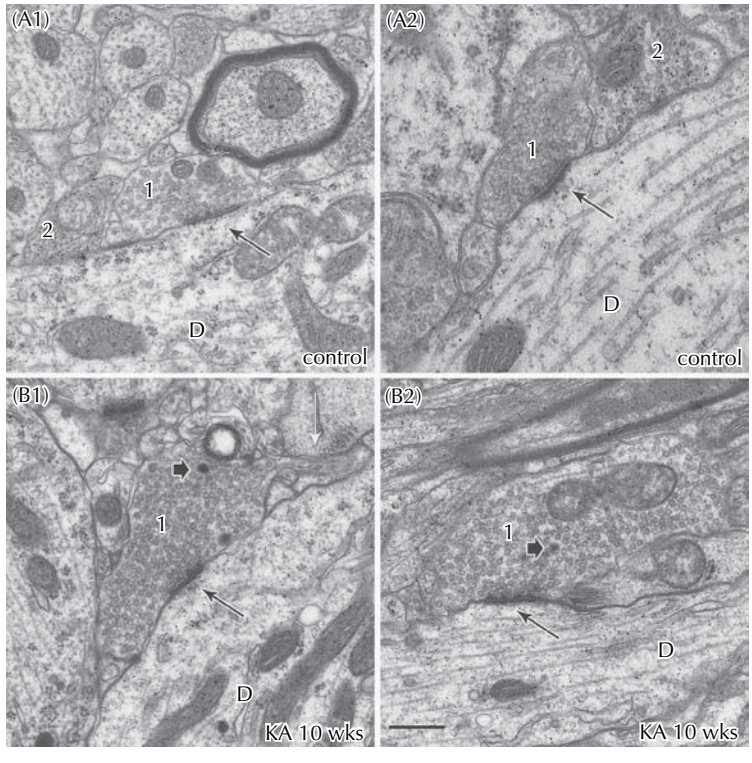

Figure 34–4. Gamma-aminobutyric acid immunocytochemical electron microscopy of the dentate inner molecular layer 10 weeks after saline or kainate (KA)-induced status epilepticus (SE). **A1,2.** In control sections, proximal dendrites (D) of GABA-positive interneurons are contacted by small immunonegative boutons (terminal 1 in both panels) establishing asymmetric synaptic contacts, and by GABA-positive terminals (terminal 2 in both panels) forming symmetric synapses. Arrows point to asymmetric synaptic contacts. **B1,2.** Ten weeks after KA injection, numerous large terminals, densely filled with clear synaptic vesicles and containing dense-core vesicles (thick black arrows), emerge from thin, unmyelinated preterminal axons (white arrow in **B1**). These mossy fiber boutons establish asymmetric synaptic contacts (thin black arrows) with GABA-positive dendritic shafts (D) in the inner molecular layer. Scale bar: 0.5 μm in **B2** (applies to **A1-B2**). From ref. 51.

fact that hilar mossy cells normally constitute a long-distance, longitudinally projecting axonal system,[20,55] whereas aberrant mossy fiber sprouting is more localized[56] and presumably cannot fully restore the translamellar influences that are lost when mossy cells die.[20] In addition, clustering of spontaneous seizures[39] and the duration of the interictal period, that is, seizure frequency, could be powerfully influenced by both the net inhibitory effects of mossy fiber sprouting and the upregulation of glutamic acid decarboxylase 67 (GAD67) and gamma-aminobutyric acid (GABA) that seizure activity produces specifically in granule cells.[57] Clearly, the roles of cell loss, synaptic reorganization, glial abnormalities, and altered expression of transmitters, receptors, and channels remain to be addressed in animal models that reliably exhibit confirmed hippocampal-onset seizures.

GRANULE CELL DISPERSION

Granule cell dispersion in temporal lobe epilepsy, first described by Houser,[58] is another example of a frequently observed structural abnormality that may or may not play a role in altered dentate gyrus excitability.[16] In the normal dentate gyrus, granule cells are tightly packed, forming a clearly delineated and relatively uniform cell layer. Although there is some structural variability among these neurons, particularly in the primate brain,[59] granule cells send their cone-shaped dendrites to

the molecular layer, with virtually all dendrites reaching the hippocampal fissure. Mossy fiber axons emerge from the granule cell somata and enter the hilus. This bipolarity of dentate granule cells clearly separates the input region of the cell from its output region, resulting in minimal granule cell-granule cell connectivity under normal conditions. In granule cell dispersion, the compact lamination of granule cell bodies is lost. As a result, the axons of granule cells dispersed into the molecular layer traverse the molecular layer for some distance and could contact the dendrites of more deeply located neurons, possibly increasing granule cell interconnectivity. Since granule cell dispersion is found in tissues from epileptic patients, the following scenario appears plausible: migration defects of granule cells during development, or dispersion of granule cells following hippocampal injury, might result in increased granule cell interconnectivity and hyperexcitability.

The results of studies conducted over the last 10 years suggest a different scenario. In tissue samples from epileptic patients, the expression of the extracellular matrix protein Reelin was found to be significantly decreased.[60] Moreover, it was noticed that the extent of granule cell dispersion correlated with the extent of decreased Reelin expression. Reelin is known for its role in layer formation in the cerebral cortex, cerebellum, and hippocampus,[61–67] and Reelin-deficient "reeler" mutants show a severe loss of granule cell lamination,[68–70] which is at least structurally reminiscent of granule cell dispersion in epilepsy. Thus, Reelin apparently stabilizes dentate gyrus architecture, and an injury-induced decrease in Reelin expression might cause granule cell dispersion. To test this hypothesis, Heinrich and colleagues[71] infused a Reelin-neutralizing antibody into the dentate gyrus of mature mice. They unexpectedly observed granule cell dispersion at sites of Reelin antibody infusion, and this effect could not be induced when the Reelin antibody was replaced by a nonspecific immunoglobulin G (IgG). The interpretation of these findings is that Reelin establishes or maintains the laminated organization of the dentate gyrus, and that decreased Reelin expression or antibody blockade of Reelin results in granule cell dispersion.

Unilateral granule cell dispersion is reliably produced in normal mice during the first month following unilateral intrahippocampal injections of the glutamate receptor agonist kainate,[72] and it has been shown that Reelin expression was dramatically decreased on the kainate-injected side, but not contralaterally.[71] These results suggest that granule cell dispersion results from decreased Reelin expression after cell loss or hypermethylation of the Reelin gene.[73] Although Reelin appears to play an important role in stabilizing cortical architecture in the mature brain,[67] it remains to be determined whether granule cell dispersion directly influences granule cell interconnectivity and excitability. In this regard, it is notable that reeler mice, which are deficient in Reelin and exhibit granule cell dispersion, do not show spontaneous seizures. In addition, recent recordings from dispersed granule cells in kainate-treated epileptic mice provided evidence of reduced, rather than increased, granule cell excitability.[74] Importantly, many patient hippocampi do not exhibit granule cell dispersion, and other animal models that exhibit confirmed granule cell-onset epilepsy do not show granule cell dispersion.[41,43] Although intrahippocampal kainate injection causes both granule cell dispersion and epilepsy in mice, perforant pathway stimulation-induced hippocampal injury in mice produces epilepsy without producing granule cell dispersion.[75] Thus, the pathophysiological implications of granule cell dispersion, if any, remain to be clarified.

THE LATENT PERIOD AND EPILEPTOGENESIS

The belief that all status epilepticus models exhibit a silent postinjury latent period during which seizures do not occur[33–36] is no longer tenable for the reasons cited above.[31,37–41,76] Although there is no delay between injury and epilepsy after prolonged status epilepticus in animals, and although a similar lack of any detectable latent period has been reported after prolonged status epilepticus in humans,[77] delays in the appearance of clinical seizures after injury usually exist.[34,76,78] Why do seizures sometimes develop in humans immediately after injury but, in other cases, only after years or decades? Unfortunately, estimates of the latency to the appearance of clinical epilepsy

are inherently unreliable because they are almost always based on the time that elapses between a presumed injury and the observation of a significant behavioral event.[78] This is understandable, as the proper metric, that is, the time of onset of the first focal epileptiform discharges, cannot be determined. For example, should a patient who has experienced a clinically unrecognized aura for 30 years, prior to a first clinical seizure, be regarded as having had epilepsy ever since the first aura, or only after the first clinical seizure has been observed and recognized? That is, does epileptogenesis really take 30 years to mature in this case, with the 30-year-long period of subclinical auras considered to be a preepileptic state during which a single epileptogenic process was slowly maturing? From a neurobiological perspective, the important event for the concept of epileptogenesis would seem to be the first onset of epileptiform discharges that produced the first aura (a focal seizure), regardless of whether the first discharges spread sufficiently to disrupt behavior or consciousness and become clinically obvious. We contend that delays in the appearance of clinical seizures following brain injuries have been inferred incorrectly to indicate that epileptogenesis is a specific and progressive unitary process that is as long in duration as the time it takes for generalized or clinically obvious seizures to appear and be recognized. Clearly, the calculated latent period cannot reflect the length of epileptogenesis if the time to the appearance of the first epileptiform discharges cannot be accurately assessed. Regardless, recent results indicate that highly experimenter-controlled hippocampal injuries consistently produce immediate hippocampal epileptogenesis that is coincident with initial neuron loss.[41]

Based on our most recent studies,[41,43] we suggest that acquired temporal lobe epilepsy involves a relatively straightforward two-stage process. First, an injury causes changes that result in spontaneous principal cell epileptiform discharges, which are presumably subclinical in most cases. This stage (*epileptogenesis*) might be most effectively impeded in the immediate postinjury period by a neuroprotective treatment that minimizes the extent of initial neuron loss, some of which is delayed,[42] and may be initially susceptible to treatment. Second, subclinical discharges increase gradually in duration, and invade and recruit other neuronal populations that act initially as barriers to seizure spread, ultimately causing clinical epilepsy, which includes subtle focal seizures.[41] This distinct second phase (*epileptic maturation*) might be most effectively targeted by treatments that retard the kindling process or that interfere with pro-epileptic secondary processes such as glial abnormalities, neurogenesis, synaptic reorganization, altered receptor expression, and so on.

