
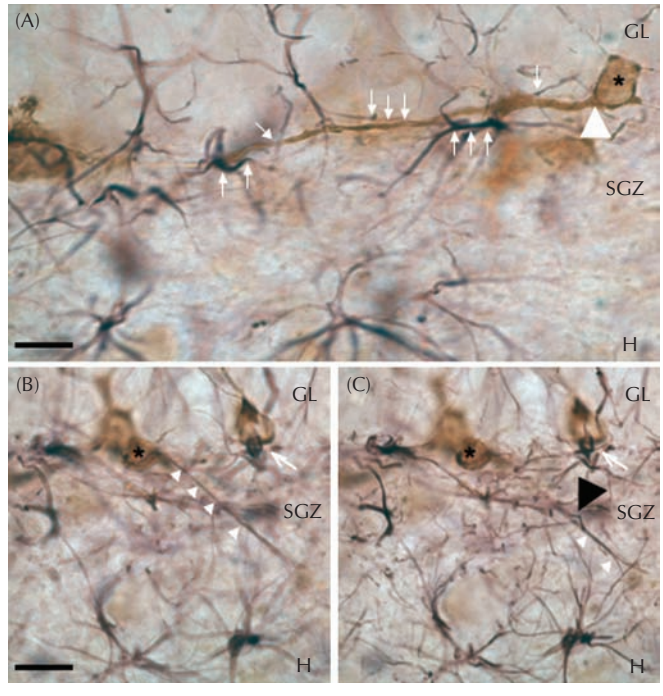

Figure 36–5. Light micrographs of doublecortin-labeled newborn neurons with basal dendrites adjacent to GFAP-labeled processes from the epileptic rats. **A.** A doublecortin-labeled newborn neuron (asterisk) at the border between the subgranular zone (SGZ) and the granule cell layer (GL). Note the basal dendrite (white arrowhead) emanating from the basal portion of the cell body and extending horizontally along the base of the GL. Two GFAP-positive astrocytes can be seen along the extent of the basal dendrite with their processes (white arrows) adjacent to the basal dendrite. **B,C.** Two different planes of focus of a doublecortin-labeled newborn neuron (asterisk) located in the SGZ. Note the basal dendrite (white arrowheads) emanating from the basal portion of this cell and extending into the hilus. This basal dendrite is adjacent to GFAP-labeled processes and can best be visualized in **C**, where a kink in the GFAP-labeled process (black arrowhead) reveals how close the dendrite is to the GFAP-labeled process. Scale bars: 8 μm. From ref. Shapiro et al.[54]

granule cell layer; following seizures, these radial glial-like cells appear hypertrophied and sprout a horizontal process that forms an ectopic glial scaffold to guide the aberrant growth of basal dendrites into the hilus. Therefore, the extension of both the radial glial-like cell's horizontal process and the granule cell's basal dendrite into the hilus can be thought of as a seizure-induced change.

More recently, additional support for this hypothesis was provided by Foresti et al.,[61] who showed that after seizures, the radial glial-like cells at the border between the granule cell layer and the subgranular zone express the chemokine receptor CCR2. Such expression is rarely seen in control animals.[61] Moreover, the horizontal processes from the radial glial-like cells that orient toward the hilus also show expression of CCR2.[61] Previous studies have shown that CCR2 expression on neuroblasts, together with that of its ligand CCL2, guides the migration of neuroblasts to sites of inflammation.[62–65] These data suggest that this chemokine/receptor complex is involved in the ectopic growth and migration of immature neurons, and thus may play a role in extension of newborn granule cell basal dendrites into the hilus.

Chapter 37

Perturbations of Dendritic Excitability in Epilepsy

Cha-Min Tang
Scott M. Thompson

The dendrite is where thousands of excitatory and inhibitory synaptic inputs are received by the neuron. But rather than just being a simple antenna, the dendrite is also the location where these inputs actively interact with intrinsic conductances. The interactions are complex and are still incompletely understood. The synaptic inputs are distributed in time and space, and each of the many intrinsic dendritic conductances is also distributed in its own unique spatial pattern. The interactions lead to signal transformations whose significance may be best appreciated in terms of elementary steps in signal processing and computation. Under pathological conditions, changes to these interactions may result in aberrant excitability and contribute to neurological disease.

Rather than compiling a list of dendritic conductances and their linkages with epilepsy, which is done in other chapters of this book, the purpose of this chapter is to integrate these results, with an emphasis on how perturbations of the elementary steps in dendritic integration affect the way neurons process their inputs and promote aberrant neuronal excitability.

A BRIEF HISTORY OF THE ACTIVE DENDRITE

Our view of the role of dendrites in epilepsy has evolved with increased understanding of the roles dendrites play in normal physiology.

For most of the previous century, the dendritic arbor was viewed as a structure that gathered and faithfully funneled inputs to the soma and axon hillock, where nonlinear processing—in the form of action potential initiation—was thought to reside. This view of the dendrite as a passive antenna does not suggest that the dendrite plays a pivotal role in neuronal hyperexcitability. The possibility that apical dendrites of pyramidal neurons are active was first demonstrated by Spencer and Kandel when they described events they called *fast prepotentials*.[1] Similar *dendritic spikes* were reported from neocortical neurons by Purpura.[2] The concept of the active dendrite was further advanced with the demonstration of calcium electrogenesis in dendrites by Llinas, Schwartzkroin, Wong, Prince, and Sakmann and their colleagues.[3–6] Magee and Johnston further extended the concept of the active dendrite by demonstrating high levels of expression of sodium channels throughout the apical trunk in hippocampal pyramidal neurons.[7] Stuart and Sakmann and others showed that action potentials can propagate bidirectionally in the dendritic arbor.[8] This bidirectional signaling provided the means for coincidence detection, which was postulated to serve an important role in triggering acute and long-term changes in excitability such as spike timing-dependent plasticity.[9] Several other members of Johnston's and Sakmann's groups also investigated the properties of calcium electrogenesis at the apical tuft region of layer 5 pyramidal neurons, showing that these calcium channels help amplify synaptic inputs from the more distal branches[10–12] and that backpropagating action potentials (bAPs) can trigger calcium spikes localized to the apical tuft.[13] Next, Schiller and colleagues demonstrated the ability of *N*-methyl-D-aspartate (NMDA) receptors to generate local spikes on tertiary basal dendrites of cortical pyramidal neurons.[14] The capacity of NMDA receptors for regenerative depolarization under appropriate conditions provided an additional mechanism of excitability that is unique to dendrites and is not observed in other excitable membranes such as axons and muscle. Thus, over a span of 20 to 30 years, the view of the dendrite as a passive antenna evolved to that of a highly excitable structure that rivaled the soma. This change in perspective also led to a greater interest in and understanding of the role of dendritic excitability in epilepsy.

ELECTRICAL COMPARTMENTALIZATION OF DENDRITES: THE INTERSECTION OF FORM AND FUNCTION

The organization of this chapter is based on the premise that dendrites serve signal processing and computational needs that are fundamental to the function of the nervous system. Because nontrivial computation generally requires some form of nonlinear operation, it is informative to examine the source of nonlinearity in dendritic integration. One obvious source of nonlinearity is active conductances. A less obvious but important determinant of nonlinearity is electrical compartmentalization.

Electrical compartmentalization is like the parentheses in mathematics. It separates the variables that are included in an operation from those that are excluded. The ability to segregate variables and "bind" them for nonlinear operations is as fundamental to orderly signal processing as it is in mathematics. At the level of the dendrite, binding of synaptic inputs can be implemented by electrical compartmentalization within different regions of the dendritic arbor and individual dendritic segments.[15–17] Electrical compartmentalization can be functionally defined as a condition in which local interactions within a confined space occur quasi-independently of the influence of the rest of the cell. At rest, all dendritic regions are close to isopotential. During activity, a region of the dendritic arbor (i.e., a *compartment*) may be at a membrane potential that is significantly different from the potential of other nearby dendrites and the cell body. For example, nearly synchronous activity in a set of synaptic inputs that arrive on a single dendritic segment can trigger a variety of active electrical responses, such as plateau potentials.[15] These responses functionally bind together the original inputs and are amplified and transmitted to the soma reliably. In contrast, inputs arriving on different dendritic branches, or arriving with insufficient temporal synchrony to allow such binding, fail to trigger active dendritic responses; consequently, they will not be amplified and will exert lesser influence on the output of the neuron.

Electrical compartmentalization is determined by three factors: the passive electronic properties of the dendritic arbor, the expression of active conductances on these structures,

and the temporospatial pattern of excitation. Factors favoring compartmentalization within the dendritic tree are high output impedance of the dendritic segment and high expression of regenerative voltage-dependent conductances. Electrical compartmentalization can be dynamic, and changes in the extent of ongoing synaptic activity (both excitatory and inhibitory) can change the impedance of the dendrite. Because the voltage-dependent blockade of NMDA receptors by Mg^{2+} can effectively add a nonlinear excitability to the dendrite, the tempospatial pattern of synaptic excitation within a dendritic domain is a strong determinant of the extent of the compartment.

Two functional dendritic compartments will be discussed in detail in the context of epileptogenesis. One is the compartment comprising the individual terminal dendritic branches, which receive >80% of synaptic inputs to pyramidal neurons.[18] The other is the region on the distal apical trunk, near the base of the apical dendritic tuft, which has a high propensity for generating calcium spikes.[6,19]

Experimental observation has shown that distal and proximal dendritic compartments express distinct intrinsic conductances. In fact, dendritic information processing can be modeled as a two-layer system of distal and apical domains, each with distinct functions that are connected to the soma.[20]

THE TERMINAL DENDRITE AS AN ELECTRICAL COMPARTMENT

The terminal dendrite of cortical and hippocampal pyramidal neurons has attributes that favor electrical compartmentalization. Contrary to frequent belief, the dendritic arbor of pyramidal neurons does not mimic the arbor of a typical tree. Whereas the diameter of branches of a tree gradually tapers with each division and becomes progressively shorter, the diameter of the terminal dendritic branch of pyramidal neurons is markedly thinner than its parent branch and the terminal branch is typically the longest segment of the dendritic arbor.[19] Interestingly, the diameter of the terminal dendrite is not tapered, in contrast to the apical trunk or the branches of a tree; it is <1 μm in diameter both where it joins the main apical trunk and at its distal tip 100 μm away. This geometry is well suited for electrical compartmentalization, because synaptic currents are gathered from a large surface area within a high-resistance anatomically defined region. Thus, even a relatively modest level of synaptic current flowing into the long terminal dendritic process produces significant depolarization over a considerable portion of its length. This depolarization can then secondarily trigger the activation of voltage-dependent sodium and calcium conductances and the unblocking of glutamate-bound—but Mg^{2+}-blocked—NMDA receptors.[14,15] The result is a regenerative spike in the thin terminal dendrite that appears as a slow plateau potential at the soma (Fig. 37–1A). Calcium imaging suggests that the spike originates from and is largely confined to the terminal dendritic compartment (Fig. 37–1B).

The regenerative depolarization of these thin distal processes is mediated by a combination of NMDA and voltage-gated channels. The relative contribution of NMDA and voltage-gated calcium conductances is hard to determine precisely. We will therefore use the term *plateau potential* to refer these regenerative all-or-none depolarizations. The impedance mismatch of the terminal dendrite where it joins the main apical trunk results in marked attenuation of the distal depolarization—which allows the terminal dendrite to function quasi-independently of the apical trunk.

Perturbations Affecting the Thin Distal Electrical Compartment

What factors limit the generation of dendritic plateau potentials? The answer includes both extrinsic and intrinsic conductances. Modeling of the excitability of the thin terminal dendrites shows that the level of GABAergic (GABA, gamma-aminobutyric acid) inhibition is a very potent modulator of plateau potential generation.[21] A local inhibitory current 20-fold lower in amplitude than the current underlying the plateau potential is sufficient to prevent its initiation. Further, the impact of a conductance on excitability of the dendrite will depend, in part, on the level of its expression relative to the input impedance/leak conductance of the electrical compartment. The steepness of the negative slope of the current–voltage activation relationship of the NMDA and

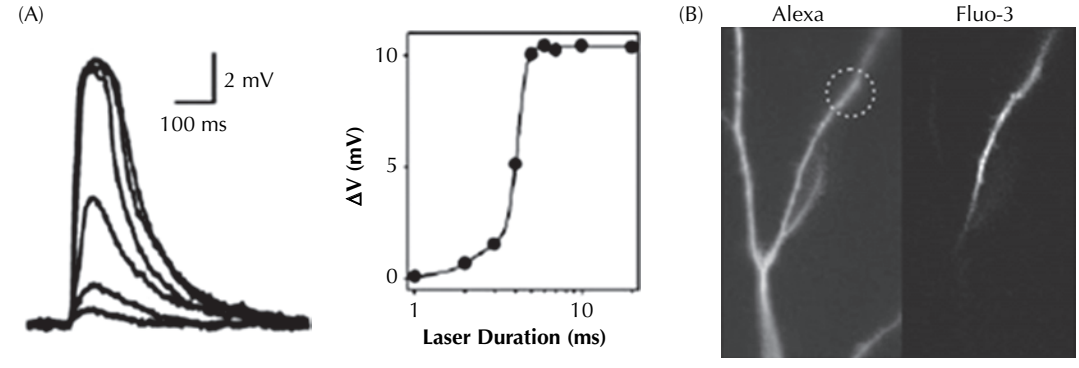

Figure 37–1. Compartmentalized and spiking property of terminal dendrites. **A.** Progressive increase in the strength of glutamate photolysis stimulus directed at a thin terminal dendrite leads to a nonlinear response. **B.** Calcium imaging with Fluo-3 during such a plateau potential reveals that the electrogenesis is largely confined to the terminal dendritic compartment (dotted circle).

voltage-dependent Ca^{2+} channels (VDCCs) that underlie plateau potential generation are also critical. One possible explanation for the extraordinary sensitivity of the plateau potential to inhibition is that the negative slope of the NMDA and VDCC current–voltage activation relationship is not steep compared to that of sodium channels at the axon initial segment. Intrinsic inhibitory voltage-dependent conductances may similarly exert powerful control over the excitability of the terminal dendrites. These conductances include I_A and I_h, which are activated at or near rest, and SK-type calcium-activated K^+ channels (I_{SK}), which are activated subsequent to depolarization. All three channel types are found in abundance in the thin distal dendrites. This distribution of channels creates a system that is normally well balanced but is vulnerable to overexcitation when inhibition is reduced. Thus, factors that attenuate I_A, I_h, and I_{SK} will lead to aberrant excitability of distal dendrites that subsequently feed into the burst-generating apical trunk compartment of the dendritic arbor.

Attenuation of I_A Lowers the Threshold for Regenerative Spiking

I_A is a rapidly inactivating voltage-gated K^+ conductance that is mediated by Kv4.2 potassium channels in pyramidal cell dendrites. Its expression on apical trunk dendrites has been directly measured by patch-clamp methods and has been found to increase with distance from the soma up to at least 350 μm.[22] On the thin terminal dendrite, however, the expression of I_A must be inferred by indirect means because it is not possible to record from these thin structures directly. Fluorescent monitoring of intracellular calcium levels in response to somatically evoked bAPs has provided a convenient indirect measure for the presence of I_A.[23] Under control conditions, the bAP-evoked calcium signal in thin oblique dendrites was similar to that observed in the apical trunk. After application of the I_A blocker, 4-aminopyridine (4AP), the calcium signal was markedly increased in the oblique dendrites to a much greater extent than in the trunk dendrite.[23] This observation confirms that I_A is expressed on the oblique dendrites. But it may lead to overestimation of the density of I_A in the oblique dendrite, because I_A can exert highly nonlinear control over the generation of NMDA and calcium channel-dependent spikes (Fig. 37–2). Because the threshold for NMDA spike generation is significantly lower in the oblique dendrites than in the main apical trunk due to cable properties, increased sensitivity to I_A as indirectly monitored by calcium influx does not necessarily mean that there is increased expression of I_A in the oblique dendrites. Regardless of the absolute density of I_A on the thin terminal dendrites, I_A exerts powerful control over regenerative excitation. Indeed, when NMDA receptor-mediated glutamate responses in thin oblique dendrites are examined in the presence of an alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate

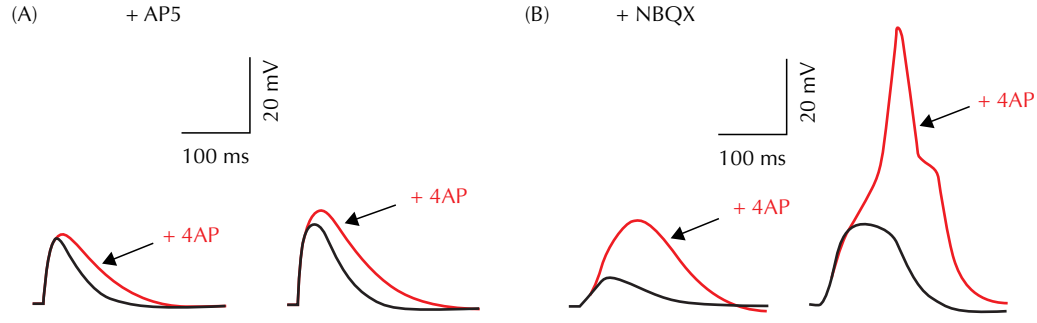

Figure 37–2. Disparate effect of I_A on regenerative and nonregenerative dendritic excitation. **A.** A hippocampal CA1 oblique dendrite in an acute hippocampal slice is stimulated by photolysis of caged glutamate at two intensities in the presence of an NMDA receptor antagonist (AP5, black). The stimulation is then repeated in the presence of 4AP (red). **B.** An oblique dendrite is similarly stimulated at two intensities in the presence of an AMPA receptor antagonist (NBQX) (black), and stimulation is then repeated in the presence of 4AP (red).

(AMPA) receptor antagonist (Fig. 37–2B), removing the inhibitory influence of I_A (by applying 4AP) has a much more dramatic effect on regenerative spike initiation than on AMPA-mediated depolarization (Fig. 37–2A).

I_A is a highly regulated conductance in dendrites. Its activity is altered by the recent history of activation, by the baseline membrane potential, and by the activity of a number of protein kinases.[24–26] I_A inactivates rapidly at voltages close to the resting membrane potential. High-frequency inputs will therefore inactivate I_A and release the regenerative capacity of the terminal dendrites from its inhibitory influence. High-frequency inputs are thus far more effective in triggering plateau potentials.[27] Tight regulation of I_A provides hints to its central role in controlling excitability within the dendritic arbor and the development of short- and long-term plasticity.[28] Most recent attention has focused on the role played by I_A in the apical trunk in regulating the extent to which somatic action potentials can backpropagate into the distal dendritic arbor. In addition to changes in bAP propagation, however, it is important to remember that changes in the properties of I_A can also promote epilepsy by altering the compartmentalization and regenerative activity of distal dendrites.

Factors that attenuate or downregulate the activity of I_A are well recognized as proconvulsants. Blockade of I_A with 4AP is a well-established in vitro model of epilepsy.[29] Local application of 4AP to the distal apical dendrite of CA1 pyramidal neurons causes the afterhyperpolarization to change to an afterdepolarization and the normal single evoked spike to change to bursts of spikes.[30] In the pilocarpine model of temporal lobe epilepsy (TLE), attenuation of I_A and increased excitability of pyramidal cell dendrites are believed to be secondary to extracellular-signal-regulated kinase (ERK)-dependent phosphorylation of the Kv4.2 channels.[31] In another study of the chronic phase of the Li-pilocarpine animal model, there is downregulation of Kv4.2 channel expression.[32] Surgical tissue obtained from patients with hippocampal sclerosis showed decreased immunoreactivity to Kv4.2 in the dendritic region of the CA1 and CA3 hippocampus[33] but increased immunoreactivity in the soma of the surviving neurons. Unfortunately, the limited resolution of light microscopic methods did not allow a determination of whether the decrease was localized to the apical trunk or the thin tertiary branches, or whether it was due to an overall loss of dendrites.

While these studies show a solid correlation between attenuated dendritic I_A and epilepsy, one is still faced with the classic dilemma of not knowing whether the change in I_A is the cause or the result of epilepsy. It remains important to determine whether the perturbation is localized to the apical trunk, or to the terminal dendrite, or occurs throughout the dendritic arbor. The action of I_A on the backpropagation of action potentials (APs) and the interaction between the soma and the apical tuft are well documented and will be discussed later.

Whether perturbation of I_A on the terminal dendrites contributes significantly to the epileptic conditions described above is not known. The observations shown in Fig. 37–2 provide one plausible pro-convulsant mechanism. I_A can regulate the threshold for regenerative NMDA and calcium spikes. This issue requires further investigation, for if hyperexcitability were to originate from the terminal dendrite, it would involve mechanisms that are distinct from those of APs propagating backward from the apical trunk and soma.

Downregulation of I_h Increases Input Impedance

I_h is a mixed sodium and potassium cation conductance activated by membrane hyperpolarization and gated by intracellular cyclic nucleotides. I_h is mediated by the hyperpolarization-activated cyclic nucleotide-gated (HCN) family of ion channels, which are highly expressed on distal dendrites of CA1 and cortical pyramidal neurons.[34,35] In conjunction with potassium channels, I_h controls the resting membrane potential especially for dendrites of pyramidal neurons farther away from the soma.[36] Activation of this conductance leads to membrane depolarization with a reversal potential near –30 mV. Because its activation would be expected to move the membrane potential toward –30 mV, it may be considered excitatory. But I_h also significantly reduces the input impedance of the distal dendrites, thereby decreasing the efficacy of excitatory synaptic inputs. In this respect, I_h may be considered a stabilizing or inhibitory conductance. These opposing actions on membrane excitability have led to conflicting opinions as to the role of I_h in epilepsy. Whether the net effect of I_h is increased or decreased excitability depends on a combination of factors, including the preexisting input impedance, resting membrane potential, membrane time constant, timing of synaptic inputs, neuronal subtype, and the age of the animal[37] (see Chapter 7 by Poolos in this edition). Like I_A, I_h may serve different roles in different locations of the neurons. Because of the high baseline input impedance of the distal dendritic compartment, the stabilizing action of increased shunting by I_h is likely to be more important than its depolarizing action. I_h-mediated decreases in input impedance attenuate the depolarization of glutamatergic inputs and speed the decay of excitatory synaptic events. The net result is reduced summation of excitatory postsynaptic potentials (EPSPs).[34,38]

A large body of evidence supports the idea that I_h is predominantly a stabilizing conductance with respect to epilepsy. In the kainate model of TLE, decreased I_h conductance is linked to the latent period of epileptogenesis.[39] In a hippocampal deafferentation model of epilepsy created by lesioning the entorhinal cortex, there is a decrease in the expression of HCN1 channels.[40] Also consistent with this notion is the observation that two anti-convulsants, lamotrigine and acetazolamide, both enhance I_h,[41,42] although questions remain about whether it is their action on I_h that provides them with their anti-convulsant actions.[43] The more general question of whether promoting I_h is pro- or anti-convulsant does not have a simple answer. Different seizure types respond differently to I_h modulation. In the rat febrile seizure model, I_h is enhanced and its blockade reduces hyperexcitability.[43] Interestingly, I_h has also been implicated in thalamically generated absence epilepsy. In a genetic model of absence epilepsy in rats, a rapid decline in the expression of HCN1 channels precedes the onset of seizures.[44] Similarly, enhancing I_h prevents experimentally induced thalamic hyperexcitability.[45]

Another possibility is that I_h serves as a shunt to maintain the membrane potential of distal dendrites at a steady value and decreases its time constant. This action may be beneficial by acting as a bias current to regulate the voltage-dependent block of NMDA receptors by Mg^{2+}. Because of the high affinity of NMDA receptors for glutamate, subthreshold synaptic excitation of terminal dendrites results in an appreciable fraction of NMDA receptors on that branch that are in the bound-but-blocked state. In this state, the NMDA receptor is not conducting current; however, it reverts to a conducting state if the membrane becomes sufficiently depolarized. I_h is ideally suited for such a depolarizing purpose. Because the bound-but-blocked state of the NMDA receptor contains information about the recent activity at that receptor (dating back hundreds of milliseconds), it may provide an energy-efficient, high-capacity mechanism for short-term memory.[46]

Downregulation of SK Channels Leads to Prolonged Spikes in Terminal Dendrites

I_A and I_h play a role in limiting dendritic depolarization and the initiation of regenerative dendritic events such as plateau potentials. SK-type Ca^{2+} activated K^+ channels, in contrast, are critical for termination of plateau potentials. Although single Ca^{2+}-activated K^+ channels have not been observed in recordings from the main apical trunk, there is evidence that Ca^{2+}-activated K^+ channels are expressed on oblique and thin terminal dendrites. SK-type channels have also been detected in dendritic spines, where they are activated by NMDA receptor-mediated Ca^{2+} influx.[47] Activation of voltage-dependent calcium channels, and relief of NMDA channel block by Mg^{2+} during the depolarization of the plateau potential, lead to large and relatively long-lasting elevations of the intracellular concentration of Ca^{2+} at the site of active initiation.[15] This elevated Ca^{2+} activates SK-type channels that are responsible for termination of the plateau potential.[27] Addition of the toxin apamin, a selective SK channel blocker, or chelation of intracellular calcium markedly increases the duration of the plateau potential without affecting its amplitude.

We have obtained evidence that alterations in SK channel function may contribute to epileptogenesis after traumatic brain injury. In many neurological conditions associated with abnormal excitability, such as posttraumatic epilepsy, neural damage leads to cellular degeneration and loss of nerve tracts. In addition, rapid acceleration/deceleration of the brain leads to axonal injury due to damaging shear forces. One consequence of these injuries is to produce chronic partial deafferentation of large populations of neurons. In a study of the effects of chronic deafferentation resulting from Schaffer collateral transections in hippocampal slice cultures, we observed increased excitability in area CA1 beginning with a delay of several days after transection. Comparable hyperexcitability is observed in the neocortex after deafferentation and axonal injury produced by cortical undercuts.[48] Hyperexcitability in denervated CA1 cells is accompanied by a marked prolongation of plateau potentials due to a functional downregulation of repolarizing SK channels.[49] The molecular mechanisms remain unclear, but decreases in mRNA levels or protein expression could not be detected, suggesting posttranslational regulation of channel conductance, trafficking, or Ca^{2+} sensitivity. Interestingly, SK channel enhancers such as 1-ethyl-2-benzimidazolinone (EBIO) have recently been shown to be effective against an in vitro model of epilepsy.[50]

Why does prolongation of plateau potentials lead to hyperexcitability? Excitatory postsynaptic potentials occurring in distal thin and oblique dendrites have a relatively low probability of triggering APs compared to main apical dendrites.[50] Plateau potentials in terminal apical dendrites or oblique dendrites elicit APs in <10% of trials in normally innervated CA1 cells. Similarly, strong activation of temporoammonic inputs to distal apical dendrites in stratum lacunosum/molecular is relatively ineffective in triggering somatic APs.[51] Both pharmacological prolongation of plateau potentials with SK channel blockers and deafferentation-induced prolongation of plateau potentials markedly facilitate AP initiation.[27] One week after deafferentation, >80% of terminal apical and oblique dendrites display APs as the result of plateau potential initiation. Although AP initiation can occur in apical trunk dendrites, the threshold for initiation is higher than at the soma and the axon hillock.[52] Facilitation of AP initiation by prolonged plateau potentials in chronically deafferented dendrites results from a lowering of the effective threshold for dendritic initiation of APs. In a population of neurons coupled by recurrent excitatory synapses, such as those in the hippocampus, such maladaptive plasticity will be amplified in a feedforward synergistic manner and promote hyperexcitability and epileptiform discharge.

THE APICAL TRUNK AS AN INDEPENDENT ELECTRICAL COMPARTMENT

From a morphological standpoint, the apical trunk, with its direct high-conductance connection to the soma, is an unlikely structure to behave as an independent electrical compartment. But dual electrode recordings have clearly shown that the distal apical trunk can generate electrical behavior that is independent of that of the soma.[53] In contrast to the

thin terminal dendritic compartment, which is created in large part by its passive cable properties, electrical compartmentalization of the apical tuft at the distal apical trunk is largely created by the distribution of active intrinsic conductances. The high expression of VDCCs near the apical tuft allows the regenerative calcium current produced there to overwhelm and escape the electrotonic control of the soma. The expression of VDCCs is lower in the region between the tuft and the soma in layer 5 pyramidal neurons.[6] This spatially restricted expression, combined with the tapering geometry of the apical trunk, normally limits the ability of calcium spikes generated at the apical tuft to propagate regeneratively to the soma. The distinct electrical excitability of the thin terminal dendrites and the apical tuft in response to focal photolysis is illustrated in Fig. 37–3.[15] These dendritic calcium spikes, even when confined to the apical tuft, are still able to drive action potential firing at the soma.

Wong and Stewart showed that depolarizing current injection into the apical trunk of guinea pig CA1 pyramidal neurons initiated burst firing, whereas current injection at the soma elicited single APs.[19] These observations show the electrical independence of the apical trunk and its special role in driving burst firing that are particularly powerful in recruiting downstream neurons within a neural network.

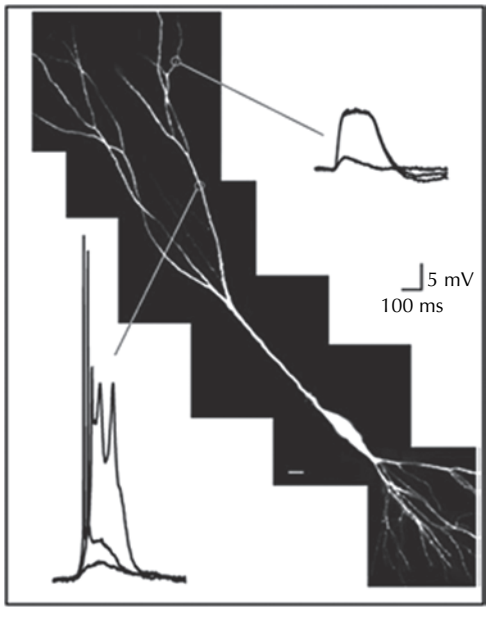

Figure 37–3. Distal and proximal dendritic compartments. Photolysis of caged glutamate directed at the terminal dendrite evokes a spatially restricted plateau potential. Photolysis directed at the main apical trunk near the base of the tuft evokes higher-amplitude depolarizations that are dominated by calcium spikes.

Perturbations of the Apical Trunk Compartment

With the demonstration of dendritic calcium spikes, considerable attention was given to the linkage between these calcium spikes and burst firing patterns that are closely associated with epileptiform discharges. In particular, Wong and Prince[54] noticed the parallels between the dendritic calcium spikes and the intrinsic burst discharges displayed by CA3 pyramidal cells in acutely prepared hippocampal brain slices, in which a burst of 2–10 high-frequency APs rides on a slow depolarizing envelope of about 20 mV in amplitude and about 100 ms in duration. This discharge bore considerable resemblance to the so-called paroxysmal depolarization shift, the discharge displayed by pyramidal cells during interictal electroencephalographic (EEG) activity in various models of epilepsy.[55] Performing the first direct recordings from dendrites, Wong and Prince[56] showed that burst discharges can be elicited from CA1 cell dendrites in response to direct depolarization, much like those described previously in the large dendrites of alligator Purkinje cells by Llinas and Nicholson.[3] Nevertheless, these dendritic bursts are not normally elicited by orthodromic synaptic stimuli. Wong and Prince showed that the short-latency hyperpolarization produced by the feedforward inhibitory postsynaptic potential (IPSP) prevents synaptically evoked bursting under normal conditions. Convulsants such as penicillin, bicuculline, or picrotoxin diminish this IPSP (because they are $GABA_A$ receptor antagonists) and thereby disinhibit this endogenous burst capacity of the apical dendrites.

Computer modeling studies suggested that intrinsically bursting neurons are pivotal in the generation of epileptiform activity.[57,58] In vitro studies of convulsant-induced discharge in the neocortex also showed that cells with intrinsic burst firing were critical for the initiation of epileptiform events.[59–61] In the pilocarpine model of TLE, 54% of CA1 pyramidal cells,

which normally fire in a regular mode, are persistently converted to a bursting mode after an episode of status epilepticus induced by the convulsant.[62] Evidence suggests that T-type calcium channels located in the apical dendrites are drivers of de novo burst firing in the pilocarpine model of hippocampal epilepsy. Burst firing in this model could be suppressed by focally applying the putative T-type calcium channel blocker Ni^{2+} to the apical dendrites but not to the soma. Severing the distal apical dendrites approximately150 μM from the pyramidal layer also abolished this activity.[63]

COUPLING BETWEEN DIFFERENT DENDRITIC COMPARTMENTS

Coupling between the soma, apical tuft, and terminal dendritic compartments is mediated by both passive and active mechanisms. Due to the asymmetric geometry of the dendritic arbor, passive cable theory predicts that the reliability of regenerative spikes propagation will be different, depending on the direction of propagation.[64] The smaller diameter of higher-order dendritic branches creates a significant impedance mismatch at the branch point. Signals leaving thin branches would experience a significant drop in impedance as they enter the larger branch. This mismatch would result in significant voltage attenuation, whereas little attenuation would be expected for signals traveling from the larger branch toward the thinner branch. Thus, under normal conditions, short-duration plateau potentials in the terminal dendrites are ineffective in generating somatic APs,[15] and sodium and calcium spikes generated at the apical tuft may not always propagate to the soma. In contrast to poor orthodromic propagation, cable theory predicts that back-propagation of APs from the soma toward the dendrites should be more reliable. Contrary to this prediction, however, direct patch-clamp recordings from the distal apical tufts of pyramidal neurons revealed that bAPs only partially propagate into the dendritic arbor. The bulk of the evidence suggests that two dendritic conductances, I_A and I_h, actively regulate the extent of bAP invasion of distal dendrites, thereby explaining the discrepancy between the prediction of cable theory and actual experimental observation. The fast kinetics of I_A and the Kv4.2 potassium channel are well suited to attenuate the fast kinetics of the bAP.[22] In contrast, the slower kinetics of I_h and the HCN family of channels have been shown to be important in the regulation of bursts of bAPs in layer 5 pyramidal neurons.[65] It is important to note, however, that this understanding has been challenged by a recent report in which voltage-sensitive dyes were used to monitor membrane depolarizations. With this technique, robust invasion of bAPs into the very tips of thin terminal dendrites was observed.[66]

What functional advantages might the tight regulation of AP backpropagation in the dendritic arbor serve? Two ideas have been proposed: control of synaptic plasticity and control of dendritic excitability. Precise coincident activation of a presynaptic glutamatergic synaptic input and the firing of an AP of the postsynaptic neuron underlie a form of synaptic plasticity called *spike timing-dependent plasticity* (STDP).[9,67] Robust AP backpropagation enables the somatic depolarization of the postsynaptic cell to reach the synaptic site. It has been suggested that regulation of the coupling between the soma and the apical tuft via the bAP is one means for regulating synaptic plasticity.[24–26] As discussed above, I_A limits synaptic plasticity by regulating AP backpropagation. Conversely, synaptic plasticity is accompanied by regulation of I_A. The Kv 4.2 channels underlying I_A are phosphorylated by a number of activity-dependent kinases, which shift their activation to more depolarized potentials and effectively decrease their activation.[24]

Robust AP backpropagation into the distal dendrite may also trigger calcium spikes in the apical tuft and plateau potentials in the thin terminal dendrites.[12,65] Bursts of four to five bAPs over a narrow frequency range (10–20 Hz) are particularly effective in eliciting large calcium spikes in the apical tufts of layer 5 pyramidal neurons.[12] These calcium spikes at the apical tuft can, in turn, lead to burst firing at the axon hillock.

Perturbations of Coupling Between the Soma and the Apical Tuft

As discussed earlier in this chapter, conditions associated with attenuated I_A or I_h are strongly linked to epilepsy. Studies of these conditions postulated that the key mechanism responsible

for the epilepsy was an increase in somato-dendritic coupling. In support of this hypothesis, dual recording from the soma and the apical tuft were used to measure the increased somato-dendritic coupling and the lowering of the frequency threshold for generating dendritic calcium spikes in the rat absence epilepsy model due to decreased HCN1 channels.[44] Similarly, in the pilocarpine model of TLE, with its decreased expression of Kv4.2 and increased phosphorylation of the Kv4.2 channels, evidence was obtained indicating that there is increased penetration of bAPs into the dendritic arbor.[31] Despite these findings, it is still not possible to conclude definitively that altered somato-dendritic coupling is the sole consequence of altered I_A and I_h. Loss of I_A and I_h also increases coupling between the terminal dendrite and apical tuft compartments, directly increases the intrinsic excitability of all dendritic compartments, and increases coupling from the apical tuft to the soma. To address these issues, it will be interesting to focally apply blockers of these two conductances to different regions of the dendritic arbor and/or examine dendritic excitability in response to orthodromic, physiological synaptic stimuli.

THE EPILEPTIC NEURON VERSUS THE EPILEPTIC NETWORK

While it is generally accepted that epilepsy exists in many forms and has many different pathophysiological mechanisms, opinions over the years have shifted between two extreme emphases: the epileptic neuron and the epileptic network. One would think that epilepsy associated with dendritic hyperexcitability would clearly place this mechanism in the epileptic neuron category. But this categorization can still be problematic because the changes in the expression of dendritic conductances could be a primary event—but also could be secondary to changes in dendritic input. In certain examples, such as in the rat absence epilepsy model due to decreased HCN1 expression, it is possible to determine which event comes first.[44] But in other cases, it is not clear whether the changes in I_A expression associated with epilepsy are the result of repeated seizures. In yet other cases, such as the downregulation of SK channels following deafferentation, the change in dendritic excitability is secondary to injury, but the dendrite is still the primary source of aberrant hyperexcitability, so aberrant excitability in this model would fall best in the epileptic neuron category. This issue is reminiscent of the controversy about the origin of the paroxysmal depolarization shift. One school of thought postulated that the paroxysmal depolarization shift is an abnormal intrinsic dendritic event,[56] whereas another postulated that it is secondary to a giant synaptic potential.[68] After 30 years, this issue, and many others relating to the role of dendrites in epilepsy, remain incompletely understood.

Controversies in epilepsy were an important early driving force in the study of dendrites. We now hope that recent rapid advances in techniques to study dendritic excitability will lead to a better understanding of many epilepsies.

Chapter 38

Neurogenesis and Epilepsy

Jack M. Parent
Michelle M. Kron

Medial temporal lobe epilepsy (mTLE) is a common and often intractable form of epilepsy. Approximately 50 million people suffer from different epilepsies worldwide,[1] 30%–40% of whom may continue to have poorly controlled seizures despite therapy.[2,3] Medial TLE is estimated to be the most common cause of intractable epilepsy in this population.[4] In addition to chronic seizures, the long-term morbidity of mTLE includes an increased incidence of depression[5,6] and problems with learning and memory[7,8] that may progress despite adequate seizure control.[9] Thus, progress in the study of mTLE is critical for developing better therapies to ease the large burden of this disorder.

Humans with mTLE often have an initial precipitating event, followed by a latent period and subsequent development of epilepsy later in life. This knowledge has led to the development of the most common animal models of mTLE. In these models, a prolonged seizure (termed *status epilepticus,* SE) is induced by either electrical stimulation or a chemoconvulsant, leading to injury as the initial precipitating event. After a seizure-free latent period, spontaneous seizures develop and persist for the lifetime of the animal.[10,11] The two most commonly used chemconvulsant-induced SE models of mTLE are the kainic acid and pilocarpine models.

ADULT NEUROGENESIS IN THE EPILEPTIC BRAIN

Neurogenesis persists throughout adulthood in mammals, specifically in the subgranular zone of the hippocampal dentate gyrus and the subventricular zone (SVZ) of the forebrain lateral ventricles. Neural progenitor cells migrate from the dentate subgranular zone to the granule cell layer, and from the SVZ through the rostral migratory stream into the olfactory bulb. While the majority of cells are generated early in life, new dentate granule cells (DGCs) arise at a lower rate throughout adulthood and into senescence in both rats[12,13]

and humans.[14,15] Adult-born neurons make up about 6% of the granule cell layer in rats,[16] and these cells are thought to integrate into hippocampal circuitry and acquire characteristics of mature DGCs.[17,18] Additionally, bromodeoxyuridine (BrdU) labeling studies indicate that DGCs born during adulthood that become integrated into circuits will survive to maturity. These DGCs are very stable and may replace DGCs born during development.[19] Adult-born neurons are thought to play an important role in certain types of learning and memory or in regulating anxiety.[20–25]

In the rat pilocarpine model of mTLE, the rostral SVZ exhibits increased neurogenesis within weeks following prolonged seizure activity.[26] Neuroblasts generated in the SVZ migrate more rapidly to the olfactory bulb, and some exit the migratory stream prematurely.[26] As assessed by the expression of Ki-67, an endogenous cell proliferation marker, or short-pulse BrdU mitotic labeling, the dentate gyrus also responds to SE by increasing cell proliferation in the subgranular zone.[27,28] After either pilocarpine- or kainic acid-induced SE, dentate gyrus cell proliferation increases 5- to 10-fold after a latent period of several days and persists for several weeks.[27,29] In the dentate, this early proliferative response seems to be mediated by radial glial-like neural progenitor cells,[30] as well as through activation of transit-amplifying cells that are actively proliferating before SE.[31] Interestingly, even single seizure-like discharges modestly increase DGC neurogenesis.[32] Between 75% and 90% of cells newly generated after SE express mature DGC markers within 4 weeks,[27,28] and SE appears to accelerate the maturation and integration of adult-born DGCs.[33]

Approximately 3–4 weeks after an SE episode, proliferation rates return to baseline levels.[27] In fact, chronic mTLE is associated with a decrease in neurogenesis, as levels are substantially below baseline by 5 months after kainic acid-induced SE.[34] These findings may also be relevant to human epilepsy, as the dentate gyrus of children who have had frequent seizures shows decreased numbers of proliferating cells and immature neurons.[35] Potential reasons for this decrease include exhaustion of the progenitor pool, loss of needed growth/trophic factors, or altered cellular interactions (reviewed in ref. 36).

MORPHOLOGICAL ABNORMALITIES IN MTLE: ROLE OF NEUROGENESIS

The epileptic hippocampus in human mTLE is associated with numerous cellular abnormalities, including CA1 and CA3 pyramidal cell loss as well as hippocampal astrogliosis. Damage to the hilus of the dentate gyrus (DG), known as *endfolium sclerosis*, is the most commonly observed lesion in the brains of patients with mTLE.[37] Status epilepticus provoked by kainic acid or pilocarpine mimics this phenotype, destroying about half of the neurons in the dentate hilus.[38,39] The human DG also shows distinct morphological abnormalities, including mossy fiber sprouting, granule cell layer dispersion, ectopically located DGCs, and DGCs with very prominent hilar basal dendrites (HBDs).[40,41] In rodent models of SE such as the pilocarpine model, hippocampal pathways exhibit structural plasticity mirroring these changes.[11]

Mossy Fiber Sprouting

Mossy fibers are the axons of the hippocampal DGCs. The mossy fiber pathway normally projects to the pyramidal cells and interneurons of hippocampal area CA3 as well as to the dentate hilus. In the nonepileptic brain, this pathway is thought to make few, if any, recurrent synapses onto granule cells. A common feature of human mTLE,[40,41] however, and of animal models of temporal lobe epilepsy, is the development of numerous mossy fiber–granule cell synapses.[42,43]

In the epileptic human DG, Timm staining, dynorphin immunoreactivity, and biocytin cell fills reveal that mossy fibers sprout into the dentate inner molecular layer.[41,44,45] In the rat pilocarpine model of mTLE, Timm staining, used to visualize the zinc present in mossy fiber axons, also reveals significant amounts of mossy fiber sprouting in the dentate inner molecular layer.[11] Electron microscopy studies demonstrate that mossy fibers synapse onto neighboring DGCs, creating recurrent excitatory synapses.[42]

Over a dozen years ago, we first hypothesized that mossy fiber sprouting in experimental mTLE arises from adult-born rather

than preexisting DGCs.[27] When we used irradiation to kill adult-born cells in the setting of SE, however, we did not block inner molecular layer mossy fiber sprouting 4 weeks later, suggesting that DGCs generated after SE do not send axons aberrantly into the dentate inner molecular layer. To address this question more definitively, we recently used retroviral reporter labeling to birth date DGCs in combination with low-dose irradiation to transiently suppress DGC neurogenesis.[46] At 4 weeks after pilocarpine-induced SE in adult animals, we found that neither neonatally generated DGCs nor those born after SE contributed to sprouting; instead, only DGCs that were 2–4 weeks old at the time of SE showed aberrant axonal reorganization. This finding is consistent with retroviral reporter labeling studies from another group who observed that adult-generated DGCs born 4 weeks before kainic acid-induced SE contributed to inner molecular layer mossy fiber sprouting.[47] When we labeled adult-born DGCs 4 days after SE but allowed the animals to survive for 10 (instead of 4) weeks, in contrast, we found that the adult-born DGCs contributed robustly to mossy fiber sprouting[46] (Fig. 38–1).

The finding of mossy fiber remodeling only by developing or newborn, and not mature, DGCs has key mechanistic implications for understanding seizure-induced DGC plasticity. Rather than recapitulating development, mossy fiber sprouting after SE appears to involve an alteration of ongoing development. This sprouting is thought to be progressive in nature, beginning 2 weeks after SE and peaking at around 100 days post-SE.[11,48] The idea that successive generations of adult-born DGCs sprout aberrantly as they develop is consistent with this progression of mossy fiber reorganization for several months after SE.[11] In fact, the timing of transiently increased neurogenesis for 2–3 weeks after the initial seizures[27] followed by a potential suppression of neurogenesis chronically,[34] along with the delay in adult-born neurons manifesting aberrant axonal outgrowth, fits well with a model in which most or all of the newborn DGCs eventually sprout. Such a time course would lead to a peak in mossy fiber sprouting at about 2–3 months after SE.

Hilar Ectopic Granule Cells

The vast majority of neurons born in the subgranular zone during adult life migrate into the granule cell layer. After SE, many DGCs migrate instead into the dentate hilus or through the granular layer into the molecular layer.[27,34,49–51] These ectopic cells are found in rodent models of epilepsy[27,49,50] (Fig. 38–2), and similar ectopically located granule-like neurons appear in the epileptic human hippocampus.[51,52]

Hilar ectopic granule cells may result from abnormal migratory behavior of DGC

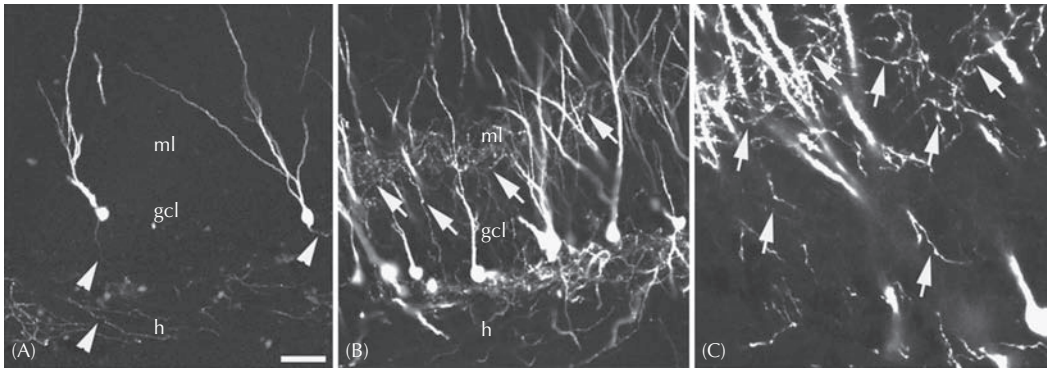

Figure 38–1. Mossy fiber sprouting by adult-born DGCs. **A–C.** Confocal images of coronal brain sections through the dentate gyrus of adult rats injected with retrovirus carrying a green fluorescent protein reporter (RV-GFP) and immunostained for GFP. A control received an injection of RV-GVP 4 days after saline treatment and survived for 10 weeks (**A**). Note the labeled DGC bodies in the granule cell layer (gcl), dendrites in the molecular layer (ml), and axons (arrowheads) in the hilus (h). An epileptic rat received a RV-GFP injection 4 days after pilocarpine treatment and survived for 10 weeks (**B**). Note the labeled mossy fibers (arrows) coursing through the inner ml orthogonal to the larger-caliber DGC dendrites. **C.** A higher-magnification view of the dentate gyrus in **B**. Scale bar (in **A**): 25 μm for **A**,**B**; 15 μm for **C**.

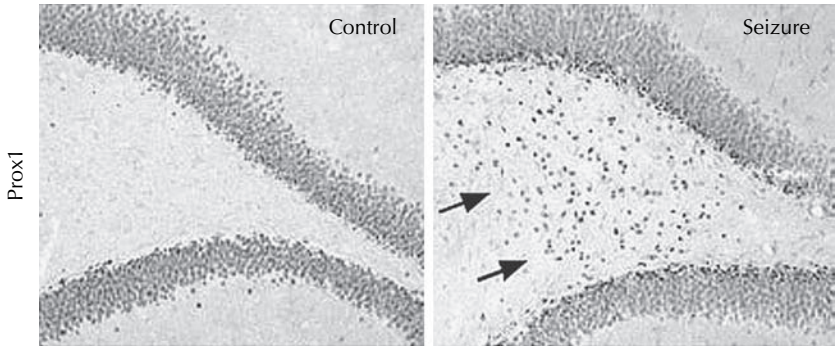

Figure 38–2. Hilar ectopic DGCs in experimental mTLE. Prox1 immunolabeling of DGCs from adult rats 35 days after saline (Control, left panel) or pilocarpine treatment (Seizure, right panel). Note the abundant Prox1-immunoreactive DGCs in the hilus of the epileptic rat (arrows).

progenitors after epileptogenic insults, as SE appears to cause aberrant chain migration of DGC progenitors to the hilus and the molecular layer.[51] Some propose a critical period after the birth of adult-generated neurons during which they are vulnerable to being recruited into epileptogenic neuronal circuits,[53] and indeed, we find that only DGCs generated after SE migrate ectopically.[46] One proposed cause of the aberrant migration is loss of the migration guidance cue Reelin, which is expressed in the adult rodent hippocampus.[54]

Hilar Basal Dendrites

The persistence of HBDs, normally a feature of only immature DGCs, may be a mechanism contributing to the hyperexcitability of adult-born DGCs in epilepsy. The percentage of granule cells with HBDs is probably substantially higher in persons with mTLE,[55] and this finding is recapitulated in several animal models in which prolonged seizures induce an increased percentage of granule cells with basal dendrites located at the hilar border and extending into the granule cell layer.[56,57] Many of these basal dendrites have numerous spines, suggesting that they are postsynaptic to axon terminals.[49,50,58] Using Thy1-GFP mice, Walter and colleagues[53] found that almost 50% of immature granule cells in mice exposed to pilocarpine-induced SE exhibited HBDs, and newborn cells were even more severely impacted than immature cells. In the rat pilocarpine model, about a third of adult-born DGCs that are 2 weeks old at the time of SE, or born 4 days after SE, develop HBDs.[46]

Electron microscopy demonstrates that HBDs form asymmetric synapses and are innervated by mossy fibers, potentially creating recurrent excitatory circuits.[59,60] Hilar basal dendrites can form on granule cells as early as 1 week following SE. Although the molecular mechanisms for the persistence of these HBDs are not well defined, they may involve changes in the glial scaffold.[61]

FUNCTIONAL IMPLICATIONS OF DGC ABNORMALITIES IN MTLE

A large body of information supports the hypothesis that cellular abnormalities such as mossy fiber sprouting, ectopic DGCs, and HBDs contribute to epileptogenesis in experimental and human mTLE. The functional implications of these abnormalities, however, and the contribution of adult-born DGCs to intact or epileptic hippocampal network function remain unclear. Here we describe the potential effects on hippocampal function of the different types of seizure-induced plasticity associated with aberrant neurogenesis.

Mossy Fiber Sprouting

Seizures in mTLE have been proposed to result from hyperexcitability due to aberrant excitatory recurrent axon collaterals between

granule cells.[62,63] Integration of light microscopic and electron microscopic data suggests that the majority of synapses formed by mossy fibers in the granule cell and molecular layers are with other granule cells, leading to recurrent excitation.[42,62,63] Additionally, evidence suggests that normal gamma-aminobutyric acid (GABA) inhibition is diminished by mossy fiber terminals, further contributing to hyperexcitability.[64] Recent data also suggest that interventions to block mossy fiber sprouting reduce the severity of seizures.[65]

However, further levels of complexity likely underlie epileptic pathogenesis. Although the aberrantly sprouted mossy fibers clearly form at least some recurrent excitatory synapses with other granule cells, some work suggests that DGC sprouting contributes to the synaptic drive onto inhibitory interneurons.[66] Anatomical analysis of epileptic rat hippocampi reveals that some aberrant granule cell axons densely innervate inhibitory neurons.[42,67] Furthermore, the density of mossy fiber sprouting may not be associated with the total number of lifetime seizures or the seizure frequency in experimental or human TLE.[68] These data suggest that other mechanisms in addition to mossy fiber sprouting might contribute to enhanced hippocampal excitability during epileptogenesis.

HBDs and Hilar Ectopic Granule Cells

Many studies have found that compared with controls, an increased number of granule cells in epileptic rats extended a basal dendrite into the hilus, providing a potential route for recurrent excitation.[59,60] Modeling studies suggest that even a relatively small percentage of DGCs, if hyperinnervated by excitatory input (so-called *hub* cells), could lead to spontaneous seizures.[69] Adult-born DGCs with long HBDs that receive excessive excitatory input may be just such cells.

Hilar ectopic granule cells themselves are also thought to be hyperexcitable. They have been shown to be postsynaptic to mossy fibers and have less inhibitory input on their somata and proximal dendrites than DGCs in the granule cell layer.[49,70] This finding is consistent with results showing that hilar ectopic granule cells are more excitable than granule cells in the granule cell layer, and they burst fire in synchrony with spontaneous, rhythmic bursts of area CA3 pyramidal cells that survive SE.[50] Consistent with these data is the finding that ablating neurogenesis after SE, the time when ectopic cells form,[46] attenuates subsequent epileptogenesis, with a reduction in the frequency and severity of spontaneous recurrent seizures.[71]

One study, however, suggests the opposite, namely, that adult-born neurons that integrate normally may compensate for hyperexcitability after an epileptogenic insult. Jakubs and colleagues[72] induced SE with electrical stimulation and then labeled adult-born neurons with retrovirus-expressing green fluorescent protein (GFP). They recorded from the GFP-labeled cells in acute hippocampal slices and found that they showed increased inhibitory drive and decreased excitatory input compared to GFP-labeled cells in controls and mature DGCs in epileptic rats. However, they only studied adult-born neurons that integrated normally. These findings suggest that increased DGC neurogenesis after SE leads to heterogeneous populations of adult-born DGCs, some of which integrate aberrantly and may become hyperexcitable, while others integrate normally and may restore inhibition (Fig. 38–3).

COMORBIDITIES ASSOCIATED WITH MTLE

The comorbidities associated with epilepsy include cognitive, behavioral, and emotional difficulties. Persons with epilepsy are at increased risk for depression, anxiety, sleep disturbances, and cognitive impairment (reviewed in ref. 73). Cognitive impairments include problems with memory, verbal fluency, and executive function.[7,74] Approximately 70% of patients with mTLE have problems with memory function, which represents the most common cognitive impairment in this group.

Neurons generated during epileptogenic insults may impact learning in several ways, including interference with normal network function caused by aberrantly integrated neurons (Fig. 38–3). This idea is supported by the finding that inhibition of seizure-induced neurogenesis with valproic acid (acting as a histone deacetylase inhibitor) protects epileptic animals from deficits in hippocampal-dependent object recognition.[75] Alternatively, suppression

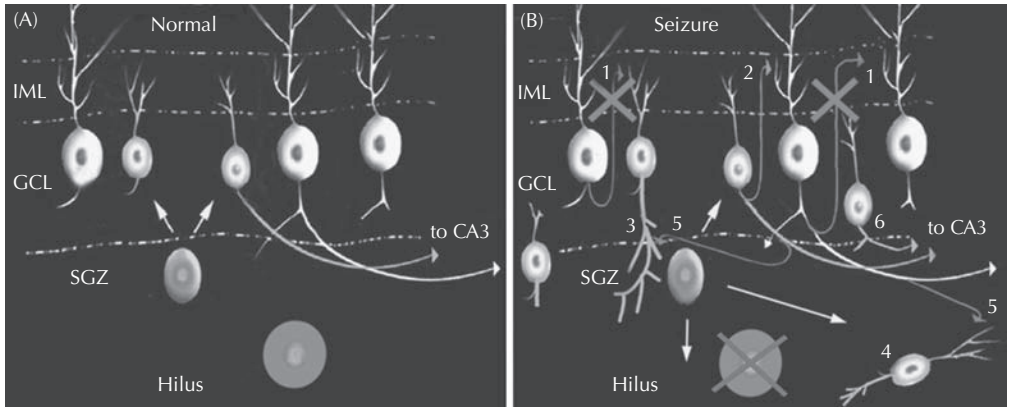

Figure 38–3. Aberrant neurogenesis in experimental mTLE. Schematic of the intact adult dentate gyrus (**A**) with a DGC progenitor in the subgranular zone (SGZ) giving rise to immature DGCs (arrows). In the epileptic dentate gyrus (**B**), mossy fiber sprouting does not come from mature DGCs (1), but instead arises from developing or newborn DGCs (2), which also display HBDs (3), ectopic migration (4), and possibly axonal sprouting onto DGCs with HBDs or ones that are ectopic (5). Some newborn DGCs appear to integrate normally and may restore inhibition (6). IML, inner molecular layer; GCL, granule cell layer.

of neurogenesis during chronic epilepsy could interfere with learning and memory.[34]

Depression is another important comorbidity in epilepsy (reviewed in ref. 76). Adult neurogenesis is unlikely to be related to the development of depression per se, but some studies suggest that the production of DGCs is necessary for an adequate response to antidepressants in rodent models of depression (reviewed in ref. 77). Even more compelling is recent work suggesting that loss of adult-born DGCs leads to an anxiety phenotype.[24] Thus, both cognitive and emotional behaviors have been linked to the production of adult-born DGCs. In summary, altered adult neurogenesis in the chronic epileptic state deserves further study to evaluate its potential role in the development of mTLE and its associated comorbidities.

Chapter 39

Temporal Lobe Epilepsy and the BDNF Receptor, TrkB

James O. McNamara
Helen E. Scharfman

INTRODUCTION

One of the most difficult but most important goals of epilepsy research today is to address the underlying mechanisms that contribute to seizures. Another important issue is understanding epileptogenesis—the transformation of the normal brain to a chronic epileptic state. If these issues can be effectively addressed, the resultant insights may lead to the development of better antiepileptic drugs (AEDs) to treat seizures and antiepileptogenic drugs that can prevent the disease. Current AEDs target many ion channels known to contribute to neuronal excitability. This broad "net" can help reduce seizures, but it also leads to side effects. Further, sometimes seizures cannot be controlled even with high doses of these drugs (pharmacoresistance). Mesial temporal lobe epilepsy (MTLE) is a good example of a condition with a complex set of causes and a subset of patients who are pharmacoresistant. Therefore, understanding the mechanisms of MTLE has been a subject of avid interest. Combining a clear clinical characterization of MTLE with insights from research using animal models,

as discussed below, has revealed a potential control point for new antiepileptic and antiepileptogenic therapy: the neurotrophic factor brain-derived neurotrophic factor (BDNF) and its receptor, TrkB.

MTLE: A PROGRESSIVE DISORDER IN HUMANS AND ANIMAL MODELS

Mesial temporal lobe epilepsy, the most common form of partial epilepsy, is a progressive disorder in a substantial number of affected individuals.[1,2] The progression is evident in part as persistence of disabling seizures despite anticonvulsant therapy, the refractoriness to therapy sometimes arising years after onset of the disorder.[3] Progression is also evident as destruction of hippocampus and parahippocampal gyrus and temporal lobes, as revealed in multiple magnetic resonance imaging (MRI) analyses conducted over time in patients with MTLE compared to normal controls.[4] Additional evidence of progressive atrophy of neocortical gray matter has been demonstrated by an independent group of investigators using MRI analyses in a cross-sectional study of MTLE patients compared to age-matched controls as well as a longitudinal study in which patients served as their own controls.[5]

What underlies the progression of MTLE in this subset of affected individuals? An astute clinician, Sir William Gowers, proposed that seizures themselves contributed to the progression of epilepsy.[6] Discovery of the kindling phenomenon, by Graham Goddard and colleagues,[7] almost a century later, validated Gowers' idea. In this model, repeated induction of brief focal seizures by chemical or electrical stimuli eventually results in longer and more severe focal and tonic-clonic seizures. Once established, this enhanced sensitivity to electrical stimulation persists for the life of the animal. While 15 or so stimulations (e.g., in the amygdala) are required to induce this lifelong enhanced sensitivity, additional stimulations (80+) lead to the emergence of spontaneous seizures[8,9] and destruction of cortical gray matter.[8] That is, periodic induction of isolated seizures (e.g., at daily intervals) in an animal model is sufficient to induce a progressive increase in the severity of evoked seizures, emergence of spontaneous seizures, and destruction of cortical gray matter.[10] Indeed, a progressive increase in seizure frequency is evident in a diversity of additional animal models, including models in which epilepsy is induced by stroke, or status epilepticus.[11–13] Whether seizures themselves cause the progression in these models is currently under investigation. That said, study of the kindling model clearly demonstrates that recurrent isolated seizures, not simply status epilepticus, are sufficient to produce spontaneous recurrent seizures and destruction of cortical gray matter.[7–10] Given the presence of recurrent seizures in a subset of humans with medically refractory MTLE and progressive increase in seizure frequency in animal models (e.g., status epilepticus and stroke), it seems plausible that recurrent seizures per se constitute one factor contributing to the progression of the epileptic state.

SEIZURES: A PATHOLOGICAL FORM OF NEURONAL ACTIVITY

Elucidating the molecular mechanisms by which recurrent seizures promote worsening of the epileptic condition, evident as spontaneous recurrent seizures and destruction of cortical gray matter, may provide novel targets for drugs aimed at limiting worsening of the condition in humans and also provide clues to the underlying cellular mechanisms. The recurrent isolated seizures that cause worsening of seizures and death of cortical neurons in the kindling model consist of an abnormal form of neuronal activity. Thus, the question arises as to how fleeting changes in neuronal activity (i.e., isolated recurrent seizures) produce lasting changes in brain structure and function (i.e., more severe seizures and destruction of neurons). Similar questions are being posed with respect to physiological forms of activity, the idea being that fleeting experiences are associated with fleeting patterns of neuronal activity. For example, how are fleeting visual experiences during development transformed into the lasting structural and functional modifications that underlie normal vision? How are brief experiences transformed into a memory that persists for a lifetime? Gene transcription is one molecular mechanism by which fleeting experiences can be encoded as persistent

changes in neuronal structure and function. This "answer," in turn, raises the question of which particular gene(s) might underlie the lasting modifications of neuronal structure and function that culminate in worsening of the epileptic condition in MTLE.

BDNF: AN ATTRACTIVE CANDIDATE GENE

If gene transcription provides a molecular mechanism underlying worsening of MTLE, what are the features of that particular gene (or genes), the transcription of which might lead to the lasting modifications of neuronal structure and function underlying worsening of MTLE? Important criteria for such a gene include the requirements that its expression is regulated by seizure activity, and that structural and functional consequences of its expression in model systems mimic features of an epileptic brain.

One gene meeting those criteria encodes BDNF. Yves Barde and colleagues[14] purified BDNF protein from pig brain extracts in their search for a factor that supported the survival and neurite outgrowth of embryonic chick sensory neurons. Subsequently, BDNF was found to activate a receptor tyrosine kinase named TrkB.[15] Packaged in dense core vesicles in axon terminals, BDNF is a 14 kDa secreted protein that binds to the ectodomain of TrkB, thereby inducing receptor dimerization, activation of receptor tyrosine kinase activity, and phosphorylation of select tyrosines in the cytoplasmic domain—which creates docking sites for adaptor proteins (shc) or enzymes (PLCγ1) that couple these receptors to intracellular signaling cascades. Relatives of BDNF include the other neurotrophins: nerve growth factor (NGF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4). Likewise, relatives of TrkB include two other receptor tyrosine kinases, TrkA and TrkC; NGF serves as the ligand for TrkA, BDNF and NT-4 for TrkB, and NT-3 for TrkC.

Seizure-regulated expression of BDNF, together with its effects in simplified model systems, make the genes for BDNF and its receptor (TrkB) attractive candidates for promoting worsening of MTLE. Seizures induce dramatic increases in BDNF mRNA and protein expression in both animal models and humans with epilepsy.[16–21] Moreover, activation of TrkB by BDNF produces structural plasticities of the hippocampal dentate granule cells[22] similar to those identified in the epileptic brain.[23–27] In addition, BDNF promotes enhanced efficacy of excitatory synapses connecting principal neurons, a form of long-term potentiation[28–36] that is a type of plasticity identified at synapses of animal models of epilepsy.[37] Brain-derived neurotrophic factor-mediated activation of TrkB can also compromise gamma-aminobutyric acid (GABA)-mediated inhibition.[38]

EVIDENCE IMPLICATING BDNF AND TrkB IN MTLE

Animal Models In Vivo

Because blood-brain barrier-permeable drugs that selectively inhibit the activation of TrkB by BDNF have not been available, elucidating a causal role of BDNF and TrkB signaling in animal models of MTLE has required the development of genetically modified mice. Although mice lacking both *BDNF* alleles in the germline die in the neonatal period, elimination of just one *BDNF* allele results in a striking inhibition of development of kindling.[39] An alternative approach utilized *Trk receptor bodies*, recombinant proteins that bind and thereby scavenge neurotrophin ligands selectively for either TrkB or its relatives, TrkA and TrkC. Intraventricular infusion of TrkB receptor bodies markedly inhibits the development of kindling in adult rats, whereas infusion of TrkA or TrkC receptor bodies has no effect.[40] These findings demonstrate that scavenging BDNF de novo in the adult brain inhibits kindling development, suggesting that the consequences of absent BDNF during development are not sufficient to explain the impaired kindling found by Kokaia et al.[39] Moreover, these findings suggest that the neurotrophin receptor pivotal for seizure progression in this model is TrkB, not TrkA or TrkC. This suggestion was reinforced by the discovery that a conditional deletion of TrkB from subsets of central nervous system (CNS) neurons eliminated all behavioral evidence of seizure-induced progression of epilepsy in the kindling model[41] (Fig. 39–1). This conditional deletion of TrkB is the sole genetic or pharmacological perturbation known to eliminate all vestiges of behavioral evidence of kindling

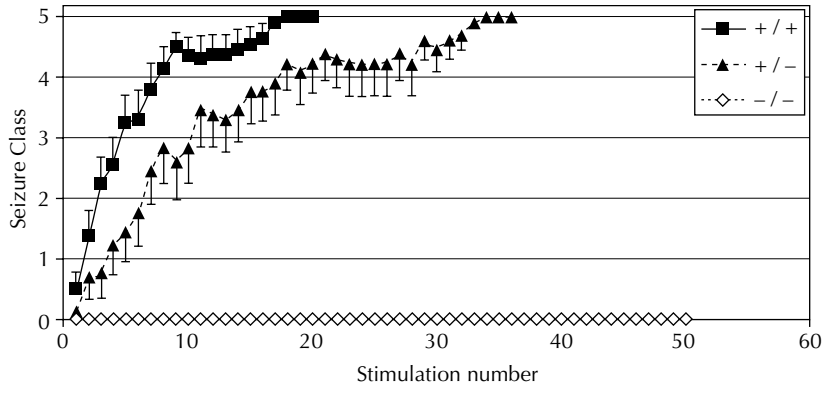

Figure 39–1. Inhibition of kindling by conditional deletion of TrkB. Kindling was compared in three groups of mice: $TrkB^{-/-}$, $TrkB^{-/+}$, and $TrkB^{+/+}$. The seizure score was determined in response to each kindling stimulation using the Racine scale (Stages 1–5). The seizure score increased progressively with kindling stimulation in $TrkB^{+/+}$ mice but was reduced in $TrkB^{-/+}$ mice, and no seizures were elicited in $TrkB^{-/-}$ mice. From ref. 41.

development. Taken together, these findings provide compelling evidence that TrkB is necessary for seizure-induced progression of epilepsy in the kindling model and suggest that BDNF contributes, at least in part, to activation of TrkB in this condition.

In additional studies, the issue of whether increasing expression of BDNF or TrkB is sufficient to induce hyperexcitability and limbic epilepsy has been addressed. Indeed, intrahippocampal infusion of BDNF, or transgenic overexpression of either BDNF or TrkB in transgenic mice, proved sufficient to increase seizure susceptibility or severity or induce seizures outright.[42–45] These findings support the conclusion that enhanced BDNF-mediated activation of TrkB is *sufficient* to induce hyperexcitability and limbic epilepsy. The evidence of both the sufficiency and necessity of BDNF and TrkB signaling in these animal models in vivo raises the question of whether this signaling pathway may be instructive for seizure-induced progression of MTLE. If so, then seizures themselves would be expected to produce enhanced activation of TrkB.

Limbic Seizures Enhance TrkB Activation

The occurrence of enhanced TrkB activation as a consequence of seizures would strengthen the likelihood that signaling activated by TrkB serves an instructive role in seizure-induced progression of MTLE. If seizures induce enhanced activation of TrkB, then elucidating the anatomical locale of this enhancement could pinpoint a specific population of neurons at which to investigate the cellular consequences of the enhanced activation of TrkB. And if seizures induce enhanced activation of TrkB, this would raise the question of the molecular mechanism by which seizures lead to enhanced activation of TrkB in vivo.

How does one measure activation of a receptor tyrosine kinase like TrkB? In contrast to ionotropic receptors for glutamate or GABA, the activation of which can be measured with electrophysiological techniques, a commonly used method for measuring activation of receptor tyrosine kinases utilizes antibodies that recognize phosphorylated tyrosines in the cytoplasmic domain of these proteins. Because activation of TrkB involves phosphorylation of specific tyrosine residues in its cytoplasmic domain,[46] the availability of antibodies that selectively recognize the phosphorylated form of Trk receptors (p-Trk) provides a surrogate measure of TrkB activation in Western blot studies of membrane fractions or in immunohistochemical studies. Immunohistochemical evidence of increased TrkB activation, evident as increased p-Trk immunoreactivity in the mossy fiber pathway of hippocampus, has been shown following induction of seizures by diverse patterns of electrical stimulation and diverse chemoconvulsants in rats and mice.[41,47–49] Interestingly, the biochemical and immunohistochemical evidence of TrkB

activation is evident beginning several hours after the occurrence of seizures and dissipates within 1 week.[47]

Potential Cellular Consequences of TrkB Activation Induced by Seizures

The demonstration that seizure-induced progression of epilepsy is inhibited in the TrkB and BDNF mutant mice, together with evidence of enhanced TrkB activation in diverse seizure models, suggests that the cellular consequences of enhanced activation of TrkB may promote progression of MTLE. The anatomical localization of the increased p-Trk immunoreactivity to the mossy fiber pathway directed our study of potential cellular consequences of TrkB activation to this locale. Both ex vivo and in vivo studies of animal models raise the possibility that long-term potentiation (LTP) of excitatory synapses between principal cells may contribute to limbic epileptogenesis[37]; that is, potentiation of these synapses may facilitate propagation of seizure activity through synaptically coupled neuronal populations throughout the limbic system and beyond. In support of this hypothesis, we showed that development of LTP of the synapses made by mossy fiber axons of the dentate granule cells with CA3 pyramidal cells requires TrkB kinase activity.[50] Further, study of hippocampal slices isolated from animals following induction of seizures in vivo (in the kainic acid model) revealed that the mossy fiber–CA3 synapse had undergone LTP.[51] The requirement for TrkB-dependent signaling for LTP of this synapse, together with immunohistochemical evidence of increased TrkB activation in the mossy fiber pathway in sections ex vivo from these models,[46,47] suggests that activation of TrkB in vivo may contribute to the LTP of this synapse induced by seizures.

The results of these in vitro and ex vivo electrophysiological studies in animal seizure models are consistent with those of earlier studies of hippocampal slices isolated from naive rats; those studies revealed that transient tissue exposure to recombinant BDNF led to potentiation of the mossy fiber–CA3 synapse.[52] Potentiation was long-lasting, continuing long after exposure to BDNF, as shown also for BDNF-induced potentiation in area CA1.[32] The effects of BDNF in area CA3 appeared to be specific to the mossy fiber input, because activation of the recurrent collaterals or input from fibers in the fimbria did not exhibit synaptic potentiation. Furthermore, the intrinsic properties of CA3 neurons did not appear to be affected by this treatment,[53] and fiber volleys were also unaffected by BDNF.[52] Potentiation was Trk-dependent, as shown by its blockade by the antagonist K252a.[52]

Notably, enhanced excitability in models of epilepsy is often accompanied (and likely caused) by both enhanced function of excitatory synapses and impaired function of inhibitory synapses. Might enhanced activation of TrkB also compromise inhibitory function and thereby contribute to the increased excitability seen in limbic epilepsy? One interesting possibility is that enhanced TrkB activation reduces expression of the K-Cl cotransporter, KCC2, resulting in accumulation of $[Cl^-]_i$ and a shift of E_{GABA} in a depolarizing direction.[54] Direct study of human epileptic tissue,[55,56] as well as extensive study of diverse in vivo and in vitro models,[54,57–61] suggests that reduced expression of KCC2 and resulting accumulation of $[Cl^-]_i$ is an important molecular and cellular mechanism contributing to limbic epilepsy. Further, in vitro studies demonstrate that TrkB-mediated activation can suppress KCC2 expression.[54,57] Whether TrkB-mediated activation is responsible for reductions of KCC2 expression described in the kindling and pilocarpine models[57,60] in vivo is unclear.

WHAT IS THE MOLECULAR MECHANISM MEDIATING TrkB ACTIVATION BY SEIZURES IN VIVO?

The localization of the increased p-Trk immunoreactivity to the mossy fiber pathway provided us with the opportunity to examine the molecular mechanism by which seizures induced the increased p-Trk immunoreactivity. The striking seizure-induced increases in BDNF immunoreactivity in the mossy fibers occurred with a time course similar to that of increased p-Trk immunoreactivity, thus supporting the idea that BDNF was responsible for the increase in p-Trk immunoreactivity. Unexpectedly, seizures induced increased p-Trk immunoreactivity in the mossy fiber

pathway in conditional BDNF null mutant mice similar to that seen in wild-type control mice.[41] What mediated the increased TrkB activation in the mossy fiber pathway following seizures in the *BDNF* $^{-/-}$ mice? The increased expression of NT-3 protein in the *BDNF* $^{-/-}$ mice is an interesting possibility, both because of NT-3's ability to activate TrkB[15,62,63] and because of the localization of NT-3 to the dentate granule cells,[64,65] whose mossy fiber axons coincide with the spatial distribution of the activated TrkB. Alternatively, transactivation of TrkB by zinc may contribute. *Transactivation* refers to the process whereby a given receptor and its downstream signaling are activated by a stimulus that does not interact directly with the receptor,[66] a mechanism distinct from activation of TrkB by neurotrophins. The seizure-induced activation of TrkB is localized to the mossy fiber pathway,[67–69] and the mossy fiber axons contain the highest concentration of zinc in mammalian forebrain.[70] Zinc is packaged in synaptic vesicles together with glutamate and is released with glutamate by physiological stimulation.[71] We demonstrated that zinc transactivates TrkB by a neurotrophin-independent and Src-dependent mechanism that is regulated by neuronal activity.[50] One functional consequence of zinc-mediated transactivation of TrkB is LTP of the mossy fiber–CA3 pyramid synapse. While zinc can transactivate TrkB in vitro, whether endogenous zinc contributes to TrkB activation in the hippocampal mossy fiber pathway following seizures in vivo awaits further study.

THE POTENTIAL ROLE OF BDNF IN CATAMENIAL EPILEPSY

The discussion above provides compelling arguments for a role of BDNF and TrkB in limbic epileptogenesis and MTLE. In addition, BDNF and TrkB signaling can potentially answer some questions that have puzzled scientists who study epilepsy, such as the reason a subset of patients appear to become progressively worse. For example, pharmacoresistance may develop, progressive structural deterioration may occur, as shown by neuroimaging, or cognitive side effects may become increasingly severe. Another common question—albeit one that seems very different—is the reason the reproductive endocrine system has such powerful effects on seizures. Below, we discuss this question as it relates to BDNF and suggest that although progression in MTLE and the effects of reproductive steroids on seizures seem very different, both may be explained, at least in part, by the effects of BDNF.

One of the reasons the relationship between reproductive hormones and seizures has remained unclear is that effects of estrogen, progesterone, and testosterone, the major reproductive steroid hormones, are usually inconsistent. The reasons for the lack of consistency are unclear and may be based in biological complexity, or there simply could be an appearance of inconsistency because of differences in experimental procedures across studies.[72]

The clinical observations that suggest a role of reproductive steroids in epilepsy are diverse. They include reports of changes in seizures at times of life when the reproductive status is altered, such as puberty, when epilepsy is often diagnosed for the first time.[73] In pregnancy or at menopause, other times of life when large fluctuations in levels of reproductive steroids occur, there also are changes in seizure severity in women with epilepsy,[74,75] although they are not universal. Other clinical data that support an influence of reproductive hormones on epilepsy are based on studies that have evaluated circulating levels of specific reproductive hormones, such as estrogen and progesterone, and have shown that when these levels fluctuate, seizures often fluctuate in severity.[72,76–79]

Here we address the effects of reproductive steroids on seizures by focusing on seizures during the menstrual cycle, a condition that is easier to study than puberty or menopause because it occurs at a relatively stable time of life (adulthood) and is relatively short in length (28 days). In addition, the menstrual cycle is repetitive, providing scientific advantages because measures can be repeated. However, studies of seizures during the menstrual cycle present some challenges. One problem is the ability to distinguish the effects of hormones like estrogen and progesterone from other changes that occur during the menstrual cycle, such as changes in luteinizing hormone or follicle stimulating hormone. Fluid retention, which often occurs during the perimenstrual period, can have effects on seizures that are independent of the effects of reproductive steroid levels.[80–82] In addition,

there are potential confounds of seizures in studies of the menstrual cycle in women with epilepsy, because there can be acute effects of a seizure on the endocrine system (even a single seizure), such as elevation of prolactin.[82] Effects of repeated seizures also have consequences for the endocrine system. Long-term, chronic seizures appear to have adverse effects on reproductive function, such as irregular or anovulatory cycles and polycystic ovarian syndrome (PCOS).[74,83] These adverse effects have been suggested to be due to AEDs such as valproic acid, but there is evidence that seizures also contribute to the disruption of the menstrual cycle and PCOS.[84,85] A strong argument for a role of chronic seizures in reproductive dysfunction (including irregular cycles and PCOS), instead of a role of AEDs, is that laboratory animals show signs of acyclicity and PCOS after repeated seizures—without ever being treated with AEDs.[85–89] Another challenge to research is that the endocrine systems of women and laboratory rodents are very different. The differences are exemplified by a comparison of the ovarian cycle of women and the laboratory rat. As shown in Fig. 39–2A, the rat cycle (estrous cycle) is only 4 days, in contrast to the 28-day menstrual cycle in women. In addition, there is primarily one surge in estrogen during the estrous cycle in rats that

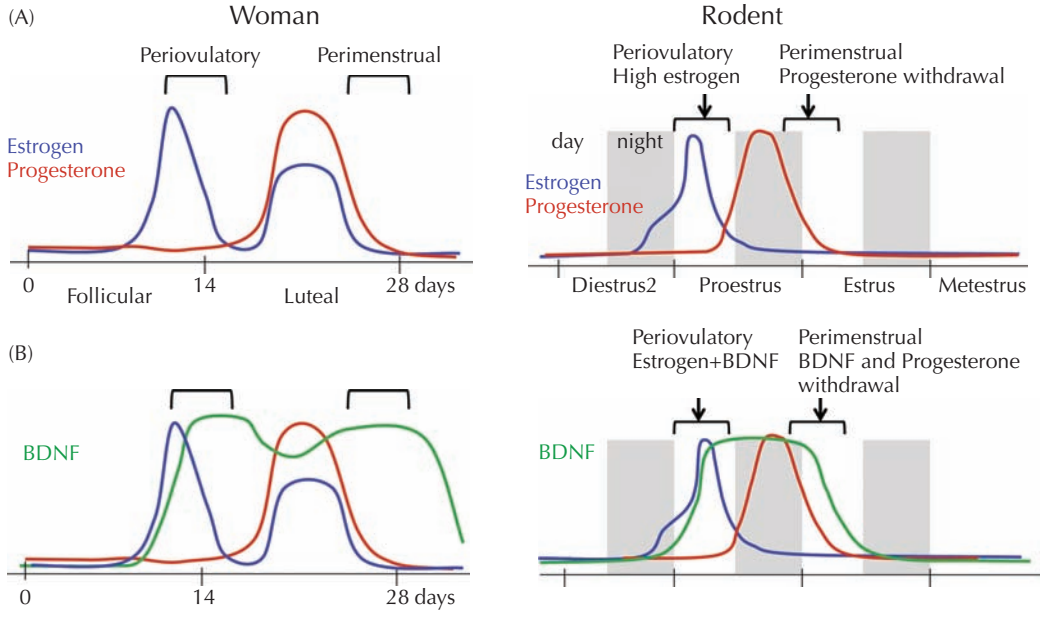

Figure 39–2. Explanations for catamenial epilepsy.

Top: The estrogen/progesterone hypothesis for catamenial epilepsy is shown schematically. The changes in serum estrogen and progesterone levels during the ovarian cycle are diagrammed for the rat (A) and the woman (B). In the rat, there is a 4-day cycle called the *estrous cycle*. In women, the 28-day cycle is divided into a follicular and a luteal phase. In catamenial epilepsy, the periovulatory and perimenstrual periods of the menstrual cycle are typically the times of the menstrual cycle when seizures worsen; the analogous times are marked for the rodent and human cycles.[72] One of the most common hypotheses to explain catamenial epilepsy is based on the idea that estrogen is pro-convulsant and progesterone has the opposite effect.[72,77] In addition, when progesterone levels fall dramatically at the end of the luteal phase, increased excitability has been demonstrated, and this contributes to perimenstrual seizure exacerbation.[72,76,77,78,145,146]

Bottom: An alternative hypothesis for catamenial epilepsy based on the role of BDNF in actions of estrogen and progesterone. A. The rise in hippocampal BDNF during the estrous cycle in the female rat is shown schematically, based on immunocytochemistry,[99] and illustrates a long-lasting elevation in BDNF after the preovulatory surge in estrogen. B. Based on the rodent data, a schematic is shown that illustrates the predicted rise in BDNF levels that would occur in women, that is, a long-lasting rise in BDNF following the preovulatory rise in serum estrogen levels. Because estrogen also rises during the luteal phase, BDNF could remain elevated during the entire luteal phase and the perimenstrual period. This prediction has support from measurements of serum BDNF in women, which is high during the luteal phase relative to the follicular phase.[112] Note that the times when BDNF is elevated and progesterone is low correspond well to the periovulatory and perimenstrual periods, in both rats and women, providing an alternative hypothesis for catamenial epilepsy.

occurs just before ovulation, but in women, there is a preovulatory surge as well as a secondary increase in estrogen between days 14 and 28, the luteal phase (Fig. 39–2).

CATAMENIAL EPILEPSY: DEFINITION AND POTENTIAL MECHANISMS

Catamenial epilepsy refers to seizures that increase in frequency or severity at specific stages of the menstrual cycle[90] and has been known for a long time. One of the first descriptions was published by Gowers in the same monograph that is discussed in the first section of this chapter.[6] In the last few decades, as the effects of hormones on excitability became better documented, there has been a more focused discussion about hormone-sensitive seizures. The ensuing clinical research studies that defined the incidence of catamenial epilepsy have not always been in agreement, with many investigators not completely convinced that catamenial epilepsy is a robust, reliable phenomenon[91] and others reporting, in contrast, a substantial prevalence— approximately one-third of women with epilepsy.[92]

Bäckstrom[93] was one of the first to document seizures in women that varied during the menstrual cycle. Both the seizures and the response to AEDs seemed to fluctuate, and did so mostly at two times of the menstrual cycle: (1) in midcycle, when ovulation occurs, and (2) at the end of the cycle, when menstruation begins. The times when seizures worsened did not coincide exactly with the time of ovulation or the onset of menses, leading to the terms *periovulatory* and *perimenstrual* to describe the two patterns.

Bäckstrom[93] suggested that the fluctuations in seizures were due to changes in serum levels of estrogen and progesterone, because of the large increase in circulating estrogen concentration that occurs just before ovulation, and a dramatic fall in progesterone levels at the end of the menstrual cycle (Fig. 39–2A). Bäckstrom suggested that the relative levels of estrogen and progesterone (the estrogen/progesterone ratio) helped explain the rise and fall in seizures: high ratios explaining seizure exacerbation and low ratios correlating with times when seizures were controlled by AEDs or were less severe/less frequent.

Herzog and colleagues[90] described three patterns of catamenial epilepsy: (1) seizures that worsen during the periovulatory period, (2) seizures that worsen during the perimenstrual period, and (3) seizures that worsen during anovulatory cycles when there is a failure of luteal rise in progesterone. The third seizure pattern helped to describe some women with epilepsy who developed irregular cycles or reproductive dysfunction in the course of epilepsy and experienced more severe or frequent seizures. Herzog and colleagues[90] echoed the suggestion of Bäckstrom that high estrogen levels were responsible for periovulatory seizures, and that the dramatic fall in progesterone late in the menstrual cycle caused perimenstrual seizure exacerbation. Furthermore, anovulatory cycles, associated with exacerbation of seizures, were attributed to low levels of progesterone.[90]

The basis for the idea that estrogen and progesterone levels explain seizure frequency was based on an emerging understanding of estrogen and progesterone actions in the brain at the time. To a large extent, experimental data suggested that estrogen was excitatory, and some investigators showed that it facilitated seizures or was pro-convulsant.[72] In contrast, progesterone appeared to be inhibitory, an effect mediated by its metabolite allopregnanolone (see below). As a result, progesterone or allopregnanolone were considered anti-convulsant. These ideas were attractive as a parsimonious way to explain clinical data and were consistent with neuroendocrinological findings outside of the field of epilepsy. However, the actions of estrogen and progesterone can also be potentially explained by their effects on BDNF.

ALTERNATIVE EXPLANATIONS FOR CATAMENIAL EPILEPSY BASED ON THE INTERPLAY BETWEEN ESTROGEN, PROGESTERONE, AND BDNF

The Role of BDNF in the Actions of Estrogen

It has been known for some time that estrogen targets growth factors, and in early life this interaction is thought to be critical for

appropriate neurodevelopment.[94] However, it was only recently suggested that estrogen may target growth factors in the brain, and specifically the neurotrophins.[94] In 1995, the link between estrogen and BDNF in the brain became better defined when Sohrabji and colleagues identified an estrogen response-like element on the gene for BDNF, and showed that ovariectomy of adult female rats reduced BDNF levels in the brain and estrogen treatment reversed the effect[95] (see also ref. 96). These studies raised the following question: do physiological fluctuations in estrogen also induce BDNF synthesis? In addition, where in the brain would estrogen-induced BDNF synthesis occur? One would think that it would occur wherever BDNF protein synthesis normally occurs, such as in the mossy fiber axons of dentate gyrus granule cells, one of the areas of the brain where BDNF protein expression is most robust.[16,97,98]

To answer these questions, intact female rats were compared at various stages of the estrous cycle. Expression of BDNF protein, evaluated with immunocytochemistry using hippocampal sections, increased in the mossy fiber pathway on proestrous morning, the time when serum estradiol peaks during the estrous cycle.[99] These data supported the hypothesis that periodic increases in circulating estradiol during the normal estrous cycle led to an increase in BDNF protein content in areas of the brain where it normally was synthesized.

Remarkably, the peak of BDNF levels in the mossy fiber pathway was actually not on proestrous morning, when serum concentrations of estradiol are highest, but the next day, long after serum levels of estradiol returned to baseline in the rat.[99] Therefore, BDNF levels were increased with a time course that outlasted the preovulatory surge in serum estradiol concentration. Furthermore, BDNF levels were highest at the time of the estrous cycle that is analogous to the perimenstrual period, when it is most common for seizures to worsen in women with epilepsy.[100]

These data suggested a potential explanation for catamenial seizure exacerbation: elevated BDNF levels increase seizure susceptibility. The locations where BDNF increased supported that idea, because BDNF protein was elevated in areas that are thought to be important in seizure generation, such as hippocampus. In addition, the amygdala showed an increase in BDNF protein by immunocytochemistry (Scharfman et al., unpublished). It is especially interesting that the areas where BDNF was increased contribute to temporal lobe epilepsy (TLE), because catamenial epilepsy appears to be most common in TLE.[100]

The increase in BDNF levels that occurred in the mossy fiber pathway of female rats provided an opportunity to test the hypothesis that increased levels of BDNF exert functional effects that are consistent with a pro-convulsant action.[16,97,98] Therefore, we made recordings in hippocampal slices and compared slices that were prepared from female rats during different estrous cycle stages. We found that the increase in mossy fiber BDNF was correlated with an increase in mossy fiber transmission. The nature of the increase in mossy fiber transmission was interesting because it suggested hyperexcitability. However, this type of hyperexcitability was not simulated by perfusion of slices with convulsants, such as $GABA_A$ receptor antagonists, so it seemed to be a novel form of hyperexcitability.[53] Most convulsants, such as the $GABA_A$ receptor antagonist bicuculline, induce area CA3 population discharges that occur spontaneously and rhythmically. In contrast, female rats with elevated mossy fiber BDNF protein did not demonstrate spontaneous burst discharges in area CA3 (or any other area of the slice). Instead, hyperexcitability was manifested in a different way. Stimulation of the mossy fibers at 1 Hz using pairs of stimuli (40 ms interstimulus interval at 50% maximum stimulus strength) produced multiple population spikes (after each stimulus), with only three to six pairs of stimuli required.[52,53,99] The population spikes that followed each stimulus occurred in trains with approximately 10–20 ms between each spike, and the entire train did not last more than 100 ms. Therefore, the hyperexcitability was different from the synchronized population bursts that occur in area CA3 after bicuculline exposure.[53] Spreading depression often followed the evoked trains of population spikes that were elicited by 1 Hz stimulation of the mossy fibers.[52,53,99] These data were interesting because both the pattern of population spike trains after stimulation and the spreading depression episodes were also observed after exposure of male rat slices to recombinant BDNF.[52] However, the female rat slices had no exposure to recombinant BDNF. All of the effects that were recorded in slices from

female rats at cycle stages with high mossy fiber BDNF protein expression were similar to the effects that had been previously described in slices from male rats exposed to recombinant BDNF.[52,99] Importantly, the effects that were evident in slices from female and male rats were blocked by K252a, a Trk receptor antagonist, consistent with the interpretation that BDNF was responsible.[99]

These data suggested that during every estrous cycle, the rise in serum levels of estradiol triggers BDNF synthesis in pathways like the mossy fibers, and the net effect is increased susceptibility to epileptiform activity. Therefore, it seemed plausible that actions of estrogen that increased seizure susceptibility in catamenial epilepsy are mediated by BDNF. Actions of estrogen could explain both periovulatory seizure exacerbation and the increase in seizures during the perimenstrual period because BDNF protein is elevated in the rat at the analogous times of the estrous cycle, that is, proestrous morning and estrous morning. Furthermore, Trk-dependent epileptiform activity was evoked by mossy fiber stimulation on both proestrous and estrous mornings. The experiments in female rats also suggested a potential reason why perimenstrual seizures might be more common in women than periovulatory seizures: BDNF levels were highest in the female rat at the time that is analogous to the perimenstrual period, estrous morning, and stimulus-evoked epileptiform activity in the female rat was most severe at that time.[99]

Many neuromodulators are altered on proestrous morning in the female rat, not only BDNF. For example, there are changes in norepinephrine and corticosterone levels.[101,102] Therefore, it was important to use another approach so that we could dissociate the effects of estrogen from the potential effects of norepinephrine and corticosterone. Therefore, ovariectomized rats were treated with a series of injections that simulates the rise in 17β-estradiol (estradiol) during the estrous cycle.[103] These experiments demonstrated that estradiol treatment per se could reproduce the effects observed in the intact rat, and supported the hypothesis that estradiol was responsible for the increase in mossy fiber BDNF and increased mossy fiber transmission in the intact rat. Together these experiments suggest new mechanisms that mediate the effects of estrogen in catamenial epilepsy. Estrogen may increase seizure susceptibility indirectly by inducing BDNF synthesis. In turn, BDNF exerts effects that facilitate seizures.

It is important to note that the effects of estrogen on BDNF may not be mediated by the estrogen-response element on the BDNF gene. It has been suggested that estrogen acts on GABAergic neurons to cause disinhibition.[104–107] Therefore, BDNF levels may increase because of activity-dependent expression.[107]

The reason BDNF levels remain high long after estrogen levels return to normal during the estrous cycle is unclear. One contributing factor to the long-lasting nature of increased BDNF expression may be effects of progesterone, which rises immediately after estrogen during the estrous cycle (Fig. 39–2A) and therefore is increased at a time that is well suited for a modulatory action. Although progesterone is commonly thought to counteract estrogen action, the actions of progesterone during the estrous cycle can facilitate estrogen action, at least with respect to reproductive behavior.[72,108] The experiments that have addressed the effects of progesterone on BDNF, however, have produced variable results. One study showed that BDNF was increased by progesterone acting at progesterone receptors.[109] Another study showed that ovariectomized animals treated with estrogen exhibited increased BDNF expression, and a subsequent injection of progesterone inhibited that effect.[110] Other studies have found little effect of progesterone on BDNF.[111]

Importantly, evaluation of BDNF levels in women suggests that cycle-dependent changes in serum BDNF in women are similar to changes in BDNF levels in hippocampus of female rats. Thus, analysis of serum BDNF in normal women showed that BDNF levels were high at ovulation and during the luteal phase relative to the follicular phase.[112] Although BDNF levels in brain were not studied, the data from serum samples are consistent with the idea that the ovulatory and luteal rise in estrogen in women is associated with an increase in BDNF levels in the brain.

In light of the data from the female rat, one explanation for catamenial epilepsy would be that estrogen and progesterone modulate BDNF synthesis, with estrogen and progesterone potentially increasing BDNF synthesis and allopregnanolone keeping any pro-convulsant

effects in check. This hypothesis would explain the three types of catamenial epilepsy suggested by Herzog and colleagues, as shown in Fig. 39–2B. During the periovulatory period, pro-convulsant effects of BDNF would emerge because of an increase in BDNF synthesis induced by the preovulatory surge in estrogen. During the luteal phase, high levels of allopregnanolone would be likely to keep the effects of elevated BDNF, that is, an increased predisposition for seizures, in check. However, during the perimenstrual period when progesterone levels fall, seizure exacerbation would be predicted because BDNF levels would still be high, but the effects of BDNF would no longer be counterbalanced by enhanced inhibition (Fig. 39–2). This view suggests that estrogen and progesterone are modulators of BDNF and do not cause the fluctuation in seizures during the menstrual cycle by direct effects.

A key component of this hypothesis is the argument that BDNF has effects that facilitate seizures and can explain many of the actions of estrogen. There is a great deal of data to support this idea. Effects of estrogen are mainly inferred from studies of the major bioactive form of estrogen, 17β-estradiol (estradiol), which is produced in the periphery (primarily in the ovaries) and also can be produced centrally from cholesterol metabolism. The effects of estradiol are extremely diverse both inside and outside the CNS, but they appear to be mediated entirely by three receptors: a membrane-bound receptor (mER) and two types of receptors that can migrate to the nucleus (nuclear receptors; ERα and ERβ) and act on target genes.

During the 1960s and 1970s, investigators showed that estradiol increases excitatory (glutamatergic) transmission, and some of the data suggested that the facilitation of glutamatergic transmission was strong enough to lead to seizures.[113,114] One of the first studies that supported this view used a bolus of estradiol applied directly to the cortex in anesthetized cats and found that the cortical electroencephalographic (EEG) activity increased, similar to a seizure.[113] Since that time, estradiol has been shown to produce many effects in the brain. Almost all of them are consistent with a net excitatory effect. For example, estradiol increases glutamatergic transmission,[115] facilitates LTP,[115,116] and induces dendritic spine growth.[117] The increase in glutamatergic transmission and LTP is potentially mediated by several mechanisms, including actions that are presynaptic as well as postsynaptic.[118,119]

Interestingly, many of the effects of estradiol can also be induced by BDNF.[108,120] For example, exposure of hippocampal slices to recombinant BDNF potentiates glutamatergic transmission,[32,52,53] and BDNF is required for LTP in hippocampus.[33,35,50,121] In addition, BDNF has potent effects on *N*-methyl-D-aspartate (NMDA) receptors and dendritic spine morphology, like those of estradiol, although the effects on spines may not be identical to those that have been reported for estradiol.[122] Estradiol also increases the rate of postnatal neurogenesis,[123] which is an effect of BDNF as well.[124] Estradiol decreases GABAergic transmission by decreasing levels of the synthetic enzyme for GABA, glutamic acid decarboxylase (GAD),[125] and via other mechanisms[104,126]; BDNF can also reduce GABAergic inhibition, although a specific action on GAD has not been identified.[38,127,128] Studies of BDNF in vivo in the context of seizures and epilepsy demonstrated that it is potentially pro-convulsant (as discussed above). Therefore, the actions of estrogen could be mediated, at least in part, by BDNF.