A GRID CELL HYPOTHESIS OF TEMPORAL LOBE EPILEPTOGENESIS

The data discussed above regarding the possible epileptogenicity of damage in the entorhinal cortex and dentate gyrus permit a conceptual synthesis that may have implications for thinking about temporal lobe epileptogenesis and devising strategies to prevent it. If all animals subjected to a uniform insult exhibit pathological changes that closely resemble the human neurological condition, and if all of these animals exhibit spontaneous hippocampal-onset seizures that develop without delay,[41] then epilepsy in these animals is the likely result of the immediate effects of injury, rather than being the result of delayed secondary processes that develop after the animal is already epileptic.[41,76]

If hippocampal injury causes immediate granule cell hyperexcitability, and if no recurrent excitatory connections are necessary for epileptiform discharges to occur, why do granule cells spontaneously generate only brief, intermittent seizure discharges and behavioral seizures[41] rather than continuous epileptiform discharges and status epilepticus? We hypothesize that some of the answers may lie in the nature of incomplete hilar and entorhinal cortex neuron loss, and the behavior of layer II entorhinal neurons, which form the main excitatory input to the dentate granule cells.[79] Layer II entorhinal cortical neurons (EC2) are hyperexcitable following status epilepticus,[45] presumably as a consequence of cell loss in the adjacent layers III (EC3) and V (EC5)[44,80,81] or other closely related nuclei. Recent studies in normal animals have shown that EC2 neurons constitute a system of *grid cells* in which individual EC2 neurons form an

environment-independent spatial coordinate system.[82,83] These grid cells normally discharge strictly independently in a spatial environment and exhibit discrete inhibitory surrounds.[82] Apparently, the independent firing patterns of EC2 grid cells constitute a universal map of the spatial environment, and these grid cells feed this information to their target cells in the dentate gyrus.[84] We predict that the pathology reliably produced in the EC3 and EC5 layers by prolonged convulsive or nonconvulsive status epilepticus[41,43,44] reduces the size of the grid cell inhibitory surround and decreases the location-based specificity of EC2 neuron discharges. EC2 neuron hyperexcitability may occur as a result of the loss of EC3 and EC5 neurons, which normally influence EC2 neurons.[85] Loss of EC2 neuronal inhibition would cause EC2 pyramidal cells to coalesce functionally, to disrupt the grid function that establishes normal spatial memory, and to generate abnormal synchronous discharges that propagate directly to the granule cell layers.[86] Therefore, we predict that after extensive stimulation-induced injury of hilar neurons and EC3 and EC5 cells,[41,43] EC2 grid cells should lose their inhibitory surrounds and their spatial separation immediately, and begin to generate synchronous discharges that cause the spontaneous granule cell layer depolarizations, population spikes (apparent biomarkers of imminent epileptiform discharges), and epileptiform discharges that we have consistently recorded in awake rats prior to each granule cell-onset seizure[41,43] (Fig. 34–1). Changes in the GABAergic projection from entorhinal cortex to hippocampus[87] might also affect hippocampal excitability.

CONCLUSION

In summary, we suggest that acquired temporal lobe epileptogenesis involves two causal pathologies: (1) extensive hilar neuron (mossy cell) loss, which reduces translamellar granule cell inhibition,[20] causing granule cell hyperexcitability to afferent input,[29,32] and (2) entorhinal cortex damage, which causes a loss of functional separation in layer II grid cells, resulting in abnormal and synchronous excitation of disinhibited granule cells, which generates spontaneous granule cell-onset seizures.[32,41,43] We hypothesize that widespread brain damage, such as that caused by prolonged convulsive status epilepticus, can result in immediate clinical epilepsy in both rats and humans[41,77] because all cortical and subcortical barriers to the spread of focal seizures are damaged or functionally altered by the initial insult. Conversely, after more limited injury in the entorhinal cortex and hilus, it may take time for EC2 neurons to begin to generate abnormal discharges. Once begun, it may require additional time for entorhinal discharges to overcome the granule cell inhibition that remains as a result of incomplete hilar neuron loss. Thus, granule cell seizures would not start until the entorhinal cortex generates abnormal discharges capable of overcoming granule cell inhibition and evoking granule cell epileptiform activity. From this perspective, the inhibitory effects of mossy fiber sprouting may establish or extend the latency to the first granule cell-onset seizures by making granule cells more resistant to generating their first epileptiform discharges.[30,31,51]

A postinjury delay of the first spontaneous granule cell discharges, plus additional time needed to recruit hippocampal pyramidal cells and to overcome downstream barriers to seizure spread, could explain the prolonged period of subclinical focal discharges that precedes the appearance of clinical life-disrupting seizures. The hypothesis that the progression from subclinical to clinical epilepsy involves a time-consuming kindling process[88] that should be targeted in the immediate postinjury period[41,43] is not original, but it is wholly consistent with the ideas of Graham Goddard, which were cogently summarized in Goddard's obituary by Frank Morrell.[89] Thus, we suggest that two mechanisms should be primary targets for pharmacological treatment: (1) initial neuron loss, which has a delayed component[42] that may constitute a therapeutic window that remains open for several days, and (2) a kindling process,[88] interruption of which could, at least theoretically, extend the latent period to clinical seizures indefinitely, even if epileptogenic neuron loss cannot be substantially reduced.

In addition to the need for experimental resolution of a variety of issues using animal models that reliably involve hippocampal epileptogenesis, it may be worthwhile to consider that the terms *epileptogenesis*, *latent period*, and *kindling* are names of concepts created by the human mind, rather than being real and readily definable or identifiable neurobiological

entities.[90] Giving the name *epileptogenesis* to a probably multifactorial process of unknown nature has implications for how we think about that process, and implies that it is something singular that can be prevented or aborted if only "it" can be identified. Similarly, the term *latent period* is a conception that confers significance on an ill-defined time period with an uncertain beginning and an unknown maturation date.[34,76] The use of the term *latent period* has significant implications for the importance we ascribe to a perceived interval during which nothing is observed. Clearly, an inability to hear a distant conversation is not evidence that nothing has been said. Given these considerations, the clarity of the discussion of the process that causes the brain to generate abnormal synchronized discharges for the first time (epileptogenesis), and of the secondary processes that enable focal epileptiform discharges to spread and become clinically detectable (epileptic maturation), might benefit from referring to the neurobiological processes themselves, rather than using created names applied to difficult-to-define subjective conceptions of those processes.[90]

Finally, given that many endogenous homeostatic mechanisms normally limit excitation, epilepsy may be viewed as an unusually powerful network defect that, once established, cannot be completely suppressed by any combination of homeostatic mechanisms and cannot be easily controlled pharmacologically. If any pharmacological intervention can successfully interfere with the processes of epileptogenesis and epileptic maturation, the combination of a neuroprotective compound and an antikindling compound in the immediate postinjury period, followed by long-term treatment with an antikindling compound alone, might be the most logical treatment approach.

SYNOPSIS

The mechanisms that cause acquired temporal lobe epilepsy are unknown. Suspected mechanisms include neuron loss, synaptic reorganization, and granule cell dispersion, but determining which abnormalities mediate epileptogenesis has been problematic because the most frequently used chemoconvulsant-based animal models exhibit extreme variability and minimal evidence of hippocampal epileptogenesis. Continuous monitoring of behavior and granule cell layer activity in awake rats after hippocampal injury caused by stimulation-induced status epilepticus has now shown that granule cells generate spontaneous field depolarizations, population spikes, and epileptiform discharges in the first days postinjury, prior to each generalized behavioral seizure. Thus, injury-associated hippocampal epileptogenesis is coincident with initial neuron loss, not delayed secondary processes. We hypothesize that neuron loss in the entorhinal cortex disrupts the functional separation of Layer II "grid cells," causing abnormal synchronous discharges that invade the dentate gyrus. This, in turn, produces population spikes and epileptiform discharges in granule cells disinhibited by injury-induced hilar neuron loss. Long delays between injury and generalized behavioral seizures, when they occur, may primarily involve a "kindling" process in which initially focal (subclinical) discharges gradually increase in duration and cause clinical seizures. Neuroprotection in the immediate post-injury period, and prolonged anti-kindling therapy, might be the most effective anti-epileptic strategy.

Chapter 35

Alterations in Synaptic Function in Epilepsy

Christophe Bernard

Epilepsy is characterized by the occurrence of seizures and by the presence of comorbidities such as cognitive deficits. Their underlying mechanisms remain unknown. Since seizures and cognition usually involve large networks of millions of neurons, it is difficult to formulate working hypotheses regarding potential mechanisms. The activity of these networks is controlled by numerous parameters. Hence, why should a given parameter (or a set of parameters) be considered to play a more important role than any other? Further, some parameter changes may be crucial for epilepsy, while others may be central for the associated comorbidities. Which parameters are common to both issues, and which ones are specific to the various aspects of epilepsy? Since we do not have a comprehensive understanding of how the brain works, it is very difficult to generate a sound hypothesis-driven research strategy to uncover the mechanisms of epileptogenesis. Our strategy must rely simply upon correlations and comparisons with normal circuits. Since one major locus for the transfer of information/activity is the synapse, it seems reasonable to propose that synaptic modifications may be involved in epilepsy and associated comorbidities.

What do we mean by the phrase *synaptic modifications*? A synapse includes three compartments: the presynaptic terminal, the postsynaptic site, and the glial cell processes surrounding them. The extrasynaptic space will not be considered, although it is known to play a central role in controlling synaptic transmission. A simplified scheme of the transfer of information between two neurons involves the release of neurotransmitters by a presynaptic terminal, the activation of postsynaptic receptors, and the uptake of the neurotransmitters (Fig. 35–1). Many features of the synapse can be modified. The number of synapses established

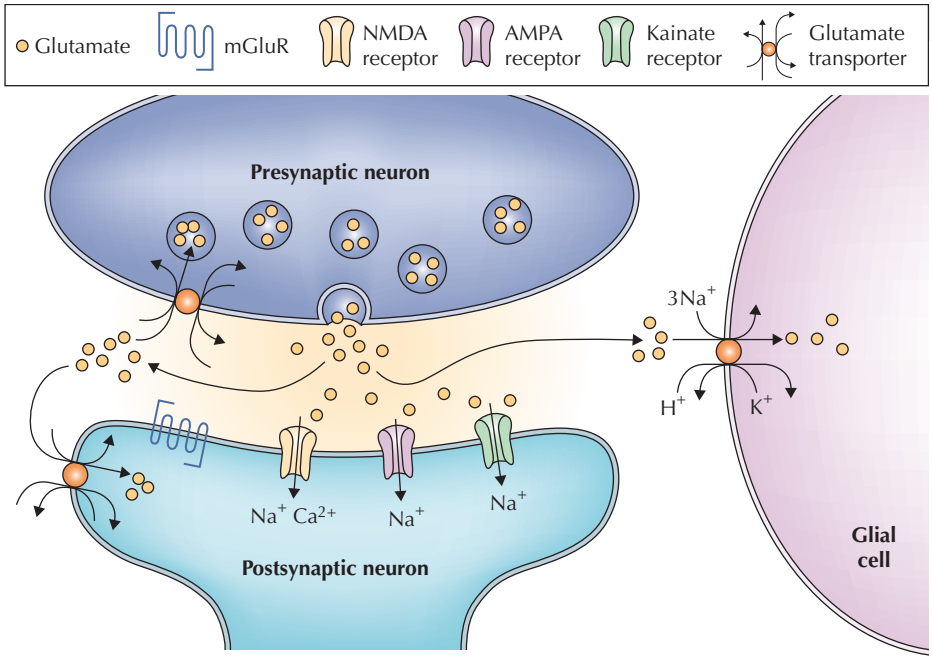

Figure 35–1. Schematic drawing of a glutamatergic synapse, with postsynaptic alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), *N*-methyl-D-aspartate (NMDA), kainate, and metabotropic receptors. Glutamate transporters are present on the presynaptic and postsynaptic sites, as well as on the nearby glial cell process. From Attwell D, Gibb A. Neuroenergetics and the kinetic design of excitatory synapses. *Nat Rev Neurosci*. 2005;6:841–849.

by a given neuron on its targets can decrease (*pruning*, or death of the presynaptic neuron) or increase (sprouting, neosynaptogenesis). The properties of the presynaptic terminal can be changed (release probability, neurotransmitter concentration in vesicles, control by presynaptic receptors). On the postsynaptic site, the number, subunit composition, and function (e.g., phosphorylation, anchoring) of the receptors can be changed. Finally, alterations at the glial cell level may affect the environment of the synapse and its function (neurotransmitter uptake, energy supply to neurons, etc.).

How do alterations in synaptic function relate to seizures and their comorbidities? This question has been particularly difficult to address since epilepsy is often a time-dependent disorder, involving (for example) an initial insult (which may involve genetic alterations, meningitis, brain trauma, etc.) and the subsequent trigger of a number of network modifications. Ultimately, some of these modifications may be directly linked to seizure generation and/or comorbidities. It is therefore important to understand the time course of these changes. This issue has been extensively investigated in experimental models of temporal lobe epilepsy, which are characterized by a latent seizure-free period of about 2 weeks following the initial insult (usually a period of status epilepticus). We will use these models to describe synaptic remodeling and its possible functional consequences in the adult brain, focusing on the hippocampus.

PRESYNAPTIC MODIFICATIONS

Neurons receive information from different sources; information from other neurons is generally transmitted at the level of the synapse. The transfer of information starts with the release of neurotransmitter from the presynaptic terminal. The transfer of information ends with the transformation of this chemical signal into an electrochemical one (the flux of ions via the opening of ionotropic receptors and/or the activation of second messengers via metabotropic receptors).

There are multiple ways to change the transfer of information at the presynaptic level between two neurons. These changes can involve the disappearance of the presynaptic terminals themselves, a modification of the neurotransmitter content in the vesicles, and an alteration in control of the release machinery. Several of these modifications have been described in epilepsy. They are presented below, starting with the most drastic one, the loss of the presynaptic terminals.

Cell Death

The loss of the presynaptic terminals can result from the death of the source neuron. Early work demonstrated the rapid loss of glutamatergic synapses on CA1 pyramidal cells due to the death of CA3 pyramidal cells following kainic acid injection in adult animals.[1–3] Similarly, GABAergic (GABA, gamma-aminobutyric acid) synapses disappear due to the death of interneurons soon after status epilepticus.[4–6] Interestingly, interneuron loss is cell-type specific and an early event. For example, it affects axo-axonic cells and oriens lacunosum moleculare (O-LM) interneurons, which project to initial segment and the distal part of the dendritic tree of pyramidal cells, respectively[5,6] (Fig. 35–2).

How does neuron loss affect the network/system? Certainly, neuronal death should change the way these networks process information. For example, the loss of O-LM interneurons is associated with a decreased GABAergic drive in the distal dendrites of CA1 pyramidal cells and with a large facilitation of entorhinal inputs (which O-LM cells control under normal conditions).[6] This reorganization occurs soon after the initial status epilepticus, during the latent period, days before the first spontaneous seizure.[7] Clearly, such a loss of neurons and synapses is not sufficient, in itself, to facilitate/trigger seizures. Using a theoretical approach, we have proposed that the decreased GABAergic drive provides sufficient conditions for the emergence of interictal activity,[7] which

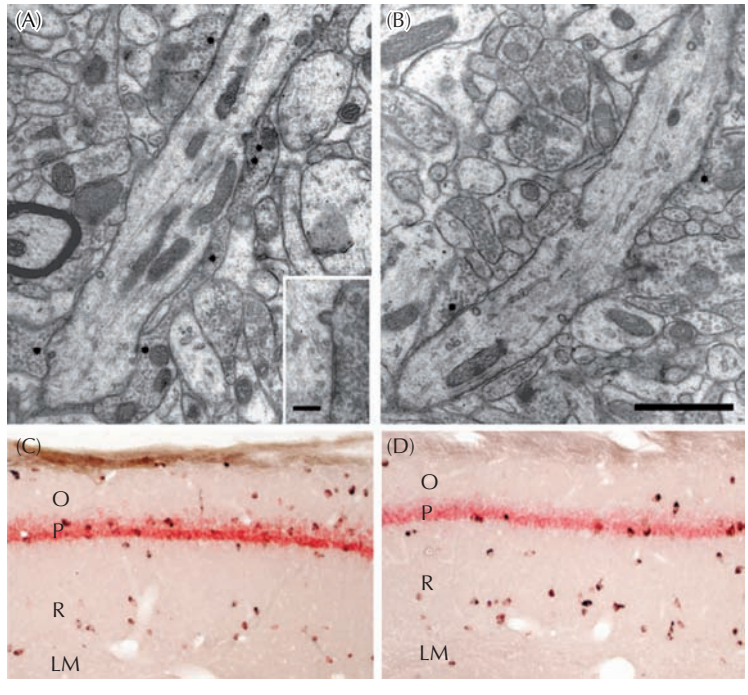

Figure 35–2. Loss of GABAergic synapses. Photomicrograph showing the loss of coverage by symmetrical (GABAergic) synapses (*) of the initial segment of the axon of CA1 pyramidal cells in pilocarpine-treated rats (**B**) compared to controls (**A**). Scale bar, 0.5 µm. **C.** In a control animal, many NeuN- (red) and GAD65 mRNA- (dark) containing neurons can be seen in CA1 stratum oriens (O). Many of these neurons are lost in pilocarpine-treated animals (**D**). They include O-LM interneurons. Adapted from ref. 5.

appears soon after the status epilepticus and which is predictive of epileptogenesis.[7–10] We have also proposed that this reorganization would be causally linked to the degradation of theta rhythm and spatial memory found soon after status epilepticus in these models.[11]

Another example is provided by the loss of cholecystokinin (CCK) basket cells.[12] Basket cells target the soma and proximal dendrites of CA1 pyramidal cells. Two major classes of basket cells can be distinguished based on their neurochemical content: CCK and parvalbumin (PV).[13] Cholecystokinin basket cells appear to degenerate soon after status epilepticus occurs,[12] further supporting the idea that the loss of GABAergic cells is not sufficient to trigger seizures. Cholecystokinin basket cells carry type1 cannabinoid (CB1) receptors on their presynaptic terminals.[14] The activation of CB1 receptors decreases the release of neurotransmitter, in particular GABA, from CCK basket cells.[14] The functional consequence of the loss of such a regulatory pathway remains to be investigated. One might hypothesize that the disappearance of CCK basket cells would increase the functional weight of PV basket cells. Since the latter appear to play a key role in synchronizing large sets of neurons to produce oscillations, an increased PV basket cell contribution may increase the ability of the network to synchronize in a pathological manner.[12,13] It is important to note that the number of CB1-containing GABAergic terminals is not modified in the dentate gyrus from epileptic patients,[15] so it is unclear if this subpopulation of GABAergic neurons is selectively lost in human brain. A change in the CCK/PV basket cell ratio may be species- and/or brain region-dependent.

Finally, the loss of interneurons affects not only GABAergic cells that target principal cells, but also calretinin GABAergic interneurons that contact other interneurons.[16] Such reorganization would remove an inhibitory drive onto interneurons, which may, in turn, contribute to their hyperexcitability in epileptic animals.[6] Since calretinin interneurons may play a central role in synchronizing large ensembles of interneurons, their loss may hamper the capacity of the networks to generate/propagate physiological oscillations[16]—which may help explain the observed decrease in theta rhythm and associated cognitive deficits in epilepsy.[11] Whether the loss of calretinin interneurons increases the synchronization associated with seizures remains to be investigated.

This functional scheme, as intuitively simple as it seems, is based upon what we think we know about brain function. It is in fact simplistic. Losing GABAergic function is generally considered to be bad for the system. But is it? Mutations in the $\alpha 7$ and $\beta 2$ neuronal nicotinic acetylcholine receptor subunit genes result in epilepsy (i.e., GEFS+) . Yet, mouse models of such mutations are characterized by *increased* GABAergic activity, and spontaneous seizures are abolished by the injection of low doses of the $GABA_A$ receptor antagonist picrotoxin.[17]

Similarly, we know that the activation of GABAergic axo-axonic cells can directly excite their targets; GABA has an excitatory action in the initial segment due to the low level of expression of the KCC2 transporter at this site.[18] It could therefore be argued that losing axo-axonic synapses in epilepsy[5,19] would in fact be protective by removing a powerful excitatory and synchronization mechanism. These two examples clearly show that it is very difficult to interpret the observations made in a pathological tissue, if only because we lack a conceptual framework that accounts for the various physiological components of the system.

The loss of neurons can be seen as a drastic modification of the architecture of the network. However, new synapses can be generated, perhaps as a direct consequence of the loss of neurons.