The time required for estradiol to exert its effects—relative to the time required for BDNF-dependent effects—is important to consider if one is to argue that BDNF contributes to the effects of estrogen during the menstrual cycle. Although the exact timing of estrogen and BDNF actions during the ovarian cycle are not clear in rodents or in women, from what is known, it is possible that BDNF mediates actions of estrogen. Thus, even the "rapid" effects of estrogen in rodents during the periovulatory period that are detected 12–18 h after the start of the preovulatory surge in estrogen can be explained by estrogen-induced BDNF synthesis because 12–18 h is long enough for induction of protein synthesis.

Importantly, the effects of estradiol do not seem to be universally "convulsant" (for review, see ref. 72). One explanation is that estrogen has a pro-convulsant effect because of its induction of BDNF synthesis, and estrogen also exerts an effect that is indirectly anti-convulsant because it leads to an increase in levels of neuropeptide Y (NPY), which has effects that are usually anti-convulsant.[129,130] The effect of estrogen on NPY levels could be mediated by BDNF, because

BDNF induces NPY synthesis following TrkB activation.[131–134] Therefore, some of the reasons estrogen is convulsant could be due to its effects on BDNF synthesis, and some of the reasons it is not convulsant could also be due to BDNF-mediated effects (see also ref. 135).

The actions of estrogen that are protective are also relevant to a discussion of epilepsy, particularly TLE, because limbic pathology (e.g., neuronal loss) is a characteristic of TLE that appears to be influenced by estradiol. However, effects of estradiol on neuronal damage after experimental seizures seem to vary from study to study.[72,108,120] Interestingly, the same is true for BDNF. Brain-derived neurotrophic factor can exacerbate toxicity to convulsants such as kainic acid in culture,[136] similar to estradiol, but it also appears to protect neurons against excitotoxicity in other experiments, which is also similar to the results of some studies on the effects of estradiol.[137] One explanation that has been used to explain the varied effects of estradiol is that high doses or chronic treatment can downregulate estrogen receptors (ERs)[138–140] (see also ref. 141). The same explanation has been used to explain the varied effects of BDNF: high doses decrease TrkB receptors at the plasma membrane.[45]

The Role of BDNF in the Actions of Progesterone

If the effects of estrogen on seizures can potentially be explained, at least in part, by BDNF, is the same true for progesterone? Many would think not, because the effects of progesterone on seizures that many investigators consider to be most robust are mediated by allopregnanolone, which binds directly to the $GABA_A$ receptor. However, the effects of BDNF may still play a role here, because BDNF can alter several aspects of GABAergic transmission.

Effects of progesterone are mediated by membrane and nuclear receptors analogous to estrogen. Whereas actions of estrogens can be mediated by different forms (estrone, estriol, estradiol), the effects of progesterone are due to progesterone itself, as well as its metabolites. The effects of progesterone at progesterone receptors (PRs) have effects that alter excitability,[142,143] but most is known about the metabolite allopregnanolone. Allopregnanolone is an allosteric modulator of the $GABA_A$ receptor; when allopregnanolone binds, the effects of GABA at $GABA_A$ receptors are potentiated.[144,145] Unlike effects of estradiol and BDNF, which seem to be very sensitive to experimental conditions, the anticonvulsant effects of allopregnanolone are very consistent from one experimental paradigm to the next.[76]

The available clinical data support the view that allopregnanolone controls seizures during the luteal phase of the menstrual cycle in women because allopregnanolone levels rise at that time. In addition, increased seizure severity during the periovulatory, perimenstrual, and anovulatory cycles can be explained by low levels of allopregnanolone. Therefore, progesterone, or other drugs that simulate neurosteroids acting at $GABA_A$ receptors, such as ganaloxone, have been suggested as AEDs.[146]

Although fluctuations in allopregnanolone levels can provide an explanation for the three types of catamenial epilepsy, there may be an influence of BDNF on the effects of allopregnanolone that is important to consider. For example, the $\alpha 2$, $\beta 2/3$, and $\gamma 2$ subunits of $GABA_A$ receptors are downregulated when neurons are exposed to BDNF in culture, which increases excitability.[147] However, cell surface expression of δ subunits increase in response to BDNF,[149] which should enhance the effects of allopregnanolone, not diminish them, because δ subunits typically facilitate for actions of allopregnanolone at $GABA_A$ receptors.[149] The effects of BDNF on $GABA_A$ receptors are complex because it appears that BDNF not only modulates receptor subunit expression, but also influences GABAergic transmission by increasing GABAergic synapse density[150] and modulating GABA release[151] and KCC2 expression.[152]

Perimenstrual seizure exacerbation has been explained not only by low levels of allopregnanolone, but also by the rapid reduction in progesterone levels at the end of the ovarian cycle.[146] This condition of *progesterone withdrawal* is associated with seizure susceptibility, which has been explained by an increase in $\alpha 4$ subunits of $GABA_A$ receptors.[153] Brain-derived neurotrophic factor has been shown to increase $\alpha 4$ expression by activating the transcription factor Egr3.[154] Therefore, the elevation of BDNF during the luteal phase of the menstrual cycle could lead to $\alpha 4$ upregulation by the end of the luteal phase, explaining the increase in

seizure susceptibility during the perimenstrual period. In addition, BDNF may contribute to progesterone "withdrawal" in other ways. For example, falling levels of allopregnanolone at the end of the menstrual cycle would be likely to cause disinhibition, which could lead to an increase in BDNF levels because BDNF synthesis is activity-dependent. An increase in BDNF protein would increase excitability by the facilitatory effects of BDNF on synaptic transmission.

Brain-derived neurotrophic factor may have other effects that increase excitability by actions on $GABA_A$ receptor subunits besides δ or α4 subunits. For example, it has been shown that upregulation of BDNF decreases α1 subunits.[155] This is important because of the evidence, in an animal model of epilepsy, that increasing α1 receptors reduces seizures.[156]

SUMMARY

Actions of estrogen and progesterone have been used to explain the changes in seizure frequency or severity in women with catamenial epilepsy. An alternative hypothesis is that BDNF is responsible, because estrogen causes an increase in BDNF expression that can have both acute effects on excitability and delayed, indirect effects by changing GABAergic transmission and $GABA_A$ receptors. Allopregnanolone may hold many of the excitatory effects in check during the luteal phase, but two phases of the cycle may be unprotected, the periovulatory and perimenstrual phases. This hypothesis helps explain why progesterone therapy may not always be efficacious in catamenial epilepsy and suggests that control of BDNF would be a logical complementary strategy.

CONCLUDING REMARKS

The evidence from diverse methods, and diverse animal models, strongly suggests that BDNF contributes to epilepsy, and does so in many ways. In acute seizures, BDNF is likely to play a role because of its rapid actions at many excitatory synapses and possibly at inhibitory synapses. In epileptogenesis, BDNF appears to be part of a cascade that initiates—and then perpetuates—the process of epileptogenesis. The activity dependence of BDNF and its specific expression in parts of the brain that regulate seizure susceptibility are two of many specific characteristics of BDNF and TrkB that are likely to make BDNF so influential in epileptogenesis. However, the role of BDNF is not only important in acute seizures and epileptogenesis, but is also likely to be important in chronic epilepsy, where factors that trigger seizures, such as fluctuations in gonadal hormones, may do so because, at least in part, they increase BDNF synthesis. In light of the multitude of pro-convulsant effects of BDNF, the molecular mechanisms that control BDNF synthesis and molecular mechanisms of TrkB signaling are attractive targets for anti-convulsant and anti-epileptogenic drug development.

Chapter 40

Alterations in the Distribution of $GABA_A$ Receptors in Epilepsy

Carolyn R. Houser
Nianhui Zhang
Zechun Peng

Changes in gamma-aminobutyric acid A receptors ($GABA_AR$) in epilepsy are particularly complex and intriguing because of the multiple subunits that can be altered. The numerous $GABA_AR$ subunits (α1–6, β1–3, γ1–3, δ, ε, θ, π, and ρ1–3) typically form heteropentameric receptors that are generally composed of two α, two β, and either one γ, δ, or other more minor subunit. The different subunit combinations create a diversity of receptor subtypes that differ in their function, pharmacology, and regional and cellular localization (see refs. 1 and 2 for reviews). Such diversity provides challenges for understanding the functional effects of $GABA_AR$ subunit alterations in epilepsy, but it may also offer unique possibilities for treatment of this disorder.

MULTIPLE CHANGES IN $GABA_AR$ SUBUNITS IN EPILEPSY

Previous descriptions and reviews of the localization of $GABA_AR$ subunits in human temporal lobe epilepsy[3,4] and related animal models of acquired epilepsy[4–9] have emphasized the multiple changes that can occur in $GABA_AR$

subunit labeling in seizure disorders. Within the same tissue or model, some subunits exhibit increases, whereas others show decreases in expression. There is as yet no clear, unifying view of these changes and their functional significance, but new ideas are developing as the findings are considered in the context of other findings in the field. This review will focus on several of the most consistently observed alterations and their relationship to the rapidly expanding knowledge of $GABA_A$Rs and their functional characteristics.

In studies of $GABA_A$R subunit distributions in epilepsy, an increased expression of several subunits has been a predominant finding. In surgical tissue from patients with temporal lobe epilepsy, increased labeling of α2, γ2, β2, and β3 in granule cells of the dentate gyrus has been particularly striking.[3,4] Likewise, in animal models, increased expression of α4, γ2, and β subunits has been observed frequently in the hippocampal formation.[5,7,10,11] Such findings have generally been interpreted as a compensatory response to increased excitability of the region. However, decreased labeling of some subunits, beyond that associated with cell loss, has also been observed. Most notably, decreased expression of the α5 and δ subunits has been found in the hippocampus and dentate gyrus, respectively, in several animal models.[5,7,10,12–14]

FRAMEWORK FOR VIEWING $GABA_A$R SUBUNIT CHANGES IN EPILEPSY

Initially, the multiple subunit changes appeared random and unrelated. However, current views of $GABA_A$R subunit partnerships and function have suggested some interesting patterns. First, distinctions between tonic and phasic inhibition have provided a new perspective from which to view the changes. While phasic or synaptic inhibition has been the focus of GABAergic inhibition for many years and is critical for rapid, precisely timed inhibitory activity, it has become clear that tonic inhibition, generated by low, maintained levels of GABA, makes substantial contributions to the overall GABAergic inhibition in the brain and may be particularly critical for controlling the excitability of neuronal networks.[15–18]

Distinctions between phasic and tonic inhibition can be related to different $GABA_A$Rs that have their own unique characteristics and localization. The $GABA_A$Rs that mediate phasic inhibition are located directly at the postsynaptic density where they can respond to synaptically released GABA, whereas $GABA_A$Rs involved in tonic inhibition are located outside the synapse, at either peri- or extrasynaptic locations, where they are well positioned to respond to ambient levels of GABA within the extracellular space or to spillover of GABA at the synapse.[19,20] Consistent with their locations, $GABA_A$Rs that mediate phasic inhibition generally have relatively low affinity for GABA and desensitize rapidly, whereas those responsible for tonic inhibition have high affinity for GABA and slower rates of desensitization.[21,22]

These characteristics of $GABA_A$Rs are conveyed by their particular subunit composition. In the hippocampal formation, receptors mediating phasic inhibition generally contain the γ2 subunit,[23,24] whereas the major $GABA_A$Rs responsible for tonic inhibition contain either the δ or α5 subunit, along with appropriate subunit partners.[25–28] Importantly, some receptors that mediate tonic inhibition, such as those that contain the δ subunit, are exquisitely sensitive to modulators, including neurosteroids and low levels of ethanol that can greatly enhance $GABA_A$R function and zinc that can reduce such function.

As studies of the effects of subunit variations in normal $GABA_A$Rs have progressed, it has become evident that the alterations in $GABA_A$R subunit expression that are found in epilepsy could have a powerful impact on the kinetics of these receptors, the modulators and pharmacological agents that affect the receptors, and the overall response of the receptors during periods of increased network activity.

DECREASED EXPRESSION OF $GABA_A$R SUBUNITS IN PRINCIPAL CELLS

The α5 and δ subunits show striking decreases in labeling during the chronic period in several models of temporal lobe epilepsy. Interestingly, both subunits are key components of $GABA_A$Rs that mediate tonic inhibition in the hippocampus and dentate gyrus.

Decreased α5 Subunit Expression

Strong decreases in α5 mRNA and protein have been found in several epilepsy models, including both the kainate and pilocarpine models in rats[5,6,10,12–14] (Fig. 40–1A,B) and the pilocarpine model in mice (Peng and Houser, unpublished data) (Fig. 40–1C,D). In normal animals, the α5 subunit is most prominent in the hippocampus, with the highest levels of expression in CA1 and CA2 in the rat (Fig. 40–1A) and CA3 in the mouse (Fig. 40–1C). The labeling is concentrated in the dendritic layers, strata radiatum, and oriens, where it appears to be confined to pyramidal cell dendrites. In pilocarpine-treated rats, α5 labeling was decreased throughout the dendritic layers of the hippocampus (Fig. 40–1B). The decreases were greatest in CA2, large to moderate in CA1, and slight in CA3 (Fig. 40–1B). In the pilocarpine-treated mouse, a moderate, more uniform decrease in labeling was found throughout CA1–CA3 (Fig. 40–1D). Although some cell loss can occur in CA1 and CA3 in these animal models, the decrease in subunit labeling cannot be explained solely by such loss since other subunits were strongly labeled in remaining pyramidal cells in the region.[12] In addition, remaining cell bodies exhibited decreased mRNA labeling that could be detected with in situ hybridization methods.[12]

Decreased δ Subunit Expression

Labeling of the δ subunit is also substantially decreased in the hippocampal formation in several epilepsy models.[7,10] The changes are most marked in the dentate gyrus, where the δ subunit is normally expressed on granule cell somata and dendrites in the molecular layer (Fig. 40–2A–D). Although relatively low levels of δ subunit labeling are normally found in CA1 and the adjacent subiculum and entorhinal cortex, these regions frequently exhibit a further decrease in δ subunit labeling in epileptic animals, suggesting that the changes in δ subunit expression extend throughout much of the limbic region. Consistent with these findings, a microarray analysis identified the δ subunit mRNA as one of a broad group of mRNAs that was significantly decreased at 2 weeks after status epilepticus in the rat pilocarpine model.[29] Interestingly, mutations of the δ subunit gene have also been found in humans with at least two forms of generalized epilepsy.[30]

Considering the complementary patterns of α5 and δ subunits, with a predominance of

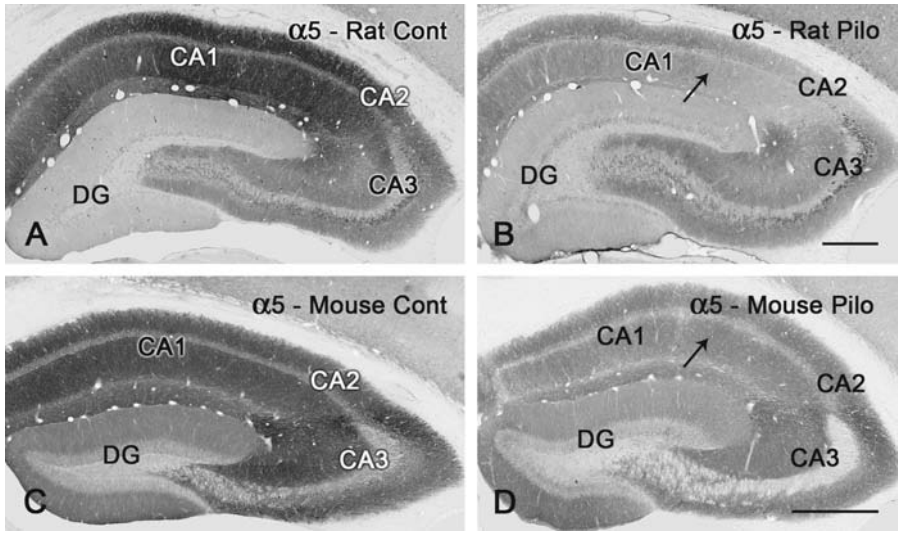

Figure 40–1. Alpha 5 subunit labeling is decreased in the hippocampus of pilocarpine-treated (Pilo) rats and mice compared to controls (Cont). **A,B.** In the rat, α5 subunit labeling is substantially decreased in dendritic layers of CA1 (arrow in **B**) and to an even greater extent in CA2. Less change is found in CA3 and the dentate gyrus (DG). **C,D.** In the mouse, a decrease in α5 subunit labeling is evident in dendritic regions (arrow in **D**) of the hippocampus (CA1–CA3). A slight decrease is also found in the dentate gyrus (DG). Scale bars: **A,B**, 500 μm; **C,D,** 500 μm. **A** and **B** adapted from ref. 12.

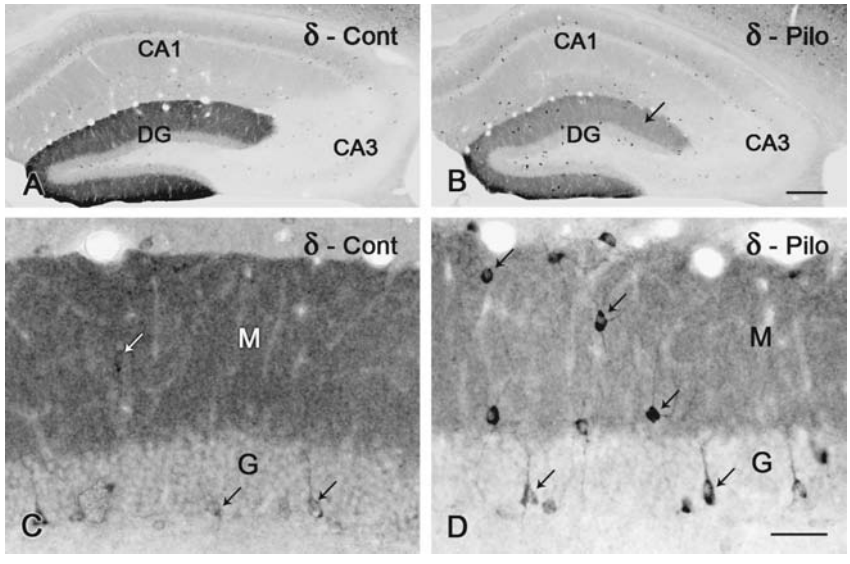

Figure 40–2. Delta subunit labeling is decreased in principal cells but increased in interneurons in pilocarpine-treated (Pilo) mice compared to controls (Cont). **A,B.** Diffuse labeling of the δ subunit is substantially decreased in the molecular layer (arrow in **B**) of the dentate gyrus (DG) in pilocarpine-treated mice. Less change is evident in CA1 and CA3, where δ subunit expression is normally low. **C,D.** In contrast, δ subunit labeling of interneurons (arrows) in the molecular layer (M) and along the base of the granule cell layer (G) is increased in pilocarpine-treated animals. Scale bars: **A,B**, 200 μm; **C,D**, 40 μm. Adapted from ref. 7.

α5 subunit labeling in the hippocampus and δ subunit labeling in the dentate gyrus, a marked decrease in subunits that mediate tonic inhibition occurs throughout the hippocampal formation.

Decreased α1 Subunit Expression

The α1 subunit is a third subunit that is decreased in some studies of epilepsy models. Utilizing single-cell mRNA amplification techniques, a significant decrease in α1 subunit mRNA has been identified in dissociated granule cells during the chronic period in the rat pilocarpine model.[11] A decrease in immunohistochemical labeling of the α1 subunit was also observed in the dentate gyrus in a group of drug-resistant epileptic rats following status epilepticus induced by electrical stimulation of the amygdala.[14] However, several other immunohistochemical and in situ hybridization studies of animal models have found either no significant change or an increase in α1 subunit expression in the dentate gyrus.[5,6,10,31] These discrepant findings could be related in part to the normal expression of the α1 subunit in both interneurons and principal cells.[32,33] In immunolabeled sections of the hippocampus, the α1 subunit is strongly expressed in interneurons, and the labeling of the interneurons and their processes could occlude labeling of principal cells, making changes in subunit expression in granule and pyramidal cells more difficult to detect. Likewise, immunoblot analyses of changes in the α1 subunit protein would not distinguish between cell type-specific changes. By contrast, in the biochemical studies of single cells,[11] the analysis was restricted to granule cells, thus perhaps making it easier to detect decreases in α1 mRNA in this class of neurons. However, in a study of human tissue, increased labeling of the α1 subunit was described on the cell bodies and proximal dendrites of dentate granule cells.[3] Thus, it remains difficult to reconcile the varying descriptions of α1 subunit changes in the epileptic hippocampus in different studies.

Functional Consequences of Decreased α5 and δ Subunit Expression in Principal Cells

The consistent decreases in α5 and δ subunit expression in principal cells in the hippocampus and dentate gyrus have led directly to the hypothesis that tonic inhibition could be

decreased in principal cells of the hippocampal formation. However, contrary to that prediction, a decrease in tonic inhibition has not been found. Indeed, tonic GABAergic inhibition was maintained or even greater in CA1 pyramidal cells of pilocarpine-treated rats than in control animals.[13] Likewise, in the rat model, tonic inhibition was maintained in granule cells within the granule cell layer and even increased in those aberrantly located in the hilus.[34] Tonic inhibition was thus maintained in dentate granule cells in both the mouse and rat pilocarpine models of recurrent seizures during the chronic period.[35,36]

The lack of noticeable changes in GABAergic tonic inhibition in the hippocampus and dentate gyrus following decreases in the α5 and δ subunits, respectively, is surprising and still unexplained. This could indicate that either relatively low levels of the subunits are required for maintaining tonic inhibition or compensation by other subunits has occurred. It also remains possible that tonic inhibition could be compromised in vivo even though such changes have not been detected with current in vitro analysis.

The $GABA_A$Rs that are mediating this retained tonic inhibition have not been determined with certainty. One possibility is that α5 and δ subunit-containing receptors substitute for each other. Thus, following a decrease in α5 subunit expression in the hippocampus, receptors containing the δ subunit might assume a greater role. Likewise, in the dentate gyrus, following the decrease in δ subunit expression, α5-containing receptors could become the primary mediator of tonic inhibition.[34] Such compensation has been described previously in mice that lack either the α5 or δ subunit.[28] Other $GABA_A$Rs that express only the α and β subunits also could be mediating tonic inhibition[37] in the seizure-prone animals.

However, in the mouse pilocarpine model, a change in the composition of $GABA_A$Rs that mediate tonic inhibition has also been suggested. In this epilepsy model, the γ2 subunit that is normally found in greatest abundance directly at synaptic contacts was found predominantly at perisynaptic sites in epileptic animals during the chronic period.[35] This change suggested that a receptor with an altered subunit composition, α4βγ2, could be mediating tonic inhibition in the dentate granule cells in the epileptic animals. This idea is supported by the finding of increased association of α4 and γ2 subunits in the dentate gyrus of epileptic animals.[36,38] Such a change in subunit composition could alter the kinetics and functional response of the receptor in critical ways.

Despite the apparent preservation of tonic inhibition in epileptic animals, functionally important alterations occur. In instances where the δ subunit is decreased, a marked decrease in modulation of the tonic current by neurosteroids is consistently found.[34–36] Thus, despite a maintained baseline level of tonic inhibition, the normal responsiveness of these receptors to physiological modulators is likely to be lost. Such alterations could be particularly important at times of stress or during hormonal fluctuations, precisely when an increase in tonic inhibition could be needed to control neuronal excitability.

The α5 subunit also contributes to $GABA_{A,slow}$ synaptic inhibition, and such inhibition has a strong influence on the ability of pyramidal cells to generate action potentials and thus influence network excitability.[39] It will be important to determine if this type of inhibition is decreased in animals with recurrent seizures, as it is in transgenic mice that are deficient in α5 subunit function.[40]

INCREASED EXPRESSION OF $GABA_A$R SUBUNITS IN PRINCIPAL CELLS

While several $GABA_A$R subunits exhibit increased expression in the hippocampus in epilepsy models and tissue from humans with temporal lobe epilepsy, increases in the α4 and γ2 subunits are among the most consistent.

The α4 subunit is a particularly plastic subunit, and increased α4 expression has been detected following rapid withdrawal from progesterone treatment,[41] following withdrawal from chronic intermittent ethanol treatment,[42,43] and in models of status epilepticus-induced epilepsy.[7,10,11,36] In the hippocampal formation, the α4 subunit is normally expressed at high levels in the molecular layer of the dentate gyrus, with lower levels of labeling in the hippocampus (Fig. 40–3A). Thus, throughout the hippocampal formation, the labeling pattern closely resembles that of the δ subunit. In epileptic animals, the labeling is

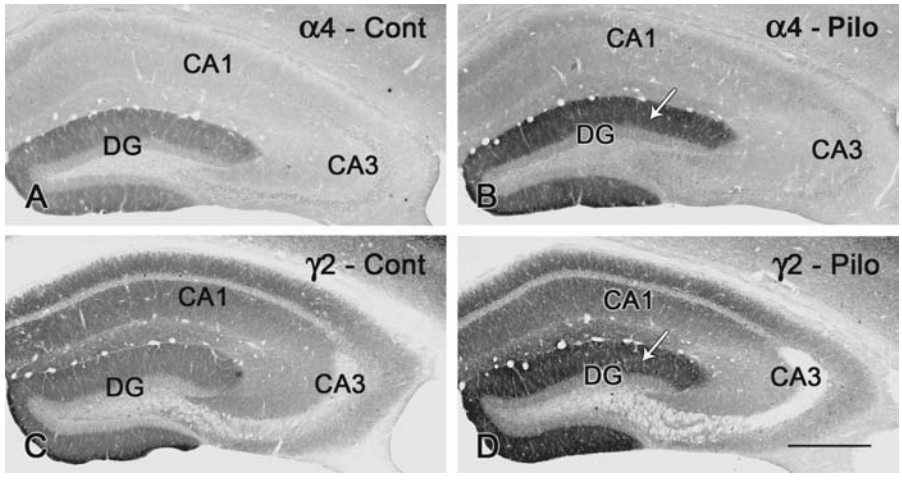

Figure 40–3. Alpha 4 and γ2 subunit labeling is increased in the hippocampal formation of pilocarpine-treated (Pilo) mice compared to controls (Cont). **A,B.** A substantial increase in α4 subunit labeling is present in the molecular layer (arrow in **B**) of the dentate gyrus (DG). A slight increase in α4 labeling is also evident in CA1. **C,D.** An increase in γ2 subunit labeling is most prominent in the dentate molecular layer (arrow in **D**) but is also evident in CA1. Scale bar: **A–D,** 500 μm.

increased substantially in the dentate molecular layer (Fig. 40–3B), in precisely the regions with decreased diffuse labeling of the δ subunit (Fig. 40–2B).

An increase in the γ2 subunit has also been observed in several epilepsy models,[7,10] and in most models, the increase has been particularly prominent in the molecular layer of the dentate gyrus (Fig. 40–3C,D).

Functional Consequences of Increased $GABA_A$R Subunit Expression in Principal Cells: Potential Alterations in Subunit Composition

The increased expression of these $GABA_A$R subunits has generally suggested a compensatory response of the receptors. However, in several instances, the partners of these subunits do not show parallel increases in expression. For example, the δ and α4 subunits are major partners in the forebrain, and yet the δ subunit is decreased while the α4 subunit is increased in the epilepsy models in which both subunits have been studied.[7,10] Likewise, the γ2 and α1 subunits are common partners, and yet the increase in γ2 labeling may be accompanied by a decrease in the α1 subunit in some cell types and models, and decreased association of α1 and γ2 has been reported in the dentate gyrus of epileptic rats.[38]

The concurrence of increases and decreases in different subunits within the same tissue suggests that the subunit composition of $GABA_A$Rs in these regions could be altered, with subunits that exhibit increased expression replacing those with decreased expression. Three $GABA_A$R subunits with unique interrelationships (α4, δ, γ2) are altered in several epilepsy models and could lead to $GABA_A$Rs with altered subunit composition. In the forebrain, the α4 and δ subunits have very similar anatomical distributions and are considered to be preferential partners.[44–46] However, α4 can also associate with the γ2 subunit. Thus, the δ and γ2 subunits may compete for partnership with the α4 subunit, and the presence of one of these subunits will exclude the other.[47–49] In δ subunit-deficient animals, expression of the γ2 subunit is increased, and its association with the remaining α4 subunit is likely to be increased.[46,49,50]

In pilocarpine-treated mice, while the δ subunit is decreased, both α4 and γ2 subunits are increased and could thus form a functional partnership. The time course of the changes in these three subunits supports this suggestion. An initial sharp decrease in α4 and γ2 subunits is followed a few days later by a gradual parallel increase in these two subunits, while the labeling intensity of the δ subunit remains decreased.[7]

However, electron microscopic studies of the α4 and γ2 subunits in normal mice have demonstrated different subcellular locations of these two subunits, with γ2 exhibiting strong synaptic localization (Fig. 40–4E) and α4 being preferentially located at nonsynaptic sites, including perisynaptic locations where the δ subunit is also localized[35] (Fig. 40–4A,C). Thus, if the partnership of the α4 and γ2 subunits were increased in the pilocarpine-treated mice, some change in their subcellular localization would be expected, with either the α4 subunit acquiring a synaptic localization or the γ2 subunit increasing at perisynaptic or extrasynaptic locations.

Ultrastructural studies suggest that a change in subunit localization indeed occurs.[35] First, a substantial decrease in δ subunit labeling in the pilocarpine-treated mice was observed, consistent with the light microscopic findings. A large

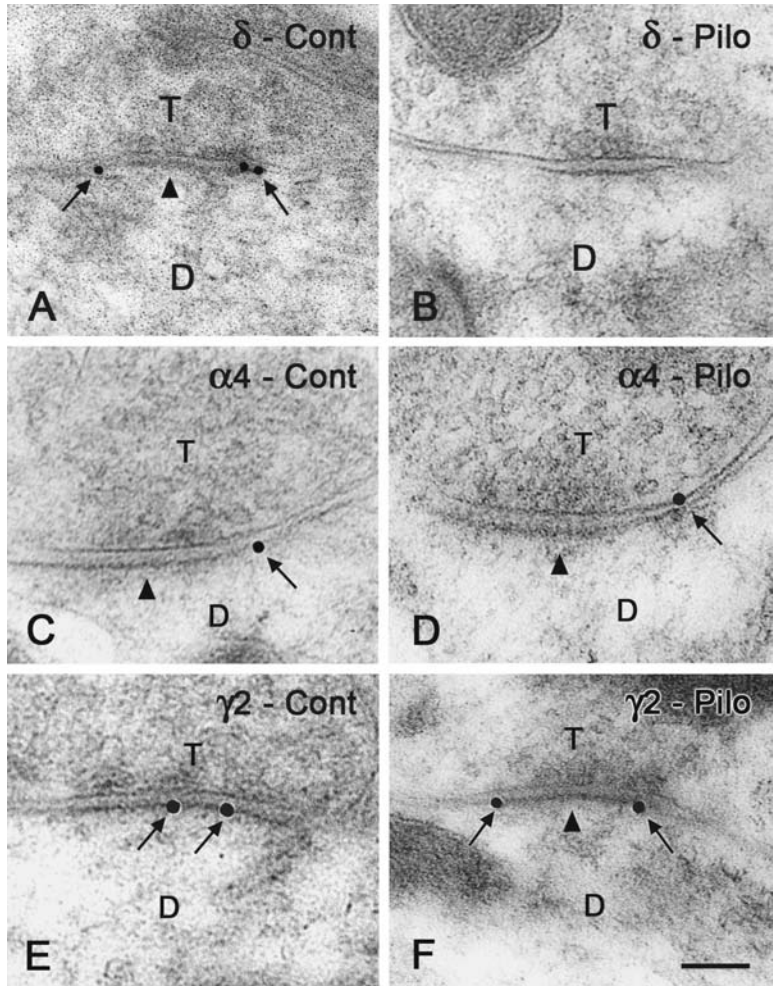

Figure 40–4. The subcellular localization of the δ, α4, and γ2 subunits in dendrites of granule cells suggests a preferential shift in the location of the γ2 subunit in pilocarpine-treated (Pilo) mice compared to controls (Cont). All electron micrographs illustrate synapses between a presynaptic axon terminal (T) and a postsynaptic dendrite (D). Arrowheads indicate the center of the synaptic contact, and arrows point to immunogold particles that label each subunit. **A,B.** The δ subunit is predominantly located at perisynaptic sites in control mice but is often absent at synapses in pilocarpine-treated mice. **C,D.** The α4 subunit is located primarily at the edge of synaptic contacts in control mice and remains at these locations in pilocarpine-treated mice. **E,F.** The γ2 subunit is located predominantly within or near the center of synaptic contacts in control mice but is frequently found at perisynaptic locations in pilocarpine-treated mice. Scale bar: 0.1 μm for all panels. Adapted from ref. 35.

(~62%) decrease in gold particles was found at perisynaptic locations, where the δ subunit is normally most abundant (Fig. 40–4A,B). In contrast, an increase in γ2 labeling was found at perisynaptic sites (Fig. 40–4F), where labeling of the α4 subunit was retained (Fig. 40–4D). Unexpectedly, while γ2 subunit labeling increased at perisynaptic locations, labeling directly at the synapse decreased (Fig. 40–4F). Such changes suggest that a subunit switch could have occurred, with the γ2 subunit forming a partnership with the α4 subunit in receptors at perisynaptic locations, where the δ subunit had previously been localized. Thus, the maintained tonic inhibition that has been found in dentate granule cells in these animals could be mediated in part by α4βγ2-containing perisynaptic receptors. While the similar subcellular localization of the α4 and γ2 subunits is not evidence of their presence in the same receptor, a similar location would be necessary and is consistent with an altered subunit partnership. In further support of a subunit switch, recent studies have demonstrated that a larger amount of the α4 subunit coimmunoprecipitated with the γ2 subunit in the hippocampus of epileptic animals compared to controls.[36,38]

Surprisingly, but in agreement with a decrease in γ2 labeling at the synapse, phasic inhibition at granule cell dendrites was decreased in the pilocarpine-treated mice.[35] In this instance, it appears that a shift in the γ2 subunit to perisynaptic locations, while possibly contributing to the preservation of tonic inhibition, may have compromised synaptic inhibition.

Analysis of similar subunit changes in other studies, using the rat pilocarpine model, has yielded somewhat different findings, although a change in receptor subunit composition is also suggested. In the rat model, ultrastructural studies demonstrated a shift of the α4 subunit from a perisynaptic to a synaptic location.[51] The reasons for the different findings in these studies remain unclear, but they could be related to species differences, the focus on dendritic synapses in the mouse and somatic synapses in the rat, or other technical issues. Consistent with possible species differences, a shift in α4 labeling from perisynaptic to synaptic locations was observed previously in a rat model of alcohol withdrawal syndrome in which a decrease in δ subunit expression also occurred in conjunction with an increase in the expression of α4 and γ2 subunits.[43] Despite some discrepancies in the epileptic animals, a marked decrease in modulation of inhibition by neurosteroids, due to the decrease in δ or the increase in α4 subunit expression, has been a consistent finding.[35,36,51]

Other studies have also suggested that the increase in α4 subunit expression could be associated with a change in subunit composition of $GABA_A$Rs, but they have emphasized the possible replacement of the α1 subunit by α4.[11,38,52] Comparison of the functional properties of $GABA_A$Rs in in vitro systems has revealed several interesting differences between receptors with the putative subunit compositions. In order to compare the kinetic properties of α4β3γ2 currents to those of α1β3γ2 currents, a rapid application of GABA was delivered to recombinant $GABA_A$Rs in HEK 293T cells.[53] A number of differences were identified, and two features were particularly striking. While both types of receptors were able to respond adequately to brief low-frequency stimulation, the α4β3γ2 receptors responded poorly to repetitive stimulation such as might occur during seizures. In addition, α4β3γ2 receptors were less effective than α1β3γ2 receptors after exposure to prolonged low levels of GABA, such as might be found in the extrasynaptic space. Thus, the investigators concluded that replacement of α1β3γ2 with α4β3γ2 receptors would be likely to impair inhibitory transmission.[53]

Such changes in $GABA_A$R responses would be consistent with the increased run-down of $GABA_A$ currents that has been observed in receptors from human temporal lobe epilepsy specimens and pilocarpine-treated rats following expression in oocytes. Similar use-dependent decreases (run-down) of $GABA_A$ currents were observed following repetitive activation of $GABA_A$Rs by application of GABA in CA1 pyramidal cells in pilocarpine-treated rats.[54] A decrease in the ratio of α1 to α4 subunits was also identified in the pilocarpine-treated animals compared to controls.[55] Thus, the receptors from the epileptic tissue, suggested to include α4βγ2 receptors, could function relatively normally under baseline conditions but failed to be effective when increased inhibitory responses were needed. While these electrophysiological changes were observed in phasic inhibition, responsiveness to spillover of GABA at perisynaptic sites could also be affected. Thus, it would be interesting to know if α4βγ2 receptors at perisynaptic locations might have

less than optimal function when compared to the original δ subunit-containing receptors.

These findings suggest that even an increase in abundance of specific subunits, such as the α4 subunit, could lead to compromised inhibition. Thus, increased expression of some $GABA_A$Rs may be less compensatory than was originally expected.

Other Proposed Effects of Altered $GABA_A$R Subunit Composition

Alterations in $GABA_A$R subunit composition could influence GABAergic function in additional ways. One particularly interesting possibility is that $GABA_A$R subunit changes may underlie the zinc-induced collapse of inhibition in kindled and pilocarpine-treated animals.[56,57] The hypothesis is that the reorganized mossy fibers in the inner molecular layer of the dentate gyrus may release zinc, along with glutamate, during repetitive firing at the time of seizure activity, and this could reduce $GABA_A$R activity at precisely the times when it is most needed to control excessive activity of dentate granule cells. Since the application of zinc did not affect $GABA_A$R responses in control animals, a change in $GABA_A$R subunit composition in the epileptic animal could be responsible for the altered inhibitory responses. The specific subunits that could underlie the altered zinc sensitivity in the epilepsy models have not been identified, although a shift from a predominance of α1- to α4-containing receptors has been suggested.[58]

While the emphasis in these studies has been on altered synaptic receptors, nonsynaptic receptors might be even more likely to be affected by the released zinc, as δ subunits are especially sensitive to the effects of zinc.[59,60] However, the reduced expression of the δ subunit in the dentate gyrus argues against a primary role for the δ subunit-containing receptors in the zinc-induced decrease in inhibition. Other possibilities for mediating the zinc effects include extrasynaptic αβ subunit-containing receptors that make modest contributions to tonic inhibition in normal animals and are quite sensitive to the influences of zinc.[37] Whether such receptors increase in the epilepsy models is unknown, but, as mentioned previously, such receptors remain a possible mediator of tonic inhibition in the epileptic animals.

ALTERED $GABA_A$R SUBUNIT EXPRESSION IN INTERNEURONS

While emphasis has been placed on altered $GABA_A$R subunits on principal cells, alterations have also been observed in remaining interneurons in the hippocampal formation. Strong labeling of the α1 subunit on persisting interneurons in surgical specimens from patients with temporal lobe epilepsy has indicated a preservation or possible increase in α1 subunit expression.[3] In the mouse pilocarpine model, an increase in δ subunit labeling occurs in many remaining interneurons in the hippocampus and dentate gyrus, and this contrasts with the substantial decrease in diffuse δ subunit labeling of granule cell dendrites in the dentate molecular layer[7] (Fig. 40–2D). The interneuron labeling increased progressively following the initial episode of status epilepticus and was maintained.

Consistent with an increase in δ subunit expression, initial findings suggest that some of the interneurons, including those in the molecular layer of the dentate gyrus, may exhibit increased tonic inhibition during the chronic period when the mice are experiencing recurrent seizures (W. Wei and I. Mody, unpublished findings). It is hypothesized that the enhanced tonic inhibition could lead to decreased excitability of the interneurons and thus less inhibitory control of their targets, such as in the dentate granule cells. These functional alterations could be particularly detrimental at the time of excessive stimulation of the granule cells when interneurons are normally recruited to control the increased input.

The differential changes in δ subunit expression in principal cells and interneurons in the epileptic animals are striking and raise many questions about the mechanisms underlying such cell-type specific changes. These changes also present challenges to pharmacological treatment since treatment that increases tonic inhibition in principal cells could also enhance tonic inhibition in interneurons, and the effects could counteract each other. However, the subunit composition of the δ subunit-containing receptors appears to differ in principal cells

and interneurons, with the δ subunit forming a strong partnership with the α4 subunit in granule cells but with the α1 subunit in interneurons.[61] Thus, pharmacological agents that would selectively target δ subunit-containing receptors in either principal cells or interneurons, and enhance or reduce their function, respectively, could be beneficial.

SUMMARY

Emerging Views and Questions

Several patterns are beginning to emerge from the numerous diverse changes that occur in $GABA_A$Rs in epilepsy. First, subunits that are primarily responsible for tonic inhibition show the most marked and consistent decreases in several models of acquired epilepsy, and appear more likely to be decreased than subunits of $GABA_A$Rs that mediate phasic inhibition. Yet, the preservation of GABA-mediated tonic current in principal cells of both the hippocampus and dentate gyrus, despite decreases in α5 and δ subunits, respectively, raises further questions. One suggestion has been that the tonic inhibition is maintained or enhanced in temporal lobe epilepsy as a homeostatic mechanism to counteract decreases in phasic inhibition.[18] In this view, an enhanced tonic current in principal cells, which was observed in response to increased GABA concentrations, could prevent or limit seizure activity and thus be compensatory.[13]

Alternatively, decreases in the α5 and δ subunits could represent critical changes that lead to the upregulation of other $GABA_A$R subunits and expression of altered or new nonsynaptic receptors with different functional properties. The kinetic properties of the receptors could be altered in ways that could reduce their effectiveness during increased stimulation. Likewise, even though capable of producing tonic inhibition, the replacement receptors could be unable to respond to specific modulators that normally influence the nonsynaptic receptors. Clearly, the decrease in δ subunit-containing receptors leads to reduced neurosteroid sensitivity that could make the receptor less sensitive to enhancement of tonic inhibition in response to stress and hormonal fluctuations.[18,62–64]

Such changes in subunit composition and the associated changes in functional properties of the receptors could alter their response to pharmacological agents, potentially reducing the response to some agents that are normally effective. However, once the composition and characteristics of the reorganized receptors are known, new pharmacological treatments could be designed.

Increases or decreases in $GABA_A$R subunit expression may not translate directly into either compensation or impairment, respectively, as the functional effects will depend on the resulting subunit composition in remaining receptors and the cell types in which the changes occur. Increased expression of the δ subunit in $GABA_A$Rs in interneurons could lead to suppressed activity in these neurons and their decreased inhibitory control of granule cells. However, the decrease of δ subunit in principal cells could lead to direct effects on these cells, including altered tonic inhibition and impaired modulation of such activity.

Several of the changes that are currently being identified in $GABA_A$Rs in epilepsy are precisely the types of alterations that might be anticipated in a disorder where network activity appears relatively normal for much of the time and then periodically shifts to excessive, synchronized activity, possibly due to the inability of $GABA_A$Rs to respond to increased demands.

Future Prospects and Challenges

Modulation of $GABA_A$R function continues to hold great promise for the treatment of epilepsy. As the mechanisms responsible for the changes in $GABA_A$R subunit expression are determined, ways of preventing these changes may be developed, with the hope of halting the epileptogenic process. In addition, as the subunit composition of $GABA_A$Rs in the epileptic regions is further elucidated, treatment approaches may be developed to target the reorganized receptors. Mechanisms responsible for dynamic changes in $GABA_A$R function are also being identified and could be particularly important for the development of novel treatment approaches. The high sensitivity of nonsynaptic receptors to specific modulators suggests that such agents could be developed to enhance $GABA_A$R function at times of stress or

excessive network activity.[65,66] Likewise, rapid changes in surface expression of $GABA_A$Rs could impair receptor function at the time of spontaneous seizures, as has been found during status epilepticus,[67,68] and new methods to limit internalization of receptor subunits could be therapeutic. Finally, phosphorylation of $GABA_A$Rs provides another avenue by which $GABA_A$R function can be rapidly altered.[69,70] All of these areas suggest new routes for $GABA_A$R-mediated treatment and, potentially, prevention of epilepsy.

Chapter 41

$GABA_A$ Receptor Plasticity during Status Epilepticus

Suchitra Joshi
Jaideep Kapur

Status epilepticus (SE) is a prolonged, self-sustained seizure that can manifest as a prolonged convulsion, subtle facial or limb twitching, or simply altered mental status, always in association with a persistent electroencephalographic (EEG) seizure pattern. In clinical trials, convulsive seizures lasting longer than 5 min are often treated as SE,[1] whereas epidemiological studies have defined 30 min of continuous convulsive seizures or intermittent seizures without recovery of consciousness as SE.[2] There are 126,000 to 195,000 episodes of SE associated with 22,000 to 42,000 deaths each year in the United States when SE is defined as 30 min of seizures.[2] As many as 50% of patients older than 65 years of age who suffer from SE die within 30 days of the episode. Although mortality is far less common in younger patients, they are at risk for neurological morbidity, such as injury to the hippocampus[3] and neuropsychological dysfunction.[4] Prolonged seizures can also lead to significant systemic complications, including pulmonary congestion and edema, cardiac arrhythmias, hypotension, elevation of body temperature, hypoglycemia, acidosis, and rhabdomylosis. These systemic complications tend to worsen as more seizures occur.[5]

It has long been recognized that SE is a dynamic and rapidly evolving condition.[5,6] Ongoing seizures rapidly modify neuronal activity and synaptic function.[7] This rapid neuronal plasticity is manifest in changes in behavioral seizures, EEG patterns, sensitivity

Table 41–1 **Characteristics, Clinical Manifestations, and Treatment of SE**

	Early/Impending/ Convulsive	Refractory/Subtle	Late/Established
Clinical manifestation	Generalized convulsions	Subtle motor manifestations	Coma
EEG	Repeated seizures	Seizures merge	Periodic discharges and suppression mixed with seizures
Systemic effects	Hyperventilation, hypertension		Respiratory depression
Brain damage	No evidence	Starting	Increases with time
Treatment	Lorazepam/ diazepam	Benzodiazepines fail:? phenytoin/levetiracetam/ valproic acid	Anesthetics:? propofol, midazolam, barbiturates
Mortality (adults)	19.6%[8]	?	31.4%[8]
Animal models: behavior	Stage 1–2 seizures	10 min after first stage 5 seizure	60 min after first stage 5 seizure
Animal models: EEG	Discrete seizures	Continuous seizures	Seizures with suppression

Source: Modified from refs. 2 and 8.

to drugs, and evolution of neuronal injury and death. Although these changes are continuous, it is convenient to divide SE into stages for the purposes of investigation and treatment (Table 41–1).

ANIMAL MODELS OF SE

Animal models and in vitro cell culture models have proved very useful in understanding the cellular and molecular mechanisms underlying the seizures of SE (for review see ref. 9). In experimental animals, SE can be induced by either administration of chemo-convulsants or electrical stimulation of limbic structures. In addition, SE can be induced by activation of muscarinic receptors by the administration of the cholinergic agonist pilocarpine,[10] without or with the use of lithium (4 mEq/kg, 4–20 h prior to pilocarpine injection[11,12]), or by organophosphates, which inhibit the enzyme cholinesterase. Also, SE can be produced by stimulation of glutamatergic receptors by kainic acid. In addition, prolonged self-sustaining seizures of SE can be induced by electrical stimulation of limbic structures such as the hippocampus, entorhinal cortex, or amygdala.[13,14] The behavioral seizures and EEG in the animal models of SE evolve over time, with many similarities to the progression of human SE. Furthermore, the efficiency of benzodiazepines in controlling the seizures of SE diminishes with the duration of SE.[15–20]

Two in vitro models that mimic the repeated bursting activity of neurons characteristic of SE include the use of reduced/zero magnesium and high potassium concentrations in the media of hippocampal or cortical neuronal cultures. Reducing magnesium below physiological levels induces recurrent bursting in hippocampal slices and cultured neurons.[21–24] Elevating extracellular potassium results in prolonged depolarization and also induces spontaneous seizures.[25]

Metabolic mapping and EEG studies during SE demonstrate activation of the hippocampus, subiculum, entorhinal cortex, and parts of the thalamus and cortex.[26] The circuitry linking the entorhinal cortex, hippocampus, and subiculum forms a reentrant path facilitating recurrent seizures. The entorhinal cortex is connected by the perforant path to hippocampal dentate granule cells (DGCs), which project to CA3 pyramidal neurons via mossy fibers. CA3 pyramidal neurons, in turn, project to CA1 pyramidal neurons via Schaffer collaterals.[27] Axons of CA1 pyramidal neurons innervate the subiculum, which connects to layers IV and II of the

entorhinal cortex, thus forming a loop that can mediate self-sustaining seizures. Neurons in the CA1 region and entorhinal cortex are capable of generating recurrent bursting patterns characteristic of seizures.[28,29] Given the centrality of the hippocampus in this reentrant circuit, many studies aimed at understanding the cellular and molecular mechanisms underlying the seizures of SE have focused on the hippocampus.

REDUCED GABAERGIC NEUROTRANSMISSION DURING SE

Reduced inhibitory neurotransmission mediated by gamma-aminobutyric acid (GABA) type A receptors (GABARs) is proposed to be one of the underlying mechanisms of the self-sustaining and progressive nature of SE. Benzodiazepines, such as diazepam and lorazepam, are the preferred drugs to treat the seizures of SE[30]; they act on GABARs, which mediate the majority of inhibitory neurotransmission in the forebrain. In addition to these first-line drugs, phenobarbital, pentobarbital, midazolam, and propofol, used in intensive care units to treat refractory SE,[31] also modulate GABARs.

GABARS

These are pentameric ligand-gated anion channels. The subunits are derived from α, β, γ, δ, and ε gene families, some of which have multiple members, such as α 1–6, β1–3, and γ1–3. The majority of the receptors appear to be composed of 2α, 2β, and γ or δ subunits. The sensitivity of the receptor to many of the aforementioned modulators depends on its subunit composition.[32] Subunit composition-dependent properties of GABARs relevant to SE and epilepsy are their sensitivity to benzodiazepines such as diazepam, lorazepam, and midazolam, to the divalent cation Zn^{2+}, and to neurosteroids. Diazepam sensitivity requires the presence of a γ2 subunit, and the relative affinity of diazepam to the receptor also depends on the subtype of the α subunit.[33,34] In contrast, sensitivity to Zn^{2+} is reduced by the presence of a γ subunit, but relative sensitivity to Zn^{2+} is also regulated by the subtype of α subunit.[35–37]. The presence of a δ subunit confers higher GABA and neurosteroid affinity to the receptor.[38,39] In addition to pharmacological modulation by different drugs, subunit composition influences the kinetic properties of the receptors. For example, δ subunit-containing receptors desensitize slowly and more incompletely than γ2 subunit-containing receptors.

Subunit composition also determines receptor targeting. The presence of a γ2 subunit is necessary for synaptic localization of GABARs,[40,41] whereas GABARs composed of the δ subunit remain exclusively in the peri- and extrasynaptic membrane.[42,43] Synaptic GABARs mediate fast inhibition in response to the high concentration of GABA released in the synaptic cleft, whereas extrasynaptic receptors respond to GABA spilled over from synapses and contribute to the persistent background inhibition commonly referred to as *tonic inhibition*.[44–47]

Specific subunit assembly is present in various brain regions. For example, in hippocampal DGCs and cerebellar granule neurons, the δ subunit associates with α4 or α6 subunits, respectively,[48–50] whereas most of the γ2 subunit-containing receptors in the hippocampus and thalamus contain an α1 subunit.[51–53]

GABAR-MEDIATED INHIBITION IS DECREASED DURING SE

During SE, GABAR-mediated inhibition is reduced in the hippocampi of animals. The GABA-evoked GABAR whole cell currents recorded from DGCs and CA1 pyramidal neurons were smaller in animals 45 min after the onset of SE than those of naive animals.[17,54] Decreased synaptic and/or tonic inhibition mediated by GABARs could contribute to this reduction of whole cell currents. To determine whether synaptic inhibition mediated by GABARs was diminished during SE, miniature inhibitory postsynaptic currents (mIPSCs) were recorded from DGCs or CA1 pyramidal neurons 30–60 min after the onset of lithium-pilocarpine-induced SE.[55–57] These studies revealed that the amplitude of mIPSCs

recorded from DGCs and CA1 pyramidal neurons from animals in SE was smaller than that of controls. Furthermore, the amplitude reduction in mIPSCs in DGCs occurred as early as 30 min after the onset of forelimb clonus.[58] In addition to decreased mIPSC amplitude, mIPSC frequency was reduced.[55] The reduced amplitude and frequency of mIPSCs recorded from DGCs of animals in SE suggest presynaptic and postsynaptic changes. Reduced GABA release from presynaptic terminals may result in decreased amplitude and frequency, whereas diminution in the number of functional receptors at the postsynaptic membrane could cause decreased amplitude. Whether GABA release from presynaptic terminals is diminished in animals in SE is not known. However, biochemical studies have revealed a decrease in the number of functional receptors on the postsynaptic membrane in the hippocampi of animals in SE.[55,57] A biotinylation assay used to study the expression of GABAR subunits in surface membrane proteins in the hippocampi of animals in SE revealed decreased expression of γ2, β2/3, and α1 subunits, which form the majority of synaptic receptors, along with decreased expression of the α2 and α4 subunits[55,57] (Fig. 41–1). Reduced surface expression could be due to genomic effects such as decreased transcription or translation of GABAR subunits or altered receptor trafficking to the membrane. However, the time course of the changes in surface expression was very rapid, suggesting altered trafficking to be a likely underlying factor. Therefore, later studies addressed whether SE changed receptor trafficking, that is, insertion, which adds new receptors to the surface membrane, and internalization, which removes existing receptors.

INCREASED INTERNALIZATION OF SYNAPTIC GABARS DURING SE

Internalization of the γ2 and β2/3 subunits increased in in vitro models of SE.[24,55] Incubation of cultured hippocampal neurons in

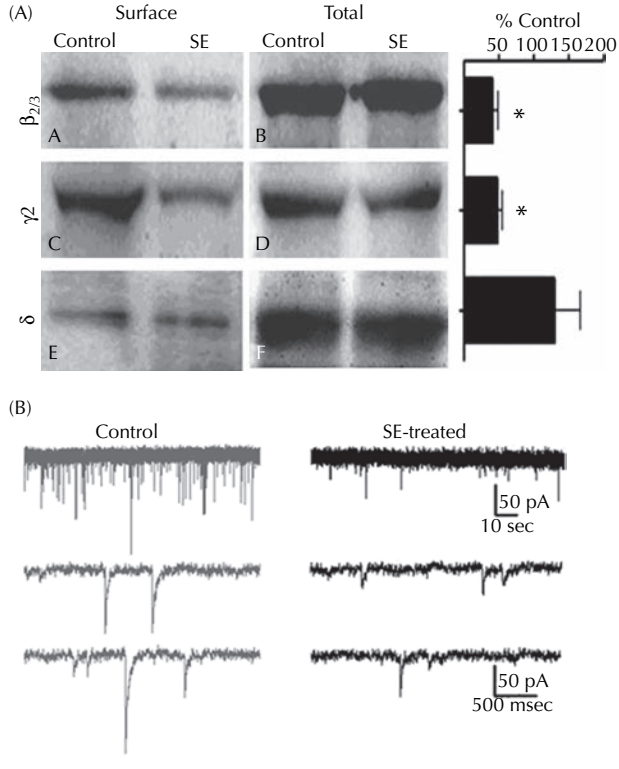

Figure 41–1. A. Decreased surface expression of the γ2 and β2/3 subunits in animals during SE. **B.** Reduced synaptic inhibition evident from decreased frequency and amplitude of mIPSCs in animals in SE.[55]

zero magnesium or high potassium-containing medium, which mimic the recurrent bursting characteristic of SE, resulted in increased internalization of the γ2 and β2/3 subunits.[24,55] Studies in animals in SE also suggested that increased internalization of GABARs likely reduced their surface expression. GABARs undergo clathrin-mediated internalization by their association with the AP2 complex of endocytotic machinery. In the hippocampi of animals in SE, an increased association between the β3 subunit of GABARs and the AP2 complex was observed,[57] which would facilitate internalization. Whether assembly and insertion of GABARs are also reduced during SE is not known.

Factors that may trigger increased internalization of GABARs during SE include neuronal firing, depolarization, *N*-methyl-D-aspartate (NMDA) receptor activation, and ligand binding. In studies of the mechanisms eliciting internalization of the γ2 subunit-containing receptors during bursting in cultured neurons, incubation with GABA did not accelerate receptor internalization.[55] Similarly, in organotypic hippocampal slice cultures, incubation with GABA in the presence of the uptake blocker NO711 did not decrease surface levels of the γ2 subunit, suggesting that ligand binding was unlikely to trigger increased internalization of GABARs during SE. In contrast, bursting-induced internalization of receptors was mimicked by NMDA receptor activation. In organotypic hippocampal slice cultures, incubation in a medium containing high extracellular potassium and NMDA decreased surface expression of the γ2 subunit. These studies suggested that activation of NMDA receptors, which occurs during SE,[16] contributes to accelerated internalization of the γ2 subunit.

SE-INDUCED DEPHOSPHORYLATION OF GABARS DECREASES THEIR CELL SURFACE STABILITY

A potential mechanism regulating the surface stability of GABARs is their phosphorylation and dephosphorylation.[59,60] Calcium influx through NMDA receptors activates second messengers such as protein kinase C (PKC) and calcineurin,[61,62] which can regulate phosphorylation of GABARs. In animals in SE, activity of PKCα, PKCβ, and PKCγ was decreased, and there was reduced phosphorylation of the β3 subunit. This was associated with increased interaction between the β3 subunit and the AP2 complex of clathrin endocytotic machinery.[57] Conversely, activation of PKC in hippocampal slices isolated from animals in SE reversed reduction of the β3 subunit surface expression. Thus, dephosphorylation of the β3 subunit facilitated its internalization during SE. However, it should be noted that PKC activity and its regulation of GABARs during SE is complex,[63] and in contrast to the report by Terunuma and colleagues,[57] other studies have shown an association between PKC activation and seizures.[64–66] The difference in findings may be due to multiple PKC isoforms.

In addition to regulation by PKC, GABAR surface stability is also determined by protein phosphatase II or calcineurin.[67] The activity of protein phosphatase II or calcineurin is increased during SE,[68,69] and treatment of hippocampal slices isolated from animals in SE with the calcineurin inhibitor FK506 prevented reduction in the phosphorylation of the β3 subunit. Whether it also reversed downregulation of surface expression of the β3 subunit is not known. However, progression of seizures was not attenuated in animals administered FK506 prior to the induction of SE. Therefore, in addition to phosphorylation-dependent mechanisms, other factors may also contribute to decreased GABAR function during SE. A reduction in the number of synaptic receptors observed in animal and cell culture models of SE may also explain reduced sensitivity to benzodiazepines (reviewed in ref. 70).

DECREASED BENZODIAZEPINE SENSITIVITY WITH SEIZURE PROGRESSION IN ANIMAL MODELS OF SE

Benzodiazepines are very effective in terminating early SE, but they become ineffective in controlling prolonged SE. In adult animals, diazepam was effective in controlling seizures when it was given 10 min after pilocarpine administration, but it failed after 45 min.[17] Correspondingly, diazepam enhancement of GABA-evoked currents was lower in DGCs

isolated 45 min after the onset of seizures; 1 μM diazepam enhanced GABA-evoked currents by 92 ± 6% in neurons from naive animals, whereas in neurons from SE animals, 3 μM diazepam enhanced GABAR currents by only 51 ± 8%.[17] Because benzodiazepines act on γ2 subunit-containing GABARs, reduced surface expression of these receptors, discussed above, could contribute to the loss of diazepam sensitivity associated with seizure progression.

TONIC INHIBITION MEDIATED BY GABARS DURING SE

As discussed above, the smaller amplitude of GABA-evoked whole cell currents recorded from DGCs and CA1 pyramidal neurons from animals 45 min after the onset of SE could also be due to reduced tonic inhibition. However, tonic currents recorded from DGCs of animals in SE remained unaltered or increased[55,56] (Fig. 41–2). In accordance, the number of surface-expressed δ subunit-containing receptors remained either unchanged or increased in the hippocampi of animals in SE.[55,57] The surface expression and internalization of δ subunit-containing GABARs also remained unaltered in cultured hippocampal neurons incubated in medium containing high extracellular potassium.[55] This could be due to slower constitutive internalization of the δ subunit[71] or signaling mechanisms that are distinct from those regulating the γ2 subunit-containing GABARs. Preserved surface expression of the δ subunit-containing receptors during SE is physiologically significant. GABARs containing a δ subunit have higher sensitivity to neurosteroids. In one study, neurosteroids were effective in treating pilocarpine- and kainite-induced SE.[72] In these animals, 5α3α or 5β3α isomers of tetrahydrodeoxycorticosterone (THDOC) and pregnanolone were potent in controlling SE when administered before pilocarpine. Furthermore, 5α3α pregnanolone was effective in aborting ongoing SE; in 50% of animals, 15 mg/kg 5α3α pregnanolone administered 15 min after the onset of seizures resulted in their termination.

GABAR FUNCTION IN CATAMENIAL EPILEPSY

In experimental animals, SE often results in the development of temporal lobe epilepsy.[73,74] A seizure-free period (latent period) spans the time between SE and the onset of a first spontaneous seizure,[75] and can range from months to years in human beings and from days to weeks in experimental animal models. GABAergic inhibition of hippocampal neurons undergoes a complex set of changes during this latent period in humans and in epileptic animals. These changes are discussed elsewhere in this book. We will focus on the neurosteroid modulation of GABARs, which is physiologically significant in the hormonal regulation of seizures in temporal lobe epilepsy.

In DGCs of epileptic animals, neurosteroid potentiation of whole cell GABAR currents, synaptic currents, and tonic currents is diminished.[76–79] Cyclic fluctuations in neurosteroid levels in women with epilepsy are often associated with periodic seizure exacerbation, often referred to as *catamenial epilepsy*.[80] In

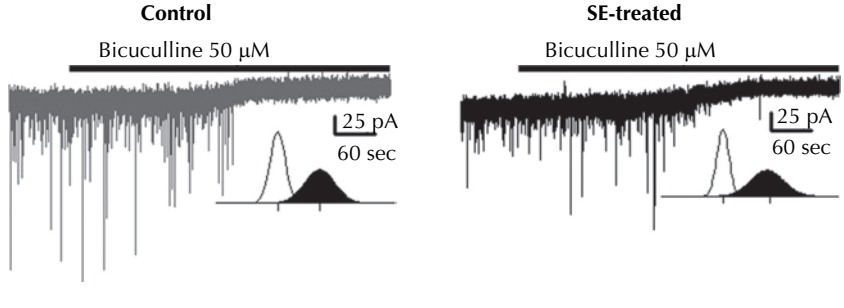

Figure 41–2. Tonic inhibition mediated by persistently open GABARs, measured in terms of the shift in the baseline holding current after application of bicuculline, was preserved in DGCs of animals in SE. Modified from ref. 55; synaptic currents have been removed to emphasize tonic inhibition.

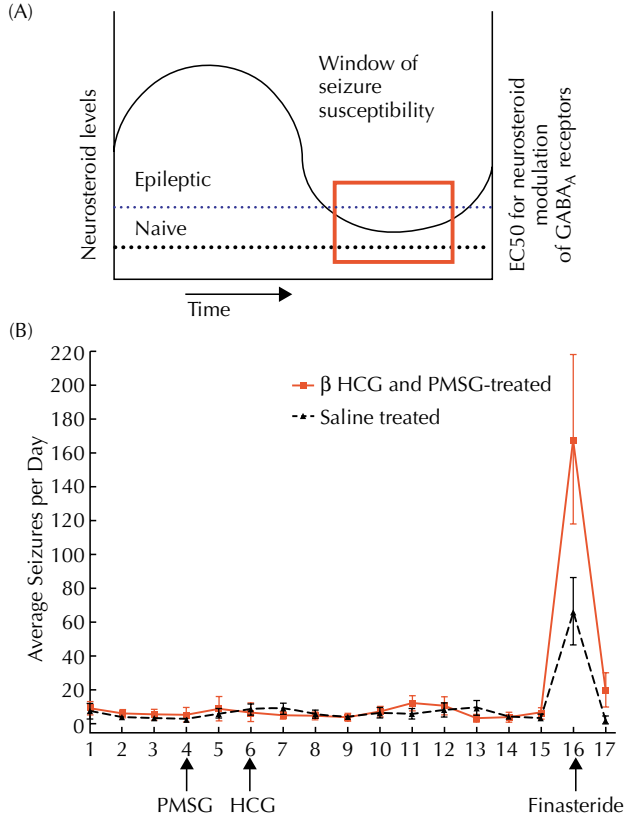

Figure 41–3. A. Schematic representation of neurosteroid levels and seizure susceptibility. **B.** Increased frequency of seizures following finasteride administration.[84] Animals were treated with pregnant mare serum gonadotropin (PMSG) and β-human chorionic gonadotropin (βHCG) to elevate their progesterone levels and then with finasteride to block neurosteroid synthesis. Seizure frequency increased following finasteride administration in animals with (βHCG- and PMSG-treated) or without increased progesterone levels (saline-treated).

a clinical study, exogenous administration of progesterone decreased seizure frequency in a woman with catamenial epilepsy.[81] However, administration of finasteride, a blocker of 5α-reductase, the enzyme catalyzing the rate-limiting step in the conversion of progesterone to allopregnanolone, abolished the anti-convulsant effects of progesterone, indicating that protective effects of progesterone were due to the synthesis of the neurosteroid allopregnanolone. In addition to anti-convulsant effects, allopregnanolone has action during the latent period[82]; inhibition of allopregnanolone synthesis accelerated development of spontaneous seizures following pilocarpine-induced SE.

Gonadal steroid hormones and neurosteroids regulate the expression of GABARs. Increased progesterone levels augment surface expression of δ subunit-containing receptors.[83] Progesterone levels are higher during the diestrus phase and decrease during the estrus phase, and levels of allopregnanolone fluctuate accordingly. A rapid decline in allopregnanolone levels during the estrus phase is thought to create a seizure susceptibility window (Fig. 41–3). However, a recent study in animals demonstrated that elevated progesterone levels are not necessary for seizures precipitation[84] (Fig. 41–3). Even at basal progesterone levels, inhibiting allopregnanolone synthesis greatly increased seizure frequency. Hence, endogenous neurosteroids are important regulators of seizure frequency.

CONCLUSIONS

Prolonged self-sustaining seizures, commonly referred to as *SE*, constitute a neurological

emergency because they can cause neuronal damage. Prompt treatment of these seizures with benzodiazepines can terminate SE. However, in many patients, benzodiazepines are not effective. Also, SE is a progressive condition in which refractoriness to benzodiazepines can develop over time. As seizures go on, there is reduced GABAergic inhibition of principal neurons in the hippocampus. This is due in part to reduced synaptic inhibition. Seizures accelerate the internalization of surface receptors in the synapses, perhaps via dephosphorylation. Interestingly, tonic inhibition and the number of diazepam-insensitive extrasynaptic receptors are preserved during SE. These insights into the mechanisms of SE suggest novel therapies targeting tonic inhibition. In addition, SE causes long-term changes in hippocampal GABARs; they become less sensitive to neurosteroids, which might contribute to seizure precipitation in epileptic animals.

Chapter 42

Plasticity of $GABA_A$ Receptors Relevant to Neurosteroid Actions

Istvan Mody

It is now widely accepted that phasic (synaptic) and tonic (extrasynaptic) GABAergic influences on neuronal excitability are mediated by different receptors with different pharmacological profiles. This chapter will focus on the plasticity of the neurosteriod-sensitive δ subunit containing gamma-aminobutyric acid A ($GABA_A$) receptors (δ-$GABA_A$Rs) in animal models of temporal lobe epilepsies (TLE) and its possible consequences for modulating the excitability of the dentate gyrus.

$GABA_A$RS RESPONSIBLE FOR TONIC INHIBITION

The GABAergic system of the mammalian brain consists of neurons that release GABA and receptors that bind GABA. The GABA-releasing cells are extraordinarily diverse and highly specialized.[1] Some GABAergic cells control the activity in a local network (interneurons, INs), while others constitute the output of a well-defined structure (e.g., striatal medium spiny neurons, MSNs). The receptors for GABA are also diverse and specific.[2] $GABA_A$Rs are members of the Cys-loop receptor family and are present on virtually every neuron in the brain, performing different functions, depending on their synaptic or extrasynaptic localization.

In the mammalian central nervous system (CNS), GABA synapses were long known to generate fast, precisely timed activity in the form of inhibitory postsynaptic currents (IPSCs or phasic inhibition).[3] Over the past decade, diffusional inhibitory transmission, mediated by $GABA_A$Rs located outside the synapses and activated by the GABA levels present in the extracellular space or spilled over from other synapses, has triggered a great deal of interest.[4–9] This form of inhibition is generally referred to as *tonic inhibition*, while the conductance generated by the $GABA_A$Rs involved is known as *tonic conductance*.[10]

The five coassembled subunits of $GABA_A$Rs consist of at least three different proteins

selected from 19 subunits. These include α1–6, β1–4, γ1–3, δ, ε, θ, π, and ρ1–2.[11,12] The assembled subunits determine the specific anatomical localization of $GABA_A$Rs,[13] probably due to various anchoring and trafficking mechanisms specific to subcellular compartments or brain regions,[14] The receptors' developmental profiles, and their physiological and pharmacological properties, are also determined by their subunit composition[2,15] and constitute an area of great interest as highly specific drug targets in the CNS.[12] $GABA_A$Rs responsible for mediating a current that is "always on" should fulfill certain criteria. One of the first requirements would be to have a sufficiently high affinity for the agonist to be activated by the near-micromolar GABA concentrations present in the extracellular space,[16] This is in sharp contrast to the $GABA_A$Rs situated at synapses, which do not have to be of high affinity to react rapidly to fast rises in GABA to 1.5–3 mM that decay within a few hundred microseconds.[17] However, it is not trivial to establish the correct affinity of native $GABA_A$Rs. Another important factor in the tonic activation of $GABA_A$Rs is desensitization,[18] This common property of ligand-gated ion channels refers to their state characterized by long closed periods while the agonist is still bound. Simultaneous openings of a very large number of desensitizing receptors could easily sum to produce a tonic current, but receptors with little desensitization, devoid of such long nonconducting states, would certainly be better suited to mediate conductance in the continuous presence of a ligand.

The $GABA_A$Rs containing δ subunits in combination with either α4 or α6 and β2 or β3 subunits satisfy both the high-affinity and limited-desensitization criteria. Their half-maximal activation by GABA (EC_{50}) is in the tens of nanomolar range, well within the range of GABA found in the extracellular space,[19,20] The δ subunit-containing $GABA_A$Rs also have a low degree of desensitization.[21–23] In addition, these subunits have two other interesting properties that render them the prime mediators of tonic inhibition throughout the brain. The first is their extra- and perisynaptic ocalization. The δ subunit-containing $GABA_A$Rs are scattered over the surface of cerebellar granule cells[24] at locations far from the synapses (extrasynaptically). In the granule cells of the dentate gyrus, another area of the brain with high levels of δ subunits, the same receptors are localized somewhat closer to the outside edges of synapses (perisynaptically); this is an ideal location to sense GABA spilled over following vesicular release from nearby boutons or to be activated by the ambient levels of GABA present in the extracellular space.[25] The second property of the δ subunit-containing $GABA_A$Rs is the inefficiency of coupling GABA binding to channel gating; that is, GABA is a low-efficacy agonist at δ subunit-containing $GABA_A$Rs. It is not intuitively obvious why GABA should be a low-efficacy agonist at δ subunit-containing $GABA_A$Rs while their affinity for GABA is very high. But this interesting property means that the predominant mechanism for enhancing the function of these receptors may involve increasing the efficacy of GABA as an agonist instead of increasing their already exceptionally high affinity for GABA. This property may be critical in mediating the actions of the most potent positive endogenous modulators of $GABA_A$R function, that is, the actions of 3α-hydroxy ring A-reduced pregnane steroids (neurosteroids) that are brain-derived metabolites of ovarian steroids and corticosteroids with sedative-hypnotic, anti-convulsant, and anxiolytic effects.[26,27]

Neurosteroids act to enhance the efficacy of GABA at δ-$GABA_A$Rs.[22,23] The low efficacy of GABA at these receptors also means that there might be other compounds that are more efficacious than GABA and may thus have specific therapeutic application. The GABA agonist THIP (4,5,6,7-tetrahydroisoxazolo-[5,4-c]pyridine-3-ol, or Gaboxadol) is such a compound[28] and has been proposed for the treatment of insomnia[29] and premenstrual dysphoric disorder[30] through its actions at δ-$GABA_A$Rs. Physiological/pharmacological approaches and the use of null mutants have shown unequivocally that in several cell types, including the cerebellar granule cells,[31] dentate gyrus granule cells,[31] thalamic neurons,[32,33] layer 2/3 pyramidal cells,[34] interneurons of the dentate molecular layer,[35] and neurogliaform cells of the cerebral cortex,[36] these receptors underlie the generation of a tonic GABA-dependent conductance. In addition, $GABA_A$Rs containing α5 subunits have been shown to be critically involved in mediating tonic currents in CA1 and CA3 pyramidal cells (PCs)[37,38] and in cortical layer 5 PCs.[39] Receptors devoid of γ subunits, that is, containing only α and β subunits that are highly sensitive to Zn^{2+}, have also

been shown to contribute to the tonic current recorded in hippocampal neurons.[40] Moreover, ε subunit-containing $GABA_A$Rs may not even require GABA for ligand-independent openings that could underlie a tonic current.[41] Several types of tonically active receptors may be found on the same cell, but their activation may require different conditions.[10,42]

Of the many $GABA_A$R types capable of mediating a tonic conductance, only some may be active during a given condition. As conditions change around the neurons, for example through alterations of extracellular GABA levels,[42] the presence of modulators, changes in GABA uptake, changes in localization of the GABA source, or some other factors, different fractions of tonically active $GABA_A$Rs may contribute to the total measured tonic current.[10] It is very likely that in any given cell the openings of various types of $GABA_A$Rs sum up to generate a tonic conductance, albeit with different fractional contributions.

When compared to the charge carried by the phasically active (synaptic) channels, the charge carried by tonically active receptors is invariably greater by a margin of 3:1 to 5:1.[2,7] This is not to say that the phasic conductance does not have a role in controlling excitability, but its actions have to be considered in a highly timed fashion depending on the input received by the interneurons as well as by their targets. In contrast, the presence of uninterrupted GABA conductance will control the overall gain of the neuronal input-output.[5,7,43,44]

ALTERED TONICALLY ACTIVE $GABA_A$RS IN THE DENTATE GYRUS IN AN ANIMAL MODEL OF TLE

Numerous changes in $GABA_A$R subunits take place in humans with TLE and in animal models of the disease.[45–52] These changes are complex and include both increased and decreased expression of several $GABA_A$R subunits.[52] Functional consequences of these changes are difficult to predict based on the nature of the plasticity alone. The cell types and specific cellular domains (e.g., soma and dendrites) in which the alterations occur; the location of the subunits at synaptic, perisynaptic, or extrasynaptic sites; and the resulting subunit composition of the modified receptors will all influence the function of the $GABA_A$Rs altered during the process of TLE.

Certain patterns of $GABA_A$R subunit plasticity are present in several TLE models. A common finding is decreased expression of the δ subunit along with increased expression of γ2 and α4 subunits in the dentate gyrus[46,47,51,53] that could alter both tonic and phasic inhibition in the dentate gyrus. An alteration specific for tonic inhibition of the dentate gyrus granule cells in TLE is the shift of the tonically active $GABA_A$Rs from a predominantly δ-$GABA_A$R-mediated tonic conductance to that mediated by α5-$GABA_A$Rs.[53,54]

The finding that γ2 subunits have shifted to a perisynaptic location in pilocarpine-treated animals[53] may indicate that these subunits could also form partnerships with subunits other than α4. A considerable portion of the tonic inhibition in the normal dentate gyrus granule cells is mediated by $GABA_A$Rs composed of α5βγ2 subunits, as noted by single- and double-knockout animal studies.[55] In fact, the results of most knockout studies are consistent with a mutual replacement of δ-$GABA_A$R- and α5-$GABA_A$R-mediated tonic inhibition when one type of the receptor is downregulated or missing.[55] This is also the pattern in a rat TLE model, where there is clear upregulation of α5-$GABA_A$R-mediated tonic inhibition that is sensitive to the α5-$GABA_A$R-selective benzodiazepine receptor inverse agonist, L,655–70854. The switch from predominantly δ-$GABA_A$R-mediated to predominantly α5-$GABA_A$R-mediated tonic inhibition has several pharmacological implications. First, the GABA concentrations required for activation of the tonic conductance in dentate gyrus granule cells will most likely be different in control and TLE granule cells. Although because of associations with other neuron-specific proteins, and neuron-specific posttranslational modifications, the exact affinities for GABA of these two receptor types in situ may differ from those determined in expression systems, δ-$GABA_A$Rs are traditionally regarded as having a high affinity for GABA (EC_{50} <1 μM).[20,28,56] In contrast, α5-$GABA_A$Rs should respond only to about 10-fold higher GABA concentrations,[37,57] which leads some to postulate that these receptors contribute to tonic GABA currents only when extracellular GABA becomes relatively high. Unfortunately, there are no studies available on how these receptors are activated in vivo and

the corresponding ranges of GABA concentrations in the extracellular space. Experiments in brain slices may be biased by artificial changes to several cellular and molecular components that control the tonic GABA conductances. These considerations require further investigations, particularly since a blocker of one of the principal components in controlling extracellular GABA levels, the plasma membrane GABA transporter GAT-1,[58] is a clinically approved antiepileptic drug (AED).

The second main consequence of the switch from a δ-$GABA_A$R-mediated tonic inhibition to one mediated by α5-$GABA_A$Rs relates to a profound change in the pharmacological properties of tonic inhibition. $GABA_A$Rs containing δ subunits are considered to be insensitive to benzodiazepines, because the presence of γ2 subunits is required for benzodiazepine sensitivity[59] and the two subunits appear to be mutually exclusive.[60] However, one study has found cerebellar δ-$GABA_A$Rs to be sensitive to flunitrazepam at a very low (~200 nM) ambient GABA concentration that was already sufficient to activate tonic inhibition,[61] In contrast, α5-$GABA_A$Rs are sensitive to benzodiazepines, but not to the allosteric modulator zolpidem. It remains to be determined whether the function of the TLE dentate gate in vivo can be better enhanced by benzodiazepines than by zolpidem. The shift to an α5-$GABA_A$R-mediated tonic inhibition in the TLE dentate gyrus presents a possible problem for the use of α5-$GABA_A$R specific benzodiazepine-site inverse agonists, which are being developed by several pharmaceutical companies as potential cognitive enhancer drugs.[62] The use of such drugs in animal models of TLE may answer the question about the excessive involvement of α5-$GABA_A$Rs in tonic inhibition of epileptic granule cells. Our own findings[53] indicate that the contribution of α5-$GABA_A$Rs to tonic inhibition is not necessarily increased in pilocarpine-treated mice, since the diazepam potentiation of the tonic current did not increase in the epileptic animals, as would be expected from an upregulation of α5-$GABA_A$Rs following a loss of diazepam-insensitive (α4βδ) receptors. It is therefore possible that in dentate gyrus of epileptic animals, diazepam-insensitive receptors (α4βγ2)[63,64] mediate a portion of the tonic current originally mediated by δ-$GABA_A$Rs.[53]

The third important consequence is also pharmacological in nature, and it relates to the sensitivity of the tonic inhibition in TLE granule cells to neurosteroids. Neurosteroid enhancement of tonic inhibition was substantially reduced in epileptic animals,[53] most likely related to the loss of neurosteroid-sensitive δ subunits[31] and consistent with our earlier findings of decreased modulation of field potentials by tetrahydrodeoxycorticosterone (3α,21-dihydroxy-5α-pregnan-20-one; THDOC) in pilocarpine-treated mice.[51] Others have also found diminished sensitivity of $GABA_A$Rs to the neurosteroid allopregnanolone in acutely dissociated dentate granule cells from epileptic rats 4–6 weeks after status epilepticus.[65] Such deficits in the normal modulation of tonic inhibition in the dentate gyrus could limit the adaptive response of the GABA system to increased excitability, particularly at times of altered hormonal levels or increased stress.[30,66]

Finally, an alternative possibility may also be considered. Following loss of δ-$GABA_A$Rs[53] from the granule cells in TLE, α4 subunits may need to combine only with β subunits to form tonically active $GABA_A$Rs. Such αβ $GABA_A$Rs have been suggested to mediate tonic inhibition in the rat CA1 region, although they appear to account for only a small fraction of the tonic current.[40] A subpopulation of native α4-containing receptors in rat does not contain either δ or γ2,[67] and thus associations of α4 subunits with only β subunits or with other subunits cannot be ruled out, although in light of the findings in α5/δ double-knockout animals that have very little, if any, tonic current in dentate granule cells,[55] the contribution of αβ $GABA_A$Rs in these cells is unlikely.

POSSIBLE CONSEQUENCES OF ALTERED NEUROSTEROID PHARMACOLOGY IN THE DENTATE GYRUS AFTER TLE

In the previous section, the focus of neurosteroid-sensitive $GABA_A$R plasticity was on the principal cells of the dentate gyrus, the granule cells. However, molecular layer interneurons also show δ-$GABA_A$R-mediated tonic conductances, although the δ subunits are associated with α1 subunits in these neurons[35] rather than with α4 subunits, as in the granule cells. In contrast to the granule cells, the molecular layer interneurons do not lose the δ subunits. In fact,

there appears to be an upregulation in δ subunit staining in these cells in pilocarpine-treated mice.[51] We have recorded from these neurons after TLE induced by pilocarpine in mice and have established a significant increase in their tonic neurosteroid-sensitive GABA conductance (Wei and Mody, unpublished). Such an alteration may have significant consequences for the excitability of the dentate gate. In the chronic phase of TLE, the actions of neurosteroids and alcohol will no longer enhance the tonic GABAergic conductance of granule cells. In contrast, these compounds will potentiate an already larger than normal tonic GABA conductance in the feedforward interneurons, most likely resulting in disinhibition.

The effects of stress-related neurosteroids and ethanol on the function of the dentate gate in vivo remain to be determined. Nevertheless, we have carried out a set of simulations of dentate gyrus excitability (Santhakumar and Mody, unpublished) using a realistic neuron- and connectivity-based model of the dentate.[68] The model has shown that increasing a tonic GABA conductance alone in the molecular layer interneurons is not sufficient by itself to trigger repetitive activity in the dentate gyrus. However, enhancing this conductance further with the stress-related neurosteroid THDOC will result in the induction of repetitive discharges in the dentate gyrus, particularly when the altered tonically active $GABA_A$Rs of the granule cells are no longer neurosteroid sensitive, as occurs in TLE. This effect is intriguing, considering the considerable excitability-dampening effect of neurosteroids in the nonepileptic dentate gyrus where both interneuronal and granule cell tonic $GABA_A$ conductances are neurosteroid-sensitive. The diametrically opposite effects of THDOC before and after onset of TLE on perforant path-evoked field excitatory postsynaptic potentials (EPSPs) have previously been reported.[51]

An even more interesting scenario may emerge if it becomes evident that the molecular layer interneurons are in fact neurogliaform cells, which have recently been reported to have high expression of δ subunits and to be responsible for GABA volume transmission.[36] Lowering the excitability of these cells by neurosteroids in TLE may then lead to lowering of ambient GABA levels, which could affect the activation of the lower-affinity tonically active $GABA_A$Rs that have replaced the δ-$GABA_A$Rs of granule cells.

In summary, the complex changes in $GABA_A$Rs generating tonic and phasic inhibition in the dentate gyrus on principal cells and inhibitory interneurons alike will result in profound alterations in the excitability of this structure in association with TLE. In particular, the response of the dentate gate to endogenous (neurosteroids) and exogenous (e.g., alcohol, benzodiazepines) modulators will be affected, which could lead to distinct effects of these modulators in the epileptic brain that will not be encountered in controls. These findings and predictions may also be important to states comorbid with epilepsy, including stress, depression, and changes in the levels of ovarian hormones during the menstrual cycle, pregnancy, or menopause.

Chapter 43

$GABA_A$ Receptor Plasticity in Alcohol Withdrawal

Richard W. Olsen
Igor Spigelman

INTRODUCTION

Alcohol, the fruit of the vine and the braumeister's ware, has been one of the most popular drugs in the world throughout history and one of the most abused. The development of dependence after chronic use of ethanol (EtOH) depends on two parallel effects of the drug on the brain each time it is used: stimulation of the reward pathway and subsequent triggering of a small but significant withdrawal. There is rebound hyperexcitability following the initial action of EtOH as a central nervous system (CNS) depressant and triggering of some adaptive process, that is, molecular changes associated with tolerance.[1,2] Each of these "mini-withdrawals" reflects transient plasticity in the brain affecting the balance of excitation and inhibition. The simplest description of the changes could be, for example, the ratio of glutamate and gamma-aminobutyric acid (GABA) neurotransmitter activities.

Whatever the mechanism, a fairly well-supported theory of how repeated use of EtOH leads to a dependent condition is that the chronic repetition of the mini-withdrawals leads to a persistent state of withdrawal (alcohol withdrawal syndrome, AWS) in which the withdrawals become more severe and long-lasting, eventually becoming permanent. In other words, repetition turns a relatively normal brain activity involving plasticity into a pathological condition of uncontrolled hyperactivity. This is reminiscent of the kindling phenomenon in epilepsy research, in which seizures can be triggered by subconvulsant stimuli after they have been repeated over and over[3,4]; eventually, seizures can become spontaneous, and once they do, they can occur for the rest of the person's life. One facet of human alcohol dependence is increased seizure susceptibility, and delirium tremens and frank seizures are triggered by withdrawal from EtOH in very heavy abusers.[5] Greater susceptibility and/or severity of seizures is produced by greater periods of EtOH abuse and by previous withdrawals and/or withdrawal seizures. When the number of previous exposures and

withdrawal episodes reaches a certain threshold, the severe withdrawal (AWS) becomes persistent, possibly permanent. This led to the conclusion of a kindling-like phenomenon in human EtOH dependence.[6–9] However, a significant reduction in seizure threshold can be measured during the mini-withdrawals experienced in rats after EtOH administration.[10,11] This suggests that seizure susceptibility is, first, an integral component of withdrawal. Second, the increased severity and persistence of seizure susceptibility are signs of and critical ingredients of alcohol dependence. Numerous animal models employ this kindling-like regimen of intermittent episodes of EtOH intoxication and withdrawal, termed *chronic intermittent ethanol* (CIE),[12–16] and we have been studying the CIE rat model for 20 years.[11] Indeed, there are many similarities between the development of drug dependence, especially alcoholism, and the kindling model of epilepsy, as well as with other models and theories of epileptogenesis.

Our research has established that an important aspect of alcohol's acute action on the brain is enhancement of inhibition mediated by GABA and especially $GABA_A$ receptors (GABAR), and that withdrawal includes as a critical component a reduction in GABAR-mediated inhibition. The behavioral changes of AWS can be explained by persistently reduced GABAR-mediated inhibition due to EtOH-induced plasticity of GABAR. When this becomes persistent due to the CIE treatment, the condition can be termed *aberrant plasticity*. We mentioned that the receptors for the very important rapid neurotransmitters glutamate, and especially GABA, are liable to aberrant plasticity and are in a position to do the most harm. In the case of CIE, the treated individual has all the signs of AWS, which is an extreme hyperexcitable condition. Increased seizure susceptibility would seem to be a critical aspect of epileptogenesis, but we do not know what additional factors, if any, are required to generate actual spontaneous seizures (epilepsy). The CIE rats (or mice) have not been observed to exhibit spontaneous seizures, but this has not been studied carefully enough to conclude that there are none.

The ratio of excitation to inhibition is so important that a new concept called *scaling* has gained prominence; in scaling, compensatory changes in either excitation or inhibition accompany any perturbation of the other process.[17] We provide examples in which the deciding factor for aberrant plasticity is reduced GABAergic inhibitory function, which seems particularly susceptible to derangement. These examples cover several chronic drug models as well as epilepsy (see the "Discussion" section below). It is known that application of GABAergic drugs, or even GABA itself, to the mammalian cerebral cortex produces withdrawal signs upon removal[18]; that even an hour's exposure can produce long-lasting focal seizures upon termination, the *GABA withdrawal syndrome*[18–20]; and that modified GABAR are found in many types of human and experimental epilepsy[21,22] (cf. Chapter 57, this volume). Our hypothesis concerning alcohol withdrawal is that the extrasynaptic GABAR subtypes containing the δ subunit that are most sensitive to low doses of EtOH[23–26] are the first targets of acute EtOH action and the first to show plasticity in the face of chronic EtOH stimulation. Alcohol is accepted to have a GABA-mimetic effect. However, some important effects of EtOH on GABA-mediated inhibition may be presynaptic.[27] Another important concept is that plasticity most often involves changes in protein trafficking[28,29] rather than gene expression, especially for the early events. This does not necessarily apply to the events leading to persistent alterations in drug dependence or epileptogenesis.

RESULTS

The CIE Model and Its Relationship to Human Alcoholism

Twenty years ago, Kokka and Olsen set out to establish a rat model of the kindling hypothesis of alcohol dependence in humans[6] and to investigate the possible role of $GABA_A$ receptors.[11] The CIE regimen, with 5–6 g/kg EtOH administered to rats by gavage per day for 60 days, was found to reduce the seizure threshold to the GABAergic convulsant drug pentylenetetrazol (PTZ), administered by slow tail vein injection, and this change lasted at least 40 days after EtOH was stopped; importantly, the persistence of the changes (*kindling*) was dependent on the intermittent drug administration regimen, since continuous administration of EtOH for several days without withdrawal led

to one big withdrawal, possibly including seizures, upon cessation but no detectable change at 2 days or any time thereafter.[11] In other words, the animals rapidly forgot about the EtOH exposure but not the multiple withdrawals. Other workers have demonstrated that the intermittent administration of EtOH, including periods of deprivation, can increase voluntary consumption (e.g., refs. 14 and 30).

We[31] showed that in CIE, GABAR binding was not much affected throughout the brain but that GABAR function, assessed with a neurochemical assay of GABA-stimulated[36] Cl^- flux in brain slices, was impaired specifically in hippocampal formation, but not in inferior colliculus, several lobes of cortex, thalamus, striatum, or cerebellum. Using extracellular electrode recording in hippocampal slices in collaboration with Dr. Igor Spigelman, we demonstrated a parallel reduction in paired-pulse inhibition[31] that was consistent with the increase in behavioral seizure susceptibility. Veatch and Gonzalez[32] presented similar evidence that intermittent EtOH with multiple withdrawals led to elevated excitability specifically in hippocampus, as detected by electroencephalography (EEG). We have further shown small changes in benzodiazepine (BZ) modulation of GABAR radioligand binding accompanied by a significant elevation in the GABAR α4 subunit mRNA assessed by in situ hybridization histochemistry; the increase was relatively larger in hippocampus than in thalamus, despite higher levels of the subunit in thalamus.[33] This is consistent with elevated BZ-insensitive GABAR and behavioral and cellular tolerance to BZ. Indeed, with intracellular sharp electrode recordings in hippocampal slices, we showed a reduction in allosteric modulation of GABAR-mediated postsynaptic potentials by BZ and steroids but not by EtOH. Ethanol enhancement of evoked synaptic potentials was, if anything, increased.[34] In situ hybridization and reverse transcriptase-polymerase chain reaction (RT-PCR) revealed several changes in GABAR subunits in CIE rat brain, including elevated γ2S in hippocampus and increased binding of the imidazobenzodiazepine radioligand [^{3}H]Ro15–4513 to diazepam-insensitive sites in cerebellum and forebrain, considered to involve the α6 and α4 subunits, respectively.[35] Similar increases in GABAR α4 subunit and smaller changes in some other subunits were observed by others in rodents treated with chronic EtOH (e.g., refs. 36 and 37). Measurements by most groups did not include significant withdrawal periods.

Using subunit-specific antibodies, we measured GABAR subunits by Western blotting in CIE rat hippocampus and demonstrated significant, persistent elevation in the α4 and γ2 subunits with a decrease in α1 and δ—in other words, a net "subunit switch" of α1 to α4 and δ to γ2. The same subunit changes have been reported for several animal models of temporal lobe epilepsy, as reported in Chapters 40, 41, and 44 of this volume, as we noted in the previous edition of *Jasper's Basic Mechanisms of the Epilepsies*.[21] Animals treated with CIE were shown to exhibit increased anxiety in the elevated plus maze assay, and behavioral tolerance to the sedative action of EtOH, BZ, and neurosteroids.[38] Steroids and BZ showed reduced enhancement of GABAR synaptic and tonic inhibitory currents in hippocampal neurons recorded by patch-clamp electrodes in CIE rats; sensitivity to the α4-selective agonists bretazenil and Ro15–4513 was not decreased but possibly increased; the GABA analogue THIP (tetrahydroisoxazolo-pyridin-3-ol) showed reduced activation of tonic currents but increased modulation of miniature inhibitory postsynaptic currents (mIPSCs).[39] These changes in cellular pharmacology are consistent with the net switch of GABAR subunits from α1 to α4. The mIPSCs showed less inhibitory charge transfer due to the contribution of GABAR α4 subunits to the synaptic current measured in CIE rats, as well as reduced tonic inhibitory currents, consistent with the hyperexcitable state.[38,39] Rats treated with CIE also exhibited decreased levels of endogenous neurosteroids in the hippocampus and impaired spatial learning.[40]

Importantly, changes in EtOH pharmacology were also found. We observed significant enhancement of GABAR-mediated tonic inhibitory currents in CA1 neurons and dentate gyrus granule cells by 50 mM EtOH in untreated rats, with a threshold effect at 10 mM.[41] This enhancement of GABAR-mediated tonic inhibitory currents by millimolar concentrations of EtOH was observed at the same time by Wei et al.[42] in dentate gyrus granule cells and by Hanchar et al.[24] in cerebellar granule cells. Rats treated with CIE showed a decreased amplitude of tonic inhibitory current and a correspondingly decreased enhancement

by low concentrations of EtOH. On the other hand, mIPSCs showed little effect of EtOH up to 100 mM in vehicle-treated control rats, but they were significantly enhanced by 10–30 mM EtOH in CIE rat hippocampus. We confirmed that in the absence of acute EtOH, reduced charge transfer of both synaptic and extrasynaptic GABAR currents was found in CIE rat hippocampal neurons compared to control neurons, consistent with the AWS state, and its associated increased anxiety and disturbed sleep. Further, immunostaining and electron microscopy showed that the α4 subunit, normally localized to the perisynaptic membrane and not to the synaptic membrane, was observed primarily in the synaptic region. The δ subunit is typically not found in the synaptic membrane but is instead localized perisynaptically in controls and did not change in CIE rats.[41] It seems that much of the altered physiology and pharmacology of hippocampal neurons in CIE can be explained by the changes in GABAR subunit composition observed, and this might also explain much of the behavioral phenotype and contribute to EtOH dependence.

The changes found after CIE treatment did not appear to involve any gross pathology in either brain or liver.[31] Microscopic examination of tissue sections revealed no evident changes in the morphology, number, and location of GABA-synthesizing neurons in hippocampus, thalamus, or neocortex.[33] Neuronal cell counts (by the UCLA School of Medicine pathology lab) were normal in the hippocampus and in several other regions of CIE rats; no increase in damaged or dying cells or inflammation markers was observed. Unbiased stereological cell counts in the nucleus accumbens of NeuN-stained sections showed no differences between CIE, single-dose EtOH, and vehicle-treated animals (Spigelman, Ahmad, and Olsen, unpublished). This is despite evidence that exposure to a single very high dose of EtOH with blood levels of over 300 mg/dL, as experienced in human binge drinking, or to a very high level of cumulative alcohol exposure, as in human chronic alcohol abuse, produced significant neuronal cell death.[43,44] We found no evidence for a significant increase in newborn neurons or for stem cell death in dentate gyrus of CIE rats versus normal controls (Spigelman, Olsen, and Crews, unpublished). Thus, in our hands, high blood levels of EtOH administered by gavage, exceeding 250 mg/dL for several hours but not exceeding 275 mg/dL,[45] were insufficient or too brief to produce the damage reported by other extreme exposures to alcohol. Nevertheless, CIE treatment is definitely a severe, abnormal stress to the brain.

In order to learn more about the mechanism of GABAR plasticity induced by CIE, we attempted to determine the minimum dose, duration, and frequency of EtOH administration required to produce the changes. We found that a single intoxicating dose of EtOH administered by gavage was able to induce many of the same changes in behavior, GABAR subunit composition, and hippocampal neuron pharmacology seen in CIE, but the changes were transient.[45] Thus, we showed that within 1 h the α4 and δ subunits, but not the α1 or γ2 subunits, were reduced at the cell surface, accompanied by loss of EtOH enhancement of tonic inhibitory currents but no change in synaptic pharmacology. Thus, the first target of EtOH action, the extrasynaptic δ subunit-containing GABAR,[25] are the first to respond with plastic changes. After 24 h but not at 1 h, one could detect increased cell surface and increased total levels of γ2 and α4 subunits, decreased levels of α1 subunit, and a tolerance to BZ enhancement of both extrasynaptic and synaptic currents. It appears that these changes are the result, at least in part, of altered gene expression. It is not known if these changes are triggered by the reduced tonic inhibition or even the reduced synaptic inhibition seen at several hours post-EtOH, or if altered protein synthesis may also be initiated by the EtOH exposure but requires a longer time to be measurable. Also, at 12–24 h, the animals exhibited tolerance to BZ-induced loss of righting reflex (LORR), and the synaptic currents became more sensitive to EtOH (as in CIE), but they returned to normal within a few days. The δ subunit remained low for 1–2 days and then returned to normal.[45] All the changes require repetition of the CIE regimen to become more persistent. These EtOH-induced plastic changes in GABAR are summarized in Fig. 43–1. Current studies are examining the precise time course of changes in GABAR subunits and function, demonstrating subunit partnerships using co-immunoprecipitation, and examining association of GABAR with other proteins such as trafficking chaperones and clustering factors, as well as kinases and phosphatases, looking for some causal relationships.

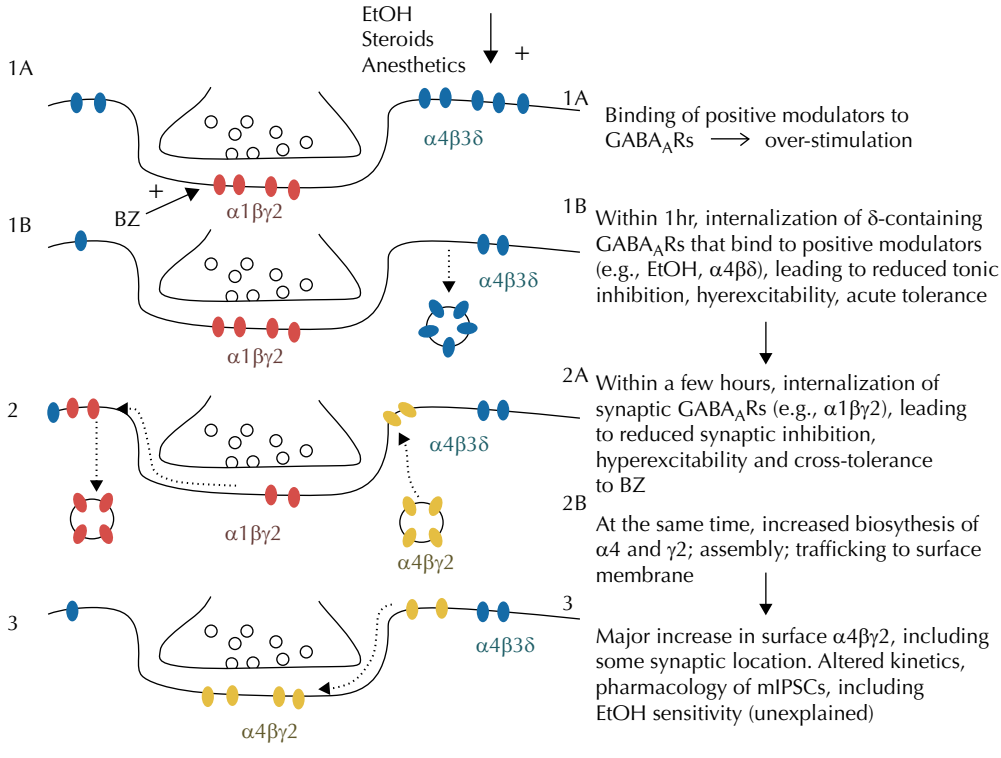

Figure 43–1. GABAR plasticity hypothesis.

One additional observation made about GABAR plasticity induced by CIE[46] demonstrated a correlation between the degree of tolerance induced for a series of GABAergic sedative-hypnotic drugs to produce LORR and the degree of tolerance induced for the same drugs to enhance GABAR-mediated tonic inhibitory currents in hippocampal neurons. Since the hippocampal neurons do not mediate LORR, or at least not all of the response, we suggest that EtOH-induced changes in extrasynaptic GABAR in other brain regions may be very relevant to the soporific action of these agents. Likewise, since one of the prevalent and problematic signs of alcoholism is insomnia, and resistance to commercial sleep aids, we suggest that those hypnotics that do not show complete tolerance to LORR and modulation of extrasynaptic GABAR in the CIE rat model might retain some efficacy to assuage the insomnia problems of human alcohol abusers.

In summary, the CIE model and our combination of behavioral, biochemical, and electrophysiological measurements have demonstrated the critical role of GABAR in many of the signs and symptoms of AWS and thus have implicated GABAR in EtOH dependence.

Remarkable plasticity of GABAR is induced by acute EtOH, and the biochemical mechanisms should be decipherable. The same changes are produced by CIE, but notably they become persistent, lasting up to 120 days post-EtOH.[45] Mechanisms for the change to persistence are under study. Approaches include extension of the CIE model to the mouse to allow use of genetically engineered animals, such as GABAR subunit knockouts and knock-ins. Knockdown of GABAR subunits in critical brain regions has been demonstrated in rats to reduce alcohol consumption.[47]

DISCUSSION

The CIE Model of Alcoholism and GABAR

Two conclusions have been presented about the rat CIE model of alcoholism and the

mechanistic role of GABAR. First, even a single rather large dose of EtOH can trigger within minutes to hours plastic changes in GABAR subunit composition and function, with behavioral correlates, lasting many hours to days, but transient, not persistent.[45] The model has recently been extended to the mouse and to primary cultured rat hippocampal neurons (Olsen and Spigelman, unpublished). Second, chronic administration of moderately high doses of EtOH involving intermittent episodes of intoxication and withdrawal leads to those same plastic changes in GABAR becoming persistent, reminiscent of the kindling of epileptic seizures.[41]

One might ask if the CIE model more closely follows the regimen of the human alcohol abuser who is continually imbibing or that of a binge-type drinker. Although our model requires blood alcohol levels sufficient to produce the mini-withdrawal (~3 h at ~50 mM), the CIE regimen is not exactly like binging since we administer alcohol every day, and we do not reach the blood levels shown in binge studies to be necessary for neuronal toxicity,[44] so we regard the model as more closely approximating the regimen of the alcohol abuser with sporadic use patterns, which could be fairly frequent, including almost every night but not drinking all day, every day.

We recently established the minimum dose, frequency, and duration of the regimen needed to produce long-lasting (>40 days after the last EtOH dose), if not permanent, changes in GABAR function and behavior. In the rat this amounts to about 2.5–3.0 g/kg per day, once every 2 days, for at least 15 doses (Spigelman and Olsen, unpublished). The major question under study, and of most relevance to the topic of this chapter, is how does the plasticity produced become permanent? This question appears to be highly analogous to the same question raised in epileptogenesis, and only with more understanding of the mechanisms of the change to persistent plasticity can and will cures to the process be developed. We have been examining the period of early plastic changes and later-period plasticity induced by CIE in hopes of determining, firstly, what is changed; secondly, what sorts of additional changes occur; and thirdly, how the plasticity becomes aberrant and persistent.

The CIE rats exhibit hyperexcitability in locomotion, rearing, and exploratory behavior. They have a quantitative reduction in seizure threshold to PTZ, increased anxiety, impaired hippocampal spatial memory, perturbed sleep patterns, and tolerance to the soporific actions of EtOH, BZs, neurosteroids, and several general anesthetics, including most commercial sleep aids. They are not altered in sensorimotor performance. Rodent studies using regimens analogous to CIE lead to increased voluntary consumption and presumably craving.[14,30] Using patch-clamp recording in hippocampal slices from CIE rats, we showed that neurons in CIE rat brain have reduced inhibitory synaptic and extrasynaptic (tonic) currents. They have reduced EtOH enhancement of GABAR-mediated tonic inhibitory currents, but no tolerance for EtOH enhancement of GABAR-mediated inhibitory synaptic currents and, ndeed, increased sensitivity. Cross-tolerance to BZ and steroids is seen in both synaptic and tonic GABAR currents, and a change in GABAR channel kinetics and pharmacology was observed that was consistent with the subunit switch in GABAR observed (replacement of normal subunit subtypes with the $\alpha4\beta\gamma2$ subtype). Synaptic inhibition is reduced in total charge transfer due to the more rapid decay of $\alpha4$- versus $\alpha1$-containing GABAR. The BZ-sensitive $\alpha1$ subunit and the EtOH-sensitive δ subunit are persistently downregulated.[41,43] In rats treated acutely with EtOH, these GABAR properties are similarly altered in some other regions, including basolateral amygdala (Spigelman, Liang, and Olsen, unpublished), and probably in ventral tegmentum.[48] In the nucleus accumbens, CIE-induced changes are persistent and pharmacologically similar to those in the hippocampus. However, single dose EtOH-induced alterations exhibit differences not observed in other brain regions (Spigelman, Liang, and Olsen, unpublished observations).

Animals treated with CIE show tolerance to the sedative-hypnotic action of GABAergic drugs, although to varying degrees, apparently related to the fraction of action of each drug on extrasynaptic tonic inhibition.[46] Thus, the symptoms, primarily alcoholic insomnia, can still be treated with GABAergic drugs that do not show much tolerance for action on the GABAR-mediated tonic inhibitory currents and in LORR behavior (e.g., propofol, gaboxadol, and barbiturates). Interestingly, the anti-convulsant actions of EtOH, and especially of neurosteroids, and most of the other GABAergic drugs, do not show much tolerance, and the same

can be said for the anxiolytic actions.[38,40] The modulation of GABAR-mediated synaptic currents by EtOH does not exhibit tolerance, and in fact, the synaptic currents in hippocampal neurons actually become more sensitive to EtOH.[34,41,45] This increased modulation of mIPSCs by EtOH is also seen in the GABAR α4 subunit knockout mouse and might account for the lack of reduction in many EtOH behaviors in this mouse.[49,50]

Therefore, we asked: what might be the subunit composition of GABARs accounting for this increased EtOH sensitivity of synaptic currents? In CIE we observed an increase in α4βγ2 GABAR, including movement of the α4 into the postsynaptic membrane. The δ subunit was not elevated and did not accumulate in the synaptic membrane, and the increased EtOH modulation of mIPSCs was also observed in the GABAR δ subunit knockout mouse.[41] The increased sensitivity to EtOH in mIPSCs in the α4 subunit knockout mouse rules out the α4βδ and α4βγ2 for the EtOH-sensitive GABAR pentamer, so we are examining other possibilities. One cannot help suggesting that some unknown factor(s) other than subunit composition alone might affect EtOH sensitivity. Perhaps this is related to subcellular location, and/or associated proteins, and/or some protein phosphorylation event(s).

Other Studies on Chronic EtOH and Other Drug-Induced GABAR Plasticity

GABAR subunit changes have been reported by others in chronic EtOH-treated animals or cells.[37] Mhatre et al.[51] demonstrated that chronic EtOH treatment in rats produced a hypersensitivity to the behavioral effects of the BZ alcohol antagonist Ro15–4513, followed by biochemical evidence[36] for upregulation of [^{3}H] Ro15–4513 binding to diazepam-insensitive (DZ-IS) sites (shown elsewhere to reflect α4- and α6-containing GABAR). We showed that CIE treatment led to elevated levels of α6 mRNA and protein in cerebellum as well as elevated γ2S mRNA in forebrain[35] and elevated α4 mRNA in hippocampus but not thalamus or cortex.[33] Western blots revealed elevated α4 and γ2 protein as well as reduced α1 and δ polypeptides in CIE hippocampus.[38] In retrospect, the elevated Ro15–4513 binding polypeptide reported in forebrain following chronic EtOH administration by Mhatre and Ticku[36] was undoubtedly the α4 subunit. Meanwhile, the lab of Morrow et al. showed that chronic EtOH administration led to elevated levels of α4 and reduction of α1 involving phosphorylation-regulated trafficking in some forebrain regions.[52,53] A few other subunits were altered, including especially elevated γ1. Similar subunit changes were observed in the lab of Biggio and colleagues for rats and neurons, with an emphasis on the requirement of several hours of withdrawal for EtOH-induced plastic changes in GABAR subunits and behaviors.[54] What falls out of the summarized literature is that chronic EtOH leads to upregulation of the GABAR α4 subunit, which appears to be a very "plastic" subunit, subject to changes in levels under many conditions of stress or overactivity.[21] The α4 subunit is available to replace other α subunits, and this leads to tolerance to sedative drugs given chronically but also to an abnormally excitable state. It suggests the possibility that in the epilepsy models there is overactivity of GABA-mediated inhibition leading to a similar increase in α4 that has some benefit but also produces hyperexcitability. Recent work describes how the GABAR α4 subunit is indeed regulated at the promoter level for gene expression by immediate early genes including heat shock proteins[55,56] and early growth response factors (Egr3),[57,58] which are elevated under various stressful and overstimulation conditions including alcohol exposure[56] and prolonged seizures.[57,58] The α4 subunit polypeptide can be partnered with γ or δ subunits, leading to different pharmacological and functional properties; thus, which of these isoforms is involved is likely very important. We have shown that in fact the α4βδ GABAR are downregulated and the α4βγ2 GABAR are upregulated,[38,41] and play an important role in AWS and EtOH dependence and provide a profound example of aberrant plasticity in the CIE model.

Interestingly, Hu and Ticku[59] were able to reproduce many of the effects of CIE on rats in vivo on cortical cultured neurons in vitro, including hypersensitivity to blockade of GABAR function by PTZ. Primary cultured neurons may therefore provide a good model of alcohol dependence allowing more defined studies of mechanism including GABAR

plasticity. It is critical to establish that primary cultured neurons can mimic as much as possible of the phenotype of the mature brain neurons and the critical plastic changes induced by EtOH. We have now demonstrated in primary cultured hippocampal neurons that one brief exposure to EtOH produces many changes in GABAR[60] that we found in vivo in rats.[45]

GABAR changes have been seen in animals or cells treated with chronic BZ.[61–66] In all of these examples, one can conclude that overstimulation of the receptor by any positive modulator or agonist leads to downregulation of the GABAR subtypes, and only those, that are sensitive to that ligand. In some cases, the function (chloride current) is monitored, whereas in other cases, BZ modulation of GABA site ligand binding is reduced (uncoupling). All of these examples are likely due to removal of the activated GABAR protein from the cell surface, which, depending on the time of the study, can result in reversible return to normal or, at longer times, in degradation of the receptor protein. The BZ effects are limited to action on the subtypes of GABAR that respond to BZ, namely, the γ2-containing isoforms containing α1, α2, α3, or α5.[62] The result is not just a loss of BZ modulation of GABAR function but also a silencing of the GABAR function at that site for a period of time ranging from hours to days (e.g., ref. 63). The loss of cell surface GABAR by endocytosis can be demonstrated. However, basal binding of BZ ligands may persist because the protein in intracellular pools can bind ligand but it is not subject to modulation by GABA in the test tube (uncoupled) because of the low pH of the endosome environment.[62,64,66] GABAR plasticity is also triggered by chronic[67,68] or acute administration of neurosteroids.[69,70] Chronic administration of steroid as a drug produces CNS depression with measurable withdrawal[68] that is accompanied by a tolerance of electrophysiologically recorded GABAR currents to steroids but more dramatically to BZ, accompanied by a switch in subunit composition from traditional BZ-sensitive synaptic GABAR (α1, α2, α3, α5) to the BZ-insensitive α4 subunit. There does not appear to be downregulation of the highly steroid-sensitive α4βδ GABAR subtypes. The in vitro and in vivo pharmacological changes as well as the withdrawal behavior are all reduced by preventing the increase in α4 subunit with anti-sense mRNA.[63]

The plasticity appears to be a variant on the usual mechanism of use-dependent downregulation. More importantly, the neurosteroids are endogenous ligands with in vivo mechanisms of homeostasis, including linkage to the endocrine system.[67,68,71,72] It might not be healthy if steroid-sensitive GABAR were downregulated every time they were modulated for more than a few seconds by endogenous modulatory neurosteroids. And what sort of severe overstimulation by GABA itself is required before downregulation is triggered?

Indeed, the function of GABAR is tightly coupled to the state of neurosteroid activity in the CNS. It appears that high levels of stimulation of the highly sensitive α4βδ type GABAR by neurosteroids leads to plasticity, probably involving mechanisms similar to those mentioned above. GABAR changes are observed in pregnancy and parturition,[72,73] at puberty,[74] and during the estrus cycle,[75] possibly related to premenstrual syndrome. Neurosteroids have even been postulated to mediate at least some of the effects of EtOH occurring minutes to hours after administration.[76] It is therefore likely that neurosteroids play a role in EtOH-induced plasticity of GABAR observed in AWS and dependence. These are early days in this field, but the implications for epileptogenesis are obvious (cf. Chapter 42, this volume).

GABAR Plasticity in Epilepsy

GABAR changes similar to those described in CIE have been reported after seizures, after status epilepticus, and in other epilepsy models.[21,22,77] Nusser et al.[78] demonstrated that experimental epilepsy leads to an increased number of synaptic GABAR measured by electron microscopy in rat hippocampus. Brooks-Kayal and Russek (Chapter 44, this volume)[79] showed that epileptic animals exhibit a switch in GABAR from α1 to α4 and that development of epileptogenesis could be inhibited by preventing the GABAR subunit switch.[80] Banerjee et al.[81] observed a decrease in allosteric modulation by neurosteroids of [^{35}S]TBPS binding to GABAR during absence seizures in rats only in the affected brain cells in thalamus. We interpreted this to reflect a switch in GABAR subunit composition involving both trafficking and gene expression. This conclusion was further supported by Banerjee et al.,[82]

who demonstrated rapid (within 1–2 h) changes in GABAR α1 and α4 subunit gene expression in thalamic neurons during absence seizures. Naylor et al.[83] demonstrated that status epilepticus produced downregulation in the γ2-containing synaptic GABAR, interpreted as overstimulation by massive GABA synaptic release; they also postulated a protection of extrasynaptic GABAR-mediating inhibitory tonic currents. Subunit-selective regulation of synaptic GABAR trafficking and localization has been demonstrated by Kapur and colleagues[84–86] (Chapter 41, this volume). The mechanism of status epilepticus-induced internalization of synaptic GABAR has been shown to involve increased dephosphorylation-regulated binding of GABAR to clathrin for endocytotic removal from the cell surface.[87] Status epilepticus-induced spontaneous seizures were shown to be accompanied by alterations in the synaptic versus perisynaptic localization of α4βγ2– and α4βδ-type GABAR[88] (Houser et al., this volume).

In conclusion, we suggest that the plasticity observed in alcohol withdrawal involving GABAR and especially extrasynaptic α4βδ-type GABAR is indicative of the common use of GABAR (and GLUR) plasticity in normal brain functions including learning and memory. Further, the mechanisms responsible for GABAR (and GLUR) plasticity have the propensity for aberrant plasticity leading to seizure susceptibility: a model of epileptogenesis? We continue to study this hypothesis. Current studies involve CIE treatment in the mouse and examination of genetically engineered animals (e.g., refs. 89 and 90) and a cultured rat hippocampal neuron model.[60] Finally, recent studies increasingly implicate changes in GABAR-mediated tonic inhibition in epilepsy physiology (see Chapters 40, 41, 42, and 44 in this volume).

ACKNOWLEDGMENTS

We thank Jing Liang for helping with the CIE model and for meaningful discussions, and Antonio Delgado-Escueta and Carolyn Houser for helpful discussions about epilepsy, as well as Amy Brooks-Kayal for careful editing of this chapter.

Chapter 44

Regulation of $GABA_A$ Receptor Gene Expression and Epilepsy

Amy R. Brooks-Kayal
Shelley J. Russek

Results of research in animal models as well as from human retrospective studies suggest that an initial precipitating event such as status epilepticus (SE), stroke, or traumatic brain injury can increase the risk of later development of the recurrent spontaneous seizures that define epilepsy. The process by which a normal brain transforms into one capable of producing recurrent spontaneous seizures, known as *epileptogenesis*, is likely to be complex and multifactorial. Among the many changes that occur during epileptogenesis are alterations in expression of a wide variety of genes. Determining what molecular pathways regulate these changes in gene expression, and which of them are consequential or causative of disease, are two of the major challenges of research in this area, and are critical to effectively utilizing this information to develop new therapies for the prevention and treatment of epilepsy.

ROLE OF $GABA_A$ RECEPTORS IN EPILEPSY

Many laboratories, including our own, have focused on the role of gene regulation in determining changes in gamma-aminobutyric acid (GABA) receptor plasticity that begin during the latent period after brain insult and persist after the development of the epileptic state. GABA is the major inhibitory neurotransmitter in the mature brain, and several drugs that enhance GABAergic inhibition are commonly used as antiepileptic medications. Conversely, drugs that block GABAergic inhibition can induce seizures in animals, further supporting the potential importance of alterations in GABAergic transmission in the etiology of epilepsy.

Three types of GABA receptors, $GABA_A$, $GABA_B$, and $GABA_C$, are found in the mature central nervous system. $GABA_A$ and $GABA_C$ are ionotropic receptors, whereas $GABA_B$ is a metabotropic receptor. Most fast synaptic inhibition in the mature brain is mediated by $GABA_A$ receptors (GABARs), whereas slow inhibition is mediated by $GABA_B$ receptors. GABARs are composed of multiple subunits from a variety of subtypes (α1–6, β1–3, γ1–3, δ, ε, π, θ, and ρ1–3) that form a pentameric anion-selective channel.[1] GABAR subunit composition determines the intrinsic properties of each channel, including GABA affinity, kinetics, conductance, allosteric modulation,

probability of channel opening, interaction with modulatory proteins, and subcellular distribution.[2] The typical in vivo subunit composition is two α, two β, and one γ or δ subunit. Synaptic GABARs in cortex and hippocampus most commonly contain a γ subunit in combination with an α1 or α2 and β_x- subunit, whereas those located at perisynaptic and extrasynaptic sites contain predominantly a δ subunit in combination with an α4 and a β_x subunit or a γ subunit in combination with an α5 and a β_x subunit.[3] There is remarkable receptor heterogeneity, with subtype combinations varying in different brain regions, cell types, and membrane locations and during different times in ontogeny.[2,4–6]

Prolonged seizures (SE) result in alterations in the expression and membrane localization of several GABAR subunits (α1, α4, γ2, δ) in hippocampal dentate granule neurons.[7–9] These alterations, which are associated with changes in phasic and tonic GABAR-mediated inhibition, decreased GABAR modulation by benzodiazepines and neurosteroids, and increased inhibition by zinc, begin soon after SE and continue after animals become epileptic.[7–13] In the pilocarpine model of SE in adult rats, GABAR α1 subunit mRNA expression decreases and α4 subunit mRNA expression increases in dentate granule cells of the hippocampus, and animals uniformly go on to develop epilepsy. These changes in subunit mRNA expression correlate with a decreased presence of α1γ2-containing receptors[14] and an increased presence of α4γ2-containing receptors,[11,14] as well as an increase in perisynaptic localization of γ2 subunits, likely partnering with α4.[9] GABAR functional and subunit expression changes have also been observed in neurons from surgically resected hippocampus from patients with intractable temporal lobe epilepsy (TLE).[15–17] The changes in GABAR subunit expression and function in dentate granule cells of epileptic animals precede the development of epilepsy, suggesting that these changes contribute to the epileptogenic process. In contrast, neonatal SE (postnatal day 10) in rats results in increased GABAR α1 subunit expression and does not lead to the subsequent development of epilepsy.[18]

These studies suggest that GABAR subunit alterations may be critical contributors to epileptogenesis. To determine this more directly, we utilized gene transfer to mitigate GABAR subunit changes and examined the effect on epilepsy development. Specifically, we tested the hypothesis that the expression of higher α1 subunit levels would inhibit development of epilepsy after SE by using an adeno-associated virus (AAV) gene transfer vector (AAV2)-serotype 5 designed to express a bicistronic RNA that codes for both the GABAR α1 subunit and the reporter, enhanced yellow fluorescent protein (eYFP).[19] Expression of this RNA was placed under control of the GABAR α4 subunit gene (*GABRA4*) core promoter region, because it had been previously shown to be markedly activated in dentate gyrus following SE.[20] Thus, following SE, activity of the α4 promoter was upregulated, resulting in enhanced α1 transgene expression. Adeno-associated virus vectors containing either the α1/eYFP fused cDNA (AAV-α1) or the eYFP-reporter only (AAV-eYFP) were injected into dentate gyrus of adult rats, and SE was induced 2 weeks later by intraperitoneal injection of pilocarpine (385 mg/kg).[19] Rats injected with AAV-α1 showed threefold higher levels of α1 subunits in dentate gyrus by 2 weeks after SE compared to the control groups. Rats were continuously video-electroencephalogram (EEG) monitored to determine the latency for the development of spontaneous seizures. Injection of AAV-α1 resulted in a three-fold increase in the mean time to the first spontaneous seizure following SE, and only 39% of AAV-α1-injected rats were observed to develop spontaneous seizures in the first 4 weeks after SE compared to 100% of rats receiving sham injections. Because all groups of rats experienced similar SE after pilocarpine injection, these findings provide the first direct evidence that increasing the levels of a single GABAR subunit in dentate gyrus can inhibit the development of spontaneous seizures after SE. Together, these data support a role for GABAR α-subunit changes in the process of epileptogenesis.

MECHANISMS REGULATING $GABA_A$ RECEPTOR SUBUNIT EXPRESSION

α1 Subunit Regulation

Although viral gene transfer is a promising therapeutic avenue to modify the aberrant

gene expression associated with epileptogenesis, producing the optimal level of expression over a prolonged period can be challenging. Another potential approach is to modify the mechanisms regulating gene expression. Recent work in our laboratories has established cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) and inducible cAMP early repressor[14,21] as transcriptional regulators responsible for decreased GABAR α1 subunit mRNA and protein levels occurring after SE in the dentate gyrus. CREB is a stimulus-induced transcription factor that is activated by phosphorylation at its Ser 133 site. Phosphorylated CREB (pCREB) dimerizes, or forms heterodimers with CREB family members, and binds to cAMP response element (CRE) motifs on promoters that contain the consensus sequence TGACGTCA.[22] Along with the chromatin modifier, CREB binding protein (CBP), pCREB serves as an activator to increase transcription of its target genes. Transcriptional regulation through CREB has been implicated in mechanisms of cell survival, plasticity, and learning and memory.[22] Target genes of pCREB include CREB family members, which consist of cAMP response element modulator (CREM) and activating transcription factor. These paralogs and homologs of CREB also bind CRE elements to modulate the transcription of particular genes, often as heterodimers with CREB. The CREM gene produces many gene products, including truncated forms that are missing the activation domain and, hence, function as transcriptional repressors. A collection of such repressors, produced by the alternative use of an internal promoter region in a downstream intron of CREM, is inducible cAMP early repressor, a group of 4 proteins (α, β, γ, and δ).[23,24] The γ form is most prevalent and acts as a homodimer at the CRE site or heterodimerizes with CREB to directly block CREB-induced transcription.

The human α1 promoter *(GABRA1-p)* contains a functional CRE site,[25] and several studies using adult animal models of epilepsy suggest that seizures increase levels of the activated form of CREB (pCREB) and CREM/inducible cAMP early repressor (ICER) activity.[26,27] Our laboratories have found sustained increases in the levels of both pCREB and ICER in the dentate gyrus of the hippocampus 1–48 h after pilocarpine-induced SE.[14] Using chromatin immunoprecipitation (ChIP) and DNA pulldown studies, it was determined that there was also increased binding of pCREB and ICER to the endogenous *GABRA1-p* in dentate gyrus after SE.[14] Further, results of *GABRA1-p*/luciferase reporter assays in transfected primary hippocampal neurons show that overexpression of CREB and ICER produces robust decreases in *GABRA1-p* activity, and overexpression of ICER alone produces a marked decrease in the levels of endogenous α1 subunits at the cell surface.[21] These findings suggest that CREB and ICER are important regulators of seizure-induced changes in α1 subunit expression.

The excessive neuronal activity associated with SE stimulates many different signaling pathways that could lead to enhanced phosphorylation of CREB and expression of ICER.[28] We focused our studies on brain-derived neurotrophic factor (BDNF) as a potential regulator of ICER because BDNF expression increases markedly after SE[29–33] and because BDNF differentially regulates the abundance of both α1 and α4 subunits in cultured neurons.[32] Our results demonstrated that BDNF treatment of primary hippocampal neurons in culture produces changes in α subunit levels similar to those observed after SE. Twenty-four hours after BDNF treatment, α1 levels decrease 42% and α4 levels increase 120%.[32] We further found that BDNF regulates α1 subunit levels via activation of the Janus kinase (JAK)/signal transducer and activators of transcription (STAT) pathway, which, in turn, controls the synthesis of ICER, which then represses *GABRA1* transcription.

The JAK-STAT pathway can be activated by a variety of methods, including cytokines binding to their specific receptors, resulting in transphosphorylation of JAKs, which then lead to phosphorylation of STAT proteins.[34–38] Phosphorylation of STATs on tyrosine residues leads to STAT homo- or heterodimerization, translocation from the cytoplasm to the nucleus, and binding to specific DNA elements (STAT-recognition sites) to regulate target gene expression.[37,38] There is a STAT-recognition element in the ICER promoter, and using ChIP, we have shown that pSTAT3 association with this site is enhanced after SE in dentate gyrus.[14] Furthermore, siRNA knockdown of STAT3 inhibits BDNF-induced ICER increases, as does blockade of the JAK/STAT signaling pathway with pyridone 6 (P6) in

primary hippocampal cultures.[14] Most importantly, P6 administration in vivo into rat dentate gyrus prior to SE blocks both ICER induction and decreased transcription of *GABRA1*.[14] These findings suggest that the interplay of the CREB, JAK/STAT, and BDNF signaling pathways is critical for the decrease in α1 subunit levels that occurs in response to SE and that these pathways may provide novel therapeutic targets for epilepsy. In fact, several drugs that specifically inhibit the activity of JAK2 or block downstream STAT activation[39–42] have already been identified as potential agents in cancer chemotherapy and are in clinical trials. We are currently testing these agents to determine whether they may also provide alternative therapy for the future prevention or treatment of epilepsy.

α4 Subunit Regulation

GABARs that contain α4 subunits have unique pharmacological properties, such as insensitivity to benzodiazepines and increased sensitivity to zinc blockade.[43] Receptors containing α4 subunits are most often found with the δ rather than the γ subunit in combination with αβ. These α4βδ GABARs are localized to extrasynaptic sites and contribute to tonic inhibition. A minor population of α4βγ2 GABARs are found within dentate gyrus synapses, where they are proposed to affect both the rise time and decay of synaptic currents.[44] In addition to the decrease in α1 subunit expression, there is a marked increase in α4 subunit expression in dentate granule cells during epileptogenesis in TLE models[7–9] that results in an increase in the abundance of α4γ2-containing receptors[9,11,14] and a reduction in α1γ2-containing receptors.[14] The change in receptor subtype from α1βγ2 to α4βγ2 may contribute to epileptogenesis, as α4-containing GABARs have been shown to desensitize rapidly, especially when assembled with β3 subunits.[45] In addition, GABARs containing the α4 subunit are very sensitive to zinc blockade,[43] as are GABARs on dentate granule cells in the epileptic brain.[7]

Our studies have shown that the alteration in α4 levels after pilocarpine-induced SE is transcriptionally mediated via an increase in the expression of the transcription factor early growth response factor 3 (Egr3).[20] Egrs are a family of four proteins (Egr1, 2, 3, and 4) that share nearly identical zinc finger DNA binding domains and bind to a common Egr response element consensus sequence (ERE), GCG T/GGG GCG.[46] Our laboratories have shown induction of Egr family transcription factors after SE, with increases in protein levels of Egr3 and enhanced binding of Egr3 to the promoter of the endogenous α4 subunit gene (*GABRA4*) in the dentate gyrus of the hippocampus 24 h after pilocarpine-induced SE.[20] α_4 Subunit upregulation has also been demonstrated following withdrawal of progesterone-derived neurosteroids, such as allopregnanolone and pregnanolone,[47,48] resulting in enhanced neuronal excitability, seizure susceptibility, and benzodiazepine resistance. This increase in α4 subunit expression is thought to be a potential molecular basis of catamenial epilepsy, a neuroendocrine condition that occurs around the perimenstrual period and is characterized by neurosteroid withdrawal-linked seizure exacerbations in women with epilepsy. Recently, neurosteroid withdrawal-induced α4-subunit upregulation was found to be mediated by Egr3 inhibition, similar to the role played by this transcription factor in upregulating α4 after SE.[49]

Similar to its critical role in decreased expression of α1-containing GABARs, BDNF again is the endogenous signal that induces Egr3 synthesis and overexpression of α4 subunits—now, however, through different signaling pathways, protein kinase C (PKC) and mitogen activated protein kinase (MAPK).[32] In addition to its role in regulation of α1 and α4 subunit gene transcription after SE (for a summary, see Fig. 44–1), BDNF, acting via activation of TrkB receptors, has been shown to play an important role in determining the surface expression of the α2, β2,3 γ2, and δ subunits.[50–52] In combination, these findings establish BDNF's role as a multifunctional regulator of altered inhibition during epileptogenesis.

In addition to changes in α1 and α4 expression, an increase in γ2-subunit and a decrease in δ-subunit surface expression in dentate granule cells, with associated diminished neurosteroid sensitivity of tonic currents, has also been demonstrated in rodent models of TLE.[8,9,53,54] As for the α4 subunit, studies support an important role for the neurosteriods in the regulation of γ- and δ- subunit expression during the ovarian cycle and in pregnancy,[47,48,55,56] although the specific molecular mechanisms regulating

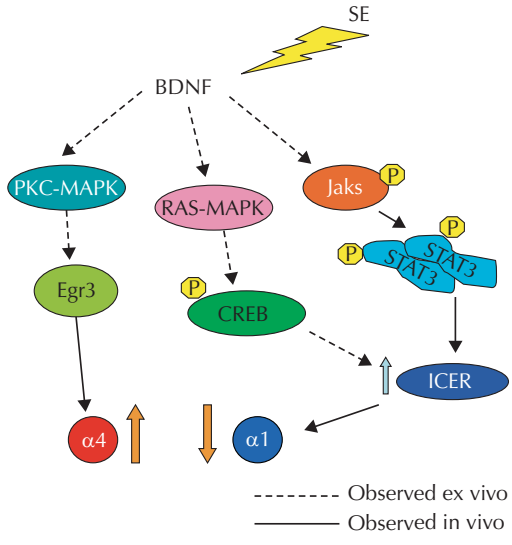

Figure 44–1. Differential expression of $GABA_A$ receptor α_4-subnits nits via BDNF-stimulated signal transduction pathways. Whether a $GABA_A$ receptor has an α1 or α4 subunit in its complex may have dramatic effects on brain inhibition. The results of our research show that BDNF may be responsible for flipping the switch in α subunit expression, with decreased α1 and increased α4, all in response to the activities of one signaling molecule, BDNF. Dramatic increases in the levels of BDNF associated with SE may drive distinct changes in gene expression through activation of at least three pathways: PKC/MAPK, Egr3, and JAK/STAT. Evidence to support this model comes from in vitro, ex vivo, and in vivo studies. From Brooks-Kayal AR, Raol YH, Russek SJ. Alteration of epileptogenesis genes, *Neurotherapeutics.* 2009;6(2):312–318.

changes in expression of these subunits during epileptogenesis remain to be determined.

CONCLUSION

The full range of gene expression changes that are involved in epileptogenesis and the molecular mechanisms that underlie them are just beginning to be characterized. Studies using animal models suggest that modulation in the transcription of a number of these genes via viral-mediated delivery of DNA binding proteins or RNA silencers, or the manipulation of their upstream regulation via selective inhibition of signal transduction pathways, may be useful therapeutic tools for the future treatment of epilepsy.

Recent work characterizing the functions of the BDNF, JAK/STAT, CREB/ICER, and Egr3 signaling pathways in GABAR α1 and α4 subunit changes in the dentate gyrus after SE provides an important lead for the future development of molecular therapies aimed at restoring the balance of excitation and inhibition in the nervous system. However, the upstream components of these pathways, and the exact means through which they confer vulnerability to epilepsy, must be further elucidated. Further, as these pathways regulate myriad genes with diverse functions, modulation of any of these pathways may have a multitude of downstream effects, many of which may involve cell- and region-specific responses throughout the brain. Therefore, the final impact of pathway blockade on epileptogenesis may be difficult to predict. For example, although the enhanced GABAR α1-subunit expression in dentate gyrus that results from JAK/STAT pathway blockade and subsequent ICER inhibition would be expected to have an antiepileptic effect, mutant mice lacking ICER have accelerated kindling[57] and develop more severe epilepsy following pilocarpine-induced SE.[58] Consistent with this finding, ICER-overexpressing mice show retardation of kindling development.[57] Whether the effects of acute and transient blockade of ICER upregulation at the time of SE specifically in the hippocampal formation will have an effect on epileptogenesis similar to that of constitutive under- or overexpression of ICER globally in the brain remains to be determined. Finally, as several of these signaling pathways have been implicated in the regulation of learning, memory, and cell survival, the effects of modulation of these pathways on these critical parameters will need to be closely monitored.

Chapter 45

Chloride Homeostasis and GABA Signaling in Temporal Lobe Epilepsy

Richard Miles
Peter Blaesse
Gilles Huberfeld
Lucia Wittner
Kai Kaila

Defects in GABAergic signaling have often been linked to the epilepsies. Suppressing fast inhibition mediated by gamma-aminobutyric acid A ($GABA_A$) receptors initiates interictal-like activities in healthy brain tissue,[1,2] and specific subgroups of interneurons seem to be especially sensitive to the neuronal death associated with temporal lobe epileptic syndromes.[3–5] However, defects in the neuronal homeostasis of chloride have only recently been linked to epileptiform activities. Intraneuronal levels of chloride control GABAergic signaling postsynaptically.[6] So, changes in chloride homeostasis can affect the strength and even the sign of GABAergic signals. We will describe work on tissue from patients with pharmacoresistant epilepsies of the temporal lobe that provided the first insight that chloride homeostasis might be altered in the epilepsies.[7,8] We will examine molecules that control chloride homeostasis, evidence that they are modulated by pathological stressors including denervation, anoxia and the sclerotic cell death associated with some focal epilepsies. We ask whether changes in chloride homeostasis contribute to ictal events, arguing that potassium efflux mediated by K-Cl cotransporters may contribute to prolonged ictal excitation. Finally, we examine how differences in chloride regulation may contribute to neonatal epilepsies and ask whether molecules targeting chloride homeostasis might be effective anti-epileptic drugs.

HUMAN INTERICTAL ACTIVITY AND CL^- HOMEOSTASIS

The first hint of a link between defects in Cl^- homeostasis and temporal lobe epilepsy (TLE)

emerged in work on slices of tissue from adult patients.[7] The subiculum, downstream from the sclerotic CA1 region, generated spontaneous interictal-like activity (Fig. 45–1). This population synchrony was suppressed by either GABAergic or glutamatergic antagonists, suggesting that both transmitter systems were involved in its expression. Depolarized reversal potentials for isolated GABA-mediated synaptic events in some subicular pyramidal cells suggested that Cl^- homeostasis was altered.

More specific evidence of changes in Cl^- homeostasis in brain tissue from patients with TLE, from in situ hybridization and immunostaining, suggests expression of two cotransporter molecules, NKCC1 and KCC2, may be altered. Expression of the Na-K-2Cl cotransporter, NKCC1,[9] which usually functions to import Cl^-, appears to be increased in epileptic tissue, while expression of the Cl^--extruding K-Cl cotransporter, KCC2,[10] seems to be reduced.[8,11,12] NKCC1 appears to be functional in tissue from adult TLE patients and contributes to the genesis of interictal activity.[8] Earlier work on human epileptic tissue showed some evidence suggestive of changes in Cl^- homeostasis.[13,14] Later results, from slice and animal models of focal epilepsies, confirmed that changes in Cl^- homeostasis can contribute to epileptiform activities by reducing the strength of hyperpolarizing GABAergic signaling, sometimes resulting in depolarizing responses.[15–17]

However, cellular studies in human tissue reveal a situation more complex than a uniform downregulation of KCC2 and upregulation of NKCC1. Firstly, GABA reversal potential (E_{GABA}) differs, suggesting that basal Cl^- homeostasis is not affected similarly in all neurons. Instead, there is a wide variation in driving force for GABAergic inhibition: in most principal cells it remains hyperpolarizing, while GABAergic events depolarize only a minority (~20%) of subicular pyramidal cells (Fig. 45–1). The proportion of cells depolarized during interictal events was similar to that of cells where E_{GABA} was depolarized with respect to resting potential.[8] Secondly, immunostaining reveals no KCC2 signal (Fig. 45-1A) in only a proportion of this minority of cells.[8] Perhaps low levels of KCC2 in some neurons of this interictal network cannot effectively assure hyperpolarizing responses to GABA, possibly KCC2 is expressed but inactivated by posttranscriptional mechanisms, or perhaps other Cl^--regulating molecules are involved.

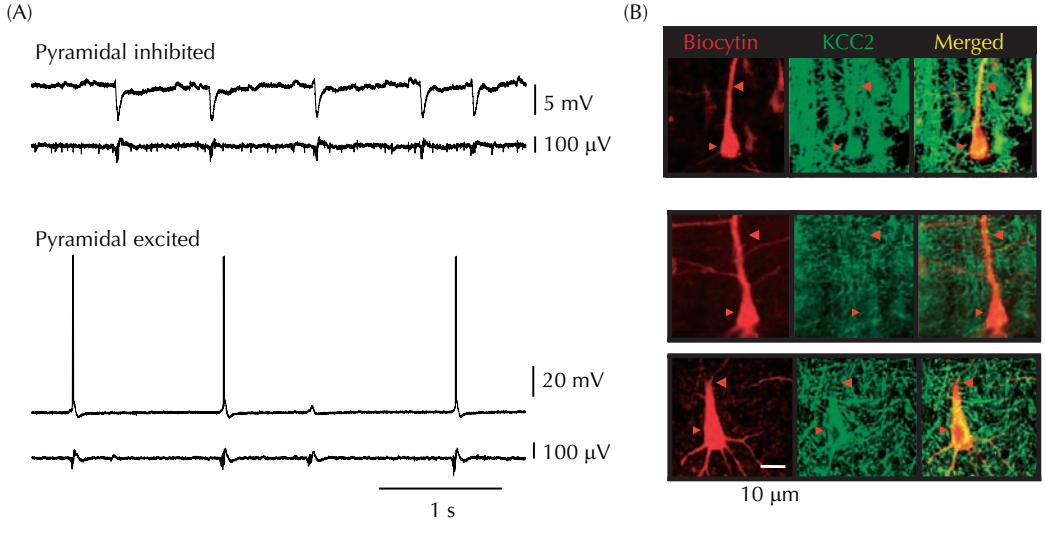

Figure 45–1. Correlation of pyramidal cell behavior during interical discharges with KCC2 expression in the human postoperative subiculum. **A.** Combined intracellular (top trace) and extracellular recordings (bottom trace) of a pyramidal cell inhibited by GABA (≈80%, upper recording) and a pyramidal cell depolarized and excited by GABA (≈20%, lower recording) during interictal events. **B.** Immunostaining for KCC2 (green) in cells identified by biocytin filling (red). All cells hyperpolarized during epileptiform events expressed KCC2 (yellow on merging, top cell). Most cells depolarized during interictal discharges did not express KCC2 (middle cell), but some of them have a clear staining for KCC2 (bottom cell). Modified from refs. 7 and 8.

Thirdly, while changes in Cl^- homeostasis seem to account for the generation of interictal-like activity in the subiculum, distinct mechanisms, possibly involving rearrangements in excitatory synaptic connectivity, may be responsible for a distinct interictal-like activity generated in the CA2 region.[18] Finally mechanisms of the interictal population synchrony remain to be explored. A population activity dependent on both GABAergic and glutamatergic signaling seems at first similar to the giant depolarizing potentials (GDPs) of immature hippocampus,[19] where interneurons may play a permissive role in rhythmogenesis.[20,21] However, interictal events of human epileptic tissue seem to be initiated by inhibitory cell firing,[22] suggesting that some interneurons should induce principal cell firing in the human epileptic subiculum.

GABA AND Cl^- REGULATION SYSTEMS

These data point to a defect in GABAergic signaling due to altered Cl^- homeostasis in some epilepsies. Neuronal Cl^- homeostasis depends in part on cation chloride cotransporters (CCCs). They are glycoproteins with 12 membrane-spanning segments and two cytosolic termini.[23,24] Adult pyramidal neurons are known to express the Na-K-2Cl cotransporter (NKCC1) and the K-Cl cotransporter isoforms, KCC2 and KCC3.[25] The KCC2 isoform is expressed only in central neurons. Alternatively spliced variants may support distinct regulatory mechanisms, via phosphorylation for instance, but their physiological role is unclear. The available evidence suggests that CCCs exist as homodimers in vivo and that dimerization probably plays a role in the regulation of their function.[26–28]

Neuronal CCCs are secondary transporters in that they do not consume adenosine triphosphate (ATP) but rather derive energy for ion transport from gradients established by the sodium-potassium adenosine triphosphatase (Na-K ATPase). Thus, Cl^- extrusion via KCCs is driven by the K^+ gradient, while NKCC1-mediated Cl^- uptake depends on the Na^+ gradient.[29–31] Since KCC2 operates close to its thermodynamic equilibrium, even a small increase in extracellular K^+ will reverse transport, from Cl^- efflux to influx. Even so, activity-dependent increases in internal Cl^- shift the equilibrium so that KCC2 may induce large transient increases in external K^+. Cation chloride cotransporters are electroneutral, with a stoichiometry of 1:1; K:Cl for KCCs and of 1:1:2; Na:K:Cl for NKCC1. Thus, electrophysiological methods cannot directly measure CCC transport. Most work has relied instead on Cl^--permeable channels, such as $GABA_A$ and glycine receptors, to estimate intracellular Cl^-, which has also been measured with specific optical probes.[32–34]

Synaptic events mediated by GABA or glycine have often been used to assess cotransporter function, but two reservations should be noted. First, while the basal inhibitory postsynaptic potential (IPSP) reversal potential is related to cotransporter action, function is better measured by imposing a defined Cl^- load on a neuron and measuring the consequent shift of E_{GABA}.[6,35,36] A second distinct point is that the direction, hyperpolarizing or depolarizing, of postsynaptic potential change provoked by a GABA- or glycine-mediated synaptic event does not completely describe its effects on postsynaptic excitability. The conductance increase due to receptor activation reduces local excitability at the synaptic site whether the membrane is depolarized or hyperpolarized.[37,38]

A differentially, selective pharmacology would facilitate work on the function of these cotransporters. The loop diuretic furosemide blocks both NKCC1 and KCCs with similar potency at millimolar (mM) concentrations, but also affects *N*-methyl-D-aspartate (NMDA) and $GABA_A$ receptors.[39] The diuretic bumetanide has a much higher affinity for NKCC1 than for KCC2, and 1–10 uM provides a selective inhibition.[24] Intracellular Cs^+, sometimes used in pipette solutions to enhance space clamp, is an antagonist of KCC2.[24,40]

NKCC1 and KCC2 seem to be expressed at distinct subcellular neuronal sites. Immunohistochemistry shows significant expression of KCC2 on somatic and dendritic membranes, including spines, but not at axonal sites.[41,42] This localization agrees with point measurements of E_{GABA}.[43–45] KCC2 expression by dendritic spines may contribute to morphogenic functions. KCC2 interacts with the cytoskeleton and may be involved in neuronal maturation[46] and specifically in spine formation.[47] Defining patterns of neuronal NKCC1 expression is difficult

due to the questionable specificity of available antibodies.[25]

Heterogeneous membrane expression of KCC2 and NKCC1, should impose gradients on subcellular Cl^- and so generate differences in basal E_{GABA} at different neuronal sites. Indeed, physiological data suggest that NKCC1-mediated Cl^- import may occur at the axon initial segment of mature neurons. Depolarized reversal potentials have been measured for GABAergic synaptic events induced by axo-axonic cells[43,45] and responses to GABA[44,48] at the axon initial segment. However, E_{GABA} is typically measured from somatic responses to the activation of GABAergic synapses, and axo-axonic inputs may have relatively small influence on this value. Other transporters, including the Cl^-/HCO_3^- exchanger, AE3, may also contribute to control of somatic levels of Cl^-.[44]

The $GABA_A$ receptor is permeable to HCO_3^- as well as Cl^-.[49,50] HCO_3^- carries significant current, which may exceed Cl^- currents in neurons with especially hyperpolarized resting potentials in vitro.[51] The resting membrane potential (V_m) is more positive in hippocampal neurons in vitro, so their E_{GABA} values are less strongly influenced by the HCO_3^- current.[6] Slice preparation may affect internal Cl^- values,[52] and of course, values of E_{GABA} determined for neurons in slices do not provide accurate data on E_{GABA} values in the intact animal, where Cl^- loads may be much higher.

Changes in Cl^--Regulating Systems in Pathological States

Neuronal Cl^- regulation is affected in multiple pathophysiological conditions.[53,54] KCC2 expression is downregulated, leading to a decreased efficacy of inhibition or even to excitatory actions of GABA, in response to kindling,[55] in models of concussion,[56] and by ischemia,[57–59] after axotomy,[60,61] after mechanical isolation of the neocortex,[16] and in nerve section models of chronic spinal pain.[62–64] Such trauma-induced downregulation of KCC2 is often accompanied by upregulation of NKCC1.[8,65]

Thus, the acquired epilepsies[17] may be a particular example of a more general response to brain trauma. Possibly, changes in KCC2 and NKCC1 expression and function participate in epileptogenesis; alternatively, they may be protective or adaptive mechanisms triggered by the trauma. Thus, the downregulation of KCC2 could usefully decrease energy expenditure in pathological states associated with an energy deficit.[25] In a similar way, Na-K ATPase is downregulated by neuronal damage.[66,67] Alternatively, changes in Cl^- homeostasis could contribute to more general processes of neuronal dedifferentiation induced by trauma. They may, for instance, tend to promote rewiring of damaged circuitry for recovery.[7,24]

In these diverse traumatic situations, KCC2 downregulation may be related to activation of the TrkB receptor by brain-derived neurotrophic factor (BDNF).[62] Exogenously applied BDNF was first shown to downregulate KCC2 via TrkB receptors in culture.[55] Work with animals expressing specific point mutations of the TrkB receptor has shown that both the Shc/FRS-2 (src homology 2 domain containing transforming protein/FGF receptor substrate 2) and PLCϒ–CREB (phospholipase Cγ-cyclic adenosine monophosphate response element binding) pathways must be activated to reduce KCC2 transcription. In contrast, the activation of Shc/FRS-2 alone via the TrkB receptor enhances KCC2 synthesis.[36] This observation points to divergent actions of BDNF on neuronal Cl^- regulation. It could explain how BDNF exerts opposing actions on KCC2 synthesis in mature and immature or in intact and damaged neurons.[65] The source of the BDNF involved in the different forms of trauma is not always clear. It is secreted by various types of neurons.[68] More likely however, may be that the BDNF involved in responses to deafferentation is liberated by activated microglia. In a nerve section model of spinal neuropathic pain, microglia migrate to sites of damage and liberate BDNF, thus altering Cl^- homeostasis via TrkB receptors.[62,63]

In these studies, traumatic stimuli reduce KCC2 transcription and thus the total cellular pool of the transporter, typically measured by immunoblots of the protein. However, KCC2 function depends on the fraction of cellular protein present in the cell membrane rather than on the total protein pool. Thus, as for other transporters, changes in membrane trafficking contribute crucially to KCC2 function.[69,70] Cotransporter function might also be modulated by changes in the intrinsic ion

transport rate, but details of whether and how this parameter is modulated are not yet clear.

NKCC1 and KCC2 function is also regulated by phosphorylation. For instance, the kinases WNK (with no lysine (K) kinase) and SPAK (Ste20p-related proline alanine-rich kinase)/OSR1 (oxidative-stress-responsive kinase 1) both activate NKCC1 and inhibit KCC2.[71–73] The phosphorylation state of KCC2 is changed by trauma, oxidative stress, or epilepsy.[69,74] It affects trafficking, including degradation,[69,70,74] and may alter the rate of cotransport by KCC2.[74] Early work stressed a reciprocal regulation in which phosphorylation activates NKCC1 and inhibits KCCs, while dephosphorylation inhibits NKCC1 and activates KCCs.[75] However, more recent work has shown that phosphorylation at different sites of the KCC2 molecule may exert opposing functional effects.[69,70]

Both short- and relatively long-term changes in transporter function can be explained by changes in membrane expression or cotransport rate due to phosphorylation state or by changes in expression due to altered transcription. But transporter function may be persistently altered over months and years after traumatic injuries and in the epilepsies.[7,8] One possible explanation is that of a maintained stimulus due perhaps to chronic inflammation. Maintained neuropathic pain is associated with the persistent release of pro-inflammatory cytokines and chemokines from glial cells.[76] Pro-inflammatory molecules are also involved in the pathogenesis of epilepsy and are present in the chronically epileptic brain.[77] Cells of the blood-brain barrier, whose permeability increases after a seizure, are targets for cytokine signaling.[78] Thus, inflammatory mechanisms may contribute to the evolution of chronic epilepsy.[79] Possibly pro-inflammatory molecules control, directly or indirectly, neuronal cotransporter function.

Cl^- HOMEOSTASIS AND ICTAL ACTIVITIES

Mechanisms of initiation of ictal events in focal epilepsies are not well understood. The human condition is quite well modeled by chronic animal models such as pilocarpine or kainate treatment.[80] They exhibit a similar pattern of sclerotic hippocampal cell death and show a delay between the initial convulsion and the emergence of recurring seizures. However, chronic epilepsy models have so far provided few insights into mechanisms of ictogenesis. Instead, most concepts derive from work on slices from healthy animals exposed to convulsants.[81–83]

Recent work on the genesis of epileptiform activities has emphasized a glial contribution,[84–86] and glial control of external levels of both potassium and glutamate may be compromised in an epileptic brain.[78,87] However, synaptic mechanisms involving both glutamatergic and GABAergic signaling certainly contribute to ictal discharges. Indeed, convulsants activate interneurons particularly strongly,[88,89] and ictal events are suppressed by agents, such as opiate receptor agonists, that selectively reduce interneuron activity.[81]

The chloride flux due to high-frequency activation of inhibitory synapses engages Cl^- homeostatic mechanisms. The cotransporters KCC2 and NKCC1 may then contribute to, and even favor, seizures. If Cl^- extrusion mechanisms cannot maintain low levels of intracellular chloride,[48,90,91] synaptic signals mediated by inhibitory cell firing may change from hyperpolarizing to depolarizing. Such a dynamic switch should enhance and prolong an ictal event. Furthermore, even if the polarity of GABAergic events is reversed, the KCC2 transporter continues to export not only Cl^- but also K^+ ions.[92] The strong activation of $GABA_A$ receptors during an ictal event leads to a large electrogenic uptake of Cl driven by the depolarizing HCO_3^- current (Fig. 45–2). The resulting surge in external K^+[93] adds to that due to massive neuronal firing. It increases neuronal excitability at both somatodendritic and axonal sites, with a consequent increase in antidromic firing.[94,95] The water influx into cells tends to reduce extracellular volume, enhances ephaptic neuronal interactions, and increases local concentrations of glutamate and K^+.[96]

A seizure-promoting action of KCC2 due to an increase in external K^+ is also consistent with the anti-convulsant actions of carbonic anhydrase (CA) inhibitors. Intracellular CA activity is needed to replenish the HCO_3^- and drive further Cl^- uptake.[50,93] A KCC2-mediated extracellular K^+ transient may also partly explain the anti-convulsant actions of furosemide.[97,98] However, elevated extracellular K^+[75] reverses

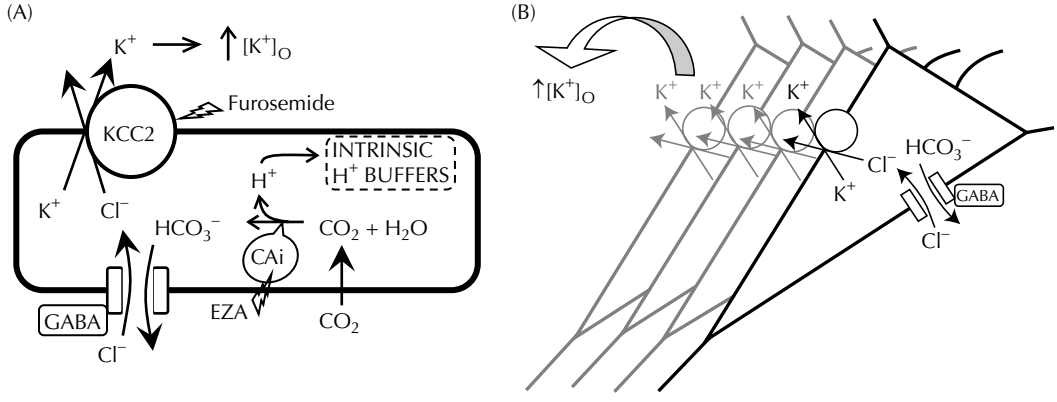

Figure 45–2. KCC2 in the generation of seizure-promoting $[K^+]_o$ transients. **A.** HCO_3^- efflux via a $GABA_A$ receptor channel causes depolarization of the membrane potential that drives a conductive uptake of Cl^-, and net hydration of CO_2 catalyzed by cytosolic carbonic anhydrase (CA) replenishes HCO_3^- during its efflux.[50] H^+ ions are produced at the same rate as HCO_3^- ions and bound by intrinsic cytosolic buffers, which is essential in the maintenance of the HCO_3^- electrochemical gradient during prolonged $GABA_A$ receptor activation. The HCO_3^--dependent intraneuronal accumulation of Cl^- drives K-Cl cotransport by KCC2, thereby giving rise to a net efflux of K^+. **B.** During intense activation of $GABA_A$ receptors in a population of neurons, the KCC2-mediated net efflux of K^+ can be large enough to lead to a large increase $[K^+]_o$, which is a characteristic feature of seizure activity. Note that the chain of events depicted in **A** can be blocked by furosemide or by membrane-permeable inhibitors of intracellular CA (CAi), such as ethoxyzolamide, both of which are known to exert anti-convulsant actions. Modified from ref. 93.

KCC2 cotransport of K^+ and Cl^-[99], so the surge in external K^+ should be self-limiting.

Cl^- REGULATION AND EPILEPTIFORM ACTIVITIES IN THE YOUNG

In contrast to the adult brain, seizure activity in neonatal rat hippocampus upregulates KCC2 activity via activation of TrkB receptors.[100] Interestingly, TrkB may also trigger events that enhance KCC2 expression in the normal neonate, initiating the hyperpolarizing shift of E_{GABA} during development.[101] In the neonate, BDNF-TrkB signaling induces an increase in membrane $GABA_A$ receptors, but it initiates a decrease in more mature neurons.[102] TrkB activation then synergistically enhances both the voltage and conductance effects of GABAergic inhibition in immature neurons but has opposite effects in the mature brain, possibly due to the activation of different signaling pathways.

In the adult, activity-dependent acidosis may be a key factor in seizure termination.[103] In contrast, neonatal seizures may be terminated in part by a seizure-induced increase in the efficacy of GABAergic inhibition.[100] We note that CA is not expressed by neonatal pyramidal neurons.[104] In its absence, transport mediated by KCC2 after strong GABAergic activity during a seizure should not produce a pro-convulsant increase in extracellular K^+. NKCC1 may play a key role in loading neonatal pyramidal cells with Cl^-, since the antagonist bumetanide seems to suppress neonatal seizures[105] and also reduces the resistance to pro-GABAergic drugs that occurs due to Cl accumulation during recurring ictal-like events in slices.[52]

MOLECULES REGULATING Cl^- HOMEOSTASIS AS TARGETS FOR ANTI-EPILEPTIC DRUGS

There is a strong need for new drug targets in TLE[106,107] Might pathways controlling Cl^-homeostasis be a useful target?

A compromised control of intracellular Cl may contribute to interictal rhythmogenesis. However, as we have discussed, residual cotransporter activity should tend to elevate extracellular K^+ in response to repetitive activation of inhibitory synapses and so contribute to the prolonged depolarization underlying an ictal event. Anti-epileptic drugs need to counter ictal rather than interictal events. Nevertheless, there has been interest in the diuretic molecule

bumetanide,[108] which can be used to block the Cl-importing cotransporter, NKCC1, without affecting the exporting transporter, KCC2.

Bumetanide should tend to shift the driving force for GABAergic actions in a hyperpolarizing direction. This action suffices to suppress interictal-like activity in slices of adult human epileptic tissue.[8] Similar results have been reported in different models of neonatal epilepsies.[52,109,110] However, bumetanide is reported not to have anti-ictal effects in chronically epileptic animals[111] and in some neonatal slice models.[111,112]

It has been suggested that compounds that selectively enhance KCC2 actions should increase the efficacy of postsynaptic inhibition and thereby act as anticonvulsant drugs.[108] Paradoxically, however, the role of KCC2 in promoting ictal discharges (Fig. 45–2) suggests that the opposite may be true. Indeed, furosemide, which inhibits both KCC2 and NKCC1, has anti-epileptic actions in focal cortical epilepsies,[97,98] although the high doses needed to block KCC2[93] probably preclude the use of this molecule as an anti-convulsant.

Proteins that regulate the expression, trafficking, and activity of the CCCs may offer alternative targets for anti-convulsant drugs. In practice, however, the importance of cotransporter function in regulating electrolyte balance and cell volume throughout the body implies that some means of targeting such molecules to neurons, or perhaps subsets of neurons, will also be needed

Chapter 46

Astrocytes and Epilepsy

Jerome Clasadonte
Philip G. Haydon

Glia, Greek for "glue," was discovered by Rudolph Virchow, a German anatomist, in the mid-nineteenth century. The name reflects the original view that glia played merely a structural or metabolic support role for neurons. Glial cells, especially astrocytes, are much more than glue or merely quiescent and display their own set of activities. Studies over the last 20 years show that astrocytes perform a series of complex functions that go well beyond the uptake and recycling of neurotransmitters and the buffering of extracellular potassium.[1,2]

Morphologically, astrocytes are characterized by a highly ramified structure of thin processes with which they contact neurons, blood vessels, and other astrocytes. Astrocyte-astrocyte contacts mediate gap-junction coupling between adjacent glial cells to form a cellular network called *astrocytic syncytium*.[3] Although astrocytes form a highly interconnected network, they are structurally organized in nonoverlapping spatial domains with limited interdigitation of processes between adjacent cells.[4,5] Within its own domain of occupancy, each astrocyte can contact tens of thousands of synapses and hundreds of dendrites[4,5] (Fig. 46–1A). The contact between the astrocyte and the neuron is a highly dynamic structure,[6,7] and the extent of astrocytic coverage of the neuronal terminals is activity-dependent.[8]

While astrocytes have been considered nonexcitable cells, because unlike neurons they do not fire action potentials,[9] they display a form of excitability that is based on variations of the intracellular Ca^{2+} concentration.[10] Astrocytes express a plethora of receptors for

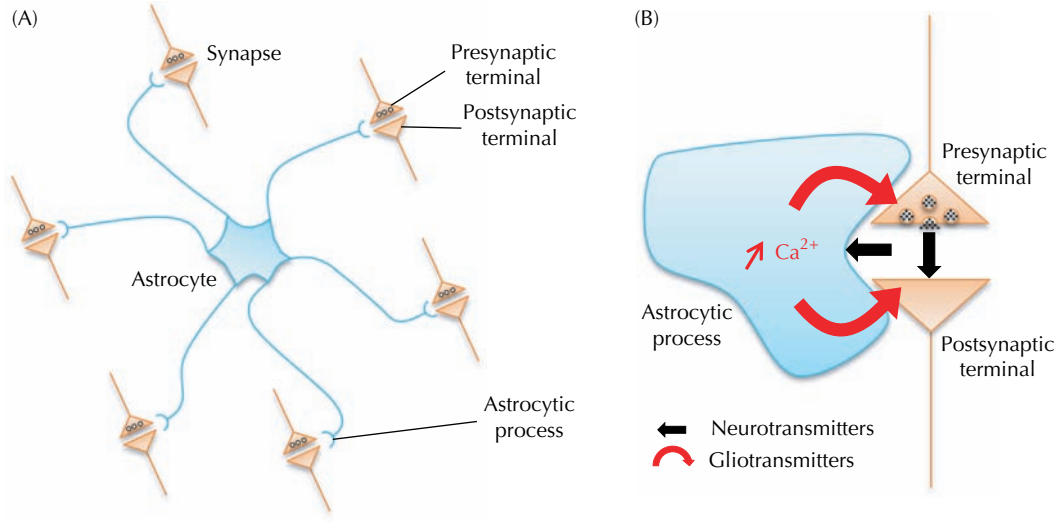

Figure 46–1. The tripartite synapse. **A.** A single astrocyte sends out processes that enwrap a number of synapses. One synapse results from the association between the pre- and postsynaptic terminals. **B.** At the synapse, neurotransmitters released from the presynaptic terminal activate an astrocyte, which responds with Ca^{2+} elevations. In turn, Ca^{2+} elevations lead to the release of neuroactive substances called *gliotransmitters.* which act to the synapse to regulate the presynaptic function and modulate the postsynaptic response.

neurotransmitters whose activation leads to increases in intracellular Ca^{2+} concentration that can propagate to neighboring astrocytes as an intercellular Ca^{2+} wave.[10–12] These Ca^{2+} increases promote the release of neuroactive substances, the so-called *gliotransmitters* (Fig. 46–1B). These gliotransmitters can control diverse brain processes, such as vasculature tone[13] and neuronal activity,[1,2] and can also modulate mammalian behavior such as sleep.[1,2]

In keeping with the currently accepted concept that astrocytes form an integral and active part of excitatory and inhibitory synaptic transmission and communicate back to synapses,[14] emerging evidence has suggested a critical role for these glial cells in the pathogenesis of neurological disorders such as epilepsy.[15–17] Astrocytes become reactive in the epileptic brain and show changes in the expression of metabolic enzymes such as glutamine synthetase and adenosine kinase leading to modification of neuronal excitability. Astrocytes also release glutamate through a Ca^{2+}-dependent mechanism that can synchronize neuronal firing and modulate neuronal excitability and synaptic transmission. In this chapter, we will focus on current lines of evidence suggesting the involvement of reactive astrocytes and gliotransmission in experimental studies of epilepsy, and possible underlying mechanisms.

CA^{2+} SIGNALS IN ASTROCYTES

In Vitro and In Situ Studies

The development of video imaging techniques and fluorescent indicators of Ca^{2+} has allowed us to observe dynamic spatiotemporal changes in Ca^{2+} concentration[18] in neurons and glial cells simultaneously. Unlike neurons, astrocytes do not produce action potentials, and thus they were thought to be quiescent. However, in the early 1990s, initial cell culture studies reported that the excitatory neurotransmitter glutamate elicited Ca^{2+} elevations in individual astrocytes that can propagate to neighboring astrocytes as an intercellular Ca^{2+} wave involving dozen of cells, suggesting long-distance communication between these cells.[10–12] Further evidence for neuronal activity-dependent Ca^{2+} elevations in astrocytes comes from studies showing that the stimulation of Schaffer collateral in hippocampal slices preparation also increases the intracellular Ca^{2+} concentration in these glials cells.[19]

The synaptic control of astrocytic Ca^{2+} signals is due to the fact that astrocytes express a wide range of functional receptors for different neurotransmitters.[20] Many of these receptors are of the metabotropic type, such as metabotropic glutamate receptor 5 (mGluR5) and metabotropic receptor activated by purines such as P_2Y_1. These receptors are associated with G proteins that, upon activation, stimulate phospholipase C and formation of diacylglycerol and inositol (1,4,5)-triphosphate (IP_3). In turn, IP_3 increases the intracellular concentration of Ca^{2+} through the release of Ca^{2+} from intracellular IP_3-sensitive Ca^{2+} stores.[21] Subsequently, several lines of evidence coming from brain slice preparations demonstrated that excitatory neuronal activity can trigger Ca^{2+} elevations in astrocytes.[21]

In Vivo Studies

Recent studies using two-photon microscopy[22,23] and specific fluorescent dyes that selectively label astrocytes[24] convincingly demonstrate that neuronal activity can trigger Ca^{2+} signals in astrocytes in vivo. Using these two revolutionary techniques, Hirase et al.[25] were the first to analyze changes in Ca^{2+} signals in cortical astrocytes from living anesthetized rat. More than 60% of the imaged astrocytes showed a complex pattern of changes in intracellular Ca^{2+} concentration. However, these changes occurred with relatively low frequency under basal conditions and showed a limited degree of correlation with nearby astrocytes.

The first evidence that astrocytes respond to neuronal activity by increasing their intracellular Ca^{2+} concentration in vivo was the observation that the application of gamma-aminobutyric acid A ($GABA_A$) receptor antagonists such as bicuculline[25] or picrotoxin,[26] which increase neuronal activity by triggering epileptic-like discharges, resulted in an increase in Ca^{2+} signaling in cortical astrocytes. Additionally, these Ca^{2+} signals were correlated between pairs of nearby astrocytes,[25] suggesting that in vivo neuronal activity leads to synchronous Ca^{2+} signals in multiple astrocytes. Subsequently, sensory stimulation was shown to increase Ca^{2+} signals in astrocytes in anesthetized animals. In the mouse, whisker,[27] limb,[28] and odor stimulation[29] causes Ca^{2+} elevations in astrocytes in the whisker barrel, the primary somatosensory cortex, and the olfactory bulb, respectively. Generally, these Ca^{2+} increases in astrocytes were delayed by a few seconds compared with the neuronal responses[27,30] and were significantly correlated with the strength of the sensory stimulation.[27] Moreover, a study in ferrets[30] demonstrates that visual stimulation can also induce Ca^{2+} signals in astrocytes in the visual cortex. Interestingly, this study found that astrocytes were even more sharply tuned for stimulus orientation and frequency than neurons.

More recently, neuronal activity in awake, behaving mice was shown to correlate with Ca^{2+} elevations in astrocytes. Two-photon microscopy through a cranial window of an awake, head-restrained mouse allowed to run on a Styrofoam ball was used to visualize Ca^{2+} signals in cortical neurons and astrocytes.[31] Repetitive Ca^{2+} signals were associated with the running behavior and were temporally correlated in multiple astrocytes over a distance of almost 100 μm.[31] Similar studies were performed in the cerebellum, where radial Bergmann glia signals were found to correlate with locomotor behavior and were sensitive to blockade of neuronal activity.[32] Interestingly, in these studies, Nimmerjahn et al.[32] described three different forms of Ca^{2+} signals; one of them was initiated during locomotor behavior and correlated with changes in blood perfusion, suggesting that these glia networks modulate macroscopic changes in brain dynamics and blood flow.[32]

In vivo pharmacological studies have been performed to elucidate the mechanisms underlying activity-mediated Ca^{2+} signals in astrocytes. In vivo application of the mGluR1 or mGluR5 antagonists LY367385 or 6-methyl-2-(phenylethynyl)-pyridine (MPEP), respectively, reduced the whisker activity-induced Ca^{2+} elevations in astrocytes, while the application of the ionotropic alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)/kainate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) had no effect on the astrocytic Ca^{2+} response,[27] indicating a role for both mGluR1and mGluR5 but not for ionotropic receptors in astrocyte activation. Additionally, another in vivo study has shown that application of the astrocytic glutamate transporter inhibitor DL-threo-β-benzyloxyaspartate (TBOA) reduced Ca^{2+} elevations in astrocytes induced by visual stimulation,[30] suggesting a role for

glutamate transporters in the modulation of Ca^{2+} signals in astrocytes.

Together, these in vivo results demonstrate that, in response to sensory stimulations, astrocytes exhibit complex and extremely finely tuned intracellular Ca^{2+} signals generated by the synaptic release of glutamate that activates mGluRs and glutamate transporters at the astrocytic surface. More importantly, recent studies suggest that these astrocytic Ca^{2+} signals are important for the regulation of the arteriole diameter,[33–40] the modulation of the hemodynamic response that generates the intrinsic optical signal,[30] and the control of blood flow associated with motor behavior.[32] While astrocytic Ca^{2+} signals appear to play important physiological roles, as evidenced by the aforementioned studies, they also are activated by pathological neuronal activities, such as during epileptiform discharges,[25,26] and might participate in seizure generation and maintenance, as described later in this chapter.

ASTROCYTES RELEASE CHEMICAL TRANSMITTERS TO MODULATE NEURONAL AND SYNAPTIC FUNCTIONS

The functional consequence of the astrocytic Ca^{2+} signals is the release of gliotransmitters that have been shown to modulate neuronal and synaptic functions[1,2,41] (Fig. 46–1B). Several of these gliotransmitters, such as glutamate, adenosine triphosphate (ATP), adenosine, and D-serine, are released in a Ca^{2+}-dependent manner[21,42] through vesicle[43–46] and lysosome exocytosis.[47–49] Astrocytes in culture express the soluble *N*-ethylmaleimide-sensitive fusion protein receptor (SNARE) complex,[43,50–52] which is colocalized with small vesicles positive for vesicular glutamate transporters,[43,50–52] ATP-storing vesicles,[49,53] and D-serine-containing vesicles.[54] Furthermore, ultrastructural studies in situ have shown that astrocytic processes contain small synaptic-like vesicles with a diameter of 30 nm, which are located in close proximity to synapses.[43,44] While Ca^{2+}-dependent exocytosis represents the better-characterized pathways of astrocytic release of glutamate, ATP, adenosine, and D-serine, alternative release mechanisms have also been proposed. These mechanisms include reversal of glutamate transporters, connexin/pannexin hemichannels, pore-forming P_2X_7 receptors, and swelling-induced activation of volume-regulated anion channels.[55]

In accordance with the concept of the *tripartite synapse* (Fig. 46–1A,B), in which astrocytes are considered to be functionally associated with the pre- and postsynaptic nerve terminals as a third signaling element at the synapse,[56] it is now well accepted that astrocytes not only respond to neuronal activity but also regulate neuronal excitability, synaptic transmission, and behavior by releasing gliotransmitters.[1,2,14] The mechanisms and consequences of this bidirectional communication between neurons and astrocytes are grouped in a process called *gliotransmission*.[2] The better-characterized gliotransmitters involved in gliotransmission are discussed below.

Release of Glutamate

Glutamate, one of the first gliotransmitters released from astrocytes to be identified, has been reported to exert many effects on synaptic transmission and neuronal excitability. Several studies have shown that glutamate release from astrocytes through a Ca^{2+}-dependent mechanism activated receptors located at the presynaptic terminals. Through activation of mGluR1[57,58] or *N*-methyl-D-aspartate (NMDA) receptors,[44] astrocytes enhance the frequency of spontaneous and evoked excitatory synaptic currents. Additionally, astrocytic glutamate induces the depression or potentiation[59] of inhibitory synaptic transmission by activation of presynaptic mGluR2/3[60] or kainate receptors,[61] respectively. Moreover, it has been shown that Ca^{2+}-dependent glutamate release from astrocytes at single hippocampal synapses participated in the generation of long-term potentiation (LTP) through the activation of the presynaptic mGluR1.[58] Thus, all of these studies indicate that Ca^{2+}-dependent release of glutamate from astrocytes modulates synaptic strength and plasticity.

Furthermore, various studies have shown that glutamate release from astrocytes activates postsynaptic NMDA receptors to generate slow inward currents (SICs).[62] The observation that spontaneous Ca^{2+} spikes in astrocytes correlates in thalamic neurons with the detection of SICs suggests that these spontaneous

Ca^{2+} signals mediate the release of glutamate from astrocytes to modulate neuronal excitability. Following this observation, multiple experiments performed to determine the nature of these SICs have shown that different protocols used to induce Ca^{2+} signals in astrocytes also increased the occurrence of the SICs.[2,41] For example, ligands that induce astrocytic Ca^{2+} signals,[63–68] photolysis of caged Ca^{2+} that has been selectively loaded into astrocytes,[64,69] single-astrocyte depolarization,[70] and electrical stimulation of excitatory presynaptic terminals[64,69] all resulted in Ca^{2+} elevations in astrocytes and occurrence of SICs in nearby neurons. Additionally, SICs have been described in different brain regions[71] such as the thalamus, the cortex, the hippocampus, the nucleus accumbens, the olfactory bulb, and, more recently, the brainstem.[72] Typically, SICs are mediated by the activation of a specific group of extrasynaptic NMDA receptors containing the NR2B subunit since they are inhibited by ifenprodil, a selective antagonist of NR2B-NMDA receptors.[64] Furthermore, SICs are insensitive to tetrodotoxin (TTX) and tetanus neurotoxin (TeNT), two substances that block the generation of action potential and the synaptic release of neurotransmitters, respectively,[64] confirming their nonneuronal origin. A recent study also demonstrated that the generation of SICs depends on the duration and kinetics of the Ca^{2+} signals in astrocytes,[68] although Fiacco et al.[73] suggested an alternative interpretation. More importantly, when SICs reach sufficient amplitude, they can trigger burst of action potentials that occur with a high degree of synchronicity in hippocampal pyramidal neurons over short distances of 100 μm.[63,64] Thus, glutamatergic gliotransmission increases neuronal excitability and operates as a nonsynaptic mechanism for neuronal synchronization. This form of communication between neurons and astrocytes could represent a significant source of excitation during epileptic discharges, as discussed later in this chapter.

Release of D-Serine

The presence of serine racemase, an enzyme required for the conversion of L- to D-serine, in astrocytes has led to the idea that the amino acid might be a significant player in the regulation of the NMDA receptors by acting as the natural substrate for glycine binding sites on the receptor.[74,75] D-Serine-containing vesicles are released from astrocytes in a Ca^{2+}-dependent manner and act as a coagonist of the NMDA receptor.[54] In the supraoptic nucleus of the hypothalamus, the dynamic astrocytic coverage of synapses dependent on physiological signals influences extracellular levels of astrocytic D-serine and consequently leads to a certain form of metaplasticity.[76] For example, the high degree of synaptic coverage by astrocytes seen in virgin rodents induces LTP, whereas the reduced astrocytic coverage of synapses that occurs during lactation induces long-term depression.[76] More recent work has addressed the role of D-serine release in NMDA receptor-dependent LTP in the Schaffer collateral-CA1 synapses.[77] In this work, the selective inhibition of serine racemase in one astrocyte suppressed local LTP induction, demonstrating that one astrocyte is the direct source of D-serine in the hippocampus and can modulate synaptic input plasticity on nearby neurons.

Release of ATP

The release of ATP from astrocytes has been known for a long time and was initially proposed as a mechanism for the propagation of intercellular Ca^{2+} waves through the astrocytic syncytium.[3,11,78] First, ATP is released from astrocytes during Ca^{2+} wave propagation.[11,79] Second, the propagation can be abolished by antagonists of purinergic P_2Y receptors[11,79–81] or the ATP-degrading enzyme apyrase.[11,81] Third, visualization of the release of ATP demonstrates that its velocity correlates with that of the Ca^{2+} wave in astrocytes.[81] These results suggest that ATP could be an extracellular messenger and a primary signal for the Ca^{2+} wave propagation. While mechanisms of glutamate and D-serine release from astrocytes are experimentally well described, the mechanisms underlying the release of ATP from astrocytes are less well understood. The release of ATP is reduced by inhibitors of several anion channels,[82,83] gap junctions, hemichannels,[78,84,85] and pore-forming P_2X_7 receptors,[86] suggesting the involvement of different pathways in the release. Additionally, ATP release from astrocytes is partly Ca^{2+}- and SNARE proteins-dependent.[84,87] Further, astrocytes also display vesicles that contain

ATP, and vesicular adenosine triphosphatase (ATPase) inhibitors block the release of ATP.[53,87] More importantly, Pascual et al.[88] generated inducible transgenic mice that express a dominant-negative SNARE (dnSNARE) domain of vesicle-associated membrane protein 2 (VAMP2) selectively in astrocytes to suppress the exocytotic release of chemical transmitters from astrocytes. Interestingly, using these transgenic astrocyte-specific dnSNARE mice, it was shown that astrocytes regulate the activation of neuronal A1 receptors that are responsible for presynaptic inhibition of excitatory synaptic transmission in the hippocampus and cortex.[88–90] Bioluminescence imaging demonstrated that this molecular genetic manipulation led to reduced extracellular ATP, and pharmacological evidence was consistent with the notion that astrocyte-derived extracellular ATP is hydrolyzed to adenosine to cause a tonic suppression of synaptic transmission.[88] The mechanism of release of these purines has not been investigated further. The recent discovery of Sawada et al.[91] demonstrated that a novel member of an anion transporter family functioning as a vesicular nucleotide transporter was highly expressed in astrocytes. Together these findings raise the possibility that astrocytes release ATP by exocytosis. However, before such a conclusion is drawn, considerable additional studies will be required.

Once ATP is released from astrocytes, it can exert physiological effects modulating neuronal excitability. For example, in hypothalamic slices, astrocytes express α-1 adrenergic receptors, and in response to adrenergic input they release ATP, which acts on P_2X_7 receptors localized on nearby magnocellular neurosecretory cells (MNCs). As a result, there is an enhancement of AMPA receptor surface expression and an increase in the amplitude of miniature excitatory postsynaptic current in these cells.[92] More recent studies have confirmed postsynaptic effects of ATP on MNCs. Using combined two-photon Ca^{2+} imaging, photolysis of caged compounds, and electrophysiology, it has been shown that there is a mGluR1-dependent Ca^{2+} increase in astrocytes along with ATP release resulting in an increase in the amplitude of miniature excitatory postsynaptic currents of MNCs through the activation of postsynaptic P_2X_7 receptors.[93] Additionally, another study by Zhang et al.[94] in hippocampal cultures has shown that the release of ATP from stimulated astrocytes was able to depress glutamatergic neuronal transmission through the direct activation of P_2Y receptors. Interestingly, using hippocampal slices, Zhang et al.[94] also stated that the glutamatergic synaptic depression was due to the ATP metabolite adenosine, which acted on the A1 adenosine receptors. Altogether, these results suggest that ATP release from astrocytes can modulate neuronal excitability and synaptic transmission through direct and indirect actions. The indirect action of astrocytic ATP requires its conversion to adenosine, a metabolite known to have multiple effects on neuronal and synaptic functions, as described below.

Adenosine Derived from Astrocyte-Released ATP

Once ATP is released into the extracellular space, a variety of ectonucleotidases hydrolyze ATP to AMP and then a 5′-nucleotidase converts AMP to adenosine,[95] which is known to be a powerful modulator of synaptic activity via its actions on the G-protein-coupled adenosine receptor subtypes (A1, A2, and A3).[96] In the retina, adenosine derived from astrocyte-released ATP can activate A1 receptors coupled to K^+ channels, which hyperpolarize neurons and decrease their excitability.[97] In the hippocampus, the adenosine thus produced results in presynaptic inhibition of excitatory synaptic transmission mediated by the activation of A1 receptors.[88,94,98] Moreover, chelating Ca^{2+} in astrocytic syncytium and the use of glia-specific toxins interfere with the A1-dependent synaptic depression, confirming the glial origin of this process.[98] In addition to the mechanisms described above, astrocytes can directly release adenosine, especially in response to hypoxic stimulation,[99,100] even though release of adenosine is more typical of neurons.[101] In that case, the release of adenosine from astrocytes depends on export of adenosine through the equilibrative nucleoside transporters.

Recent work using dnSNARE animals has shown that astrocytic adenosine is important for sleep homeostasis by participating in the accumulation of sleep pressure and contributing to cognitive deficits associated with sleep loss.[90] Moreover, another study has shown that the dnSNARE animals displayed a 50%

reduction in surface expression of NMDA receptors, resulting in a decrease in cortical slow oscillations.[89] Thus, these studies identify astrocytes as a major regulator of the activation of neuronal A1 receptors, and thus presumably as a source of adenosine in the brain, and suggest that purinergic gliotransmission plays an important role in synaptic transmission, plasticity, and behavior.

REACTIVE ASTROCYTOSIS AND EPILEPSY

Reactive changes in astrocytes are frequently encountered in the hippocampus in association with temporal lobe epilepsy (TLE) in humans[102] and with animal models of epilepsy.[103,104] These reactive changes, termed *reactive astrocytosis*, generally involve increases in astrocyte size and number[103,104] and often occur together with neuronal loss and synaptic rearrangements.[103,105] Reactive astrocytes exhibit increased expression of glial cytoskeletal proteins, glial fibrillary acidic protein (GFAP), and vimentin, which are therefore used to assess the development of reactive astrocytosis.[106,107] Interestingly, recent studies have shown that reactive astrocytosis was also accompanied by a loss of astrocytic domain organization[108] and the generation of new astrocytes from stem cells.[109] More importantly, in addition to morphological changes, many proteins are up- or downregulated in reactive astrocytes, leading to changes in cellular functions.[17] Whether these functional changes modify seizure susceptibility is an intriguing notion receiving increased attention. In the following sections, we discuss recent evidence suggesting that changes in expression of two astrocyte-specific enzymes, glutamine synthetase (GS) and adenosine kinase (ADK), could promote seizures in the epileptic brain.

Reactive Astrocytosis and GS Downregulation in Epilepsy

In the brain, GS is expressed almost exclusively by astrocytes[110] and is responsible for the conversion of synaptically released glutamate into glutamine after the neurotransmitter is taken up by transporters into the synaptically associated glia[111] (Fig. 46–2). This glutamate-glutamine cycle normally serves as a major mechanism for ammonia detoxification in the brain and also as a buffered reservoir of a precursor (glutamine) for glutamate and GABA synthesis[112] (Fig. 46–2).

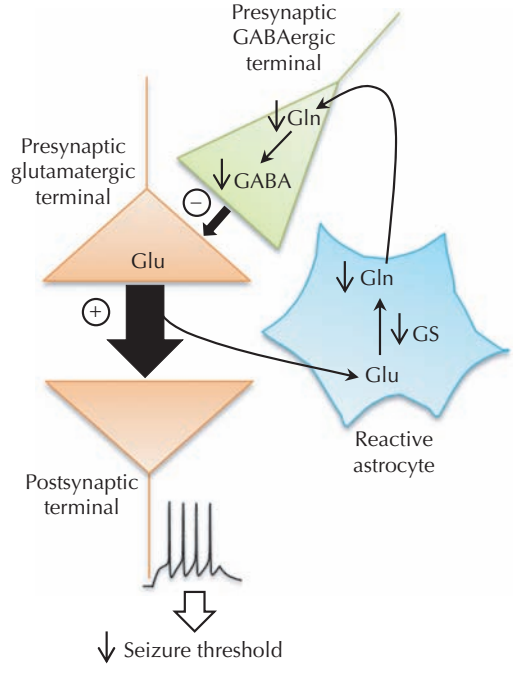

Figure 46–2. The activity change of glutamine synthetase (GS) in reactive astrocytes contributes to seizure development. Glutamate (Glu) released at the excitatory synapse is converted into glutamine (Gln) through activity of GS in astrocytes. Glutamine is used as a precursor for synthesis of GABA in GABAergic neurons. The loss of GS in reactive astrocytes leads to a decrease in Gln and GABA levels in GABAergic terminals. Consequently, presynaptic GABAergic inhibition is reduced, increasing presynaptic release of Glu. In turn, Glu enhances the excitability of postsynaptic neurons, leading to a reduction in the seizure threshold.

Early studies performed during epilepsy surgery demonstrated that the accumulation and impaired clearance of hippocampal glutamate in TLE were due to a slowing in the conversion of glutamate to glutamine,[113] suggesting a role for GS deficiency in epilepsy. Later, this observation was supported by two discoveries showing the loss of GS in clinical and experimental epilepsies. First, hippocampal tissue removed from patients with TLE during epilepsy surgery was characterized by downregulation of GS.[114] Second, GS was downregulated with elevated GFAP immunoreactivity during the chronic phase of epilepsy in an animal model

of TLE.[115] More recently, an animal model of chronic GS deficiency in the hippocampus has been developed to replicate the situation in human TLE.[116,117] In these studies, freely moving rats monitored with video and electroencephalography developed clusters of spontaneous recurrent seizures and neuropathological changes like those seen in human TLE after a continuous intrahippocampal infusion of the GS inhibitor methionine sulfoximine (MSO).

More importantly, recent studies suggest that downregulation of GS and the consequent reduction in the pool of the GABA precursor glutamine could partially deplete inhibitory synaptic terminals of GABA and impair GABAergic inhibition. In support of this notion, Liang et al.[118] showed that selective blockade of GS by MSO reduced the amplitude of inhibitory postsynaptic currents (IPSCs) in CA1 pyramidal neurons during repetitive stimulus trains. Interestingly, the MSO effect was prevented by the replenishment of glutamine in the bath perfusion.[118] Additionally, recent experiments performed with the same preparation showed no significant effects of MSO on glutamatergic transmission.[119] Together, these results suggest that the glial glutamate-glutamine cycle is the major contributor to synaptic GABA release and regulates inhibitory synaptic strength.

More recently, we tested the hypothesis that GS deficits may be contributing to TLE by reducing synaptic inhibition in the vicinity of reactive astrocytes.[120] First, in this study, a higher-titer viral transduction of astrocytes with enhanced green fluorescent protein (eGFP) via bilateral injections of adeno-associated virus into the mice hippocampus led to reactive astrocytosis. Reactive eGFP astrocytes showed high levels of expression of GFAP and vimentin, while nearby neurons and microglia were not altered. Second, consistent with the studies suggesting that reduced GS expression levels are associated with the development of astrocytosis,[111,114,115] a pronounced downregulation of GS associated with enhanced GFAP and vimentin expression was observed. Third, we hypothesized that the GS downregulation and, therefore, the reduced glutamine could generate a deficit in the inhibitory synaptic transmission in neurons located in the eGFP-positive areas. To test this hypothesis, we used brain slices to record evoked IPSCs (eIPSCs) and spontaneous miniature IPSCs (mIPSCs) in CA1 pyramidal neurons located in the eGFP-positive areas from mice treated with the adeno-associated virus. As expected, the amplitude of eIPSCs and the amplitude/frequency of mIPSCs were reduced while evoked excitatory postsynaptic currents (eEPSCs) were not altered, suggesting that only inhibitory synaptic transmission was impaired in CA1 pyramidal neurons proximal to reactive astrocytes. Furthermore, MSO had no effect on the amplitude of eIPSCs in CA1 neurons located in the vicinity of eGFP-positive reactive astrocytes, confirming that the evoked failure was due to GS deficiency. Interestingly, bath application of glutamine increased the amplitude of eIPSCs, providing further proof that eIPSC failure was mediated by neuronal glutamine starvation. These results suggest that reactive astrocytosis-induced GS downregulation leads to an interrupted neuronal glutamine supply, impaired neuronal production of GABA, and compromised inhibitory synaptic transmission (Fig. 46–2). Finally, to determine whether reactive astrocytosis was associated with network hyperexcitability, we used voltage-sensitive dye imaging techniques and stimulation of the temporoammonic pathway between the entorhinal cortex and CA1, a particular technique of stimulation known to constrain excitatory postsynaptic potentials (EPSPs) by triggering feedforward inhibition. In eGFP-positive hippocampal slices, the EPSPs propagated much further than in control slices from untreated animals. Furthermore, bath perfusion of eGFP-positive hippocampal slices with exogenous glutamine reduced the areas activated by the temporoammonic pathway stimulation. Thus, inhibitory deficits associated with reactive astrocytosis lead to hyperexcitability of the hippocampal network and this can be prevented by exogenously supplied glutamine. Altogether, these results suggest that the GS loss seen during reactive astrocytosis could contribute to elevated seizure susceptibility in TLE by reducing neuronal inhibition (Fig. 46–2). Consequently, protecting GS function might represent a promising therapeutic strategy to prevent seizures.

Reactive Astrocytosis and ADK Upregulation in Epilepsy

Under physiological conditions extra- and intracellular levels of adenosine are rapidly equilibrated via distinct families of nucleoside transporters.[121] Intracellularly, adenosine

is rapidly metabolized by phosphorylation to AMP via ADK,[121] the key enzyme of adenosine metabolism,[122] which, in adult brain, is predominantly expressed in astrocytes.[123] Thus, ADK is ideally located to control the astrocyte-based adenosine cycle by driving the influx of adenosine into the cell via bidirectional nucleoside transporters[122] (Fig. 46–3). Adenosine, in particular, plays a prominent role in seizure regulation and has been found to be elevated in patients following seizures, leading to the conclusion that adenosine released during a seizure mediates seizure arrest and postictal refractoriness.[124] The adenosine A1 receptor-mediated functions are largely responsible for the anti-convulsant and neuroprotective activity of adenosine.[96] Thus, binding of adenosine to A1 receptors that are highly expressed in the hippocampus leads to decreased neuronal excitability and synaptic transmission through postsynaptic membrane hyperpolarization and inhibition of presynaptic release, respectively[96] (Fig. 46–3). Consequently, changes in the homeostasis of the astrocyte-based adenosine cycle are to be expected in the epileptic brain.

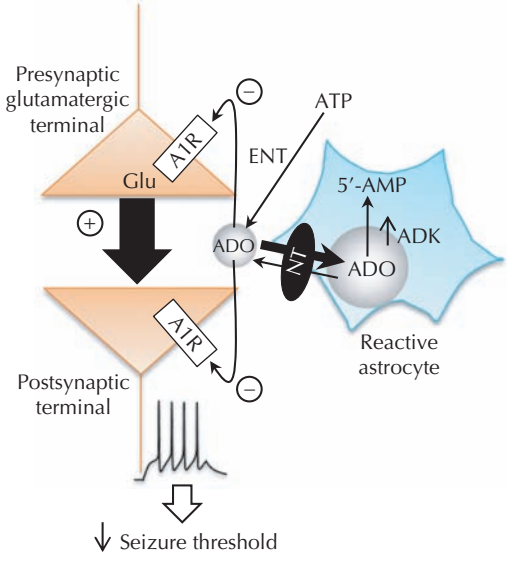

Figure 46–3. The activity change of adenosine kinase (ADK) in reactive astrocytes contributes to seizure development. Extracellular ATP is rapidly degraded into adenosine (ADO) by ectonucleotidases (ENT). Adenosine exerts both pre- and postsynaptic inhibitory effects via adenosine A1 receptors (A1R). The extra- and intracellular levels of ADO are equilibrated via nucleoside transporters (NT). The intracellular level of ADO depends on the activity of ADK in astrocytes that converts ADO into 5′-adenosine-monophosphate (5′-AMP). Overexpression of ADK in reactive astrocytes increases the influx of ADO into the cell, decreasing extracellular levels of ADO. Consequently, pre- and postsynaptic inhibitory effects of ADO are reduced, leading to a decrease in seizure threshold.

Recent studies from Boison's group have identified ADK as molecular link between reactive astrocytosis and neuronal dysfunction in epilepsy leading to the *ADK hypothesis of epileptogenesis.*[122] Thus, transgenic mice overexpressing ADK in the brain displayed a reduced tone of the endogenous anti-convulsant adenosine, leading to the emergence of spontaneous chronic seizures.[125] Furthermore, a direct association between the development of reactive astrocytosis and the upregulation of ADK has been shown.[125,126] Conversely, transgenic mice with a forebrain-selective reduction of ADK were resistant to seizure development.[126] Together, these studies indicate that reactive astrocytosis causes overexpression of ADK, which was shown to be sufficient to trigger seizures (Fig. 46–3). Thus, reconstitution or augmentation of adenosine and/or inhibition of ADK constitutes a pharmacological rationale for seizure suppression. In support of this notion, it has been demonstrated that intrahippocampal implants of ADK-deficient stem cell-derived neuronal precursors suppress kindling epileptogenesis, suggesting that any therapy leading to focal augmentation of the adenosine system has the potential to prevent epileptogenesis.[121,127,128]

ASTROCYTIC CA^{2+} SIGNALS, GLUTAMATE RELEASE, AND EPILEPSY

Several lines of evidence indicate that Ca^{2+} elevations in astrocytes leading to glutamate release and synchronization of neuronal firing (see above) could be involved in epilepsy. Thus, below, we discuss recent studies supporting the potential role for astrocytic Ca^{2+} signals and glutamate release in the generation of epileptiform activity.

Astrocytic Ca^{2+} Signals and Epilepsy

Under physiological conditions, Ca^{2+} signals in astrocytes arise to activation of mGluRs (see above). Interestingly, it has been shown that the protein expression levels of mGluRs were

increased in reactive astrocytes in animal models of epilepsy[129,130] and in hippocampal specimen from patients with TLE.[131] Furthermore, hippocampal cultured astrocytes derived from patients with TLE show increases in Ca^{2+} signals.[111] More recently, studies have shown that cortical epileptiform activity induced in vivo in anesthetized mice with bicuculline,[25] picrotoxin,[26] or the A-type K^+ channel blocker 4-aminopyridine[132] (4-AP) were associated with increases in Ca^{2+} signals in astrocytes, which could be suppressed by intraperitoneal injections of several anti-epileptic drugs including valproate, gabapentin, and phenytoin.[132] This positive correlation between increased astrocytic Ca^{2+} signaling and epileptiform activity onset suggests that these Ca^{2+} signals might contribute to seizure generation.