Neosynaptogenesis

Axonal sprouting of glutamatergic neurons has been identified in all hippocampal subfields, including dentate gyrus (mossy fibers), Schaffer collaterals, and CA1 pyramidal cell collaterals.[1,2,20–23] In the CA1 region, the sprouting of CA1 pyramidal cell axons can clearly be identified during the chronic period (i.e., when animals have spontaneous seizures),[22,23] although its time course after the initial insult remains to be established. Interestingly, in the chronically epileptic animal, CA1 axon collaterals innervate the stratum radiatum (Fig. 35–3; a region rarely contacted by CA1 collaterals in normal control animals[23]) and extend farther into the subiculum.[24]

The targeting of new regions has also been established for mossy fibers.[25] The

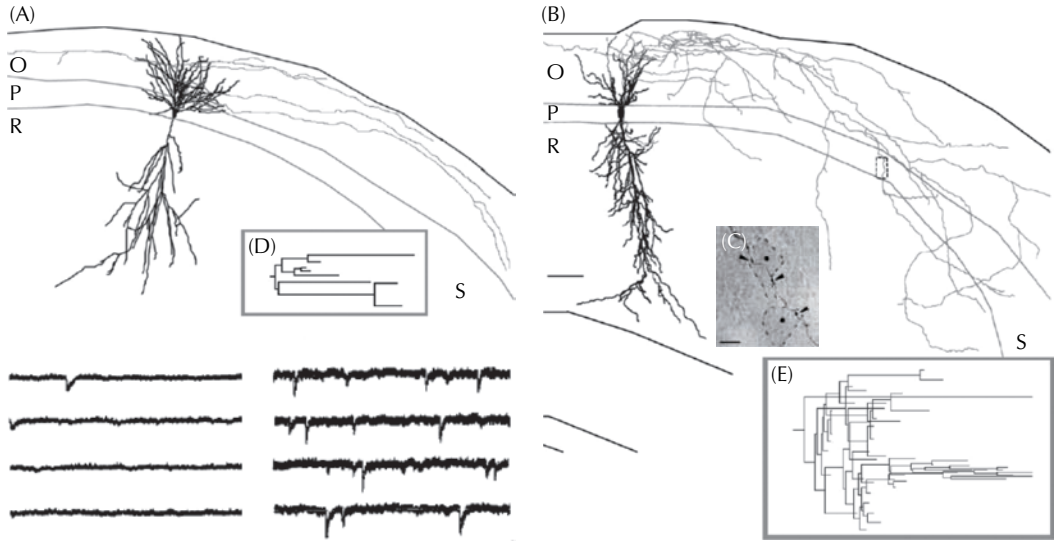

Figure 35–3. Sprouting of CA1 pyramidal cell axon in epileptic animals and increased glutamatergic activity received by pyramidal cells. **A.** Tridimensional reconstruction of a CA1 pyramidal cell in a control animal. Note that the axon (light gray) emits few branches in stratum oriens (O), as shown on the axogram (**D**). **B.** Tridimensional reconstruction of a CA1 pyramidal cell in an epileptic animal. Note that the axon (light gray) displays profuse branching, as shown on the axogram (**E**). Axonal branches cross the pyramidal cell layer (P; panel **C**) and enter stratum radiatum (R), which rarely occurs in control animals. **F.** Patch-clamp recording of the control cell. The downward deflections represent spontaneous AMPA receptor-mediated currents. These glutamatergic events are rare. In contrast, in an epileptic animal, the frequency of these events is considerably increased as a consequence of sprouting (**G**). P: stratum pyramidale, R: stratum radiatum, LM: stratum lacunosum moleculare, S: septum. Adapted from ref. 23.

collateralization of this system appears to depend upon the activation of a serine/threonine kinase (mTOR) that controls protein synthesis linked to cell growth.[26,27] Sprouting is associated with the formation of new synapses[1, 2, 21, 25] that appear to be functional.[23,28] The functional consequence of this neosynaptogenesis include increased connectivity between principal cells and increased glutamatergic drive.[23,28] Although glutamatergic neosynaptogenesis onto GABAergic cells remains to be established, indirect evidence based upon the measure of the frequency of glutamatergic currents received by the surviving interneurons suggests that the sprouting of excitatory axons also targets interneurons.[6]

Early work on the Schaffer collateral pathway led to the hypothesis that the loss of synapses due to presynaptic neuronal death would trigger sprouting and reactive synaptogenesis.[1,2] Whether the death of interneurons following the initial insult also triggers a similar mechanism remains to be clearly established. If it does, it does not fully compensate for the initial loss, since the number of GABAergic synapses on principal cells remains decreased in epileptic animals compared to controls.[5] However, a class of GABAergic cells located in the hilus, and containing somatostatin, displays axonal sprouting and establishes more synaptic contacts with granule cells in epileptic animals.[29] It has been argued that such sprouting may act as a mechanism to compensate for some of the GABAergic neurotransmission that is lost after the death of vulnerable populations of GABAergic interneurons.[29] It will be important to determine the time course of this sprouting after the initial insult in order to relate it to epileptogenesis.

Available information indicates that sprouting of glutamatergic and GABAergic fibers is not an early event. It is tempting to propose that it is causally related to the occurrence of seizures, that is, that increased connectivity is necessary for seizure genesis and propagation. According to this hypothesis, sprouting in the dentate gyrus would create hub cells, which could favor seizure genesis.[30,31] At present, we can only propose a correlation, not causality.

In addition to a morphological reorganization (loss of terminals and neosynaptogenesis),

presynaptic terminals function is modified in epileptic tissue.

Presynaptic Terminal

One key function of presynaptic terminals is the release of neurotransmitter, a process that involves complex machinery regulated by numerous proteins, including presynaptic receptors. There are numerous ways to affect neurotransmitter release, many of which could play a role in epileptogenesis and seizure genesis/propagation. The end product of such modifications is the modulation of the amount of neurotransmitter that is released.

The filling of vesicles can be dynamically modulated. For example, the filling of glutamate vesicles requires allosteric activation by Cl^-.[32] Ketone bodies compete with Cl^- for this allosteric activation and reduce glutamate content in the vesicle, which may contribute to the antiepileptic effect of the ketogenic diet.[32] The filling of GABAergic vesicles can also be modulated. Reactive astrocytosis induces downregulation of glutamine synthetase, which results in decreased GABA synthesis and GABA content in synaptic vesicles (cf. the section "Glial Modifications" later in this chapter).[33] Inflammation, reactive astrocytosis, and decreased glutamine synthetase activity occur soon after the initial insult and are maintained during epileptogenesis.[34,35] These changes should result in decreased GABA content in vesicles. Since there is currently no direct way to measure precisely the neurotransmitter content in vesicles, one must rely on the amplitude distribution of miniature inhibitory postsynaptic currents (mIPSCs) for an indication. In CA1 pyramidal cells, the amplitude of mIPSCs is decreased in epileptic animals, lending support to this hypothesis.[36] In contrast, the amplitude of mIPSCs is increased in dentate granule cells[37] (but see ref. 38). Since the amplitude of mIPSCs depends upon many factors (including the subunit composition, the number of receptors, their phosphorylation state, etc.), it is difficult to draw strong conclusions regarding synaptic filling based on mIPSC analysis (it only provides indirect arguments).

In addition to altered vesicle filling, defects in neurotransmitter release may alter synaptic transmission. A decrease in the reserve pool of GABA-containing vesicles in presynaptic terminals contacting CA1 pyramidal cells may explain a decrease in mIPSC frequency,[36] since miniature events appear to reflect release of the reserve pool rather than release from the immediate releasable pool, at least in glutamatergic terminals.[39] Paired recordings between basket cells and dentate granule cells revealed a decreased probability of release despite a larger size of the immediate releasable pool.[40] Changes in the release machinery (e.g., in presynaptic Ca^{2+} channels) or a different tonic control by presynaptic receptors (e.g., by $GABA_B$, mGluRs, CB1) may explain these modifications.

For example, there is a downregulation of CB1 receptors and of the endocannabinoid machinery in human epileptic tissue.[41] Interestingly, CB1 downregulation affects glutamatergic but not GABAergic terminals, which would remove an important regulatory component of glutamate (excitatory neurotransmitter) release and act as a pro-epileptic factor.[14,42]

The presynaptic terminal is a complex unit of signal integration with multiple control pathways. There are thus countless ways to alter synaptic transmission, many/all of which may be brain state-dependent, since the transmission of information between pre- and postsynaptic elements depends upon the frequency and duration of presynaptic signals. At present, it is not possible to provide a clear picture of the real functional consequences of these reorganizations.

Once neurotransmitters are released, they activate postsynaptic receptors. As is the case for the presynaptic terminal, there are countless ways to change the transfer of information by altering components of the postsynaptic site.

POSTSYNAPTIC MODIFICATIONS

The mechanisms that are known to control $GABA_A$ receptors will be used below as typical examples of how postsynaptic receptors might be modulated; similar considerations could be developed for ionotropic and metabotropic glutamate receptors. These mechanisms are described in the caption of Fig. 35–4.

One key point about this synapse is that $GABA_A$ receptor trafficking is very fast (5 min for subunit assembly, 20 min for cycling).