Astrocytic Glutamate Release and Epilepsy

Studies performed by Kang et al.[66] first demonstrated that Ca^{2+}-dependent release of glutamate from astrocytes might be involved in the generation of epileptiform discharges. In brain slices, the infusion of IP_3 through a patch-clamp pipette to increase Ca^{2+} signals into astrocytes was followed by the occurrence of slow, decayed transient inward currents (STCs) in nearby CA1 pyramidal neurons.[66] In current-clamp, STCs were able to depolarize the neuronal membrane and trigger firing of action potentials. This neuronal depolarization was reminiscent of the paroxysmal depolarization shift (PDS) underlying an interictal epileptiform event[133] that is known to be synchronized over many millimeters of epileptic brain.[134]

Later work from the same group supports the role of astrocytes in generating epilepsy.[132] Using 4-AP to induce interictal epileptiform activity in hippocampal slices, Tian et al.[132] showed that PDSs persisted in the presence of both TTX and different Ca^{2+} channel blockers that suppressed presynaptic release but were blocked by the ionotropic glutamate receptor antagonists CNQX and D-AP5. Thus, these results suggest that PDSs were triggered by release of glutamate from extrasynaptic sources. To determine whether Ca^{2+} signals in astrocytes are associated with PDSs, the authors used photolysis of caged Ca^{2+}. However, photolysis of caged Ca^{2+} in one astrocyte induced local PDS in the presence of TTX, suggesting that Ca^{2+} elevations in astrocytes lead to glutamate release, which targets nearby neurons to generate PDSs, the hallmark of epileptic activity.[133]

In contrast to studies from Nedergaard's group described above, our work[135] suggested that glutamate release from astrocytes was not necessary for the generation of epileptiform activity but rather that it could be modulatory. In this work, we induced both ictal and interictal epileptiform activity in hippocampal slices by removing Mg^{2+} (0 Mg^{2+}) in the presence of picrotoxin. The epileptiform activity thus generated triggered Ca^{2+} signals in astrocytes and increased the frequency of NMDA-receptor-mediated SICs that share certain properties with STCs. However, when slices were preincubated with D-AP5 to block NMDA-receptor-mediated SICs, treatment of the slices with 0 Mg^{2+} and picrotoxin was still able to trigger epileptiform activity, suggesting that glutamate release from astrocytes and SICs per se were not required to initiate epileptiform activity. Interestingly, D-AP5 reversibly reduced the duration of both ictal and interictal epileptiform events, suggesting that astrocytic glutamate, even though it is not necessary for the generation of epileptiform activity, might be important in determining the strength of epileptiform discharges.[135]

Faced with these two conflicting studies,[132,135] recent work by Gomez-Gonzalo et al.[65] attempted to determine the role of astrocytes in the generation of focal ictal discharges. First, the authors showed in enthorinal cortex (EC) slices from rats that while 0 Mg^{2+}/picrotoxin induced both ictal and interictal discharges, only ictal discharges were associated with Ca^{2+} elevations in astrocytes. Second, the frequency and duration of ictal discharges, as well as their associated astrocytic Ca^{2+} signals, were attenuated by mGluR5 and P_2Y receptor antagonists, whereas interictal discharges were unaffected, indicating that astrocytic Ca^{2+} elevations mediated by mGluR5 and P_2Y receptors do not have a role in the generation of interictal discharges. Furthermore, the selective stimulation of astrocytes with the peptide Thr-Phe-Leu-Leu-Arg-NH_2 (TFLLR-NH_2), known to induce astrocytic glutamate release and SICs via activation of the PAR-1 thrombin receptor,[68,136] was able to generate ictal discharges in the presence of 0 Mg^{2+}/picrotoxin, suggesting that

astrocytic glutamate release was sufficient to initiate ictal discharges in EC slices prone to generate epileptiform activity. Through a series of elegant experimental manipulations, Gomez-Gonzalo et al. were able to show that while neuronal activity is critical for the generation of ictal discharges, astrocytes can modulate the threshold for the generation of this epileptiform activity.[65]

In addition to its potential role in the generation of epileptiform activity, our recent study suggested that Ca^{2+}-dependent release of glutamate from astrocytes could also contribute to the typical delayed neuronal death observed after status epilepticus (SE).[137] Using two-photon in vivo microscopy and the pilocarpine model of epilepsy to induce SE in mice, we have shown that SE enhanced Ca^{2+} signals in astrocytes for 3 days and that this enhancement was associated with the period of delayed neuronal death.[137] More importantly, we found that post-SE administration of MPEP to block mGluR5 mediated Ca^{2+} signals in astrocytes (see above) and ifenprodil to selectively block NMDA-NR2B receptors mediated SICs (see above) provided significant neuronal protection.[137] Furthermore, we have shown that selective loading of Ca^{2+} chelators into astrocytes after SE also led to neuronal protection, suggesting neurotoxic roles for glutamatergic gliotransmission in epilepsy.[137] This notion is also supported by previous studies demonstrating that the activation of extrasynaptic NMDAR-NR2B receptors stimulates cyclic adenosine monophosphate response element binding protein (CREB) dephosphorylation and neuronal death.[138]

While controversial observations exist concerning the involvement of astrocytes in the generation of seizures, it is clear that astrocytic Ca^{2+} signals and astrocytic glutamate play an important role in the mechanisms of epilepsy. However, we now await the introduction of astrocyte-selective inhibitors to define the role of astrocytes in the process. Thus, gliotransmission should be considered as a potential therapeutic target in epilepsy.

CONCLUDING REMARKS

The extraordinary evolution of in vivo Ca^{2+} imaging techniques allowed us to appreciate the highly dynamic nature of Ca^{2+} signaling in astrocytes under physiological conditions. This Ca^{2+} excitability represents an original pathway for astrocytes to integrate and process the neuronal information in the brain. In response to neuronal activity, astrocytes release gliotransmitters to modulate both excitatory and inhibitory synaptic transmission, and consequently affect brain plasticity and mammalian behavior. It is striking to see how astrocytes react to epilepsy by changing their shape and functions. This glial reactivity leads to increases in neuronal excitability and consequently accelerates the evolution of this neuronal disorder. In addition to astrocytic reactivity, extensive experimental research suggests that astrocytic Ca^{2+} signaling and gliotransmitter release participate in the generation of seizures. However, data coming from this research are currently controversial, mainly due to the different experimental approaches and lack of selective pharmacological tools to block astrocytic Ca^{2+} signaling and gliotransmission. In the future, the development of transgenic animals bearing specific deficiencies interfering with astrocytic Ca^{2+} signals and gliotransmission, and the use of chronic models of epilepsy that more closely mimic the complex feature of seizures in epileptic patients, will represent new approaches to identify the role of astrocytes in the generation of seizures and rigorously evaluate the idea that these glial cells represent a target for developing new therapeutic strategies for epilepsy.

Chapter 47

Astrocyte Dysfunction in Epilepsy

Christian Steinhäuser
Gerald Seifert

Recent work has identified glial cells, and astrocytes in particular, as active partners in neural information processing.[1] Application of advanced electrophysiological and Ca^{2+} imaging techniques revealed that astrocytes in acute brain slices or after fresh isolation from the tissue express a broad spectrum of functional ion channels and transmitter receptors similar to that of neurons.[2] The presence of ionotropic and metabotropic neurotransmitter receptors led to the conclusion that astrocytes are endowed with the machinery to sense and respond to neuronal activity. In 1994 two groups discovered that elevation of the intracellular Ca^{2+} concentration $[Ca^{2+}]_i$ in cultured astrocytes upon membrane receptor activation can induce glial release of glutamate.[3,4] This astonishing finding demonstrated for the first time that astrocytes sense neuronal activity and feed back to neurons to modulate central nervous system (CNS) signaling.[5] Later studies corroborated the view that astrocytes are direct communication partners of neurons and interact dynamically with synapses through uptake of neurotransmitters, receptor-mediated Ca^{2+} signaling, and subsequent gliotransmitter release. The intimate morphological and physiological interconnection between both cell types gave rise to the term *tripartite synapse*, which comprises not only pre- and postsynaptic elements but also the astrocytic process.[6,7]

According to a long-standing concept, astrocytes supply neurons with nutrition metabolites and oxygen. Fundamental new insight into this aspect of astrocyte function was gained through the discovery that astrocytes control cerebral blood flow, in an activity-dependent manner, by releasing vasoactive substances such as polyunsaturated fatty acids, adenosine, and prostaglandins. [8–10] In addition to the only recently discovered modulatory actions on brain signaling and circulation, astrocytes have been known for decades to serve homeostatic functions, including the clearance of neuronally released K^+ and glutamate from the extracellular space. Astrocytes are abundantly

coupled through gap junctions allowing them to redistribute elevated K^+ from sites of excessive neuronal activity to sites of lower extracellular K^+ concentration.

Despite the fact that the pathways enabling activation of these cells under physiological conditions are still ill-determined, evidence is emerging suggesting a critical role of astrocyte dysfunction in the pathogenesis of neurological disorders, including epilepsy.[11] Investigation of specimens from patients with pharmacoresistant mesial temporal lobe epilepsy (MTLE) and corresponding animal models of epilepsy revealed alterations in expression, subcellular localization, and function of astroglial K^+ and water channels, resulting in impaired K^+ buffering. Moreover, malfunction of glutamate transporters and the astrocytic glutamate-converting enzyme, glutamine synthetase (GS), as observed in epileptic tissue, suggested that astrocyte dysfunction is the cause of hyperexcitation, neurotoxicity, and the generation or spread of seizure activity. Accordingly, dysfunctional astrocytes should be considered promising targets for new therapeutic strategies. In this chapter, we will summarize current knowledge of astrocyte dysfunction in MTLE and discuss putative mechanisms underlying these alterations.

IMPAIRED K^+ BUFFERING IN TEMPORAL LOBE EPILEPSY

Loss of Inwardly Rectifying K^+ Channels in MTLE

Neuronal activity, propagation of action potentials, and synaptic activity after local depolarization lead to rapid fluctuations of the extracellular K^+ concentration $[K^+]_0$ because of the restricted volume of extracellular space.[12] If increases in $[K^+]_0$ remain uncorrected, the resting potential would become more positive and affect activation of transmembrane ion channels, receptors, und transporters. During neuronal hyperactivity in vivo, $[K^+]_0$ may increase from 3 mM to a ceiling level of 10–12 mM.[13] Such high $[K^+]_0$ levels can generate epileptiform activity in acute brain slices. Two different mechanisms are thought to balance $[K^+]_0$ during neuronal activity: K^+ uptake and spatial K^+ buffering (for review, see ref. 14). K^+ uptake, mediated by Na,K-ATPase (Na,K-adenosine triphosphatase) or Na-K-Cl cotransporters, is accompanied by cell swelling and local depolarization of astrocytes. Spatial K^+ buffering is driven by the glial syncytium membrane potential and the local K^+ equilibrium potential. This allows transfer of K^+ from regions of elevated $[K^+]_0$, through the syncytium, to regions of lower $[K^+]_0$. Spatial buffering depends on proper distribution and function of astrocytic K^+ channels, water channels, and gap junctions. In astrocytes, the inward-rectifying K^+ channel Kir4.1, which is activated by intracellular adenosine triphosphate (ATP), is thought to allow for K^+ influx at negative membrane potentials (for review, see refs. 15 and 16).

Because of their presumed role in K^+ homeostasis, the properties of astroglial Kir channels have been investigated in experimental and human epilepsy. Measurements of $[K^+]_0$ with ion-sensitive microelectrodes and patch-clamp studies suggested that impaired K^+ buffering in sclerotic human hippocampus resulted from altered Kir channel expression. Differences were observed in the effect of Ba^{2+} on stimulus-induced changes in $[K^+]_0$ in the CA1 region of hippocampal brain slices obtained from MTLE patients with hippocampal sclerosis (MTLE-HS) or without sclerosis (non-HS). In non-HS tissue, Ba^{2+} application significantly enhanced $[K^+]_0$, while this effect was not observed in HS specimens. Since Ba^{2+} is a blocker of Kir channels in astrocytes of the hippocampus,[17] this finding suggested impaired function of these channels in the sclerotic tissue.[18,19] The hypothesis could be confirmed with patch-clamp analyses demonstrating downregulation of Kir currents in the sclerotic human CA1 region of MTLE patients.[20,21] Accordingly, in MTLE-HS, impaired K^+ buffering and enhanced seizure susceptibility result from reduced expression of Kir channels. However, it is still unclear whether these changes are the cause or the consequence of the condition.

Fine mapping of a locus on mouse chromosome 1 identified *KCNJ10*, the gene encoding Kir4.1, as a candidate gene exhibiting a potentially important polymorphism with regard to fundamental aspects of seizure susceptibility.[22] Similarly, variations in *KCNJ10* in the human genome associate with multiple seizure phenotypes. Missense mutations of *KCNJ10* influence the risk of acquiring forms

of human epilepsy.[23] Mutations in the *KCNJ10* gene encoding Kir4.1 channels cause a multiorgan disorder in patients with clinical features of epilepsy, sensorineural deafness, ataxia, and electrolyte imbalance.[24,25] These patients suffer from generalized tonic-clonic seizures and focal seizures since childhood. Single nucleotide mutations in the *KCNJ10* gene cause missense or nonsense mutations on the protein level in the pore region, transmembrane helices, or the C terminus, the last resulting in deletion of a postsynaptic density, drosophila disc large tumor suppressor and zonula occludens-1 proteins (PDZ) binding domain and improper membrane localization of Kir4.1. These loss-of-function mutations of *KCNJ10* are homozygous or compound heterozygous. Experiments with heterologous expression systems demonstrated that the mutations indeed affect channel function and lead to reduced transmembrane currents.[24]

Genetic downregulation of Kir4.1, the main Kir channel subunit in astrocytes,[17,26–28] profoundly reduced the ability of astrocytes to remove glutamate and K^+ from the extracellular space, both in cell culture[29] and in vivo.[30] General knockout of Kir4.1 leads to early postnatal lethality, and mice with astrocytic deletion of the channel developed a pronounced behavioral phenotype, including seizures.[30,31] Thus, dysfunction of Kir4.1 is observed in different forms of epilepsy (Fig. 47–1).

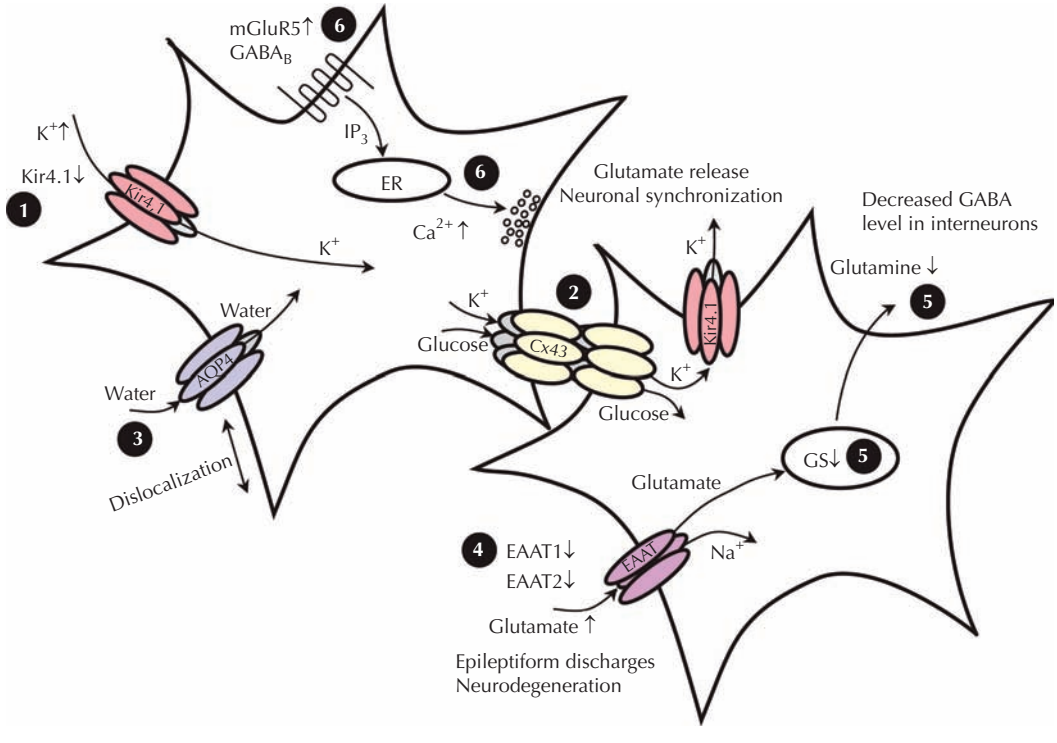

Figure 47–1. Epilepsy-associated alterations of functional properties in astrocytes. (1) Seizure activity leads to an increase in extracellular K^+ concentration. Downregulation of Kir channels was observed in astrocytes in human and experimental epilepsy. (2) Gap junctions mediate spatial redistribution of K^+. Genetic ablation of gap junction entails impaired K^+ buffering and hyperactivity. (3) Dislocation of water channels contributes to impaired K^+ buffering. (4) Astrocytes are primarily responsible for glutamate uptake. Reduction of the proteins excitatory amino acid transporters 1 and 2 (EAAT1 and EAAT2) is observed in human epileptic hippocampus. Elevated extracellular glutamate decreases the threshold for seizure induction. (5) Glutamate is converted into glutamine through glutamine synthetase (GS). In human epileptic hippocampus, loss of GS resulted in elevated extracellular glutamate levels. In experimental epilepsy, downregulation of GS was observed in the chronic phase. (6) Ca^{2+} elevations in astrocytes are mediated by metabotropic receptors. Activation of mGluR5 leads to increases in intracellular Ca^{2+}. The Ca^{2+} rise may oscillate and initiate Ca^{2+} wave propagation within the astrocyte network, activate Ca^{2+}-dependent ion channels, and induce glutamate release from astrocytes. Enhanced mGluR5 levels are observed in experimental and human epileptic tissue. ER, endoplasmic reticulum; IP_3, inositol (1,4,5)-triphosphate.

Interestingly, spinal cord injury-induced downregulation of Kir4.1 in the spinal cord can be partially rescued by administration of β-estradiol. Inhibition of estrogen receptors also reduces Kir4.1-mediated currents, suggesting that Kir4.1 channel expression depends on nuclear estrogen receptor signaling under physiological conditions.[32]

Gap Junctions and K^+ Buffering

A prerequisite for the operation of spatial K^+ buffering is the presence of Kir channels and connexins forming gap junctions.[14,33] According to this concept, K^+ entry into the astrocytic network occurs at sites of maximal extracellular K^+ accumulation, driven by the difference between the glial syncytium membrane potential and the local K^+ equilibrium potential. Since K^+ propagates through the glial network, at sites distant to elevated $[K^+]_0$ a driving force for K^+ efflux results because there local depolarization exceeds the K^+ equilibrium potential. Surprisingly, clearance and redistribution of K^+ are still preserved in the hippocampal stratum radiatum (but not in the lacunosum moleculare) of mice with coupling-deficient astrocytes, indicating that gap junction-independent mechanisms add to K^+ homeostasis in the brain (e.g., indirect coupling[34]; Fig. 47–2). Nevertheless, genetic deletion of astrocyte gap junctions leads to impaired K^+ buffering, spontaneous epileptiform activity, and a decreased threshold for eliciting seizure activity.[34]

Interplay between Kir Channels and AQP4 in K^+ Buffering

Ultrastructural analyses in rat demonstrated spatial overlap of Kir4.1 and the water channel aquaporin 4 (AQP4) in astroglial endfeet contacting the capillaries.[35,36] This finding gave rise to the hypothesis that K^+ clearance through Kir channels might depend critically on concomitant transmembrane flux of water in a given cell to dissipate osmotic imbalances due to K^+ redistribution. Subsequent functional work corroborated this idea by showing that in mice the clearance of extracellular K^+ is compromised if the number of perivascular AQP4 channels is decreased.[37] Similarly, impaired K^+

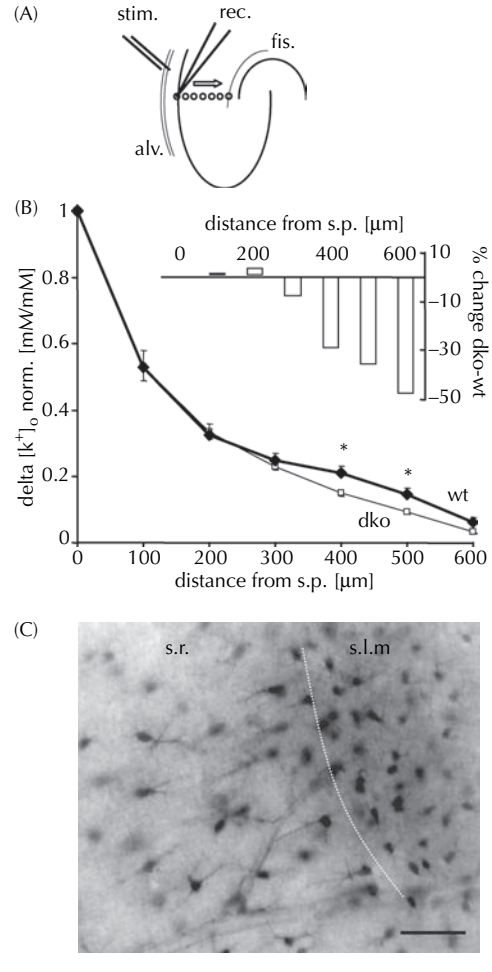

Figure 47–2. Impaired spatial buffering in the stratum lacunosum moleculare of mice with genetic deletion of C×43 and C×30 in astrocytes (dko mice). **A.** Experimental setup for the analysis of laminar profiles of changes in $[K^+]_0$. Stimulation was performed in the alveus (20 Hz, 100%), while the recording electrode was stepped from the stratum pyramidale to the hippocampal fissure (100 µm step size). **B.** Mean rises in $[K^+]_0$ (normalized to rise at the stratum pyramidale, s.p.) plotted against the distance from the stratum pyramidale (thin line, wild-type [wt]: $n = 8$ animals, 13 slices; thick line, dko, $n = 8$ animals, 15 slices). Normalized $[K^+]_0$ in dko mice reached lower levels at 400, 500, and 600 µm from the s.p. compared to the wt. See the inset for relative changes. *Changes differ significantly. **C.** The difference in astrocyte morphology and orientation in the stratum radiatum versus the stratum lacunosum moleculare, obtained after biocytin injection into a stratum radiatum astrocyte proximal to the stratum lacunosum moleculare. The white line indicates the boundary between stratum radiatum and stratum lacunosum moleculare. Note the small size and random orientation of cells in the stratum lacunosum moleculare. Scale bar: 50 µm. alv., alveus; fis., fissure; stim., stimulation electrode; rec. recording electrode; s.r. stratum radiatum; s.l.m., stratum lacunosum moleculare. From ref. 34.

buffering and prolonged seizure duration were observed in AQP4 knockout mice.[38] However, later work provided evidence against the concept of functional coupling of AQP4 and Kir4.1 channels.[39,40] Thus, there is a need to identify alternative mechanism(s) underlying the hyperactivity associated with AQP4 deficiency.

Epileptic rats show mislocalization of AQP4 in astrocytic endfeet contacting blood vessels in the hippocampus. Eight weeks after status epilepticus, immunohistochemistry revealed loss of AQP4 in vacuolized astrocytes of the hippocampus. Instead, AQP1 was found in astrocytes, a protein not expressed by these cells under physiological conditions. Nonvacuolized astrocytes still contained AQP4, even at higher levels, and in addition expressed AQP9.[41] In MTLE-HS patients, immunostaining indicated loss of AQP4 in vasculature-associated astrocyte endfeet compared with specimens from non-HS patients.[42] The decrease in perivascular AQP4 channels might be secondary, following disruption of the dystrophin complex that is essential for anchoring of AQP4 in the plasma membrane.[43] Together, these findings suggest that in MTLE-HS, dislocation of water channels in concert with decreased expression of Kir channels in astrocytes might underlie impaired K^+ buffering and increased seizure propensity (Fig. 47–1). The functional consequence of the upregulation of AQP subunits other than AQP4 in astrocytes of epileptic tissue remains unclear. Characterization of DNA variations in MTLE-HS patients with antecedent febrile seizures (MTLE-FS) identified single nucleotide polymorphisms (SNPs) in the *KCNJ10* gene, in the region between *KCNJ9* and *KCNJ10*, and in the *Aqp4* gene. The combination of *KCNJ10* and AQP4 gene variations was associated with MTLE-FS, supporting the hypothesis that impaired K^+ and water homeostasis is involved in the etiopathogenesis of MTLE.[44]

In addition to spatial buffering, transient K^+ accumulation can be counterbalanced by net K^+ uptake through Na,K-ATPase and the Na-K-Cl cotransporter NKCC1, at the cost of cell swelling due to concomitant water influx (reviewed in ref. 14). In rodent hippocampus, Na,K-ATPase was reported to have a potential role in maintaining low $[K^+]_0$ levels and to clear elevations in $[K^+]_0$ after epileptiform activity.[45,46] However, whether alterations in net K^+ uptake contribute to the increased $[K^+]_0$ levels seen in epileptic tissue has still to be determined.

AMBIGUOUS ROLE OF GAP JUNCTIONS IN EPILEPTOGENESIS

The abundant expression of gap junctions in astrocytes and their formation as a functional syncytium enables long-range intercellular exchange of ions, nutritional metabolites, amino acids, and nucleotides. The permeability of gap junctions is regulated by endogenous membrane receptors, second messengers, and pH (for review, see ref. 47). Thus, trafficking of nutritional metabolites such as glucose-6-phosphate and lactate through astrocytes is controlled by endogeneous compounds that are released by endothelial cells, astrocytes, and neurons in an activity-dependent manner.[48] In addition to the aforementioned homeostatic functions, astrocytic gap junctions may affect neuronal migration and proliferation. [49–51] Recent work has revealed that inhibition of gap junction coupling not only enhances glucose uptake, synthesis of nucleic acids, and proliferation of astrocytes.[52] Gap junctions formed by C×43 and C×30 also allow intercellular trafficking of glucose through the astrocytic network and deliver energetic metabolites from blood vessels to neurons to maintain synaptic transmission in the murine brain[53] (Fig. 47–1). Glucose uptake and trafficking was dependent on synaptic transmission: it was increased during epileptiform activity and, in turn, glucose delivery through the astrocytic network was needed to sustain epileptiform activity. Neuronal activity was sustained by the transport of nutrition metabolites through the astrocytic network even under conditions of transient limited substrate availability (see also ref. 51).

C×43 and C×30 are the main connexins forming gap junctions in astrocytes of the CNS[54] and, as discussed above, their cell type-specific deletion in mice led to the generation of spontaneous epileptiform activity and a decreased threshold for evoking seizure activity.[34] Disruption of the blood-brain barrier and albumin-dependent generation of epilepsy in rat is accompanied by a transient decrease of both connexin transcripts.[55,56] These findings

are in line with the long-standing concept that astrocyte gap junctions are essential for proper K^+ regulation[57] and help to counteract the generation of epileptiform activity. However, the opposite effect was observed in organotypic hippocampal slice cultures where long-term block of gap junctions through C×43 mimetic peptides attenuated spontaneous seizure-like events (but not evoked epileptiform responses[58]). The authors also observed that serum deprivation strongly reduced spontaneous recurrent network activity, and they assigned this effect to a neuroprotective role of gap junction communication. Hence, a decrease in gap junction permeability seems to exert opposite effects on excitability: a fast onset, pro-convulsive effect due to impaired K^+ redistribution but a delayed antiepileptic effect because of disruption of neuronal energy supply.

Despite these intriguing new insights into astrocyte function, the role of gap junctions in human epilepsy is still unresolved. Published data are not always consistent, indicating that (1) human epilepsy cannot be considered a uniform condition, (2) most of the currently available gap junction blockers do not distinguish between neuronal and glial gap junctions, and (3) these blockers usually have dramatic side effects.[59] Moreover, analysis of tissue samples is restricted to the chronic phase of the disorder and is likely to be affected by patients' long-lasting treatment with different antiepileptic drugs (AEDs), a problem inherent in experiments with neurosurgically resected specimens. Increased expression of C×43 protein was observed in low-grade tumors and reactive astrocytes of human epileptic cortical tissue surrounding tumors, although high-grade gliomas exhibited great variations in C×43.[60] Specimens from pharmacoresistant MTLE-HS patients showed strongly enhanced C×43 immunoreactivity and transcript levels.[61-,63] The authors speculate that upregulation of connexins might represent a compensatory response of astrocytes to cope with the enhanced K^+ release during seizure activity. However, in light of the aforementioned findings, enhanced coupling could also serve to fuel hyperactivity and thereby exacerbate generalized seizures. Importantly, it has to be emphasized that any functional evidence of enhanced gap junction coupling in human epilepsy is missing, which considerably limits conclusions that can be drawn from the above studies.

GLUTAMATE UPTAKE IN EPILEPSY

Glutamate Transporter in Astrocytes

The uptake of glutamate that helps to terminate the action of this neurotransmitter at CNS synapses is mediated mainly by transporters localized at the astrocytic membrane. The high efficiency of these glial transporters ensures the maintenance of low concentrations of extracellular glutamate to prevent excitotoxic cell death.[64,65] They are densely packed and keep the extracellular glutamate concentration in the nanomolar range, preventing significant receptor activation.[66–68] Fine tuning of extrasynaptic glutamate through glial glutamate transporters is important for proper synaptic function and plasticity.[69–72] Downregulation of glial glutamate transporters or metabolic inhibition of the glutamate-to-glutamine converting enzyme, GS, immediately causes extracellular accumulation of the transmitter, which, if it reaches micromolar concentrations, causes depolarization, compromised synaptic transmission, and induced neuronal death.[66,73–75] It is therefore not surprising that dysfunction of the astrocytic glutamate excitatory amino acid transporters 1 and 2 (EAAT1 and EAAT2) is observed under various pathological conditions, including epilepsy[11] (Fig. 47–1).

Excess of extracellular glutamate is found in human epileptogenic tissue and can induce recurrent seizures and neuronal cell death.[76,77] This may occur through the activation of neuronal and glial glutamate receptors. Indeed, a large body of evidence has shown that the activation of astrocytes by neuronal activity-derived glutamate is due mainly to activation of the metabotropic glutamate receptors (mGluRs) mGluR3 and mGluR5. Activation of these receptors affects cyclic adenosine monophosphate (cAMP) accumulation and leads to increases in intracellular Ca^{2+}, respectively. The Ca^{2+} rise may oscillate and initiate Ca^{2+} wave propagation within the astrocyte network, activate Ca^{2+}-dependent ion channels, and induce glutamate release from

astrocytes (cf. Chapter 52 in this volume). In epilepsy models, elevated protein levels for mGluR3, mGluR5, and mGluR8 have been found[59] (Fig. 47–1). High-resolution analysis of hippocampal specimens from TLE patients detected mGluR2/3, mGluR4, and mGluR8 in reactive astrocytes, suggesting involvement of these mGluRs in gliosis.[78] Enhanced levels of astroglial mGluR2/3 and mGluR5 were also observed in epileptic specimens from patients with focal cortical dysplasia.[79] Since their activation affects expression of EAAT1 and EAAT2[80] and elevates $[Ca^{2+}]_i$, astrocytic mGluRs might contribute to the generation of seizure foci.

Different reports exist about the regulation of glial glutamate transporters in patients presenting with pharmacoresistant MTLE. Employment of in situ hybridization and Western blot analysis in specimens from patients with HS[81] did not reveal changes in EAAT1 or EAAT2. In contrast, other groups reported downregulation of EAAT2 immunoreactivity in the CA1 region displaying profound neuronal loss in human HS.[82,83] It was found that EAAT1 was increased in the sclerotic CA2/3 region.[83] Later work showed downregulation of EAAT1 and EAAT2 in the CA1 region in HS and emphasized that it is still unclear whether this reduction is the cause or a consequence of the condition.[84] A critical analysis of immunohistochemical, Western blot, and mRNA data hinted at a redistribution, rather than a reduction, of glial glutamate transporter in human epilepsy, which was considered inadequate to account for the high glutamate concentrations during seizures.[85] The authors concluded that under these conditions, glutamate uptake is influenced by factors other than transporter protein levels, such as changes in the cells' metabolic state and downregulation of GS (see the next section).

Recent work reported that expression of EAAT2 is critically dependent on synaptic activity. In this study, EAAT2-mediated uptake was decreased after nerve fiber transection or neurodegeneration in a mouse model of amyotrophic lateral sclerosis (ALS).[86] Beta-lactam antibiotics increased glutamate uptake in primary human astrocytes through NFκB-mediated EAAT2 promoter activation.[87] Hence, the antibiotics might represent a therapeutic tool to counteract glutamate transporter dysfunction in neurological disorders such as ALS and epilepsy.[88]

Depolarization of astrocytes by inadequate K^+ buffering led to compromised functioning of the glial transporters.[29,30] In a rat model of cortical dysplasia, pharmacological inhibition of glial glutamate transporters in the lesion area led to opening of neuronal *N*-methyl-D-aspartate (NMDA) receptors, prolonged synaptic currents, and decreased the threshold for the induction of epileptiform activity.[89] This enhanced activity of NMDA receptors also triggered dephosphorylation of Kv2.1 K^+ channels, produced a negative shift of its voltage-dependent activation, and hence modulated excitability and neuronal plasticity in mice.[90]

Conversion of Glutamate to Glutamine by Astrocytes

For effective removal of excess extracellular glutamate, the transmitter must be converted by GS into the receptor-inactive substrate glutamine under consumption of ATP and ammonia. Increasing evidence indicates a loss of this astrocyte-specific enzyme in epilepsy. In MTLE-HS patients, loss of GS in the hippocampus was accompanied by elevated extracellular glutamate levels.[91–93] Infusion of ^{13}C-labeled glucose before resection of the hippocampus from MTLE-HS patients revealed an increased glutamate concentration, slowed glutamate-to-glutamine cycling, and decreased glutamine concentrations. Thus, failure of glutamate detoxification could account for continuing excitotoxicity and contribute to the pathogenesis.[94]

In experimental epilepsy, upregulation of GS and glial fibrillary acidic protein (GFAP) was observed in the latent phase, prior to recurrent seizure onset, while in the chronic phase GS was downregulated, with persistence of elevated GFAP immunoreactivity.[95] By contrast, glutamate dehydrogenase, another glutamate-degrading enzyme, remained unaltered in this rat model. Compatible with a potential causative role of GS loss in initiating epilepsy was the finding that pharmacological inhibition of GS produced recurrent seizure activity and rat brain pathology resembling MTLE-HS.[96] In the pentylenetetrazol epilepsy model, immunohistochemistry revealed unchanged GS protein levels. However, the enzyme underwent stress-induced nitration and partial inhibition

in severely affected hippocampal regions, which might result in locally altered glutamate and gamma-aminobutyric acid (GABA) metabolism.[97] Genetic inactivation of GS in mice leads to early embryonic lethality, while GS deletion on one allele increases the susceptibility to febrile seizures.[98]

Inhibition of GS in astrocytes and/or glutamine transporters in neurons reduced the amplitudes of evoked inhibitory postsynaptic currents (IPSCs) and GABA release from interneurons in the hippocampus (Fig. 47–1). Hence, in the rat, the glial glutamate-glutamine cycle is a major contributor to synaptic GABA release and regulates inhibitory synaptic strength,,[99] while inhibition of GS does not significantly affect glutamatergic transmission in the same species.[100] However, during periods of intense neuronal or epileptiform activity, a glial supply of glutamine and its transport into neurons are required.[101]

MTLE-HS is characterized by neuronal loss and reactive astrogliosis. In a model of selective astrogliosis, which leaves properties of neurons and microglia unaltered, deficient neuronal inhibition was observed in the hippocampus, while excitatory neurotransmission remained unchanged. Decreased inhibition resulted from impaired GS activity, compromised glutamine availability, and reduced GABA release from interneurons.[102] These astrogliosis-associated deficits generated hyperactivity, emphasizing the importance of proper GS function for inhibitory neurotransmission and prevention of seizures generation.

CONCLUDING REMARKS

The novel view of astrocytes as communication partners of neurons rather than "brain glue" has rekindled the question regarding the role of these cells in neurological disorders such as epilepsy. Indeed, an increasing body of evidence has documented astroglial dysfunction, and even dysregulation of astroglia-specific functions, in human and experimental epilepsy. This particularly concerns impaired uptake/conversion of glutamate and removal/redistribution of K^+, as observed in MTLE-HS. However, a number of key questions need to be addressed before a unifying picture can be proposed. For example, it is still unclear whether the reported glial alterations are a cause or a consequence of the condition. In addition, difficulties arise from the fact that the term *astrocyte* covers a heterogeneous group of cells, and this complicates comparison of individual studies. It is worthwhile, however, to emphasize that the molecular, functional, and structural characterization of astroglial heterogeneity is a rapidly evolving field that may soon lead to a better definition of astroglial subtypes. In a comprehensive approach that uses modern molecular genetics and in vivo models, we may now have the opportunity to clarify the specific roles of astroglia in epilepsy and to develop novel therapeutic approaches to fight this disorder.

Chapter 48

Glia–Neuron Interactions in Ictogenesis and Epileptogenesis

Role of Inflammatory Mediators

Annamaria Vezzani
Stephan Auvin
Teresa Ravizza
Eleonora Aronica

Over the past decade, an increasing number of observations have shown the existence of rapid regulatory and reciprocal cross-talk between neurons and glia during synaptic transmission.[1] In particular, neurotransmitters released from active synapses can stimulate receptors on glial cells, resulting in internal calcium elevation and activation of glia, which in turn can produce a neuromodulatory response by triggering gliotransmitter release.[2]

When a local inflammatory reaction is triggered in the brain following an injury, microglia and astrocytes become activated and start releasing a number of pro-inflammatory mediators that can alter profoundly the properties of glia via autocrine actions and perturb glia–neuron paracrine signaling.

Understanding which soluble mediators and what molecular mechanisms are crucially involved in these interactions is instrumental in demonstrating whether an imbalance in physiological glia–neuron communication may increase neuronal network excitability and reduce cell viability.[2,3] In support of this hypothesis, there is increasing evidence that pro-inflammatory cytokines released by

glia play prominent roles in hyperexcitability leading to seizure precipitation and recurrence, as well as in excitotoxic cell damage associated with seizures.[3,4] Moreover, recent evidence in rodent models of childhood infections and central nervous system (CNS) inflammation points to the role of specific cytokines in determining a chronic decreased seizure threshold, and long-term behavioral deficits, which mimic comorbities associated with epilepsy (see below).

Experimental data corroborate clinical evidence of activation of specific pro-inflammatory pathways in human epilepsies.[5–7]

This chapter reports clinical observations in drug-resistant epilepsies and experimental findings in adult and immature rodent models of seizures and epileptogenesis that causally link brain inflammation to the epileptic process. We discuss the role of specific inflammatory mediators of glia–neuron communication in the etiopathogenesis of seizures.

CLINICAL FINDINGS

Accumulating evidence indicates that activation of both innate and adaptive immune systems occurs in human epilepsy. The resulting inflammatory response, which chiefly involves resident brain cells such as glia and neurons, may contribute to the generation of seizures, neuronal damage, and cognitive impairment.[6,7]

Inflammatory and Immunological Biomarkers

Levels of some cytokines such as interleukin-6 (IL-6), IL-1β, and IL-1 receptor antagonist (ra) transiently increase in serum or plasma after various types of seizures.[8,9] There is also evidence of seizure-dependent increases in the cerebrospinal fluid (CSF) levels of these and other cytokines.[8,10–14] A recent study showed increased CSF levels of IL-6 and IL-1ra after tonic-clonic seizures or prolonged partial seizures, while IL-1β levels were decreased compared to those in control CSF.[14] This observation is at variance with previous reports showing an increase in IL-1β production, thus representing one example of the great variability observed when measuring cytokines in the blood or CSF of patients with epilepsy (for review see refs. 4 and 7). A major limitation of studies on CSF biomarkers (including inflammatory/immunological biomarkers) is the small sample size in distinct subpopulations of epilepsy patients. In addition, time of sampling, short half-life of cytokines, storage, and type of analysis may introduce additional variability in quantification. The challenge for future studies on CSF biomarkers in neurological disorders, including epilepsy, is to define the specific molecules that monitor the dynamics of pathological processes and to combine detection of these biomarkers with outcome data to improve diagnostic and prognostic accuracy.[15]

Numerous studies on plasma and CSF cytokine profiles after febrile seizures (FS) have the same limitations noted above. Accumulating data suggest that inflammation has an important role for both the development and long-term consequences of FS.[16–18] The involvement of an inflammatory response in FS development and/or recurrence has not yet led to advances in the treatment of FS. Clinical trials using nonsteroidal anti-inflammatory drugs did not prevent FS recurrence[19] and suggest that specific inflammatory pathways should be targeted as indicated by experimental studies (see the section "Experimental Models").

Genetic Studies

Several studies have examined the genetic association of IL-1β, IL-1α, and IL-1ra gene polymorphisms with temporal lobe epilepsy (TLE) and FS susceptibility. However, these studies did not have statistical power and hence provided contradictory and inconclusive results.[20,21] Thus, there is a need for collaborative collection of a large number of patients with pediatric and adult epilepsy that can provide the statistical power to associate inflammation and genetic susceptibility with seizures and epilepsy.[20]

Anti-inflammatory Drugs in Epilepsy

Although the role of inflammation in human epilepsy is still hypothetical, steroids and adrenocorticotropic hormone (ACTH), with

anti-inflammatory and immunomodulatory properties, as well as high doses of immunoglobulins, have been used to treat seizures in children with Rasmussen encephalitis (RE), West syndrome, and Lennox-Gastaut and Landau-Kleffner syndromes.[22] In addition, some antiepileptic drugs (AEDs), such as valproate and carbamazepine, also display anti-inflammatory actions.[23]

This evidence suggests that activation of immune/inflammatory processes in epilepsy is not a mere epiphenomenon of the underlying disease but might contribute to the pathophysiology of seizures.

Infectious and Autoimmune Diseases

Different common infectious or autoimmune diseases often present with seizures, or seizures develop during the course of the disease.[6,22] Neurotropic viruses, such as the herpes viruses, have been implicated in the development of seizures,[6,24] and recent studies detected human herpes viruses 6B in astrocytes of patients with hippocampal sclerosis and pregressive febrile status epilepticus.[25] An association between childhood immunizations (such as measles, mumps, rubella [MMR] vaccination) and an increased risk of FS has been suggested.[6,26]

Seizures arise in different autoimmune diseases affecting the CNS, such as systemic lupus erythematosus, stiff man syndrome, and Hashimoto's encephalopathy.[6,22,27] The detection of autoantibodies against neuronal proteins such as voltage-gated potassium channels, glutamic acid decarboxylase, and glutamate receptors in subpopulations of patients with epilepsy and seizure-related diseases supports the role of immune system dysfunction in certain forms of epilepsy.[28,29] Recently, attention has focused on the syndrome of noninfectious, nonparaneoplastic limbic encephalitis (LE) as a precipitating event in adult-onset TLE.[27,29]

Seizures have been recognized to occur in common immunologically mediated diseases such as multiple sclerosis (MS).[30] The mechanisms underlying the development of seizures in MS patients are still unclear.[30] A working hypothesis is that seizures may result from cortical demyelinating lesions (with or without inflammation). However, magnetic resonance imaging (MRI) evidence of cortical inflammation has been reported to be associated with epilepsy in MS.[31]

The prototype of inflammatory epileptic encephalopathy is represented by RE, a severe disease characterized by focal seizures and progressive deterioration of motor and cognitive functions.[32] Neuropathological features of RE include cortical inflammation restricted to one brain hemisphere, with microglial and astrocytic activation, T lymphocyte infiltration, and neuronal loss.[32,33] Pardo et al.[32] performed a comprehensive pathological evaluation of RE tissues and demonstrated that the cerebral cortex pathology within the affected hemisphere is multifocal and progressive. Different stages of inflammation coexist in the same patient. These observations are consistent with a progressive immune/inflammatory-mediated process involving both glia and lymphocytes and leading to neuronal damage.[32,34] The autoimmune nature of RE was suspected when autoantibodies against glutamate-receptor subunit 3 (GLUR3) were discovered.[35] However, these autoantibodies have also been detected in other epilepsy patients with severe early-onset disease and intractable seizures and are significantly associated with seizure frequency.[36] Although the etiology and pathogenesis of this severe inflammatory disease are still enigmatic, recent studies suggest as a key pathogenetic mechanism an antigen-driven major histocompatibility complex (MHC) class I restricted cytotoxic CD8+ T-cell-mediated attack of both neurons and astrocytes.[34,37] The therapeutic options for RE presently include surgery (hemispheric disconnection) to control seizures refractory to AEDs and long-term immunotherapy against structural and functional deterioration.[38,39]

Focal Epilepsy (Noninfectious, Nonautoimmune)

The occurrence of a complex and sustained inflammatory reaction, involving chiefly the activation of microglia and astrocytes and the related production of pro-inflammatory molecules, has been shown in the brain tissue of patients undergoing surgery for pharmacologically refractory focal epilepsy (Figure 48–1).

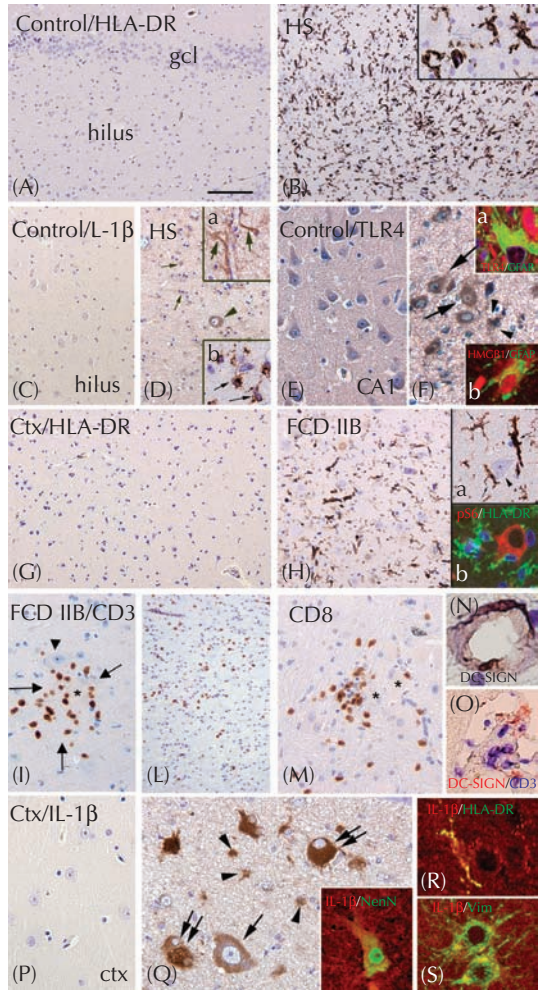

Figure 48–1. Inflammatory processes in chronic epilepsy patients: focal epilepsy.
Panels A–F: Hippocampal sclerosis (HS)[42]. **A,B**. human leukocyte antigen- (HLA-DR) immunoreactivity (IR) in the dentate region of control hippocampus (**A**; gcl: granule cell layer) and HS (**B**), showing strong, diffuse microglial activation in HS. **C,D**. Interleukin-1β IR in the hilar region of control hippocampus (**C**) and HS (**D**), showing HS expression in residual neurons (arrow) and reactive glial cells (arrows and inserts a and b; insert b shows IL-1β immunoreactivity in perivascular astrocytic endfeet). **E,F**. Toll like receptor (TLR4) IR in the CA1 region of control hippocampus (**E**) and HS (**F**), showing in HS expression in residual neurons (arrows) and reactive glial cells (arrowheads)[51]. Insert a in **F**: colocalization of TLR4 (red) with GFAP (green) in a reactive astrocyte. Insert b in **F**: High Mobility Group Box 1 (HMGB1; red) IR, showing both nuclear and cytoplasmic localization in astrocytes (GFAP, green) in HS.
Panels G–O: Focal cortical dysplasia (FCD) type IIB[65,67]. **G,H**. Human leukocyte antigen-DR IR in control cortex (**G**) and HS (**H**), showing strong, diffuse microglial activation within the dysplastic cortex; insert a in **H** shows activated microglial cells (arrows) surrounding a dysmorphic neuron (arrowhead); insert b in **H**: merged image showing HLA-DR-positive microglial cells (green) surrounding a phospho-S6 ribosomal protein (pS6)-positive balloon cell (red). **I,L**. An FCD specimen with CD3-positive cells in cortex (**I**) and white matter (**L**); arrows in **I** show lymphocytes surrounding a balloon cell (asterisk) and a dysmorphic neuron (arrowhead); **M**. CD8-positive T lymphocytes in FCD surrounding balloon cells (asterisks). **N–O**. An FCD specimen showing perivascular DC-SIGN (CD209)-positive cells. **O**. Perivascular distribution of DC-SIGN-positive (red) and CD3-positive (blue) cells.
Panels P–S: Interleukin-1β IR. **P,Q**. Interleukin-1β IR in control cortex (**P**) and in FCD (**Q**)[65,67]. Strong IL-1β IR was observed in large, dysplastic neurons (single arrow), in glial cells (single arrowheads), and in balloon cells (double arrowheads) within the dysplastic cortex (FCD; Q). Insert in Q: colocalization of IL-1β (red) with NeuN (green) in a dysmorphic neuron. **R**. colocalization of IL-1β (red) with HLA-DR (HLA; green) in a microglial cell. **S**. Colocalization of IL-1β (red) with vimentine (VIM; green) in astroglial cells.
Scale bar in **A**: **A-D**, **G-H**, **L**: 160 μm; **E-F, I, M, P-Q**: 80 μm. **N**: 20 μm. **O**: 40 μm; **Q-R**: 25 μm.

HIPPOCAMPAL SCLEROSIS

Hippocampal sclerosis (HS), also known as *Ammon's horn sclerosis*, is the most common neuropathological finding in patients undergoing surgery for intractable TLE. The minimal criteria for the diagnosis of HS are summarized in an International League Against Epilepsy (ILEA) Commission report[40] and include selective neuronal cell loss and gliosis in CA1 and endfolium. Astrogliosis is a major feature of HS. It can be confirmed by immunostaining for glial fibrillary acidic protein (GFAP), showing dense astrogliosis in the hilar region of the dentate gyrus as well as in cornu ammonis (CA) subfields, where prominent neuronal loss is observed (CA3, CA1). This often includes fibrillary gliosis, which supports the chronicity of the process. Microglial activation has also been shown within the hippocampus in HS cases.[41–44] In contrast to the prominent activation of glial cells, few cells of adaptive immunity (CD3/CD8-positive T lymphocytes, mainly associated with microvessels) have been detected in human TLE hippocampi.[42]

Crespel et al.[45] reported the activation of NFκB, a transcriptional factor activated by inflammatory molecules and responsible for transcriptional upregulation of various pro-inflammatory genes, in reactive astrocytes and surviving neurons in human HS specimens. A more recent histological study[42] demonstrated prominent and persistent activation of the IL-1β system, both in activated microglia and astrocytes and in neuronal cells, thus largely confirming the findings reported in chronic epileptic rats.[46]

The activation of inflammatory pathways in human TLE is supported by gene expression profile analysis[44] and includes the complement pathway, which was shown to be overexpressed by both reactive astrocytes and microglia/macrophages.[47] These observations suggest the existence of a reinforcing feedback between the pro-inflammatory cytokine system and the components of the complement cascade, which may be critical for the propagation of the inflammatory response in human TLE with HS.

A recent study demonstrated activation of the plasminogen system, as exemplified by increased expression of tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) in human HS.[48] This may critically influence both neuronal activity and the inflammatory response. Since IL-1β, complement components, and plasminogen activators have been reported to affect the permeability properties of the blood-brain barrier (BBB),[4] we might speculate that the leaky BBB that is observed in HS[49,50] might be partly sustained by the inflammatory actions of different molecules that surround the blood vessels.

Attention has recently focused on the role in seizure precipitation and recurrence of Toll-like receptor (TLR) signaling pathways[51] (see the section "Experimental Models" and ref. 51). Interestingly, prominent and persistent overexpression of TLR4 and its endogenous ligand, high mobility group box 1 (HMGB1), has been demonstrated in glia and neurons in human TLE within the hippocampus, with a cellular distribution that confirm the findings reported in chronic epileptic mice (Figure 48–2).[51]

FOCAL MALFORMATIONS OF CORTICAL DEVELOPMENT

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is an autosomal dominant multisystem disorder resulting from a mutation in the *TSC1* or *TSC2* gene.[52] In addition to autism and cognitive disabilities, epilepsy is the most common neurological symptom of TSC. Epilepsy is present in 70%–80% of individuals with TSC (reviewed in ref. 52). The characteristic brain lesions of TSC are cortical tubers, subependymal nodules, and subependymal giant cell tumors.[53]

Activation of inflammatory pathways in cortical tubers was suggested initially by the presence of macrophages and alterations in the expression of tumor necrosis factor-α (TNF-α), NFκB, and cell adhesion molecules in these lesions.[54] A subsequent study demonstrated that prominent inflammatory changes (i.e., activation of the complement cascade and IL-1β signaling) observed in these lesions include both activated microglia and astrocytes, as well as the adaptive immune response.[55] In addition, focal changes in BBB permeability were detected in both cortical tubers and SEGA, as demonstrated by perivascular leakage of serum albumin, with uptake into astrocytes.[55] Gene expression analysis of cortical tubers showed that inflammatory genes and cell adhesion

molecules are highly expressed in tubers compared with autopsy controls.[48,56] Various potential mechanisms may underlie the presence of inflammatory cells in the TSC-associated lesions, and further investigation is required to ascertain the involvement of the mTOR pathway, influencing both brain parenchymal and adaptive immune responses.[57,58]

A recent study suggests that astrogliosis in tubers is a dynamic process, with progression of astrocytes from "reactive" to "gliotic."[59] In addition, apoptotic cell death is observed in cortical tubers.[54–56] Thus, prominent activation of the inflammatory cascade could also play a role in the dynamics of TSC lesions and might contribute to progressive neuronal and glial cell injury in TSC patients.

Finally, whether the presence of a prominent population of inflammatory cells may contribute to the behavioral disorders in TSC deserves further investigation. Immunological dysfunctions and microglial activation occurring early during development have been implicated in autism, which is common in TSC patients (for reviews, see ref. 60).

Focal Cortical Dysplasias

Focal cortical dysplasias (FCD) are sporadic architectural and cytoarchitectural malformations of the cerebral cortex that are recognized causes of chronic medically intractable epilepsy in children and young adults.[61–63] According to the current histopathological classification system, FCD have been classified as type I, characterized by cortical dyslamination, and type II, characterized by additional cytoarchitectural abnormalities (i.e., the presence of dysmorphic neurons and balloon cells).[62] Evidence of both necrotic and apoptotic cell death has been reported in pediatric FCD cases, suggesting that intractable epilepsy in childhood due to FCD could be associated with progressive cell injury.[64]

Activation of astrocytes and cells of the microglia/macrophage lineage has been described in FCD specimens from both pediatric and adult patients.[64–66] In a cohort of FCD patients, the density of activated human leukocyte antigen- (HLA-DR)-positive microglial cells (but not CD68-positive macrophages), and the level of expression of IL-1β in parenchymal glia and neurons, correlate positively with the duration of epilepsy, as well as with the frequency of seizures prior to surgical resection.[66,67] The number of HLA-DR-positive cells was significantly higher in FCD type II compared to type I despite the absence of significant differences in seizure frequency and duration.[65] Activation of complement and IL-1β signaling pathways and the chemokine monocyte chemoattractant protein-1 (chemokine (C-C motif) ligand 2, CCl2) in activated microglia, astrocytes, dysplastic neurons, and balloon cells were also more pronounced in FCD type II.[65] These results indicate that activation of inflammatory processes is not simply an effect of seizure activity, suggesting a role for the underlying neuropathology. mTOR activation observed within the cellular components of type II but not type I FCD could also contribute to the inflammatory response.

Some degree of activation of adaptive immunity has also been observed in FCD, and the presence of CD8+ T lymphocytes was greater in FCD type II specimens than in FCD type I.[65] In the same study, dendritic cells (antigen-presenting cells involved in the initiation of the adaptive immunity) were detected around intraparenchymal blood vessels only in FCD type II specimens.[65]

Increased levels of pro-inflammatory cytokines and chemokines have also been shown in pediatric FCD cases.[64] There is also evidence of activation of plasminogen,[65] toll-like receptors (TLR),[68] and vascular endotheliala growth factor (VEGF)-mediated signaling,[55] which, through different mechanisms, could contribute to glial activation and associated inflammatory reactions.

Glioneuronal Tumors

Glioneuronal tumors (GNTs), including ganglioglioma (GG) and dysembryoplastic neuroepithelial tumors (DNTs), are well-differentiated, slowly growing neuroepithelial tumors. They are rare tumors, representing approximately 1.3% of all brain tumors.[69] However, GG appear to constitute the most frequent tumor entity in young patients undergoing surgery for intractable epilepsy.[70]

Glioneuronal tumors are characterized by a mixture of dysplastic neurons and glial cells

and have been included in the group of developmental disorders characterized by abnormal cell proliferation.[71] Abundant populations of activated microglial cells and perivascular lymphocytes are common features of these tumors.[69,72] In both GG and DNT, a significant number of microglia/macrophages are observed within the tumor and in the peritumoral regions. The density of activated microglial cells, as well as the IL-1β levels in parenchymal cells, correlate with the duration of epilepsy, as well as with the frequency of seizures prior to surgical resection.[67,72] In GG, both gene expression and immunocytochemical studies[72,73] provide evidence of prominent activation of the inflammatory response, including the presence of perivascular T-lymphocyte and T-cell receptor signaling pathways within the tumor.[73] Upregulation of IL-1β and IL-1R1, as well as activation of the complement cascade and the Toll-like receptor pathway in glia and neurons, are consistent features of GG.[73]

EXPERIMENTAL MODELS

Experimental models of seizures and epilepsy were instrumental in investigating the causes of brain inflammation in human epilepsy, and in demonstrating that specific inflammatory pathways are crucially involved in seizure precipitation and recurrence.

Models of Seizures in Adult Animals

SEIZURES AND INFLAMMATION

A novel concept emerging from experimental findings is that seizure activity in adult mice or rats triggers the synthesis and release of various pro-inflammatory molecules in the brain. In particular, a pro-inflammatory response occurs during seizures provoked by chemoconvulsants or electrical stimulation in brain areas where seizures are generated and spread.[4] This response includes a rapid-onset rise in pro-inflammatory cytokines in glia and may also involve neurons. This phenomenon is accompanied by upregulation of TLR and their endogenous ligands, such as HMGB1,[51,74] followed by a cascade of downstream inflammatory events that include the activation of NFκB, chemokine production, complement system induction, and increased expression of adhesion molecules.[4,47,75–77] Upregulation of receptors for pro-inflammatory cytokines both in glia and neurons in seizure models suggests that both autocrine and paracrine actions take place, with possible different functional outcomes (for review, see ref. 4).

The astrocytic endfeet impinging on brain microvasculature and the endothelial cells of the BBB also produce inflammatory molecules during seizures, suggesting that brain inflammation is involved in the BBB damage described in experimental and human epileptogenic tissues (for reviews, see refs. 4, 7, and 78). Indeed, pro-inflammatory cytokines have been shown to cause the disassembling of the tight junctions, the production of nitric oxide (NO) and the activation of matrix metalloproteinases in endothelial cells.[3,4,78–80]

The cascade of inflammatory mediators in brain parenchyma, production of chemokines, and upregulation of adhesion molecules on endothelial cells may in principle recruit immunocompetent cells from the bloodstream, resulting in brain extravasation of macrophages, leukocytes, and lymphocytes. However, this peripheral inflammatory component is not prominent in animal models of TLE.[42,74] T and B cells, but not neurotrophils, were transiently detected in mouse brain between 24 and 72 h after generalized seizures induced by maximal electroshock test (MES).[81]

Importantly, seizures can induce cytokine expression independently on cell death, as clearly shown in nonlesional models of seizures.[17,81–83] By contrast, inflammation caused by seizures precedes cell loss in lesional models[42] and may contribute to it. The causal role of inflammation in cell loss is supported by findings in developmental models of seizures[84] and by the evidence that injections of inflammatory mediators can exacerbate apoptotic and excitotoxic cell death.[85,86]

ROLE OF INFLAMMATION IN SEIZURES

The injection of pro-inflammatory molecules such as IL-1β,[82,87] TLR agonists,[51] complement system components,[88] or specific prostaglandins[76,89] in rodent brain results in receptor-mediated pro-convulsant effects. In contrast, the intracerebral injection of specific antagonists of some of these pro-inflammatory

molecules, or interference with related intracellular signaling pathways, mediates powerful anti-convulsant or neuroprotective effects.[51,87,90–95] Transgenic mice with perturbed cytokine signaling show significant changes in seizure susceptibility or cell damage,[83,96–99] thus supporting the pharmacological evidence of a modulatory role of cytokines in neuronal excitability. IL-6 and TNF-α have either pro-convulsant or anti-convulsant effects, depending on the cytokine receptor subtype predominantly activated and/or the specific mechanism underlying epileptic activity initiation and spread (for review, see ref. 4). Similarly, cyclooxygenase-2 (COX-2) inhibition produces different outcomes on seizures, depending on the experimental models.[76] Pro-ictogenic or anti-convulsant effects are likely due to the types of prostaglandins produced in the various models of seizures. Thus, prostaglandin factor 2 (PGF2) has anti-convulsant properties,[92] while PGE2 is a pro-neurotoxic and pro-convulsant prostaglandin.[89,100]

Interleukin-1β has pro-convulsant activity in different models of acute seizures; accordingly, intracerebral application of IL-1ra or inhibition of IL-1β synthesis using caspase-1 inhibitors also provides anti-convulsant effects in models of AED-resistant seizures.[83,90,91,93,95] (for review, see ref. 4). HMGB1, an endogenous ligand of Toll-like and RAGE receptors with pro-inflammatory properties,[101] upon its release from neurons following injury or hyperexcitability, contributes to the precipitation and recurrence of seizures in mice.[51]

ROLE OF INFLAMMATION IN EPILEPTOGENESIS

Inflammatory responses induced by brain-damaging events such as neurotrauma, stroke, infection, FS, and status epilepticus are associated with acute symptomatic seizures and a high risk of epilepsy development.[102,103] In particular, immunohistochemical analysis of IL-1β and its receptor, IL-1R1, and complement factors showed that brain inflammation induced by status epilepticus persists during epileptogenesis and is still detectable in chronic epileptic tissue characterized by spontaneous recurrent seizures. These pro-inflammatory changes occur predominantly in activated microglia and astrocytes, although they also involve neurons and endothelial cells of the BBB.[42,47,51] COX2 shows a dual profile of induction since it is induced in neurons during status epilepticus, while it is significantly upregulated in astrocytes in epileptogenesis and during chronic seizures.[76,104,105] Microarray studies have shown that pro-inflammatory signals linked to the immune/inflammatory response are among the biological systems mostly upregulated during epileptogenesis.[106–108]

The evidence of lasting brain inflammation after various pro-epileptogenic injuries,[7,103,109] together with the established contribution of specific inflammatory mediators to the seizure threshold and epileptic activity, suggests that inflammation in the brain may have a role in the development of epilepsy. Pharmacological studies were therefore designed to interfere with specific pro-inflammatory pathways during epileptogenesis.

In this context, different COX-2 inhibitors were tested in the lithium-pilocarpine or electrical status epilepticus models, starting the treatments after status epilepticus and continuing drug administration for different lengths of time. Two studies, using celecoxib or parecoxib, showed a reduction in the percentage of epileptic rats and a decrease in spontaneous seizure frequency and duration, or reduced seizure severity, respectively. Reduced cell loss and milder microglia activation were also reported.[104,110] Conversely, no effects of COX-2 inhibitors on spontaneous seizure onset and severity or neuropathology were reported when SC8236 was used[111]; however, in this study, a longer duration of status epilepticus was allowed before treatment and drug administration during epileptogenesis was shorter.

Ravizza et al.[112] showed that blockade of IL-1β biosynthesis using systemic administration of a specific interleukin converting enzyme (ICE)/caspase-1 inhibitor prevents the acquisition of stage 5 seizures in the rapid kindling model of epileptogenesis without changing the afterdischarge duration. After drug withdrawal, electrical stimulation did not evoke generalized seizures; moreover, drug administration in fully kindled rats did not affect stage 5 convulsions. These results suggest an antiepileptogenic effect due to inhibition of IL-1β production in astrocytes. These results are supported by lack of IL-1β immunostaining in glia of treated rats compared to control kindled rats. In contrast, anti-convulsant effects of IL-1β were reported

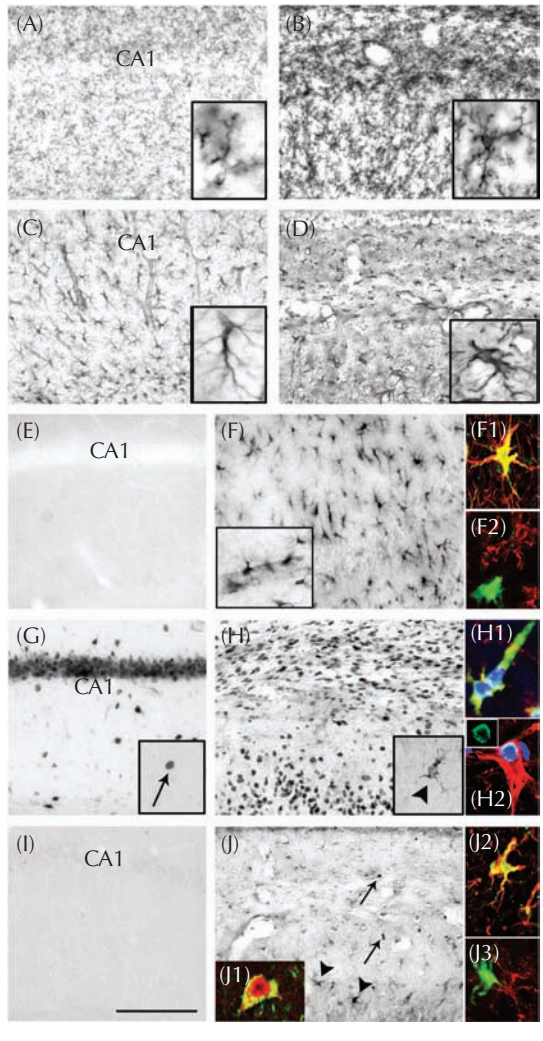

Figure 48–2. Inflammatory processes in the hippocampus of epileptic mice[51,95].
Panels A,D. Immunohistochemical evidence of gliosis: CD11b (**A,B**) and GFAP (**C,D**) staining in control (**A,C**) and epileptic mice (**B,D**). Insets report high magnification of immunopositive glia cells. In control mice, CD11b staining was observed in resting microglia cells (**A**), and GFAP immunoreactivity was observed in stellate-shaped astrocytes with thin processes denoting their resting state (**C**). In epileptic mice, CD11b denotes strongly immunopositive cells with a round shape and thick processes (**B**); GFAP immunostaining was increased in astrocytes exhibiting hypertrophic cell bodies and processes (**D**).
Panels E–F2. Interleukin-1β immunostaining control (**E**) and epileptic mice (**F–F2**). In control mice, IL-1β staining was absent (**E**), while in epileptic mice, it was increased in GFAP-positive parenchymal astrocytes (**F**; colocalization in **F1**: IL-1β green, GFAP red) and in perivascular astrocytes (inset in **F**). CD11b-positive microglia did not express IL-1β (**F2**: IL-1β green, CD11b red).
Panels G–H2. HMGB1 immunoreactivity in control (**H**) and epileptic mice (**H–H2**). In control mice HMGB1 was observed in the nuclei of pyramidal neurons, and in the nuclei of scattered cells in strata radiatum-lacunosum molecolare (**G** and its inset). Epileptic mice have an increased number of HMGB1-positive cells (**H**), and HMGB1 signal is also present in the cytoplasm of cells with glial morphology (inset in **H**). Colocalizations show that HMGB1 is present in the cytoplasm of CD11b-positive microglia-like cells (colocalization in **H1**: HMGB1 green, CD11b red, Hoecsht blue), and around nuclei in GFAP-positive astrocytes (colocalization in **H2**: HMGB1 green, GFAP red, Hoecsht blue; see also HMGB1 alone in the inset).
Panels I–J3. TLR4 signal in control (**I**) and epileptic mice (**J–J3**). TLR4 immunoreactivity is not detected in control mice (**I**), while in epileptic mice it is present in neurons (arrows in **J**; colocalization in **J1**: TLR4 green, NeuN red) and in GFAP-positive astrocytes (arrowheads in **J**; colocalization in **J2**: TLR4 green, GFAP red). CD11b-positive microglia do not express TLR4 (colocalization in **J3**: TLR4 green, CD11b red). Scale bar: **A–J**, 100 μm; insets in **A–J, F1, F2, H1, H2, J1–J3**, 20 μm.

in one study showing reduction of afterdischarge and stage 5 seizure duration in fully amygdala-kindled rats after intracerebroventricular (icv) cytokine injection.[113] Reduction of the kindling rate was also observed in the same study after repetitive daily icv injections of low doses of IL-1β. This cytokine, given by the icv route, might have caused increased levels of glucocorticoids in response to direct hypothalamic-pituitary-adrenal (HPA) axis activation, which in turn could be responsible for the protective effects in kindling.

The role of the leukocyte-endothelial cell adhesion mechanism in epileptogenesis was studied in lithium-pilocarpine-treated mice.[77] The underlying hypothesis is that leukocyte adhesion to brain microvessels would impair BBB permeability functions contributing to chronic hyperexcitability. Thus, leakage of serum albumin into brain parenchyma, and its subsequent astrocytic uptake, has been shown to decrease the K^+ buffering and glutamate reuptake capacity of glia leading to ionic imbalance and increased extracellular glutamate, which would favor the development of seizures.[114,115] The administration of specific antibodies against adhesion molecules after status epilepticus for 20 days resulted in a reduced frequency of spontaneous seizures, as assessed during antibody treatment, but no changes in their onset time or duration. Decreased neuropathology and preservation of exploratory behavior were observed in treated epileptic mice. Although these data suggest the potential involvement of leukocytes in epileptogenesis, one important caveat is that pilocarpine itself stimulates leukocytes via a primary peripheral inflammatory action. This effect provokes BBB leakage and ionic imbalance, and allows enough systemic pilocarpine to enter the brain to trigger seizures and epileptogenesis.[116] Therefore, it remains to be proven in additional experimental models whether this mechanism is generally operative in epilepsy.

T and B cells do not appear to play a significant role in epileptogenesis. This is suggested by two studies. One study showed that tacrolimus, an immunosuppressant drug blocking T-cell activation, did not modify the onset of spontaneous seizures, or their frequency and duration, when administered after electrically induced status epilepticus for 2 weeks.[117] The other study showed that mice lacking T and B cells develop status epilepticus and spontaneous seizures similarly to their wild-type controls.[118]

Models of Seizures in Immature Animals

Seizures occur more frequently early in life. Febrile seizures are the most frequent etiology of seizure in childhood. In humans, initial precipitating injuries, including FS during childhood, are risk factors for the development of epilepsy.[119] Animal models have been used to elucidate the underlying mechanisms of seizure occurrence and epileptogenesis in immature brain, and inflammation has emerged as a possible major contributor.

If inflammation facilitates seizure occurrence in mature brain in almost all models, it affects seizures differently in immature brain, depending on the trigger of seizures.

Interleukin-1β lowers the core temperature threshold that results in seizures in a postnatal (PN) day 14 mouse model of febrile convulsions, acting on IL-1R1.[16] Similarly, using a subconvulsive dose of kainate in PN14 rats, Heida and Pittman[120] showed that lipopolysaccharide (LPS) exerts pro-convulsant effects when the animals are febrile by favoring seizure precipitation in 50% of rats. At the onset of seizures, IL-1β was significantly increased in the hippocampus only in rats experiencing seizures after administration of LPS and kainate. When IL-1β was given icv in LPS-treated febrile rats, the percentage of animal seizing after a subconvulsant dose of kainate was significantly increased and the onset time to seizures was reduced. The opposite was found after icv injection of IL-1ra. These studies show that FS may be caused by excessive amounts of IL-1β in the hippocampus.

In contrast, LPS at low doses that do not increase the core temperature did not change acute susceptibility to short hyperthermic seizures in both PN11 and PN16 rats.[121] However, these animals developed a decreased threshold to pentylentetrazol (PTZ) as adults. A similar nonfebrile dose of LPS did not exacerbate lithium-pilocarpine-induced status epilepticus at PN7 and PN14. On the contrary, it induced

a delay in the onset of status epilepticus. However, these rats developed increased seizure-induced hippocampal damage.[122] Nonfebrile doses of LPS have been reported to decrease the seizure threshold in adult mice exposed to PTZ[123] and to accelerate the onset of seizures in lithium-pilocarpine-treated adult rats (Auvin et al., unpublished data).

It appears from these findings that relatively low doses of LPS in immature rats, which do not cause an increase in core temperature, do not alter the acute susceptibility to seizures, although they increase the seizure-induced cell loss and the long-term predisposition to seizures. Moreover, the effects of LPS in immature and adult animals clearly differ since nonfebrile doses exacerbate seizures in adults. The mechanisms underlying these effects, and the role played by fever and brain inflammation in determining the short- and long-term changes in seizure threshold, remain to be to be elucidated. Interactions between LPS-induced cytokine production and activation of the HPA axis, with consequent production of anti-inflammatory glucocorticoids, may be important determinants of the outcomes since both phenomena are developmentally regulated and may be differently affected by the experimental setting adopted to induce seizures.

Inflammation and Seizure-Induced Cell Injury in Immature Brain

The relationship between seizures and neuronal injury in rodents is specific to the stage of development and the model employed to precipitate seizures. The younger the animal, the lower the level of seizure-induced cell injury.[124,125] The key determinants of the age-dependent occurrence of seizure-induced injury are still incompletely understood. Recent data point to the possible involvement of inflammatory mediators, as exemplified below.

When PN9 to PN21 rats are exposed to status epilepticus induced by kainate, both cytokine expression and glia activation occur from the second postnatal week on; this temporal pattern of seizure-induced inflammation closely overlaps with that of seizure-induced cell injury. Moreover, brain inflammation precedes evidence of cell loss, suggesting that pro-inflammatory cytokines may contribute to its occurrence.[84] A causal link between inflammation and cell death in immature brain is further supported by the evidence that LPS given prior to lithium-pilocarpine-induced status epilepticus increases cell injury in hippocampus at PN7 and PN14.[122] This effect occurs in the absence of changes in body temperature or in the duration of status epilepticus.[122]

These studies suggest that inflammation during postnatal development may enhance cell injury following prolonged seizures, highlighting a possible contribution to the development of epileptogenesis.

Long-Term Consequences of Inflammation for Immature Brain

Systemic or CNS inflammation *by itself* during a critical postnatal period is able to induce long-term changes in neuronal excitability and alterations in physiological behaviors.

When LPS was given to rats on PN7 or PN14, but not before (PN1) or afterward (PN20), seizure susceptibility was increased when these rats become adults, as assessed using PTZ, lithium-pilocarpine, and kainate. Brain inflammation induced in PN14 mice by icv injection of polyinosinic:polycytidylic acid (Poly I:C), a TLR3 agonist that mimics viral infections, was also responsible for the increased seizure susceptibility in adulthood, as shown using PTZ and lithium-pilocarpine.

A deficit in contextual fear conditioning memory was reported in both experimental settings, while retention of spatial memory was affected only by the LPS treatment.

The LPS study points out the involvement of TNF-α and activated astrocytes[126] in the long-term consequences of brain inflammation, while the Poly I:C study highlights the possible involvement of IL-1β and activated microglia.[127] This suggests that different inflammatory mechanisms may be activated, depending on the first trigger. Interestingly, in both models of inflammation, long-term changes in hippocampal levels of several glutamate receptor subunits were reported,[127,128] revealing a pathophysiological relationship between brain cytokines, glutamate receptors, behavior, and seizures.

Inflammation in immature brain also seems to act as a disease modifier when it is *coupled*

to a second hit. Systemic injection of low and nonfebrile dose of LPS in PN14 rats before lithium-pilocarpine did not change the severity of acute status epilepticus but resulted in more severe (stages 3–4) spontaneous seizures in adulthood.[121] Administration of LPS did not change the number of rats that became epileptic or the frequency and duration of spontaneous seizures. No significant changes in cell number in the CA1 sector was observed in LPS-pretreated rats, although in some animals Fluoro-Jade-positive cells were detected, suggesting ongoing neurodegeneration, which was absent in rats not preexposed to LPS. A more intense reactive gliosis was also found in CA1 in rats pretreated with LPS.[129]

It was found that LPS enhanced rapid kindling progression in P14 rats and increased hippocampal excitability after kindling completion. These effects were prevented by IL-1ra, indicating the involvement of IL-1β in the mechanisms of hyperexcitability.[129,130] The possibility that brain inflammation contributes to epileptogenesis, is supported by the work of Marcon et al.[131] By inducing status epilepticus in PN9 and PN21 rats, these authors showed long-lasting brain inflammation and vascular changes, including BBB damage and angiogenesis, in PN21 rats but not in PN9 rats. Notably, P21 rats, but not P9 rats, showed a propensity to develop epilepsy after status epilepticus.

Mechanisms of Hyperexcitability

Emerging evidence has shown that nonconventional intracellular signaling pathways are activated by pro-inflammatory mediators in the epileptogenic tissue in addition to the classical induction of NFκB-mediated gene transcription described during peripheral inflammation. These novel mechanisms are likely to contribute to the neuronal hyperexcitability underlying seizures and to mediate at least part of the inflammation-related glia–neuron interactions. For example, cytokines can modify the function of glutamate and GABA receptors by altering receptor trafficking and their subunit assembly at neuronal membranes. Cytokines can also modulate glutamate receptor-mediated calcium influx in neurons by promoting alpha-amino-3-hydroxy-5-methyl-4-isoxalzolepropionate (AMPA)-GLUR2 and *N*-methyl-D-aspartate (NMDA-NR2B) receptor subunit phosphorylation via PI3K or Src kinases, respectively.[132] Recently, activation of IL-1R/Toll-like receptor signaling in neurons, either by IL-1β or by HMGB1, has been shown to play a pivotal role in seizure precipitation and recurrence via rapid Src kinase-catalyzed phosphorylation of NMDA-NR2B receptors.[51,87]

Cytokines and prostaglandins can also directly alter voltage-gated ion channel function.[132] In particular, somatic and dendritic membrane excitability was significantly reduced in CA1 pyramidal neurons using a selective COX-2 inhibitor, and PGE2 produced increased firing and excitatory postsynaptic potentials, most likely by reducing potassium currents in CA1 neurons.[133,134]

Activation of the complement system and membrane attack complex (MAC) assembly in erythrocyte membranes leads to the formation of channel conductances, resulting in Ca^{2+} and Na^{+} influx and K^{+} efflux, with the net effect of depolarizing the membrane potential.[135] If this mechanism is also operative in neurons, it may explain why MAC assembly in the hippocampus provokes seizures.

In addition, cytokines and prostaglandins inhibit glutamate reuptake by astrocytes[136,137] and enhance its astrocytic release,[138] thus resulting in increased extracellular glutamate concentration. In this regard, astrocytic glutamate release appears to contribute significantly to seizure-like events.[139,140]

Finally, inflammatory mediators can also increase vascular permeability and angiogenesis (for review, see refs. 3 and 141); their overexpression in perivascular astrocytes and endothelial cells in epilepsy may affect BBB permeability and promote excitability in surrounding neurons.[4,78]

CONCLUSIONS

Clinical and experimental evidence substantiates the role of brain inflammation in the etiopathogenesis of seizures. Clinical studies show that brain inflammation is a common substrate in epilepsies of different etiologies.

Experimental studies show that recurrent seizures can trigger and perpetuate brain inflammation even in the absence of cell loss or other concomitant or preexisting neuropathology.

Long-term inflammation, in turn, promotes chronic hyperexcitability, is detrimental to neuronal survival, induces behavioral dysfunctions, and may contribute to the maladaptive plasticity underlying epileptogenesis.

Pharmacological studies in models of seizures and epilepsy, including models of drug-resistant epilepsy, demonstrate that interfering with specific pro-inflammatory pathways can effectively reduce seizures.

These findings therefore envision novel therapies for epilepsy by targeting specific pro-inflammatory pathways. This approach has two advantages: the possibility of using drugs already available in clinical practice for septic shock or autoimmune diseases and the likelihood of interfering with a mechanism involved in the pathophysiology of seizures. This approach may therefore provides curative rather than merely symptomatic treatment.[142]

Chapter 49

Glia–Neuron Interactions

Neurosteroids and Epileptogenesis

Giuseppe Biagini
Carla Marinelli
Gabriella Panuccio
Giulia Puia
Massimo Avoli

BACKGROUND

The relationship between glial and neuronal cells has become a central topic in research aimed at establishing therapeutic strategies to restore brain functions after damage.[1–4] A brain lesion may be rather selective, involving only neuronal cells, as occurs in neurodegenerative diseases (e.g., Parkinson's disease), or it can affect all cell types present in the tissue, as in the case of pannecrosis found after cerebral ischemia or traumatic brain injury. In the latter case, regeneration and repair depend on the specific properties of the cell type that has to be replaced.

Regeneration is limited for neurons, whereas glial cells can proliferate and invade the damaged brain area that needs to be restored. These properties of glial cells lead to formation of a glial scar, consisting of astrocytes, microglial cells, macrophages, and extracellular matrix, which replace the damaged nervous tissue; a classical example of a glial scar is found in the CA1 region of patients affected by mesial temporal lobe epilepsy. Figure 49–1 illustrates reactive astrocytes and microglial cells, identified by their markers, glial fibrillary acidic protein (GFAP) and heme oxygenase-1 (HO-1), respectively, which can be found 1 week after exposure to pilocarpine-induced status epilepticus (SE) lasting for 30 min (cf. ref. 5). Evolution of the lesion into a scar has long been interpreted as the most important factor dampening the capacity to restore the normal

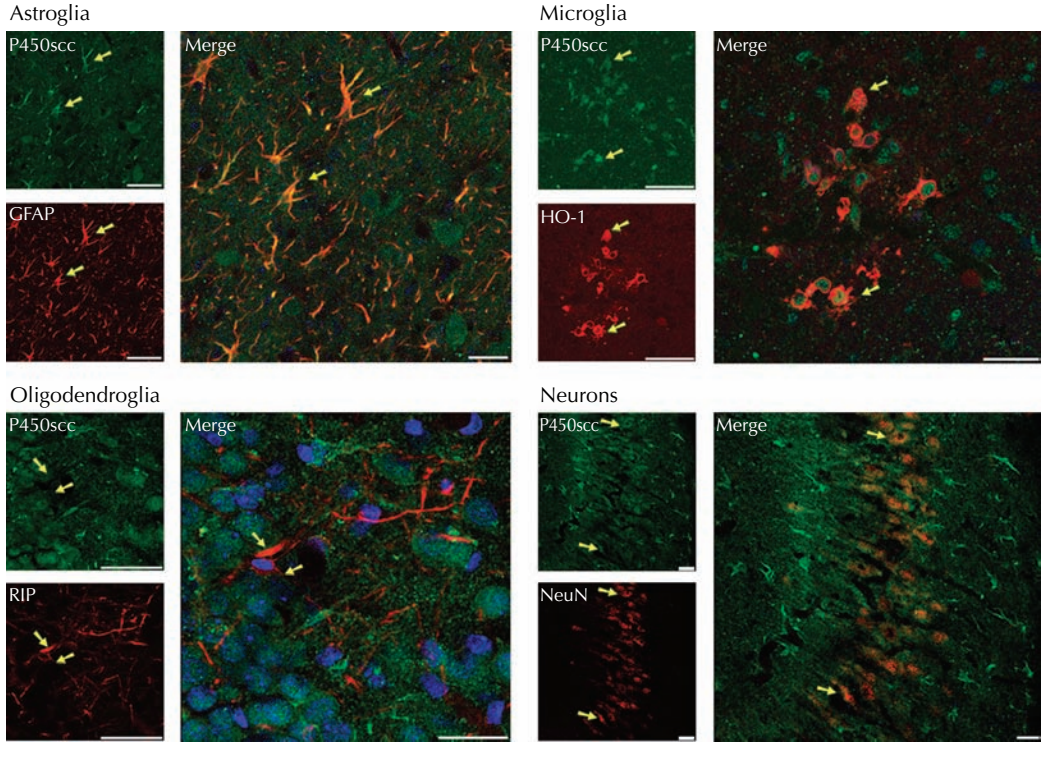

Figure 49–1. Identification of cell types involved in neurosteroid synthesis in the CA3 region of pilocarpine-treated rats. Microphotographs illustrating the colocalization of the cytochrome P450scc with markers of astrocytes (identified with GFAP), microglial cells (HO-1, expressed in the activated microglia), oligodendrocytes (RIP, which identifies the enzyme 2′,3′-cyclic nucleotide 3′-phosphodiesterase), and neurons (neuron-specific nuclear protein [NeuN]) in rats exposed to pilocarpine-induced SE lasting for 30 min 1 week after the treatment. Arrows point to examples of cells costained with P450scc and the respective cell-specific marker. Note that especially reactive astrocytes and, secondarily, neurons express the highest levels of P450scc immunoreactivity. The vast majority of HO-1-positive microglial cells also appear to present P450scc staining. At variance, RIP-positive oligodendrocytes present very low levels of P450scc immunoreactivity. Scale bars, 25 μm.

function of neuronal networks.[3] Although this process can be modulated by a variety of molecules synthesized in response to damage by the different cell types involved, astrocytes and neurons have in common the ability to secrete neurosteroids, which are able to deeply influence the outcome of a lesion.[6]

In contrast to neuroglia (astrocytes, ependymal cells, and oligodendrocytes), microglial cells are mesodermal in origin and serve as the central nervous system's innate immune apparatus.[4] Resting microglial cells, as they are found in normal conditions, are resident but not functionally silent elements, as they make transient but regularly recurrent contacts with synapses.[7] Following an insult, microglial cells become reactive by expanding their ramified morphology and assuming an ameboid structure that enables them to migrate. It is highly controversial whether only resident or also circulating precursor cells may be transformed into reactive microglia.[8,9] In any case, resident microglial cells have the potential to develop into mature macrophages, acting as phagocytes to remove dying cells and as regulators of the inflammatory reaction by releasing cytokines.[4] Although there is evidence of a neurotoxic role for reactive microglia,[10] a neuroprotective effect of microglial cells has been found in different models of neurodegeneration or acute lesions.[4]

Following the development of a lesion, astrocytes, which are the main glial cell type involved in assisting neuronal transmission in normal conditions,[11] transform into reactive cells by developing hypertrophic cytoplasmic processes and somas and by overproducing intermediate filaments (GFAP, vimentin, and

nestin), trophic factors (ciliary neurotrophic factor, basic fibroblast growth factor, and nerve growth factor), or pro-inflammatory (interleukins [ILs], prostaglandins) and neurotoxic (protein S100β in its reduced state, nitric oxide) molecules.[2] As in the case of microglial cells, the role of astrocytes in the recovery from a lesion is controversial, but lines of evidence suggest that these glial cells contribute to preserve spared neurons and keep them from dying.[3] A further intriguing aspect of astrocyte reactivity is that gliosis can be directly elicited by neuronal overactivation, such as that occurring during brief seizures in the absence of overt neuronal damage.[12] At variance, spreading depression was also demonstrated to produce upregulation of GFAP synthesis.[13] This evidence suggests that neuronal damage is not necessary to activate a glial response and that astrocytes are indeed responsive to perturbations in neuronal network functioning.

MULTIFACETED GLIAL MODULATION OF NEURONAL EXCITABILITY

One of the recent major achievements of neuroscience is the recognition of the role played by astrocytes in modulating neuronal transmission.[10,14–16] Transmitters released by glial cells (*gliotransmitters*), such as adenosine or adenosine triphosphate[17] and D-serine,[18] have been proved to modulate synaptic plasticity in the hippocampus, whereas glia-derived gamma-aminobutyric acid (GABA) and glutamate are both able to influence the properties of postsynaptic currents (cf. ref. 11). For instance, slow inward currents are generated by hippocampal neurons in response to glutamate released by astrocytes, a recently identified mechanism of neuronal synchronization that is particularly evident in the juvenile rodent brain.[19–21]

In the epileptic brain, decreased astrocytic expression of glutamine synthetase may favor extracellular glutamate accumulation by altering the glutamate-GABA metabolic cycle.[22] Notably, ictogenesis is observed in mice when the astrocytic glutamate uptake function is impaired by genetic ablation of the glutamate transporter 1/excitatory amino acid transporter 2 (GTL-1/EAAT2).[23] Nonetheless, glial cells may also prolong epileptogenesis by releasing neurosteroids,[24,25] which are potent modulators of GABAergic transmission.[26] Thus, astroglial cell function could likely have important consequences for the ability of neurons to synchronize and generate epileptic activity (cf. ref. 27).

The impact of these diverse glial functions on neuronal synchronization is expected to be more pronounced in the presence of brain damage, when glial cells are activated to aid in recovery from a lesion. In this situation, the astrocytic release of trophic factors[3] and cytokines,[28] or of regenerative molecules such as neurosteroids,[6,29] may deeply alter the modulatory effects of glial cells on neuronal transmission.

Astrocyte–Neuron Interactions Leading to Synchronization in Undamaged Tissue

Astrocytes play an important role in neuronal synchronization in undamaged tissue; thus, they can potentially participate in generating seizures in the presence of ictogenic stimuli. Accordingly, glutamate is released by astrocytes in response to calcium oscillations in the hippocampus, thereby acting as a gliotransmitter contributing to synchronous neuronal firing.[20]

In vitro experiments have demonstrated that the frequency of calcium oscillations significantly increases in astrocytes during epileptiform activity, a phenomenon that is sensitive to antiepileptic drugs.[21] More recently, experiments performed in the rat entorhinal cortex in vitro and in the guinea pig whole brain preparation[30] have demonstrated that calcium elevation in astrocytes correlates with the initiation and maintenance of ictal-like activity, which is further enhanced by stimulation of astrocytic calcium signaling. In contrast, interictal-like discharges are not correlated to or influenced by changes in astrocytic calcium elevations.

This evidence further supports the view that glia and neurons are reciprocally engaged in a loop of recurrent excitation, which, in turn, may initiate and sustain ictal-like synchronization. It is important to stress that astrocytes can synthesize dehydroepiandrosterone[31] and its sulfated form, which, along with other neurosteroids, such as sulfated pregnenolone and

pregnanolone, can potently modulate glutamatergic transmission.[32–34] Therefore, it would be relevant to understand if and how these glia-derived neurosteroids may influence the astrocyte-neuron excitatory loop contributing to ictogenesis.

Astrocyte–Neuron Interactions Leading to Synchronization in Damaged Tissue

The role of glial cells in regulating neuronal synchronous activation leading to ictogenesis may be more pronounced in damaged tissue, where gliotic processes are triggered to aid in brain repair. In light of this view, neuronal hyperexcitability seen in postlesional epilepsies, which follow a brain damage, may represent a paradoxical consequence of reactive gliosis and the resulting glial scar. As shown in a recent study,[35] focal increase in reactive astrocytes in CA1 leads to impairment of inhibitory synaptic currents, which is paralleled by a relative increase of synaptic excitability consequent to impairment of the astrocytic glutamate-glutamine cycle.

Whereas the functional consequences of the glial scar are still a matter of controversy,[3] there is evidence suggesting that astrocytes can provide protection from secondary neurodegeneration.[36] Accordingly, by selectively ablating newly formed astrocytes in transgenic mice, it has been shown that neuronal cell loss is significantly increased a week after a moderate traumatic brain injury.[37] Thus, therapeutic strategies aimed at activating astrocytes may be beneficial to the progression of epileptogenic brain lesions.[1,2,38]

Various mechanisms are altered because of the astroglial reaction to tissue damage, and they have been suggested to be involved in promoting neuronal synchronization.[27,39] First, astrocytes are key players in buffering increased extracellular potassium, but this function is disrupted in the presence of blood-brain barrier leakage; accordingly, active transport of extravasated albumin into astrocytes induces the release of transforming growth factor β (TGF-β), which, by an autocrine mechanism, impairs potassium transport in astroglial cells.[39,40] Notably, potassium homeostasis can be further dysregulated by downregulation of channels involved in mediating water flow from the interstitium to blood vessels, especially aquaporin 4, as seen in the astrocytes of patients affected by mesial temporal lobe epilepsy.[41] Second, astrocytes are normally organized in nonoverlapping domains that are exclusive for each astroglial cell,[10] but this segregation is partially lost in epileptic mice: this change appears to be specifically related to seizure activity, and it is accompanied by morphological modifications in neuronal shape consisting of hypertrophy of apical dendrites and increased spine density.[42] Third, astrocytes are actively involved in metabolizing the endogenous anti-convulsant adenosine by the enzyme adenosine kinase (ADK); consistently, in ADK-deficient mice, the reactive gliosis consequent to kainate-induced neuronal damage is not accompanied by development of spontaneous recurring seizures.[43] Fourth, astrocytes activated by brain damage produce and secrete pro-inflammatory molecules, such as IL-1β, which displays pro-convulsive effects.[44] Although it is unclear whether these mechanisms can be affected by neurosteroids, some studies have shown that neurosteroids such as progesterone and allopregnanolone can modulate astroglial reactivity[45] and aquaporine 4 expression[46] and can interfere with inflammatory processes.[47]

Microglia–Neuron Interactions

Inflammation is generally regarded as pro-convulsive. Not only central but also peripheral inflammation (e.g., in the gut) has been shown to decrease the threshold to pentylenetetrazole-induced seizures, probably by increasing microglial cell activation and tumor necrosis factor-α (TNF-α) release in the hippocampus.[48] Microglial cells are activated within 15 min of a brain insult and synthesize IL-1β, which, in turn, is required to activate astrocytes.[49] Other cytokines and mediators released by activated microglial cells, such as IL-6 and the vascular endothelial growth factor (VEGF), have been found to be increased in the brain or plasma of animals exposed to seizures and in patients affected by epilepsy.[50] At least in the case of IL-1β, a well- defined molecular mechanism linking this glial cytokine with increased neuronal excitability has been identified, and it involves the activation of NR2B-containing *N*-methyl-D-aspartate (NMDA) receptors.[44] Although

there is no direct evidence that neurosteroids interfere with the pro-epileptogenic effects of microglial cell activation, a few studies suggest that progesterone and allopregnanolone may interact with the complement cascade to decrease inflammation[51] or to reduce the peaks of IL-1β and TNF-α induction after traumatic brain injury.[47]

NEUROSTEROIDS AND EPILEPTOGENESIS

At the beginning of the 1980s, Baulieu and colleagues found that brain levels of the steroid dehydroepiandrosterone sulfate were independent of peripheral synthesis, and that they were clearly increased by stress in castrated and adrenalectomized rats.[52] This was the first demonstration of local steroid synthesis in neural tissue and it opened the door to the concept of *neurosteroids,* that is, molecules that are directly synthesized from cholesterol in the brain. Later, it was found that the cytochrome P450 cholesterol side chain cleavage (P450scc) enzyme—which is involved in transforming cholesterol into the steroid precursor pregnenolone (Table 49–1)—is localized mainly in myelinated fibers of the white matter, (i.e., in oligodendrocytes), with the exception of scattered neuronal cells that were found to express P450scc in some limbic structures.[55] Further investigation has demonstrated that the P450scc enzyme can be found in neurons of different brain regions, including the cerebellar Purkinje cells[63] and hippocampal pyramidal cells,[56] as well as in astrocytes.[31]

We have recently reported that P450scc immunoreactivity colocalizes with HO-1, which is also expressed in reactive microglial cells[54] (Fig. 49–1). Interestingly, increased neurosteroid synthesis was found to accompany astrocytosis in the brain of postnatal myelin mutant jimpy mice,[64] suggesting that, contrary to what is found in normal neural tissue,[56] reactive astrocytes represent an important source of neurosteroids in pathological conditions.

P450scc and Epileptogenesis

Based on the localization of enzymes involved in neurosteroid synthesis in a multiplicity of brain cells (Table 49–1), and on the fact that P450scc expression can be changed by varying the glial cell's metabolic state, we surmised that neurosteroid levels could be altered in epilepsies associated with brain damage. In this context, neurosteroid levels could be downregulated because of a substantial loss of synthesizing cells due to damage or, alternatively, upregulated as a consequence of glial cell reactivity. To assess how these changes could affect epileptogenesis, we have recently characterized P450scc immunoreactivity after pilocarpine-induced SE in adult rats.[24,54] In this model, induction of both excitotoxic and vascular lesions is dependent on the duration of SE and presents with a regional specificity:[5] in the medial entorhinal cortex, layer III neurons are largely lost because of sustained glutamate release,[65] whereas a highly predictable ischemic-like lesion (pannecrosis) develops in the stratum lacunosum-moleculare of CA3 (Fig. 49–2), causing disappearance of myelinated fibers and astrocytes (cf. ref. 5).

According to quantification of P450scc immunoreactivity, the induction of this enzyme exhibits an increasing gradient from parahippocampal to hippocampal regions that is also dependent on SE duration (Fig. 49–3). Interestingly, the most significant increase in P450scc immunoreactivity in the hippocampus is found both in neurons and in glial cells in the surroundings of the ischemic lesion identified in CA3 stratum lacunosum-moleculare[24] (Fig. 49–2). However, the neuron-specific changes are limited to the first week after SE, whereas those in glial cells are long-lasting and approximately equivalent to the latent period, that is, the time lag preceding the appearance of spontaneous recurrent seizures following SE. The prevalence of P450scc induction in hippocampal astrocytes can be clearly appreciated in experiments of colocalization with cell-specific markers. In this way, we unambiguously identified the different P450scc-positive cell types in tissue obtained 1 week after pilocarpine-induced SE (Fig. 49–1). It should be emphasized that the time course of increased expression of glial P450scc does not parallel that of astrocyte reactivity since GFAP immunoreactivity is still remarkably intense even 3 weeks after SE, when P450scc immunoreactivity is already largely reduced (Fig. 49–2). This phenomenon may explain why gliosis, which is always present in postlesional epilepsies, does

Table 49–1 **Cellular Localization of Enzymes Involved in the Synthesis of Neurosteroids Able to Modulate $GABA_A$ Receptor Currents in the Rat Brain: Allopregnanolone (3α,5α-Tetrahydroprogesterone) and Allodeoxycorticosterone (3α,5α-Tetrahydrodeoxycorticosterone)**

Abbreviations: A, astrocytes; AA, activated astrocytes; AM, activated microglial cells; N, neurons; ND, not determined; O, oligodendrocytes; P450scc, P450 cholesterol side chain cleavage enzyme.

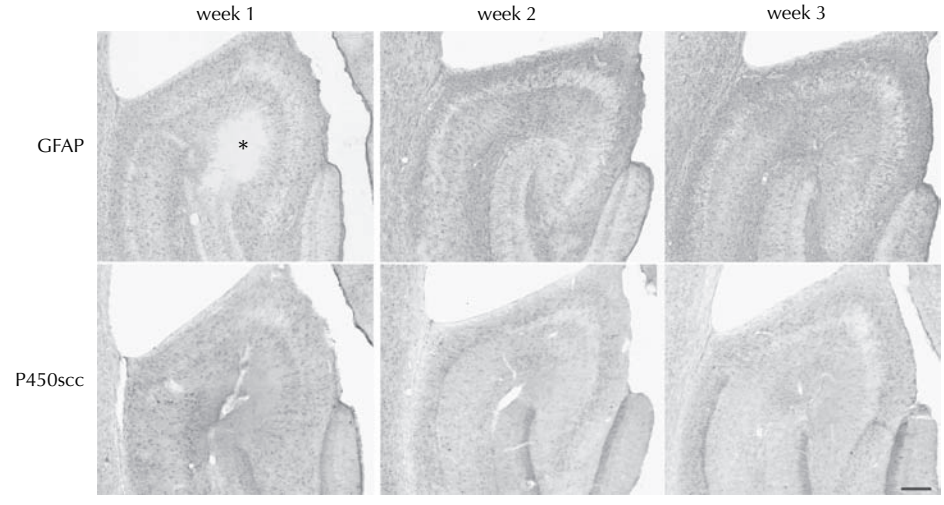

Figure 49–2. Time course of astrocyte reactivity following SE lasting for 30 min. Changes in GFAP and P450scc enzyme immunoreactivity in rats exposed to pilocarpine-induced SE lasting for 30 min 1, 2, and 3 weeks after the treatment. Note that the GFAP staining is increased 2 weeks compared to 1 week after SE, and it is still maintained 3 weeks after SE. Conversely, the P450scc staining decreases progressively from 1 to 3 weeks after SE, suggesting a very different time course in the upregulation of these astroglial proteins. The asterisk points to the ischemic-like lesion in CA3 stratum lacunosum-moleculare (cf. ref. 5), around which the glial reaction takes place. Scale bar, 200 μm.

not control (and indeed contributes to) ictogenesis in the epileptic focus.

During the first weeks after SE, the extent of P450scc induction in hippocampal astrocytes appears to have major consequences for epileptogenesis. By varying the duration of the initial SE induced by pilocarpine, we discovered that the length of the latent period progressively decreases as pharmacological cessation of SE by diazepam administration is anticipated

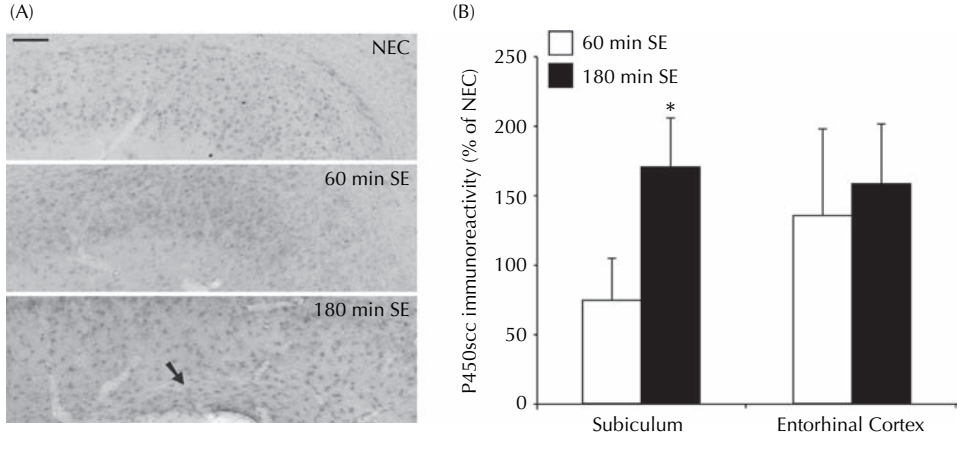

Figure 49–3. Changes in P450scc immunoreactivity in the subiculum and entorhinal cortex of pilocarpine-treated rats. **A.** In the subiculum, P450scc immunoreactivity is found in neurons in the pyramidal cell layer of nonepileptic control (NEC) rats. This distribution is unchanged after exposure to 60 min of SE 1 week after pilocarpine treatment. In contrast, in tissue obtained from animals exposed to 180 min of SE, P450scc immunopositive cells are found in all of the subicular layers. These cells also appear to be represented by glial cells (arrow). **B.** Quantification of P450scc immunoreactivity demonstrated a significant increase ($^*p < .05$, analysis of variance followed by Tukey's test; data are expressed as mean ± SEM) in the group exposed to 180 min of SE compared to NEC rats. An increase in P450scc immunoreactivity was also seen in the entorhinal cortex of both groups of pilocarpine-treated rats, but it was not significantly different from NEC values. Scale bar, 100 μm.

from 180 to 90, 60, and 30 min.[24,54,66] Notably, this correlation between SE duration and the duration of the latent period was also found to be paralleled by P450scc induction. It should also be emphasized that young, 3-week-old rats exposed to short-duration (60 min) SE present with a more pronounced induction of P450scc than that seen in adult animals,[66] and they rarely present with stage 5 seizures[67] during the chronic epileptic period.[5] However, the ischemic-like lesion seen in CA3 stratum lacunosum-moleculare of adult animals infrequently develops in young pilocarpine-treated rats,[5] suggesting that the more pronounced induction of P450scc synthesis in this group is probably due to the age-related hyperreactivity of astrocytes to brain damage, as described in young rats exposed to kainate[68] or to mechanical injury.[69]

5α-Reduced Neurosteroids and Epileptogenesis

Increased P450scc synthesis after SE is suggestive but not predictive of increased neurosteroid levels, since it has been established that the cholesterol transport machinery in mitochondria represents the real rate-limiting event in neurosteroid synthesis.[70,71] Therefore, we further challenged the role of neurosteroids in delaying seizure onset in the pilocarpine model by treating rats exposed to SE with finasteride (100 mg/kg), a specific and irreversible inhibitor of 5α-reductase (Table 49–1). This procedure anticipated the onset of spontaneous recurrent seizures in pilocarpine-treated rats,[24] a phenomenon that was probably related to decreased synthesis of neurosteroids modulating $GABA_A$ receptors. In fact, at 10 mg/kg, finasteride was shown to acutely deplete allopregnanolone without affecting 3α-dihydroprogesterone, progesterone, or deoxycorticosterone.[72] When repeatedly administered at a dose of 25 mg/kg, finasteride significantly decreases both allopregnanolone and allotetrahydrodeoxycorticosterone brain levels.[73] However, whether chronic treatment with finasteride could affect brain concentrations of other neurosteroids in the long term is still a matter of debate (see ref. 74).

In order to exclude the possibility that modulation of epileptogenesis by finasteride could be explained by other variables, we have tested its effect in different paradigms of SE duration and addressed whether the effect of 5α-reductase inhibition correlates with the extent of P450scc induction. Consistent with the correlation between SE duration, P450scc induction, and the duration of the latent period, finasteride was able to anticipate the appearance of stage 5 seizures in rats experiencing at least 180 min of SE, whereas it was ineffective in rats exposed to 90 min or less of continuous pilocarpine-induced seizures.[54,66] In addition, we compared the effects of finasteride administration on adult (8-week-old) and young (3-week-old) rats exposed to 60 min of SE and found that finasteride was ineffective in altering the duration of the latent period in adult rats, which presented with spontaneous recurrent seizures as early as 7 days after SE, as it occurs in rats with an insufficient induction of P450scc.[24] Consistently, administration of finasteride to young rats anticipated seizure manifestation in approximately 50% of the animals during the first 7 days following SE, when P450scc levels are increased. Then finasteride was not able to disclose other stage 5 seizures in the further treatment days,[66] when P450scc reached its peak level (Fig. 49–4). Notably, these experimental groups clearly differed in the extent and duration of P450scc induction in the CA3 hippocampal subfield (Fig. 49–4). Therefore, these findings suggest that neurosteroid synthesis is related to the extent of P450scc induction in glial cells following SE and that neurosteroids influence epileptogenesis.

Neurosteroids, Epileptogenesis, and Inhibition

Neurosteroids may decrease neuronal excitability by enhancing $GABA_A$-mediated inhibition.[26,75] Allopregnanolone and allotetrahydrodeoxycorticosterone, two major products of neurosteroid synthesis[25] (cf. Table 49–1), interact with $GABA_A$ receptors at nanomolar concentrations as positive allosteric modulators, whereas at micromolar concentrations they can directly open $GABA_A$ receptor channels.[26,76] Of particular interest are extrasynaptic $GABA_A$ receptors, since they appear to be the preferential target of neurosteroids (cf. ref. 75). In contrast to synaptic $GABA_A$ receptors, which generate "phasic" inhibitory postsynaptic currents (IPSCs), extrasynaptic $GABA_A$

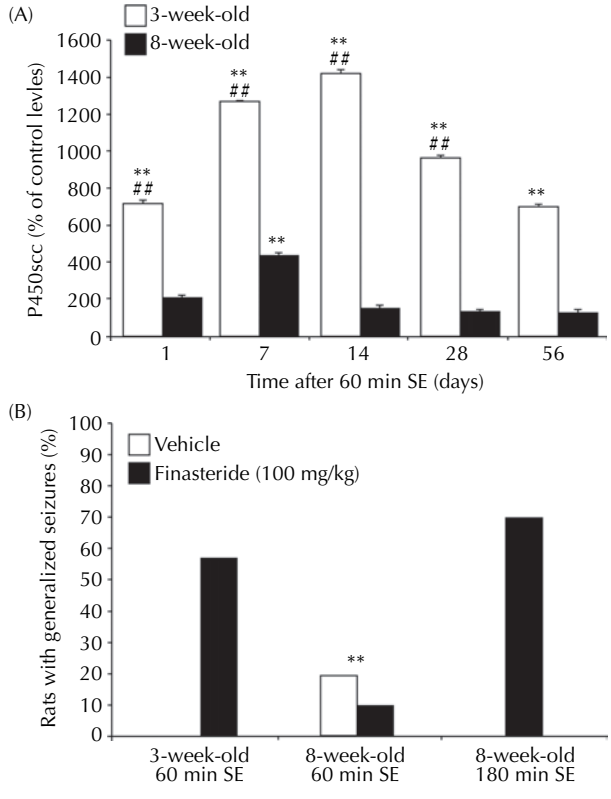

Figure 49–4. Effects of changes in neurosteroid metabolism on epileptogenesis. **A.** Time course of the changes in P450scc immunoreactivity in rats exposed to pilocarpine-induced SE lasting for 60 min, at different ages (3 and 8 weeks), and studied 7, 14, 28, and 56 days after the treatment. Note that P450scc immunoreactivity is higher in young rats at any time interval. $^{**}p < .01$ versus control values; $^{\#\#}p < .01$ versus 8-week-old rats, analysis of variance followed by the Games-Howell test; data are expressed as mean ± SEM. In **B**, the percentages of rats presenting with generalized seizures (stage 5 of Racine's scale[67]) are shown in groups with different levels of P450scc induction (cf. refs. 54 and 66 and panel **A**); note that these values refer to generalized seizures manifest during the first 7 days of treatment with the neurosteroid synthesis inhibitor finasteride (100 mg/kg/day, starting on the 4th day after SE) or the vehicle (cf. ref. 5). Stage 5 seizures were not observed in the groups of 3-week-old rats exposed to 60 min of SE or 8-week-old rats exposed to 180 min of SE, in which we found high levels of P450scc immunoreactivity (cf. refs. 54 and 66). Interestingly, finasteride treatment revealed stage 5 seizures in the majority of rats in these groups. In contrast, in 8-week-old rats exposed to 60 min of SE, in which P450scc was scarcely induced, generalized seizures were observed in vehicle-treated animals during the first 10 days after SE. Finasteride was not able to alter this finding. $^{**}p < .01$, chi-square test.

receptors maintain a constant inhibitory tone by generating a "tonic" (always-on) current. They are characterized by lack of the gamma subunit, consist of alpha, beta and delta subunits assemblies, and differ from those mediating inhibitory synaptic activity in that they are insensitive to benzodiazepines; moreover, they have a higher affinity for GABA and exhibit minimal or no desensitization.[77,78] The presence of the delta subunit in the receptor assembly contributes to the high sensitivity of extrasynaptic $GABA_A$ receptors to neurosteroids.[79]

An increased synthesis of allopregnanolone and allotetrahydrodeoxycorticosterone may parallel the induction of P450scc following pilocarpine-induced SE,[54] leading to the question of whether the ability of endogenous neurosteroids to delay the manifestation of spontaneous recurrent seizures after an epileptogenic insult[24] may stem from their interaction with extrasynaptic $GABA_A$ receptors, and thus from the enhancement of tonic inhibition. We addressed this question in subicular neurons, since this parahippocampal structure is particularly relevant to temporal lobe epileptogenesis. In fact, the subiculum gates hippocampal output activity[80] and reciprocally interacts with the entorhinal cortex to sustain

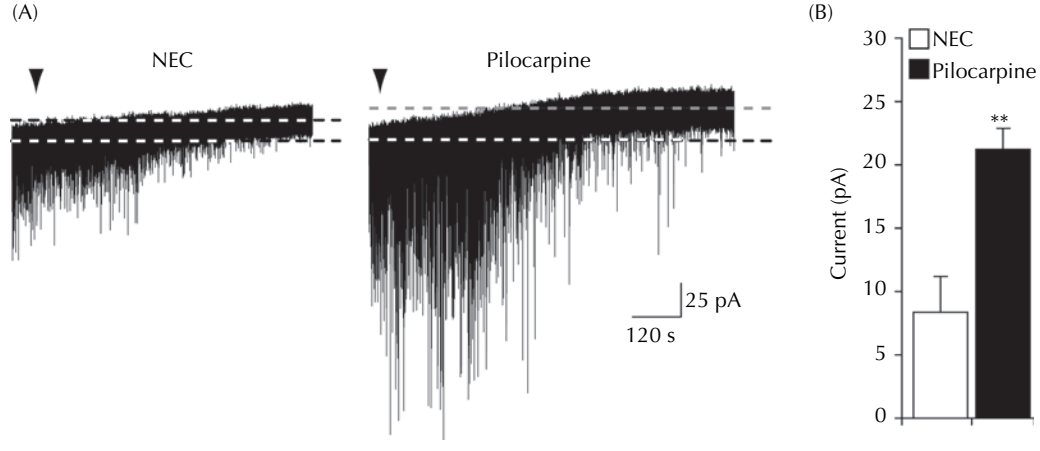

Figure 49–5. Early enhancement of tonic inhibition of subicular neurons following pilocarpine-induced SE lasting for 2 h. **A.** Representative whole-cell voltage-clamp recordings obtained from subicular neurons of NEC and pilocarpine-treated rat tissue 4 days after induction of SE lasting for 2 h. Bath application of the $GABA_A$ receptor blocker picrotoxin (PTX, 100 μM, arrowheads) reveals the presence of a tonic current, which is larger in the subicular neuron exposed to SE. Recordings were performed at $V_m = -70$ mV, in the symmetric chloride condition, and at room temperature (~21°C). Measurements of the holding current before and after application of PTX were taken at the levels indicated by the dashed lines. **B.** Tonic inhibition is significantly increased in subicular neurons during the latent period (NEC: 9.06 ± 3.02 pA; pilocarpine: 22.97 ± 1.78 pA; $n = 7$ and 5, respectively; $^{**}p < .01$, unpaired Student's t-test; data are expressed as mean ± SEM).

ictogenesis in pilocarpine-treated epileptic tissue.[81] In addition, P450scc induction is significantly increased in the subiculum following pilocarpine-induced SE (cf. Fig. 49–3). Remarkably, preliminary findings obtained in our laboratory[66] indicate that tonic inhibition is increased in subicular neurons 3–5 days after pilocarpine-induced SE lasting for 2 h (Fig. 49–5). This phenomenon may represent an early compensatory mechanism to dampen the spread of excitation from the hippocampus to parahippocampal regions following an epileptogenic insult. It remains, however, to be established if this phenomenon is consequent to the increased expression of P450scc and/or of $GABA_A$ receptor subunits mediating the tonic current,[77,78] as well as its temporal profile until the establishment of the chronic epileptic condition.

CONCLUSIONS

Overall, the evidence reviewed in this chapter indicates a complex interaction between glia and neurons in postlesional epilepsies, depicting a scenario similar to that found when analyzing the role of glial cells in the recovery from brain damage. Indeed, astrocytes may exert both pro-epileptogenic and anti-epileptogenic roles through (1) indirect modulation of neuronal function via release of inflammatory cytokines and neurosteroids, or by altering neurotransmitter release, and (2) by directly influencing neuronal activity via release of gliotransmitters.

Neurosteroids seem to play an important role in regulating epileptogenesis. As such, neuroactive steroidal compounds, which are synthetic analogues of endogenous neurosteroids, are currently attracting much attention among the potential antiepileptic drugs under investigation, thanks to their improved pharmacokinetics. However, depending on their chemical composition, these compounds can also increase neuronal excitability by inhibiting GABAergic signaling or enhancing glutamatergic transmission, leading to the need for carefully addressing their potential use for epilepsy treatment. Moreover, the synthesis and release of endogenous neurosteroids appear to be time-dependent and influenced by several factors, among which the most important is the glial response to damage; accordingly, the degree of tissue injury determines the extent of P450scc induction.

Clarifying these aspects may help shed more light on how an epileptogenic insult may trigger physiological processes of brain repair, which

should be beneficial but may lead paradoxically to the development of a chronic epileptic condition. For this purpose, the most important goal for future research may be to dissociate the increase in neurosteroid synthesis by astrocytes (or other possible sources) from insult to nervous tissue.

Chapter 50

Genetic Epidemiology and Gene Discovery in Epilepsy

Ruth Ottman
Neil Risch

Over the last two decades, more than 20 genes with a major effect on the risk for human epilepsy have been identified, providing important clues to pathogenic mechanisms and enabling some patients to discover the cause of their disorder.[1] However, the genes identified so far affect risk in a very small proportion of patients—primarily those from families consistent with Mendelian modes of inheritance. Most epilepsies occur in the absence of a significant family history, and identifying and characterizing the genetic mechanisms in these *complex epilepsies* is a major challenge for the next decade.[2] Here we discuss the meaning of *complex inheritance* as it applies to epilepsy, findings from current research, and approaches likely to be advantageous for gene identification in these forms of epilepsy.

EPILEPSY AS A COMPLEX DISEASE

Epilepsy is familial and genetically influenced: risk is increased two- to fourfold in the first-degree relatives of people with epilepsy of unknown cause (either idiopathic generalized epilepsy [IGE] or nonlesional focal epilepsy [NFE])[3–5]; twin studies consistently show higher concordance in monozygotic than dizygotic pairs[6–9]; and a large number of genes with a major effect on susceptibility has already been identified.[10–12] Yet, most people with epilepsy have no affected relatives. For example, in the Epilepsy Family Study of Columbia University (EFSCU),[4,5,13] we collected family history information on 1957 people with epilepsy ascertained from voluntary organizations without regard to their family histories. The proportion of subjects with a positive family history (one or more first-degree relative with epilepsy) was 15% in those with IGE and 12% in those with NFE. Most of those with a family history had just one affected relative, and very few families appeared consistent with a Mendelian model.[14]

Several mechanisms could account for the apparent paradox that a disorder with a genetic component usually occurs sporadically (i.e., in

the absence of a family history). First, as with many common disorders, inheritance in the majority of cases is likely to be multifactorial, with most of the genetic influence consisting of complex disease genes—that is, genetic variants that individually have a small or modest effect and act in concert with each other and with (as yet unspecified) environmental factors in their influence on epileptogenesis. In this model, relatives will be affected only if they inherit sufficient pathogenic variants at multiple disease loci and/or multiple nongenetic risk factors. The allele frequency distribution of these contributing loci can range from common to rare, with penetrances from low to moderate. We say *moderate* because genes with high penetrance are considered Mendelian and tend to lead to strong segregation patterns in families. The distribution and types of genetic variants underlying complex epilepsies are unknown, but have an important influence on optimal study designs for gene identification, as we discuss below.

While family studies provide the basis for examining genes that are inherited, some cases may also have a genetic contribution but not due to inheritance. These result from de novo germline mutations and somatic mutations occurring in critical brain regions. The importance of de novo mutations is already well documented. They are extremely important in Dravet syndrome, where more than 70% of patients have *SCN1A* mutations and more than 95% of these arise de novo.[15,16] Such de novo mutations most often account for a high proportion of severe early-onset forms of epilepsy in which affected subjects seldom reproduce (and hence mutations are not generally inherited). However, rare de novo mutations have also been identified in genes identified in Mendelian epilepsies, in some isolated cases phenotypically similar to those in the families in which the genes were found.[17–22] Also, copy number variants (CNVs) have recently been associated with complex epilepsies and many of these occur de novo, although associated risks appear to be moderate rather than Mendelian.[23]

As is true for many complex diseases, there is no clear dividing line between Mendelian and complex epilepsy genes. Many genes likely influence risk for epilepsy, with wide variation in the magnitude of their effects. As mentioned above, genes with larger effects (higher penetrance) produce Mendelian patterns of inheritance, whereas those with smaller effects (lower penetrance) produce complex patterns. The genes identified so far have generally fallen in the high range of this continuum, which is why they were easiest to identify. However, even for many of these genes, penetrance is incomplete, suggesting that other genes or environmental factors influence their effects. Also, similar pathogenic mechanisms may be involved in Mendelian and complex epilepsies, and the discovery that most of the Mendelian genes identified so far have encoded voltage-gated or ligand-gated ion channels points to this class of genes as prime candidates for the genetically complex epilepsies.

Complexities in Phenotype Definition: Lessons from Mendelian Epilepsies

Evidence from Mendelian epilepsy syndromes provides important information about complexity in the relationship of genotype to phenotype that is likely to be relevant for non-Mendelian epilepsies. First, genetic heterogeneity is extensive and occurs at multiple levels. At the highest level, different genetic mechanisms—Mendelian, genetically complex, or even acquired—can cause the same syndrome, making it very difficult, if not impossible, to classify syndromes according to genetic mechanisms in any consistent way.

For example, mutations in the leucine-rich, glioma inactivated 1 gene (*LGI1*) are found in approximately 50% of families with autosomal dominant partial epilepsy with auditory symptoms (ADPEAF), defined as families containing two or more individuals with temporal lobe epilepsy with ictal auditory symptoms or receptive aphasia.[24] However, very few patients with the clinical features that define this syndrome come from families with autosomal dominant inheritance; the vast majority are sporadic, and de novo mutations in *LGI1* are found in <2% of these sporadic cases.[19,20,25–27] The same phenotype is observed in other patients with lesional epilepsies.[28] Thus, this syndrome is due to dominant mutations in *LGI1* (or other unidentified genes) in a few rare cases and genetically complex or acquired in most.

The same principle applies to the IGEs. Recurrence risk is higher in siblings than in most other forms of epilepsy; in a recent population-based study, the risk of epilepsy to age 40 was 7.6% in the siblings of incident IGE patients compared with 4.6% for siblings of all incident patients.[29] This higher recurrence risk is consistent with a range of different underlying genetic and nongenetic models. Mutations in *GABRA1* or *EFHC1* have been identified in some unusual families with a very high incidence of juvenile myoclonic epilepsy,[30,31] and other monogenic forms of IGE may yet be discovered. However, like other forms of epilepsy, most IGEs are presumably genetically complex, caused by a mixture of genetic and nongenetic factors. In three major twin studies that examined IGEs specifically, concordance rates in monozygotic twins ranged from 65% to 80% and in dizygotic twins from 0% to 33%.[6,7,9]

The International League Against Epilepsy Commission on Classification and Terminology recently recommended that the name *genetic generalized epilepsy* be used instead of *idiopathic generalized epilepsy* for these disorders.[32] Although the Commission explicitly stated that the use of this term "does not exclude the possibility that environmental factors (outside the individual) may contribute to the expression of disease," we believe it is misleading to incorporate the term *genetic* into the name of a disorder in the absence of Mendelian inheritance patterns in families or molecular information about the specific genes involved. Use of this term implies that IGE is exclusively genetic (which is obviously incorrect based on the evidence from monozygotic twins) and suggests that genetic forms of generalized epilepsy can be distinguished clinically from nongenetic forms.

At the second level of genetic heterogeneity, within epilepsies with clear-cut Mendelian inheritance, mutations in different genes (often encoding different subunits of the same receptor) have been found to cause the same syndrome in different families (locus heterogeneity).[2,11] At the third level, in families with a mutation in the same gene, the specific molecular change usually varies among families (allelic heterogeneity).

A second complication is variable expressivity: mutations in a single gene can produce different epilepsy phenotypes in different individuals. The best example of this is genetic epilepsy with febrile seizures plus (GEFS+), in which the phenotypes within a family with a single mutation in *SCN1A* can range from typical febrile seizures to febrile seizures plus (i.e., febrile seizures persisting beyond age 6 or accompanied by afebrile generalized tonic seizures), IGEs, temporal lobe epilepsy, myoclonic-astatic epilepsy, or Dravet syndrome.[33,34] As with complex inheritance, this variability is likely to result from the modifying effects of other genes or environmental factors.

GENE IDENTIFICATION IN THE COMPLEX EPILEPSIES

Positional Cloning

The armamentarium of methods for gene identification in complex disorders includes an array of approaches (Table 50–1). Almost all of the genes identified so far in the epilepsies were found using positional cloning: linkage analysis followed by sequencing of the genes in the chromosomal regions with evidence for cosegregation with disease in families. This is the optimal approach for Mendelian disorders, with a long history of success for a wide range of diseases. However, it has limited power with complex disorders, in which the effect of the gene sought through linkage may be too low to be detected by this approach.[35] Also, practical problems complicate the design of linkage studies in complex diseases, such as the scarcity of families containing multiple affected individuals and uncertainty about how to define the phenotype and about what mode of inheritance should be assumed in the analysis.

Substantial efforts have focused on gene mapping in the IGEs, but few findings have been replicated, probably because of a combination of phenotypic variability, genetic heterogeneity, and low statistical power. Linkage disequilibrium mapping at two linkage regions on chromosomes 6p21.3 and 18q21.1 suggested two potential susceptibility genes (*BRD2*, *ME2*) predisposing to common IGE subtypes,[36,37] but some studies have not confirmed these findings[38–42] and causative mutations have not yet been identified in these genes.

Table 50–1 **Methods for Gene Identification in Genetically Complex Epilepsies**

Method	Basic Strategy	Advantages and Disadvantages	Application to Epilepsy
Positional cloning	(1) Localize a disease gene to a small chromosomal region by evaluating cosegregation of genetic markers with disease within families; (2) sequence genes in the linkage region to identify the mutation	Excellent for identification of Mendelian genes; low power for complex disease genes	Most previously discovered genes found with this approach
Association study	Evaluate difference in allele frequency between affected and unaffected individuals	Better power than positional cloning for genes with low penetrance; susceptible to population stratification; not applicable to rare variants	
Candidate genes	Restricted to variants within genes hypothesized to affect the disorder	Good if biology is known, but pathogenic variants and genes may be missed by restriction to candidates	Large number of studies but few replicated findings
Genome-wide SNPs	SNP evaluated genome-wide to detect either causal variants or variants in linkage disequilibrium with causal variants	No gene assumptions; powerful for common moderate-risk alleles but not for rare high-risk variants	One negative published study to date; others currently in progress
Copy number variants	SNP typing or massively parallel sequencing used to identify small deletions or duplications with increased frequency in affected individuals	Increased chance of functional significance; genome-wide detection strategy	Several new findings, but associated risks remain to be determined
Massively parallel sequencing	Next-generation high-throughput sequencing carried out genome-wide to detect disease-associated variants	Applicable to rare variants with high risk; large numbers of variants detected; methods for statistical analysis under development	
Whole genome	Covers the full genomic sequence	Still relatively expensive (but cost dropping)	Studies underway
Whole exome	Restricted to protein-coding sequences	Much less expensive and focused on genomic regions of high functionality but may miss some important variants	Studies underway

Allelic Association Studies

Allelic association studies are aimed at detecting genetic variants (usually single nucleotide polymorphisms [SNPs]) that are more common in people with epilepsy than in unaffected persons from the same population. They have greater statistical power for the detection of genes with small effect[35] and do not require families with multiple affected individuals. While most studies have been based on a case-control design, affected individuals with parents (triads) have also been used for early-onset disorders, testing for transmission disequilibrium to the affected child.[43] In the design and interpretation of case-control studies (but not triads), the potential for confounding due to population stratification must be considered. It arises when the cases and controls in a study have different genetic ancestries, and the ancestral groups differ in their allelic distributions, so that cases and controls differ in the frequency of a SNP for reasons unrelated to the disease. While triads require no formal correction for confounding due to stratification, for case-control studies several methods have been developed to control for this potential confounding, including genomic control,[44] structured association tests,[45] and, more recently, the use of principal components analysis to define the major sources of population structure and then adjust for them in a logistic regression analysis (for discrete outcomes) or linear regression (for continuous outcomes).[46] The large number of SNPs typically genotyped in a genome-wide association (GWA) study makes these approaches very powerful for detecting and adjusting for population structure. Once population stratification has been taken into account, a significantly increased frequency of a variant in people with epilepsy would suggest that it either directly affects risk or is in linkage disequilibrium with a nearby causal variant.

Most of the association studies carried out in epilepsy so far have been relatively small, candidate gene-based studies, and few findings have been confirmed. Many of the published studies have had methodological limitations such as small sample size, lack of control for potential population stratification, and failure to adjust for multiple statistical tests.[47] One large multisite study of common variations in 279 candidate genes failed to identify clear associations across multiple sites.[48] However, the association findings are more convincing for some candidate genes, such as the calcium channel subunit gene *CACNA1H*.[49–51]

Genome-wide association studies have yielded confirmed associations of common variants with a wide range of complex diseases,[52] although in most cases the associated variants explain little of the heritability of the diseases in which they have been found.[53,54] The epilepsy field has lagged behind others in the investigation of common genetic variation. Only one GWA study has been published so far and that study, which included nearly 4000 European patients with a wide array of nonlesional and lesional focal epilepsies, was essentially negative; none of the variants examined reached genome-wide significance.[55] Power was sufficient to exclude variants with an odds ratio of 1.3 or greater, and thus the results argue against common genetic effects of this magnitude that are shared across different (and likely heterogeneous) forms of focal epilepsy in European populations. Although sample sizes of specific subgroups (e.g., nonlesional as opposed to lesional focal epilepsies, in which family studies show a stronger genetic influence[4]) will be smaller, leading to potentially reduced power, the effect sizes are likely to be larger in these more homogeneous subgroups, and so this type of analysis is still worthwhile to pursue. Genome-wide association studies are underway in other forms of epilepsy, such as the IGEs, and their success in identifying common variants that influence susceptibility remains to be seen.

However, studies of structural variation have made progress in identifying rare genomic variants that contribute to the risk for genetically complex epilepsies.[23] In several studies, approximately 1% of individuals with IGE were found to carry a rare microdeletion at chromosome 15q13.3 that had previously been identified in individuals with intellectual disability, schizophrenia, and autism.[56–58] Five additional candidate microdeletions that had also been found in other neuropsychiatric disorders, at chromosomes 1q21.1, 15q11.2, 16p11.2, 16p13.11, and 22q11.2, were observed collectively in 1.8% of IGE cases, with a significant excess of the 15q11.2 and 16p13.11 variants.[58] A genome-wide analysis

of CNVs in a wide range of epilepsies (not only IGE) found an excess of large deletions (>100 kb) at chromosome 16p13.11 in cases with highly variable phenotypes.[59] Another genome-wide study of patients with a range of idiopathic epilepsy types found deletions at chromosome 15q11.2, 15q13.3, or 16p13.11 in approximately 3% of patients.[60] In studies with available family data, a substantial proportion of these microdeletions have been found to be de novo, and among those that are inherited, cosegregation with epilepsy in families appears to be inconsistent, with some affected family members failing to carry the variant present in the proband.[56–58] This lack of cosegregation with disease in families, despite very high estimated odds ratios for the variants (e.g., an estimated odds ratio of 68 for the 15q13.3 microdeletion),[57] is paradoxical and requires explanation. The associations of these microdeletions with a wide range of neuropsychiatric disorders, including intellectual disability, autism, schizophrenia, and epilepsy, raise intriguing questions about shared pathogenic mechanisms for these disorders.

Massively Parallel Sequencing

Although the findings from GWA studies are not yet available for most forms of epilepsy, evidence from other complex disorders suggests that the individual contribution of common variants to the overall genetic component of the epilepsies is likely to be small. On the other hand, the findings from studies of structural variation suggest that rare genetic variants play an important role in the genetic architecture of the epilepsies. The potential for GWA studies to identify rare variants (i.e., less than 2% in frequency) is limited because most are not represented, either directly or indirectly (through high linkage disequilibrium), on the panel of SNP genotypes investigated. However, rare variants can now be investigated using massively parallel sequencing approaches, so-called *next-generation sequencing* (NGS), applied either to whole genomes or to protein-coding regions (whole exome sequencing) at costs that are not prohibitive (at least on a small scale, to date).[61] Several recent studies using this approach have succeeded in identifying genes for Mendelian disorders, using very small numbers of patients or families.[62] Most of these studies focused on extremely rare Mendelian disorders with high penetrance—an optimal situation for disease gene detection (just as it is for linkage analysis and positional cloning). However, application of NGS is expanding rapidly to include disorders with more complex features such as locus heterogeneity and uncertainty about phenotype definition.[63,64] We are currently conducting a study of whole genome sequencing in multiplex epilepsy families,[65] and another major collaborative NGS study in the epilepsies has recently begun.

One of the challenges in this field concerns the development of study designs and statistical approaches for analysis of the large number of variants identified through NGS.[66] The strategy used in our current study of multiplex epilepsy families is to sequence two affected individuals in each family, selected to be as distantly related as possible, and "connected" by family branches that also contain affected individuals. The underlying assumption is that families containing multiple affected individuals are likely to harbor genomic variants with a strong risk-raising effect, and affected individuals in the same family are likely to carry the same pathogenic variants. Since distant relatives are unlikely to share rare variants by chance, the sharing of variants between the sequenced family members can be used as a "filter" to reduce the number of potentially causative variants for further analysis. Restriction to distant relatives connected by family branches containing other affected individuals protects against the possibility that the two relatives have different genetic causes of their epilepsy.

So far, we have completed whole genome sequencing to an average coverage of 38× in two affected individuals from each of nine families with various forms of nonacquired epilepsy (average 6.2 affected per family).[65] The total number of variants averaged about 4.4 million per individual, and restriction to rare, shared, potentially functional (i.e., missense, protein truncating, or splice site-disrupting) variants reduced the number to an average of 108 per family. Our planned follow-up studies include genotyping in other family members to evaluate cosegregation with epilepsy and case-control analyses in larger cohorts.

Cosegregation with disease is the hallmark of rare high-penetrance variants, so multiplex

families such as these are indispensable for validating any such findings. However, linkage analysis in these same pedigrees did not produce convincing evidence for any particular chromosomal region(s), and so if rare, high-risk variants are involved, there must be extreme locus heterogeneity to account for the negative linkage results. Rare variants with moderate to low penetrance will be more difficult to identify and validate, as these will not segregate in families, similar to common, low-penetrance variants.

PHENOTYPE DEFINITION

One of the most challenging issues for genetic research on epilepsy is the extreme clinical and etiological heterogeneity of the disorder. The epilepsies, defined broadly as recurrent unprovoked seizures, include a wide array of different syndromes presumed to have different pathogenic mechanisms. However, the extent to which the different clinical entities also differ with respect to their genetic contributions remains unclear, and hence it is uncertain which features should be used to separate the epilepsies into subgroups likely to share susceptibility genes. This lack of clear information about the relationship of phenotype to genotype dramatically impedes efforts at gene discovery because it results in samples with uncontrolled heterogeneity and reduced statistical power.[67]

Here we review two types of studies that have been used to advantage to elucidate shared and distinct genetic influences on different clinically defined subsets of epilepsy. Each of these approaches can also be used to study the possibility of shared genetic susceptibility to epilepsy and other disorders, such as migraine or depression.

Familial Aggregation Studies

Familial aggregation studies are epidemiological designs that examine familial risks in a population context. A sample of probands with epilepsy is ascertained and divided into subsets based on syndrome or other clinical features (age at onset, seizure type, etc.). Then in the first stage of analysis, the risk of all types of epilepsy is examined in the relatives of different subgroups of probands and compared with the risk in the population or in the relatives of unaffected controls. The results of this analysis provide information about the relative genetic contribution to different types of epilepsy and guidance about which probands are likely to be most informative for molecular genetic studies. They also provide extremely useful information for genetic counseling.[29,68,69] Family studies have provided evidence for several important predictors of familial risk. First, probably the most consistent observation in the genetic epidemiology of the epilepsies is the *maternal effect*: the risk for epilepsy is approximately twice as high in the offspring of affected women as in the offspring of affected men.[70–72] Although this phenomenon remains unexplained, several possible causes have been excluded, such as effects on offspring epilepsy risk of intrauterine exposure to antiepileptic medications or maternal seizures or X-linked genetic models (since the risks are similar in male and female offspring).[70,71] Second, the risk of epilepsy is increased in the relatives of probands with epilepsy of unknown cause (either IGE or NFE), but not in the relatives of probands with symptomatic epilepsy (defined as epilepsy associated with structural or metabolic insults to the central nervous system, such as severe head trauma, stroke, brain tumor, etc.).[4] This suggests either that the genetic contributions are minimal in symptomatic epilepsies or that the genes involved raise susceptibility only in the presence of the (uncommon) risk factors and thus the majority of relatives, in whom the risk factors are absent, do not have an increased risk. Third, the increased familial risk is greatest when the relatives are younger than 35 years and also if the proband has onset before age 35.[4] Fourth, recurrence risk patterns differ, depending on the relationship to the proband and the proband's epilepsy type (IGE vs. NFE). In data from EFSCU, risks in parents and siblings were greater if the proband had IGE versus NFE.[5,73] However, this pattern was not observed in offspring, either in EFSCU[5,73] or in a population-based study in Rochester, Minnesota.[74]

In the second stage of analysis, the risk for specific clinically defined subtypes of epilepsy

(or other disorders) is examined in the relatives of specific subgroups of probands. If different genes influence the risk for different types of epilepsy (distinct genetic effects), risk in the relatives should be increased only for the same type of epilepsy as in the proband. In contrast, if the same genes influence the risk for different types of epilepsy (shared genetic effects), the increased risk in the relatives will not be restricted to the same type as in the proband. In two previous family studies, the risk for NFE was significantly increased in the relatives of probands with IGE, providing evidence for shared genetic influences on IGE and NFE.[73,74]

Family Concordance Studies

Hypotheses about shared and distinct genetic influences on different clinically defined subsets of epilepsy can also be tested using family concordance studies.[75–77] As opposed to familial aggregation studies, in which a systematic sampling scheme is used to ascertain probands, these studies assess the concordance of epilepsy types (syndromes, seizure types, or subsets defined by other clinical features) in sets of families containing multiple affected individuals, which are often ascertained unsystematically. The rationale for family concordance analysis is that if some of the genetic influences on different epilepsy types are distinct, families will tend to be concordant, that is, the proportion of families in which all affected individuals have the same type of epilepsy will exceed that expected by chance. The expected proportion of concordant families is assessed using a permutation approach, taking into account the overall proportion of individuals with a given clinical feature in the dataset, the number of affected individuals in each family, and the proband's epilepsy type.[75] The results of research using this approach have provided evidence for distinct genetic influences on IGE and NFE[76] and, within the IGEs, for distinct genetic influences on myoclonic and absence seizures.[77–79]

With regard to the shared and distinct genetic influences on IGE and NFE, the results of familial aggregation studies and family concordance studies appear to differ, but this may be an artifact of study design. In familial aggregation studies, the null hypothesis is that all genetic effects are distinct. This hypothesis is rejected (leading to the conclusion that some genetic effects are shared) when a significant increase in risk in relatives is observed for an epilepsy type different from that in the proband. In family concordance studies, the null hypothesis is exactly the opposite: that all genetic effects are shared. This hypothesis is rejected (leading to the conclusion that some genetic effects are distinct) when families show excess concordance for a specific epilepsy type. Taken together, the results of these two study designs indicate that there are both shared and distinct genetic influences on generalized and focal epilepsies, as has already been observed, for example, in families with GEFS+.

RECOMMENDATIONS FOR FUTURE STUDIES

What approaches are most promising for future studies of the genetic contributions to the complex epilepsies? First, efforts to identify, clinically characterize, and carry out positional cloning studies in families with Mendelian epilepsies should continue. Although Mendelian epilepsy syndromes are rare, identification of the genes that cause them can provide extremely important information about basic epileptogenic mechanisms and suggest candidate genes to be investigated in complex epilepsies. Genome-wide association studies already underway should soon provide evidence about the importance of common variants in the epilepsies. Current evidence suggests that additional rare variants are likely to contribute to genetic susceptibility in epilepsy, and NGS has the greatest promise for identifying them. However, the failure to identify additional loci harboring high-risk variants through linkage analysis, in numerous multiplex families, suggests either a limited role for additional high-penetrance mutations or extreme locus heterogeneity. Collaborative efforts, rigorous phenotyping, and study designs that allow analysis of subgroups predicted to share susceptibility genes are crucial to maximize the likelihood of success.

Chapter 51

Strategies for Studying the Epilepsy Genome

Thomas N. Ferraro
Dennis J. Dlugos
Hakon Hakonarson
Russell J. Buono

Current leading theories on the etiology of the group of diseases called epilepsy implicate both genes and factors in the environment. Genetic research has the potential to identify molecular and cellular mechanisms that can be targeted directly for therapeutic intervention. Although nearly two decades have passed since the discovery of the first epilepsy-causing gene mutation[1] and mutations in about a dozen other human genes are now well characterized,[2,3] the vast majority of genetic variation that contributes to the development of epilepsy is undiscovered. Thus, there is a critical need to continue to elucidate the epilepsy genome. This chapter will review the comprehensive genome-wide approaches that are being used to achieve this goal.

THE EPILEPSY GENOME

The epilepsy genome has expanded slowly until now. Initially, it consisted of a handful of genes that were identified using traditional linkage and positional cloning methods in a few rare or sometimes even single Mendelian families. The genes discovered in this way are sufficient to cause epilepsy by themselves when mutated. Twenty years later, it is well understood that most genetic influences on epileptogenesis are more complex and that the majority of epilepsy cases result from multiple genetic susceptibility factors interacting with each other, with genetic background alleles, and with environmental factors.[4,5] Discovering genetic variants that have only partial effects and that act in concert to determine common complex clinical phenotypes involving seizures is a daunting task that requires new approaches.

The size of the epilepsy genome is unknown, but some perspective is provided by prior human studies as well as by studies of model organisms. In humans, although relatively few genes are considered proven at this time to be causative for epilepsy when mutated, there are over 100 genes that have been documented to

have at least one nominally or statistically significant genetic association result,[6] thus identifying them as potential susceptibility factors. Studies in mice with targeted gene defects indicate that over 400 different genes (~2% of all genes) are known to cause spontaneous seizures or alter the seizure threshold when they are inactivated.[7] The possibility that a similar large subset of all genes may influence seizure susceptibility in humans supports the contention that most of the genetic vulnerability to development of epilepsy remains to be characterized.

MODELING COMMON FORMS OF EPILEPSY FOR GENOMIC STUDIES

Phenotypic Models

Several key issues in studying the genetics of epilepsies involve the choice of patients. Given the enormous clinical heterogeneity associated with the disease, a variety of experimental designs and patient cohorts can be considered for use. Most studies to date have involved patients with two or more unprovoked seizures, although patients with one unprovoked seizure and an abnormal electroencephalogram (EEG) or magnetic resonance imaging (MRI) scan may also be genetically informative. More controversial is whether patients with no clinical seizures, but with a family history of epilepsy and an epileptiform EEG, should be enrolled and considered along a spectrum of presumed genetic susceptibility to epilepsy.[8] A major distinguishing feature in classification of the epilepsy etiology is the presence or absence of an identifiable remote symptomatic cause, such as stroke, head trauma, brain tumor, or central nervous system (CNS) infection. Cases with no known identifiable cause are presumed to be determined, at least in part, by genetic vulnerability and have been most commonly recommended and used for genetic studies.[9] However, even cases with no identifiable cause based on medical records, study interviews, and neuroimaging could harbor occult structural lesions below the level of resolution of current MRI scans. Thus, genetic studies of focal (also called *localization-related* or *partial*) epilepsy of unknown cause could, in fact, be genetic studies of microscopic malformations of cortical development with epilepsy as a secondary symptom. Cases with obvious acquired risk factors for epilepsy may also be influenced by genetic factors associated with susceptibility to epilepsy,[10] but such cases likely involve at least partly different sets of genes compared to those that influence idiopathic (presumed genetic) epilepsies. Nongenetic influences in acquired epilepsy may be so strong that the potential effect of genetic factors is mollified. Thus, one major study design question is whether to include both symptomatic and idiopathic cases or to focus on the groups separately. Most previous studies have attempted to focus separately on idiopathic and acquired epilepsies. A caveat for studies designed to focus only on idiopathic cases is the potential for environmental influences, such as minor traumatic brain injury, to go unaccounted for, particularly if these events occurred at a time long before the onset of seizures and the diagnosis of epilepsy.

Another key aspect of the epilepsy phenotype that may have a major impact on genetic studies is whether seizures are focal or generalized. Clearly, there are families with members who exhibit both focal and generalized seizures[11]; some patients have both types,[12] while other patients cannot be easily classified. Changes in seizure semiology or epilepsy classification over the course of development[13,14] further complicate the phenotypic landscape in epilepsy research. The potential difference between bona fide generalized epilepsy and focal epilepsy with seizures that are secondarily generalized[15] also warrants consideration. Studies suggest that generalized epilepsy has a higher recurrence risk ratio than focal epilepsy,[16] indicating possibly more genetic influence with the former. At least one large genetic study of focal epilepsy did not find any statistically significant associations between cases and controls,[17] although both symptomatic and idiopathic cases were included, potentially diluting genetic signals. In contrast, a recent study of idiopathic generalized epilepsy reported a statistically significant association with genetic alterations on chromosome 15q13.3.[18] These results have reinforced suspicions, perhaps prematurely, that cohorts of generalized epilepsy are more likely to be genetically informative than cohorts of focal epilepsy. The issue

is by no means settled, however, and virtually all questions regarding phenotype in studies of epilepsy genetics remain unresolved.[19] As a result, there are several available study designs for epilepsy genetics investigations. At one end of the design spectrum, patients may be segregated into groups according to very strict demographic and/or clinical categories. Factors such as age at seizure onset, gender, and seizure profile (including parameters like seizure type, frequency, and circadian pattern), may each have unique genetic signatures. Thus, there is a rationale for dividing patients into very specific diagnostic categories to allow all such factors to be analyzed separately.[20] At the other end of the spectrum, studies can be conducted using a single status for affected individuals. This model assumes that there are some genetic factors that predispose to all or most types of common epilepsy. This hypothesis is supported by the phenotypic heterogeneity observed in families in which the same single-gene mutation results in different clinical phenotypes.[21]

Hypothetical Genetic Models

A substantial body of experimental evidence now supports a multifactorial, polygenic basis for common forms of epilepsy. A major question affecting the direction of current research is whether common, sporadic forms of idiopathic epilepsy are influenced by genetic variants that are common in the general population or by genetic variants that are unique to each individual, or a mixture of both.[22] Until recently, sporadic cases of common idiopathic epilepsies were investigated primarily under the *common variant* hypothesis, which posits that susceptibility to common forms of epilepsy results from the assortment of a specific subset of DNA polymorphisms, typically single nucleotide polymorphisms (SNPs). Single nucleotide polymorphisms are single base substitutions, insertions, or deletions that occur throughout the genome and many SNPs alter gene function. They are considered common if their minor allele frequency is >1% when measured in several hundred chromosomes. In addition to SNPs, there are larger insertions, deletions, or duplications known as *copy number variations* (CNVs) that can span a few nucleotides to millions of bases. Common CNVs have been identified that are associated with epilepsy,[18,23] and certain epilepsy-related CNVs are associated with a wider spectrum of diseases including schizophrenia and autism.[24,25] The composition of all possible common genetic variants that act as epilepsy susceptibility alleles contributes to the specific clinical features of the disease in any individual. Since so many putative epilepsy susceptibility alleles exist, the number of different possible subsets of susceptibility alleles is large and thus the phenotypic diversity of the disease is high. Strategies to elucidate genetic variants that predispose to epilepsy under this hypothesis are based largely on resources such as dbSNP (http://www.ncbi.nlm.nih.gov/projects/SNP/index.html) and other similar databases, including those hosted by HapMap, 1000 Genomes, UCSC, and Illumina, that catalog common human genetic variations for use in association studies.

Equally compelling is the *rare variant* hypothesis of common forms of epilepsy. Although still based on the perspective that the disease is genetically complex, the mechanism of epilepsy under this hypothesis is based on the premise that novel SNPs, indels, or other polymorphisms such as CNVs, unique to each individual, act together and in concert with common genetic variants and environmental factors to cause disease. Evaluation of the rare variant hypothesis requires different analytical approaches than those used with the common variant hypothesis.[26,27]

Based on recent findings concerning other complex human diseases, it is likely that both common genetic variation found in the population and rare variants private to each individual contribute to the etiology of epilepsy. Thus, there may be thousands of alleles that constitute the broader epilepsy genome, and combinations of these will increase susceptibility or resistance to epilepsy in any given individual. Ultimately, any variant, common or rare, may be considered to be a putative susceptibility allele if there is statistical evidence to show that it is present significantly more often in cases compared to controls. Variants identified as putative susceptibility alleles also require independent confirmation and validation, the hallmark of a true association between a variant and a phenotype. This is usually achieved by the study of additional patient and control populations. This presents an obstacle to the

confirmation of rare variants, which, by definition, are infrequent in the general population. Validation of variants as bona fide susceptibility alleles comes from biological studies performed in vitro, using biochemical or cell-based assay systems.[28] Less frequently, in vivo validation schemes are utilized.[29] Rare variants may have effects of a larger magnitude compared to common variants, and this can facilitate the validation process.

In the following sections, we describe two new genome-wide approaches being used to establish the genetic landscape in the epilepsies: genome-wide association studies (GWAS), which focus on common variants as epilepsy susceptibility alleles, and whole-genome sequencing (WGS), which aims to identify rare variants associated with susceptibility to epilepsy. We also present a summary of recent data generated in our laboratories and discuss how, together, these whole-genome approaches have the potential to allow full elucidation of the epilepsy genome.

NEW RESEARCH APPROACHES TO THE EPILEPSY GENOME

Genetic Association

SNPS AND CANDIDATE GENES

Until recently, available technologies limited genetic association studies in epilepsy to the analysis of candidate genes. These studies have taken advantage of results of the Human Genome Project,[30] which led to the establishment of SNPs as the most common form of genetic variation.[31] Single nucleotide polymorphisms comprise a large set of biallelic genomic variants that are found on average approximately every 100–300 bp throughout the genome, although less frequently in protein-coding DNA sequences. Overall, there are estimated to be up to 10 million SNPs in the human genome. Given this extraordinary abundance, SNPs offer a powerful means of assessing genetic association, allowing essentially any gene to be surveyed for variants that may associate with a disease. The most popular experimental design for genetic association studies involves direct comparison of SNP genotypes between patients and controls, the so-called *candidate gene case-control study*.

PITFALLS AND LIMITATIONS

A variety of pitfalls must be avoided in the conduct of association studies involving the case-control candidate gene approach. In epilepsy, failure of a number of high-priority candidate genes to show consistent replication is the likely result of some of these pitfalls, such as misinterpretation of data, mismatching of case and control populations, and lack of statistical power.[32] Study design obstacles specific for epilepsy phenotypes have also been cited as reasons for lack of replication in candidate gene studies.[33] Nonetheless, careful control of experimental variables and adherence to standardized design guidelines can facilitate a candidate gene approach and lead to confirmed susceptibility loci.[6] An often-cited limitation of candidate gene studies is that they rely on prior information about epilepsy and its biological basis, and this bias reduces the chance of identifying novel mechanisms. Restricting genes to those that are positional candidates, based on human or animal linkage studies, has enhanced the candidate gene approach.[34–36] Thus, if candidate gene association studies can be optimized to identify key molecules that funnel into final common pathways related to seizure biology, new ideas for treating epilepsy may be developed without having to identify all of the genetic factors involved. A Web site devoted to cataloging all candidate gene association studies in epilepsy has been established as a valuable resource (http://www.epigad.org/page/show/homepage).

GENOTYPING SNPs AND CONSTRUCTING HAPLOTYPES

The previous emphasis on candidate gene association studies was driven in part by a desire to exploit the biological information that was known on epilepsy, but more so by available genotyping methodologies. In particular, the development of SNP DNA markers and related Taqman genotyping technology[37] facilitated the widespread appeal for studies of candidate genes. Methods have been developed to prioritize SNPs for selection in candidate gene studies based on various characteristics including location (e.g., exon vs. intron) and predicted effect on protein abundance or function.[38] Further studies of SNPs have since led to elucidation of the haplotype block structure of the human genome, and the concept of *tagging*

SNPs was introduced to enhance the efficiency of genotyping strategies. The HapMap project integrates linkage disequilibrium data on SNPs to generate haplotypes and also begins to take the population structure of the human species into account with respect to ethnicity and race.[39] Despite attempts to carefully match comparison groups, however, hidden racial/ethnic differences between assembled populations of patients and controls are an impediment to success in genetic association studies. Genomic control genotyping is a valid means to account for the influence of cryptic population substructure[40]; however, this method is resource-intensive and has not been employed commonly in epilepsy studies. Ancestry informative markers (AIMs) have been developed as an alternative means to control for population substructure.[41] Population substructure does not significantly influence the outcome of genetic association determined using the transmission disequilibrium test (TDT) in families,[42] and such designs may be considered preferable to case-control studies. On the other hand, the families required for TDT are generally harder to recruit compared to individual sporadic cases,[43] and this is reflected by the relative dearth of candidate gene studies in epilepsy that have employed the TDT.

GENOME-WIDE ASSOCIATION STUDIES

The logical extension of genetic association analysis from candidate genes to the full genome was predicted in a landmark paper published by Risch and Merikangas[44] when the concept of a full-genome study of genetic association was first described. Now the genome-wide association study (GWAS) has been applied to a multitude of traits and disease states. The GWAS involves analysis of a dense set of SNP markers, as many as 1 million or even more, spaced across all chromosomes in patients and controls, allowing unbiased genome scans to look for genetic variations associated with a particular disease. The method is robust and permits multiple study designs.[45] Key aspects of study design that influence the conduct of GWAS are similar to those affecting candidate gene association studies, including both technical genotyping issues and statistical data analysis issues.

From a technical standpoint, the development of microarray-based SNP genotyping[46] has made it economically feasible to analyze hundreds of thousands of markers in thousands of individuals; however, the very large number of genotypes generated in GWAS present unique problems for data quality control.[47] Basic genotype parameters should be checked to eliminate errors, including analysis of the Hardy-Weinberg Equilibrium (HWE) for all markers in both case and control populations. Genotypes from study groups that contain related individuals (e.g., parent-progeny trios) should be checked for consistency with Mendelian inheritance patterns. Missing genotypes are also a potential cause of data analysis artifacts if the loss is nonrandom and related to a systematic error.

SAMPLE SIZE AND STATISTICAL POWER

The common variant hypothesis predicts weak genetic effects (i.e., odds ratios of 1.20–1.25); thus, very large sample sizes are required to boost the genetic "signal" over the "noise" produced by environmental variables and other genetic factors. Power analyses conducted with standard tools such as QUANTO[48] indicate that comparisons must involve thousands of patients and equal numbers of control individuals to detect gene effects of this magnitude with a relatively high degree of confidence (e.g., 80% power). An alternate way to increase the signal-to-noise ratio is to reduce phenotypic heterogeneity (i.e., noise) by refining the disease affection model, thus enriching for a smaller subset of susceptibility alleles.

DATA ANALYSIS

The goal of genetic association data analysis is to determine whether the distribution of alleles at specific genetic loci is significantly different between patients and controls.[26] Analysis of data derived from unrelated individuals can be accomplished using conventional statistical methods such as the chi-square test with genotype × disease status contingency tables. Covariates may be incorporated using approaches involving analysis of variance or logistic regression. Dividing case and control groups into random halves and conducting data analysis in two stages allows for replication of significant results,[49] the hallmark of a true association. Increases in statistical power can be achieved primarily by expanding the sample size, an effort facilitated by the establishment

of consortia between research groups[50,51] or by meta-analysis of multiple datasets generated independently.[52]

SIGNIFICANCE THRESHOLDS AND MULTIPLE TESTING

Determining thresholds for declaring statistical significance in genetic studies of complex trait phenotypes has been a long-standing concern that led to early establishment of generally accepted guidelines.[53] More recent studies carried out by the HapMap consortium to determine the appropriate statistical significance threshold for GWAS have led to the suggestion that a *P*-value threshold of 10^{-8} is required to overcome potential type 1 error and for statistical significance to be achieved.[39] On the other hand, *P*-values should not be summarily disregarded if they do not meet or exceed the current standard for genome-wide significance and should be examined in the context of the study being conducted, the population under study, and the statistical analysis being performed. Permutation analysis is an alternative method to correct for multiple testing that is also useful for analyzing data from a full genome scan.[54]

GWAS IN FOCAL EPILEPSIES

Although several GWAS have been published for many common human illnesses (http://www.genome.gov/gwastudies/), only one GWAS has been completed and published in epilepsy.[17] Data for this study were collected from a multinational, clinically heterogeneous group of focal epilepsy patients of Caucasian descent (N = 3445), including many individuals with symptomatic causes of disease such as tumors, head trauma, and stroke.[17] Genome-wide association analysis compared to neurologically normal controls (N = 3668) failed to identify genetic variants that satisfied the most stringent criteria for reaching genome-wide statistical significance; however, a number of strong findings were reported, as shown in Table 51–1.

GWAS IN IDIOPATHIC GENERALIZED AND FOCAL EPILEPSIES

We have recently completed an epilepsy GWAS on patients of European ancestry with idiopathic generalized (N = 412) and (non-symptomatic) focal (N = 295) epilepsy. The results presented in Table 51–2 show SNPs with the lowest *P*-values (i.e., *top hits*) following comparison of all epilepsy patients (N = 707 patients) to a large group of neurologically normal controls (N = 6158) by contingency analysis. All individuals were genotyped on the Illumina 610Q platform. Only markers with a *P*-value of 10^{-8} or lower are shown. None of the loci or genes from the list of top hits corresponds with loci or genes identified in the study by Kasperaviciute et al.[17] Separate comparison of generalized and focal patients versus controls revealed both overlapping and independent top hits as well as novel hits not observed in the combined analysis (data not shown). The candidate genes identified from our analysis thus far are largely related to developmental neurobiology based on the expression and function of the encoded proteins. Similar to results from

the focal epilepsy GWAS, there is surprisingly little evidence for involvement of genes that encode ion channel proteins, a result that contrasts with the *channelopathy* concept of the epilepsies.[55]

Other GWAS in epilepsy are in progress (e.g., Epicure). However, published data from those studies have focused on CNVs, novel genetic deletions, and duplications that are more consistent with rare variant hypotheses of epilepsy pathogenesis. Our preliminary work identified new CNVs associated with idiopathic generalized epilepsy as well as replication of previous CNV results.[18,23] Thus, we detected deletions at 15q11.2, 15q13.3, and 16p13.11 in 1.7% of our idiopathic generalized epilepsy patients compared to 0.5% of controls and found them associated with this common form of epilepsy ($P = 1.5 \times 10^{-3}$). Such results on CNVs have stimulated interest in the potential utility of whole-exome and whole-genome sequencing in individual patients, as will be described below.

Next-Generation Sequencing

The results of the initial GWAS described above suggest that common genetic variation makes only a modest contribution to epilepsy susceptibility and are consistent with results concerning other human diseases of the nervous system. Thus, the fraction of unaccounted variation (the *heritability gap*) left by GWAS and other genetic association approaches is hypothesized to be associated with unique or private genetic variation discoverable only through in-depth sequence analysis of individual genomes. This is now possible through *next-generation sequencing* (NGS), in which hundreds of thousands of short DNA molecules are sequenced in parallel, permitting in-depth (i.e., "deep") DNA sequence analysis in individual patients at low cost.

NGS STRATEGIES

A variety of strategies are now being employed to take advantage of massively parallel DNA sequencing[56] to yield new discoveries in epilepsy. These include whole-genome sequencing (WGS)[57] and whole-exome sequencing (WES),[58] the latter involving sequence analysis of only gene coding regions. Another strategy being employed collects mRNAs from pathological tissue of an individual with a known disease, or from a subject after medical treatment, and converts these mRNAs into to cDNAs for sequencing of the *transcriptome*.[59] In this way, gene expression profiles (transcription) influenced by disease or medical treatment can be identified using the new sequencing technology. Finally, targeted sequencing of specific disease genes can be done on a much larger scale. Thus, if a specific gene mutation is linked to or associated with an epilepsy phenotype, it would be possible to sequence the entire coding and putative regulatory regions of that specific target gene in hundreds or thousands of patients to determine if the same or novel mutations are discovered that can be linked to or associated with disease. In addition, a set of 100 or more target genes can be interrogated all at once by NGS in additional patients to determine if rare mutations exist. Recent studies exemplify the use of NGS technologies to identify disease-causing DNA variations.[58–66]

NGS-BASED GENE DISCOVERY IN THE EPILEPSIES

At the time of this writing, there are no published papers in the epilepsy field using the new sequencing strategies; however, an abstract at the 2010 annual meeting of the American Epilepsy Society describes the use of WGS on the two most distantly related members of each of nine separate families affected with nonacquired epilepsy to look for potential epilepsy mutations.[66] On average, each relative pair shared ~100 rare variations that could potentially be related to their disease; however, very few were found in multiple families. These data confirm that the epilepsy genome is complex and potentially very large, as previously emphasized.

Our laboratories have recently performed WGS on four individuals from a family with a rare inherited type of epilepsy known as *autosomal dominant nocturnal frontal lobe epilepsy* (ADNFLE). Prior work has shown that mutations in the genes that encode subunits of the nicotinic acetylcholine receptor genes *CHRNA2*, *CHRNA4*, and *CHRNB2* are sufficient to cause ADNFLE (http://www.ncbi.nlm.nih.gov/omim). Additional families have been studied in which linkage to chromosomes 3 and 8 was demonstrated, but causative genes were not identified, suggesting that significant genetic heterogeneity exists even for this rare familial form of epilepsy.[67–69] We obtained DNA from an affected individual and three children of the proband. One child was unaffected. The family was too small to use traditional linkage and positional cloning strategies, and after screening the *CHRN* genes and finding no mutations, we were not able to proceed with analysis for several years. In late 2010, we used WGS at ~15x coverage and generated full genomic sequence data in less than 30 days. Bioinformatic analysis conducted to date reveals that the affected relatives share ~100 rare exonic variations that are not found in the unaffected relative. However, only several candidates exist with functional variation in exons of brain-expressed genes. . The prime candidate is a putative disease-causing SNP that leads to a nonconservative amino acid change in a gamma-aminobutyric acid (GABA) receptor-related protein that is predicted to be deleterious to the tertiary structure of the protein. The mutation was not found in the unaffected relative or in any public database or in hundreds of controls tested. The finding is currently being validated by direct sequencing, further analysis of additional samples from an expansion of the original pedigree, and functional studies of the mutation in a biological assay. This would be one of the first examples of WGS being used in isolation to identify a causative mutation in a small family with any autosomal dominant transmitted disease.

FUTURE PROSPECTS FOR NGS

Next-generation sequencing will become a significant tool for clinical utility once causative mutations linked to specific monogenic phenotypes are defined. However, since complex human traits could be caused by hundreds to thousands of alleles, each with the potential to interact with another, it may take decades before NGS data make a substantial impact on clinical decision making in epilepsy patients without a family history of epilepsy. Nonetheless, NGS is a major technological improvement that will enable rapid discovery of the many rare alleles related to disease phenotype and response to medications if enough genomes are sequenced. It may take decades, but over time it will be possible to integrate NGS information from many sources and determine the variations linked to the converging common biological pathways that cause epilepsy when altered. The epilepsy genome will slowly be elucidated as WGS/WES and other methods are applied to families and unrelated sporadic cases with various seizure disorders. At a minimum, a large list of candidate disease-related alleles will be identified and systematically studied until improved statistical modeling and candidate filtering methods are developed. At best, large-scale studies will show a plethora of rare variations that eventually cluster into a finite set of genes and gene networks related to specific epilepsy phenotypes. Identification of these variations within converging common biological pathways linked to epilepsy will provide accurate diagnostics and insight into molecular mechanisms that will offer new opportunities for therapeutic intervention.

CONCLUDING REMARKS

Complex human traits, including susceptibility to common diseases, are influenced by both

genetic and environmental factors. Common forms of human epilepsy are such multifactorial diseases. Epidemiological studies in twins, sporadic epilepsy patients, and families with a strong history of epilepsy provide strong evidence that genetics play an important role; however, only a small number of genetic risk factors have been identified to date. Whole genome approaches including GWAS and NGS offer the potential to identify many or all of the genetic risk factors for the epilepsies. Although it will likely be many years before such goals are achieved and the epilepsy genome is fully elucidated, whole genome strategies promise to reveal the full nature of epilepsy pathogenesis and exert a major impact on the development of new therapies.

Chapter 52

Sodium Channel Mutations and Epilepsy

William A. Catterall

INTRODUCTION

While many pathophysiological changes contribute to seizure susceptibility, recent work suggests that genetic factors are especially important. Polygenic inheritance patterns have been associated with febrile seizures and idiopathic epilepsy and may be important in determining susceptibility to acquired epilepsy following brain injury. Monogenic inheritance patterns are seen in a number of epilepsies associated with mutations in ligand-gated or voltage-gated ion channels. The genes most frequently associated with epilepsy encode brain sodium channels.

VOLTAGE-GATED SODIUM CHANNELS

Voltage-gated Na^+ channels in the brain are complexes of a 260 kD α subunit in association with auxiliary β subunits ($\beta1$–$\beta4$) of 33 to 40 kD (see ref. 1 and Chapter 4). The α subunit contains the voltage sensors and the

ion-conducting pore.[1] The β subunits modify the kinetics and voltage dependence of gating and serve as cell adhesion molecules interacting with the extracellular matrix, other cell adhesion molecules, and the cytoskeleton.[2,3] The mammalian genome contains nine functional voltage-gated sodium channel α subunits, which differ in patterns of tissue expression and biophysical properties. The $Na_V1.1$, $Na_V1.2$, $Na_V1.3$, and $Na_V1.6$ channel subtypes, encoded by the *SCN1A*, *SCN2A*, *SCN3A*, and *SCN8A* genes, respectively, are the primary sodium channels in the central nervous system[1,4–6] (see also Chapter 4). $Na_V1.1$ and $Na_V1.3$ channels are primarily localized in cell bodies,[7,8] $Na_V1.2$ channels in unmyelinated or premyelinated axons and dendrites,[7,8] and $Na_V1.6$ channels in myelinated axons and in dendrites.[9–11] These channels participate in the generation of both somatodendritic and axonal action potentials, and also conduct subthreshold persistent and resurgent Na^+ currents following action potentials.[12–16] In rodents, $Na_V1.3$ channels are highly expressed in the brain during embryonic life, and their expression declines after birth as $Na_V1.1$, $Na_V1.2$, and $Na_V1.6$ channels take over the primary role in action potential generation.[17,18] $Na_V1.1$ expression is first detectable at postnatal day 7 and increases steadily through young adulthood.[17,18]

SODIUM CHANNEL MUTATIONS IN GENERALIZED EPILEPSY WITH FEBRILE SEIZURES PLUS

Screening of human patients with inherited epilepsy first led to the identification of mutations of $Na_V1.1$ channels in two large families with the autosomal dominant epilepsy disorder generalized epilepsy with febrile seizures plus, OMIM 604233 (GEFS+).[19] More than 20 different missense mutations were subsequently identified in GEFS+ patients, spread throughout the α subunit (Fig. 52–1). A mutation in the $Na_V\beta1$ subunit also causes GEFS+ epilepsy, probably by impairing expression and function of $Na_V1.1$ channels.[20] Mutations in GEFS+ alter multiple biophysical properties of the Na^+ channels expressed in nonneuronal cells[21] (see also below). However, GEFS+ is

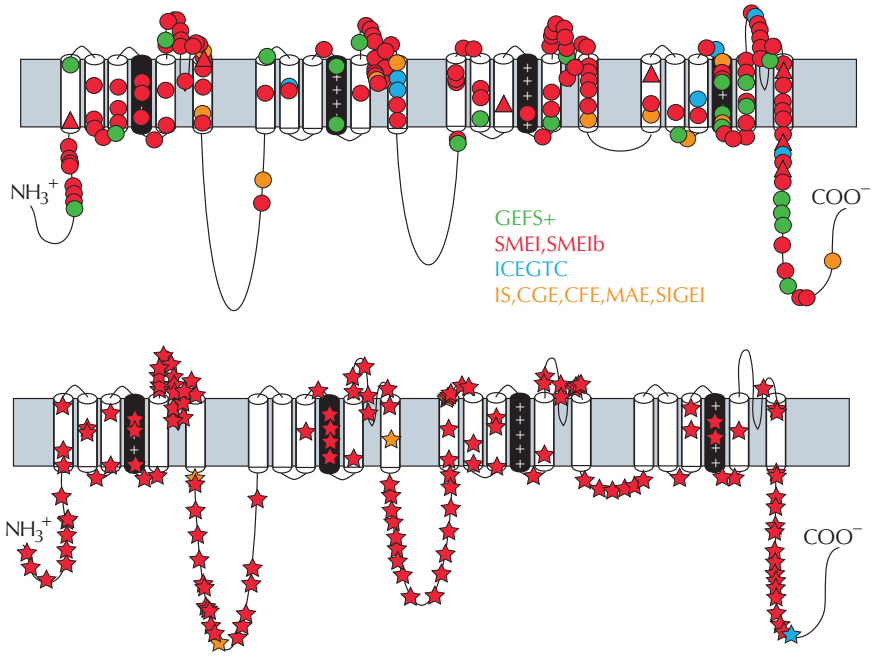

Figure 52–1. Mutations in NaV1.1 channels in patients with epilepsy. Top panel: missense mutations (circles) and in-frame deletions (triangles). Bottom panel: truncation mutations (stars). The clinical type of epilepsy is indicated by color: GEFS+, generalized epilepsy with febrile seizures plus; SMEI, severe myoclonic epilepsy of infancy.

usually a relatively mild epilepsy syndrome. Seizures are typically well controlled by antiepileptic drugs, and no cognitive impairment is observed. Nevertheless, it has been difficult to determine the molecular mechanisms and genotype–phenotype correlations for GEFS+ epilepsy.

Effects of GEFS+ Mutations Expressed in Nonneuronal Cells

Functional effects of GEFS+ mutations were first studied by expression in nonneuronal cells and whole-cell voltage-clamp analysis. The initial study of two mutations inserted in rat $Na_V1.1$ and expressed in *Xenopus* oocytes revealed that one was a gain-of-function mutation because of destabilized slow inactivation, whereas the second was a loss-of-function mutation because of enhanced slow inactivation.[22] In contrast, the first three mutations inserted in human $Na_V1.1$ and studied by expression in human somatic cells revealed a different functional effect: all three caused impaired inactivation and an increased persistent sodium current, leading to the hypothesis that gain of function of mutant sodium channels due to loss of inactivation is responsible for GEFS+ epilepsy.[23] However, further studies of several GEFS+ mutations expressed in mammalian cells[24,25] or *Xenopus* oocytes[26–28] have again revealed a mixture of loss-of-function and gain-of-function effects that were caused by several different changes in the biophysical properties of $Na_V1.1$ channels. These studies did not clearly define the functional basis for hyperexcitability in GEFS+ epilepsy.

Defective Protein Folding and Partial Rescue of GEFS+ Mutants

Studies of GEFS+ mutations in families with variable disease penetrance revealed that loss of function resulted from folding and/or trafficking defects that prevented channel expression in the absence of β subunits and reduced expression significantly in the presence of β subunits.[29,30] Remarkably, these two GEFS+ mutations can also be partially rescued by treatment with antiepileptic drugs, which apparently stabilize the mutant channels by contributing their binding energy to stabilization of the correctly folded protein.[29,30] These results indicate that loss-of-function effects can result from changes in biophysical properties and/or defects in folding and cell surface expression.

GEFS+ Mutations in Mouse Genetic Models

Considering the confusing picture emerging from studies of the functional effects of GEFS+ mutations in transfected nonneuronal cells, it is important to determine the functional effects of these mutations in neurons in vivo. To this end, the GEFS+ mutation R1648H was incorporated into the mouse genome using a Bac transgene strategy, providing an animal model of GEFS+ that permitted detailed analysis of the effect of mutations on neuronal sodium currents in vivo. The transfected $Na_V1.1$ channel contained both the GEFS+ mutation and an additional amino acid substitution that prevents block by the pore blocker tetrodotoxin (TTX), allowing selective block of endogenous sodium channels by TTX.[31] Mice expressing the transgene had increased sodium channel expression and a reduced threshold for seizure induction by kainic acid. The level of transgene-induced sodium current was much greater in inhibitory neurons than in excitatory neurons, as expected from previous studies of $Na_V1.1$ knockout mice showing selective effects in inhibitory neurons.[32, 33] The R1648H channels showed reduced function in both excitatory and inhibitory neurons, but the biophysical mechanisms were different: reduced peak sodium currents and enhanced slow inactivation in inhibitory neurons versus negatively shifted voltage dependence of fast inactivation in excitatory neurons. These functional effects were predicted to have the net result of reduced excitability of inhibitory neurons. Thus, this GEFS+ mutation causes selective impairment of excitability of GABAergic inhibitory neurons in vivo,[31] as previously demonstrated for complete loss-of-function mutations that cause severe myoclonic epilepsy of infancy in mice[33] (see also below). More recent studies of a mouse model in which the R1648H mutation has been inserted into the mouse genome under the native promoter led to similar

conclusions.[34] In light of these results, GEFS+ epilepsy may be caused by mutational effects that selectively impair firing of GABAergic inhibitory neurons.

SEVERE MYOCLONIC EPILEPSY OF INFANCY

Severe myoclonic epilepsy of infancy (SMEI; also known as *Dravet syndrome*) begins during the first year of life, with seizures often associated with elevated body temperature due to fever or bathing, and progresses to prolonged, clustered, or continuous seizures and to status epilepticus.[35,36] During the second year of life, patients develop comorbidities including psychomotor delay, ataxia, and cognitive impairment. Medically refractory seizures including frequent and prolonged episodes of status epilepticus contribute to an unfavorable long-term outcome.[36,37] Thus, SMEI is a much more severe form of epilepsy than GEFS+. Therefore, it was surprising that identification of familial *SCN1A* mutations in GEFS+ epilepsy was soon followed by a report of *SCN1A* mutations in children with SMEI, OMIM 607208.[38] These children carry de novo mutations in one allele of the *SCN1A* gene, leading to haploinsufficiency of $Na_V1.1$ channels.[38–43] More than 600 *SCN1A* mutations in the coding sequences of the *SCN1A* gene have been identified (Fig. 52–1), accounting for more than 70% of cases[21] (http://www.molgen.ua.ac.be/SCN1AMutations/home/Default.cfm). Since only coding regions of the gene have been sequenced, it is possible that the many of the remaining 30% of SMEI patients harbor mutations in regulatory regions of the gene outside of the coding sequences that impair or prevent channel expression. In addition, duplications and deletions of segments of the *SCN1A* gene can impair expression and/or function.[44] Mutation hot spots, including several sites of CpG deamination, account for approximately 25% of new mutations.[45,46] More than half of the SMEI mutations cause loss of function due to stop codons or deletions, demonstrating that haploinsufficiency of *SCN1A* is pathogenic. Missense mutations of $Na_V1.1$ channels in patients with SMEI are concentrated in the transmembrane segments of the protein, where they may prevent channel folding or severely impair channel function (Fig. 52–1). In addition, recent studies show that homozygous loss-of-function mutations in the $Na_V\beta1$ subunits cause SMEI, probably by impairing expression of $Na_V1.1$ channels on the cell surface.[47]

Loss of Excitability of GABAergic Interneurons and Hyperexcitability in SMEI

It was a surprise to find that haploinsufficiency of a Na_V channel causes epilepsy, because reduced sodium current should lead to hypoexcitability rather than hyperexcitability. To understand the mechanistic basis for hyperexcitability and comorbidities in SMEI, an animal model was generated by targeted deletion or mutation of the *Scn1a* gene in mouse.[32,33] Homozygous null $Na_V1.1(-/-)$ mice developed ataxia and died on postnatal day (P) 15.[32,33] Heterozygous $Na_V1.1(+/-)$ mice exhibited spontaneous seizures and sporadic deaths beginning after P21, with a striking dependence on genetic background.[33] Loss of $Na_V1.1$ did not change voltage-dependent activation or inactivation of sodium channels in hippocampal neurons.[33] However, the sodium current density was substantially reduced in inhibitory interneurons of $Na_V1.1(+/-)$ and $Na_V1.1(-/-)$ mice, but not in their excitatory pyramidal neurons (Table 52–1). This reduction in sodium current caused a loss of sustained high-frequency firing of action potentials in hippocampal and cortical interneurons[32,33] (Fig. 52–2A), thereby impairing their in vivo inhibitory function that depends on generation of high-frequency bursts of action potentials. These results suggest that reduced sodium currents in GABAergic inhibitory interneurons in $Na_V1.1(+/-)$ heterozygotes may cause the hyperexcitability that leads to epilepsy in patients with SMEI. Loss of excitability of GABAergic inhibitory interneurons would allow hyperexcitability of dentate granule and pyramidal neurons, and this gain-of-function effect may cause epilepsy. Failure of firing of additional classes of interneurons in the cerebral cortex and thalamus may also contribute to this complex seizure phenotype. Considered together with the later results on GEFS+ mutations expressed in mice (see above), these studies suggest that selective loss of function of

Table 52–1 Functional Impact of Deletion of the $Na_V1.1$ Channel

Functional Effect	Heterozygous Knockout (%)	Homozygous Knockout (%)
Na^+ current in hippocampal pyramidal cells (% WT)	100 ± 5.1	96 ± 6.0
Na^+ current in hippocampal interneurons (% WT)	47.0 ± 7.4	27.5 ± 5.4
Na^+ current in Purkinje neurons (% WT) peak; persistent; resurgent	57.6 ± 0.6; 44.9 ± 4.1; 49.6 ± 5.5	41.6 ± 0.5; 41.0 ± 3.7; 31.2 ± 3.5
Ataxia	Significant at P21	Severe at P11–14
Na^+ current in RNT neurons	77.5 ± 2	54.1 ± 2
Rebound action potential firing of RNT neurons	50	50
Ventral/dorsal Ca^{2+} transients in the suprachiasmatic nucleus	50	30
Circadian rhythm defect	++	Not tested
Thermally induced seizures	First observed at P20, increasing thereafter	Not tested
Spontaneous seizures	First observed at P21, increasing thereafter	P11–14
Premature death	Increasing premature death after P21	Death at P15

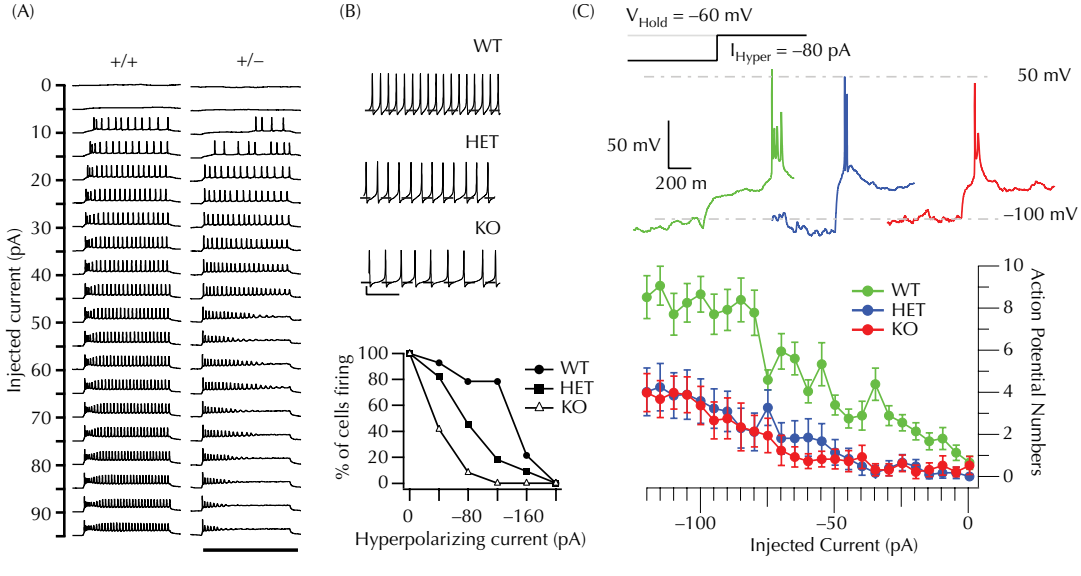

Figure 52–2. Action potentials in different brain regions in wild-type, heterozygous, and null mutant neurons in $Na_V1.1$ knockout mice. **A.** Action potential traces recorded from wild-type (+/+) and heterozygous (+/–) interneurons during 800 ms injections of depolarizing current in +10 pA increments from a holding potential of –80 mV.[53] **B.** Top: rates of spontaneous firing of cerebellar Purkinje neurons with a 50 ms depolarization from a holding potential of –90 mV to potentials ranging from –80 to +30 mV in 5 mV increments. Bottom: resistance of action potential firing to hyperpolarizing current injection. **C.** Hyperpolarization-release firing of RNT neurons. The number of action potentials fired after a hyperpolarizing pulse is illustrated above and plotted versus the hyperpolarizing current below.

Na^+ channels in GABAergic inhibitory neurons may be a common mechanism underlying both of these epilepsy syndromes.

Selective Deletion of $Na_V1.1$ Channels in Inhibitory Neurons

In order to definitively test the hypothesis that selective loss of Na^+ channels in GABAergic inhibitory neurons is the causative change in SMEI, Lox P sites were inserted on both sides of the last coding exon of the *Scn1A* gene in mice, and the resulting Floxed mice were mated with a mouse strain expressing the Cre recombinase in GABAergic inhibitory neurons in the cerebral cortex and hippocampus under the DLX5,6 promoter, which is selectively expressed in migrating inhibitory neuron precursors destined for these brain areas. These mice die prematurely and have spontaneous seizures that are as severe as those of $Na_V1.1$ KO mice,[48] confirming that loss of action potential firing in inhibitory neuron cause SMEI.

Loss of Excitability of GABAergic Interneurons and Comorbidities in SMEI

Ataxia, failure of motor coordination, and other comorbidities contribute substantially to the developmental delay and functional impairments of SMEI patients and are major determinants of their poor quality of life, burden of care, and premature deaths[49,50] (Dravet syndrome: http://www.ilae-epilepsy.org/ctf/dravet.html). How might loss of $Na_V1.1$ channels cause ataxia and failure of motor coordination? Purkinje cells are GABAergic inhibitory neurons that serve as the output pathway for information on movement, coordination, and balance from the cerebellar cortex. Degeneration of Purkinje neurons and abnormal expression of voltage-gated ion channels within them are associated with ataxia.[51–54] Behavioral assessment indicated severe motor deficits in homozygous $Na_V1.1$ knockout mice, including irregularity of stride length during locomotion, impaired motor reflexes in grasping, and mild tremor in limbs when immobile, consistent with cerebellar dysfunction.[33,55] A milder impairment of normal gait was observed in the heterozygotes after P21.[55] $Na_V1.1$ and $Na_V1.6$ channels are the primary sodium channel isoforms expressed in cerebellar Purkinje neurons.[55] The amplitudes of whole-cell peak, persistent, and resurgent sodium currents in Purkinje neurons were reduced by 58% to 69%, without a detectable change in the kinetics or voltage dependence of channel activation or inactivation (Table 52–1). Current-clamp recordings revealed that the firing rates of Purkinje neurons from mutant mice were substantially reduced, with no effect on the threshold for action potential generation[55] (Fig. 52–2B). Moreover, the firing of $Na_V1.1^{+/-}$ and $Na_V1.1^{-/-}$ mice is less resistant to extinction by injection of hyperpolarizing current compared to wild-type mice (Fig. 52–2B). These results show that $Na_V1.1$ channels play a crucial role in the excitability of cerebellar Purkinje neurons, with major contributions to peak, persistent, and resurgent forms of sodium current and to sustained action potential firing. Loss of these channels in Purkinje neurons may be sufficient to cause ataxia and related motor deficits.

Children with SMEI also have a significant impairment of sleep,[56] and $Na_V1.1^{+/-}$ mice have reduced non-REM sleep.[57] Sodium currents and action potential firing are impaired in GABAergic neurons of the reticular nucleus of the thalamus (RNT), which participate in a trisynaptic circuit with thalamic relay cells and cortical pyramidal cells that generates the sleep spindles in the cerebral cortex that drive sleep behavior.[57] In contrast, there is no effect on sodium current in thalamic relay cells. The RNT neurons fire bursts of action potentials upon release from hyperpolarization, which are required for the burst of cortical activity that generates sleep spindles. Recordings from dissociated RNT neurons reveal a major deficit in rebound action potential firing (Fig. 52–2C), suggesting that this is the basis for the reduction of non–rapid eye movement (non-REM) sleep in SMEI.

$Na_V1.1^{+/-}$ mice also have impaired circadian rhythms.[58] Circadian rhythms are generated in the suprachiasmatic nucleus (SCN) of the hypothalamus, which receives direct input from the retina via the optic nerve. $Na_V1.1$ channels are expressed in the GABAergic neurons of the ventral SCN, and expression is impaired in $Na_V1.1^{+/-}$ mice. Communication from ventral to dorsal SCN, which is required for normal

circadian rhythm, is also impaired as a consequence of reduced $Na_V1.1$ channel expression.[58] These results suggest that impaired firing of GABAergic neurons in the SCN is responsible for the circadian defect in SMEI. Therefore, selective decrease in action potential firing in GABAergic neurons in different parts of the brain may be responsible for both the comorbidity of ataxia and the comorbidity of sleep and circadian rhythm disturbance in SMEI.

Thermally Induced Seizures in a Mouse Model of SMEI

Children with SMEI frequently have seizures with elevated body temperature as their first symptom of the disease.[59] Experiments with a mouse model of SMEI demonstrated that haploinsufficiency of $Na_V1.1$ channels is sufficient to allow induction of seizures by elevated body temperature.[60] P17–18 mice with SMEI did not have thermally induced seizures, but nearly all P20–22 and P30–46 mice with SMEI had myoclonic seizures followed by generalized seizures with elevated core body temperature. Spontaneous seizures were only observed in mice older than P21, indicating that mice with SMEI become susceptible to temperature-induced seizures before spontaneous seizures. Interictal spike activity was seen at normal body temperature in most P30–46 mice with SMEI but not in P20–22 or P17–18 mice, suggesting that interictal epileptic activity correlates with seizure susceptibility. These results define a critical developmental transition for susceptibility to seizures in a mouse model of SMEI and reveal a close correspondence between human and mouse SMEI in the striking temperature and age dependence of SMEI onset and progression.

Balancing Excitation and Inhibition with Genetic Compensation and Drug Treatment

The net electrophysiological properties of a neuron are the product of its total ion channel activity, so inheritance of genetic variants of ion channels may contribute to polygenic inheritance or variable penetrance among family members. Since SMEI is apparently caused by loss of sodium current and failure of firing of GABAergic interneurons,[33,55] it may be compensated for by mutations that reduce the sodium current and action potential firing of excitatory neurons and thereby rebalance excitation and inhibition in the brain. Such genetic compensation can be studied by mating mouse lines having different well-defined genetic deficiencies. $Na_V1.6$ channels encoded by the *Scn8a* gene are highly expressed in excitatory neurons, and their functional properties are well suited to driving repetitive firing.[50,61,62] Double heterozygous mice with haploinsufficiency for both *Scn1a* and *Scn8a* did indeed have reduced susceptibility to drug-induced seizures and an increased lifespan compared to $Na_V1.1$ heterozygotes.[63] These results support the concept that loss-of-function mutations in $Na_V1.1$ channels in SMEI cause an imbalance of excitation over inhibition in the brain and that this imbalance can be partially compensated for by a corresponding reduction in the activity of $Na_V1.6$ channels.

In principle, the imbalance between excitation and inhibition can also be corrected by drug treatment. One practical result of the discovery that haploinsufficiency of $Na_V1.1$ channels causes SMEI is avoidance of treatment with non-subtype-selective sodium channel-blocking antiepileptic drugs, which exacerbate symptoms in patients with reduced expression of *SCN1A*.[64,65] Unfortunately, there are no drugs that selectively inhibit $Na_V1.6$ channels. However, an alternative approach to rebalancing excitation and inhibition is to enhance GABAergic neurotransmission by drug treatment. The reduced frequency of action potentials in GABAergic inhibitory neurons in SMEI would decrease the phasic release of GABA and impair inhibitory neurotransmission. Drugs such as tiagabine increase the concentration of GABA in the synaptic cleft by inhibiting its reuptake into nerve terminals and glia, and benzodiazepines such as clonazepam increase the response of the postsynaptic $GABA_A$ receptors to GABA. Using febrile seizures in a mouse model of SMEI[60] as a test system, we found that combinations of tiagabine and clonazepam are effective in completely preventing thermally induced myoclonic and generalized tonic-clonic seizures.[66] These encouraging results suggest that similar combination drug therapies may be useful for children with SMEI.

POTENTIAL ROLE OF MUTATIONS IN $Na_V1.1$ CHANNELS IN FEBRILE SEIZURES IN CHILDHOOD

Febrile seizures are common in childhood, but the basis for their prevalence is unknown. Recent evidence suggests that mild loss-of-function mutations or polymorphisms in $Na_V1.1$ channels may cause a significant proportion of febrile seizures. Mantegazza et al.[67] characterized a mild loss-of-function mutation in $Na_V1.1$ channels in a family with familial febrile seizures. This mutation caused reduction of peak sodium currents and a positive shift in the voltage dependence of activation when expressed in nonneuronal cells, providing the first evidence for association of mild loss of function of $Na_V1.1$ channels with familial febrile seizures.

There has been considerable controversy regarding claims that routine childhood vaccination may be associated with the onset of both febrile and afebrile seizures and mental decline. Berkovic et al.[68] studied 14 children with this diagnosis and identified *SCN1A* mutations in 11 of them. Their observations indicate that vaccination and its associated fever may trigger the first seizure episode of an underlying genetic disorder, GEFS+ or SMEI, which often presents first as febrile seizures. These studies further implicate dysfunction of $Na_V1.1$ channels in childhood febrile seizures.

Most recently, human genetic studies have also suggested an association of genetic alterations in $Na_V1.1$ channels with nonfamilial febrile seizures.[69] In normal development, the mRNAs encoding $Na_V1.1$, $Na_V1.2$, and $Na_V1.3$ channels undergo a regulated change in alternative splicing of exon 5,[70,71] which has a striking effect on the voltage dependence of channel activation.[72] Regulation of this alternative splicing process is disrupted by a single nucleotide polymorphism (SNP IVS5N+5 G>A).[73,74] The presence of this SNP has been correlated with an altered response to antiepileptic drugs[73,74] and with the risk of febrile seizures in a large cohort of epilepsy patients from Germany and Austria.[69] On the other hand, correlation of this SNP with febrile seizures was not observed in a similar study of Australian epilepsy patients.[75] Nevertheless, even considering these negative data, the combination of results from studies of familial febrile seizures,[67] vaccination-related seizures,[68] responsiveness to antiepileptic drugs,[73,74] and febrile seizures in a German/Austrian cohort of patients[69] all point to a key role of $Na_V1.1$ channels as molecular determinants of the risk of epilepsy in the general population and raise the possibility that febrile seizures in children are often caused by mild loss-of-function mutations or polymorphisms of $Na_V1.1$ channels in combination with environmental precipitating factors.

A UNIFIED LOSS-OF-FUNCTION HYPOTHESIS FOR $Na_V1.1$ GENETIC EPILEPSIES

$Na_V1.1$ channels are highly expressed in many GABAergic inhibitory neurons and are responsible for essentially all of the sodium current in the cell bodies of hippocampal interneurons.[33] Loss of function of these sodium channels greatly impairs the ability of these inhibitory neurons to fire action potentials at high frequency and therefore would greatly reduce their phasic release of GABA.[33] It is likely that this loss of action potential firing by inhibitory neurons leads to an imbalance between excitation and inhibition in the brain and consequently to febrile seizures and epilepsy. Although more work is needed to develop definite genotype–phenotype correlations for the $Na_V1.1$ epilepsies, we extend here the previous proposal[76] suggesting the unifying hypothesis that the spectrum of severity of the $Na_V1.1$-associated forms of epilepsy results from a spectrum of increasing severity of loss-of-function mutations of $Na_V1.1$ channels and increasing impairment of action potential firing in GABAergic inhibitory neurons (Fig. 52–3). Mild impairment of $Na_V1.1$ channel function causes febrile seizures; moderate to severe impairment of $Na_V1.1$ function by missense mutations and/or altered mRNA processing causes the range of phenotypes observed in GEFS+ epilepsy; and very severe to complete loss of function causes SMEI. The severity of the phenotype in these genetic diseases is also influenced strongly by genetic background effects, as illustrated by striking differences in phenotypes among GEFS+ patients with the same missense mutation,[77] different severity of disease of SMEI patients with complete loss-of-function mutations,[78,79] and dramatic differences in sensitivity among mouse strains

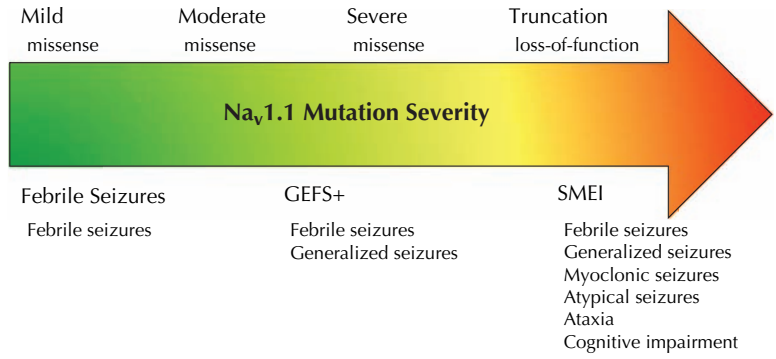

Figure 52–3. The unified loss-of-function hypothesis for Na$_V$1.1 genetic epilepsies. Increasing severity of loss-of-function mutations of Na$_V$1.1 channels, noted above the arrow, causes progressively more severe epilepsy syndromes ranging from familial febrile seizures to GEFS+ and finally SMEI, noted below the arrow. Major symptoms of each syndrome are also listed.

to the same loss-of-function mutations.[33] This unifying hypothesis may bring increasing clarity to the understanding of the genotype–phenotype correlations in this family of epilepsy syndromes.

MUTATIONS OF OTHER NA$_V$ CHANNELS IN EPILEPSY

Benign familial neonatal-infantile seizures (BFNIS) is a mild seizure syndrome caused by dominant mutations in Na$_V$1.2 channels.[80] Affected individuals have onset of seizures in early infancy.[81] Typically, ictal episodes begin as partial seizures, which often become generalized. Febrile seizures are rare.[81] Fortunately, these seizures respond favorably to treatment with antiepileptic drugs, and they generally remit by 1 year of age.[81]

Na$_V$1.2 channels are closely related to Na$_V$1.1 channels in amino acid sequence and in their primary expression in the central nervous system.[5] They are primarily expressed in unmyelinated axons in adult rodent brain,[7] and they are replaced by Na$_V$1.6 channels during formation of the myelin sheath of myelinated axons.[82] As with Na$_V$1.1 channels, their expression increases during the first 4 weeks of postnatal life in rodents.[17,18] The relationship between the functional alterations in Na$_V$1.2 channels and the hyperexcitability of BFNIS is not clear. Some missense mutations cause a gain of sodium channel function via negative shifts in the voltage dependence of activation or impairment of inactivation.[83] On the other hand, some missense mutations cause reduced Na^+ channel activity.[84] In addition, one missense mutation caused a selective gain of sodium channel function in the embryonic isoform of Na$_V$1.2 channels,[85] which has a more positive voltage dependence of activation than the adult isoform.[70,72] These seizures remitted during neonatal development, following a time course similar to that of the normal increase in voltage sensitivity of the wild-type Na$_V$1.2 channel.[85] These results suggest that increased excitability of the mutant embryonic isoform of Na$_V$1.2 channels can cause early-onset epilepsy. This epilepsy remits with development because the enhanced excitability of the mutant embryonic isoform of the Na$_V$1.2 channel is comparable to that of wild-type channels after alternative splicing to the mature form of Na$_V$1.2 is completed. Thus, in this case, remission of the seizure phenotype is apparently caused by the fact that the mutant Na$_V$1.2 channel is no more excitable than wild-type Na$_V$1.2 after the wild type is converted to the adult isoform by alternative splicing of its mRNA. In addition to BFNIS, de novo dominant mutations in Na$_V$1.2 channels can cause other, more severe seizure syndromes.[86–88] These results broaden the spectrum of epilepsies that can be caused by mutations in Na$_V$1.2 channels, which is now similar to the spectrum of seizure syndromes observed for Na$_V$1.1 mutations (Fig. 52–3).