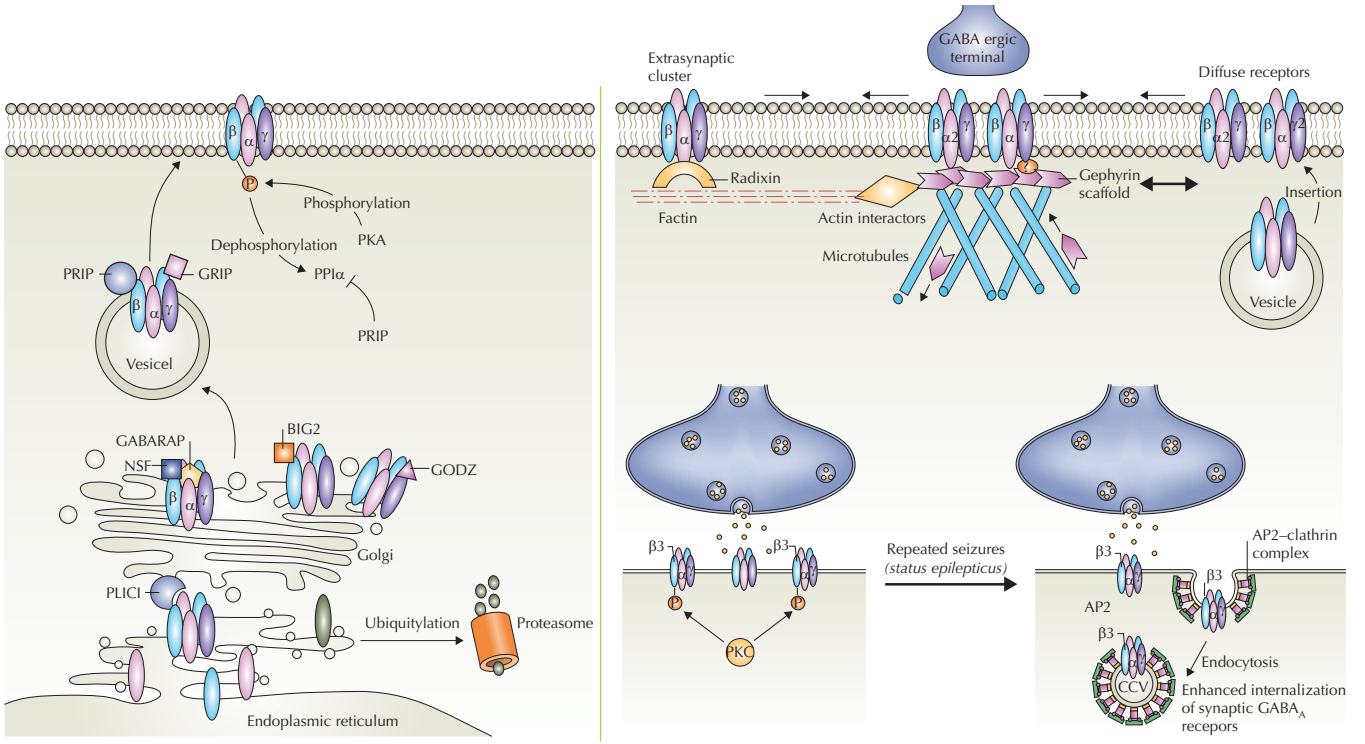

Figure 35–4. Gamma-aminobutyric acid A receptor trafficking. Left panel: Gamma-aminobutyric acid A receptors have a pentameric structure usually made of two α, two β, and one γ subunit. These subunits are assembled in the endoplasmic reticulum to form the receptor. Some of these are ubiquinated to be degraded by the ubiquitin-proteasome system. The ubiquitin-like protein PLIC1 prevents this degradation. Exit from the Golgi apparatus is facilitated by a number of proteins, which can associate with β subunits including GABARAP ($GABA_A$ receptor-associated protein), NSF (*N*-ethylmaleimide-sensitive factor), BIG2 (brefeldin-A-inhibited guanosine diphosphate/guanosine triphosphate exchange factor 2), and γ2 subunits such as GODZ (palmitoyltransferase Golgi-specific DHHC zinc-finger-domain protein). The receptors are then trafficked to the membrane in vesicles, a process that depends upon other proteins such as PRIP (phospholipase-C-related catalytically inactive protein) and GRIF ($GABA_A$ receptor-interacting factor protein). Once inserted, $GABA_A$ receptor properties can be modulated by phosphorylation and dephosphorylation processes. Right top panel: Mobility of $GABA_A$ receptors. Postsynaptic receptors are anchored to microtubules via the interaction between α2 subunits and gephyrin. Gephyrin is also associated with γ2 subunits via an unknown interacting protein. Gamma-aminobutyric acid A receptors can diffuse into and out of the synapse (lateral diffusion). In addition to postsynaptic clusters of receptors, extrasynaptic $GABA_A$ receptors can also be identified. They contain the α5 subunit, which links them to radixin, which is bound to F-actin. These receptors participate in the tonic current. Right bottom panel: Internalization of $GABA_A$ receptors during status epilepticus. Status epilepticus leads to the dephosphorylation of β3 subunits (usually phosphorylated by protein kinase C [PKC]). As a consequence, AP2 (clathrin-adaptor protein 2) can associate with $GABA_A$ receptors, leading to clathrin-dependent endocytosis. Adapted from Jacob TC, Moss SJ, Jurd R. GABA(A) receptor trafficking and its role in the dynamic modulation of neuronal inhibition. *Nat Rev Neurosci*. 2008;9:331–343.

Although many mechanisms and interacting proteins remain to be identified, the schemes presented in Fig. 35–4 clearly show the diversity of the postsynaptic control systems of GABAergic neurotransmission. These various mechanisms reflect the many parameters that can be altered in epilepsy.

Trafficking of $GABA_A$ Receptors in Epilepsy

After a status epilepticus, $GABA_A$ receptors are internalized.[43,44] The resulting loss of postsynaptic $GABA_A$ receptors may explain why status epilepticus may become pharmacoresistant, at least in response to drugs targeting $GABA_A$ receptors such as benzodiazepines.[43,44] The underlying mechanism involves the dephosphorylation of the β3 subunit, which enables the association between clathrin adaptor 2 (AP2) and β3, and internalization[45] (Fig. 35–4). As might be predicted, blocking this pathway restores GABAergic activity.[45] In addition to internalization, network hyperexcitability increases the lateral diffusion of receptors, which naturally occurs in physiological conditions (Fig. 35–4). As a result, fewer $GABA_A$ receptors are present postsynaptically in hyperexcitable brain, decreasing the amplitude of mIPSCs.[46] These two mechanisms—receptor internalization and receptor diffusion—constitute two examples of fast removal of $GABA_A$ receptors from the postsynaptic site. Whether increased lateral diffusion and endocytosis occur after a spontaneous seizure, and whether they constitute a stable feature during epileptogenesis and the chronic period, remain to be investigated.

Changes in Subunit Composition

A straightforward way to change GABAergic function (in a permanent fashion) is to alter the subunit composition of the receptors.[47] Such modifications constitute a hallmark of human epileptic tissue.[48,49] The modifications observed in human tissue are very similar to those reported in experimental animal models.[50] These changes are area-specific; for example, $GABA_A$ receptors appear to be upregulated in the dentate gyrus but downregulated in CA1.[50] A detailed analysis of the dentate gyrus revealed a change in subunit composition, which appears early during epileptogenesis and persists during the chronic phase.[51] This reorganization is associated with increased GABAergic currents, decreased sensitivity to zolpidem (a nonbenzodiazepine that can potentiate $GABA_A$ receptors), and increased inhibition by Zn^{2+}.[51] Since network function may depend upon the kinetics of receptors, alterations in $GABA_A$ receptor kinetics may potentially lead to altered network dynamics. The functional impact of these changes remains to be addressed.

As displayed in Fig. 35–4, $GABA_A$ receptor clusters can also be formed extrasynaptically. They are responsible for the presence of a tonic GABAergic current, which represents more than 75% of the total (transient and tonic) GABAergic current received by principal cells.[52] The subunit composition of extrasynaptic receptors is also modified after the initial insult.[53,54] In particular, there is decreased expression of the δ subunit, which results in decreased sensitivity of the tonic current to neurosteroids.[55] Despite the loss of δ subunit-containing receptors, the magnitude of the tonic current is not modified in epileptic animals, suggesting the presence of compensatory mechanisms.[54] A redistribution of the γ2 subunit to the perisynaptic domain may also participate in the decrease of the amplitude of synaptic GABAergic currents in epileptic tissue.[54]

Alterations in Chloride Homeostasis

Two main ions can transit via the channel opened by $GABA_A$ receptors: Cl^- and bicarbonate. Bicarbonate leaves the cell, but the direction of Cl^- flux critically depends upon the intracellular concentration of Cl^-.[56] If it is low, Cl^- enters the cell, which hyperpolarizes the membrane. If it is high, Cl^- leaves the cell, which depolarizes the membrane. The internal concentration of Cl^- depends upon various transporters (e.g., KCC2, which extrudes Cl^-, and NKCC1, which pumps Cl^- into the cell) and chloride channels (e.g., ClC2). These systems can be dynamically regulated. For example, GABA appears to have an inhibitory action in physiological conditions in the immature intact hippocampus in vitro,[57] and also in vivo in the cerebellum,[58] but shifts to a depolarizing

action after several seizures due to hyperactivity of NKCC1.[57] This result may explain why seizures become resistant to drugs potentiating $GABA_A$ receptors at early developmental stages in humans. Counteracting NKCC1 with the diuretic bumetanide restores the inhibitory action of GABA and renders seizures sensitive to drugs potentiating $GABA_A$ receptors.[57]

In adult human epilepsy, 20% of subicular cells are depolarized by GABA[59] due to the downregulation of the KCC2 transporter in these cells.[60] A shift to a depolarizing action in a minority of cells may be sufficient to favor the occurrence of interictal spikes.[59]

GLIAL MODIFICATIONS

Astrocytes play crucial roles in regulating numerous functions, from blood flow to neuronal activity. In addition to controlling extracellular levels of K^+ and neurotransmitters (e.g., glutamate), they can respond to various neurotransmitters and hormones and release several factors, such as glutamate, adenosine triphosphate (ATP), and others.[61,62] Alterations in astrocytic function in epilepsy may directly alter synaptic function. Several important modifications have been reported.[62] Only alterations that could change synaptic function are described below.

The first obvious change is morphological. Epileptic tissue is characterized by the presence of reactive astrocytes, as assessed by the overexpression of glial fibrillary acidic protein (GFAP). What could be the functional consequences of this reaction? Astrocytes possess an extensive network of processes. One astrocytic domain can cover approximately 150,000 synapses, a volume that does not overlap with that of neighboring astrocytes in normal conditions. This organization is lost in experimental epilepsy, where there is a 10-fold increase in overlap.[63] The functional consequence of such reorganization is not known, but it has been suggested to be linked to the parallel increase in dendritic spines.[63]

Increased overlap of astrocytic domains could facilitate neuronal synchronization. Astrocytes can release glutamate (or D-serine), producing *N*-methyl-D-aspartate (NMDA) receptor-dependent slow inward currents in neurons, which, in turn, may facilitate neuronal synchronization.[64] Such a scheme has been proposed to play a central role in seizure genesis,[65] although the issue remains controversial.[66] Furthermore, the release of glutamate appears to be increased in astrocytes in epilepsy.[62,67–69] Reactive astrocytes and microglia release tumor necrosis factor α (TNFα), a cytokine that can act on TNFR1 receptors. The activation of TNFR1 increases the production of prostaglandin 2, which, in turn, can amplify glutamate release. If such a mechanism is at play in epilepsy, there should be an increase of slow inward currents in neurons, which remains to be tested experimentally. Another important cytokine released by reactive astrocytes is interleukin 1β (IL-1β). Interleukin 1β can boost NMDA receptor responses via the activation of Src tyrosine kinases and subsequent NR2A/B subunit phosphorylation, which could favor hyperexcitability.[70]

Under physiological conditions, NMDA receptors are blocked most of the time by Mg^{2+}, that is, they do not conduct any current when activated by glutamate. In contrast, in the epileptic hippocampus, NMDA receptors contribute directly to glutamatergic neurotransmission and produce a long-lasting depolarization of neurons.[71] The origin of such an increase in the NMDA contribution has remained elusive, although a change in the redox state of NMDA receptors has been proposed as an important contributing factor.[72]

Other changes in astrocytic function may increase the likelihood of neuronal synchronization. Astrocytes play an active role in regulating the extracellular concentration of glutamate, K^+ and water content.[62] Epileptogenesis is associated with changes in gene expression in astrocytes.[73] A marked downregulation of two genes coding for two astrocytic glutamate transporters results in reduced astrocytic glutamate uptake. Current data suggest that the functional consequence of this change is marginal and is seen only during high-frequency (>100 Hz) stimulation.[73] In addition to glutamate transporters, there is a marked reduction in the expression of the inwardly rectifying K^+ channel, Kir4.1, in astrocytes, resulting in decreased K^+ buffering capacity and facilitation of glutamatergic synaptic responses.[73]

It is important to note that Kir1.4 acts in concert with aquaporin 4 (AQP4) to regulate K^+ and water levels in the extracellular space. Seizure genesis leads to cell swelling, reducing

the extracellular space and favoring hyperexcitability.[74] The downregulation of APQ4 and its redistribution away from the astrocytic endfeet in epilepsy[75,76] may further impair K^+ buffering and favor hyperexcitability.