Surprisingly, no mutations in Na$_V$1.3 or Na$_V$1.6 channels have been described that cause epilepsy. Na$_V$1.3 channels are primarily expressed in embryonic life, so severe

mutations within them may cause premature termination of pregnancy, and mild mutations may not have major effects because expression of these channels declines soon after birth. On the other hand, $Na_V1.6$ channels drive the excitability of excitatory neurons,[89] so gain of function should cause hyperexcitability and epilepsy. The lack of such mutations in the human population may indicate that even mild increases in the function of $Na_V1.6$ channels have such deleterious consequences that individuals with gain-of-function mutations die prematurely from causes other than epilepsy.

Chapter 53

Potassium Channelopathies of Epilepsy

Robert Brenner
Karen S. Wilcox

INTRODUCTION

Channelopathies are inherited genetic changes in ion channel genes that generate a disease. Given the pivotal role of voltage-dependent potassium channels in moderating neuronal excitability, it is not surprising that these channels are well represented among the channelopathies contributing to epilepsy. Voltage-dependent potassium channels are regarded as the "initial responders" that shape and moderate depolarization of excitable cells. However, this oversimplification belies a heterogeneous mix of diverse voltage-dependent potassium channels in the nervous system that are specialized for function in different subcellular compartments, in different neuronal types, and, indeed, even at different voltages. Consistent with this, the uncovering of epilepsy channelopathies during the past two decades has revealed a number of potassium channels that contribute to epilepsy in distinct ways when genetically altered. This chapter provides a brief overview of the various potassium channelopathies that have so far been identified to contribute to epilepsy. In so doing, it also highlights the distinct functions that different potassium channels serve in regulating excitability and how they contribute to epilepsy when such functions are altered.

WHAT ARE POTASSIUM CHANNELS?

The minimal structures that comprise potassium channels are best represented by the

inward rectifier potassium channels (*KCNJ* family, Fig. 53–1). These channels include two transmembrane segments that flank a pore-loop domain. The transmembrane segments form an aqueous channel, and the pore-loop domain filters ions to selectively allow potassium flux. These components are conserved in all potassium channels. Binding of magnesium and polyamines at the intracellular vestibule of the channel is a property unique to the inward rectifier class of potassium channels that controls ion flux. Binding and occlusion of the pore occur at relatively positive but not negative voltages, therefore giving these channels the property of inward rectification (larger inward than outward conductance).[1] Conduction through the channel is also regulated by conformational changes in the channel, either near the selectivity filter or at the second transmembrane segment that allows some inward rectifiers, such as the adenosine triphosphate (ATP)-sensitive potassium channels, to gate channel opening in response to intracellular signals such as ATP concentration.[2]

Evolution and gene duplication have diversified the potassium channel family to include the twin pore channels (Fig. 53–1), which are thought to contribute to the "leak" resting potassium current and therefore affect resting membrane potentials.[3] As well, an additional 4-transmembrane segment (S1–S4 segment) has been appended to the channel pore (S5–S6 segment) to create the 6-transmembrane channel family (Fig. 53–1). The 6-transmembrane family has diversified extensively, both to maintain potassium-selective channels and evolve members of nonselective cation channels not shown here. Among the 6-transmembrane potassium channels, some have evolved an intracellular domain that mediates the response to intracellular ion fluxes such as calcium-activated (*KCNN*) and sodium-activated (*KCNT*) potassium channels. The voltage-activated potassium channel family has charged transmembrane residues, located in the S4 segment, but additional residues may occur in the S1–S3 segment, which senses the membrane electric field and allosterically couples to the channel gate to promote channel opening. The voltage sensor domain not only affects the voltage sensitivity of channels (the relative change in open probability per change in voltage) but also determines the voltage ranges at which channels open. For example, voltage sensors may

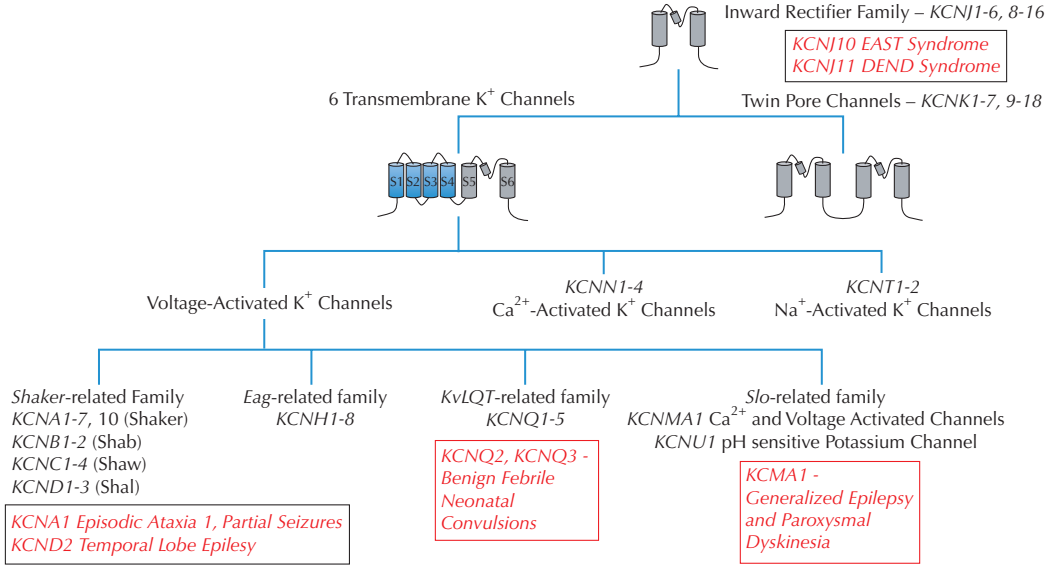

Figure 53–1. The potassium channel gene family and epilepsy channelopathies**.** Family members are organized according to transmembrane structure. Genes within each family that are known to occur with epilepsy channelopathy mutations are boxed below in red. *shaker*-related channel genes that encode nonconducting subunits (*KCNF, KCNG, KCNS*, and *KCNV* channel genes) are not included in the diagram.

be tuned to activate at voltages below threshold to affect the resting membrane potential, near threshold to affect the action potential firing frequency, or at high voltages to contribute only to spike repolarization.

A subset of voltage-dependent potassium channels can undergo inactivation. This includes some members of the *shaker* and *eag* families of potassium channels. Inactivation is a transition from channel opening to closing despite continued depolarization. Inactivation is often mediated by an amino-terminal sequence (ball-and-chain sequence) that plugs the pore following channel opening and is called *N-type inactivation*.[4] N-type inactivation is often relatively quick (in the tens to hundreds of milliseconds) and is mediated by amino terminal sequences intrinsic to the channel pore-forming subunit, or it can be conferred by accessory subunits that contain a ball-and-chain sequence. Inactivation can also be of a slow type (occurring over hundreds of milliseconds to seconds), called *P-* or *C-type inactivation*, that occurs by conformational changes at the pore.[4–6] Fast inactivation of potassium channels is seen as A-type potassium currents. These currents repolarize membrane voltages during one or the first few action potentials but inactivate over multiple spikes.[7] This may lead to a broadening of action potentials or higher action potential frequency during the late components of a spike train.[7]

Members of the voltage-dependent potassium channels include a very large family, perhaps encompassing 32 channel genes in humans (see the HUGO list at http://www.genenames.org/genefamily/kcn.php) and outside the scope of this introduction. Figure 53–1 highlights those genes that have human epilepsy mutations. From this chart, we can see that the inward rectifier potassium channel family contain two members, *KCNJ10* and *KCNJ11*, that contribute to inherited epilepsies as part of more complex disorders (ataxia, sensorineural deafness, and kidney tubulopathy [EAST] and developmental delay, epilepsy, and neonatal diabetes [DEND] syndromes, respectively). The remaining and majority of the epilepsy potassium channelopathies reside among the voltage-dependent potassium family members. These include two members of the *shaker*-related family (*KCNA1* and *KCND2*), two members of the KvLQT family (*KCNQ2* and *KCNQ3*), and one member of the *Slo*-related family, *KCNMA1*. Below, we will provide a review of these various channel genes that contribute to epilepsy when mutated and attempt to describe what is known regarding the physiological basis for increased excitability.

KCNA1

Historically, human *KCNA1* (Kv1.1) mutations were first identified as an autosomal dominant ataxia channelopathy[8] that has subsequently been classified as episodic ataxia type 1 (EA1).[9] Episodic ataxia type1 occurs as brief episodes of discoordination induced by startle, stress, or heavy exertion. Patients may also experience continuous muscle movement (myokymia) either during or between attacks of ataxia.[9] It was later found that a subset of individuals with *KCNA1* mutations, T226R and A242P, also experience partial seizures.[10–12] The T226R mutation causes EA1, myokymia, and partial-onset epilepsy.[12] The A242P mutation does not cause ataxia, but does cause partial epilepsy and myokymia.[10,11] An interesting observation was that the T226R mutation is penetrant for epilepsy only in some families or family members,[12,13] suggesting that the KCNA1 epilepsy phenotype is sensitive to secondary environmental or genetic influences. As well, *KCNA1* mutations have been identified that exhibit different comorbidities, such as partial epilepsy and myokymia but no ataxia, or mutations that exhibit myokymia alone.[10] Thus, the different nature of *KCNA1* mutations appears to also confer phenotypic variability.

Effect of *KCNA1* Epilepsy Mutations on Potassium Currents

KCNA1 encodes potassium channels related to the *Drosophila shaker* family of voltage-gated potassium channels. *KCNA1* currents differ from the *shaker* A-type currents due to a lack of intrinsic fast inactivation. However, in some cells, coassembly with the Kvbeta1 accessory subunits[14] or heteromeric assembly with *KCNA4* subunits[15,16] confers fast inactivation. *KCNA1* channels are often ascribed to a low-voltage-threshold, fast-activated delayed rectifier potassium current that inactivates over a slow time period (hundreds of milliseconds). The two *KCNA1* mutations causing epilepsy, T226R[12] and A242P, are located in the

S2 transmembrane domain[10,11] The common feature is that both mutations are likely to be hypomorphs since they dramatically reduce expression or trafficking of channels in expression systems.[10,12,17,18] The T226R mutation also reduces channel function by shifting the conductance voltage relationship to positive potentials and dramatically slowing the activation time.[17]

The correlation between *KCNA1* hypomorphic mutations and epilepsy is also strengthened by knockout studies of the *KCNA1* gene in mice.[19] *KCNA1* knockout mice have frequent spontaneous seizures, although ataxia is not apparent. Electrophysiological studies suggest normal intrinsic excitability but enhanced excitability related to axonal repolarization and propagation. These results are consistent with *KCNA1* channel preferential expression in axons and presynaptic terminals.[20,21] Studies of *KCNA1* mutations expressed in neurons also suggest that epilepsy mutations (T226R) perturb presynaptic function rather than intrinsic excitability.[22]

KCNA1 and Sudden Unexplained Death in Epilepsy

Recently, work on Kv1.1 channels has significantly advanced the understanding of the potential mechanisms of sudden unexplained death in epilepsy (SUDEP), which refers to death of unknown cause in individuals who have epilepsy. Death in these individuals is approximately 40-fold higher than in individuals without epilepsy.[23] The work of Glasscock and colleagues indicates that increased excitability at parasympathetic nerves may contribute to SUDEP.[24] This was revealed using *KCNA1* knockout mice that are predisposed to SUDEP and have cardiac arrhythmias, including atrioventricular conduction block that is increased during seizures. The authors used the parasympathetic antagonist atropine to correct the arrhythmias, suggesting that *KCNA1* channel defects may increase vagus nerve activity sufficiently to cause SUDEP.

KCNA1 Channelopathy as a Consequence of *LGI1* Mutations

Voltage-dependent potassium channels are heavily regulated to alter their properties or expression, depending on the needs of the neuron. Mutation of the *LGI1* protein presents one example of a situation in which genetic alteration of a potassium channel regulatory protein may contribute indirectly to epilepsy. The *LGI1* protein was first identified as a candidate gene that is absent or downregulated in malignant brain tumors.[25] Its acronym is based on the finding that it is a *leucine*-rich *gene* that is *inactivated* in *gliomas*. The *LGI1* gene encodes a single transmembrane protein with leucine-rich repeats in the extracellular amino terminus that is similar to a family (F-20) of cell adhesion proteins and receptors.[25] Linkage analysis and cloning have identified mutations in this gene as a cause of the inherited disorder autosomal dominant lateral temporal lobe epilepsy (ADLTE), also named *autosomal dominant partial epilepsy with auditory features* (ADPEAF).[26–29] ADLTE occurs as simple partial seizures, of temporal lobe origin, with acoustic and sensory hallucinations. Some individuals also have a less frequent, secondarily generalized seizure. The *LGI1* locus carries mutations in about 50% of all ADLTE families.[28,29]

A connection between *LGI1* and *KCNA1* channels was discovered using biochemical purification of *KCNA1* complexes that revealed coassembly of *LGI1* protein.[30] The *KCNA1* channel also copurified a number of other proteins, including *KCNA4* (Kv1.4) channels and *KCNB1* (Kvbeta1), both of which assemble with and confer fast N-type inactivation properties on *KCNA1* channels. A pivotal finding was that *LGI1* occludes *KCNB1*-mediated increases in inactivation rates. This presumably creates a more sustained A-type current and may reduce excitability in neurons. The finding that ADLTE *LGI1* mutants do not have antagonistic effects on *KCNB1* inactivation suggests that *LGI1* mutations may increase excitability in ADLTE patients through increase inactivation of *KCNA1*-containing, A-type currents.[30]

A more thorough understanding of *LGI1* mutation on the neurophysiology of ADLTE was provided using genetic mouse models of the disease. Knockout of the *LGI1* gene causes severe myoclonic seizures in early life (12–20 days), and mice die shortly thereafter.[31] Interestingly, heterozygous *LGI1* null mice do not show a seizure phenotype, whereas ADLTE LGI1 individuals are heterozygous for a mutant allele.[28] A transgenic study suggests that this can be explained by the mutant *LGI1*

protein in ADLTE patients acting in a dominant negative manner on wild-type protein.[32]

Consistent with *LGI1* protein action on *KCNA1* channels, *LGI1* knockout had no effect on intrinsic properties of neurons, but it increased spontaneous glutamate-mediated excitatory postsynaptic potentials.[31] In addition, transgenic expression of the ADLTE truncation mutant of *LGI1* in mice also increased excitatory synaptic transmission.[32] However, studies suggest that *LGI1* has multiple interacting protein targets and that the mechanism for increased excitability is complex. Besides producing mutant *LGI1* effects on presynaptic *KCNA1* channels.[32] *LGI1* interacts with the postsynaptic protein *ADAM22*[33] and has effects on synapse maturation[32] that may also contribute to seizures when mutated.

KCND2

KCND2 AND A-TYPE CURRENTS

The *KCND2* channel contributes to voltage-gated potassium currents that undergo fast inactivation and are broadly classified as A-type currents (I_A). Among the genes contributing to A-type current, *KCND2* and its family members (*KCND1–3*, also called Kv4.1-Kv4.3) are activated at subthreshold voltages and enriched in somato-dendritic compartments, and therefore have the more specialized designation of the I_{SA} current.[34] One of these family members (*KCND3*) also underlies the transient outward (I_{TO}) current of the cardiac action potential in humans.[35]

KCND2 Channelopathy Mutation

The *KCND2* potassium channel is an ion channel that has been heavily studied for its role in acquired epilepsy, whereas its role as a potassium channelopathy gene requires further study. Evidence of *KCND2* channels as a channelopathy mutation is limited to a report of a single individual identified in a genetic screen of individuals with temporal lobe epilepsy.[36] Sequencing of the *KCND2* locus identified a carboxyl terminal 5 nucleotide deletion that leads to a premature stop codon and truncation of the last 44 amino acids of the protein.[36] Electrophysiology studies in transfected HEK293 cells did not detect discernible effects on channel gating. However, the average current density of transfected cells is reduced by approximately half, suggesting that the mutation is a hypomorph due to reduced current density. Whether this mutation is responsible for, or coincident with, epilepsy in this single patient is uncertain, particularly since genetic ablation of *KCND2* is insufficient to cause spontaneous seizures in mice.

Acquired Changes in *KCND2* and Seizures

Our understanding of I_{SA} current and KCND channels in epilepsy mainly concerns their role in the control of dendritic excitability. These currents have often been studied in CA1 dendrites that are sufficiently large at distances from the soma at which they can be detected by sophisticated patch-clamp recording techniques. The I_{SA} current is expressed as a gradient, being more enriched at distal versus proximal dendrites.[37] The contribution of this current by *KCND2* is confirmed by immunohistochemistry[38] and also by gene knockout of *KCND2* that largely eliminates the dendritic I_{SA} current.[39] An important function of this I_{SA} gradient is to limit the amplitude of backpropagating action potentials to distal dendrites.[37,40] This provides a repolarizing current that limits excitability and activation of *N*-methyl-D-aspartate (NMDA) receptors that otherwise enhance the long-term potentiation of synapses. Importantly, the I_{SA} current is inhibited by both protein kinase A and protein kinase C phosphorylation that is upstream of ERK kinase phosphorylation of channels. The sensitivity of *KCND2* to these kinases makes dendrites particularly prone to enhanced excitability following changes in any number of signaling cascades that alter these kinases. With regard to epilepsy, ERK inhibition of Kv4.2, coupled with transcriptional downregulation, appears to mediate enhanced dendritic excitability and seizures following pilocarpine-induced status epilepticus.[41] In addition models of cortical and hippocampal malformations that are prone to seizures also show a correlative reduction in Kv4.2 expression and current in heterotopic cell regions.[41] Finally, knockout of Kv4.2 also demonstrates increased susceptibility to seizures following convulsant stimulation.[41]

KCNMA1

KCNMA1 AND THE BK CHANNEL

The *KCNMA1* gene encodes large-conductance potassium channels that are dually activated by calcium and voltage. In accordance with their name (*BK channel*, "big K conductance"), these channels tower over most voltage-gated channels in single-channel conductance (~250 pS, more than 20-fold larger than *shaker*-type potassium channels) and can potentially have dramatic effects on membrane voltage.[42] Interestingly, only the single *KCNMA1* gene encodes this class of potassium channel. Their large conductance combined with their broad distribution means that these channels are relatively easy to detect and have been characterized in many cell types. BK channels are observed in skeletal and smooth muscle cells, central nervous system (CNS) and peripheral nervous system (PNS) neurons, endothelial and kidney epithelial cells, and other cell types. Gene identification was made possible by cloning of the *Drosophila* Slowpoke gene locus and cDNA.[43] Therefore, these channels are also called *slo* channels or *mslo* or *hslo* for their mouse or human orthologues, respectively. Although they have structural homology to other voltage-dependent potassium channels, BK channels have an additional amino-terminal transmembrane domain (designated S0) and a large carboxyl terminal domain that has structural domains for two calcium-binding sites per subunit.[44] Finally, a family of four tissue-specific accessory β subunits modulates the biophysical properties and pharmacology of BK channels.[45]

KCNMA1 Gating Properties

Understanding the biophysical properties of BK channels allow us to infer some principles of channel function that are borne out by studies in native cells. The first is that BK channels are effectively activated by calcium concentrations (micromolar) not normally occurring at global concentrations (hundreds of nanomolars). The BK current evoked by action potential-shaped voltage waveforms provides an estimate of 14 μM calcium required to evoke half-maximal current.[46] Thus, BK channels often require colocalization with a calcium source for significant activation.[47] Second, there are examples of BK regulation by numerous mechanisms, including alternative splicing, accessory subunits, phosphorylation status, and redox state. Therefore, BK channel gating properties appear to be tightly regulated for their local calcium environment. Finally, BK channel opening is sensitive in a roughly additive fashion to both calcium and voltage.[48] Thus, BK channels are well tailored for repolarization of action potentials that are coincident with calcium transients, such as occur during action potentials in the soma or in presynaptic nerve terminals. The combined voltage and calcium sensitivity also means that BK channels deactivate following repolarization of action potentials, which restrict their contribution to the fast component of the afterhyperpolarization. Other purely calcium-sensitive potassium channels, such as SK channels, are not deactivated by repolarization and usually contribute to a more sustained (medium) afterhyperpolarization.[49]

BK Channel Function in Neurons

Owing to their broad tissue distribution, the physiological roles of BK channels are quite diverse. Indeed, limiting the focus of this review on epilepsy overlooks a large body of knowledge concerning BK channels outside the nervous system. These include control of tonic and phasic smooth muscle constriction, in renal control of potassium secretion, and control of hormone release of many secretory cells. However, even in the nervous system, BK channels have been studied within many different neuronal compartments and within many neuronal types.

BK channel effects are often uncovered with the highly specific scorpion toxin iberiotoxin, or with charybdotoxin, which also blocks intermediate-conductance potassium channels (IK channels).[42] Worth noting is that the affinity for scorpion toxin is reduced by some beta accessory subunits and shows little block with the accessory beta4 subunit.[50] However, organic blockers, such as paxilline, which have more recently come into use, block BK channels independently of beta subunit composition.[51] Blocking BK channels causes broadening of the action potential and, in some neurons, eliminates the fast component of the afterhyperpolarization.[49] In CA1 and lateral amygdala

pyramidal neurons, BK channel effects are limited to the first few spikes in the action potential train.[52,53] This is likely due to inactivation of BK channels in these cells during repetitive firing and is manifested as frequency-dependent action potential broadening. Interestingly, the consequence of BK channel block on firing patterns is neuron-specific. In CA1 and dentate gyrus (DG) neurons of the hippocampus, BK channels increase rather than decrease the firing rate.[54,55] Both result from action potential sharpening that secondarily affects other currents to increase excitability. For example, in CA1 neurons, BK channel sharpening of action potentials removes sodium channel inactivation and reduces delayed rectifier potassium channel inactivation.[54] In DG neurons, sharpening of action potentials reduces recruitment of SK-type potassium channels to increase the firing rate.[55]

BK Channels and Acquired Epilepsy

The first evidence that BK channels may enhance the excitability related to seizures was obtained in cultured cortical neurons.[56] The gamma-aminobutyric acid (GABA) antagonist and convulsant pentylenetetrazol (PTZ) causes bursting activity in cultured cortical neurons. Treatment of cells with the BK channel blocker iberiotoxin inhibited bursting activity in PTZ- treated and pro-epileptic L mouse cortical neurons. In a picrotoxin seizure model, it was also observed that increased firing rates in cortical neurons could be attenuated by BK channel block.[57] Interestingly, the effectiveness of BK channel block occurs during the second but not the first picrotoxin treatment. This suggests that BK channels are part of a maladaptive upregulation in cortical neurons following seizures. Further, it was shown that systemic injection of the BK channel blocker paxilline was effective in protecting against subsequent picrotoxin-induced seizures.[58]

Human BK Channel Epilepsy Channelopathy

The BK channel pore-forming subunit knockout mice have a plethora of defects, including slowed growth rates, cerebellar dysfunction and ataxia, defects in circadian rhythms, and a number of defects due to smooth muscle hypercontractility.[59–64] Interestingly, seizures have not been reported in *KCNMA1* knockout mice. Rather, it is a gain-of-function mutation that causes nonconvulsive seizures in humans.[65] The effect is partially penetrant, showing apparent absence type seizures in 9 of 16 affected family members. The polymorphism also causes 12 of the 16 family members to have a paroxysmal nonkinesigenic dyskinesia. The single aspartate-to-glycine (D434G) amino acid change resides in one of the calcium activation domains (RCK domain, regulator of conductance of potassium) in the pore-forming alpha subunit. Interestingly, expression of the mutant channels in *Xenopus* oocytes or cultured cells demonstrates an increased current due to faster activation and an increased open probability.[65] More detailed biophysical studies suggest that the mutation affects calcium-dependent gating[46,66,67] and may also directly reduce the energetic barrier to opening.[46]

The mechanisms by which the BK channel D434G gain-of-function mutation causes epilepsy in humans will require a transgenic animal model for greater understanding. Reduced excitability in inhibitory neurons may explain the seizures; however, BK channel expression predominates in excitatory principal neurons of most brain regions, including the cortex and hippocampus.[68,69] An exception is brainstem vestibular neurons, where BK channels moderate high-frequency action potential firing.[70,71] Alternatively, it may be that the human BK channel gain of function acts in a manner similar to that seen in CA1 pyramidal neurons, where BK channels sharpening of action potentials secondarily increases excitability.[54] A similar effect is also seen in the BK channel β4 knockout mice. The β4 accessory subunit inhibits BK channel opening through a slowing of activation,[46] and therefore the β4 knockout mice may also be considered a gain-of-function model. In these animals, epilepsy is also observed, although because of the strong localization of β4 in the hippocampus, the seizures appear to be secondarily generalized with a temporal lobe origin.[55] Thus, there are at least two genetic models[55,65] and one acquired seizure model[57,58] to support the paradoxical findings that BK potassium channels increase excitability and can lead to seizures.

KCNQ Channelopathy Mutations

The M-type potassium current (I_M) regulates the resting membrane potential and spike frequency adaptation and can contribute to slow afterhyperpolarization following action potentials.[72,73] A large number of mutations in two genes encoding the subunits that comprise the M-channel, *KCNQ2* (Kv7.2) and *KCNQ3* (Kv7.3), result in the seizure disorder benign familial neonatal convulsions (BFNC). In BFNC, seizures typically begin within the first 3 days of life and can be partial or generalized. Importantly, the seizures remit spontaneously and normal development follows in the majority of cases, although the incidence of later seizures is higher than in the general population in some families.[74–77] The initial findings implicating the Kv7.2 and Kv7.3 channelopathies in BFNC were the first to link mutations in potassium channels to a familial epilepsy. While 4 different mutations in *KCNQ3* have been identified to date, at least 63 different mutations in *KCNQ2* have been observed in families with BFNC.[77] In addition, de novo *KCNQ2* mutations have been identified in patients with benign neonatal seizures whose seizures also remit.[78] Many of these mutations result in a haploinsufficiency of these channels, while other mutations, such as those that occur in the pore region of the channels, result in a reduction of function.[76] In addition, a number of mutations in *KCNQ2* are located in transmembrane regions of channels and can alter gating properties.[76,79] Therefore, it is thought that the neonatal seizures that occur as a consequence of these mutations are due to a reduction of function of the M-type channels and a concomitant increase in excitability of neurons.

Mutations in *KCNQ2* that cause BFNC have also been associated with other disorders as well, such as rolandic epilepsy,[76,80,81] drug-resistant epilepsy, and/or mental retardation.[79,82,83] Therefore, mutations in these channels have attracted considerable attention over the last decade, especially as a novel anticonvulsant, retigabine (RGB), has as its primary mechanism of action a shift in the activation curve for I_M to a more hyperpolarized potential.[84] This finding, coupled with the genetic findings described above, have garnered enthusiasm for consideration of the M-channel as a potential and novel therapeutic target for the treatment of seizures.

KCNQ Mutations and Animal Models

To study the contribution of mutations in the M-channel to seizure disorders, a number of animal models have been developed. These include the *Kcnq2* knockout mouse, the dominant-negative *Kcnq2* G279S mutation, the *Szt1* spontaneous deletion mouse strain, the *Kcnq2* A306T knockin mouse, and the *Kcnq3* G311V knockin mouse.[85–89] Mice homozygous for both the *Kcnq2* knockout and *Szt1* mutations are lethal, dying soon after birth due to a lung defect. However, mice heterozygous for the *Kcnq2* knockout and the *Szt1* mutation, are viable. In addition, all of the knockin mice that have been generated to date are viable, even when homozygous for the mutations.[88] Electrophysiology experiments performed on CA1 neurons in the in vitro hippocampal brain slices obtained from these mouse models have uniformly found decreased $I_{K(M)}$ amplitude, decreased current density, and, when examined, a reduction in action potential accommodation compared to their wild-type C57BL/6 littermates.[77,86,90] In addition to the observed alterations found in the membrane currents, significant differences in $I_{K(M)}$ pharmacology in CA1 neurons recorded from *Szt1* mice have been observed.[90,91] These differences have intriguing parallels to the results of in vivo experiments in the *Szt1* mice, including a highly significant decrease in sensitivity to RGB.[90,91] These results have profound implications for pharmacotherapy, as they suggest that antiepileptic drugs that target the M-channel, such as retigabine and flupertine, may be less effective in patients with underlying *KCNQ2* mutations that result in a haploinsufficiency.

KCNQ1

A member of the Kv7 family of potassium channels, Kv7.1, is encoded by the *KCNQ1* gene and forms the α subunit of this potassium channel.[92] Kv7.1 is expressed in cardiac tissue, and mutations in this gene have been linked to the long QT syndrome (LQTS) and fatal cardiac arrhythmias. Over 300 mutations have been identified in this gene, and many of those mutations result in a prolongation of the cardiac action potential and sudden death.[93] It had

been thought that this gene was not expressed in the CNS, but recent work has convincingly demonstrated that in fact *KCNQ1* is expressed in brain.[94] In two mouse lines with LQTS mutations, *Kcnq1* A340E and T311I, mice heterozygous and homozygous for the mutations have cardiac abnormalities, as well as exhibiting both partial and generalized seizures.[94] In addition, at least one mouse in the study was observed to die following a prolonged period of seizure activity, bradycardia, cardiac depression, and ultimately cardiac arrest.[94] As SUDEP may be responsible for a large percentage of deaths in patients with epilepsy, these findings provide support for evaluating the LQTS genes in patients with epilepsy and concomitant cardiac irregularities.

KCNJ10

The inward-rectifying potassium channel (Kir4.1) is highly expressed in glial cells in the CNS, as well as in cochlear, cardiac, kidney, and other tissues, and is encoded by the *KCNJ10* gene. Kir channels expressed by glial cells buffer extracellular potassium in the CNS following neuronal action potentials and are primarily responsible for maintaining low extracellular levels of potassium in the CNS. Quantitative trait loci mapping experiments first identified a variation in the mouse *Kcnj10* gene that was correlated with an increase in seizure susceptibility in the DBA/2 mouse,[95] and a variation in the human *KCNJ10* has also been found to be associated with common forms of human epilepsy.[96–98] Furthermore, coding region mutations in the *KCNJ10* gene that are linked to a familial form of epilepsy with ataxia, sensorineural deafness, and kidney tubulopathy (EAST syndrome) have recently been identified.[99,100] When *KCNJ10* is expressed in CHO cells, these mutations are found to result in a loss of (or greatly reduced) function.[101] In addition, recent work has demonstrated that astrocytes from DBA/2 mice, which harbor the initially described variant, have a decreased Kir current and also exhibit a reduction in glutamate transport compared to the more seizure-resistant strain of mice, C57Bl/6.[102] Therefore, variants of *KCNJ10* may be associated with common forms of human epilepsy by reducing seizure thresholds. However, there are also rare mutations in this gene that can underlie familial types of epilepsy that are part of a more complex phenotype.

KCNJ11

The *KCNJ11* gene encodes the Kir 6.2 protein that comprises the pore region of the ATP-sensitive potassium channel (K_{ATP}).[103] Not only is Kir 6.2 highly expressed in brain, but it is also found in pancreatic β cells. When the intracellular levels of ATP are high, the ion channel in both neurons and β cells is closed, allowing for depolarization, action potential generation, and the release of neurotransmitters and insulin, respectively.[104] However, to conserve energy, when intracellular levels of ATP are low, the ion channel opens and causes a hyperpolarization of both neurons and β cells, thus inhibiting action potential generation, calcium influx, and the release of either neurotransmitters or insulin, respectively. Mutations in the *KCNJ11* gene that reduce the affinity for ATP and increase the probability of channel opening result in a syndrome characterized by developmental delay, epilepsy, and neonatal diabetes (DEND).[105,106] The diabetes results from a reduced ability to release insulin due to membrane hyperpolarization that occurs as the ion channel remains open. It is hypothesized that increased expression of K_{ATP} channels in inhibitory neurons may underlie the epilepsy that occurs in DEND. Such a gain-of-function mutation in a potassium channel is paradoxical and resembles that observed in the BK channels described above. In a recently published case study of a DEND patient, treatment with a sulfunylurea drug, glibenclamide, successfully treated the diabetes and permitted insulin therapy to be halted, most likely as a consequence of blocking the K_{ATP} channel.[106,107] This block aids in the depolarization of the β cells of the pancreas and allows insulin release to resume. Interestingly, following treatment with glibenclamide, the seizures were substantially diminished and the hypsarrhythmia observed on the patient's electroencephalogram was resolved.[106] While generalized sharp-wave activity was still observed during sleep, this patient demonstrated substantial psychomotor improvement. This suggests that early diagnosis and treatment of DEND could result in preventing seizures and concomitant psychomotor impairments.[105]

CONCLUSIONS

An exceedingly large number of familial and de novo channelopathies in several different types of potassium channels have already been found to underlie, or be associated with, many types of epilepsy. Given that the role of most potassium channels is to contribute to the maintenance of membrane hyperpolarization and repolarization, it is not surprising that loss-of-function mutations contribute to epilepsy. However, recently described potassium channelopathies resulting in gain of function can also, paradoxically, result in epilepsy. Furthermore, as many LQTS mutations arise in potassium channels, a link between epilepsy, SUDEP, and LQTS, as has now been observed for *KCNQ1*, may begin to inform prevention strategies for patients at risk for SUDEP. Finally, animal models harboring human mutations found in potassium channels have contributed greatly to our understanding of the mechanisms whereby specific channelopathies contribute to epilepsy, and it is anticipated that as this field continues to develop, advances in treatment strategies for patients will also be elucidated from such animal models.

Chapter 54

The Voltage-Gated Calcium Channel and Absence Epilepsy

Jeffrey L. Noebels

> The term epilepsy . . . should be degraded to stand for our ignorance of conditions that cause not only convulsions, but temporary failures of motor and mental functions . . . a failure of any part of the "circle" where the mind lives.
>
> John Hughlings Jackson, "A Digression on Epilepsy," *British Medical Journal,* 1866

The discovery that absence epilepsy, a "temporary failure of motor and mental function," can be linked to disruption of a single gene is now entering its 30th year.[1] Before then, few clues indicated that generalized epilepsies could be monogenic or, even more surprisingly, that an inherited alteration of one base pair in a calcium ion channel responsible for neurotransmitter release at virtually all central synapses might lead to the development of the spike-wave absence seizure phenotype, first described in a child by Berger a half century earlier.[2] Nevertheless, the detection of spontaneous cortical spike-wave discharges in the ataxic mutant mouse *tottering* led to the identification of a missense point mutation in *Cacna1a*,[3] the gene encoding the P/Q subunit calcium channel, and a parallel clinical syndrome in humans.[4] Since then, the molecular details of how dysfunction of this voltage-gated calcium channel pore-forming subunit, joined later by other auxiliary subunit members of the voltage-gated calcium ion channel family,[5,6]

leads to the distinctive spike-wave electroencephalographic (EEG) phenotype in mouse and human are steadily emerging. Together they provide an exemplary pathogenic road map revealing how early disruption of synaptic signaling patterns in the developing brain due to genetic impairment of a solitary ion channel entrains a downstream cascade of ion channel remodeling that favors neuronal burst firing and abnormal thalamocortical synchrony.

TOTTERING, ITS EPILEPTOGENIC ALLELES, AND INTERACTING SUBUNITS

The prototypical mutation, *tottering*, was the first of several spontaneous mutant gene loci underlying spike-wave seizures detected by EEG screening beginning in the late 1970s.[7] Now recognized as a single nucleotide mutation in *Cacna1a*, the gene encoding the pore-forming alpha subunit of the P/Q-type high-voltage-activated calcium channel, it shares the behavioral absence phenotype with other mutant alleles in the mouse,[8–12] the human,[13] and recently in the rat[14] (Fig. 54–1). Like many other ion channel disorders, the murine phenotype behaves as a true recessive since heterozygotes of most models appear unaffected; however, semidominant or true dominant phenotypes have recently been identified in *tottering 4J* and *wobbler* alleles.[10,11] These mutations recapitulate major neurological elements of the *tottering* syndrome, including nonconvulsive spike-wave absence epilepsy, ataxia, and episodic nonepileptic dyskinesias of variable developmental onset and severity[1]; we now appreciate that the disorder depends upon the loss of one or more functional domains of the channel protein, since full deletion of *Cacna1a* leads to a similar, more severe phenotype.[15] Interestingly, the syndrome contains a latent but beneficial neuroprotective element; the pathological activation of cortical spreading depression is strikingly diminished due to a major reduction in depolarization-induced release of glutamate and gamma-aminobutyric acid (GABA).[16] In contrast, gain-of-function

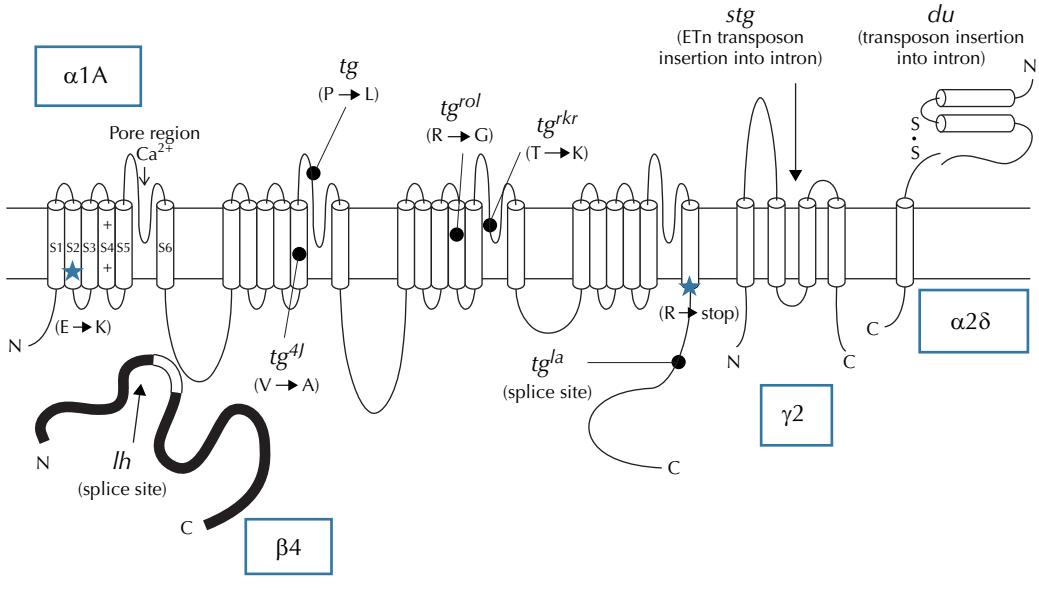

Figure 54–1. Genes for voltage-gated calcium channel subunits bearing absence epilepsy mutations. Approximate positions of spontaneous loss-of-function mutations in *tottering* (*tg*) and its alleles (*rolling*, *rocker*, *leaner*, and *tg 4J*) are shown by the black circles in the pore-forming alpha subunit (*Cacna1a*). The positions of two loss-of-function human mutations producing absence epilepsy, ataxia with/without episodic dyskinesia are shown with stars. The *lethargic* mutation interrupts interaction of the cytoplasmic regulatory beta subunit (*CacnB4*) with the alpha subunit, and *ducky* results in a defective membrane-spanning a2delta subunit (*Cacna2d2*). The *stargazer* mutation shown in the transmembrane gamma subunit (*Cacng2*) was originally considered to be a member of the voltage-gated calcium channel, as found in heteromeric muscle channels.

mutations in *Cacna1a* facilitate neurotransmitter release at central terminals[17,18] and are associated in the forebrain with convulsive seizures and episodic hemiplegic migraine mediated by a greatly reduced threshold for cortical spreading depression in the human and the mouse.[19–21] Together, these diametrically opposed presentations of calcium channelopathy offer a clear example of the spectrum of network excitability effects that arise from mutations within a single ion channel gene.

HOW LOSS-OF-FUNCTION *CACNA1A* MUTATIONS IMPAIR NEURONAL NETWORKS

Somatodendritic Compartment

Cacna1a mutations from mice displaying spike-wave epilepsy reduce P/Q current density in somatodendritic membranes. For the *tg* and *tg(rol)* mutations this is due to the lower voltage sensitivity of single-channel current activation[22–25] and in part to reduced membrane expression.[26] Human absence epilepsy mutations also reduce the P/Q current.[4,13] Interestingly, lower membrane current density may also contribute to dysfunction in gain-of-function hemiplegic migraine mutations.[27,28] In this case, the balance of the dual opposing effects of increased conductance and prolonged kinetics of single P/Q channels in the face of reduced current density may give rise to a complex array of intermediate and potentially network-specific excitability changes in these genotypes. Diminished P/Q current within somatodendritic compartments, where it is coupled to Ca^+-activated potassium channels, alters spontaneous firing patterns and postsynaptic plasticity at dendritic spines.[29,30]

Axon Initial Segment

Recent evidence indicates that P/Q channels are also active at the axon initial segment, where they play a role in membrane repolarization during spike firing by enhancing Ca^+-activated BK potassium channels.[31] Loss of P/Q current in this compartment is therefore of mechanistic interest as a pro-absence mechanism, since *KCNMA1*, one of the genes encoding brain BK channels, is highly expressed in neocortex, nucleus reticularis thalami (nRT), and relay nuclei of thalamus, and individuals with *KCNMA1* mutations show an absence epilepsy phenotype.[32]

Presynaptic Terminal and Exocytosis

Mutations in calcium channel subunits alter interactions with proteins coupled to exocytosis at the presynaptic terminal, revealing an inherant synaptic defect underlying absence epilepsy. P/Q channels are a major source of calcium ions that trigger the evoked release of neurotransmitter; this function is shared to a highly variable extent with N-type and R-type channels at central terminals, which possess distinct biophysical properties and individual contributions to the release machinery.[33] For example, P/Q channels show strong activity-dependent facilitation at the presynaptic terminal, which N channels do not.[34] Since evoked release at different interneurons depends selectively upon the P/Q type, the N type, or both,[35] the functional complexity of an inherited P/Q-type lesion makes it difficult to predict the emergent effects on excitability in any given synaptic network. In addition, in the immature brain, there is a developmental subunit switch in the channel dependence of synaptic release, where at some but not all synapses, the excitation-secretion machinery converts its reliance upon N-type release coupling to the P/Q type in the third postnatal week.[36,37] Interestingly, this switch is coincident with the postnatal appearance (P14–19) of spike-wave seizures in *tg* and other SW mutant mice.[38,39] While mechanistic details of the subunit switch are still emerging,[40] it may precipitate the onset of seizures in P/Q-type-deficient mutants, since a shift to P/Q reallocates the release machinery dependence on a source of calcium ions from functional N-type channels to defective or unavailable mutant P/Q channels, as demonstrated at *tottering* central synapses.[41] The specificity of P/Q splice variants in different cell types adds to additional release complexity within the thalamocortical network.[42,43]

When excitation-secretion coupling is assessed at central presynaptic terminals in the adult *tottering* mouse hippocampus, excitatory transmitter release is intact yet depends

almost entirely on rescue by N-type currents, since blockade by a specific P/Q toxin eliminates the majority of evoked release and spares a minor residual component presumably due to R-type current.[41] Similar results have also been seen at peripheral terminals,[44] where P/Q deficiency also increases jitter and reduces preterminal synaptic synchrony during rapid stimulation at the neuromuscular junction.[45] Intrahipppocampal inhibition is impaired, as assessed by the abnormally prolonged burst duration in *tottering* pyramidal cells.[46] At intracortical terminals of thalamic relay neurons in *tottering* mice, evoked excitatory responses in layer IV pyramidal cells are again spared (implying N-type release dependence), while evoked feedforward inhibition is impaired in this layer but not in layer V.[37] In contrast, at excitatory terminals in *tottering* thalamus, there is a defect in glutamate release.[47] Thus, P/Q deficiency has no uniform effect on synaptic signaling during brain development, and it may also alter somatodendritic firing patterns even in cells where it spares P/Q-independent exocytosis. Interestingly, impairment of the two other calcium channel alpha subunits involved in transmitter release, N type and R type, do not impact thalamocortical synchrony in the same way. Removal of N-type channels by *Cacna1b* deletion does not lead to an absence epilepsy phenotype, but it alters background cortical EEG rhythmicity at gamma frequencies.[48,49] On the other hand, deletion of *Cacna1e* eliminates R-type channels that contribute only a nominal amount to release at most measured synapses, yet it does alter the spike-wave discharge phenotype.[50]

CALCIUM CHANNEL REGULATORY SUBUNIT "RESHUFFLING" AND EMERGENT SPIKE-WAVE NETWORKS

Lethargic (*Cacnb4 lh*) and *ducky* (*Cacna2d2 du*) mutants display remarkable phenotypic similarities to the *tg* mutant. The roles of the auxiliary β[51] and α2δ2[52] subunits have been studied in detail in heterologous and neuronal systems. Although there are distinct functional and anatomical expression differences between individual family members, both types increase the current amplitude, accelerate inactivation kinetics and facilitate gating, and shift the voltage dependence of inactivation in the hyperpolarizing direction. When expressed singly with an alpha subunit in heterologous systems, loss of any one of these family members would be expected to significantly alter calcium channel signaling; however, when promiscuously binding family members are coexpressed and available in the same cell in vivo, deletion of one regulatory subunit gene leads to complex changes in the neuronal network as a whole (Fig. 54–2A). Rather than affecting all cells in which they are expressed, the extent of their loss in vivo depends on their replacement by alternative subunit family members, with functional rescue at certain alpha subunits in some cells and failure at others. Beta subunits also show variable efficacy in mediating release at presynaptic terminals.[53] This "reshuffling" phenomenon was evaluated in the *lethargic* brain,[54] where coimmunoprecipitation studies confirmed that β4 is the preferred binding subunit for both P/Q and N-type alpha subunits, and coimmunoprecipitation studies revealed novel heteromeric associations with β1 and β3, allowing for the rescue of calcium currents and functional release at various synapses in these mice (Fig. 54–2C). Indeed, electrophysiological analysis revealed that in *lethargic* Purkinje cells, somatic high-voltage–activated (HVA) currents were unaffected (Fig. 54–2D), yet release at excitatory synapses onto thalamic neurons in *tottering* and *lethargic* is sharply reduced.[47] No alteration in release at inhibitory synapses was found in *lethargic* thalamus, indicating that GABAergic neurotransmission in nRT terminals is relatively intact. This suggests that unlike *tottering*, the *lethargic* absence phenotype arises out of a global thalamocortical network lesion that is defined by the presence or absence of rescuing regulatory subunit family members. When brain expression patterns of the related beta subunit family members are compared (Fig. 54–2B), it is evident that thalamic nuclei lack significant expression of β1 and β3 subunits, pointing to a likely explanation for excitability and release defects in these cells. Thus, incomplete overlap of coexpressed heteromeric subunit family members defines a critical map of synaptic vulnerability in ion channel regulatory subunit mutant brain.

As with alpha subunits, additional complexity arises when cell-specific splicing patterns of regulatory subunits are considered. For

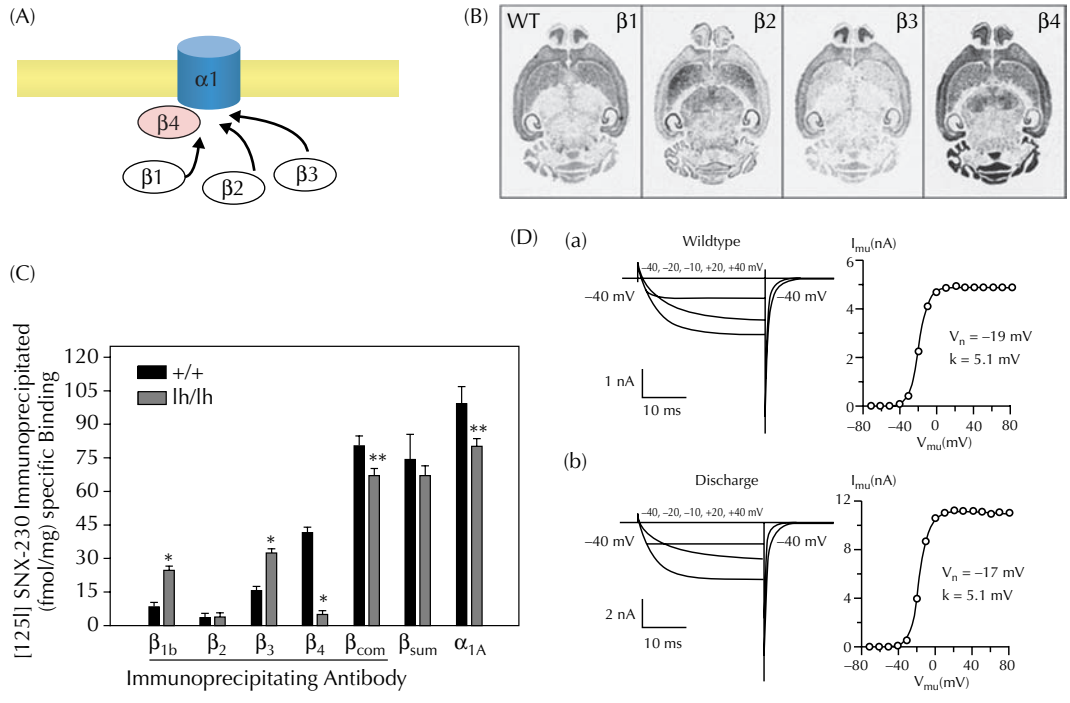

Figure 54–2. The brain lesion arising from genetic loss of a calcium ion channel regulatory subunit is more complex than that of a pore-forming alpha subunit. In **A**, due to the promiscuity of alpha subunits, absence of a single regulatory subunit (β4) in the lethargic mouse allows compensatory reshuffling of alternative family members, resulting in novel channel properties. In **B**, the distinct expression patterns of β1–4 family members in situ means that reshuffled P/Q-type alpha subunits may differ in subunit composition in different brain regions according to subunit availability. In **C**, coimmunoprecipitation patterns in lethargic brain show that α1a subunits, deprived of β4 interactions in lethargic mice, bind β1 and β3 partners instead, allowing rescue of the P/Q-type current in cerebellar Purkinje cells. **D**. Patch-clamp recordings confirm the functional rescue of normal P/Q-type currents in lethargic Purkinje cells. Different patterns of partial channel rescue throughout brain networks due to the presence or absence of available regulatory subunits may account for the spike-wave and ataxic phenotype in these mice. Adapted from ref. 54.

example, the cytoplasmic β4 subunit is alternatively spliced in different cell types, with the Cavβ4a spliceform present in Purkinje cells while Cavβ4b appears in basket cells.[55] Alternative α2δ subunit rescue is also likely to explain the pattern of release defects at selected synapses in *ducky* mice, at least at the neuromuscular junction, where it has been studied.[56]

DYSAFFERENTATION AS A CONVERGENT PATHWAY TO ABSENCE EPILEPSY IN DEVELOPING BRAIN

Among the possible sites of action of mutated P/Q channels and their regulatory subunits in epileptogenesis, several lines of evidence suggest that aberrant transmitter release is a critical defect underlying the expression of a spike-wave phenotype. The data suggest that reduced calcium entry coupled to release machinery, or the absence of key interaction domains in the α1a channel with *N*-ethylmaleimide-sensitive fusion protein receptor (SNARE) proteins essential for exocytosis, or the SNARE proteins themselves, or postsynaptic receptor loss, or deficient GABA reuptake may each suffice to alter afferent input in the thalamocortical network and produce an absence phenotype. Examples of each of these molecular steps have been defined. For instance, mutations in the first intracellular loop of *CACNA1A* block exocytosis by preventing P/Q modulation by SNARE proteins.[57] Loss of β4 not only alters calcium channel kinetics and trafficking, but eliminates a scaffolding function of this protein with synap-

totagmin1 at synapses.[58] Loss of SNAP25 in the mutant mouse *Coloboma* leads to an autosomal dominant spike-wave phenotype.[39] Loss of stargazin, the protein product of *Cacng2*, reduces alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor-mediated synaptic transmission in the mutant mouse *stargazer*, which may contribute to destabilization of the thalamocortical network.[59] Increased tonic inhibition due to loss of GABA reuptake also favors the spike-wave phenotype. For example, defective GABA reuptake by the GAT1 glial transporter exacerbates tonic inhibition, and VGAT1-deficient mice display spike-wave epilepsy; *stargazer* and *lethargic* mice share reduced GABA reuptake, while *tottering* mice do not.[60] Clearly, many molecular lesions converge on the spike-wave phenotype; however, each may exert direct and indirect downstream effects. While the loss of synaptic strength may directly produce dynamic changes in thalamocortical oscillations, a second possibility is that it incurs secondary molecular remodeling in these cells, resulting in maladaptive downstream mechanisms leading to the spike-wave phenotype.

RESCULPTING THALAMIC EXCITABILITY: INVOLVEMENT OF T-TYPE CURRENTS

Low voltage-activated, T-type currents have long been implicated in the generation of aberrant spike-wave discharges in thalamocortical circuitry based on their ability to confer rebound bursting in thalamic neurons,[61,62] the association of gain-of-function polymorphisms in human *CACNA1H*[63–65] and *CACNA1G*[66] genes in sporadic absence epilepsy, and their sensitivity to blockade by ethosuximide.[67] In animal models, targeted deletions of α1G channels suppress both $GABA_B$-receptor agonist-induced spike-wave discharges in wild-type mice and spontaneous discharges in calcium channel mutant mice,[68,69] indicating a contributing role for this gene in seizure expression. In addition, five distinct genetic mouse models of absence, *tottering*, *lethargic*, *stargazer*, *Coloboma*, and *Cacna1a* –/– show striking enhancement of thalamic T-type currents.[38,39,69] T-type current-mediated bursting is also unmasked in the *HCN2*-null mouse, where loss of Ih current generates spontaneous absence seizures,[70] and in the Genetic Absence Epilepsy Rat from Strasbourg (GAERS) rat, which exhibits elevated thalamic T-type currents and increased *Cacna1g* and *Cacna1h* mRNA expression.[71–73]

Evaluating the T-Type Contribution

In each of these models, elevated T-type current is one of many possible contributing pathogenic defects that could facilitate aberrant cortical synchronizations. Indeed, when this current was genetically reduced in *Cacna1a* –/– mice through a series of crosses with *Cacna1g* –/– mice to generate compound mutants with varying amounts of T-type channel protein, it was found that spike-wave discharges could persist even in the presence of normal rather than elevated thalamic current.[69] However, when T-type current was directly increased by overexpression of *Cacna1g* using a bac-transgenic construct under the control of its native promoter, T-type channel and functional current elevation alone was sufficient to induce a pure absence phenotype in an otherwise wild-type mouse brain (Figure 54–3).[74]

Other P/Q Channel-Induced Downstream Plasticity

Not unexpectedly, other forms of molecular and cellular plasticity have been described in the *tottering* forebrain and may participate in the epilepsy phenotype. One of the earliest, seen in both *tg* and *roller* alleles, is the presence of noradrenergic hyperinnervation.[75,76] Given the strong dependence of the compensatory N-type channels (but not P/Q-type channels) on noradrenergic modulation, and the fact that neonatal lesions in this pathway produced an essentially complete rescue of the *tottering* phenotype,[77] noradrenergic signaling appears to participate in spike-wave expression, although the exact reasons why elimination of this pathway at birth prevents spike-wave patterns remains to be elucidated. Gamma-aminobutyric acid receptor density and stoichiometry are also significantly altered in the *tottering* forebrain.[78,79] Baseline cyclic adenosine monophosphate (cAMP) levels are increased in the *tottering* forebrain, where they may play a role in potentiating T-type currents.[80,81]

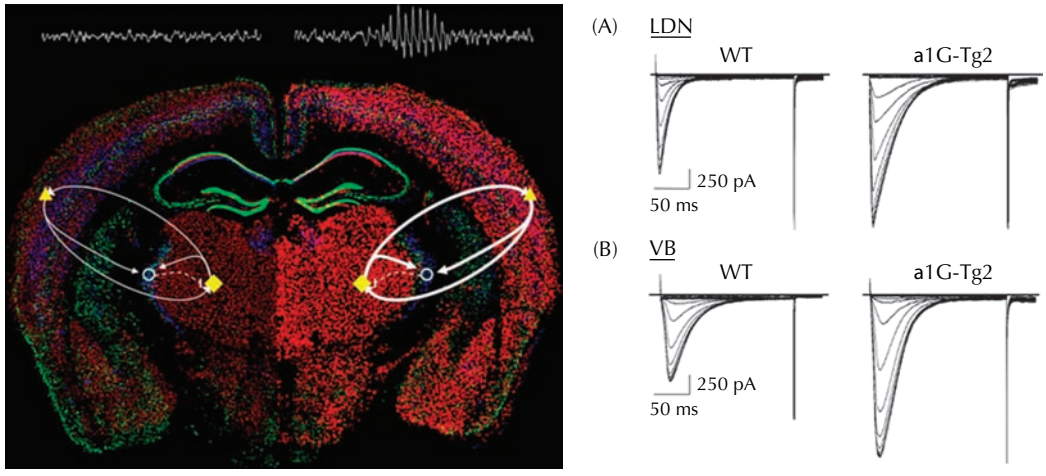

Figure 54–3. Enhancement of A1G in thalamocortical networks produces spike-wave absence epilepsy. Split composite image of in situ hybridization patterns of three genes—*Cacna1g* (red), *Cacna1h* (green), and *Cacna1i* (blue)—in adult mouse brain. The left side of the brain depicts native levels of expression and representative baseline cortical EEG activity in the wild-type mouse. The right side of the brain shows elevated transcript levels in the bac-transgenic *Cacna1g*-overexpressing mouse strain, with a typical cortical spike-wave EEG discharge above. The bac transgene drives *Cacna1g* under the control of its endogenous promoter, selectively elevating the T-type current to conform with its native pattern in brain circuitry. At the right, current traces from patch-clamp recordings of neurons in the lateral dorsal nucleus (LDN, (**A**) and the ventrobasal nucleus (VB),(**B**) in wild-type and transgenic mice show representative elevations in T-type currents in mutant neurons overexpressing *Cacna1g*. From ref. 74.

TRANSLATIONAL ADVANCES TOWARD THE TREATMENT OF INHERITED CALCIUM CHANNEL EPILEPSIES

When Does *Cacna1a*-Mediated Pathogenesis Begin?

In contrast with the neonatal and infantile epilepsies due to sodium and potassium channelopathy occurring in the first year of life, a notable characteristic of absence epilepsy is the association of various syndromes with specific developmental ages; human spike-wave seizures appear rarely in infancy but typically are recognized much later in childhood and adolescence. Unlike absence models in inbred rat strains where seizures begin in adulthood, monogenic mouse models also display an early postnatal onset (~P13–17 days) corresponding to that of human childhood.[38,39] While this interval coincides with the early enhancement of T-type currents identified in these models, it is also a period of intense refinement of synaptic innervation and molecular plasticity in the immature mouse brain, including the switch from N- to P/Q-type release dominance at selected thalamocortical synapses. Since inherited P/Q calcium channel mutations disrupt channel function at the inception of nervous system development and are responsible for extensive changes in synaptic microarchitecture in the P/Q mutant brain,[82] it is of interest to determine whether the evolving network lesion depends upon early embryonic or delayed postnatal effects of the functional release defect on synaptogenesis.

To address this question, a conditional mutant mouse was constructed that allowed ablation of P/Q channels in the critical postnatal period.[83] *Purky* is a viable mouse mutant, created by crossing a delayed-onset cre-driver PCP2 (L7) Purkinje cell promoter with floxed *Cacna1a* mice to ablate the *Cacna1a* gene throughout the brain beginning in the second postnatal week. Detailed analysis of *purky* Purkinje neurons revealed that P/Q currents are degraded by 3–4 weeks of age and are absent when the mice are examined at 6 months, consistent with a loss of P/Q channel antibody staining, abnormal spike firing patterns, and impaired transmitter release. Despite the delayed loss of P/Q channels, *purky* mice display the complete neurological phenotype of *tottering* mice, including severe ataxia, episodic dyskinesias,

and spike-wave absence seizures.[83] The *purky* mutant demonstrates that despite the role of P/Q channels in synaptic competition in developing brain, delayed postnatal onset of inherited P/Q channelopathy rather than embryonic disruption of thalamocortical circuitry is sufficient for the expression of the epileptic phenotype. This finding removes a potential therapeutic obstacle for postnatal rescue by defining a generous developmental window following birth that will allow the opportunity to pharmacologically restore function in inherited P/Q calcium channelopathy prior to the onset of seizures.

EPISTATIC INTERACTIONS

While the nonselective partial T-type antagonist ethosuximide is currently the most effective antiabsence drug, many patients remain pharmacoresistent.[84] The possibility of higher-affinity antagonists that are more selective for specific T-type channels is attractive[85,86]; however, given the heterogeneity of absence epilepsy, even these may not prove to be universally effective. A promising route to the development of additional targets for therapy of monogenic absence epilepsies is to identify modifier genes that suppress the aberrant excitability phenotype. This can be accomplished by unbiased forward genetic approaches as used in high-throughput *Drosophila* mutagenesis screening,[87] or by slower "rational" hypothesis testing that combines known murine mutations based on plausible combinatorial biological outcomes. For example, to determine whether the *tottering* P/Q transmitter release defect could be rescued and spike-wave epilepsy prevented by prolonging nerve terminal depolarization and increasing evoked release, Glasscock et al.[88] crossed *tottering* mutant mice with a Kv1.1-deficient knockout mouse strain. Kv1.1 is expressed at axonal juxtaparanodes and presynaptic nerve terminals, and its removal delays membrane repolarization, augments presynaptic nerve terminal excitability, and potentiates neurotransmitter release.[89,90] Electroencephalographic recordings from doubly homozygous *Cacana1a–/–, Kv1.1 –/–* mutant mice) revealed that spike-wave seizures were indeed abolished in the double mutant offspring (Fig. 54–4A). As a test to determine whether the phenotypic rescue of *tottering* seizures could be reproduced in the adult brain once seizures had already appeared, 4-aminopyridine (4AP), a nonspecific potassium channel blocker, was administered to adult *tottering* mutants. Like ethosuximide,

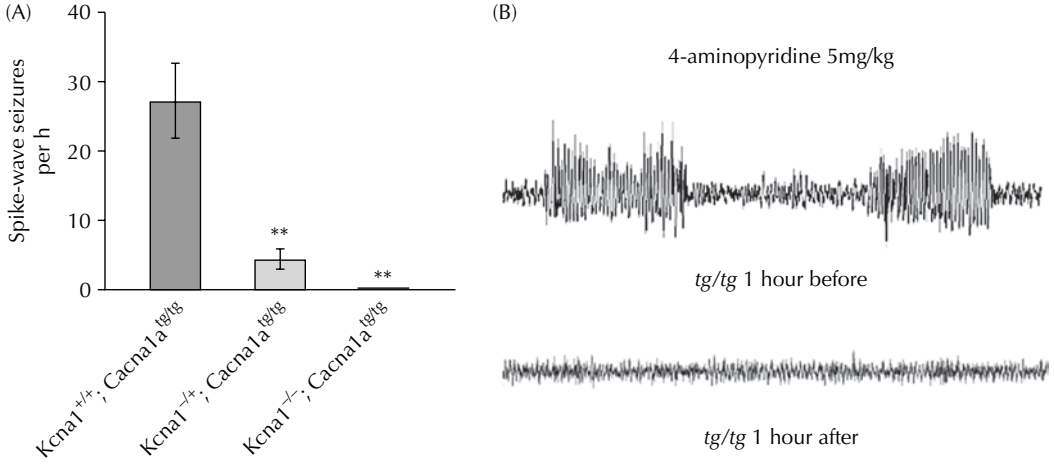

Figure 54–4. Potassium channel modification of the P/Q calcium channel spike-wave phenotype. **A.** Epistatic masking of spike-wave seizures in double mutants bearing *Cacna1a* (P/Q^{tg}) and Kv1.1 –/– mutations. There is a striking gene dosage effect showing an allelic dose-dependent decrease in seizure frequency with the removal of a single copy of the *Kcna1a* gene (middle) and complete suppression of seizure activity upon full ablation of the *Kcna1a* gene. In **B**, phenocopy experiments demonstrated suppression of cortical spike-wave absence seizures in adult *tottering* mutants following intraperitoneal injections of low doses of 4-AP, a nonspecific potassium channel blocker. From ref. 88.

4AP entirely abolished all spike-wave discharge activity in the *tottering* mutant within minutes of intraperitoneal injection (Fig. 54–4B). It is of interest that 4AP and noradrenergic blockade have also been found effective in reducing the severity of induced dyskinesias.[77,91,92] These phenocopy experiments demonstrate the ability of alternative ion channel targets to suppress phenotypes by rebalancing excitability in epileptogenic brain networks.

SUMMARY

Voltage-gated calcium channels were the first of now many genetic starting points for tracing the molecular mechanisms of spike-wave seizures, and in so doing, we have gained equally valuable information regarding the neurobiology of the P/Q-type calcium channel and its family members. Perhaps the most important lesson is that the solution of the neurological phenotype requires two steps: first, analyzing how the mutation affects the biology of the channel in a single neuron; second, determining how and when the misbehavior converts normal rebound bursting patterns in the thalamocortical network into an unstable pathological substrate for epilepsy in the developing brain. The "temporary failure of motor and mental functions" defined by Jackson arises not from enhanced excitatory release, as might be expected in paroxysmal hypersynchronous activity, but from the opposite: reduced synaptic strength within the thalamocortical network due to impaired calcium entry and diminished interactions with transmitter release machinery. This reduction in synaptic strength joins other molecular triggers, such as loss of vesicular exocytosis proteins or postsynaptic AMPA receptors, to induce downstream elevations in low voltage-activated T-type calcium channels, which may suffice to generate a spike-wave seizure phenotype. There is ample clinical and genetic evidence to suggest that there will be no uniform thalamocortical molecular pathology underlying this disorder and that alternative routes to the clinical spectrum of absence epilepsy remain to be discovered. Comparisons of their monogenic mechanisms will prove highly instructive in subsequent attempts to unravel the most elusive causes of sporadic generalized epilepsies, those that arise out of polygenic combinations. This category comprises the majority of individuals with absence seizures, and to them we remain obliged to confess our continuing ignorance of the causes of their condition.

Guy A. Rouleau

INTRODUCTION AND HISTORICAL PERSPECTIVES

Gamma-aminobutyric acid (GABA) was first identified as a biochemical substance in 1910 by Ackermann, who showed its production by decarboxylation of glutamic acid in bacteria.[1] In 1950, the presence of GABA in considerable amounts in the mammalian brain was discovered by different investigators,[2–4] and GABA was later established as the main inhibitory neurotransmitter in the brain.[5,6] Jasper and colleagues provided the first evidence that GABA is released in the brain under physiological conditions. Notably, they found variation in the release of GABA at the surface of the brain in relation to the state of activation of the cerebral cortex.[7]

GABAergic inhibition is mediated by two classes of receptor, ionotropic and metabotropic.

The GABA receptors type A ($GABA_A$) and C ($GABA_C$) are ligand-gated chloride channels that mediate fast inhibition. In turn, GABA receptors type B ($GABA_B$) mediate a variety of inhibitory effects through second messengers, affecting notably potassium and calcium conductance.[8,9] For several decades, abnormal GABAergic transmission associated with decreased inhibition of the central nervous system has been proposed as a major hypothesis for the development of epileptic seizures. Several forms of indirect evidence initially supported the role of this *GABA hypothesis of epileptogenesis.*[5,9–11] Early studies showed that pharmacological agents decreasing GABA levels or GABA-mediated inhibition through its receptors are pro-convulsant. In turn, increased GABA content or activation of its receptors is generally associated with an anti-convulsant effect. Also, whereas anti-GABA drugs can generate epileptic discharges in various animal models, pro-GABA agents generally decrease epileptic activity in these models. In addition, $GABA_A$ receptors are the molecular target of anti-convulsant drugs used in clinical practice, either by acting directly on its receptor (e.g., barbiturates, benzodiazepines) or by increasing GABA levels (e.g., vigabatrin). Finally, altered $GABA_A$ and $GABA_B$ receptor function has been observed in the brains of epileptic humans and in animal models of the disease.[10,12,13]

More recently, genetic studies have provided additional evidence supporting the role of GABA in epilepsy. First, mice deficient for two subunits of the $GABA_A$ receptors (*GABRB3*, *GABRG2*),[14,15] as well as two $GABA_B$ receptors (*GABBR1*, *GABBR2*), have been associated with epileptic seizures.[16–18] In humans, Minassian et al. found that typical and atypical absence attacks are present in Angelman syndrome patients whose chromosome 15q11–13 deletion includes *GABRB3.*[19] It is thus possible that haploinsufficiency of this gene may explain the severe epilepsy in this syndromic form of epilepsy associated with mental retardation and autistic features. However, the study of familial forms of idiopathic generalized epilepsies provided the first direct evidence that impaired $GABA_A$ receptor function is associated with epilepsy in humans.[20–24] We will review the various mutations in $GABA_A$ receptors associated with a variety of epilepsy phenotypes in humans, as well as their functional consequences in cellular and animal models.

DEFINITION AND CLASSIFICATION

Epilepsy is a pathological state characterized by recurrent unprovoked epileptic seizures.[25–27] Epileptic individuals may exhibit a wide range of clinical presentations, not only in terms of seizure manifestations, but also in terms of age of onset, etiology, prognosis, and so on. Therefore, epilepsy is clearly not a single condition, but rather a diverse family of disorders, called *the epilepsies*, having in common an abnormally increased predisposition to seizures.[26]

Despite great heterogeneity among the various epilepsies, clusters of clinical signs and symptoms have been observed among epileptic individuals, allowing physicians to identify relatively unique clinical entities called *epileptic syndromes*. In 1985, the International League Against Epilepsy (ILEA) started to make an inventory of the epileptic syndromes widely accepted in the epilepsy community, a process that is still underway.[27–30] The International Classification of the Epilepsies and Epileptic Syndromes rests on two criteria: (1) *seizure type*, which may be generalized or partial, and (2) *etiology*, which may be idiopathic or symptomatic.[28] Additional criteria include age of onset, evolution of the syndrome, associated interictal signs, symptoms and electroencephalographic (EEG) patterns, and genetic basis.[27,28,30]

Symptomatic epilepsies have multiple heterogeneous causes, including brain injury, central nervous system infection, and metabolic disorders.[27,28] In turn, the majority of individuals with epilepsy (65%) have recurrent unprovoked seizures without detectable structural lesions in the brain and without showing any neurological abnormality between seizures. For these individuals, no underlying cause can be identified, and they are said to have an *idiopathic* epileptic syndrome.[27,28,30] From the beginning of the ILAE classification, the term *idiopathic epilepsies* has been used for those in which there is no underlying cause other than a possible hereditary predisposition.[27,28,30]

GENETIC EVIDENCE FOR IDIOPATHIC EPILEPSIES

There is increasing evidence that genetic factors play an important role in idiopathic

epilepsies. These strong genetic factors have been highlighted by genetic epidemiology, including familial aggregation and twin studies, as well as by the study of unusually large families with epilepsy. Among the epilepsy syndromes, idiopathic generalized epilepsies (IGEs) have the most significant hereditary component and represent approximately 40% of all the epilepsies.

Familial Aggregation Studies

Lennox first observed that generalized spike-and-wave (GSW) discharges, the classical EEG pattern associated with IGE, aggregates in families.[25,31] Following this original finding, familial aggregation studies consistently showed a threefold increased risk of epilepsy (~3%) in siblings of probands with idiopathic or cryptogenic epilepsy compared to the general population.[32–34] In contrast, symptomatic epilepsies do not increase this risk. A higher risk (6% to 8%) is observed for individuals with IGE associated with typical GSW. The occurrence of GSW in another member of the family (parent or sibling) further increases the risk in the sibling at 12% to 15%.

Twin Studies

Several studies of epilepsy in twins have consistently shown a higher concordance rate for the disease in monozygotic (MZ) pairs compared with dizygotic (DZ) pairs.[35–39] Unfortunately, most of these studies were performed before the ILAE classification of the epileptic seizures and syndromes was developed, thereby limiting the appreciation of the relative genetic contribution to the various epileptic syndromes. In contemporary twin studies, the case-wise concordances for IGEs (MZ = 0.76; DZ = 0.33) were greater than those for partial epilepsies (MZ = 0.36; DZ = 0.05), with intermediate values for febrile seizures (MZ = 0.58; DZ = 0.14).[40,41] Interestingly, in 94% of concordant MZ pairs, affected twins exhibit the same epilepsy syndrome, suggesting the existence of syndrome-specific genetic determinants rather than a broad genetic predisposition to seizures.[40]

Complex Inheritance Patterns in Idiopathic Epilepsy

The concordance rate in identical twins is thus very high for IGE, suggesting an almost complete genetic etiology for these latter syndromes.[40,42] However, clinical observations indicate that, in the vast majority of these families, a single-gene mode of inheritance is implausible and complex inheritance involving two or more genes is most likely.[43–45] These observations are further supported by genetic epidemiology studies.[32,34,40] Indeed, the relative risk of being affected for a relative of an individual with IGE (λ_R) is almost 100 for MZ twins (λ_M), 7.5 for sibs (λ_S), and 1.5 for nieces/nephews (λ_N). For IGE and cryptogenic partial epilepsy, the relative risk of being affected for a relative (λ_R) is 55 for MZ twins (λ_M), 3.5 for sibs (λ_S), and 1.5 for nieces/nephews (λ_N). Such a rapid decrease in the λ_R with each degree of relationship suggests a multiplicative (epistatic) interaction among many contributing loci for IGE and partial epilepsy.[42,46]

FAMILIAL FORMS OF IDIOPATHIC EPILEPSIES

Although the common forms of idiopathic epilepsies are complex genetic traits, several groups of investigators have identified large epilepsy families in which the pattern of inheritance is compatible with a Mendelian trait.[47,48] The identification of such large families allowed gene mapping and eventually the identification of mutations in several predisposing genes for the disease. Successful examples for idiopathic epilepsy are presented in Table 55–1 and discussed briefly here.

Molecular Mechanisms Underlying Familial Epilepsies

At least 25 genes predisposing to familial forms of epilepsy in humans have been identified, as well as more than 100 epilepsy genes in mice. The molecular mechanisms underlying these inherited epilepsies can be divided into four broad functional categories:

1. *Primary defects of membrane excitability*, caused by mutations in genes

Table 55–1 **Genes Predisposing to Idiopathic Epilepsy in Humans**

Genes	Protein Products	Idiopathic Epilepsy Syndrome	References
Voltage-dependent ion channels			
Sodium channels			
SCN1A	Nav1.1	GEFS+, partial epilepsy with FS	49, 117–119
SCN1B	β1 subunit	GEFS+	50, 120, 121
SCN2A	Nav1.2	BFNIS (benign familial neonatal infantile seizures)	122–125
Potassium channels

encoding voltage-gated sodium,[49,50] potassium,[51,52] calcium,[53] and chloride channels.[54–56]

2. *Defects in synaptic signaling*, caused by mutations in ligand-gated chloride (*GABRA1*, *GABRG2*, *GABRB3*, *GABRD*)[20–24] and ligand-gated sodium channel receptors (*CHRNA2*, *CHRNA4*, *CHRNB2*).[57–59]
3. *Impaired synaptic signaling and plasticity*, caused by defects in various proteins implicated in the *neurotransmitter release machinery* (e.g., mobilization of neurotransmitters, synaptic vesicle trafficking, exocytosis), such as *SYN1/2*, *Sv2A*, *AP3δ*, and *ZNT3*.[60–64]
4. *Abnormal brain network development and structure*, also called *cortical dysplasias*, caused by signaling defects in migration, proliferation, differentiation, and segmentation.[65–68] These latter forms of epilepsy are not considered idiopathic per se, although some conceptual overlaps may exist (see below).

Rare Syndromes Caused by Mutations in Complementary Subunits

Benign neonatal familial convulsions (BNFC) is the first epilepsy syndrome for which a gene could be localized, and mutations in *KCNQ2* and *KCNQ3*, encoding for two different subunits of the same potassium channel, have been associated with the disease.[51,52,69] Scheffer and Berkovic later identified a hitherto unrecognized IGE syndrome following single-gene inheritance, named *generalized epilepsy with febrile seizures plus* (GEFS+).[70] Recognition of this syndrome allowed the identification of at least two genes for GEFS+: the β1 and α1 subunits of the neuronal voltage-gated sodium channel (*SCN1B, SCN1A*).[49,50] Finally, *autosomal dominant nocturnal frontal lobe epilepsy* (ADNFLE) is caused by mutations in *CHRNA4*, *CHRNA2*, and *CHRNB2*, encoding for three different subunits of the ligand-gated neuronal nicotinic acetylcholine receptor (α4, α2, β2).[57–59] Although these unique Mendelian forms of IGE are rare in the general population, genetic studies of these families provided the first direct evidence for molecular mechanisms involved in idiopathic epilepsy syndromes. Interestingly, these specific epilepsy syndromes have been associated with their corresponding molecular mechanisms, with mutations identified in complementary subunits of the same protein complex.

Autosomal Dominant Forms of Classical Idiopathic Generalized Epilepsy

Various genetic mutations in families segregating classical IGE syndromes have been recently described, including those for juvenile myoclonic epilepsy (JME), childhood absence epilepsy (CAE), and epilepsy with grand mal seizures on awakening (EGMA).[71] In these rare epilepsy families, the phenotype is indistinguishable from that of classical IGE except for the occurrence of similar epilepsy syndromes in many affected individuals of the same pedigree. Mutations in the γ2 subunits of the $GABA_A$ receptor have been found in families segregating CAE with febrile seizures and GEFS families,[20,21,72–76] whereas mutations in the α1 subunits of the same receptor have been found in families with various IGE phenotypes, including JME and CAE.[22,77] More recently, mutations in the β3 subunits have been found in families with CAE.[24,78] In addition, mutations in the δ subunit of the $GABA_A$ receptor (*GABRD*) were found in small nuclear families with GEFS, CAE, and JME.[23,79] Finally, mutations in the voltage-gated chloride channel type 2 (*CLCN2*) were associated with CAE, JAE, JME, and EGMA,[54–56] and mutations in *EFHC1* were found in families with classical JME.[80] Overall, a total of six genes are implicated in these classical IGE syndromes with autosomal dominant inheritance, including four different subunits of the $GABA_A$ receptors, suggesting that impaired $GABA_A$ receptor function is an important mechanism that could lead to IGE in humans.

STRUCTURE AND FUNCTION OF $GABA_A$ RECEPTORS

Gamma-aminobutyric acid is an inhibitory neurotransmitter that activates two major classes of receptor in the central nervous system: the ionotropic $GABA_A$ and $GABA_C$ receptors, as well as the metabotropic $GABA_B$ receptors.[8,81] The $GABA_A$ and $GABA_C$ receptors are ligand-gated ion channels that are permeable to chloride and bicarbonate anions**.** The $GABA_B$ receptors are G-protein-coupled receptors that are localized on both pre- and postsynaptic membranes. Postsynaptic $GABA_B$ receptors activate inward rectifying potassium channels, which cause hyperpolarization of the neurons and generate inhibitory postsynaptic potentials (IPSPs). In turn, activation of presynaptic $GABA_B$ receptors decreases neurotransmitter release by inhibiting voltage-gated Ca^{2+} channels. This latter effect can be either inhibitory or excitatory, depending on which neurotransmitter is involved.

Distribution and Structural Diversity of the $GABA_A$ Receptors

The $GABA_A$ receptor is a heteropentamer assembled from height classes of subunit

(α1–6, β1–3, γ1–3, δ, π, ε, θ, and ρ1–3).[82] The subunits are grouped to form a central pore that constitutes the ion channel. The optimal subunit stoichiometry and composition required for functional expression of $GABA_A$ receptors is a 2:2:1 ratio of α, β, and γ subunits, respectively (Fig. 55–1). The variability in the composition of $GABA_A$ results in a functional heterogeneity of these receptors. Incorporation of a ρ subunit defines the bicuculline-insensitive $GABA_C$ receptors, whereas the $GABA_A$ receptors are blocked by the antagonist bicuculline.[83] Although there is a potential for a high variability of combinations, α1β2γ2 is the most abundant and represents approximately 60% of all $GABA_A$ receptors in brain.[82] Other major combinations are $\alpha_1\beta_{2/3}\gamma_2$, $\alpha_2\beta_3\gamma_2$, and $\alpha_3\beta_3\gamma_2$.[84] The varying subunit composition of the receptor is associated with variable GABA binding affinity, channel kinetics, and the response to pharmacological agents.[85] The different anti-convulsant drugs, such as the benzodiazepines and anxiolytics, preferentially interact with $GABA_A$ receptors containing α_x subtypes.[84] The binding sites for benzodiazepines are located at the interface between α_1 and γ_2.[86,87] Several subunits, such as δ, π, ε, θ, and ρ, are less well characterized and exhibit lower levels of expression, which could be tissue-specific. As an example, the π subunit is detected only in certain peripheral tissues, whereas ρ1–3 are expressed mainly in the retina.[88]

Genomic Evolution of $GABA_A$ Receptor Genes in *Homo sapiens*

The genomic location of all 19 genes coding for the various subunits of the $GABA_A$ receptor are now fully assigned, and 14 of them are arranged in gene clusters. Two four-gene clusters and two three-gene clusters have been identified, respectively on human chromosomes 4, 5, 15, and chromosome X (Fig. 55–2).[89] Each cluster contains genes coding for the α, β, or γ/ε class. This organization has been proposed to result from a series of gene duplication events from a single ancestral αβγ gene cluster that are believed to have occurred during early chordate evolution.[90] The *GABRQ* and *GABRE* genes encoded the θ and ε subunits, respectively, and are considered to be "β-like" and "γ-like," respectively.[90] The δ (*GABRD*) and ρ3 (*GABRR3*) subunit genes are orphans on chromosomes 1 and 3, respectively. The π-subunit gene (*GABRP*) is located on chromosome 5, but distal to and separate from the γ2α1α6β2 gene cluster. The genes coding for the ρ1 and

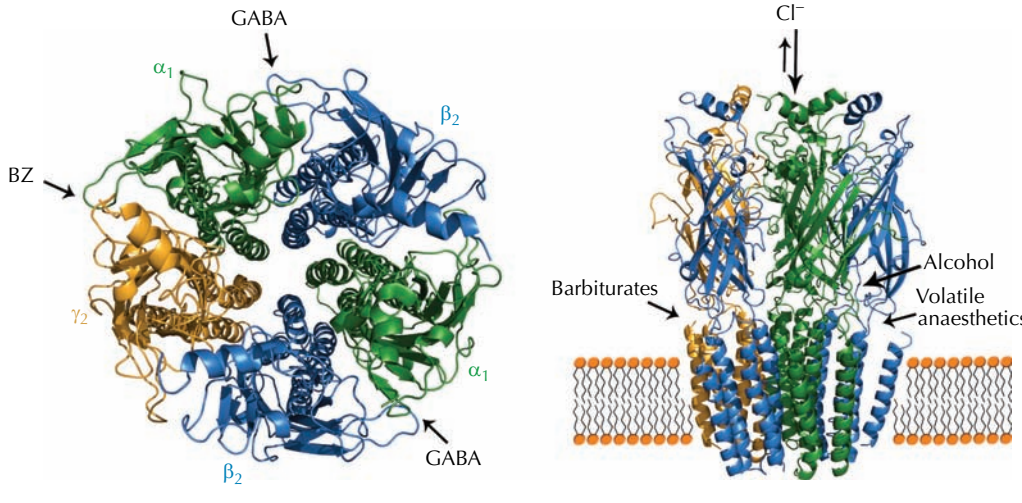

Figure 55–1. $GABA_A$ receptor models. Left: The top view of the structural model of the $GABA_A$ receptor[86] highlights the organization of the subunits within a pentameric complex as well as the proposed neurotransmitter GABA and benzodiazepine (BZ) binding sites. The locations of the GABA and BZ binding sites on the receptor occur at the interfaces of the αβ and αγ subunits, respectively. Right: The side view of the $GABA_A$ receptor model (insert) in a cell membrane is shown to illustrate some of the drug binding sites and chloride ions flux through the channel. Modified from ref. 91.

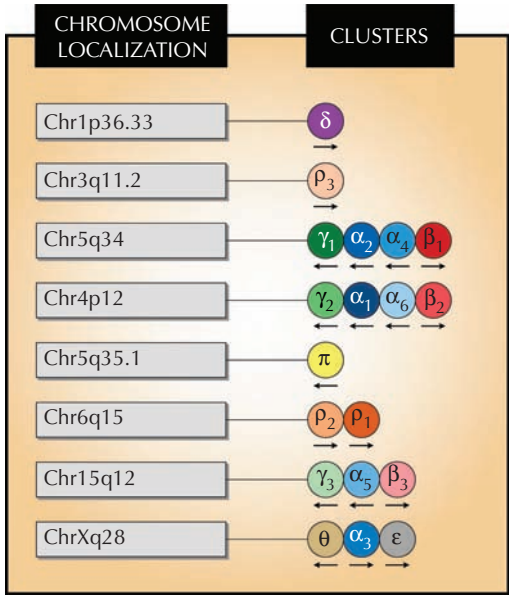

Figure 55–2. Clusters and chromosomal localization of $GABA_A$ receptor genes. The relative gene order and the transcriptional orientation (indicated by arrows) of the α, β, and γ subunit genes are conserved in each cluster. The chromosomal localization of each gene and cluster were obtained from the UCSC Genome Browser (Hg19 Assembly).

ρ2 subunits (*GABRR1-GABRR2*) have been mapped together on chromosome 6.

Functional Properties of the $GABA_A$ Receptors

Gamma-aminobutyric acid is the main inhibitory transmitter in the mammalian brain, and most of the cortical inhibitory effects of GABA are mediated through the $GABA_A$ receptor. In adult brain, the intracellular concentration of chloride inside the majority of neurons $[Cl^-]_i$ is lower than that in the extracellular space $[Cl^-]_e$ due to the activity of the K^+/Cl^- cotransporter. Therefore, when GABA activates $GABA_A$ receptors, the central pore opens and allows chloride influx, which results in hyperpolarization and a decreased probability of generating an action potential. The $GABA_A$ receptor may be modulated by several compounds, such as benzodiazepines, neurosteroïds, barbiturates, and anaesthetics. As an example, both benzodiazepines and barbiturates potentiate the action of GABA on $GABA_A$ receptors by increasing, respectively, the frequency and the length of opening of the central pore.[83] The $GABA_A$ receptor population located mainly at the synapse (α_1, α_2, α_3 or α_5 with β_x and γ_x subunits) mediates phasic inhibition in brain. Phasic inhibition is the synchronous opening of the ionotropic cluster of postsynaptic receptors participating in rhythmic activities in neuronal networks. This activation results in fast GABAergic inhibition and is sensitive to benzodiazepine modulation.[81] In contrast, the $GABA_A$ receptor population located in the extra- and perisynaptic regions (α_4 or α_6 subunits with β_x and δ subunits) mediates tonic inhibition.[81] Tonic inhibition is the activation of extrasynaptic $GABA_A$ receptors by low concentrations of ambient GABA. Tonic inhibition takes part in paracrine activity and plays a crucial role in regulating neuronal excitability. These receptors are composed mainly of δ subunit and are insensitive to benzodiazepine modulation.[81]

IMPAIRED FUNCTION OF MUTATED $GABA_A$ RECEPTORS

So far, epilepsy-causing mutations have been identified in four $GABA_A$ receptor genes: *GABRG2*, *GABRA1*, *GABRD*, and *GABRB3*, encoding respectively the γ2, α1, δ, and β3 subunits. The vast majority of these mutations have been identified in large families with a variable combination of generalized and febrile seizures. The pattern of inheritance is generally autosomal dominant, although complex inheritance and spontaneous mutation have been described as well.[23,77,78] Clinical manifestations in these families, as well as the functional impact of the mutations in $GABA_A$ receptor subunits, are summarized in Table 55–2.

Clinical Manifestations Associated with Mutations in $GABA_A$ Receptor Subunits

Mutations were first described in *GABRG2* in families with GEFS+, febrile seizures, and CAE.[20,21] Additional mutations in the same genes have been associated with similar

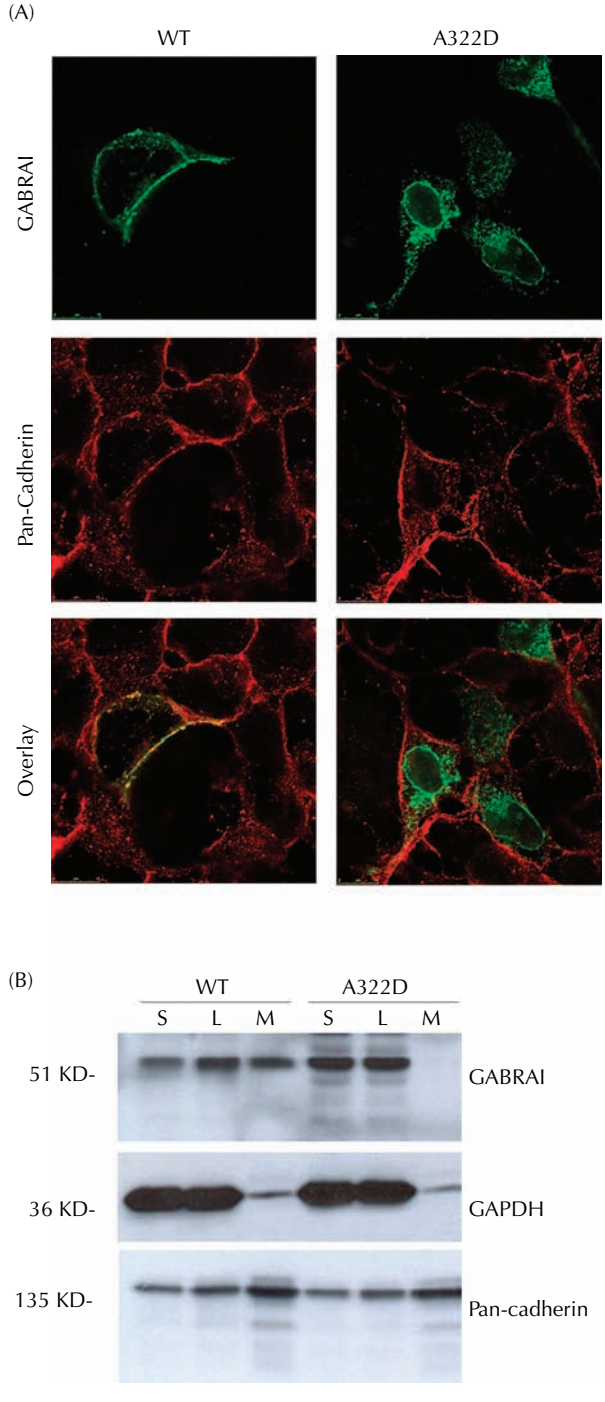

Figure 55–3. Effect of the A322D mutation on α1 subunit expression in transfected HEK 293 cells.A. Surface expression of the mutant α1 subunit. In contrast to the wild-type α1 subunit (left column), immunostaining of A322D *GABRA1* mutants did not colocalize with the marker for the cell membrane (pan-cadherin, red) when coexpressed with the wild-type β2 and γ2 subunits. B. Western blot of total (L: lysate), biotinylated (M: membrane fraction), and nonbiotinylated (S: supernatant) α1 proteins shows the absence of expression of the A322D mutation at the cell surface. Reduced glyceralehydephosphate dehydrogenase (GAPDH) was used to normalize the supernatant and lysate proteins, and pan-cadherin was used to normalize the membrane proteins. Modified from ref. 91.

phenotypes[72–76] but also have been found in one individual with severe myoclonic epilepsy of infancy (Dravet syndrome).[73] The phenotypes associated with *GABRB3* mutations appear so far to be more homogeneous, with almost exclusively absence seizures.[24,78] The first family reported with mutation in *GABRA1* had JME,[22] and a single individual with spontaneous mutation exhibited CAE.[77] We recently described two additional families with mutations in *GABRA1*: one family presents with a combination of febrile seizures and absences, whereas the other family exhibits late-onset generalized tonic-clonic seizures and photosensitivity.[91] The clinical phenotypes associated with mutations in *GABRA1* thus appear to be more heterogeneous. The small families with genetic variations in *GABRD* had either GEFS or JME syndromes.[23,79]

Mutations in $GABA_A$ Receptor Subunits Generally Produce Loss of Function

The functional impact of the mutations in various subunits of the $GABA_A$ receptors associated with epilepsy in humans has been studied by expressing recombinant receptors either in HEK 293 cells or in oocytes. These in vitro studies revealed that the majority of these mutations result in a reduction of GABA-activated chloride currents.[87,92] For at least three mutations in *GABRA1* (A322D, S326fs328X, K353delins18X),[77,78,93] it has been shown that the reduction in the amplitude of GABA-evoked current was due to reduced surface expression of receptor protein, caused by retention of mutant receptors in the endoplasmic reticulum (Fig. 55–3). Two *GABRA1* mutations (A322D and D219N) exhibit altered gating kinetics in addition to reduced surface expression.[22,91] Mutations in *GABRB3* are also associated with reduced GABA-evoked current density from whole cells, possibly because of increased glycosylation of the β3 protein.[24]

The nonsense mutation in *GABRG2* (Q390X), like those for *GABRA1* mutations, shows reduced GABA-evoked current and surface expression of the receptor protein.[73,94] However, the functional effects of the *GABRG2* missense mutations appear to be more complex. Reduced amplitude of GABA currents has been reported for the K328M and R82Q mutations, but this observation was less consistent among various investigations.[20,21,95–100] In addition, missense mutations in *GABRG2* (K328M, R177G, and possibly R82Q) can alter gating properties of the $GABA_A$ receptor.[72, 95–97] Two mutations in *GABRG2* (R82Q and P83S) are located close to the binding site of benzodiazepines. Interestingly, one of these mutations (R82Q) seems to alter the potentiation of GABA-evoked currents by the application of benzodiazepine.[21,96,97] However, these latter results are more controversial and have not been reproduced by other investigators.[95,99] It is intriguing that the other *GABRG2* mutation close to the benzodiazepine binding site (P83S) does not show obvious alteration in the function of the $GABA_A$ receptor despite strong segregation with febrile and absence seizures.[91] This observation suggests that there are additional, more subtle mechanisms by which mutation in $GABA_A$ receptors may lead to the disease.

The Complex Case of *GABRD* Mutations

Genetic variations in *GABRD* exhibit a more complex relationship to both epilepsy phenotypes and dysfunction of $GABA_A$ receptors. Two missense mutations in this gene are associated with GEFS+. One of these *GABRD* mutations (E177A), like mutations in *GABRG2* and *GABRA1*, results in decreased amplitude of GABA-evoked currents, but the other (R220C) does not. It is possible that this R220C is a rare neutral variant. Alternatively, as suggested above for another *GABRG2*, the R220C variant in *GABRD* could be associated with more subtle effects on the $GABA_a$ receptor, which remains to be determined. Another variant in *GABRD* (R220H) was first detected in a JME family, but it was also present in IGE and febrile seizures, as well as in control cases.[23,79] Interestingly, this R220H polymorphism is nonetheless associated with reduced peak amplitude of GABA-evoked current, which is expected to increase neuronal excitability. The role of this functional polymorphism in epilepsy with complex inheritance remains unclear. Such functional polymorphisms may represent candidate genes with small effects

on the phenotype, as is anticipated for common epilepsies with complex inheritance, such as JME and CAE. Consistent with this hypothesis, the P11S variation originally described as a mutation in *GABRB3*[24] was found to be a rare functional polymorphism in the French Canadian population.[78]

Animal Models with Mutations in $GABA_A$ Receptor Subunits

Knockout of genes encoding for various $GABA_a$ receptor subunits, including α1, α5, γ3, and δ, is not associated with the epileptic phenotype in mice.[101–104] However, targeted deletion of *GABRG2* in mice is lethal after birth, and mutants exhibit abnormal episodes of hyperactivity that might be compatible with neonatal seizures.[14] In addition, deletion of β3 in mice is associated with severe seizure disorder.[15,105] More recently, the R43Q mutation in *GABRG2*, which is associated with GEFS+ in humans, has been introduced in a mouse model. Interestingly, mice heterozygous for this knocked-in mutation exhibit manifestations of absence seizures, together with 6 to 7 Hz spike-and-wave discharges that are blocked by ethosuximide.[106] These authors conclude that reduced cortical inhibition is responsible for the epilepsy phenotype in this model.

MUTATIONS IN VOLTAGE-GATED CHLORIDE CHANNELS

Seven mutations have been identified in the *CLCN2* gene, five of which have been subject to functional studies.[54,56,107] Unfortunately, it appears that the mutations described by Haug et al. are not as penetrant as they were described to be, falsely, in the original report.[54,55] Nevertheless, these *CLCN2* mutations do segregate, although weakly, with epilepsy phenotypes. More importantly, at least five *CLCN2* mutations show alteration in the function of these voltage-gated chloride channels, including four mutations with loss of function.[54,56] These observations thus support the hypothesis that *CLCN2* is a predisposing gene for IGE.

CLCN2 encodes the voltage-gated chloride channel ClC-2, which is strongly expressed in the brain and notably localized in GABAergic interneurons.[108] ClC-2 channels play a role in establishing and maintaining a low intracellular chloride concentration, which is essential for neuronal inhibition mediated through $GABA_a$ receptors. Therefore, it is expected that loss of function of the ClC-2 channel may result in impaired chloride efflux, leading to an abnormal intracellular accumulation of chloride. These mutant channels are thus expected to lower the transmembrane gradient that is essential for GABAergic inhibition, resulting in increased excitability in neurons, which may lead to seizures. As with many $GABA_A$ receptor genes, *CLCN2* knockout mice do not exhibit the epileptic phenotype.[109,110]

Overall, mutations in *CLCN2* have been shown to alter the chloride gradient across the cellular membrane, which may eventually impair GABAergic neurotransmission in the brain. These findings are consistent with loss-of-function mutations found in at least four different subunits of $GABA_A$ for related epileptic syndromes. Taken together, these results suggest that impairment of the inhibition mechanisms mediated through the $GABA_A$ receptors may be central to the pathophysiology of classical IGE with autosomal dominant inheritance.