In addition to postsynaptic/extrasynaptic consequences, as described above, astrocytic dysfunction may have pro-epileptic effects at presynaptic sites. Synaptic function critically depends upon the glutamate-glutamine cycle. Glutamate transported into astrocytes is transformed into glutamine by glutamine synthetase. Glutamine is then exported to neurons, where it is transformed into glutamate by the mitochondrial glutaminase. Glutamate is then reused as such or transformed into GABA. Inhibition of glutamine synthesis results in specific downregulation of GABAergic neurotransmission involving a presynaptic mechanism (decreased vesicular GABA content).[77] Reactive astrocytosis reduces GABAergic neurotransmission,[33] perhaps since there is a downregulation of glutamine synthetase in epileptic tissue.[73] Depleted GABAergic terminals may favor the occurrence of paroxysmal discharges.

FUNCTIONAL CONSEQUENCES OF THESE MODIFICATIONS

The reorganizations occurring around the synapse are extremely diverse and complex. What could be the functional consequences? The hypotheses are admittedly very speculative, since we do not know the role of each parameter under physiological conditions. Very importantly, a drastic alteration of one parameter (e.g., the loss of GABAergic inhibition or its transformation into excitation) may have no functional impact. This is a key concept derived from Eve Marder's work,[78] summarized below. Simply put, this work, performed in the stomatogastric system of the lobster, has led to the concept that there are multiple solutions to a given biological problem. The stomatogastric system, which generates a rhythm vital for the animal, is composed of three nuclei connected to each other via different neurotransmitter systems. Knowing the types of channels expressed by the neurons in each nucleus and the types of connections, the researchers built a computer model in which each parameter (e.g., amplitude of the ionic current, strength of the connection) could take any biologically realistic value. They varied all the parameters and selected the sets of parameters that produced the same rhythm recorded in vivo. They found that there are countless possible solutions, which produce the same behavior at the network level.[78] Importantly, they also found that the system is resistant even if one type of channel is not expressed or if a connection between two nuclei is missing. Further, the values taken by a given parameter (among the sets of solutions) match the biological variability.[79,80] That is, the variability of a given parameter measured in a biological system (e.g., amplitude of $GABA_A$ receptor-mediated currents) may just reflect the different solutions that enable networks to function adequately. One might therefore consider that all the modifications occurring in epileptic networks (including those described above) may simply constitute the expression of another set of solutions to perform normal physiological function. Seizures are, after all, very infrequent events—which suggests that most of the time the system can cope with various parameters' permutations without engaging in abnormal activity.

Nevertheless, important functional changes in epilepsy appear to stem from some of the synaptic modifications identified so far. We'll consider interictal activity and cognitive deficits.

Interictal Activity

Interictal-like activity appears very early after the initial insult in experimental models, and precedes (by days) and even predicts the appearance of the chronic phase of epilepsy defined by recurrent seizures.[7,8,81] Using a crude model of hippocampal circuitry, we have tried to determine the conditions sufficient for the genesis of interictal spikes.[7] Many different solutions exist, which include decreased dendritic GABAergic inhibition and increased glutamatergic excitation,[7] in a range of values found experimentally.[6,7] This model does not explain why interictal activity is not permanent in vivo, but it suggests clues regarding its underlying mechanisms. Since interictal activity is rarely encountered in nonepileptic individuals, it has been proposed that it is pathological. Studies performed in vitro suggest that interictal-like activity can produce long-term potentiation of

synapses, thus contributing to the construction of hyperexcitable networks.[82] The presence of interictal-like activity during the earliest stages of epileptogenesis may not only constitute biomarkers for at-risk patients, but also one core mechanism of epileptogenesis.[7,8,81] One study performed in patients with temporal lobe epilepsy suggests that the size of the epileptogenic zone increases with the duration of epilepsy.[83] The brain regions outside the epileptogenic zone (i.e., the irritative zone) are often characterized by the presence of interictal spikes. Some of these regions become part of the epileptogenic zone as epilepsy evolves over time.[83] It is therefore tempting to propose that interictal spikes participate in the transformation of the irritative regions into epileptic ones.

Cognitive Deficits

Interictal spikes may have other deleterious consequences, in particular for learning and memory processes. Interictal spikes correspond to a more or less synchronous firing of large populations of cells.[84,85] In physiological conditions, groups of hippocampal cells fire in a coordinated and precisely timed fashion, in particular during replay for the storage of information or its transfer.[86] In keeping with this scheme, interictal spikes have deleterious cognitive consequences during memory retrieval in experimental epilepsy.[87]

Cognitive deficits are consistently found in epileptic patients, but their underlying basis is yet to be determined. Since hippocampal circuitry is drastically modified after the initial insult in experimental animals, it is tempting to propose that the normal physiological functions performed by these circuits are altered. Consistent with this prediction, spatial memory performance is decreased soon after the initial insult.[11] This type of memory depends upon the hippocampus (which is considerably reorganized); in contrast, nonspatial memory, which is hippocampus-independent, is preserved during epileptogenesis and the chronic period.[11] The same study showed that the theta rhythm (4–12 Hz), which plays a key role in numerous cognitive processes,[86] is altered soon after the initial insult, and that spatial performance is proportional to the power of the theta rhythm.[11] These results are consistent with the proposal that altered circuitry should result in dysfunctions. However, they are only correlative; causality has not been demonstrated.

REPAIR STRATEGIES

Several biomarkers have been proposed to predict the construction of an epileptic brain, including inflammatory factors, interictal spikes, and cognitive deficits.[7,11,81,88] Validation of these markers in prospective studies of at-risk patients would open the way to the development of preventive treatments. Since the circuitry is modified soon after the initial insult, it is important to determine the mechanisms responsible for these reorganizations. Alternatively, one could simply try to repair the circuits (without knowledge of the pathological mechanisms). As mentioned above, cell death is a hallmark of epilepsy. It is also an early event. Interestingly, the delivery of viral vectors to supply fibroblast growth factor-2 (FGF-2) and brain-derived neurotrophic factor (BDNF) after the initial insult increased neurogenesis, limited cell damage, and reduced the severity of epilepsy in an experimental model.[89] These findings suggest that the circuitry may be repaired, even partially, after the damage has been done.

Is it possible to act upstream to prevent these changes? To do so would require an understanding of the mechanisms responsible for the reorganization of the circuitry. Key aspects of the early processes triggered by the initial insult are now under investigation and include the rupture of the brain-blood barrier, oxidative stress, and inflammation.[34,35,90,91] Experimental studies have shown that acting on these parameters can be disease-modifying (i.e., may decrease the damage and/or the severity of epilepsy), although none of these attempts have managed to stop the occurrence of spontaneous seizures.[34,35,90,91]

CONCLUSION

The previous considerations clearly demonstrate that many types of reorganization take place at the synaptic level soon after an initial epileptogenic insult. Whether these reorganizations play a role in epileptogenesis, seizure genesis/propagation, or cognitive

deficits remains an open question. All of our studies are correlative. None can show causality since we do not know the role of each parameter under physiological conditions.

Granule cells of the normal adult rodent dentate gyrus generally have the typical morphology of bipolar cells. Their apical dendrites arise from one pole and arborize into the molecular layer, while the axon originates from the base of the granule cell body and extends into the hilus subjacent to the granule cell layer.[1] Two exceptions to this rule have been observed. Sometimes recurrent basal dendrites arise from the base of granule cell bodies and then curve back through the granule cell layer in the direction of the molecular layer, where they join apical dendrites.[2–4] Despite this unusual origination, dendrites of dentate granule cells in rodents arborize exclusively in the molecular layer. The other exception is the rare instance of an axon originating from the granule cell's apical dendrite or the apical pole of its cell body.[4] In this instance, the axon descends into the hilus without giving rise to collaterals. Both of these morphologies suggest that rat granule cells are more heterogeneous than was previously indicated.

Dentate granule cells from humans and nonhuman primates differ from granule cells from rodents; primate granule cells commonly have

basal dendrites. Seress and Mrzljak[5] were the first to show that primate granule cells display basal dendrites in normal brain. Other studies confirmed this observation and showed that many granule cells in monkey have basal dendrites that enter the hilus.[6] These basal dendrites have large, complex spines and smaller "stubby" spines. About 10% of granule cells in the monkey dentate gyrus exhibit basal dendrites. Pertinent to this review is the finding that greater numbers of granule cells with hilar basal dendrites are found in the temporal lobes of epileptic humans compared to normal human control tissues.[7,8] The remainder of this chapter will focus on the seizure-induced formation of hilar basal dendrites in rodents and the potential significance of hilar basal dendrites in epileptogenesis.

SEIZURE-INDUCED HILAR BASAL DENDRITES IN RODENTS

Seizure-induced hilar basal dendrites on dentate granule cells have been observed in the brains of epileptic animals (Fig. 36–1). Using rats in which the perforant path was stimulated to cause seizures, Spigelman et al.[9] showed that 6%–15% of Golgi-impregnated granule cells had basal dendrites that extended into the hilus. In contrast, basal dendrites were not observed in control animals. The presence of basal dendrites on dentate granule cells in the kainic acid model of temporal lobe epilepsy was described shortly afterward by Buckmaster and Dudek.[10] A subsequent study of rats with pilocarpine-induced seizures provided evidence for basal dendrites on dentate granule cells in yet another model of epilepsy.[3] Therefore, in three unique models of temporal lobe epilepsy, anatomical studies demonstrate the formation of basal dendrites on granule cells of the dentate gyrus. In addition, rats with amygdala kindling also have granule cells with hilar basal dendrites.[11] Therefore, it is reasonable to assume that hilar basal dendrites in rats form after both seizures and excessive neuronal activity within the limbic system.

The basal dendrites observed on granule cells from epileptic rats were densely packed with spines along their length, and these spines were similar in morphology to those found on the apical dendrites of granule cells.[9] These

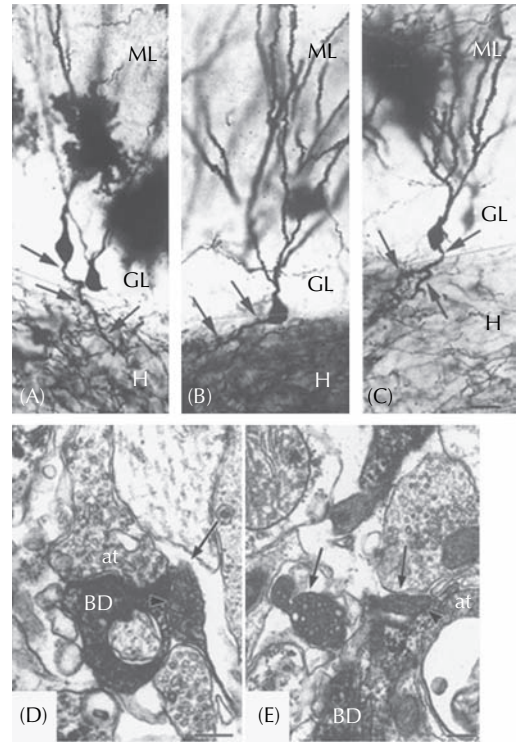

Figure 36–1. Light (**A–C**) and electron (**D,E**) micrographs of hilar basal dendrites. As can be seen in the light micrograph (**A–C**), the basal side of the neuron (arrows) has a dendritic process that extends into the deep hilus. In **D**, there is a labeled basal dendrite (BD) that is postsynaptic (arrowhead) to a labeled axon terminal (arrow). **E.** A hilar basal dendrite with a spine that is postsynaptic (arrowhead) to a labeled axon (arrows). Scale bar: 10 μm in **A–C**, 0.5 μm in **D** and **E** ML, molecular layer; GL, granule cell layer; H, hilus.

dendrites commonly originated from the base of the granule cell body (on the hilar side) and could be clearly distinguished from the axon initial segment.[3] It was rare for the basal dendrite to arise from the lateral side of the granule cell body or the apical dendrite.[9] These basal dendrites run horizontally beneath the granule cell layer or extend relatively straight into the hilus, perpendicular to the granule cell layer. The basal dendrites either branch or remain unbranched. Their lengths vary between 200 and 500 μm, and the basal dendrites populate the subgranular region of the hilus (previously defined as the first 50 μm subjacent to the granule cell layer). Most of the granule cells with basal dendrites have cell bodies located at the hilar border of the granule cell layer or within one or two cell bodies away from this border.

Using electron microscopy, hilar basal dendrites were analyzed in hippocampal slices following biocytin injections into the stratum lucidum of CA3 to retrogradely label the projecting granule cells.[3] Granule cells at the border of the hilus had spiny dendrites projecting into the hilus. Both the spines and dendritic shafts of these biocytin-labeled basal dendrites were postsynaptic to axon terminals (Fig. 36–1). The fact that some of the labeled spines and dendrites were postsynaptic to small biocytin-labeled axon terminals[3] suggested that the granule cells with basal dendrites participated in synaptic circuitry with mossy fiber synapses derived from other dentate granule cells. Subsequent electron microscopic analysis revealed that less than 10% of the synapses on seizure-induced basal dendrites were GABAergic (GABA, gamma-aminobutyric acid); the great majority appeared to be excitatory.[12] These electron microscopic data support the view that the synapses on basal dendrites of granule cells from epileptic animals are likely involved in additional excitatory feedback circuits that could play a role in seizure propensity.

SYNAPTIC CONNECTIONS OF HILAR BASAL DENDRITES

Granule cell basal dendrites are observed in temporal lobe epilepsy,[3,9,10] in other pathophysiological conditions,[13] and normally (to a variable extent) in primates.[6] The functional consequences of this special subpopulation of granule cells depend largely on the synaptic inputs received by basal dendrites and how those inputs differ from those of granule cells with only apical dendrites. Available evidence indicates that basal dendrites receive excitatory input primarily from neighboring granule cells, and this input establishes a recurrent excitatory positive-feedback circuit.[3,12] Basal dendrite involvement in additional circuits has been shown or is suspected, but many questions remain.

Excitatory Synapses

Ultrastructural evidence has been used to characterize excitatory synapses onto basal dendrites.[3,12,14–16] Ribak et al.[3] were the first to demonstrate that granule cell axons (mossy fibers) are at least one source of excitatory synaptic input onto basal dendrites. Mossy fiber synapses with basal dendrites were identified later in epileptic p35 knockout mice.[17] Mossy fiber synapses with basal dendrites create a monosynaptic and local positive-feedback circuit among granule cells. The aberrant circuit is local (and constrained along the septotemporal axis) because mossy fibers remain close to their granule cell of origin, even in epileptic animals with mossy fiber sprouting.[10] Since mossy fibers are concentrated in the hilus, they probably account for a substantial fraction of excitatory synaptic input to basal dendrites. In addition, mossy fibers from epileptic pilocarpine-treated rats are the major source of excitatory synapses to apical dendrites and somata of hilar ectopic granule cells.[18,19]

Widespread convergence of excitatory connections onto hilar basal dendrites might contribute to seizure activity in epileptic animals. For example, other glutamatergic neurons, including mossy cells and CA3 pyramidal cells, extend their axons into the hilus,[20] where they may synapse with basal dendrites. Normally in control animals, mossy cells and CA3 pyramidal cells are directly and strongly excited by granule cells. Mossy cells, in turn, project their axons into the inner molecular layer, where they synapse with granule cell apical dendrites.[21,22] To a lesser extent, some CA3 pyramidal cells also extend axons into the inner molecular layer[23,24] and likely synapse with granule cell apical dendrites. Disynaptic recurrent excitation to granule cells might be exaggerated in epileptic animals because of axonal sprouting by the surviving mossy cells and CA3 pyramidal cells[25] and the formation of new synapses between these aberrant axon collaterals with basal dendrites.

Computational models can provide additional confirmation of the significance of the increased excitatory drive due to basal dendrite formation. Several studies in recent years have demonstrated the role of reduced numbers of hilar mossy cells in subsequent hippocampal excitability.[26–29] Soltesz and colleagues[27,28] have used large-scale modeling of hippocampal excitability, in particular the dentate gyrus, to evaluate network architectural changes and their contributions to

epileptogenesis and hyperexcitability. They constructed a functional model of the dentate gyrus containing several of the major glutamatergic and GABAergic cellular subtypes. Simulations using this model demonstrated that decreasing the number of hilar cells resulted in significant decreases in global connectivity, but the sprouting of granule cell axons resulted in increased local connectivity.[27] The net effect of hilar cell loss and mossy fiber sprouting was increased hyperexcitability within the dentate gyrus. A recent extension of these computational studies suggested that granule cells with hilar basal dendrites could play an important role in generating seizure activity.[28] Specifically, using the functional model containing hilar cell loss and mossy fiber sprouting, the inclusion of various nonrandom granule cell microcircuits in the dentate gyrus was explored. It was shown that a small number of highly interconnected granule cells, or *hubs*, in the network were sufficient to enhance hyperexcitability. The establishment of new synapses on basal dendrites[12] is consistent with the predictions generated from this model. Even though the estimates for such hub cells range from 5% to 20% of the total granule cell population, the relatively low number of hubs was apparently large enough to promote hyperexcitability. In these computational models, it is also important to note that changes in GABAergic connectivity,[30–32] dentate gyrus inputs,[26] cellular geometry,[33] and alterations of intrinsic currents[29] can also modulate granule cell and network excitability. More importantly, physiological and anatomical observations can now be modeled in silico to test new hypotheses and guide future experimental work.

Most excitatory synapses with granule cell apical dendrites are axo-spinous, and that is also true for basal dendrites.[12] However, direct connections of excitatory synapses onto the dendritic shaft are up to four times more common on basal dendrites than on apical dendrites.[12] Similarly, in epileptic pilocarpine-treated rats, dendrites of hilar ectopic granule cells receive a disproportionately large fraction of mossy fiber synapses directly with the dendritic shaft.[19] It is unclear why these aberrant targets in the hilus are more likely to receive excitatory synapses on shafts versus spines, and the functional consequences of these excitatory shaft synapses remain to be elucidated.

The functional effects of basal dendrites are difficult to isolate and test because surgically resected tissue available for study from patients with temporal lobe epilepsy and animal models typically display mossy fiber sprouting into the molecular layer,[34,35] where apical dendrites are located. In these cases, aberrant recurrent excitation among granule cells could be attributable to sprouted mossy fibers that synapse with apical dendrites, basal dendrites, or both.[12,36] Control adult macaque monkeys, on the other hand, have few if any mossy fiber projections into the molecular layer, and approximately 10% of their granule cells have basal dendrites[5] (compared to control adult rodents, in which they rarely occur[9,37,38]). In hippocampal slices from macaque monkeys, mossy fibers were antidromically stimulated and synaptic responses recorded to compare recurrent excitation in granule cells with and without basal dendrites.[39] Excitatory postsynaptic currents were significantly more likely to be evoked and amplitudes were larger in granule cells with basal dendrites. However, since the stimulation paradigm might have activated other axons besides mossy fibers, the possibility of input from CA3 pyramidal cells or mossy cells to basal dendrites could not be excluded. Recordings and intracellular labeling of monosynaptically coupled pairs would be a more rigorous and direct test of the strength and efficacy of unitary synaptic events generated in basal dendrites. Even without those data, currently available functional evidence is consistent with anatomical results showing that mossy fibers synapse with basal dendrites—and thereby produce recurrent excitation among granule cells. These electrophysiological observations have also been modeled and predict virtually similar output—namely, enhanced excitation.[28]

Inhibitory Synapses

In addition to excitatory synapses, basal dendrites in epileptic pilocarpine-treated rats receive GABAergic input[12] (Fig. 36–2). The relative proportion of GABAergic versus glutamatergic synapses is different in apical versus basal dendrites. GABAergic synapses account for 20% and 28% of all synapses with granule cell apical dendrites in control and epileptic rats, respectively.[40] In contrast, GABAergic synapses

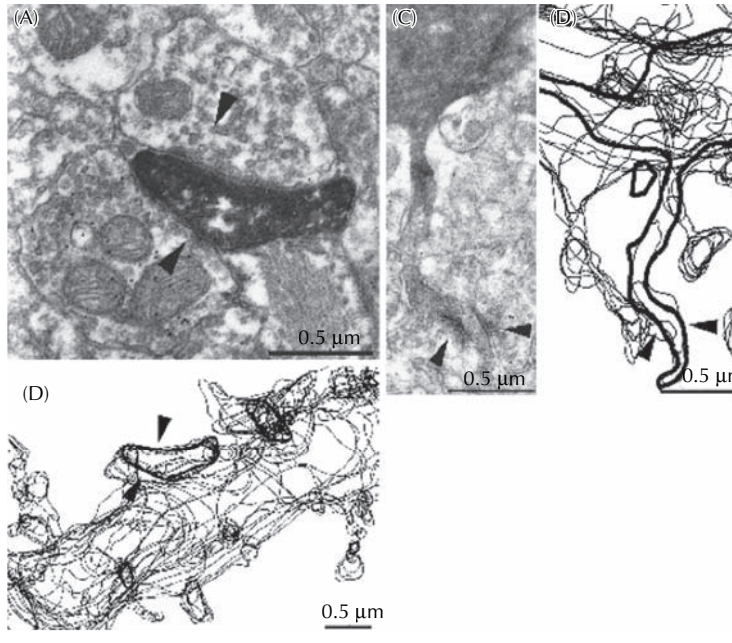

Figure 36–2. Gamma-aminobutyric acid-negative and GABA-positive axon terminals synapse (arrowheads) with the same spine of granule cell basal dendrites in epileptic rats. **A.** Electron micrograph of a spine of basal dendrite #1 labeled with an electron-dense reaction product. The bold contours are of the basal dendrite profile shown in **C**. From ref. 12.