GABA PERFORMS CRITICAL FUNCTIONS IN THE DEVELOPING BRAIN

In the adult brain, the intracellular concentration of chloride inside the neurons $[Cl^-]_i$ is lower than that in the extracellular space $[Cl^-]_e$. Therefore, when GABA activates $GABA_A$ receptors, this heteropentamer opens its central pore and allows chloride influx (inside the cell), which results in hyperpolarization. However, in the immature brain, GABA produces depolarization because of a high concentration of intracellular chloride $[Cl^-]_i$ in developing neurons.[111] Under these conditions, $GABA_A$ receptor activation produces a chloride efflux (outside the cell), with the result that neurons are depolarized (Fig. 55–4). The developmental switch from GABA-mediated excitation to inhibition is mediated by the K^+-Cl^--coupled cotransporter, KCC2,[112,113] which is responsible for pumping out Cl^-. KCC2 is thus one of the major determinants of $[Cl^-]_i$ levels in

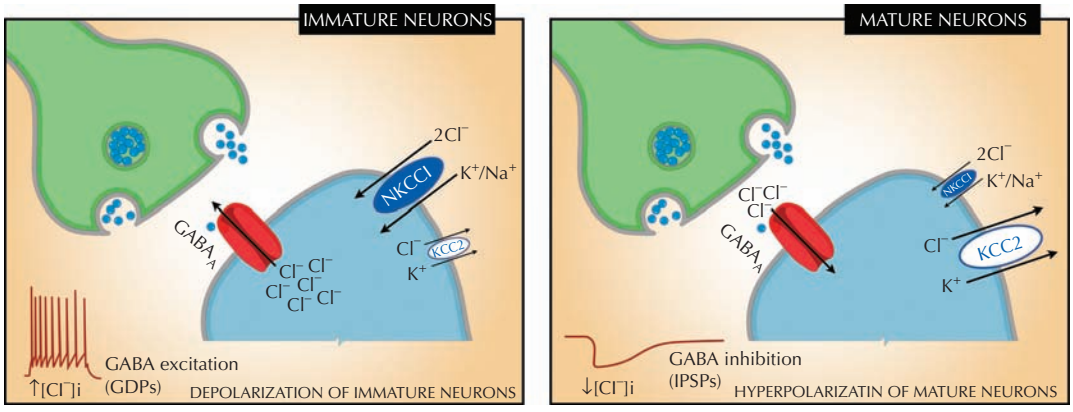

Figure 55–4. Developmental switch in chloride homeostasis during development. In immature neurons, hyperpolarizing and excitatory actions of the $GABA_A$ receptors are triggered by the higher intracellular [Cl^-] ions. The progressive switch from depolarizing to hyperpolarizing GABAergic signaling through the same receptors is generated by the developmental increase in the chloride cotransporter KCC2 and the decrease in NKCC1.

the adult brain. KCC2 is expressed at approximately the first days of life, during which reversal of the chloride transmembrane gradient occurs. Interestingly, this developmental switch mediated through KCC2 is induced by the activation of GABA synapses themselves.[114] The excitatory actions of GABA play a central role in the generation of primitive electrical activity recorded in developing circuits called *giant depolarizing potentials* (GDPs). Giant depolarizing potentials are long-lasting and recurrent depolarizing potentials that provide most of the activity in the developing brain.[111] These GDPs play an important role in modulating the developing network, including neuronal migration and growth, synapse formation, and plasticity of GABA synapses.[115] In addition, GABA has been shown to stimulate neuronal migration, cell division, and neuritic growth through other mechanisms.[111] It is generally believed that loss-of-function mutations found in familial IGE cause abnormal hyperexcitability in the mature brain by decreasing inhibitory transmission. However, one alternative and not mutually exclusive hypothesis is that impaired $GABA_A$ transmission caused by these mutations may lead to a significant decrease in excitatory GABA transmission in the developing brain. Should this be the case, one can expect that the critical functions performed by excitatory GABA transmission will also be impaired. The following and perhaps cumulative effects of the $GABA_A$ mutations could thus be anticipated: (1) decrease in the excitatory drive of GABAergic synapses in the developing brain; (2) decrease of the GDPs and their critical impact on the developing circuits; (3) delay in the developmental switch of the transmembrane gradient induced by KCC2, causing excitatory drives beyond the usual stages of development; and (4) abnormal neuronal migration, neurite elongation, and synapse formation. These potential effects, alone or in combination, could lead to aberrant neuronal networks that may be the substratum for triggering epileptic seizures in familial IGE. Interestingly, it has recently been found that impairment of *EFHC1*, another JME gene, causes marked disruption of cortical development *in vivo*.[116] We can thus speculate that abnormal development of the cortical network may represent a convergent mechanism in the pathogenesis of IGE.

FUTURE PERSPECTIVES

An increasing number of genes predisposing to epilepsy have been identified over the past 10 years. Among these genes, mutations in four subunits of the $GABA_A$ receptor appear to be important causes of familial epilepsy. So far, the majority of these mutations have been associated with a dramatic decrease of GABA-evoked currents in recombinant receptors. Because GABA is the main inhibitory transmitter in the adult brain, it is generally believed that this loss

of function would cause abnormal excitability of cortical neurons, thereby leading to clinical seizures. However, in contrast to the mature central nervous system, GABA is excitatory in the developing brain. This apparent paradox is caused by an inversion in the chloride gradient across the cell membrane that occurs during the first days of life. There is now increasing evidence supporting the hypothesis that excitatory GABA transmission plays a key role in various aspects of brain development, such as neuronal migration, shaping of dendritic trees, and synaptogenesis. It is thus very likely that epilepsy-causing mutations in $GABA_A$ receptors would be associated with abnormal development of neuronal networks, which may be one of the critical mechanisms leading to the disease. However, so far, this hypothesis has not been examined. Should it be validated, it would provide an unparalleled advance in our comprehension of the IGEs.

Chapter 56

The $GABA_A\gamma2$(R43Q) Mouse Model of Human Genetic Epilepsy

Steven Petrou
Christopher A. Reid

UTILITY OF MOUSE MODELS IN UNDERSTANDING PATHOGENESIS IN EPILEPSY

Epilepsy is a complex disease of neuronal networks; therefore, an understanding of the consequences of genetic dysfunction at clinically relevant temporal and spatial scales requires in vivo models. Although in vitro models have and will continue to shed light on aspects of molecular pathogenesis, gaining knowledge of the effects of mutations on the emergent properties of brain networks is critical if we are to fully understand disease genesis. Genetically modified animal models provide an avenue to investigate disease mechanisms of human mutations at this level of organization. Genetically engineered knockin models, in which the human epilepsy mutation is integrated into the mouse genome and replaces the endogenous allele, are potentially one of the most useful in vivo models for understanding epileptogenesis in genetic epilepsy. These mouse models most closely replicate the human genetic disorder and are becoming the gold standard for investigating the mechanisms underlying specific human epilepsy syndromes.

THE $GABA_A$ RECEPTOR

Gamma-aminobutyric acid (GABA) is the predominant inhibitory transmitter within the central nervous system and acts through three receptor classes: the ionotropic $GABA_A$ and $GABA_C$ receptors and the metabotropic $GABA_B$ receptors. The $GABA_A$ receptor is a transmitter-gated ion channel of the Cys-loop family. $GABA_A$ receptors are pentameric proteins with a central Cl^- permeant pore that is

formed from various combinations of proteins encoded by the α, β, γ, δ, ε, and θ subunit gene families. A vast array of functional $GABA_A$ receptors can be formed from combinations of these subunits in a brain-region and development-specific manner. *GABRG2* encodes the $GABA_A$ γ2 subunit in which most epilepsy-associated mutation have been found for the $GABA_A$ family.

$GABA_A$γ2 RECEPTORS AND GENETIC EPILEPSY

Two independent groups simultaneously identified mutations in *GABRG2* found in families with genetic epilepsy with febrile seizures plus (GEFS+) and childhood absence epilepsy (CAE).[1,2] Two further mutations in *GABRG2* have since been associated with GEFS+, Dravet syndrome, CAE, and febrile seizures.[3,4] A *GABRG2* mutation associated specifically with febrile seizures has also been described.[5] This chapter focuses on the $GABA_A$γ2(R43Q) mutation, for which a knockin mouse model has been engineered.[6]

$GABA_A$γ2(R43Q) FUNCTIONAL ANALYSIS IN HETEROLOGOUS EXPRESSION SYSTEMS

Several in vitro studies have been performed to determine the functional consequence of the various mutations. Analysis of the R43Q mutation was associated with changes in benzodiazepine sensitivity, receptor kinetics, assembly, trafficking, and cell surface expression.[7–10] These in vitro findings are consistent with a reduction in $GABA_A$ receptor-mediated current due to the mutation under the various conditions. The residues surrounding R43 in the γ2 subunit appear to be important for intersubunit interactions and are impaired by the Q43 mutant, providing a potential molecular basis for the kinetic and trafficking changes noted.[11] There has been some disagreement in the in vitro literature regarding whether there is altered diazepam sensitivity associated with the R43Q mutation or not, with some groups reporting altered diazepam binding or sensitivity [8,12,13] and others not.[7,9–11] The source of this discrepancy is not clear at this time and may relate to differences in subunit partners, cell lines, transfection methods, or culturing conditions that all potentially alter expression levels of the mutant R43Q subunit.

An elegant in vitro study used virally delivered R43Q subunits to demonstrate that cell surface expression of the mutant was reduced[14] (which was later confirmed in the R43Q mouse).[6] More importantly, however, Eugene et al. found that expression of the R43Q mutant subunit significantly reduced GABA-mediated tonic inhibition, presumably as a consequence of a dominant negative interaction with the GABAα5 subunit.[14] While it is intuitively satisfying to postulate that a reduction in tonic current, a major source of inhibition in the brain, could result in the absence epilepsy seen in R43Q patients, more recent data from the Crunelli laboratory clearly demonstrated a major *increase* in GABA-mediated tonic current in a rat absence model.[15] It is difficult to reconcile these findings unless one raises the idea that any disruption of the normal tonic inhibition levels within the thalamocortical circuit can result in pathological oscillations that could lead to absence seizures. Further experimental and computational studies are required to fully comprehend the fundamentals of the oscillatory behavior in this important network.

THE $GABA_A$γ2(R43Q) MOUSE MODEL

We have developed an animal model of GEFS+ based on a human *GABRG2* mutation. Patients with this mutation typically display febrile seizures and, less frequently, CAE and GEFS+ seizure types. The mouse recapitulates this core phenotype, displaying clear spike-and-wave discharges on electroencephalography (EEG) that are associated with behavioral arrest (Fig. 56–1). The mouse also displays a phenotype consistent with the febrile seizure seen in patients. Increasing the core temperature of many strains of mice caused thermal seizures that were evident on EEG and behaviorally. Using this simple assay, mice that were heterozygous for the R43Q mutation seized at lower temperatures than their wild-type counterparts (Fig. 56–2), potentially modeling the febrile seizures seen in patients with the same mutation. These mice

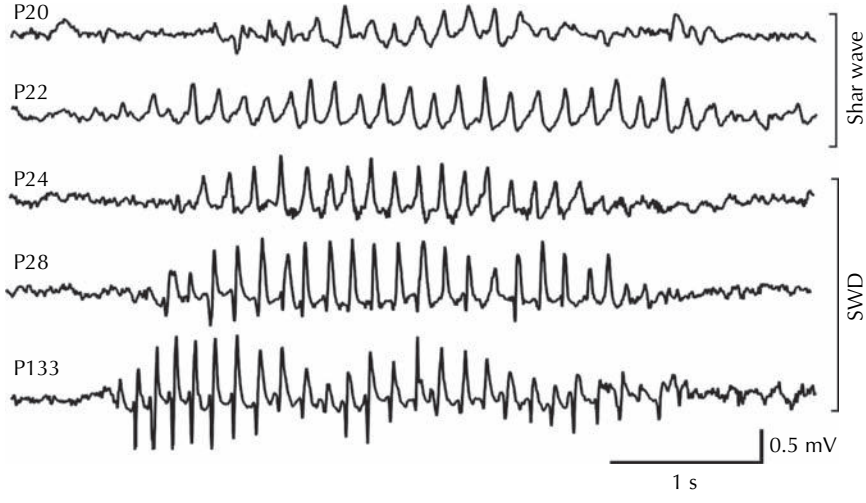

Figure 56–1. Evolution of SWDs in the heterozygous R43Q mice occurs over a short time period. The behavioral arrest phenotype (absence) was noted only after postnatal day 22 with the appearance of SWDs. From ref. 6.

are likely to provide significant insight into the mechanism underlying clinically relevant forms of epilepsy. They may also provide "disease state" screening tools for new antiepileptic drugs (AEDs) that distinguish them from chemical or physical seizure models.

Cortical Inhibition as a Common Deficit in R43Q Patients and Mice?

The thalamocortical circuit is comprised of three brain regions: the somatosensory cortex, the ventrobasal thalamus, and the thalamic reticular nucleus. This interconnected circuit has been implicated in the normal physiology of sleep and also, pathologically, in absence epilepsy. Analysis of synaptic inhibition in the heterozygous R43Q mouse points to a small reduction in cortical GABA$_A$ receptor-mediated transmission as a possible cellular mechanism underlying epilepsy (Fig. 56–3). No change in inhibition has been seen in the thalamic neurons, suggesting that cortical disinhibition is an important aspect of this particular form of genetic epilepsy and, potentially, of common forms of absence epilepsy with different genetic underpinnings. Transcranial magnetic stimulation analysis of cortical excitability in patients heterozygous for the R43Q mutation likewise suggested reduced cortical inhibition.[16] In patients with the mutation, paired pulse stimulation reduced short-interval cortical inhibition and increased intracortical facilitation, resulting in a more excitable motor cortex. In the earlier mouse studies, only inhibitory synapses onto layer 2/3 pyramidal neurons were investigated, and it is not known if other cortical inhibitory synapses were altered. In order to analyze the more global impact of this deficit on cortical function in R43Q mice, voltage-sensitive dye (VSD) studies were performed.[17] The cortical surface of the whisker barrel field in the mouse was exposed and loaded with a fluorescent VSD. A whisker that mapped to the exposed barrel region was found, and the stereotypical

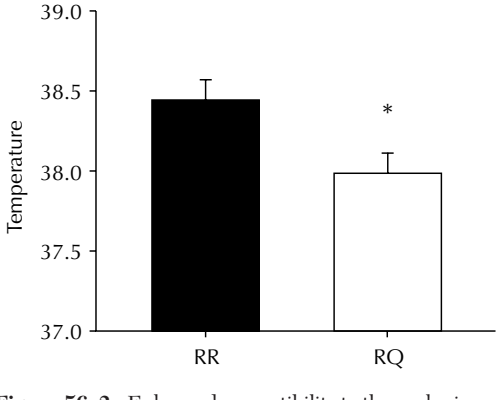

Figure 56–2. Enhanced susceptibility to thermal seizures in R43Q mice. Core temperature at which EEG seizures were first noted in control (RR, $n = 8$) and R43Q heterozygous mice (RQ, $n = 8$). Mice were heated with a stream of warm air during monitoring. $^*p < .05$.

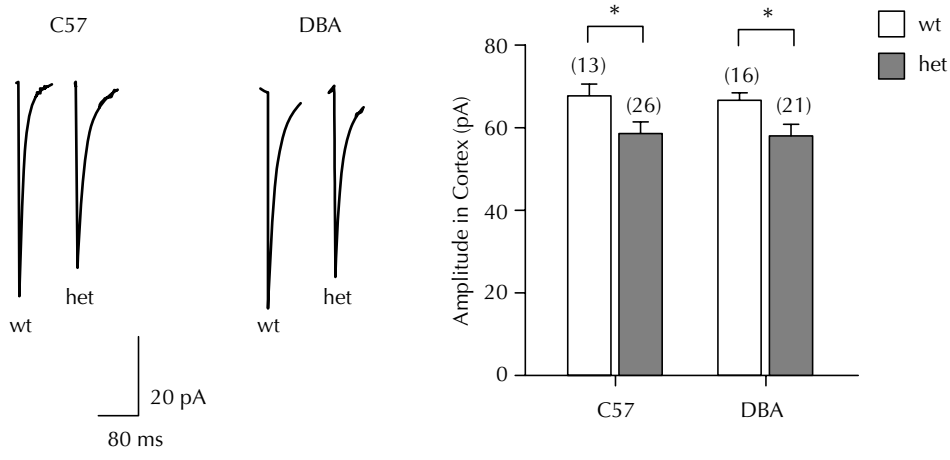

Figure 56–3. Miniature inhibitory postsynaptic current analysis in layer 2/3 pyramidal neurons reveals specific reduction in the cortical inhibition of heterozygous R43Q mice (het) in two different background strains. No such changes were observed in thalamic neurons.[6]

activation patterns caused by whisker deflection were recorded (Fig. 56–4). As can be seen in comparing the heterozygous R43Q and the control, whisker deflection caused a similar level of cortical activation (Fig. 56–4). Upon exposure to a subconvulsive dose of pentylenetetrazole (scPTZ; 40 mg/kg), the amplitude of cortical activation was reassessed. In this case, whisker deflection produced a significantly greater cortical response in the heterozygous mice compared to the controls. This result suggests that the deficit in cortical inhibition noted above (Fig. 56–3) can impact cortical function but only under conditions in which inhibitory reserves are compromised. Consistent with this argument is the episodic nature of seizures seen in both humans and mice, which suggests that spike-and-wave discharges (SWDs) and

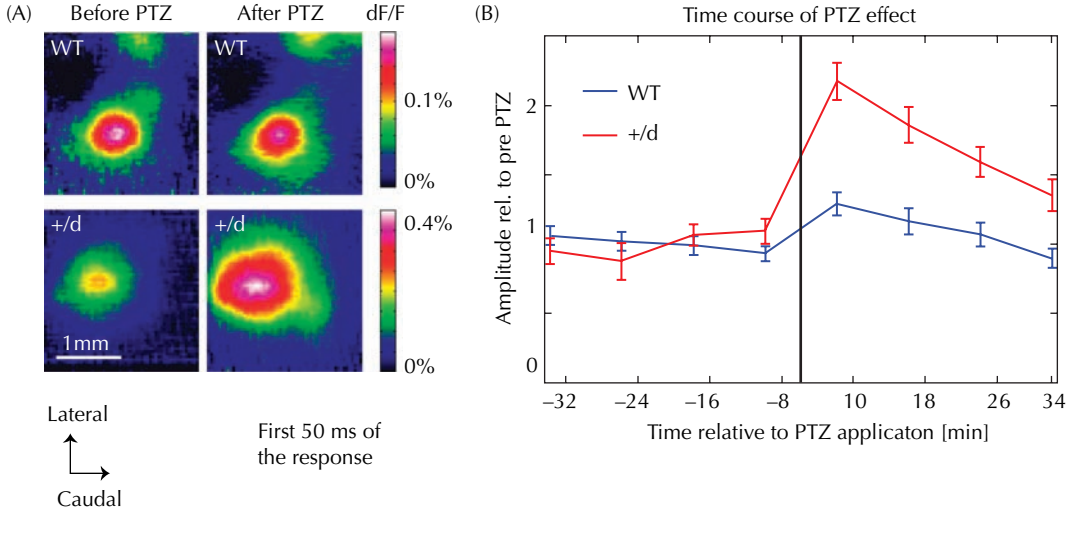

Figure 56–4. Voltage-sensitive dye imaging reveals enhanced cortical excitability in the R43Q mouse model. **A.** Imaging of a single whisker barrel demonstrates that the amplitude and extent of barrel activation following whisker stimulation are not enhanced by scPTZ in control mice (WT) and are significantly enhanced in heterozygous R43Q mice (+/d). **B.** Time course of signal amplitude showing that cortical excitability prior to administration of scPTZ was similar in controls and heterozygotes and that enhancement was prolonged for up to 30 min after exposure. Figure courtesy of H. Spors.

the attendant behavioral arrest may occur at times when the inhibitory drive is also compromised. This may be related to the finding that absence seizures emerge more readily following sleep deprivation in people[18] and during quite wakefulness in mice.[6]

Febrile Seizures in R43Q Patients and Mice

As mentioned above, febrile seizures are a common phenotype seen in R43Q patients and a common feature in many genetic forms of epilepsy. a potential cellular mechanism for febrile seizures in these patients emerged from a series of elegant in vitro experiments that demonstrated internalization of GABA$_A$ receptors containing mutant γ2(R43Q) subunits in response to heating of cell cultures. The loss of inhibitory receptors was proposed to reduce local inhibition and trigger the febrile seizures.[19] This mechanism was further investigated in the heterozygous R43Q mouse model by heating brain slices for amounts of time similar to those used in the in vitro experiments and then recording the amount of miniature inhibitory (GABA$_A$ receptor-mediated) postsynaptic current. Unlike the results found in the in vitro experiments, data from the mouse model showed that heat exposure failed to cause the expected reduction in phasic GABA$_A$ receptor-mediated inhibition[20] (Fig. 56–5). The failure of these in vivo experiments to corroborate the earlier in vitro data suggests that mutation-specific internalization during fever is not likely to be an important mechanism underlying febrile seizures in patients with the γ2(R43Q) mutation[20] (Fig. 56–5). This highlights the potential difficulty of translating in vitro findings to in vivo disease mechanisms and strengthens the need for syndrome specific models.

Developmental Role of the R43Q Mutation

Mutations that produce their effect by acutely altering gene function are also likely to alter the developmental trajectory of the circuits in which they reside. GABA$_A$ receptors in particular have been implicated as important players in normal neurodevelopment, and it would be expected that their dysfunction would likewise alter the course of neurodevelopment that could contribute to heightened seizure susceptibility. This concept has recently been tested by Chiu et al., who described a tetracycline-based conditional model based on the R43Q model that enabled activation of a hypomorphic Q43 allele at different times in the development of the mouse.[21] If the expression of the disease allele was suppressed during early development (in this case, from conception to postnatal day 21), scPTZ testing (Fig. 56–6) showed that these mice had significantly reduced seizure susceptibility. It is important to note that seizure susceptibility did not return to control levels, suggesting that a combination of acute and developmental effects contribute to determining seizure susceptibility in genetic epilepsy. Although the applicability of this mechanism to other forms of genetic epilepsy has not been investigated, it is likely to contribute more widely to pathogenesis in genetic epilepsy and provides an example of an emergent pathology that could not have demonstrated in simpler model systems. There are two therapeutic consequences of this finding: knowledge of the genetic lesion itself may not be sufficient to select therapy, and understanding of the impact of a mutation at multiple spatial and temporal scales will be necessary to enable the development of personalized medicine in epilepsy and other neurological disorders.

R43Q as a Model for Hypoglycemia-Induced Seizures

As discussed, GEFS+ has a genetic etiology. However, it is well known that environmental effects such as decreased vigilance and voluntary hyperventilation can induce absence seizures, which is one of the epilepsy phenotypes seen in R43Q patients with GEFS+. Not all environmental triggers of absence seizures are understood. The controlled experimental environment provided by using syndrome-specific animal models can be extremely valuable in investigating these issues, which may otherwise be difficult to achieve in highly heterogeneous patient populations. We have used the heterozygous R43Q mouse model to investigate the impact of low blood glucose on seizure

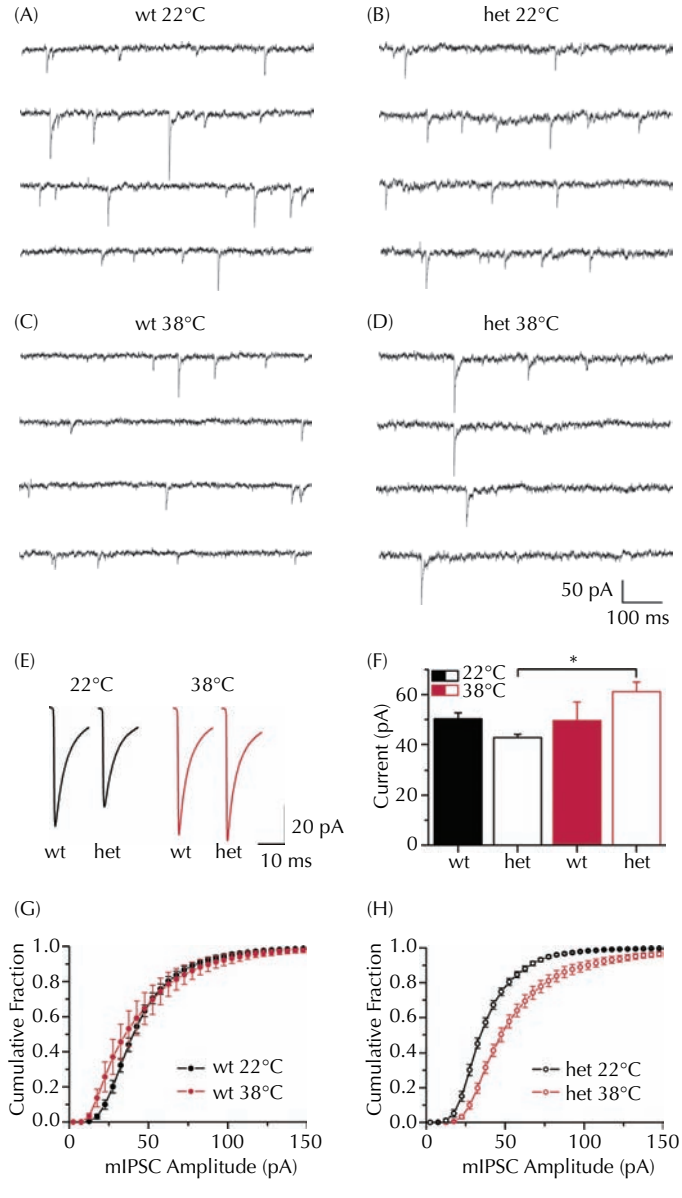

Figure 56–5. Temperature elevation causes a long-term increase in inhibitory currents in layer 2/3 cortical pyramidal neurons from the heterozygous R43Q mouse. **A–D.** Comparison of miniature inhibitory post synaptic currents (mIPSCs) from control (wt) and heterozygous R43Q mice (het) after incubation of slices at either 22°C or 38°C. **E–H.** Summary of mIPSC properties demonstrating the specific effect of preheating on neurons from the het mice only.[20]

precipitation.[22] We show that moderate lowering of blood glucose levels can precipitate seizures (Fig. 56–7). Low blood glucose may, therefore, represent an environmental risk factor in patients with epilepsy and, in particular, in those with preexisting genetic risk factors. These data provide a compelling reason to further investigate this phenomenon in absence epilepsy and have already led to clinical studies along these lines. This provides an exciting paradigm with which syndrome-specific models that recapitulate the human phenotype can be used to make predictions about human pathological outcomes.

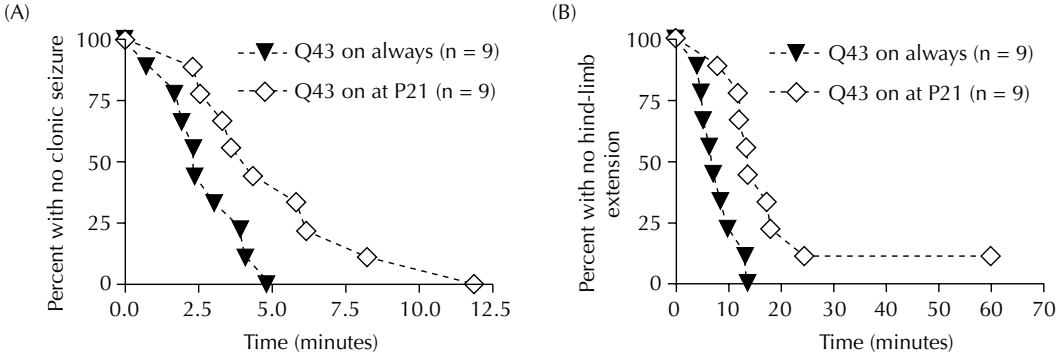

Figure 56–6. Suppression of the Q43 disease allele until day 21 reduces seizure susceptibility. Survival times for scPTZ-induced (**A)** tonic-clonic and (**B**) hind limb extension seizures.[21]

FUTURE CHALLENGES

The causal chain that extends from genetic lesion to behavioral seizure spans multiple temporal and spatial scales, crosses a range of axes from clinical to economic (for a review of the computational challenges facing the epilepsy field, see Lytton[23]), and operates on the complex substrate of the human brain. While the clinical need is clear; to develop a cure for all types of epilepsy, the challenge is to navigate this complex landscape efficiently. Genetically

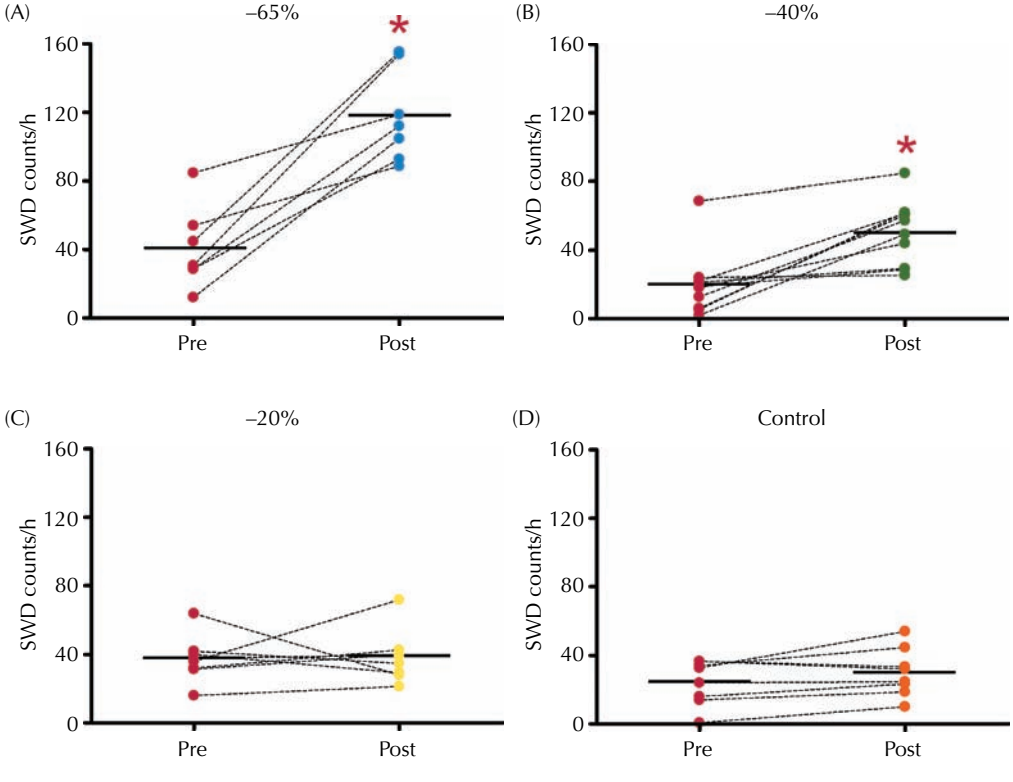

Figure 56–7. Hypoglycemic challenge increases SWDs in the heterozygous R43Q mouse model. Increasing levels of hypoglycemia are associated with an increased amount of SWDs (**A–C**). Vehicle controls did not show an increase (**D**).[22]

engineered mice, and more recently the transgenic rat model,[24] provide approaches to model many of the scales required to gain a full and predictive understanding of how our personal genome determines not only our seizure susceptibility but also the modulation of this susceptibility by external factors such as those imposed by disease (fever and chemical changes such as cytokines), diet, and lifestyle (hypoglycemia and other metabolic changes), as well as the important interaction with drugs that modify networks to abrogate seizures. The first challenge is perhaps to identify the critical path that will yield the greatest knowledge for a given scientific effort. Because epilepsy is a systems-level disorder, the methodological challenges are enormous, as experimental approaches must span genetic, molecular, synaptic, network, and behavioral levels, to name a few. Incorporating the latest methods, such as optogenetics and optophysiology, is also critical to revealing novel mechanisms and intervention strategies and for reporting on organizational scales relevant to disease genesis. A final challenge in the effort to achieve ideal therapeutic outcomes involves the translation of experimental findings into commercially sustainable drug discoveries and development.

Chapter 57

$GABA_A$ Receptor Subunit Mutations and Genetic Epilepsies

Robert L. Macdonald
Jing-Qiong Kang
Martin J. Gallagher

INTRODUCTION

Idiopathic epilepsy syndromes (IES) are common and constitute about 50% of the epilepsies diagnosed worldwide.[1] They vary in severity from the relatively benign febrile seizures (FS) and childhood absence epilepsy (CAE) to the severe epilepsy syndrome Dravet syndrome. A common IES is FS plus (FS+), which develops early in childhood with multiple FS that continue to occur beyond 6 years of age or are associated with afebrile seizures.[2] Generalized epilepsy with FS plus (GEFS+) is a familial epilepsy syndrome in which multiple family members have either FS, FS+, myoclonic-astatic epilepsy (MAE), and DS.[2]

Most IES have been thought to have a genetic basis,[3,4] and although complex polygenic inheritance is likely associated with most genetic epilepsy syndromes, rare monogenic mutations of transmembrane ion channels associated with IES in several large pedigrees and in sporadic cases with de novo mutations have been identified.[4–6] Mutations of ion channels that

either increase excitatory or reduce inhibitory neurotransmission produce neuronal hyperexcitability, thereby predisposing individuals harboring the mutant gene to experience seizures. In this chapter, we will focus on mutations in inhibitory GABA$_A$ receptor subunit genes that have been associated with IES.

GABA$_A$ RECEPTOR SUBUNIT GENES

Gamma-aminobutyric acid A (GABA$_A$) receptors are members of the cys-loop family of ligand-gated ion channels that also includes glycine, nicotinic cholinergic, and serotonin 5-HT3 receptors and are the primary mediators of fast inhibitory synaptic transmission in the central nervous system. The GABA$_A$ receptors are formed by pentameric assembly of different subunit subtypes (α1–α6, β1–β3, γ1–γ3, δ, ε, π, θ, and ρ1–ρ3) to form chloride ion channels,[7] and most GABA$_A$ receptors are thought to contain two α subunits, two β subunits, and one γ or δ subunit.[8] The GABA$_A$ receptors mediate both phasic synaptic and tonic perisynaptic or extrasynaptic inhibition, and several antiepileptic drugs, including benzodiazepines and barbiturates, act by enhancing GABA$_A$ receptor currents.[9] Therefore, it is not surprising that several different IES have been associated with mutations and variants in several GABA$_A$ receptor subunit *GABR* genes, including *GABRA1*, *GABRB3*, *GABRD*, and *GABRG2*[10,11] (see Fig. 57–1 and Table 57–1). The position of mutant amino acids in *GABRA1*, *GABRB3*, and *GABRD* associated with IES have been designated in the immature peptide that includes the signal sequence, but mutations in *GABRG2* have been designated in the

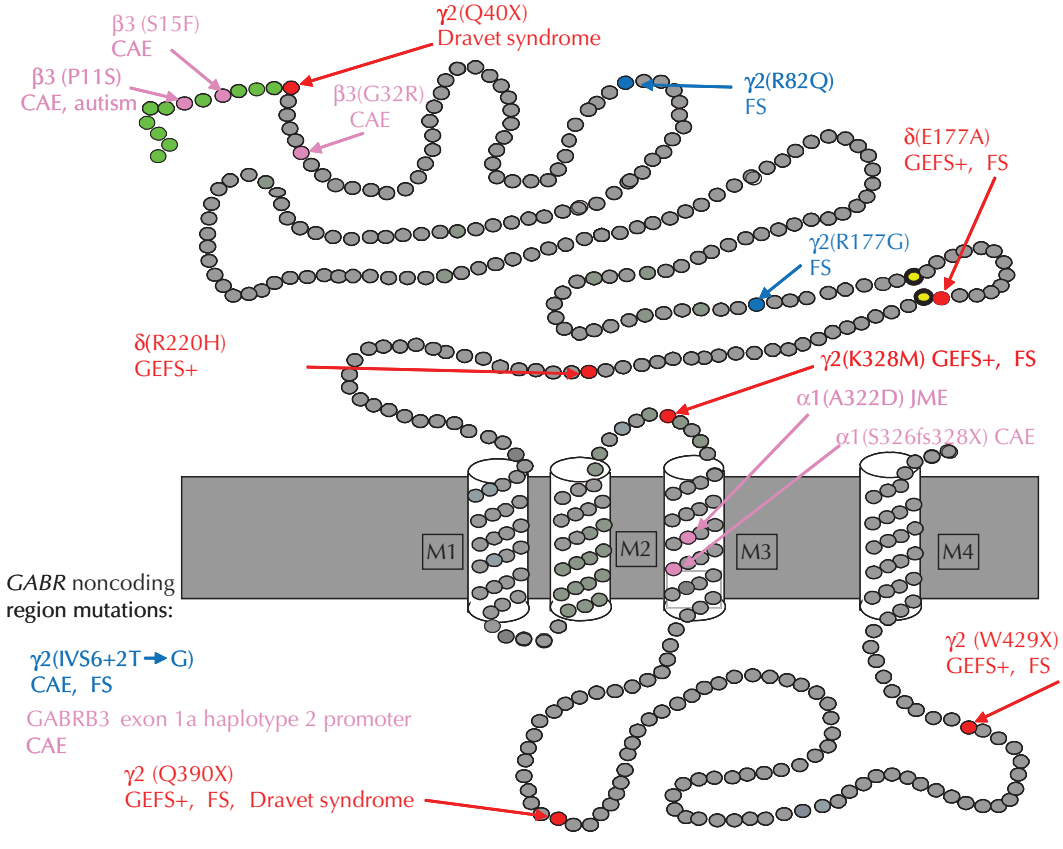

Figure 57–1. Gamma-aminobutyric acid A receptor subunit gene mutations associated with genetic epilepsy syndromes. Modified from ref. 11.

Table 57–1 **Epilepsy Mutations in *GABRs***

Mutation/Variant Original Reference	IES	Structural Feature	$GABA_A$ Receptor Dysfunction
CAE or JME (α1/β3 subunits): four missense, one promoter, and one frameshift mutation			
β3(P11S) Tanaka et al.[12]	CAE	Signal-peptide missense mutation	Abnormal N-linked glycosylation and reduced whole cell current
β3(S15F) Tanaka et al.[12]	CAE	Signal-peptide missense mutation	Abnormal N-linked glycosylation and reduced whole cell current
β3(G32R) Tanaka et al.[12]	CAE	N-terminus missense mutation	Abnormal N-linked glycosylation and reduced whole cell current
GABRB3 haplotype 2 Urak et al.[13]	CAE	Exon 1a haplotype 2 promoter	Impaired binding of N-Oct-3 transcription activator
α1(975delC, S326fs328X) Maljevic et al.[6]	CAE	Frameshift mutation and PTC in M3	NMD of mRNA followed by ERAD of subunit protein
α1(A322D) Cossette et al.[16]	JME	M3 missense mutation	Misfolded, reduced total and surface expression, reduced whole cell current
FS +/– CAE (γ2 subunit): two functional missense mutations and one nonfunctional nonsense mutation			
γ2(R82Q) Wallace et al.[5]	FS	N-terminus missense mutation	Impaired oligomerization, ER retention, reduced surface expression, reduced current
γ2(R177G) Audenaert et al.[18]	FS	N-terminus missense mutation	Altered whole cell current kinetics
GABRG2(IVS6+2T→G) Kananura et al.[19]	FS/CAE	Intron 6 splice-donor site mutation	Predicted to cause PTC at the exon 5–7 junction.
GEFS and/or DS (γ2/δ subunits): four functional missense and three nonfunctional nonsense mutations			
γ2(K328M) Baulac et al.[21]	GEFS+	M2/M3 loop missense mutation	Reduced single-channel mean open times, accelerated whole cell current deactivation
γ2(Q390X) Harkin et al.[22]	GEFS+/Dravet syndrome	M3/M4 loop nonsense mutation	ER retention, dominant negative reduction of wild-type receptors, reduced whole cell current
γ2(Q429X) Sun et al.[28]	GEFS+	M3/M4 loop nonsense mutation	Unstudied; likely unaffected by NMD and therefore produces truncated peptide
δ(E177A) Dibbens et al.[17]	GEFS+	N-terminus missense mutation	Reduced whole cell current, reduced single- channel mean open time
δ(R220C) Dibbens et al.[17]	GEFS+	N-terminus missense mutation	Reduced whole cell current, reduced single- channel mean open time
γ2(Q40X) Hirose[20]	Dravet syndrome	N-terminus nonsense mutation	Unstudied; likely triggers NMD

mature peptide. For consistency, in this chapter we will also designate the position of *GABRG2* mutations in the immature peptide.

IES ASSOCIATED WITH $GABA_A$ RECEPTOR SUBUNIT MUTATIONS

A wide range of IES have been shown to be associated with $GABA_A$ receptor subunit mutations[11] (Table 57–1). Childhood absence epilepsy alone has been associated with *GABRB*3 missense mutations located in the β3 subunit signal peptide (P11S, S15F) and the N-terminal region of the mature subunit (G32R),[12] as well as with a specific haplotype of the *GABRB3* promoter,[13] In addition, CAE is associated with a frameshift mutation in *GABRA1* (975delC, S326fs328X)[6] that produces a premature translation-termination codon (PTC). The β3 subunit (P11S) mutation has also been associated with autism pedigrees with some patients who also had epilepsy,[14,15] Juvenile myoclonic epilepsy (JME) has been associated with a missense mutation in *GABRA1* (A322D)[16] and a variant in *GABRD* (R220H).[17] Febrile seizures alone have been associated with missense mutations in *GABRG2* that are located in the N-terminal region of the mature γ2 subunit (R82Q, R177G)[5,18] and at the intron 6 splice donor site (IVS6 2T → G).[19] Generalized epilepsy with febrile seizures plus has been associated with missense and nonsense mutations in *GABRG2* (Q40X, K328M, Q390X, W429X)[20–23] and with variants in *GABRD* (E177A, R220H).[17] While a clear genotype/phenotype correlation has not been well established, to date mutations in *GABRB3* and *GABRA1* have been associated with CAE or JME alone, while *GABRG2* mutations and other *GABRD* variants have been associated with FS, FS with CAE, and GEFS+.

PATHOPHYSIOLOGY OF $GABA_A$ RECEPTOR SUBUNIT MUTATIONS ASSOCIATED WITH CAE AND JME

GABRB3(P11S, S15F, G32R)

GABRB3 has an alternative exon 1 (exon 1a) that encodes a variant signal peptide that translates a β3 subunit of identical length but with an altered mature peptide sequence. The two transcripts have different relative expression levels and distributions in fetal and adult brain, with exon 1a expression being enriched in fetal brain.[24] The *GABRB3* mutations P11S and S15F are located in exon 1a in the β3 subunit signal peptide. The *GABRB3* mutation G32R is in exon 2 and is located in the mature β3 subunit peptide near the N terminus. In HEK293T cells coexpressing each of the three β3 mutant subunits with α1 and γ2 subunits, whole cell peak currents and cell surface expression levels of the mutant β3 subunits were reduced.[12,14] It was suggested that these β3 subunit mutations may reduce $GABA_A$ receptor cell surface expression and whole cell current amplitudes by altering N-linked glycosylation of the β3 subunit.[12,14] However, the basis for the altered glycosylation of β3 subunits is unclear, and whether or not the altered glycosylation reduces receptor surface levels is also unclear. Furthermore, it is uncertain how the two signal peptide mutations alter the function of the mature β3 subunits since they are presumably cleaved prior to subunit folding and receptor assembly. Reduced expression of β3 subunit-containing $GABA_A$ receptors due to these mutations would be consistent with an epilepsy phenotype and would be expected to cause epilepsy early in development, since exon 1a is selectively expressed in fetal brain, and to remit in young adulthood since exon 1 is selectively expressed later in development.

In *GABRB3*, one of four haplotypes (haplotype 2) in the region from the exon 1a promoter to the beginning of intron 3 had a significant association with CAE.[13] Using an in vitro reporter gene assay with exon 1a promoter constructs, the haplotype 2 promoter was found to cause less transcriptional activity than the haplotype 1 promoter. Thus, it was suggested that the thymine-to-cytosine substitution in the haplotype 2 promoter impaired binding of the neuron-specific transcriptional activator N-Oct-3, leading to decreased transcription of *GABRB3* and thus presumably to a decrease in β3 subunit levels.

GABRA1(975delC, S326fs328X)

The *GABRA1* deletion mutation, 975delC, S326fs328X, causes a frameshift in *GABRA1*

that produces a premature translation-termination codon (PTC) and is associated with CAE[6] (see Fig. 57–1 and Table 57–1). Premature translation-termination codons in the last exon of a multi-exon gene or less than 50–55 nucleotides upstream of the last exon–exon junction result in production of a truncated protein. In contrast, PTCs not in the last exon of a multi-exon gene or more than 50–55 nucleotides upstream of the last exon–exon junction produce mRNA degradation through activation of nonsense-mediated decay (NMD), a cellular mRNA quality-control system that activates degradation of mutant mRNA to substantially reduce production of truncated proteins.[25] The *GABRA1* deletion mutation, 975delC, S326fs328X, is in exon 8 and is 84 base pairs upstream of intron 8; thus, this PTC activated NMD and reduced mutant α1 subunit mRNA.[26] However, the NMD was incomplete, but the truncated α1 subunit protein that was translated was degraded by endoplasmic reticulum (ER)-associated degradation (ERAD). These results suggested that the *GABRA1* mutation, S326fs328X, resulted in functional haploinsufficiency by reducing both mutant mRNA and subunit protein.

GABRA1(A322D)

The *GABRA1* missense mutation, A322D, replaces a small, neutral residue with a larger negatively charged aspartate residue in the M3 transmembrane helix and is associated with an autosomal dominant (AD) form of JME[16] (see Fig. 57–1 and Table 57–1). This non-conserved mutation was shown to impair α1 subunit folding by destabilizing insertion of the M3 domain into the lipid bilayer.[27] When mutant α1(A322D), β2, and γ2 subunits were coexpressed in HEK293T cells, both total and surface α1 subunit levels were reduced and an intermediate effect was found with heterozygous subunit expression. Loss of the misfolded mutant subunit was due to ERAD[28] and lysosomal degradation.[29] Peak GABA-evoked currents were significantly reduced with both heterozygous and homozygous α1(A322D) subunit expression, consistent with the impaired folding and assembly of the mutant α1(A322D) subunits.[6,30,31] Recently, we demonstrated that the presence of the nondegraded, misfolded α1(A322D) subunit produces small dominant negative effects that alter the composition and further reduce the expression of wild-type $GABA_A$ receptors.[32]

PATHOPHYSIOLOGY OF $GABA_A$ RECEPTOR SUBUNIT MUTATIONS ASSOCIATED WITH FS WITH OR WITHOUT CAE

In contrast to CAE and JME without FS associated with mutations in *GABRB3* and *GABRA1*, FS with or without CAE have only been associated with mutations in *GABRG2*. Two *GABRG2* missense mutations, R82Q[5] and R177G,[18] and one splice donor site mutation in *GABRG2*, IVS6+2T→G,[19] have been associated with FS with or without CAE.

GABRG2(R82Q)

The *GABRG2* missense mutation, R82Q, is located in the distal N terminus and is associated with FS[5] (see Fig. 57–1 and Table 57–1). An AD form of CAE was also present in the family pedigree, and it was demonstrated that an interaction of the γ2 subunit gene with another gene or genes is required for the CAE phenotype in this family.[33] Alignment of γ2 subunit and acetylcholine binding protein sequences revealed that R82 is positioned at the γ2/β2 subunit–subunit interface, and it was demonstrated that the mutation impaired γ2 and β2 subunit oligomerization.[34] This impaired oligomerization is likely the basis for this mutation's reduction of surface α1β2γ2 receptors,[35–38] ER retention of unassembled γ2(R82Q) subunits,[35,37] and reduction of $GABA_A$ receptor currents.[35,39] The R82Q mutation also caused intracellular retention and reduced surface expression of $GABA_A$ receptors in cortical pyramidal neurons,[40] reduced miniature inhibitory postsynaptic currents (IPSCs) in layer II/III cortical neurons, and electrographic and behavioral seizures in R82Q knockin mice. Endogenous expression of α5 subunits in cultured hippocampal neurons was reduced when coexpressed with γ2(R82Q) subunits, indicating that γ2(R82Q) subunits conferred a dominant negative effect.[38] In addition, it is possible that a deficit in γ2 subunits

caused a compensatory increase in other subunits, such as δ or β subunits. Since αβδ and αβ receptors are extrasynaptic or perisynaptic, this compensatory increase may result in a relative increase in tonic currents. Recently, it has been reported that extrasynaptic GABAergic "tonic" inhibition was increased in thalamocortical neurons from both genetic and pharmacological models of absence epilepsy,[41] consistent with this conclusion.

GABRG2(R177G)

The *GABRG2* missense mutation, R177G, is located in the N terminus and has been associated with FS[18] (see Fig. 57–1 and Table 57–1). The γ2 subunit R177 residue is conserved among γ2 subunits across species. Basic residues are conserved among other γ subunits, and in other cys-loop receptors, polar and charged amino acid residues occur at this position. Mutant α1β3γ2L(R177G) receptors had altered current kinetics and reduced benzodiazepine sensitivity,[18] but the underlying molecular mechanisms for FS associated with this mutation are unclear.

GABRG2(IVS6 + 2T→G)

The *GABRG2* splice-donor site mutation, IVS6 + 2T→G, is located in intron 6 and was identified in a family with FS and CAE[19] (see Fig. 57–1 and Table 57–1). The effect of this mutation on GABA$_A$ receptor function is unknown but was predicted to impair splicing of the intron 6. It was suggested that the mutation most likely would lead to a nonfunctional protein through exon skipping, which would result in a PTC at the fifth and seventh exon junction sites. If this is correct, the exon skipping-induced PTC would trigger NMD. However, when the mutation was made in the *GABRG2* intron 6 cloned in a bacterial artificial chromosome, a cryptic splice donor site in intron 6 was activated, resulting in retention of a portion of intron 6 and a frameshift that resulted in a PTC in exon 7 (Tian and Macdonald, unpublished). This exon 7 PTC had an exon–exon junction downstream and thus activated nonsense-mediated mRNA decay and loss of most of the mutant mRNA.

PATHOPHYSIOLOGY OF GABA$_A$ RECEPTOR SUBUNIT MUTATIONS ASSOCIATED WITH GEFS+ AND DRAVET SYNDROME

Generalized epilepsy with febrile seizures plus and Dravet syndrome have only been associated with *GABRG2* and *GABRD* mutations. One *GABRG2* missense mutation, (K328M),[21] three *GABRG2* nonsense mutations (Q40X, Q390X, and Q429X),[20,22,23] one *GABRD* mutation (R220C),[17] and a *GABRD* variant (E177A)[17] have been associated with GEFS+ with or without Dravet syndrome.

GABRG2(K328M)

The *GABRG2* missense mutation, K328M, is located in the short extracellular loop between transmembrane domains M2 and M3 and is associated with an AD GEFS+[21] (see Fig. 57–1 and Table 57–1). Brief GABA-evoked currents recorded from α1β3γ2L(K328M) receptors had unchanged current amplitudes but had accelerated deactivation.[39,42] In transfected hippocampal neurons, the K328M mutation also accelerated deactivation of IPSCs, thus reducing their duration.[38] Single-channel currents from α1β3γ2(K328M) receptors had reduced mean open times, consistent with accelerated macroscopic current deactivation.[39] Therefore, the γ2L(K328M) subunit mutation would reduce IPSC duration by accelerating its deactivation due to impaired stability of the channel open state.

GABRG2(Q390X)

The *GABRG2* nonsense mutation, Q390X, is located in the intracellular loop between transmembrane domains M3 and M4 and was identified in a family with GEFS+ and Dravet syndrome[22] (see Fig. 57–1 and Table 57–1). The PTC is located in the last (ninth) exon and therefore would not be expected to activate NMD. When cDNAs containing the mutant subunit were transfected into HEK293T cells, translation resulted in production of a truncated protein that lacked its C-terminal 78 amino acids and was retained in the ER.[43] Because the

γ2 subunit mutation (Q351X) prevents the cell surface trafficking of both α1β2γ2(Q351X) and α1β2 receptors, no GABA-evoked currents were recorded from cells transfected with α1, β2, and γ2(Q351X) subunits.[22,43] The γ2(Q390X) subunit also caused a dominant negative effect on wild-type receptors. Currents recorded following heterozygous expression of α1β2γ2/α1β2γ2(Q351X) receptors were reduced relative to hemizygous control currents, and γ2S and γ2S(Q390X) subunits and partnering α1 and β2 subunit levels were all reduced more than with hemizygous expression with only one wild-type allele, suggesting that the mutation produced a loss of function of the mutant allele and a dominant negative effect of the mutant γ2S(Q390X) subunit on wild-type receptor channels.

GABRG2(Q40X and Q429X)

The two *GABRG2* nonsense mutations, Q40X and Q429X, have been associated with Dravet syndrome and GEFS+, respectively.[20,23] The Q40X mutation likely triggers NMD, although this has not yet been demonstrated. In contrast, the Q429X mutation, which generates a PTC in the last *GABRG2* exon, would not be predicted to activate NMD and therefore would be expected to produce a truncated protein with loss of the C-terminal 39 amino acids.

GABRD(E177A, R220H, and R220C)

The *GABRD* susceptibility variants, E177A and R220H, and the *GABRD* mutation, R220C, are located in the δ subunit N terminus and are associated with an AD generalized epilepsy similar to GEFS+[17] (see Fig. 57–1 and Table 57–1). The *GABRD* (E177A) variant is adjacent to one of the two cysteines that form a disulfide bond, the signature feature of cys-loop receptors, and the *GABRD* (R220H) variant and (R220C) mutation are located between the cys-loop and the beginning of the first transmembrane domain (M1). The macroscopic current amplitudes of heterozygous and homozygous α1β2δ receptors containing the δ(E177A) subunit were significantly reduced due primarily to reduced single-channel mean channel open time.[44] There was also a small but significant reduction of mutant subunit surface levels with homozygous expression of receptors containing either variant.

DISCUSSION

Phenotype–Genotype Correlations

The pathophysiology of $GABA_A$ receptor subunit gene mutations associated with CAE and JME appears to involve a mechanism that produces developmentally regulated epilepsy and FS. Downregulation of *GABRB3* (exon 1a) function by decreasing β3 subunit surface expression (*GABRB3*[P11S, S15F]) or by decreasing *GABRB3* transcription (promoter mutation) associated with CAE should both result in epilepsy syndromes that have early onset and remit with age due to the expression of *GABRB3* exon 1a only early in development. In contrast, the *GABRA1* frameshift mutation (975delC, S326fs328X) should also occur early in development, corresponding to the onset of *GABRA1* expression, but should not remit with age if there is no functional compensation from other functionally equivalent subunits. In general, these patterns of epilepsy expression and genotype appear to be consistent. That said, it is unclear why mutations in *GABRG2* and *GABRD*, but not *GABRA1* and *GABRB3*, are associated with FS. It is tempting to speculate that this difference may have something to do with the ability of the nervous system to compensate for the loss of a $GABA_A$ receptor subunit. There are multiple α (α2–α6) and β (β1, β3) subunit subtypes that can substitute for α1 or β3 subunits and lessen the molecular defect caused by the impaired subunit function or expression, but γ2 or δ subunits do not have subunits that can readily be upregulated to compensate for their loss. Alternatively or in addition, it may be that decreased expression of γ2 or δ subunits may have some inherent temperature sensitivity that further reduces their expression or function.[45]

Expression of $GABA_A$ Receptor Subunit Mutations in Heterologous Cells and Neurons

The pathophysiology of mutant $GABA_A$ receptor subunits has been evaluated primarily by

expressing them in heterologous cells, but it is likely that $GABA_A$ receptor expression and function in heterologous cells and in neurons differ. While many fundamental features of subunit translation, folding, and oligomerization and receptor assembly and trafficking are likely similar, if not identical, in heterologous cells and neurons, heterologous cells do not express neuron-specific $GABA_A$ receptor-associating proteins that are involved in $GABA_A$ receptor biosynthesis, trafficking, and cell surface stability.[46] The processes involved in targeting $GABA_A$ receptors to dendrites in polar neurons and to subsynaptic and extrasynaptic sites are clearly not recapitulated in heterologous cells. Some, but not all, of these concerns can be overcome by expressing wild-type and mutant $GABA_A$ receptor subunits in cultured neurons. In addition to expressing neuron-specific proteins, cultured neurons form functional GABAergic synapses that obviate the need for exogenous GABA applications. Many of the initial observations in heterologous cells have been confirmed by study of mutant γ2(R82Q), γ2(K328M), γ2(Q390X), and α1(A322D) subunits transfected into cultured neurons.[32,37,38,43] For example, rapid agonist perfusion techniques applied to transfected HEK293T cells revealed that α1β2γ2(K328M) receptors deactivated significantly faster than wild-type receptors,[39] and mIPSCs recorded from hippocampal neurons transfected with γ2(K328M) subunits had shorter deactivation times than mIPSCs recorded from untransfected neurons or from neurons transfected with wild-type γ2 subunits.[38] In addition, studies in transfected neurons revealed new findings that could not have been predicted from heterologous expression alone. For example, while ER retention of mutant γ2(R82Q) subunits transfected into HEK293T cells[35,36] was confirmed in transfected hippocampal neurons,[37,38] expression of γ2(R82Q) subunits in cultured neurons also reduced nonsynaptic "tonic" GABA currents and reduced surface expression of α5 subunits.[37] These observations could not have been obtained in HEK293T cells that do not express neuron-specific proteins such as radixin, which associates with the α5 subunit.[47]

Although expression of mutant $GABA_A$ receptor subunits in cultured neurons has been useful, it is still likely that the details of the pathophysiology are incomplete using this approach. With transfection, it is not possible to regulate the levels of subunit transcription and translation; therefore, the relative amounts of wild-type and mutant subunits and assembly partners will not be physiologically correct. In addition, the epilepsy mutations may have different actions in different brain regions or in different neuronal cell types and thus could modify neuronal network function differently in different nervous system locations. Ultimately, many of these questions must be answered by studying genetically modified animals as well as human patients who possess these mutations.

Thus far, only the *GABRG2*(R82Q) mutation knockin mouse has been made and studied.[40,48] Consistent with the reports in transfected heterologous cells and neurons, γ2(R82Q) subunit neuronal surface expression was reduced.[40] Unexpectedly, mIPSC amplitudes were reduced in cortical neurons, but not in thalamic relay or reticular nuclei neurons.[40] Interestingly, the *GABRG2*(R82Q) subunit mutation produced an epilepsy phenotype only when expressed at a critical time in development,[48] indicating a long-term impact of the presence of mutant *GABRG2*(R82Q) protein by unknown mechanisms.

Pathophysiological Mechanisms of $GABA_A$ Receptor Subunit Mutations

As noted in this chapter, the types and locations of mutations in $GABA_A$ receptor subunit genes vary substantially. Missense and nonsense mutations have been reported in coding and noncoding regions. In general, there is an association of the epilepsy syndrome type with the gene, as noted above (i.e., CAE and JME associated with *GABRB3* and *GABRA1* mutations and FS with or without CAE, GEFS+ and DS associated with *GABRG2* and *GABRD* mutations) and a loose correlation with the severity of the mutation and the epilepsy phenotype (Fig. 57–1). Missense mutations in *GABRB3*, *GABRG2*, and *GABRD* are associated with CAE, FS, JME, and GEFS+, while nonsense mutations in *GABRG2* are associated with FS, GEFS+, and Dravet syndrome. In addition, mutations in noncoding regions in *GABRG2* or *GABRB3* and mutations in the signal peptide of *GABRB3* are associated with less severe epilepsies, FS, and CAE, but mutations in the mature peptide are also associated with GEFS+ and

Dravet syndrome in addition to FS and CAE. Whether or not the presence of these correlations is due only to chance, because of the small number of reported mutations, or to fundamental differences in the loss of function of specific subunits as a result of specific types of mutations remains to be seen.

It is also clear that the mutations, while all different, have some common pathophysiological features. Distal N-terminal missense mutations (*GABRB3*[P11S, S15F, G32R] and *GABRG2*[R82Q, R177G]) are associated with the less severe epilepsies CAE and FS, and proximal N-terminal missense mutations (*GABD*[E177A, R220H]) are associated with the more severe epilepsy GEFS+. The cytoplasmic M3/M4 loop nonsense mutations *GABRG2*(Q390X, W429X) are associated with the more severe epilepsies GEFS+ and Dravet syndrome.

Chapter 58

Nicotinic Acetylcholine Receptor Mutations

Ortrud K. Steinlein

Shinichi Hirose

INTRODUCTION

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) was described relatively recently as a rare but distinct familial idiopathic epilepsy in 1994.[1] Contrary to this late nosological "discovery," ADNFLE became the first idiopathic epilepsy that disclosed its underlying molecular pathogeneses, namely, nicotinic acetylcholine receptor (nAChR) mutations. As nAChR is a ligand-gated ion channel, at the same time, this molecular discovery made ADNFLE the first epilepsy to be recognized as one of channelopathies, or diseases resulting from channel dysfunction.[2] The notion that epilepsy can be a channelopathy, which was deduced from the molecular discovery on ADNFLE, has certainly contributed to knowledge of the genetics of epilepsy.[3] Supporting the notion, in fact, are some 20 other epilepsies that were recognized subsequently as *channelepsies*, that is, compounders of channelopathy and epilepsy, indicating epilepsies resulting from channel dysfunctions.[4] Such channelepsies include, among others, benign familial neonatal seizures (BFNS) resulting from mutations of potassium channels, genetic epilepsy with febrile seizures plus (GEFS+), and Dravet syndrome due to sodium channel mutations.[3] Studies of ADNFLE in association with nAChR mutations have also established a methodology for investigating the pathomechanisms of other

epilepsies. Thus, dysfunction of ion channels due to genetic abnormalities can be evaluated readily in vitro, as ion channels can be reconstituted in oocytes or cultivated cells using relevant cDNA expression systems. These ion channel dysfunctions enable us to understand the molecular and neuroscientific pathomechanisms underlying epilepsies. Furthermore, they allow us to genetically engineer animal models of epilepsy that harbor mutations homologous to those identified in human epilepsies.[5–7] Such genetically engineered animal models of epilepsy represent molecular pathomechanisms distinct from those of conventional animal models. These genetically engineered animal models, which more accurately represent the pathomechanisms in the human brain, will open new avenues for treating epilepsies and developing novel measures for epilepsy based upon a better understanding of their molecular basis. In this chapter, we demonstrate the clinicophysiological characteristics of ADNFLE and summarize the current understanding of the molecular pathomechanisms of ADNFLE resulting from nAChR mutations.

CLINICAL SPECTRUM OF ADNFLE

ADNFLE is a literally partial epilepsy inherited as an autosomal dominant trait with penetrance as high as 90%. There is also sporadic nocturnal frontal lobe epilepsy (NFLE), which is nonfamilial. Its clinical manifestations are indistinguishable from those of ADNFLE.[8,9] In fact, nAChR mutations may be found as a cause of sporadic NFLE.[10] As their names suggest, predominant ADNFLE/NFLE seizures are symptomatically comparable to those of frontal lobe epilepsy, whereas seizures occur exclusively, if at all, during non–rapid eye movement (NREM) sleep. Thus, ADNFLE/NFLE attacks occur during light sleep or even during the daytime and are characterized by clusters of brief seizures. These are often stereotyped and brief (5 s to 5 min), sometimes preceded by an aura including sensory or psychic symptoms. Such seizures may start with grunts, gasping, or vocalization followed by hyperkinetic movements including dystonia and sleep-working. These brief seizures may sometimes evolve into secondary generalized tonic-clonic seizures. Retained awareness during seizures is common. To some degree, sleep disturbance may be associated with the seizures; hence, affected individuals often complain of daytime fatigue after frequent seizure attacks during the night. Although the seizure pattern of ADNFLE/NFLE per se is stereotypic, within a family the manifestations may vary considerably, ranging from simple arousal from sleep to dramatic, often bizarre, hyperkinetic events with tonic or dystonic features.

Because of their mostly nocturnal occurrence, the attacks are often misdiagnosed as nightmares or parasomnias. Based on the observation of a large number of patients, Provini and colleagues have identified three distinct types of ADNFLE/NFLE seizure: *paroxysmal arousals*, *paroxysmal dystonia*, and *episodic wandering*. Paroxysmal arousal is characterized by brief and sudden recurrent motor paroxysmal behavior. Paroxysmal dystonia is a motor attack with dystonic-dyskinetic features. Episodic wandering is stereotypical and agitated somnambulism.[8] These cardinal manifestations may be a key to distinguishing NFLE from other parasomnias.

ADNFLE/NFLE onset ranges from infancy to adulthood. About 80% of patients develop ADNFLE/NFLE in the first two decades of life; mean age of onset is 14 years (14 ± 10 years). The age of onset, however, is known to vary among affected individuals, even those in the same pedigree. ADNFLE/NFLE is lifelong but not progressive. As an individual reaches middle age, attacks may become milder and less frequent. Still, as with seizure manifestations, there are intra- and interfamilial variations in the natural course of ADNFLE/NFLE.[9]

Apart from minor differences, the ADNFLE/NFLE clinical phenotype is mostly uniform. No proven relationship between phenotypes and genotypes of nAChR mutations (i.e., phenotype–genotype correlation) has been elucidated. To date, however, it has been reported that two clinical phenotypes may change according to the genotypes of the nAChR mutations. One such change is the intellectual impairment or cognitive deficit; the other is sensitivity to antiepileptic drugs (AEDs).[8,11,12] While in most cases neurological examinations are normal and there is no intellectual impairment, it is possible that the S284L mutation of *CHRNA4* is associated with a cognitive deficit.[9,10,13] (Details will be discussed in the following sections.)

Genotypes of nAChR mutations may be associated with sensitivity to AEDs in ADNFLE/NFLE. Carbamazepine (CBZ), often in relatively low doses, provides remission to about 70% of individuals with ADNFLE/NFLE. Hence, CBZ remains the first-choice AED for the treatment of ADNFLE/NFLE; however, resistance to AEDs, present in about 30% of affected individuals, requires a trial of other appropriate AEDs. Individuals with ADNFLE/NFLE associated with the *CHRNA4*-S284L mutation may respond only partially to CBZ but be more responsive to zonisamide (ZNS) or benzodiazepine.[11,12,14]

EEG AND BRAIN IMAGING IN ADNFLE PATIENTS

In recent years, studies with video-polysomnographic monitoring have identified a distinct form of clear-cut attacks originating from epileptic foci located in the frontal lobe and emerging almost exclusively during sleep (mainly NREM stage 2/3). During wakefulness, the electroencephalogram (EEG) of almost all patients with ADNFLE/NFLE is within normal limits and the interictal EEG during sleep is also normal.[8,15] A few ictal EEG recordings display clear-cut epileptic activity (spikes and spikes and waves), and in a few subjects, diffuse (background flattening) or focal EEG activity may be recorded (rhythmic theta or delta activity prominent over the anterior quadrants).[8,15,16] The interictal EEGs show no abnormality in more than 50% of patients with ADNFLE.[17] Therefore, without simultaneous video and polygraphic recordings of seizures, the lack of EEG epileptic abnormalities does not exclude ADNFLE/NFLE. Ictal EEGs show that seizure activity is of frontal origin and occurs predominantly in stage 2 NREM sleep[11] (Fig. 58–1). The failure to reveal abnormalities in many patients may be due to the inaccessibility of the locus to scalp EEG recordings.[11,17] Subdural grid recordings, sphenoidal or zygomatic recordings, positron emission tomography (PET), and single photon emission computed tomography (SPECT) also confirmed the frontal origin of seizures in patients with ADNFLE.[11,18–20] As for the relation between arousal and seizures, seizure onset usually preceded arousal in patients with ADNFLE. Seizure onset often coincided with the recording of K-complexes in the EEG and were sometimes triggered by sound stimuli.[21] In Japanese ADNFLE patients, the seizures were not always associated with arousal from sleep, but long seizures sometimes produced arousal.[11] A careful medical and family history of nocturnal symptoms, video-EEG monitoring of seizures, and gene analysis are enormously helpful in making an accurate diagnosis of ADNFLE.

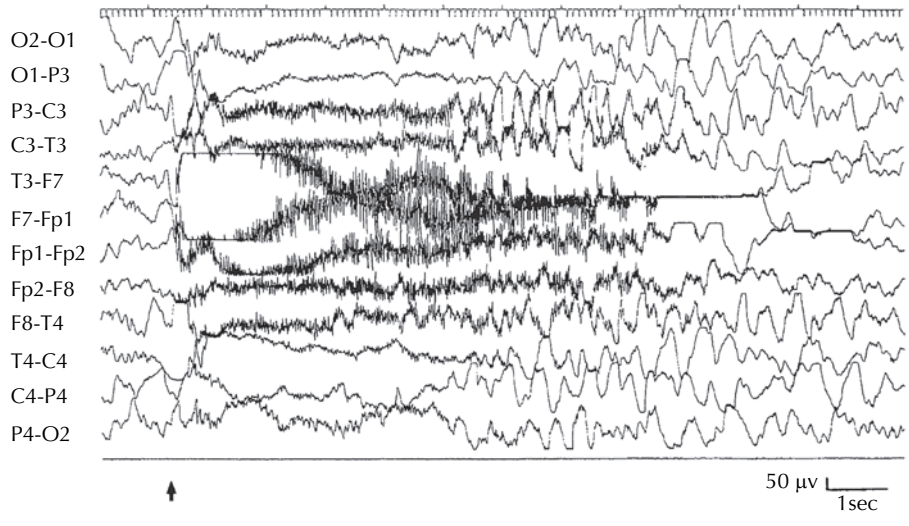

Figure 58–1. Ictal EEG of a Japanese ADNFLE patient with the mutation *CHRNA4*-S284L. Low-voltage spikes were initiated from the frontal region, gradually increased in amplitude, and were followed by high-voltage slow waves. Modified from ref. 11.

A Case

This boy's birth occurred via uncomplicated vaginal delivery after a normal pregnancy. At age 7 months, he had an afebrile general tonic convulsion during the daytime. The duration was 10 min. The interictal EEG showed no abnormality. He was diagnosed as having infantile convulsions and therefore was not treated with AEDs. At age 11 months, he began to have nocturnal seizures. His mother considered these to be nightmares. At age 1 year 3 months, he was admitted to a hospital for further evaluation. He had five to six seizures during stage 2 of NREM sleep at night and during midday naps. His seizures were sometimes provoked by movement and sound stimulation. The duration of each seizure was 10–15 s. During overnight video-EEG monitoring, five seizures were detected, and one of them was provoked by movement. All the seizures were identical in their clinical and electrographic manifestations. Magnetic resonance imaging (MRI) showed no abnormality, but SPECT detected low perfusion in both frontal lobes. Interictal EEG showed rare sporadic single spikes over the left frontopolar position. Ictal EEG showed low-voltage spikes initiating from the frontal region that gradually increased in amplitude and were followed by high-voltage slow waves (Fig. 58–1). The boy was treated with CBZ and cloxazolam. However, seizure control was not achieved.[11]

ADNFLE MUTATIONS IN nACHR SUBUNITS

ADNFLE, although classified as a partial epilepsy, turned out to be caused by mutations in genes that are ubiquitously expressed in brain. The first ADNFLE mutation had been found in 1995 in a large Australian family.[2] All affected family members available for mutation analysis carried a S280F amino acid exchange within the second transmembrane domain of *CHRNA4*. The same amino acid exchange was later found in families from Spain, Norway, and Scotland,[22–25] and additional ADNFLE mutations were identified within *CHRNA4* but also in the homologous gene *CHRNB2*.[10,23,26–32] All mutations identified so far are heterozygous. All but one of these mutations are amino acid exchanges that affect highly conserved residues. An exception is *CHRNA4*–865–873insGCT (also named 773ins3[27]), a three base pair insertion that adds a fourth leucine residue to a sequence stretch that already contains three consecutive leucines. The ADNFLE mutations cluster either in the second transmembrane (TM; *CHRNA4*) or in both the second and third TMs (*CHRNB2*). Mutations in the second TM, the major pore-forming part of each nAChR subunit, mostly affect amino acids that are part of the amino acid residue axis that rotates when agonists such as acetylcholine attach to the binding site, opening the ion channel. These mutations are therefore likely to interfere with the channel's kinetics. The pathomechanisms behind the mutations in the third TM are less well understood. It seems plausible that these mutated amino acids are in direct or indirect contact with residues in the second TM, because mutations in the third TM are also able to change the channel's opening and closing kinetics.[31] Recently, a single mutation described in a Chinese patient, C*HRNA4*-R336H (also named R308H[29]), was found downstream of TM2–3 in the second intracellular loop, a structure of unknown significance for receptor function.[29] This mutation has not yet been functionally characterized, and not enough clinical details are given in the original paper to allow a comparison with known ADNFLE phenotypes. A putative third ADNFLE gene is *CHRNA2*, a nAChR subunit gene that has been found mutated in a single Italian family with sleep-related epilepsy.[33]*CHRNA2* is one of the major nAChR subunit genes and is almost as ubiquitously expressed in brain as *CHRNA4* and *CHRNB2*. It nevertheless seems to be a much rarer cause of epilepsy than the latter two genes, as no additional mutations have been reported.[34] Overall, mutations of *CHRNA4*, *CHRNB2*, or *CHRNA2* are found in less than 20% of individuals with the ADNFLE/NFLE phenotypes,[35] suggesting genetic heterogeneity of ADNFLE/NFLE.

NEURONAL nACHRs

Neuronal AChRs are ligand-gated cationic channels composed of various combinations of five subunits arranged quasi-symmetrically around a central channel. They are encoded by nine α (α2–α10) and three β (β2–β4) subunit genes that show distinct patterns of expression

in both neuronal and nonneuronal tissues. Each subunit is composed of three different parts, which include the extracellular, cytoplasmatic, and transmembrane portions. The NH2 terminus is the largest extracellular domain, contains several glycosylation sites, and, in α subunits, contributes the main components of the high-affinity ligand binding sites that are located at the interface between neighboring subunits. This domain is important for receptor assembly and expresses the main immunogenic region. The four TM regions probably have a mixed α-helical/nonhelical secondary structure, with their helical segments forming both an inner ring (TM2) that shapes the pore and an outer shell (TM3–TM4) that shields the inner ring from membrane lipids. The different subunits assemble to build two classes of nAChRs: the homomeric or heteromeric α-bungarotoxin-sensitive receptors, which are composed solely of α subunits (α7–α10), and the heteromeric α-bungarotoxin-insensitive receptors, which consist of various combinations of α and β subunits (α2–α5, β2–β4). The mechanisms of nAChR activation, ion pore opening and closing, and desensitization are determined by highly conserved amino acid positions within the subunits. The function of the different neuronal nAChR subtypes depends on their subunit composition, their distribution within the brain, and their cellular location. Postsynaptic nAChRs often contribute to fast excitatory transmission, while preterminal and presynaptic nAChRs enhance neurotransmitter release (which, depending on the released transmitter, increases either inhibitory or excitatory synaptic impulses), and nonsynaptic nAChRs are likely to modulate neuronal excitability.[36] The nAChRs are involved in brain development and plasticity and participate in many different brain functions, including modulation of sensory inputs, locomotor activity, analgesia, attention, learning, memory, and reward mechanisms. It is therefore not surprising that genetic variants in nAChR subunit genes were found to be associated with different common disorders and behaviors, including Alzheimer's disease, schizophrenia, and smoking-related endophenotypes.[37–43] However, the only monogenic disorder so far known to be caused by high-penetrance mutations in neuronal nAChR is ADNFLE.

IN VITRO EXPRESSION OF ADNFLE MUTATIONS

The exact nAChR subtype compositions in different brain regions are not fully understood. This is due to the fact that various ligands are not subtype specific and highly specific antibodies are not yet available for all subunits. Probes for in situ hybridization on nAChR mRNAs are also not specific enough, which inevitably led to false-positive results.[44,45] The expression patterns for specific subunits may differ among species. Some nAChR subtypes, such as α2β3 and α4α6β2β3 receptor subtypes, are expressed in restricted regions of the brain and may have specific roles in brain function, while others, such as α4β2, are expressed ubiquitously and highly bind most nicotinic agonists.[46–49] To study the functional changes of mutated AChRs, whole-cell patch-clamp is often applied. Controversial data have been reported from in vitro expression studies, that is, loss of function and gain of function of receptors with *CHRNA4* mutations. Some reports indicated the acceleration of desensitization of receptors that leads to lowered Ca^{2+} permeability,[2,22,23,27,50] while increased affinity of receptors to Ach that leads to gain of function has also been reported.[10] Retardation of desensitization (V287L) or increased affinity to AChRs (V287M) has been reported for *CHRNB2* mutations.[51,52] In vitro expression studies showed that all mutations increase the receptors' sensitivity to acetylcholine, suggesting that a gain of function may be the basic mechanism behind ADNFLE.[28,34,52–54] However, the extent of the gain-of-function effect varies among mutations, and the mutated nAChRs display individual pathofunctional profiles for agonists such as nicotine or antiepileptic drugs like CBZ and ZNS. Most ADNFLE patients respond to CBZ, while patients with specific mutations, such as *CHRNA4*-S284L, are more likely to respond to ZNS.[11] A reduction of Ca^{2+} dependence may also be a common mechanism.[55] The functional involvement of the GABAergic system in the pathophysiology of ADNFLE deduced from animal models will be discussed separately.[5,7]

A recent study found that individuals with microdeletions of chromosomes affecting both *KCNQ2* and *CHRNA4* presented with only the BFNS phenotype and lacked ADNFLE/NFE semiology.[56] This finding, along with the

fact that all nAChR mutations identified in ADNFLE were heterozygous, suggests that the autosomal dominant inheritance mode of ADNFLE is attributable to the dominant negative or dominant positive effect, in accordance with the gain of function of mutant receptors. It is plausible that mutant subunits exert their effects as components of multimeric nAChRs.

ORIGIN OF SEIZURES

ADNFLE mutations in the nAChR subunits appear to modify the number and distribution of α4β2 nicotinic receptors in the living human brain. The distribution of α4β2 nicotinic receptors has been studied in nine ADNFLE patients carrying nicotinic receptor mutations (causative mutations): four patients with α4-S280F (numbered according to the reference sequence NP_000739.1; the mutation is also named S248F[2]); two with α4-S284L (also named S252L[26]); one with α4- T293I (also named T265I[28]); and two with β2-V287L) detected by a PET scan using [^{18}F]-F-A-85380, a radioligand with a high affinity for α4β2 nAChRs. This PET study demonstrated a regional nAChR density decrease in the prefrontal cortex, an observation consistent with partial epilepsy involving the frontal lobe. The increase in nAChR density in the mesencephalon suggests that these brain structures are involved in the pathophysiology of ADNFLE through the role of brainstem ascending cholinergic systems in arousal.[57] Electrophysiological studies of the receptors carrying the different mutations identified a common alteration in their properties corresponding to a gain of function. However, the precise mechanisms leading to the frontal lobe epilepsy remain elusive.

GENOTYPE–PHENOTYPE CORRELATIONS IN ADNFLE

The results of a pilot study in which 11 ADNFLE patients with different mutations were assessed by neuropsychological evaluation suggested that mild cognitive problems might be a common minor feature of the disorder.[57] However, even ADNFLE mutations that affect neighboring amino acid residues seem to differ significantly with respect to their major clinical features. Mutations such as *CHRNA4*-S280F and *CHRNB2*-V287M or V287L are usually associated with epilepsy as the sole major symptom, and additional neurological features have been reported in about 2% of patients with these mutations. This is especially obvious for *CHRNA4*-S280F, where, in 65 out of 67 known patients belonging to a total of five families with this mutation, the only reported major symptom is epilepsy.[2,22,23,25] In patients with mutations such as *CHRNA4*-S284L, *CHRNA4*-865–873insGCT (also named 776ins3[27]), or *CHRNB2*-I312M, additional major neurological features are reported in an average of 70% of patients. Comparison of unrelated families with the same ADNFLE mutation suggests that these additional major neurological features tend to be specific with each mutation. The mutation *CHRNA4*-S284L has been described in families from Japan, Korea, and Lebanon, and at least 11 of the 16 patients from these families are of borderline intelligence or mildly retarded.[10,13,26] Selective cognitive deficits that mostly affect verbal memory seem to be typical for the mutation *CHRNB2*-I312M and have been described in all four known patients from two families of different ethnic background.[13,32] Patients with *CHRNA4*–865–873insGCT show high comorbidity for psychiatric disorders such as the negative symptoms of schizophrenia.[24] The ethnic differences between families with the same mutation and the cosegregation of epilepsy and additional neurological features in multiplex pedigrees strongly suggest that the observed genotype–phenotype correlations are not coincidental, although so far, not enough families with these mutations are known to confirm this hypothesis. At first glance, it seems difficult to explain how mutations that affect amino acid residues located within the same functional domain, often only a few residues apart, could differ this drastically in their associated clinical features. It has been speculated that allosteric coupling between amino acids links functional elements within the nAChR that are far apart in the primary amino acid sequence.[58] In accordance with this theory, adjacent amino acids might differ with respect to the functional elements they interact with in other parts of the subunit. That would explain why functional

studies showed that ADNFLE mutations tend to differ from each other with respect to their biopharmacological profiles.[31] The nAChRs are involved in many important brain functions, and even such subtle functional differences are therefore likely to have an impact on the clinical phenotype.

ANIMAL MODELS OF ADNFLE: WHAT DID WE LEARN?

Several genetic animal models bearing mutant genes that have been identified in families with idiopathic epilepsy have been generated. However, to explore the pathogenesis of ADNFLE, it is important that the genetic epilepsy animal models fulfill the validation criteria for such models (face validity, construct validity, and predictive validity).[59,60] Face validity is the ability to fundamentally mimic the behavioral clinical characteristics of the disorder. Construct validity conforms to a theoretical rationale for the disorder. Predictive validity is the ability to predict previously unknown aspects of the behavior, genetics, and neurobiology of the disorder from the model.

Specific Criteria for Genetic Animal Models of ADNFLE

In general, the optimal animal model should mimic the human disorder in terms of etiology, biochemistry, symptomatology, and treatment.[61] The ADNFLE model should exhibit spontaneous epileptic seizures resembling paroxysmal arousals, nocturnal paroxysmal dystonia, and episodic nocturnal wandering, during NREM sleep. The interictal EEG may or may not be normal. The foci of ictal or interictal discharges should be localized in a frontal area or over the anterior quadrants. The age of onset of AFNFLE would ideally be around puberty. Carbamazepine might reduce both the frequency and complexity of seizures in model animals, as it does in more than 60% of patients with ADNFLE/NFLE, including those with *CHRNA4*-S280F and *CHRNA4*–865–873insGCT mutations.[14,15,62] However, CBZ efficacy is not obligate in animal models, just as some patients (individuals with *CHRNA4*-S284L,[10,11,63] *CHRNA4*-T293I,[28] *CHRNAB2*V287M,[52] and *CHRNAB2*-I312M[32]) are resistant to CBZ but susceptible to other AEDs, such as acetazolamide, benzodiazepine (BZP), topiramate, and zonisamide (ZNS), or are AED-resistant,[10,11,13–15,52,64] Among ADNFLE patients with the *CHRNA4*-S284L, mutation autism and mental retardation have been reported,[11,65] and ADNFLE patients with the *CHRNA4*–865–873insGCT mutation showed schizophrenia-like psychosis.[24] Therefore, behavioral studies should be part of the study design for animal models of ADNFLE. The knockin technique is probably appropriate to create genetic animal models of ADNFLE; however, the expression pattern and expression levels of the transgene in the genetic animal model must be confirmed because in some knockin techniques, promoters are used that do not occur naturally in rodents.

Validity of Genetic Animal Models of ADNFLE

The validity of four genetic animal models of ADNFLE is summarized in Table 58–1.[66] The phenotypes of the two strains of knockin mice with the *CHRNA4*-S280F mutation are different, since one strain exhibits spontaneous epileptic seizures (pS280F-KM), while the other does not (nS280F-KM).[5,6] The spontaneous epileptic seizures of pS280F-KM are observed during wakefulness but not during sleep.[5] They are characterized by paroxysmal onset and sudden termination. The ictal discharge of pS280F-KM shows complex patterns of spike-and-wave activity with a high-amplitude, low-frequency power spectrum; the background activities in the EEG of the pS284F-KM animal model show abnormal patterns characterized by a marked increase in δ-wave activity (0.5–4 Hz).[5] In contrast to pS284F-KM, no abnormalities are detected in the background EEG activities of nS284F-KM rat.[6]

The knockin mouse with *CHRNA4*–865–873insGCT (insL-KM) exhibits epileptic wandering-like spontaneous epileptic discharges with paroxysmal onset and sudden termination during wakefulness.[5] The EEG features of the insL-KM mice are similar to those of pS284F-KM. The ictal discharges of insL-KM show complex patterns of spike-and-wave activity with a high-amplitude, low-frequency power

Table 58–1 **Validity of Four ADNFLE Models**

Gene Mutation	insL	S280F	S280F	S284L
Genus (variety)	Mouse (C57BL/6J)	Mouse (C57BL/6J)	Mouse (C57BL/6J)	Rat (SD)
Technology	Knockin	Knockin	Knockin	Transgenic
Face validity				
Spontaneous seizure	Epileptic wandering during W	Epileptic wandering during W	No seizure	ADNFLE seizure during SWS
Background EEG	Slow-wave increase	Slow-wave increase	Normal	Normal
Construct validity				
Expression				
mRNA		Equal expression (whole brain)		Equal expression (Cor, Hip, Th)
protein			Equal expression (Cor, Hip, Th)	Equal expression (Cor, Hip, Th)
Predictive validity				
AED response			Suppressed by CBZ	Suppressed by ZNS
Nicotine-induced seizure	Potentiation generalized seizures	Potentiation generalized seizures	No difference	Potentiation partial seizures

Abbreviations: Cor, cortex; Hip, hippocampus; Th, thalamus; W, wakefulness.
Source: Data from ref. 66.

spectrum. The EEG of insL-KM during spontaneous seizures shows a more asymmetric and diffuse pattern than that of pS284F-KM. The EEG background activities of insL-KM also show a marked increase in δ-wave activity.[5]

The transgenic rat carrying the *CHRNA4*-S284L mutation (S284L-TG) exhibits the three distinct ADNFLE seizure characteristics during NREM sleep: paroxysmal arousals (brief episodes characterized by sudden frightened expression), paroxysmal dystonia (brief episodes of dystonic posturing), and epileptic wandering (episodes of longer duration ranging from 1 to 3 min, with head shaking accompanied by stereotyped paroxysmal ambulation and bizarre movements).[67] The onset of ictal discharges is synchronized with seizure behaviors. No abnormalities of background activities are observed in the EEG of the S284L-TG rat. The focus of both ictal and interictal discharges is the frontal sensorimotor cortex region. Usually the onset of interictal discharges starts after 6 weeks of age; however, the onset of spontaneous ADNFLE seizures is preceded by that of interictal discharges in the same transgenic rat. At 8 weeks of age, 90% of S284L-TG rats exhibit spontaneous seizures during NREM sleep. The characteristics of epileptic seizures of S284L transgenic rats are quite similar to those of ADNFLE patients with the same mutation.[67] The published phenotypic features of the above-described four genetic animal models of ADNFLE show that the face validity of the S248L-TG rat is adequate, whereas neither the pS280F-KM, nS280F-KM, nor insL-KM mice are suitable genetic animal models to study the clinical phenotype of ADNFLE. Both knockin mice, pS280F-KM and insL-KM, are considerably more sensitive to nicotine-induced seizures than wild-type mice. Indeed, in nicotine-induced seizure tests, these two types of knockin mice show a lower threshold dose of nicotine for generalized seizures with shorter latencies to seizure onset and exhibit longer seizure durations compared with their wild-type littermates.[5] Knockin mice with *CHRNA4*-S280F (nS280F-KM) that do not exhibit spontaneous epileptic seizures did not display a particularly different response in nicotine-induced seizure tests compared with wild-type mice. However, they developed ADNFLE-like epileptic wandering following administration of 1 mg/kg nicotine, and these seizures were prevented by supratherapeutic doses of CBZ.[6] No difference was observed between S284L-TG and non-TG littermates in the latency of nicotine-induced seizures. Nicotine-induced seizures in S284L-TG

transgenic rats were mainly partial seizures, whereas those in non-TG littermates were generalized seizures. In S284L-TG, subchronic administration (2 weeks) of diazepam and ZNS at therapeutically relevant doses reduced the frequency of interictal discharges by 43% and 48%, respectively, whereas at therapeutically relevant doses, CBZ had no effect on the frequency of interictal discharge.[67]

The results of the nicotine-induced seizure test showed different responses among the four genetic animal models of ADNFLE. However, the nS280F-KM and S284L-TG mice developed ADNFLE-like seizures, epileptic wandering (nS280F-KM and S284L-TG), paroxysmal arousal (S284L-TG), and paroxysmal dystonia (S284L-TG) in response to nicotine administration. Thus, the predictive validity of S284L-TG as a model for pharmacological effects in ADNFLE has been demonstrated, whereas neither that of nS280F-KM, pS252F-KM, nor insL-KM has been established.

The transgene promoter of S284L-TG is not a naturally occurring rodent promoter but a mammalian PDGF-β promoter that activates preferentially in certain brain tissues.[6,7] In situ hybridization using a nonselective probe (sensitive to both wild-type and S284L mutant *Chrna4* mRNA) showed no differences in the cerebral expression of *Chrna4* mRNA between non-TG and S284L-TG. The total amount of *Chrna4* mRNA (wild-type plus S284L *Chrna4*) in the frontal cortex of S284L-TG was almost equal to that in non-TG. The expression of wild-type versus S284L *Chrna4* was 45% versus 55%. In the focus region, there was no significant difference in the number of nAChR α4-immunopositive neurons between non-TG and S254L-TG. No distorted expression of wild-type or S284L *Chrna4* was observed in the cell populations of neurons, astrocytes, and oligodendrocytes. In spite of these findings, the wild-type *Chrna4* mRNA is predominantly expressed in the thalamus and cortex, whereas the S284L mutant *Chrna4* mRNA is mainly expressed in the cortex and thalamus. Laser-capture microdissection with single-cell reverse-transcription quantitative polymerase chain reaction (PCR) has demonstrated the lack of ectopic expression of the transgene in neurons and glial cells.

A question remains: why does the pS280F-KM but not the nS280F-KM exhibit spontaneous epileptic seizures? There is little or no information on the expression of mutant *Chrna4* gene or nAChR α4-subunit protein in the pS280F-KM, nS280F-KM, and insL-KM animals.[5,6] Although the promoter in these knockin techniques is a natural promoter, the mRNA and protein expression levels of S280F mutant *Chrna4* still need to be determined. At present, there are no suitable ADNFLE genetic animal models with construct validity. To study the pathogenesis and pathophysiology of ADNFLE, knockin mice with established construct validity or transgenic animal models with a natural promoter should be generated.[66]

Pathophysiology of ADNFLE

In spite of the limitations of ADNFLE model animals, it is interesting to note that S284L-TG rats showed attenuation of synaptic and extrasynaptic GABAergic transmission[1] and abnormal glutamate release during slow-wave sleep.[2] In mice bearing two engineered *chrna4* (S252F or +L263) mutations, the involvement of inhibitory synchronization of cortical networks via activation of mutant alpha4-containing nAChRs located on the presynaptic terminals and somatodendritic compartments of cortical GABAergic interneurons has been suggested.[5] Further analysis of the molecular biology of these abnormal neurotransmissions will help to uncover some of the mechanisms underlying ADNFLE, improving our understanding of its pathogenesis, epileptogenesis, and ictogenesis and ultimately leading to the development of new treatments.

KEY QUESTION: WHY DO nACHR MUTATIONS CAUSE EPILEPSY?

Most seizures are characterized by short bursts of abnormal neuronal activity that, by their origin and spreading pattern in brain, determine the clinical phenotype of the epilepsy. Seizures often arise from a state of hypersynchronization that causes groups of neurons or whole neuronal networks to fire simultaneously. In ADNFLE these episodes usually occur during NREM sleep phases[62] that can be subdivided into two main phases, one that consists of transient arousals and one that is characterized by

tonic activities in the EEG. The association between the seizures and NREM phases suggests that sleep-controlling brain structures are involved in the pathogenesis of ADNFLE. One of the main regulators of sleep is the central cholinergic system that controls both the circadian clock and the sleep-wake cycle. Important components of it are cholinergic neurons within the central reticular core of the brain, where the basic sleep-wake cycle is determined. From there, two major cholinergic cell groups are responsible for the cerebral activation that accompanies wakefulness and paradoxical sleep. One group of cells is located within the pontomesencephalic tegmentum, which projects rostrally into the nonspecific thalamocortical relay system. The other group of cells is located within the basal forebrain, which receives input from the brainstem reticular formation and projects as the ventral, extrathalamic relay upon the cerebral cortex.[67,68] Functional changes in nAChRs such as those induced by ADNFLE mutations might affect these cholinergic projections and cause aberrations in sleep stages that, for unknown reasons, render certain neuronal networks more vulnerable to sudden bursts of hyperactivity during NREM sleep. Such bursts of hyperactivity could have their origin in the gain-of-function effect caused by ADNFLE mutations in nAChRs located on GABAergic interneurons. At least two mechanisms are discussed that are both able to explain how changes in GABAergic interneuron activity might play a central role in seizure generation. The older hypothesis postulates that seizures are the result of reduced inhibition that causes an increase in excitatory neuronal activity. More recently, it has been shown that the opposite mechanism is at least as plausible, and is the one most likely involved in seizures caused by nAChR subunits. The basic principle underlying this mechanism is an enhancement of neuronal synchrony by inhibition. It has been shown that pyramidal cells connected to the same GABAergic interneuron synchronize their firing when released from the interneuron's inhibitory effect.[69] Interneurons innervating layer 2/3 pyramidal cells are known to carry $\alpha 4\beta 2$ nAChRs. Triggered by the gain-of-function effect ADNFLE mutations exhibit on these receptors, they could activate larger numbers of GABAergic interneurons that, in turn, could easily synchronize enough pyramidal cells to change local cortical activity from synchronization to hypersynchronization. Spreading of the hypersynchronization into the motor control area would then be likely to cause the types of seizures typically associated with ADNFLE. Such a mechanism, in which a gain of function of certain nAChR subunits causes hypersynchronization by increasing GABAergic inhibition, is supported by some of the above-described animal models. Gamma-aminobutyric acid antagonists such as picrotoxin have been shown to normalize the EEG and suppress spontaneous seizures in genetically altered pS280F-KM mice.[5] Nevertheless, many details of epileptogenesis in ADNFLE remain unknown and are the subject of further studies.

CONCLUSIONS

The nAChR mutations identified in ADNFLE/NFLE have increased our understanding of the pathogeneses not only of these unique and relatively rare epilepsies but also of other epilepsies. Our understanding should open new avenues to developing novel therapies against epilepsy based upon molecular pathomechanisms. Consecutive studies of ADNFLE/NFLE in association with nAChR mutations have for the first time provided compelling evidence that genetic predispositions closely associate with the pathogenesis of epilepsy on the molecular level. Thanks to the breakthrough in ADNFLE/NFLE research, novel methodologies have been established in epileptology. They range from evaluations of channel mutations in vitro to genetically engineered animal models bearing the mutations identified in human epilepsy. Continuing studies utilizing such methodologies should delineate all the pathomechanisms of single mutations or genetic predispositions that result in epilepsy. These could not have been learned through clinico-electrophysiological studies alone. Once the molecular pathomechanisms of epilepsy are revealed, it should be possible to cure epilepsy completely by blocking part of the pathomechanisms. Since the discovery of nAChR mutations in ADNFLE/NFLE, we have now reached the point where novel therapies based upon the molecular pathomechanisms of epilepsy can be designed. Such therapies will bring relief to individuals suffering from epilepsy and the adverse effects of conventional AEDs.

Chapter 59

Gene Interactions and Modifiers in Epilepsy

Miriam H. Meisler
Janelle E. O'Brien

INTRODUCTION

During the past decade, there has been great progress in identifying the genetic basis for human seizure disorders, based largely on the application of research strategies for identifying the genes responsible for monogenic disorders.[1] Positional cloning has been used when large pedigrees with clear-cut dominant or recessive inheritance patterns are available. This involves linkage analysis with molecular markers throughout the genome to define a target chromosome region, followed by sequencing genes within the region to detect the causal mutation. The second approach has been to select a *candidate gene* based on its biological function or its known role in related disorders or animal models, and then to test for mutations by sequencing the gene in a group of unrelated individuals with epilepsy.

In spite of substantial progress, the genetic factors involved in most cases of human epilepsy are not known. One likely explanation is that mutations or variants in two or more genes, with interacting effects, are involved in many types of epilepsy. Identification of multiple

interacting genes is more difficult than identification of single genes, and this field is in an early stage of development. While indirect evidence suggests that multigenic causality may be very common in human epilepsy, few specific examples have been well documented. In this chapter, we describe recent evidence for gene interaction in human epilepsy and approaches to identifying genetic modifiers that influence disease in view of the unanticipated level of rare variation in protein coding sequences. Understanding the interaction between variants in an individual genome is likely to be a major focus of research in the coming years.