account for only 7% of all synapses with hilar basal dendrites[12] (Fig. 36–3). Most GABAergic synapses are onto the dendritic shafts of basal dendrites, but there is a relatively large proportion of such synapses with spines, similar to the situation on apical dendrites.[36,41] A variety of different types of GABAergic interneurons are found in the dentate gyrus, but specific sources of interneuron input to basal dendrites have not yet been identified. The presence of inhibitory synapses with granule cell basal dendrites in epileptic pilocarpine-treated rats has special significance. The presence of such synapses confirms the long suspected but only indirectly supported hypothesis that GABAergic synaptogenesis occurs in mature epileptic animals.[42] These observations contribute to recent accumulating evidence that in epileptic tissue, surviving interneurons in the dentate gyrus sprout axons and form new synapses with granule cells.[40,43] Although basal dendrites receive these GABAergic synapses, their numbers are relatively low compared to those of the sprouted excitatory synapses. The strength and efficacy of inhibitory input to basal dendrites have not yet been evaluated.

TIME COURSE FOR BASAL DENDRITE FORMATION FOLLOWING SEIZURE ACTIVITY

Dashtipour et al.[44] were the first to address the issue of the time course for the development of basal dendrites following seizures. Using retrograde labeling with biocytin injected into the CA3 region in hippocampal slice preparations, they observed labeled granule cells with basal dendrites 7 days after pilocarpine-induced status epilepticus in rats. At the earliest time point examined in that study (3 days postseizures), no basal dendrites were found. This study indicated that basal dendrites may form on dentate granule cells as early as 1 week following pilocarpine-induced seizures.[44] However, the method that was used in this study required that a granule cell axon be present in the CA3

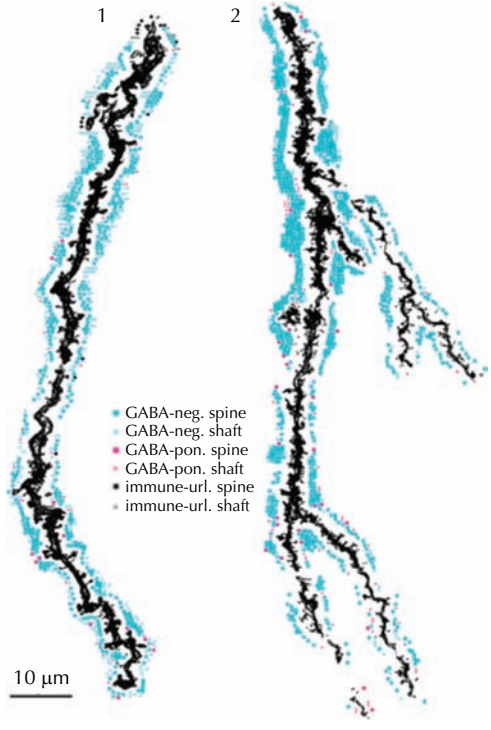

Figure 36–3. Summary of synapses with granule cell basal dendrites #1 and #2 from epileptic rats. Proximal is up, distal is down. Synapses are indicated by markers. Most synapses are with GABA-negative spines. "Immuno.-unk." synapses of basal dendrite #1 were in tissue sections that were used for the reconstruction but were not processed for immunocytochemistry. From ref.12.

region where biocytin was injected. Thus, this method would not label newborn granule cells at this time point (they require about 2 weeks to grow their axons into CA3).[45] Therefore, this study suggested that basal dendrites appeared relatively quickly after seizures (compared to mossy fiber sprouting), but it was not determined whether these dendrites originated from newborn granule cells.

DO BASAL DENDRITES ARISE FROM NEWLY GENERATED NEURONS?

Most granule cells with hilar basal dendrites are located at the hilar border of the granule cell layer,[9] and granule cell neurogenesis occurs in adults at this same location.[46–48] Therefore, it seemed logical to hypothesize that the newly generated granule cells developed hilar basal dendrites and the more mature granule cells at the molecular layer border did not display these basal dendrites. Testing the first part of this hypothesis required the use of a newborn cell marker that labels the cell body, axon, and dendrites. Doublecortin was selected for this purpose because it is a protein found in dentate newborn neurons for up to 3 weeks after their birth and is effective in labeling their growth cones, processes, and perikaryal cytoplasm.[49–52] However, one confounding problem with its use was that 31% to 55% of newborn doublecortin-labeled granule cells exhibit a basal dendrite.[51,52] Such doublecortin-labeled basal dendrites are transient.[37,53]

To determine whether basal dendrites arise from newborn neurons, doublecortin-labeled granule cells were examined 30 days after the induction of seizures. Light microscopic preparations showed that the basal dendrites from doublecortin-labeled granule cells of epileptic rats are significantly longer than those found in control rats.[54] It was also found that 20% of newborn neurons in the epileptic rat have a basal dendrite that enters the hilus at an angle greater than 30° from its cell body. In control rats, the dendrites that emanate from the basal portion of newborn neurons are typically at an angle less than 30° from their cell body and frequently do not travel in the hilus but instead curve back into the granule cell layer (i.e., form "recurrent" basal dendrites).[54] These data on doublecortin-labeled basal dendrites suggested that seizures induced morphological changes in the normally transient basal dendrite, and these changes (in length and in the angle of penetration into the hilus) may have significance for the persistence of these basal dendrites.

Another significant difference between epileptic and control animals was the presence of synapses on basal dendrites. Electron microscopy of doublecortin-labeled basal dendrites from epileptic rats showed that they had synapses.[15] This observation suggested that excitatory inputs were targeting the basal dendrites of immature granule cells as shown for mature granule cells (Fig. 36–4). In contrast, the doublecortin-labeled basal dendrites from newly generated granule cells from animals that are not epileptic lacked synapses on their basal dendrites.[15] These results were confirmed in a subsequent study in which the doublecortin-labeled basal dendrites from epileptic animals were examined on each of the first 5 days after seizures

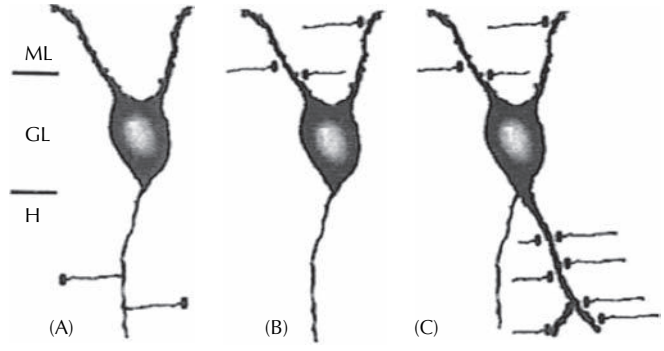

Figure 36–4. Schematic diagram of granule cells in the dentate gyrus of the hippocampal formation. **A.** A normal granule cell with its dendrites in the molecular layer (ML), cell body in the granule cell layer (GL), and axon terminals (filled circles) in the hilus (H). **B.** A granule cell from an epileptic rat showing mossy fiber sprouting (three axon terminals in the ML). Synapses made by these axon terminals provide the basis for robust excitatory responses following antidromic activation of granule cells and form a recurrent excitatory circuit. **C.** A granule cell with a hilar basal dendrite in the hilus that is postsynaptic to mossy fiber collaterals (seven axon terminals) and sprouted mossy fibers in the ML (three axon terminals). From ref. Shapiro and Ribak.[58]

were induced.[16] No synapses were found on doublecortin-labeled basal dendrites on the first 3 days following pilocarpine-induced seizures.[16] However, developing synapses were observed as early as 4 days after seizures on doublecortin-labeled basal dendrites.[16] Therefore, synapses are found on doublecortin-labeled hilar basal dendrites at both early (4–5 days after seizures) and later (30 days after seizures) time points. The fact that basal dendrites are found to have synapses after seizures (see the section "Synaptic Connections of Hilar Basal Dendrites") and have synapses on newly generated granule cell basal dendrites suggests that the early-formed synapses may persist, perhaps by the release of trophic factors at these synapses. In addition, we hypothesized that the synaptic targeting of basal dendrites of newly generated granule cells contributed to the persistence of hilar basal dendrites on neurons born after pilocarpine-induced seizures. Consistent with this hypothesis is the fact that no synapses are observed on doublecortin-labeled basal dendrites from control rats,[15] and such dendrites in nonepileptic animals are known to be transient structures.[37,52,55]

These data on the time course for the development of hilar basal dendrites indicate that basal dendrites may arise from seizure-induced de novo granule cells.[16] A recent study by Walter et al.[56] confirmed this observation and also showed that granule cells generated about a week prior to seizures may form hilar basal dendrites following seizure induction. It was suggested that those granule cells were still immature at the time seizures were induced.[56,57] Together, these studies indicate that newly generated granule cells are a major part of the population of granule cells that have hilar basal dendrites following seizures. However, it remains to be shown how the basal dendrites grow into the hilus following seizures. The following section addresses this topic.

WHAT GUIDES THE BASAL DENDRITES TO GROW INTO THE HILUS?

Shapiro and Ribak[58] initially hypothesized that hilar basal dendrites from newborn neurons in epileptic animals grow along an ectopic glial scaffold. This conjecture was based on the fact that the basal dendrites were found closely apposed to the horizontal processes of the radial glial-like cells that extend into the hilus[54] (Fig. 36–5). After seizures, these radial glial-like cells have a hypertrophied appearance indicative of an inflammatory response in this region.[58] In control rats, the radial glial-like cells rarely extend lengthy horizontal processes into the hilus. The same radial glial-like cells have vertical processes extending through the granule cell layer, and these vertical processes provide a scaffold for the apical dendrites of newborn neurons to grow through the granule cell layer.[59,60] Thus, under normal conditions, the apical dendrite of newborn neurons grows along the radial glial-like process through the