Many of the examples discussed here involve genes encoding voltage-gated sodium channels. The structure of this nine-member gene family and its role in epilepsy has recently been reviewed.[2] The most common known genetic cause of epilepsy is mutation of the neuronal sodium channel *SCN1A*. The role of this gene was first identified by positional cloning based on linkage analysis that mapped the epilepsy gene to chromosome 2q24 in two large pedigrees with generalized epilepsy with febrile seizures plus (GEFS+).[3,4] Based on our work with sodium channels and epilepsy in the mouse,[5] we sequenced *SCN1A* as a positional candidate gene in these two families and identified two causal missense mutations.[6] Subsequent functional analysis demonstrated biophysical defects associated with both mutated alleleles.[7] After the positional cloning of *SCN1A* in the GEFS+ families, it was sequenced as a candidate gene for Dravet syndrome, also known as *severe myoclonic epilepsy of infancy* (SMEI), a severe, progressive seizure syndrome that occurs as a sporadic trait in patients without a family history. Remarkably, sporadic mutations of *SCN1A* were identified in a majority of the Dravet syndrome patients tested.[8] Dravet syndrome and GEFS+ represent the extremes of a spectrum of *SCN1A*-associated disorders. Approximately 10% of GEFS+ is accounted for by heterozygous missense mutations of *SCN1A*, and >80% of patients with Dravet syndrome carry heterozygous mutations in *SCN1A* that include truncation mutations, deletions, and missense mutations. More than half of the mutations in Dravet syndrome cause loss of channel function,[9,10] demonstrating haploinsufficiency of *SCN1A*.Spontaneous seizures are also seen in heterozygous mouse models with inactivating mutations of *Scn1a*.[11,12] More than 700 different mutations of *SCN1A* have been identified in patients with Dravet syndrome; their molecular and clinical features are compiled in two recently developed databases.[13,14]

Analysis of mouse models provides an experimental system for identification of epilepsy modifier genes. When the same epilepsy mutation is bred onto multiple strains of inbred mice, the severity of the disorder often varies dramatically due to genetic differences between inbred strains. If the effect of any one modifier gene is sufficiently large, it may be identified by positional cloning in crosses between the inbred strains.[15] We have included examples of the use of mouse genetics to detect and analyze gene interaction in seizure disorders.

WITHIN-FAMILY HETEROGENEITY MAY REFLECT THE SEGREGATION OF GENETIC MODIFIERS

It is well known to clinicians that family members with identical genotypes at a disease locus may nonetheless exhibit very different clinical courses. One source of phenotypic heterogeneity may be the independent segregation of genetic variants at other loci, so-called *modifier genes*, that exacerbate or ameliorate the effect of the primary mutation.

Variability in Families with GEFS+

An example of intra-familial variation is provided by the GEFS+ pedigree in Fig. 59–1. Two categories of clinical phenotype are found in this pedigree. Seven affected individuals exhibited mild childhood febrile seizures with no progression, while five affected individuals had febrile seizures that progressed to adult epilepsy.[3] The sodium channel mutation *SCN1A*-Thr875Met was identified in all 12 affected individuals.[6] This type of intrafamily variation is suggestive of the segregation of a second variant at a modifier locus. If the pedigree is sufficiently large, both primary and modifier genes can be mapped.[16]

Mildly Affected Carriers in a Family with Dravet Syndrome

Deletion or inactivation of sodium channel *SCN1A* usually results in Dravet syndrome,

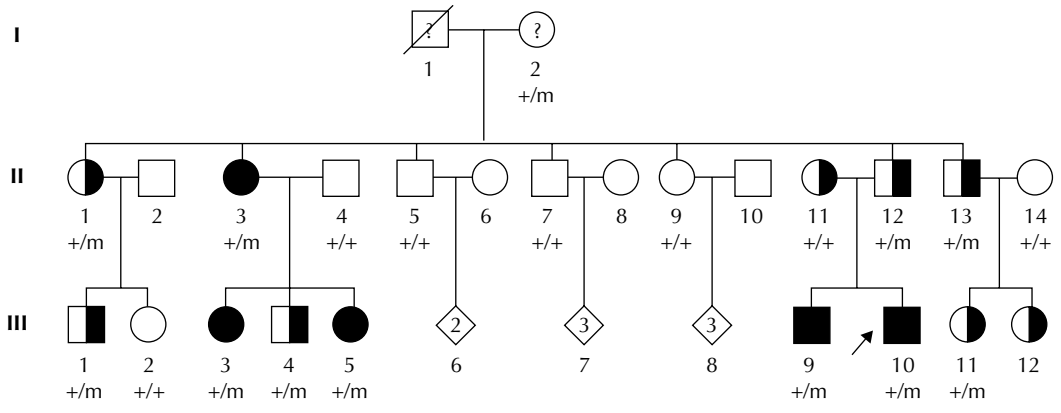

Figure 59–1. Two distinct phenotypes in affected heterozygous individuals from a GEFS+ family. The *SCN1A* mutation Thr875Met cosegregates with GEFS+; affected individuals exhibit febrile seizures only (half-filled symbols) or febrile seizures progressing to epilepsy (filled symbols). +, wild type; m, mutant; possible seizures not confirmed by relatives or medical records. Modified from ref. 5.

a haploinsufficiency syndrome that includes severe progressive seizures and impaired cognition.[10, 17] Most affected individuals are sporadic cases without affected family members, and are unable to live independently or transmit the defect. However, in 2010, Suls et al. described a four-generation Bulgarian family in which a complete deletion of the *SCN1A* gene was transmitted through three generations.[18] Two family members with the deletion exhibit typical progressive Dravet syndrome, while two others who transmitted the deletion have moderate epilepsy and are literate and living independently. The authors suggest that the differences in severity between family members may reflect the presence of one or more genetic modifiers.

Parental Mosaicism in One-Generation Families with Multiplex Dravet Syndrome

The transmission of Dravet syndrome from an unaffected parent to affected offspring has been observed in approximately 10% of cases. The parent in these families must carry the *SCN1A* mutation but does not exhibit disease. The possibility that these individuals carry a protective variant in a modifier gene has been considered. However, a different explanation emerged in a recent study describing genetic mosaicism in the transmitting parent.[19] To test for genetic mosaicism, a quantitative, allele-specific polymerase chain reaction (PCR) assay for the *SCN1A* mutation was carried out on DNA isolated from the parent's blood. The proportion of mutant *SCN1A* allele in different transmitting parents was found to vary from 0.04% to 85% of the dose expected in a normal heterozygote, which would be 50%. In one case, a reduced dosage was also observed in sperm. The most likely explanation is that the mutations arose de novo during the embryonic development of the parent, resulting in mosaicism of somatic and germline tissues. Assuming that expression of the mutant allele would also be reduced in the brain of mosaic individuals, that could account for the parents' mild clinical condition compared to that of their offspring. Mosaicism was demonstrated for 12 of the 19 cases of transmission of Dravet syndrome examined in this study.

LINKAGE EVIDENCE FOR DIGENIC INTERACTION IN HUMAN EPILEPSY

In rare families, linkage mapping for positional cloning identifies more than one chromosome region related to the epilepsy phenotype. These large families offer the potential for identification of specific pairs of interacting loci. Although the genes have not yet been identified, the linkage data strongly support a two-gene-interaction mechanism of epilepsy in these families.

Digenic Inheritance of Febrile Seizures with Temporal Lobe Epilepsy

Linkage analysis was carried out on a four-generation French family segregating febrile convulsions accompanied by temporal lobe epilepsy.[20] Family members included eight affected individuals with febrile seizures that progressed to afebrile epilepsy, one obligate unaffected carrier, and nine unaffected family members. A genome-wide scan using microsatellite markers demonstrated linkage to two chromosome regions, 1q25–31 and 18qter, with significant LOD scores of 2.3 and 3.0, respectively. All of the affected individuals carried the disease-related haplotype in both of these chromosome regions, and none inherited the disease-related haplotype at one region only, strongly indicating digenic inheritance with a requirement for the mutant genes at both loci. The same investigators studied another four-generation pedigree segregating febrile seizures in combination with temporal lobe epilepsy or childhood absence epilepsy.[21] In this family, the genome-wide linkage scan detected linkage signals on chromosomes 3p and 18p. As above, all patients with febrile seizures and epilepsy shared a common haplotype in both chromosome regions. (The lack of common linked regions in these two families is an indication of the degree of genetic heterogeneity underlying inherited epilepsy.)

Digenic Inheritance of Epilepsy in Families with Light Sensitivity and Myoclonic Epilepsy

Pinto and colleagues focused a genome-wide linkage study on 19 families with photosensitive epilepsy. The photoparoxysmal response (PPR) is defined by an abnormal electroencephalographic (EEG) response to intermittant photic stimulation. Pinto et al. studied 16 unrelated families with multiple affected members who demonstrated both PPR and epilepsy.[22] Two linkage signals of comparable strength were detected on chromosomes 7q32 and 16p13. A subsequent two-locus linkage analysis supported a multiplicative epistasis model in which each locus is necessary but not sufficient to generate the observed phenotypes.[23]

INTERACTING ION CHANNEL MUTATIONS IN MOUSE MODELS

Since the firing patterns of neurons directly reflect the overall identities and levels of their ion channel expression, it is intuitively obvious that the presence of multiple ion channel variants in the same neuron could have a combinatorial effect on firing properties. Genetic interaction between ion channel mutations would be among the most straightforward to interpret. Large-scale sequencing of 237 ion channel genes in several hundred epilepsy patients and controls revealed a comparable frequency of ion channel variants in the two groups.[23a] Studies in the mouse provide a system for testing the effects of combining two or more ion channel mutations, with the possibility of examining the effects on neuronal activity as well as seizure phenotypes. The examples described below provide proof of principle for the types of ion channel interactions that may also contribute to human epilepsy.

Mouse *Scn2a* and *Kcnq2*

Mutations in human sodium channel *SCN2A* and potassium channel *KCNQ2* can each cause inherited human epilepsy, but families with variants in both genes have not been described. To test their possible interaction, Kearney et al.[24] generated mice that were double heterozygotes for a mild mutation of *Scn2a* and a subclinical mutation of *Kcnq2*. The combination resulted in mice with severe seizures that died in status epilepticus within 3 weeks after birth. This dramatic example of gene interaction may be understood in terms of the functions of the two channels. The *Kcn2q* channel is part of a complex that produces a slowly inactivating potassium current that limits neuronal firing rates. Impaired *Kcn2q* activity would be expected to increase neuronal firing. The *Scn2a* mutation produced increased persistent current that also predisposes to a reduced threshold for neuronal firing. The presence of both mutant channels in the same cells would act in the same direction toward increased neuronal excitability. Subclinical variants of ion channels in the

human population may similarly interact in cases of apparently sporadic epilepsy.

Interaction between Mouse *Scn1a* and *Scn8a*

Mice heterozgyous for null mutations in *Scn1a* exhibit a spontaneous seizure syndrome that is a model of human Dravet syndrome.[11,12] The mechanism is thought to involve preferential reduction in the firing of inhibitory interneurons in the hippocampus. Martin et al.[25] generated mice carrying a null allele of *Scn1a* in combination with a missense mutation of *Scn8a* that reduces channel activity by shifting the voltage dependence of activation toward more positive voltages.[26] Interestingly, the double heterozygotes carrying both the *Scn1a* and *Scn8a* mutations were completely protected from seizures. The reduced activity of excitatory neurons due to the *Scn8a* mutation may compensate for the reduced activity of inhibitory interneurons due to the *Scn1a* mutation. This work predicts that mutations of human *SCN8A* could act as protective modifier variants in individuals inheriting a pathogenic allele of *SCN1A*. This prediction could be tested in families such as the one in Fig. 59–1, where the less severely affected individuals might carry a second mutation in *SCN8A*.

Mouse Calcium Channel *Cacna1a* and Potassium Channel *Kcna1*

The calcium channel *CACNA1A* and the potassium channel *KCNA1* (Kv1.1) are both localized in presynaptic terminals of neurons in the thalamus, neocortex, and hippocampus. The mouse mutant *tottering* carries a partial loss-of-function allele of *Cacna1a* that results in spike-wave absence seizures. The null mutation of *Kcna1* in the mouse results in juvenile lethality that appears to result from seizures. When these two mutations were combined in double homozygotes, survival was enhanced and seizures were suppressed.[27] The authors suggest that the increased excitability of nerve terminals lacking the potassium channel would be countered by the reduction in calcium signaling at the same terminals in the double mutant.

These three examples demonstrate that the predicted gene interactions between ion channels can be detected in vivo and can have striking effects on the clinical outcome, as summarized in Fig. 59–2. The combined effect may be either beneficial or deterimental, depending on the effects of each mutation at the cellular level. These experiments support the possibility that similar interactions will be discovered in human patients, and they suggest the value of screening for additional ion channel mutations in families with known channel mutations exhibiting clinical heterogeneity.

Human *SCN9A* as a Potential Modifier of Dravet Syndrome

SCN1A and *SCN9A* are adjacent sodium channel genes located on chromosome 2q24.[2] A mutation in *SCN9A* was recently identified in a large Utah pedigree with febrile seizures and no mutation of *SCN1A*, suggesting that *SCN9A* can also be responsible for seizures.[28] A follow-up study of 102 patients with Dravet syndrome identified 7 patients with mutations in both *SCN1A* and *SCN9A*[28] . The *SCN1A* mutations in the seven patients included one truncation mutation and three mutations in invariant splice site nucleotides, which should be sufficient to cause Dravet syndrome. The *SCN9A* mutations were missense mutations that changed amino acid residues that are evolutionarily conserved from chicken to human. The authors suggest that the *SCN9A* variants may modify the severity of Dravet syndrome in these patients with primary mutations in *SCN1A*.

INBRED STRAINS OF MICE PROVIDE ACCESS TO ADDITIONAL MODIFIERS OF EPILEPSY GENES

The inbred strains of mice were generated from wild populations during the past 100 years. Their genomes contain chromosome segments derived from two subspecies of mouse, *M. m. domesticus* and *M. m. musculus*. New mutations have accumulated in each strain during decades of laboratory breeding. The differences between any two inbred strains are

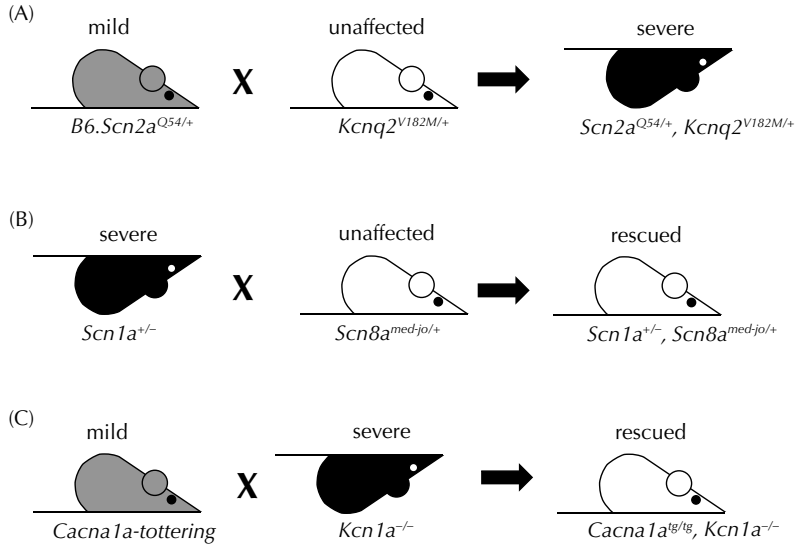

Figure 59–2. Digenic interactions between ion channel mutations in mouse models of epilepsy. **A**. Interaction between mutations in a sodium channel and a potassium channel. **B.** Interaction between mutations in two sodium channels. **C.** Interaction between mutations in a calcium channel and a potassium channel. Adapted from ref. 16.

roughly comparable to the differences between two humans. Inbred mouse strains provide an experimental opportunity to compare the effects of the same mutation in the context of different genome backgrounds, and thereby to recognize and identify modifier genes responsible for differences between strains. Interstrain variation can also be exploited to isolate genes that influence susceptibility to environmental factors and drugs, as indicated in Table 59–1.

Mouse Modifier Genes and Human Epilepsy

The conservation of basic mammalian neurobiology suggests that similar mutations would have similar effects on seizures in the human and the mouse. However, it is not known a priori whether an identified mouse modifier gene is represented by genetic variation in the human population. The practical impact of modifiers discovered in the mouse will depend on whether corresponding mutations have arisen during human history and are represented in modern human genomes.

Genetics of Complex Epilepsy

This chapter has focused on the detection of modifier mutations influencing seizure disorders whose primary cause is a single gene mutation with a large functional effect. In

Table 59–1 **Genetics of Complex Epilepsy**

Primary cause	Susceptible strains	Resistant strains	Genetic basis	Ref.
Scn1a - null	B6	129	Unknown	12
Scn2a - Q54	SJL	B6	Two candidates	29
Scn8a (ataxia)	B6	Others	*SCNM1*	15
Electroconvulsive	DBA,129	B6,C3H,SJL	Unknown	30
Electroconvulsive	DBA	B6	*KCNJ10*	31
Cocaine	A/J, SJL	B6	Unknown	32
Fluorethyl	DBA, C3H	B6	Unknown	33
Kainate	FVB/N	B6	Polygenic	34

polygenic or *complex* epilepsy, multiple susceptibility mutations with individually small effects combine to produce an epileptic phenotype. Polygenic inheritance is thought to be a major cause of common human epilepsies. Recent reviews address the subject of polygenic inheritance of epilepsy in the human and the mouse.[35,36]

FUTURE PROSPECTS FOR UNDERSTANDING GENE INTERACTION IN HUMAN EPILEPSY

The genetic basis for most cases of human epilepsy remains unknown, in spite of recent successes in identifying the roles of *SCN1A* and related ion channels. This situation is likely to change dramatically in the near future with the introduction of individual genome sequencing. Using inexpensive, high-throughput next-generation sequencing technology, >90% of the 180,000 exons in the human genome can be sequenced from individual samples. The first few exomes published in 2009 and 2010 revealed that every human carries approximately 500 rare amino acid sequence variants not previously described. A spectrum of variation extends from benign variants without functional consequences to mutations causing significant loss of function. By revealing *all* of their genetic variants, genome sequencing of epilepsy patients will accelerate the discovery of primary disease genes as well as genetic modifiers. The urgent challenge will then be to recognize the subset of amino acid substitutions that change the function of the encoded protein. Functional assays to distinguish between benign and pathogenic variants will be an increasingly important component of epilepsy research in order to interpret the abundant genetic information. Identification of additional epilepsy genes and their genetic modifiers will provide new targets for intervention and should lead to more effective treatments for seizure disorders.

Chapter 60

Rare Genetic Causes of Lissencephaly May Implicate Microtubule-Based Transport in the Pathogenesis of Cortical Dysplasias

Judy S. Liu
Christian R. Schubert
Christopher A. Walsh

INTRODUCTION

Disruption of early neural development can cause severe forms of mental retardation and epilepsy associated with defects in cortical structure, such as lissencephaly ("smooth brain"), a disorder resulting from abnormal neuronal migration. Of the six causative genes for classical lissencephaly, three—*LIS1*, *DCX*, and *TUBA1A*—encode for microtubule-related proteins, indicating the importance of this pathway for neuronal migration (Table 60–1). The lissencephaly 1 (*LIS1*) protein is an adaptor for dynein, a microtubule motor protein.[1] Doublecortin (*DCX*) encodes a microtubule-associated protein (MAP).[2,3] Finally, tubulin α1a (*TUBA1A*) is a gene that encodes an α-tubulin subunit that is enriched during brain development.[4]

These lissencephalic syndromes clinically all share a widespread disruption of lamination in the cerebral cortex (Fig. 60–1). Since all three genes appear to regulate microtubule-based transport, their functional relation and regulation during development is an area of active investigation with implications that may be

Table 60–1 **Lissencephaly Genetics**

significant for a wider cohort of patients with focal cortical dysplasias. Cortical dysplasias are a common cause of refractory epilepsy and share some of the histological features of lissencephaly, including the dyslamination and abnormal neuronal morphology.[5] Disruption of microtubule-based pathways may lead to cortical dysplasias, and the causative genes for lissencephaly are a starting point for further investigation.

Normal cognitive function is dependent on proper brain development, including the coordination of multiple steps of neuronal development throughout gestation and beyond. Disruption in the early steps of neuronal development, including neuronal migration, can result in severe cognitive deficits and epilepsy. In the cortex, subsets of neurons may be differentially affected, including excitatory pyramidal neurons that migrate radially from the ventricular zone and inhibitory neurons that migrate tangentially from the lateral and medial ganglionic eminences (Fig. 60–2A,B). As a consequence, the normal lamination of the neurons in the cortex may be altered, leading to a failure of normal circuit formation and/or the establishment of abnormal circuits leading to cognitive dysfunction and epilepsy (Fig. 60–2C).

The phenotypic characteristics of brain malformations can be correlated with defects at certain stages in development. For example, cortical development is dependent on the proliferation of neural progenitors. When the number of neural progenitors is reduced, the result may be a brain with microcephaly ("small brain") that is otherwise normal in structure. Microcephaly can be caused by a variety of environmental factors including infection [e.g., TOxoplasmosis, Rubella, Cytomegalovirus, HErpes simplex, Syphilis (TORCHES)] or toxins (e.g., alcohol).[6,7] Microcephaly can be genetic, caused by mutations in genes that regulate cell division resulting in defects in the expansion of progenitors.[8] Furthermore, defects in genes that are important for multiple stages of development can result in a patient with a malformation with multiple features. Microcephaly can also occur in combination with a migration defect, such as microcephaly with pachygyria (Norman-Roberts syndrome),[9] so that the malformation appears to reflect the disruption of function of the gene throughout development.

Generally, disruptions in neuronal migration can cause a number of malformations. Lissencephaly ("smooth brain") and pachygyria

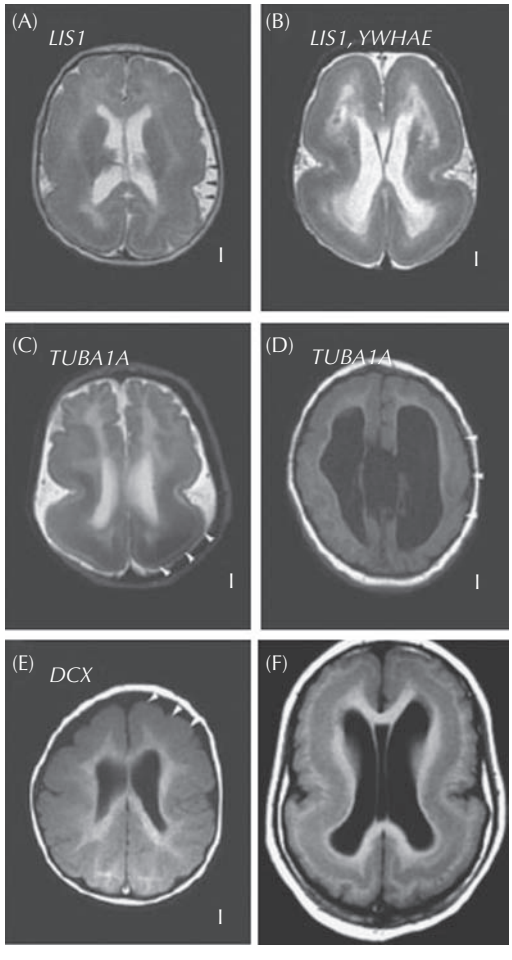

Figure 60–1. MRI of lissencephaly caused by microtubule pathway genes**.** High axial magnetic resonance imaging (MRI) scans of lissencephaly (LIS) associated with mutations in microtubule-related genes. Arrowheads on the axial images mark the most severely involved brain regions. **A.** Classic LIS gradient, posterior more severe than anterior (p > a), associated with an intragenic mutation of *LIS1*. **B.** Severe classic LIS due to deletion of 17p13.3 that results in loss of *LIS1*, *YWHAE*, and all of the intervening genes in a child with Miller-Dieker syndrome. **C.** Classic LIS with a p > a gradient caused by an intragenic mutation of *TUBA1A*. **D.** Moderate-severity LIS with cerebellar hypoplasia (LCH) with complete agenesis of the corpus callosum, large dysplastic midbrain and tectum, and severe cerebellar hypoplasia associated with another intragenic mutation of *TUBA1A*. **E.** Classic LIS gradient, anterior more severe than posterior (a > p), caused by an intragenic mutation of *DCX*. **F.** The MRI scan of a 15-year-old girl with a severe subcortical band heterotopia due to a *DCX* mutation. **A–E** adapted from *Epilepsia* 51: Dobyns, WB. The clinical patterns and molecular genetics of lissencephaly and subcortical band heterotopia, 5–9, Copyright (2010), with permission from Wiley. **F** reprinted from *Neurobiology of Disease*, 38(2): Guerrini R, Parrini E. Neuronal migration disorders, 154–66, Copyright (2010). With permission from Elsevier.

("few gyri") are malformations caused by a disorder of neuronal migration. Pachygyria and lissencephaly are often less and more severe manifestations of gene mutations causing type 1 lissencephaly including *LIS1* and *DCX* mutations. Other variants of lissencephaly that resemble type 1 have been identified, including those due to mutations in *ARX*,[10] *RELN*,[11] *VLDLR*,[12] and *TUBA1A*[13] (Table 60–1).

Type II lissencephaly, also called *cobblestone lissencephaly*, is associated with Walker-Warburg and Fukuyama muscular dystrophies and is caused by defects in the basement membrane that result from mutations in glycosyl transferase enzymes (Table 60–1). Again, mutations in additional genes involved in dystroglycan glycosylation have been observed.[14] Cobblestone lissencephaly is similar but not identical in appearance to polymicrogyria ("many small gyri"). This malformation can be regional, with variants that are perisylvian, or parietal, or predominantly bifrontal. The pathophysiology of polymicrogyria is not apparent and may be due to damage of a deeper layer or early-born neurons, resulting in overfolding of later-born or more superficial neurons, or it may be due to an abnormal expansion of the superficial layers.

Finally, defects in axonal growth and guidance can lead to the commonly observed white matter abnormalities, such as agenesis of the corpus callosum or enlarged ventricles. Interestingly, most causes of lissencephaly (non-cobblestone) are also known to be associated with defects in axon outgrowth,[15] thus implying a role for the causative genes in both stages of development and closely relating the molecular pathways regulating both neuronal migration and axon outgrowth. In addition, these defects in axonal growth are likely associated with abnormal connectivity and may very generally be associated with seizure pathogenesis, including that in patients with lissencephaly.

IMPLICATIONS OF MICROTUBULE ASSEMBLY AND MICROTUBULE-BASED TRANSPORT FOR NEURONAL DEVELOPMENT

Not only have these specific diseases described above been modeled and studied, but basic science has significantly informed the understanding

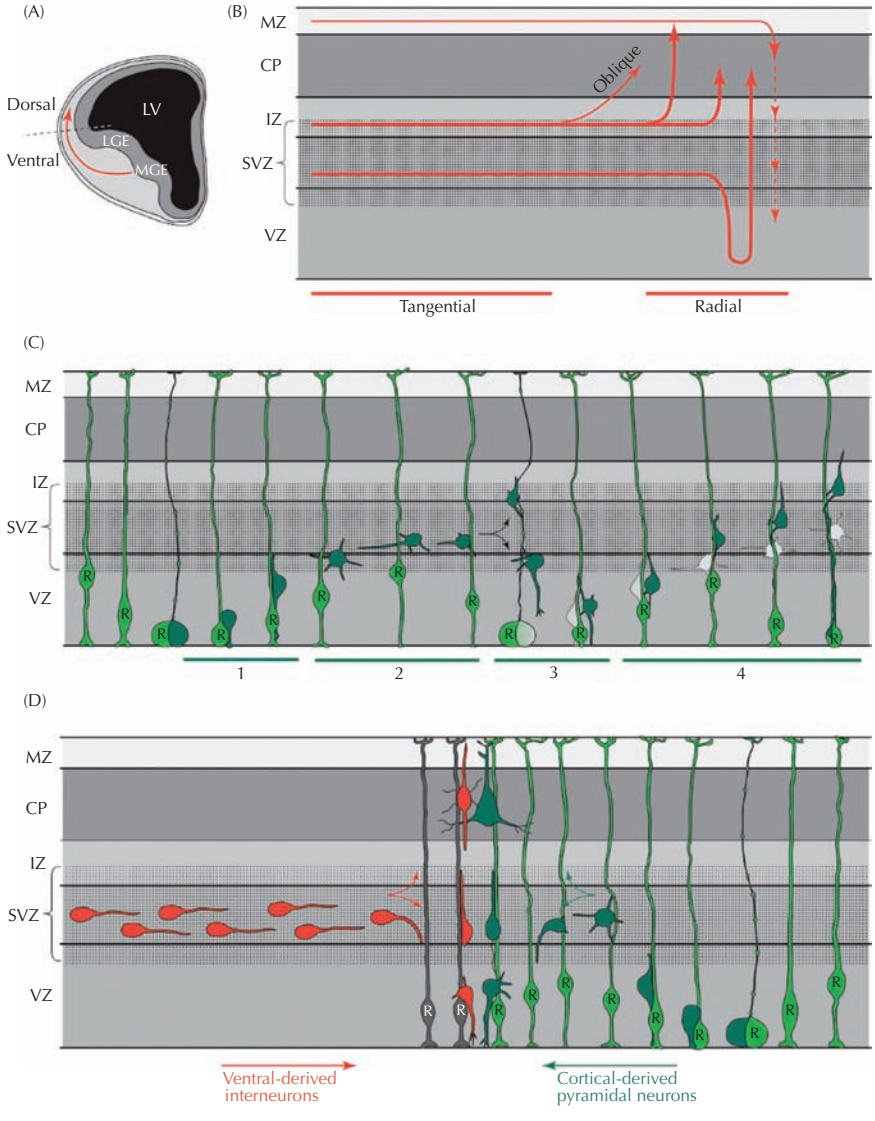

Figure 60–2. Neuronal migration. **A, B.** Cortical interneurons are derived from the ventral telencephalon and reach their final locations by migrating through specific phases. **A.** Origin of interneurons in the ventral telencephalon. Most cortical interneurons are generated in the medial ganglionic eminence (MGE) of the ventral telencephalon and migrate across the corticostriatal junction (broken line) to enter the dorsal telencephalon. **B.** Phases of interneuron migration within the dorsal telencephalon. Cortical interneurons arising in the ventral telencephalon migrate tangentially in the cortex and then change direction to enter the cortical plate (CP) by following a radial or an oblique path. The broken line indicates that some interneurons have been observed to descend radially into the CP and others to continue radially to deeper lamina. IZ, intermediate zone; LGE, lateral ganglionic eminence; LV, lateral ventricle; MZ, marginal zone; SVZ subventricular zone; VZ, ventricular zone. **C.** Cortical pyramidal neurons undergo distinct phases of locomotion migration. Phase one involves radial movement of pyramidal neurons (dark green) from the site of origin at the ventricular surface to the SVZ. In phase two, cells become multipolar, and their migration pauses in the lower IZ and the SVZ. Some neurons undergo phase three, which is characterized by retrograde motion toward the ventricle. Phase four is the final radial migration to the CP, guided by radial glial fibers. Radial glia (light green) remain mitotic, undergo interkinetic nuclear migration, and generate additional daughter cells (gray). R, radial glial cell. **D.** Migratory patterns of interneurons and pyramidal neurons converge in the dorsal cortex. This scheme depicts the apparent convergence of the migratory patterns of interneurons (red) and pyramidal cell movements (dark green) in the cortex. Subsets of both cell types display ventricle-directed migration followed by radial movement to the CP. Interneurons might migrate radially along unrelated adjacent radial glial cells (gray) to reach the CP. Reprinted from *Trends in Neurosciences*, 27(7), Arnold R. Kriegstein and Stephen C. Noctor, "Patterns of neuronal migration in the embryonic cortex," pages 392–399, Copyright (2004). With permission from Elsevier.

of human disease. Neuronal migration was studied extensively in the mouse even prior to identification of the causative genes for human syndromes. Prior to identification of *RELN* as a causative gene for lissencephaly, work on the reeler mouse identified striking neuronal migration defects.[16] The *Cdk5–/–* mouse also has similar, but not identical lamination defects, including the inverted cortical lamination,[17] and CDK5 is thought to be downstream of reelin signaling. In turn, the CDK5 protein is known to interact with both DCX and LIS1.[1,18] Thus, it has become apparent that the genes identified in mice with neuronal migration defects interact with human lissencephaly proteins, including the microtubule-related proteins, as well to define a neuronal migration signaling pathway (Fig. 60–3).

A key question is why the microtubule pathway is important and specific for neuronal migration. During development of pyramidal neurons, newly born neuroblasts undergo changes in morphology that correspond to different stages in neuronal migration[19] (Fig. 60–2B). The newly born neuroblast in the ventricular zone (VZ) passes into the subventricular zone (SVZ), where it can divide further into additional neurons or, alternatively, enter the intermediate zone (IZ). In the IZ, the neuroblast assumes a multipolar morphology, but as it migrates into the cortical plate, the neuron becomes bipolar, with a leading process that eventually becomes the dendrite and a trailing process that will become the axon (Fig. 60–2B). Transport of organelles and polarization of trafficking underlie many of these changes, and since cytoskeletal dynamics and transport regulate cell shape and structure, these pathways are critical for correct neuronal migration. Studies aimed at identifying and characterizing causative genes for neuronal migration disorders have emphasized the importance of microtubule function in human neural development (Table 60–1). *LIS1*, *DCX*, and *TUBA1A*

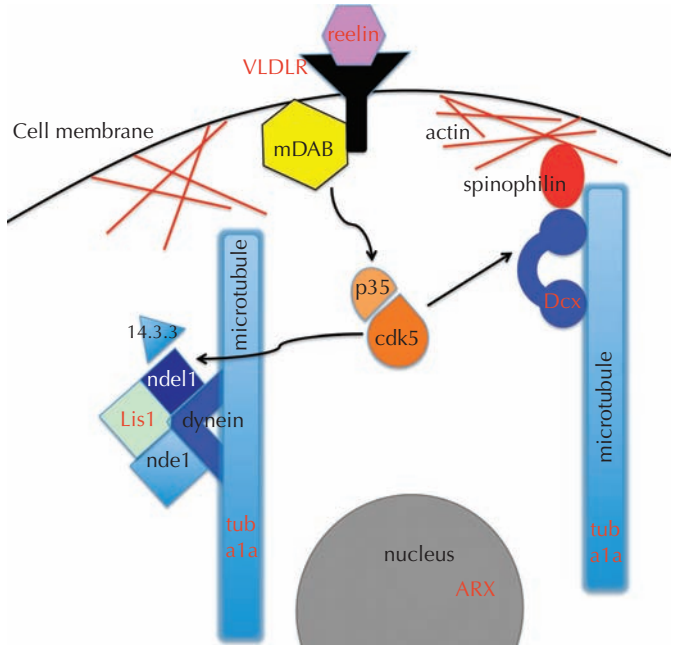

Figure 60–3. Neuronal migration signaling pathways. A simplified diagram describing the relationship between the known neuronal migration proteins in mouse and human is shown. Protein names encoded by causative genes for human lissencephaly are in red. Reelin is an extracellular ligand that binds, among other receptors, very-low-density lipoprotein receptor (VLDLR). Doublecortin (Dcx) is a microtubule binding protein; Lissencephaly 1 (Lis1) is an adaptor protein for the minus end motor, dynein, and Tuba1a is a tubulin isomer. Aristaless (Arx) is a transcription factor. Reelin signaling may activate the cdk5/p35 kinase via mDAB. Cdk5 regulates Dcx microtubule binding and assembly of the Lis1/dynein complex including NDEL1, NDE1, and 14-3-3ε. Dcx interacts with microtubules as well as actin via spinophilin and may be a mediator of actin/tubulin crosstalk.

encode proteins that are related to microtubule function and microtubule-based transport. The LIS1 protein is part of the dynein complex, a microtubule motor protein.[1] *DCX* encodes a MAP that has a role in regulating vesicle transport in developing neurites.[20] Finally, *TUBA1A* encodes an α-tubulin subunit that is enriched during brain development.[4] The other genes, *ARX*, *RELN*, and *VLDLR*, encode for a transcription factor and for the ligand and receptor of the very-low-density lipoprotein receptor system, respectively, that may define upstream or downstream events regulating neuronal migration (Fig. 60–3).

From these studies, it appears evident that the basic biology of microtubules and microtubule-based functions, including transport, is extremely important for proper neuronal development, such as neuronal migration (Fig. 60–4). Microtubules are hollow tube-shaped polymers assembled through polarized polymerization of tubulin heterodimers that are comprised of a variety of α- and β-tubulin isoforms. Tubulin subunits α and β are encoded by a family of genes that are structurally similar but have distinctive features important for specific cellular functions. *TUBA1A* is highly expressed in the nervous system during development and is a causative gene for lissencephaly.[13] Other tubulin genes are causative for different human syndromes, including tubulin β3 (*TUBB3*), an axonal-specific tubulin causing a syndrome, congenital fibrosis of the extraocular muscles (CFEOM3), that is also associated with cognitive defects and a neuropathy.[21]

Microtubule assembly is dependent on guanosine triphosphate (GTP), which binds to the soluble tubulin heterodimers and, upon hydrolysis, induces a conformational change that favors the polarized polymerization and elongation of the microtubule. Once assembled, however, microtubules are by no means static structures; not only can they be depolymerized, but they are moreover dynamically and developmentally tightly regulated so that their structure, polarization, and function are fine-tuned for the specific requirements of the cell. For example, some *TUBA1A* mutations block GTP binding, thereby preventing polymerization.[13]

In neurons, as in any other cell type, microtubule polarization results in clearly defined *plus* and *minus* ends, with elongation occurring exclusively at the plus end. In axons, the minus ends are usually oriented toward the cell body, whereas their elongating plus ends project toward the distal regions of the axon. In contrast, in dendrites, the polarity of microtubules is mixed, and the structural differences of microtubules in axons and dendrites likely reflect specific functional differences.[22] Microtubules in axons and dendrites can also be distinguished through their interacting proteins. Microtubule-associated proteins are specific for axons or dendrites and are often bound to microtubules in gradients along

(*continued from page 777*)

been described as a B-type lattice with a seam (long arrow, part A in the figure). A third tubulin isoform, γ-tubulin, functions as a template for the correct assembly of microtubules. On addition of a new dimer at the plus end, the catalytic domain of α-tubulin contacts the nucleotide exchangeable site (E site) of the previous β subunit and becomes ready for hydrolysis; the plus end generally has a minimum GTP cap of one tubulin layer that stabilizes the microtubule structure. When this GTP cap is stochastically lost, the protofilaments splay apart and the microtubule rapidly depolymerizes. During or soon after polymerization, the tubulin subunits hydrolyze their bound GTP and become nonexchangeable. Thus, the microtubule lattice is predominantly composed of GDP-tubulin, with depolymerization being characterized by the rapid loss of GDP-tubulin subunits and oligomers from the microtubule plus end. At the minus end, contact is made between the E site of the new dimer and the catalytic region of the last subunit at the end; therefore, no GTP cap should be present. The properties of microtubules depend on the tubulin isoforms they consist of—there are three α-tubulins (α1, α2, and α4) and five β-tubulins (βI, βII, βIII, βIVa, and βIVb)—and on how they have been altered by various forms of posttranslational modification, including tyrosination, detyrosination, acetylation, polyglutamylation, polyglycylation, phosphorylation, and palmitoylation. Except for tubulin tyrosine ligase, the enzyme that adds a tyrosine to nonassembled α-tubulin, most of the modifying enzymes act preferentially on tubulin subunits that are already incorporated into microtubules. Posttranslational modifications of tubulin subunits mark subpopulations of microtubules and selectively affect their functions. Although they are not directly involved in determining the dynamic properties of microtubules, posttranslational modifications of tubulin, such as the sequential tyrosination-detyrosination-acetylation, correlate well with the half-life and spatial distribution of microtubules. C. Axons have tau-bound microtubules of uniform orientation, whereas dendrites have microtubule-associated protein 2 (MAP2)-bound microtubules of mixed orientation. Dendrites also contain organelles that are not found in axons, such as rough endoplasmic reticulum, polyribosomes, and Golgi outposts. Figure 60–4. Microtubule regulation in neurons**. A, B.** Microtubules are noncovalent cytoskeletal polymers found in all eukaryotic cells that are involved in mitosis, cell motility, intracellular transport, secretion, and the maintenance of cell shape and cell polarization. They are polarized structures composed of α- and β-tubulin heterodimer subunits assembled into linear protofilaments. A single microtubule consists of 10–15 protofilaments (usually 13 in mammalian cells) that associate laterally to form a 24 nm wide hollow cylinder. The head-to-tail association of the heterodimers makes microtubules polar structures, and they have different polymerization rates at the two ends. In each protofilament, the heterodimers are oriented with their β-tubulin monomer pointing toward the faster-growing end (plus end) and their α-tubulin monomer exposed at the slower-growing end (minus end). The lateral interaction between subunits of adjacent protofilaments has

(*continues on page 776*)

neural processes,[23] serving several functions. For example, binding of MAPs provides structural stability to microtubules. In addition, MAPs can facilitate transport targeting and specificity by either blocking or enhancing motor interaction. Most MAPs compete with motors for binding sites on tubulin and thus are negative regulators of motor transport. DCX, however, does not competitively inhibit motor binding.[24,25] Moreover, DCX is a MAP that is regulated by phosphorylation by CDK5 and binds microtubules in a signal-dependent manner.[18] Our data show that DCX facilitates binding of some motors to microtubules. Posttranslational modifications of tubulin including acetylation and polyglutamylation, respectively can also confer stability and enhance motor function on microtubules.[26,27] And other modifications, such as tyrosination, interfere with motor function on microtubules.[27]

Thus, polarity, posttranslational modification, and MAP binding of microtubules are important for transport functions, but the actual transport is mediated by individual microtubule-based motors.[28] Motors are directed toward either the plus or minus ends of microtubules. For example, kinesin motors transport vesicles and organelles toward the plus ends of microtubules, and the single dynein motor transports cargo toward the minus end of the microtubule. In the axon this means that kinesins transport cargoes away from the cell body to distal parts of the axon, and dynein mediates transport back toward the cell body. While there is only 1 minus end motor, dynein, there are 45 kinesins that transport cargo toward the plus end of the microtubule. Thus, achieving cargo identification and coupling for the minus end motor, dynein, is considerably more complex than for the kinesins. The LIS1 protein actually is associated with dynein and is important as a regulator of dynein force generation.[29]

Thus, mutations in genes that have a major role in microtubule assembly and microtubule-based transport, including *LIS1*, *DCX*, and *TUBA1A*, can cause defects in neuronal migration as well as axon and dendrite outgrowth. In this chapter, describing three specific examples, we illustrate how rare genetic causes of lissencephaly may implicate microtubule-based transport in the pathogenesis of cortical dysplasias.

LIS1 IS THE CAUSATIVE GENE ASSOCIATED WITH MILLER-DIEKER LISSENCEPHALY SYNDROME

Haploinsufficiency of *LIS1* (also called *platelet-activating factor acetyl-hydrolase*) is known to cause classical lissencephaly, either in isolation (Fig. 60–1A) or as part of the Miller-Dieker syndrome of 17p13.3 deletion[30] (Fig. 60–1B). Miller-Dieker syndrome also includes facial dysmorphology, caused by haploinsufficiency of the other genes deleted in the interval. *YWHAE* encodes the protein 14–3-3ε, which is a modifier of Lis1.[31,32] Patients with *LIS1* mutations alone have lissencephaly, but are often found to have hypoplasia of the corpus callosum as well as enlarged ventricles, suggesting a role for LIS1 in neuronal migration as well as axon formation.[33] Supporting evidence is provided by the expression pattern of LIS1, which is enriched in neuronal progenitor cells in early development. Moreover, expression of LIS1 in later stages of development supports a wider role for LIS1 function outside of neuronal migration.

Functional characterization of LIS1 has been facilitated by the creation and characterization of an animal model. As predicted by human genetics, haploinsufficiency of *Lis1* results in structural defects in the brain, including dyslamination in the hippocampi.[34] Homozygosity of the mutation is lethal in early embryogenesis.[35] In addition to radial migration defects, tangential migration of interneurons is impaired.[36] However, most striking are the apparent defects in neurogenesis that were not emphasized in the initial clinical description of patients. In the mouse model, Lis1 was found to be critical for expansion of the neuronal progenitor pool through regulation of symmetric cell division. Decreased Lis1 is correlated with abnormal spindle pole orientation, a marker for the type of cell division—asymmetric to generate a postmitotic neuron or symmetric to generate two progenitors that can divide further.[37]

Mouse genetics and molecular biology have allowed the identification and characterization of proteins interacting with Lis1, most importantly dynein, Ndel1 and Nde1. Lis1 has also been found to interact with dynactin, another member of the dynein complex, and with the plus-end microtubule binding protein

CLIP-170, which may mediate the assembly of the complex.[38] These proteins have multiple functions during neuronal migration, including nuclear and centrosomal positioning, as well as neurite outgrowth.[39] It is unknown, however, if dynein transport in each of these contexts functions similarly, and likely the complexity of the dynein complex, including Lis1, facilitates specificity of function. Given dynein's role as the single motor protein responsible for minus-end microtubule transport, it is more likely that defects associated with Lis1-dynein transport are due to specific defects in the dynein cargo load. For example, neurite outgrowth problems may be due to defects in retrograde signaling, and neuronal migration and neurogenesis problems may result from disruption of nucleokinesis.[40,41]

Molecular studies have demonstrated a specific role for LIS1 in the regulation of dynein activity: LIS1 and NDE1 bind to dynein to enhance microtubule binding and prolong force production of the motor protein.[29] As a consequence, LIS1 has been shown to mediate dynein transport of relatively large and heavy cargos, such as the nucleus, while other small vesicular cargoes appear to be unaffected. Unfortunately, other aspects of LIS1 function, including its reported interaction with another lissencephaly gene, DCX, as well as its regulation by developmentally important kinases, which may explain aspects of the *LIS1* phenotype, including the seizures, remain uncharacterized to date.

DCX MUTATIONS CAUSE BOTH X-LINKED LISSENCEPHALY AND SUBCORTICAL BAND HETEROTOPIA

DCX, or doublecortin, is one of two genes that cause X-linked lissencephaly in affected males[42,43] (Table 60–1 and Fig. 60–1E). Women with *DCX* mutations classically have a migration disorder called *subcortical band heterotopia* (Fig. 60–1F). X-inactivation to achieve gene dosage compensation in females with *DCX* mutations results in cellular mosaicism: two populations of neurons occur with either the mutant gene or the normal gene. Affected mosaic females can have a range of neurodevelopmental phenotypes, including subcortical band heterotopia, a disorder in which DCX-deficient neurons arrest before reaching the cortical plate to form abnormal islands within the white matter with abnormal axons tracts rather than frank lissencephaly.[44] In addition, women with *DCX* mutations can exhibit a range of milder phenotypes, including nonsyndromic mental retardation or cryptogenic epilepsy without an overt neuronal heterotopia.[45] The degree of dysfunction and the severity of the phenotype are thought to be due to the skewing of X-inactivation of the X chromosome with the defective *DCX*.

The genetic mouse model of *Dcx* mutations significantly improved our understanding of the brain phenotype in the human condition. While the mutant mouse with a targeted deletion of *Dcx* does not have an overt cortical migration defect and is more mildly affected,[46] it has multiple other defects that have led to a closer examination of the human phenotype. For example, the *Dcx* mutant mouse exhibits disruption of lamination in the hippocampi and white matter defects.[46] These defects were subsequently also described in humans with *DCX* mutations.[47] In addition, defects in migration and morphology of GABAergic interneurons have been described, which may be a common factor in the pathogenesis of epilepsy in these disorders.

Interestingly, the female *Dcx* mutant mouse with a single undamaged copy of *Dcx* appears to be phenotypically normal.[20] Instead, short hairpin RNA interference (shRNAi) has been used in rats to model the formation and physiology of subcortical band heterotopia.[48] However, it has to be noted that the same experiment does not produce heterotopia in the mouse. The shRNAi is introduced by microinjection into the lateral ventricle of an embryonic rat and by application of an electrical pulse, the interference construct is transfected into neuronal progenitors that are adjacent to the ventricle. In these cells, the RNAi prevents the expression of *Dcx* during the migratory phase of neuronal development. Moreover, electrophysiological studies of these rats have shown a decrease of GABAergic tone in the cortex overlying the subcortical band, which is populated not only with Dcx-deficient excitatory neurons but also with normal GABAergic neurons.[49] These appear to be misdirected and unable to migrate to their normal positions in the cortex. Finally, this model has also been used to show

that reexpression of Dcx in the subcortical band neurons during adulthood initiates migration of these neurons into the cortex and further decreases the seizure threshold of the animals.

From animal models, it has become clear that Dcx is a member of a family of structurally related, functionally redundant proteins that have a role in seizure pathogenesis. In addition to the single mutant of *Dcx*, double mutants of *Dcx* and *Dclk1*[20,50] and *Dclk2*[51] have been published, showing much more severe structural effects in the double mutants than in the single mutants and proving overlapping roles for Dcx family members in development and beyond. All of these animals have been shown to have seizures (Deuel, Walsh, and Nobles, unpublished data), and the seizures in the *Dcx-/y; Dclk2–/–* mutant are thought to emanate from the hippocampus.[51] It is unknown whether seizures in humans are related to the severe temporal lobe dyslamination and how much the disruption of the microcircuitry in the neocortex contributes to seizure propagation in humans. Epilepsy surgery has not been used on lissencephaly patients; however, patients with subcortical band heterotopia have generally not had favorable outcomes after temporal lobectomy.[52]

The molecular role of DCX can be understood by its interaction with other proteins. Mutations in the tandem microtubule binding domains of DCX have been shown to abrogate microtubule binding and cause the neuronal migration defects.[53] In addition to microtubules, DCX is known to interact with spinophilin/neurabin II, an actin-binding protein, suggesting a role in actin/microtubule crosstalk, and human mutations disrupting this interaction also cause defects in neuronal migration.[54] Moreover, DCX has been shown to interact with the μ subunit of the clathrin adaptor complex,[55] which is involved in vesicle biogenesis from the Golgi complex and in endocytosis as part of clathrin-coated pits. Finally, we have identified a role for DCX in regulating microtubule-based transport.[20]

MUTATIONS IN α-TUBULIN CAUSE LISSENCEPHALY

Heterozygous missense mutations in *TUBA1A*, coding for an α-tubulin isoform that is highly expressed in developing neurons, cause a spectrum of cortical malformations that include lissencephaly and pachygyria. Affected individuals may also be microcephalic and have cortical malformations that range from agyria and posterior pachygyria in severe cases to perisylvian predominant pachygyria in the more common and less severe forms.[56] Findings from autopsies reveal abnormal cortical layering, hypoplastic and disorganized hippocampi, and clusters of heterotopic neurons interspersed within the white matter.

The *TUBA1A* phenotype (Fig. 60–1C,D) is somewhat distinct from those of *LIS1* and *DCX*, however. Patients with *TUBA1A* mutations have additional defects that are less commonly associated with *LIS1* and *DCX* mutations, including cerebellar and brainstem hypoplasia, as well as hypoplasia of the anterior limb of the internal capsule. This long tract finding appears to be extremely specific to *TUBA1A* mutations and is associated with dysmorphic basal ganglia that lack a clear separation between the caudate and putamen.[56] As with *LIS1* and *DCX* mutations, hypoplastic and disorganized white matter tracts suggest further disruption of axon growth and guidance beyond defects in cell migration. Thus, patients usually have severe neurological impairments, including mental retardation, spastic diplegia or tetraplegia, facial paralysis, and epilepsy.

In contrast to *DCX* and *LIS1* mutations, *TUBA1A* mutations have not been extensively modeled in mice. However, a mouse with a mutation in the GTP binding site on Tuba1a has been described, with abnormal hippocampal lamination but no overt migration disorder in the cortex.[13] This mouse histopathology appears very similar to that of the *Dcx* mutant mouse, and it is likely that on further examination, other abnormalities will be observed.

Mutations in genes that encode different α– and β-tubulin isoforms, including *TUBB2B*, *TUBA8*, and *TUBB3*, also cause other congenital neurological syndromes. Mutations in *TUBA8* and *TUBB2B* cause polymicrogyria with and without ocular hypoplasia, respectively.[4,57] These syndromes are associated with developmental delay and seizures. In contrast, mutations in *TUBB3* cause a defect in axon guidance; patients present with restrictions in eye movement, mild cognitive impairments, spasticity, and, later, polyneuropathy. Radiological findings reveal

hypoplastic oculomotor nerves, dysmorphic basal ganglia with or without internal capsule hypoplasia, and agenesis or hypoplasia of the corpus callosum and anterior commissure, but no cortical malformations. The *TUBB3* syndrome is thus not as severe as the other tubulin mutation syndromes in terms of central nervous system dysfunction; as a result, these patients rarely have seizures.[58]

Each of the tubulin syndromes described above can result from mutations in tubulin isoforms that inhibit the formation of microtubules by interfering with the levels of tubulin expression, folding, or function (i.e., GTP binding), yet some pathogenic mutations do not appear to have any discernible effects on these specific tubulin properties. It is thought, however, that these mutations cause the phenotypic defects by disrupting the binding of other proteins to microtubules, including motor proteins such as kinesins and dynein and/or MAPs such as DCX. For example, the R402H mutation in TUBA1A has been shown to lie directly in the groove where DCX is thought to bind to tubulin,[13] and DCX is implicated in the transport of presynaptic vesicles. In addition, TUBB3 mutations are known to disrupt the function of another kinesin motor protein, KIF21A.[58] These findings strongly suggest that the tubulinopathies may be best understood in terms of a motor defect.[59]

MICROTUBULE FUNCTION AND THE PATHOGENESIS OF SEIZURES

Defects in neuronal migration of either excitatory or inhibitory neurons result, broadly speaking, in abnormal neuronal connectivity and circuit formation, as axons are unable to find their normal postsynaptic targets. Defects in neuronal migration of excitatory neurons may result in the abnormal formation of circuits. The dyslamination of pyramidal neurons means that the GABAergic interneurons may not be able to form the correct connections. This alone may be enough to tilt the balance in cortical circuitry toward hyperexcitability. In fact, the use of RNAi in the rat model to knock down *Dcx* specifically in pyramidal neurons without affecting GABAergic neurons does result in abnormal migration of interneurons to the subcortical band. These animals have been shown to have decreased inhibition in the overlying regions of cortex.[49] However, in animal models with targeted mutations in Lis1 and Dcx, the interneurons are also affected since these proteins are expressed in every neuron.[60,61] And while interneuron migration is not totally normal, the inhibitory interneurons still successfully migrate into the cortex. However, it is unknown whether specific subsets of interneurons are preferentially affected in either *DCX*- or *LIS1*- mediated disorders.

In these migration disorders, however, there might be additional specific molecular defects in the axons themselves, and microtubule dysfunction in such axons may explain the clinical phenotypes observed through disruption of dynein- and kinesin-mediated transport processes and their specific cargoes. For example, the *LIS1* syndrome may result from failure of dynein-mediated nuclear translocation during migration. However, the continued absence of retrograde transport in these neurons following the developmental stages into maturity may affect signaling from distal regions of the axons and dendrites. Although the specific signaling pathways affected are unknown, they may be pathways that respond specifically to neuronal activity such as that of Cdk5, which is both regulated by activity and known to interact with Lis1. In comparison, *DCX* mutations may cause both a failure of migration and axon outgrowth through defects in anterograde vesicle transport in growing axons and dendrites. In fact, the defect in kinesin-medicated vesicle transport observed in DCX mutant neurons may have far-reaching effects, such as impairments of membrane addition, mislocalization of guidance receptors, and ultimately, mislocalization of ion channels.

CORTICAL MALFORMATIONS ARE AN IMPORTANT CAUSE OF PEDIATRIC EPILEPSY

Genetic causes of brain malformations have a clearly defined etiology and can be studied with animal models, yet they are relatively rare. In the pediatric population, however, other cortical malformations, especially focal cortical dysplasias (FCDs), are the underlying cause of a large percentage of first presentation with seizures (reviewed in ref. 62). Epilepsies resulting

from cortical malformations are often difficult to control, requiring multiple medications and surgeries. In addition, compared to other epilepsy patients, the societal cost for such patients is disproportionately greater in terms of both health care spending and comorbidity. However, advances in genetics and neuroimaging have resulted in significant improvements in our understanding of these disorders as well as expansion of our diagnostic capabilities, and we are poised to develop new treatment options for patients suffering from these disorders.

Focal cortical dysplasia is a heterogeneous disorder, which has a wide range of severity by histopathological appearance and thus an unknown (or poorly defined) etiology. The severity of FCD is graded and correlated with the radiological findings.[62,63] Pathological examination of magnetic resonance imaging (MRI)-negative focal epilepsies results in a diagnosis of a mild form of FCD (Type I FCD) in up to half of the patients who undergo surgery for resection of a seizure focus.[64] Type II FCD is more severe and makes up most of the cases, which are diagnosed presurgically by MRI. Thus, FCD appears to encompass a wide range of severity that may reflect multiple etiologies ranging from mild dyslamination to the more severe form with heterotopic neurons, abnormal giant neurons, and balloon glial cells.[63]

While giant neurons and balloon cells are not found in lissencephaly, changes associated with mild FCD (heterotopic neurons and abnormal neuronal polarity) are reminiscent of the histopathology seen in human lissencephaly. Studies of mild forms of cortical dysplasia demonstrate cellular defects similar to those seen in tissue from animal models of *Dcx* and *Lis1* lissencephaly, including the disruption of lamination and multipolar heterotopic neurons. Thus, the same pathways that are disrupted in genetic causes of lissencephaly may be important for the pathogenesis of cortical dysplasia, and it is reasonable to hypothesize that microtubule dysfunction may be a leading cause of cortical dysplasia.

In contrast to milder forms of FCD, severe forms, which are more readily diagnosed by imaging, include histopathological features that are also seen in tuberous sclerosis complex (TSC).[65] Both severe FCD (Type II) and TSC have, in addition to dyslamination, giant neurons and balloon cells (reactive glial cells). Thus, TSC pathway proteins, including mTOR, are other possible candidates for FCD pathogenesis. What remains unclear is whether mild FCD and severe FCD result from the extent of dysfunction of one particular pathway, or if they result from developmental disruption of separate pathways. It is not inconceivable that FCD is a heterogeneous disorder with several different causes, and that some subsets of FCD result from molecular pathway dysfunction in terms of severity and other subsets are caused by entirely different pathways. Finally, the pathways that cause FCD and lissencephaly may be related.

Recent success in the manipulation of these candidate pathways in FCD highlights the importance of understanding the pathogenesis of FCD. Manipulation of these pathways has been shown to alter epilepsy in non-FCD models: rapamycin, an mTOR inhibitor, has been successfully used for treating seizures in animal models of TSC.[66] In addition, a recent study has shown that reexpression of a lissencephaly gene, *DCX*, in heterotopic neurons of *adult* animals resulted in a decrease in the size of the heterotopia and a reduction in seizure threshold.[67] Thus, determining whether these pathways are involved in the pathogenesis of the different types of FCD may result in (1) development of an appropriate animal model and/or (2) targeting of seizure therapy. With the successful therapeutic intervention in the animal model, the possibility of helping patients with disorders stemming from disruption of the same molecular pathway becomes a real possibility, and it is critical to adequately characterize FCD to know whether this can be achieved.

This characterization of human FCD will be extremely challenging, with obstacles including sample collection, as well as the heterogeneity of the patient population in terms of age, gender, treatment, and genetic background. In addition, many of the candidate proteins are developmentally expressed, and human samples obtained are typically outside the window of expression. However, the availability of animal models in all stages of development may make detailed phenotypic assessment and correlation of molecular pathway defects in human FCD more feasible. As discussed above, mouse models of neuronal migration have been extensively characterized and can be compared with human FCD, as well as with the animal model for TSC. Thus, characterization of FCD can be

conducted with reference to the animal models of candidate molecular pathways. Furthermore, detailed characterization of the microcircuitry in both FCD and lissencephaly models may yield meaningful comparisons for understanding the development of hyperexcitability.

Chapter 61

The Generation of Cortical Interneurons

Diego M. Gelman
Oscar Marín
John L.R. Rubenstein

INTRODUCTION

Epilepsy can simplistically be conceived of as a disorder of uncontrolled brain excitation; thus, disrupting the excitation/inhibition (E/I) balance of neural transmission can predispose the brain to seizures. In the pallium (cortex and hippocampus), E/I balance is mediated largely by the relative activity of two classes of neurons, glutamatergic pyramidal cells and gamma-aminobutyric acid (GABA)-containing (GABAergic) local circuit neurons, also known as *interneurons*. In the adult cortex, pyramidal cells are excitatory, whereas GABAergic interneurons are typically inhibitory. In addition to epilepsy, disruption of E/I balance is linked to several neuropsychiatric disorders.[1–4] Furthermore, genes associated with several of these disorders regulate cortical interneuron development.[5–8] Thus, to understand the underlying causes of many forms of epilepsy, particularly in childhood, it is important to understand the genetic and cellular mechanisms that control the development of cortical interneurons. This is the focus of this chapter.

Cortical excitatory projection neurons are generated by the pallial neuroepithelium.[9] By contrast, most, if not all, pallial interneurons are generated by subpallial progenitors, at least in nonprimate mammals.[10–13] The initial observations leading to this understanding came from analysis of *Dlx2* expression in mice.[14] *Dlx2* is a homeodomain transcription factor that is expressed in most subpallial progenitors and in many immature interneurons that tangentially migrate to the pallium. Vital dye migration assays have identified a robust tangential subpallial-to-pallial migration in the prenatal mouse brain.[15–17] Mice lacking *Dlx1* and *Dlx2* expression have a severe block in interneuron migration that results in a four-fold reduction in neocortical interneurons.[16,18]

Ongoing studies are aimed at elucidating the precise regions within the subpallium that generate these cells and the mechanisms that regulate their specification, migration, and differentiation into distinct interneuron subtypes in pallial structures (e.g., cortex, hippocampus, parts of the amygdala and olfactory bulb) and in subpallial structures (e.g., striatum).

The subpallium consists of four major subdivisions that have distinct molecular and morphological features: the lateral ganglionic eminence (LGE), medial ganglionic eminence (MGE), septum (SE), and preoptic area (POA).[6,19] Sulci approximate the transitions between most of these domains at early embryonic stages; however, the caudal part of the LGE and MGE lack a clear morphological demarcation, leading this region to be called the *caudal ganglionic eminence* (CGE), even though it has distinct LGE and MGE components. Efforts are underway to identify subdivisions within the progenitor domains of the LGE, MGE, SE, and POA. One approach has used transcription factor expression patterns.[6]

It is uncertain how many interneuron subtypes exist due to the broad diversity of their morphology, connectivity, physiology, and molecular properties. For instance, in the hippocampus, it is estimated that there are at least 21 different functional types.[20] However, for this review, we have adopted a conservative grouping of GABAergic interneurons into four major classes: (1) fast spiking, PV-containing basket and chandelier cells; (2) somatostatin (SST)-containing interneurons, which typically display intrinsic burst spiking or adapting non-fast-spiking electrophysiological profiles, and many have long axons that extend into layer I; (3) non-fast-spiking and rapidly adapting interneurons with bipolar or double-bouquet morphologies, which frequently express calretinin (CR) and/or vasointestinal peptide (VIP); and (4) rapidly adapting interneurons with multipolar morphologies that express neuropeptide Y (NPY) and/or Reelin, but not SST (Fig. 61–1).

Recent progress on the origin of interneurons suggests that these different classes of cells originate from three main sources in the developing subpallium—the MGE, CGE, and POA—and reach the cortex following different migratory routes (Fig. 61–2). Here we review our current view of this process, which is largely based on studies in the mouse. The origin of some populations of GABAergic interneurons in the developing pallium of monkeys and human embryos will not be addressed in this chapter, as this topic has recently been reviewed elsewhere.[21] Also, we will not review the literature concerning the contribution of LGE-derived interneurons to the olfactory bulb.

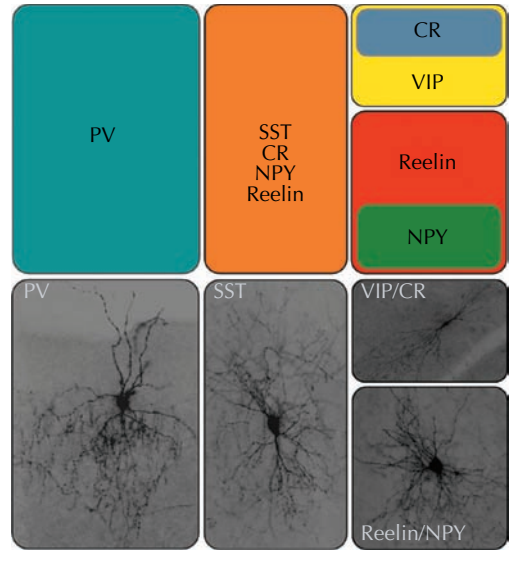

Figure 61–1. Four major groups of cortical interneurons can be distinguished in the mouse neocortex. (1) Fast spiking, PV-containing basket and chandelier cells. To date, there are no other markers that subdivide this large population of interneurons. (2) Somatostatin-containing interneurons, which typically display intrinsic-burst spiking or adapting non-fast spiking electrophysiological profiles. Many of these neurons have the morphology of Martinotti cells. This population of SST-containing cells is very heterogeneous and includes several classes of interneurons that may also express Reelin, CR, and/or NPY. (3) Rapidly adapting interneurons with bipolar or double-bouquet morphologies. These cells very frequently express VIP, and many of them also contain CR. (4) Rapidly adapting interneurons with multipolar morphologies. Most of these cells express Reelin but not SST, and many also express NPY.

THE MEDIAL GANGLIONIC EMINENCE GENERATES THE MAJORITY OF CORTICAL INTERNEURONS

The MGE is the origin of approximately 50%–60% of the population of cortical interneurons in the mouse.[13,22,23] The MGE gives rise

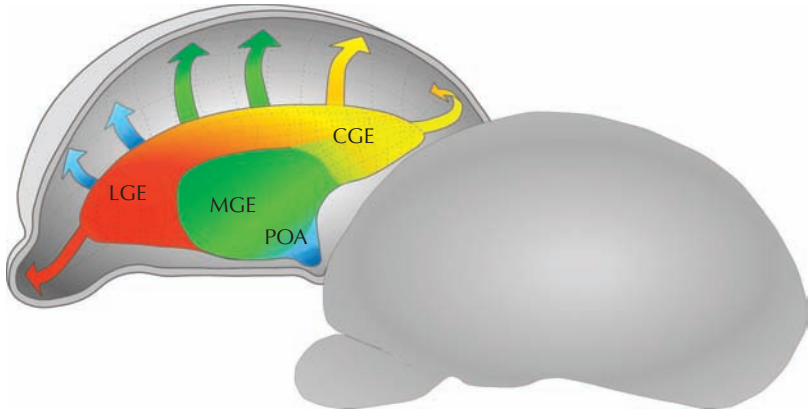

Figure 61–2. Cortical interneurons are born in the subpallium and migrate tangentially to the cortex. The schema represents an E13.5 embryo brain hemisection. The arrows show representative migratory routes. Preoptic area-derived interneurons (blue) tend to invade the cortex through its rostral region, while CGE-derived interneurons (yellow) reach the cortex primarily by its caudal pole. The lateral ganglionic eminence (red) is a major source for many olfactory bulb interneurons, although they are also produced in other regions. For simplicity, the septum and the thalamus are not depicted in the schema. ob, olfactory bulb; NCx, neocortex; PCx, paleocortex.

to most PV-containing and SST-containing interneurons (Fig. 61–3). This latter group is heterogeneous in their electrophysiological properties, morphologies, and expression of Reelin, NPY, and/or CR.[24,25]

Early studies of MGE-derived interneurons were based on the analysis of mice lacking the transcription factor *Nkx2-1*.[26] The analysis of *Nkx2-1* mutants revealed that this transcription factor is required for the generation of more than half of the GABAergic cells populating the cortex.[26] In neonatal mice, these include SST^+, NPY^+, and $calbindin^+$ interneurons.[23] However, because the *Nkx2-1* mutant dies on the day of birth due to multiple organ defects, additional work has been necessary to define the identity of the mature interneurons that depend on *Nkx2-1* function.

Subsequent studies have focused on the functions of *Nkx2-1* and other transcription factors in the development of distinct interneuron subtypes. For example, acquisition of the fast-spiking characteristics and expression of PV are regulated by the actions of the *Nkx2-1*, *Dlx5*, *Dlx6*, *Lhx6*, and *Sox6* transcription factors.[27–32]

In vitro experiments[33,34] and in vivo transplantation analyses[6,22,34–36] have revealed that the large majority of cortical interneurons derived from the MGE are PV-containing (~65%), while the remaining cells express SST (~35%). These studies have recently been confirmed by genetic fate-mapping studies that took advantage of the existence of genes with patterns of expression that are largely confined to the MGE, such as *Nkx2-1* and *Lhx6*,[37,38] as well as by the analysis of null or conditional mutants for these genes.[27,29]

A question that remains open is to what extent progenitor cells that give rise to PV- and SST-containing interneurons are spatially segregated within the MGE. The analysis of the expression pattern of dozens of transcription factors within the ventricular zone of the MGE have led to the proposal that this region may consist of up to five distinct progenitor domains, designated pMGE1 to pMGE5, which have been hypothesized to give rise to different classes of neurons.[6] Consistently, several lines of evidence suggest that the dorsal (pMGE1-2) and ventral (pMGE3-5) regions of the MGE have a tendency to preferentially give rise to SST- and PV-containing interneurons, respectively.[6,34,37] Furthermore, *Gli1* and *Nkx6-2* are expressed in the dorsal MGE.[6,39] Cre fate mapping with *Nkx6-2* provides strong evidence that the dorsal MGE generates "Martinotti" cortical interneurons (SST^+ and CR^+).[37,40] Mice lacking *Nkx6-2* or *Gli1* (in conjunction with *Gli2*) have cortical interneuron defects.[39,40]

Furthermore, recent fate-mapping analyses have suggested that the progenitor cells giving rise to PV-containing GABAergic neurons populating the basal ganglia might be

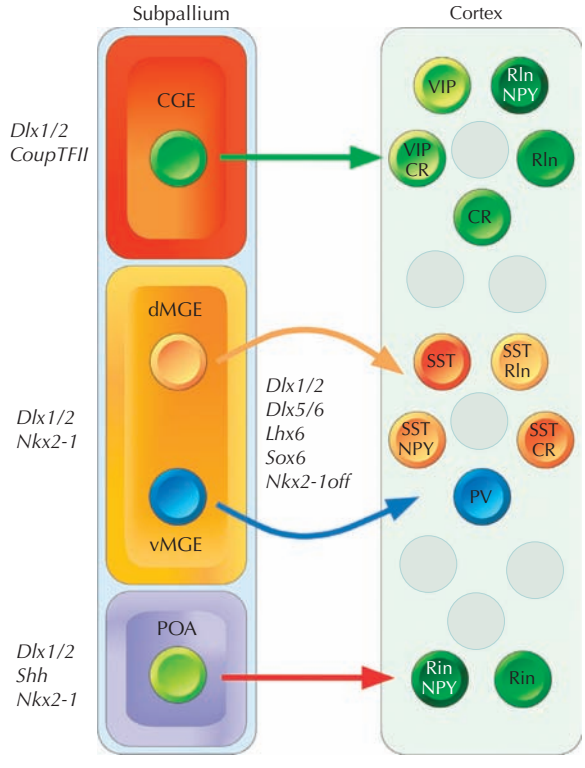

Figure 61–3. Cortical interneuron diversity largely emerges from spatially segregated progenitor cells with distinct transcriptional profiles. The schema shows the main sources of cortical interneurons—CGE, MGE, and POA—which contain progenitor cells that can be distinguished by their expression of transcription factors and other proteins. Thus, CGE cells express both *Dlx1/2* and *Couptf2*, MGE cells express *Dlx1/2* and *Nkx2-1*, and POA cells express *Dlx1/2*, *Nkx2-1*, and *Shh*. Furthermore, each of these regions seems to contain distinct progenitor domains (not shown in the schema), characterized by the expression of different transcription factors.[6] Each progenitor region produces a particular group of interneurons, although some interneuron classes may emerge from different progenitor domains. This is the case of multipolar Reelin/NPY-containing interneurons, which derive from both CGE and POA. It is possible, however, that these cells derived from a progenitor domain that bridges both structures and that is characterized by the expression of *Couptf2*.[59] The transcriptional mechanisms involved in the generation of MGE-derived interneurons are best elucidated. Thus, downregulation of *Nkx2-1* and expression of *Lhx6* and *Sox6* are necessary for the proper specification of MGE-derived interneurons. Not illustrated: the *Ascl1*, *Arx*, and *Dlx* transcription factors are required for the differentiation and migration of interneurons derived from the subpallium; *Gsx2* function is required in the CGE.

also spatially segregated from those producing PV-containing GABAergic interneurons for the cortex.[41,42] Thus, while pMGE5 seems to produce primarily PV-containing GABAergic neurons in the globus pallidus and other GABAergic neurons of the subpallium, it seems to produce very few PV-containing cortical interneurons (although these are the predominant interneuron subtype generated from this region). In turn, very few globus pallidus neurons seem to be generated from pMGE3-4, which therefore may primarily generate cortical interneurons. In sum, although progenitor domains in the telencephalon do not seem to segregate as sharply as in the spinal cord, increasing evidence suggests that the generation of distinct classes of GABAergic interneurons in the subpallium is tightly linked to the existence of distinct classes of progenitor cells (Fig. 61–3).

The mechanisms that differentially specify the generation of PV- and SST-containing interneurons are beginning to be elucidated. As mentioned above, the generation of both types of interneurons requires the maintenance of *Nkx2-1* expression in MGE progenitors, a process that involves Shh signaling.[43] Interestingly, the level of Shh signaling induced in MGE progenitors seems to dictate the type of interneuron produced, as is the case for the

spinal cord.[44] Thus, high levels of Shh signaling favor the generation of SST-containing neurons at the expense of PV-containing neurons.[45] This is consistent with previous findings that reported high levels of Shh effectors, such as *Gli1*, *Gli2*, or *Hhip1*, in the dorsal MGE.[34] What is paradoxical in this system is that the highest level of Shh activation within the ventral telencephalon occurs in the dorsal MGE, far away from the ventricular zone source of the signal in pMGE5 and the POA. This is in sharp contrast with the situation in the spinal cord. The answer to this paradox may be that the dorsal MGE receives Shh signals from Shh^+ neurons in the MGE mantle zone.[46] The fate of the large majority of PV- and SST-containing interneurons depends on *Lhx6*, a direct target of *Nkx2-1*.[47] In the absence of *Lhx6*, MGE-derived interneurons reach the pallium, but most of them fail to express PV or SST, whereas there is an increase in NPY^+ interneurons.[27,29] In addition, *Lhx6*-deficient interneurons have problems allocating into their appropriate target layers in the cortex, suggesting that genes downstream of this transcription factor regulate this process, such as *CXCR4*, *CXCR7*, and *ErbB4*.[29] Interestingly, a small population of GABAergic interneurons continues to express PV and SST in the cortex of *Lhx6* mutants,[27,29] which suggests that some of these interneurons are generated outside the MGE (see below).

Recent studies have begun to identify transcription factor genes that act downstream and/or in parallel with *Nkx2-1* and *Lhx6* in the specification and early differentiation of MGE-derived interneurons: these include *Lhx8*(7), *Sox6*, *Dlx5&6*, and *Arx*. *Lhx8*(7) is coexpressed with *Lhx6* in immature MGE cells and, like *Lhx6*, is downstream of *Nkx2-1*.[26,48] Cells that maintain *Lhx8*(7) expression do not become cortical interneurons; rather, they become basal telencephalic neurons, including globus pallidus GABAergic neurons and cholinergic interneurons of the striatum.[48,49] While *Lhx8*(7) mutants have normal cortical interneurons, *Lhx6/8* double mutants have a severe defect of MGE interneuron production and migration that is more severe than that of *Lhx6* mutants.[46]

The Sry-related HMG-box-containing transcription factor *Sox6* is expressed by most, if not all, MGE-derived immature and mature cortical interneurons. *Lhx6* function is required to maintain *Sox6* expression in migrating interneurons but not in MGE progenitors.[31,46] *Sox6* null and conditional mutant mice lack PV^+ and have reduced numbers of SST^+ interneurons.[30,31]

The *Arx* and *Dlx* homeobox genes will be discussed more extensively below in the section on the CGE. However, *Arx* and the *Dlx1,2,5&6* genes are expressed in most subpallial progenitors, including the MGE, and many of its postmitotic neuronal products.[50,51] For instance, *Dlx5* is expressed in mature PV^+ interneurons.[32] There is evidence, based on transplantation experiments, that loss of *Dlx5 or Dlx5&6* functions results in a reduction in the number of PV^+ neurons and a defect in their dendritic architeture.[32] Furthermore, $Dlx5/6^{+/-}$ mice have epilepsy and a defect in their gamma rhythm, implying an abnormality in PV^+ neuron function.[32]

Temporal regulation of interneuron neuronogenesis has an important role in defining the eventual laminar position of neurons in the neocortex.[52–55] Although the mechanisms underlying this process are unclear,[56,57] recent genetic fate-mapping analyses have shown that some types of MGE-derived neurons are preferentially generated at specific times during neurogenesis,[58] which may explain their relatively restricted laminar distribution in the cortex.

THE CAUDAL GANGLIONIC EMINENCE PRODUCES DISTINCT INTERNEURON SUBTYPES

The CGE produces 30%–40% of all cortical interneurons. Fate mapping the contribution of the CGE to the complement of cortical interneurons has been problematic because of the difficulties in consistently defining this region. Thus, while *Nkx2-1* has been a key gene for the identification of the MGE and its derivatives, the definition of the CGE has been largely based on anatomical references, which complicates the comparison between different studies. The similarities in gene expression patterns between the LGE and the CGE led to the suggestion that the CGE may indeed contains a caudal extension of the LGE progenitor domains.[6,13,50,51] Although this may actually be the case for some of the LGE

progenitor domains (in particular for pLGE3, which likely originates most GABAergic projection neurons populating the striatum and amygdala), recent studies have shown that the CGE contains progenitor domains with unique molecular profiles implying the existence of distinct CGE progenitor domains,[51,59,60] some of which are contiuous with LGE and MGE domains (compare Fig. 2A in ref. 59 with Fig. 9 in ref. 6). The *Couptf1* and *Couptf2* transcription factors are enriched in progenitor cells within the CGE, and experimental evidence suggests that *Couptf2* promotes the migration of CGE-derived interneurons to the cortex.[59]

1,1′-dihexadecyl-3,3,3′-tetramethylindocarbocyanine perchlorate (DiI) labeling studies provided evidence that interneurons are tangentially migrating through the LGE and CGE on their way to the cortex and that there are more robust migrations coming through the CGE.[16,18] However, these studies could not eliminate the possibility that some of the label was applied to MGE-derived cells. The first direct evidence supporting the origin of cortical interneurons in the CGE came from in utero transplantation studies.[54] These early observations were subsequently confirmed and extended by other studies, both in vitro and in vivo, which have demonstrated that the CGE is the main origin of interneurons with bipolar and double-bouquet morphologies, many of which express CR (but not SST) and/or VIP.[22,33] The inherent difficulty of delineating the entire population of CGE progenitors, along with the possibility that some MGE-derived cells migrate through the CGE, have complicated the precise identification of the entire complement of interneurons produced in the CGE. A recent fate-mapping study, however, has taken advantage of a *Mash1-CreER* driver line that was preferentially expressed in the LGE and CGE to report the existence of an additional population of CGE-derived interneurons that express Reelin but not SST,[25] have a multipolar morphology, and have the electrophysiological features of rapidly adapting interneurons.

The mechanisms underlying the specification of CGE-derived interneurons are beginning to be understood. The *Gsx1* and *Gsx2* (*Gsh*) homeobox transcription factor genes are required for specification of the LGE and CGE. *Gsx2* conditional loss-of-function and gain-of-function analyses demonstrate its role in generating CR^+ bipolar interneurons.[45]

Gsx2 is upstream of *Acsl1* (*Mash1*), a basic helix-loop-helix (bHLH) transcription factor. While gain-of-function analysis (ectopic expression in the cortex) shows that *Acsl1* can function in regional or at least cell type specification,[61] loss-of-function analysis primarily shows *Acsl1*'s role in the regulation of differentiation. *Ascl1*$^{-/-}$ mutants exhibit (1) loss of early-born neurons and (2) premature differentiation of secondary progenitor (SVZ)-type cells that express the *Dlx* family of homeobox genes.[62,63] *Ascl1* mutants have reduced cortical interneurons, probably due to defects in the LGE/CGE and MGE.[62] *Ascl1* is required to express Delta1, a Notch ligand, and thus, through Notch signaling, it represses differentiation.[62–64]

The *Dlx* genes are downstream of both *Gsx2* and *Ascl1*.[61,65–67] There are four *Dlx* genes that are expressed in the developing forebrain: *Dlx1, Dlx2, Dlx5*, and *Dlx6*.[68] *Dlx1&2* and *Dlx5&6* form bigene clusters that are coordinately regulated by intragenic and extragenic enhancers.[69,70] Expression of the four *Dlx* genes follows a temporal sequence: *Dlx2, Dlx1, Dlx5*, and *Dlx6*.[71,72] *Dlx1&2* are coexpressed with subsets of *Gsx2* and *Ascl1* progenitor cells; loss of *Dlx1&2* function results in maintenance of *Gsx2* and *Ascl1* expression and failure to express *Dlx5&6*.[16,50,63] Furthermore, in the *Dx1&2*$^{-/-}$ mutant, the dorsal LGE/CGE is misspecified, expressing markers of the ventral cortex, such as *Id2*.[50,51] Extensive analysis has been performed in mapping the expression of nearly 100 transcription factors in the *Dlx1&2*$^{-/-}$ mutants.[50,51] This work identified *Dlx*-dependent and *Dlx*-independent pathways of basal ganglia development.

The dorsal LGE/CGE is particularly dependent on the *Dlx*-dependent pathway, where it promotes the expression of several other transcription factors, including *Arx, Atbf1, Brn4, Dlx5, Dlx6, Er81, Esrg, Meis1, Meis2, Oct6, Pbx1, Six3, Sp8, Tshz1*, and *Vax1*. The *Dlx*-independent pathway is more robust in the ventral LGE and septum, and includes transcription factors such as *Ascl1, COUP-TFI, Gsx2, Foxg1, Hes5, Lhx2, Otx2, Pax6, Sall3, Sox11*, and *Sp9*. Furthermore, *Dlx1&2* repress the expression of transcription factors that ordinarily are not expressed in the LGE, including

Gbx1 and *Otp*, or are weakly expressed in the LGE, such as *Gsx1*. This analysis sets the stage for a systematic analysis of the transcription factor hierarchy that regulates basal ganglia development. For instance, it predicts that *Dlx1&2* and *Ascl1* regulate distinct processes; as such, compound mutants should have a more severe phenotype. Indeed, basal ganglia patterning and differentiation are rudimentary in *Dlx1&2;Ascl1* triple mutants.[50,51]

Ascl1 and the *Dlx* genes are also expressed in, and regulate the development of, the MGE. The MGE is hypoplastic in the *Ascl1* mutants[62] and has migration defects in the *Dlx1&2* mutants.[16,18] The migration defects in the *Dlx1&2* mutants appear to reflect alterations in cell shape and survival.[73] The mutant cells prematurally extend neurites, and overexpression of the *Pak3* kinase appears to contribute to this phenotype.[73] However, *Dlx1&2* mutant cells exhibit many other molecular defects that are likely to contribute to their migration defect, including reduced expression of the *CXCR4* and *CXCR7* cytokine receptor genes.[50,51]

Unlike most *Dlx* mutants, *Dlx1*$^{-/-}$ mutants are viable postnatally. In the adult cortex, *Dlx1* expression is not detected in PV^{+} interneurons (unlike that of *Dlx5, Lhx6*, and *Sox6)* but is prominent in other interneuron subtypes, including CR^{+}.[36] *Dlx1* mutants have a selective postnatal loss of dendrite-innervating interneurons, including those expressing CR, SST, NPY, and reelin.[36]

As noted above, the *Dlx* genes have a high position in the transcription factor hierarchy that directs development of ganglionic eminence derivatives. For instance, *Arx* expression is strongly downregulated in *Dlx1/2*$^{-/-}$ mutants.[74] The *Arx* homeobox transcription factor is essential for MGE differentiation, including the expression of *Lhx8*(7) and *Gbx1*[75]; in its absence, there is a block in the migration of cells out of the MGE and a deficit in cortical interneurons.[75,76] Conditional mutation of *Arx* in the ganglionic eminences results in mice with reduced cortical interneurons and epilepsy that resembles that seen in humans with *Arx* mutations.[77]

The mechanisms controlling the final allocation of CGE-derived interneurons into specific layers of the cortex may be different from those regulating the distribution of MGE-derived cells, since CGE-derived interneurons tend to occupy superficial layers of the cortex independently of their time of neurogenesis.[25] Nevertheless, most CGE-derived interneurons are produced at relatively late stages of neurogenesis in the subpallium (i.e., at around E15.5), and neurons born at this stage in both the MGE and CGE primarily colonize superficial layers of the cortex.[25]

THE PREOPTIC AREA GENERATES SEVERAL CLASSES OF CORTICAL INTERNEURONS

Recent work indicates that a proportion of interneurons may derive from the embryonic POA[78] (Fig. 61–3), which, like the MGE, expresses *Nkx2-1*. In contrast, many of the cells that emerge from this structure, at least from its ventral domain (pPOA2), do not seem to express *Lhx6*.[6] To identify interneuron derivates of the POA,[78] investigators used a *Cre* line expressed from *Nkx5-1*, which is expressed in a small population of POA cells, but not in the MGE or in any other embryonic telencephalic structure. Fate mapping this population with *Nkx5-1-Cre* revealed that the POA is the origin of a small population of multipolar GABAergic cells with an electrophysiological profile of rapidly adapting interneurons.[78] Interestingly, these cells express NPY and/or Reelin (D. Gelman and O. Marín, unpublished observations), but none of the other markers of cortical interneurons, such as PV, SST, CR, or VIP.[78] As such, these cells closely resemble those recently identified to derive from the CGE,[25] suggesting that both the POA and the CGE may contribute to this population of cortical interneurons. The POA *Nkx5-1* lineage may contribute up to 4% of the entire population of cortical GABAergic interneurons. Furthermore, recent experiments show that the progeny of an additional distinct group of POA progenitor cells that are characterized by the expression of the transcription factor Dbx1 produce a small but highly diverse population of interneurons that primarily populate deep layers of the cortex. These results indicate that the POA is the origin of nearly 10% of the total population of cortical GABAergic interneurons.[79]

OVERVIEW

Most, if not all, mouse pallial interneurons are derived from three progenitor regions in the embryonic subpallium: MGE, CGE, and POA (Fig. 61–3). While there is controversy about this in the human, there is strong evidence that the ganglionic eminences are fundamental sources for pallial interneurons in all vertebrates. Development of these regions is regulated by multiple transcription factors. *Arx, Ascl1*, and *Dlx1,2,5&6* have roles in all of these regions, whereas MGE development is regulated by *Nkx2-1, Lhx6, Lhx8*, and *Sox6*, and CGE development is regulated by *Gsx2*. Future studies should aim at elucidating the molecular mechanisms downstream of these transcription factors that regulate cell fate specification and differentiation of specific interneuron subtypes. Furthermore, because many of the transcription factors that regulate early interneuron development are expressed in mature interneurons (e.g., *Arx, Dlx1,2,5&6, Lhx6, and Sox6*), it is likely that they have roles in controlling interneuron function and/or survival, such as *Dlx1*.[36] As interneuron defects that could contribute to epilepsy include abnormalities in their production, migration, differentiation, function, and survival, the mechanisms gleaned from basic studies should provide insights into the molecular, cellular, and histological underpinnings of epileptogenesis.

ACKNOWLEDGMENTS

We are grateful to members of the Marín and Rubenstein laboratories for helpful discussions and comments and to Susan Yu for help in formatting the chapter.

DISCLOSURE STATEMENT

Work in our laboratories is supported by grants to O.M.: Spanish Government SAF2008–00770 and CONSOLIDER CSD2007-00023 and to J.R. from the Nina Ireland, Simons Foundation, CIRM, NINDS, and NIMH. D.M.G. was the recipient of a Marie Curie International Incoming Fellowship.

Chapter 62

Genes in Infantile Epileptic Encephalopathies

Eric LeGuern

INTRODUCTION

Epileptic encephalopathies (EEs) are conditions in which cognitive, sensory, and/or motor function deterioration results mainly from epileptic activity.[1] This epileptic activity, which can be frequent and severe, as in Dravet syndrome (DS), or continuous, subcontinuous, or abundant in the interictal period, as in Landau-Kleffner or Lennox-Gastaut syndrome, is believed to have a deleterious impact on the developing and mature brain, interfering with cognitive functions at different times of life.[2]

Epileptic encephalopathies have numerous etiologies, which differ from one to another.[3] For example, various causes were identified in West syndrome, including damage and malformations of the brain and, more rarely, an inborn error of metabolism. However, at least one-third are cryptogenic, without any identifiable underlying cause.[2] When the more frequent etiologies have been excluded by extensive biological and neuroimaging examinations, the possibility of a genetic cause must be addressed. In contrast, DS is the archetype of the genetically determined EE, with a mutation identified in 60%–80% of patients. In this context, genetic testing has to be provided in order to confirm the clinical diagnosis and offer genetic counseling.

Patients with EE are mainly sporadic cases, making the differentiation between an acquired and a genetic cause a challenge. In rare cases, however, the recurrence of the same phenotype in a family strongly supports the involvement of a mutated gene. In addition, because of the high phenotypic variability of genetic diseases, EE can occur in a familial context of epilepsy. Indeed, 10% of patients with DS have a familial history of epilepsy or febrile convulsions.

In this chapter, we will focus on the genes responsible for infantile EEs as the main component of the clinical picture and not on those included in complex phenotypes encountered in metabolic diseases or in contiguity syndromes due to large chromosomal abnormalities. Indeed, the association of EE with a dysmorphy or extraneurological symptoms should lead to specific metabolic or cytogenetic investigations. In the first part of this chapter, we will review the genes involved in early infantile epileptic encephalopathies (EIEEs). Although the mutations in these genes are rare, their screening has to be integrated into a rational diagnostic strategy. It is particularly important to rule out genetic etiologies since there is a risk of the disease recurring in the family. In this review, we will focus on DS as an example of a genetically determined infantile EE to emphasize the difficulties and pitfalls that might be encountered in such diseases.

THE MONOGENIC FORMS OF EIEES

Geneticists have long known that a fraction of sporadic cases of patients with developmental defects could be due to a mutation in a single gene (monogenic forms). All modes of inheritance can be hypothesized, each of them being associated with particular features (Fig. 62–1). Three of them have already been reported in EIEEs: autosomal dominant (mainly de novo mutations), autosomal recessive, and X-linked.

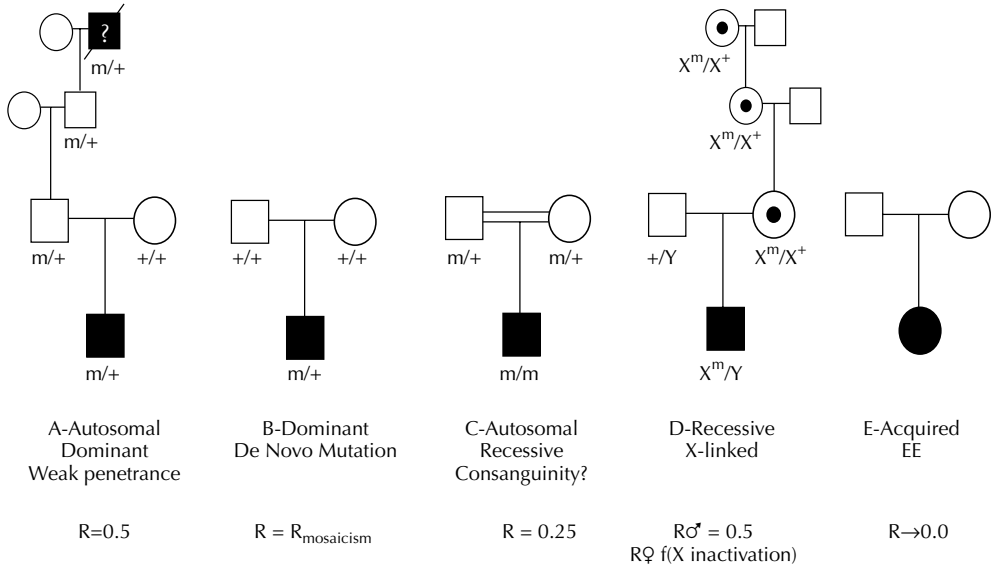

Figure 62–1. Different genetic conditions leading to isolated cases (example of an affected male). m: mutated copy of the gene; +: normal copy of the gene; X: X chromosome; Y: Y chromosome; R: risk of recurrence in the sibling. **A.** *Autosomal dominant inheritance* with weak penetrance: mutation carriers are asymptomatic over two generations, and the familial memory concerning the great-grandfather's phenotype is imprecise. **B.** *De novo mutation*: the mutation occurred in the spermatozoid or oocyte giving birth to the patient and is, therefore, absent from the parents' cells. This dominant mutation can affect a gene on the autosome (autosomal dominant) or the X chromosome (dominant X-linked). The risk of recurrence is generally low but not null: there is the risk of mosaicism (see the section "DS in a Familial Context of Epilepsy"). **C.** *Autosomal recessive inheritance*: this mode of inheritance is suspected when parents are related (see the text). **D.** *X-recessive inheritance*: hemizygous males are affected, and carrier females are mainly asymptomatic (pointed circle) or sometimes (about 10%) weakly or mildly affected. **E.** *Acquired EE:* In many EEs, this condition is the most frequent; the risk of recurrence is nearly null if the identified cause is avoided for future pregnancies.

Table 62–1 **Main Etiologies of Epilepileptic Encephalopathies (EEs)**

Epileptic Encephalopathies	Main Etiologies
Neonatal encephalopathies with suppression-bursts EEG pattern: – Ohtahara syndrome – Early myoclonic encephalopathies	*Brain damages*: malformations, perinatal anoxo-ischemic event *Metabolic diseases:* pyridoxine or pyridoxine-phosphate-dependent convulsions; hyperglycemia with ketosis; sulfate oxydase deficit; mitochondriopathies. *Genetic causes: ARX* (♂), *CG1*, and *STXBP1* genes. *Cryptogenic.*
– West syndrome – Lennox-Gastaut syndrome	*Brain damages:* acquired in the pre-, peri-, or postnatal period (60%–90% of cases): malformations, vascular insult, head trauma or infection. *Metabolic diseases:* mitochondriopathies, pyruvate dehydrogenase deficit, Menkes disease, phenylketonuria. *Genetic causes:* Down syndrome (21 trisomy); *STK9* (♀>>>♂), deletion 1p36, inv-dup chromosome 15 *Cryptogenic.*
EEs with continuous spike-waves in slow sleep Continuous spike-waves in slow sleep and related disorders (Landau-Kleffner syndrome, acquired frontal syndrome, and acquired opercular syndrome)	*Brain damages:* vascular insult (porencephalic cavity), leukomalacia, polymicrogyria, cortical dysplasia. *Mainly cryptogenic*
Migrating partial epilepsy	*Cryptogenic*
Dravet syndrome (severe myoclonic epilepsy of infancy)	*Genetic causes:* – *SCN1A* (de novo mutations and inherited mutations in a familial context of generalized epilepsy with febrile seizures plus [GEFS+]) – *PCDH19* (♀) (de novo mutations and inherited mutations in a familial context of epilepsy and mental retardation limited to females [EFMR]) – *GABRG2* (in a familial context of GEFS+)
Myoclono-astatic epilepsy with a poor outcome	*Genetic causes:* – *SCN1A* and *GABRG2*, both in a familial context of GEFS+ *Cryptogenic*
Rasmussen encephalitis	*Immune mechanisms suspected*

A genetic classification exists for genetically determined EIEE (OMIM: Online Mendelian Inheritance in Man: http://www.ncbi.nlm.nih.gov/omim): EIEE1 (OMIM 3008350) is part of the phenotypic spectrum of disorders caused by mutation in the *ARX* gene comprising a nearly continuous series of developmental disorders; EIEE2 (OMIM 300672), an X-linked disorder caused by mutation in the *CDKL5/STK9* gene (OMIM 300203); EIEE3 (MIM 609304), caused by mutation in the *CG1/SLC25A22* gene (OMIM 609302); EIEE4 (OMIM 612164), caused by mutation in the *STXBP1* gene (OMIM 602926); and EIEE5 (MIM 613477), caused by mutation in the *SPTAN1* gene (OMIM 182810). This genetic classification differs from the clinical classification of EEs based on type of seizures, age at onset, evolution, and prognosis[3] (Table 62–1). The articulation of clinical and genetic classifications will be a challenge in the coming years. The main problem is that the number of mutations identified in each gene is relatively small and is usually associated with a large phenotypic spectrum, making positive phenotype–genotype correlations difficult.

Dominant Mutations Responsible for EIEE Mostly Occur de Novo

THE DOMINANT MUTATIONS OF STXBP1 RESPONSIBLE FOR EIEE4

Dominant mutations of the *STXPB1* (also called *MUNC18-1*) gene, which is located on

chromosome 9q34.11, can cause sporadic EE. In autosomal dominant diseases, weak penetrance (the proportion of affected individuals among mutation carriers) can explain why parents are not affected, one of them being an asymptomatic carrier. However, for deleterious phenotypes like EEs, most sporadic cases are due to de novo mutations. In this case, it is hypothesized that mutations, which are eliminated from the population by their negative selective effect on patients' reproduction, are counterbalanced by the occurrence of neomutations. The mutation generally occurs in a gamete that will be involved later on in fecundation, the corresponding zygote being affected since the mutation is dominant. This is often the case for EE associated with mutations in *STXBP1*. The *STXBP1* gene contains 20 exons and encodes the syntaxin-binding protein 1. Forming a complex with the *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) protein syntaxin1, the STXBP1 protein might mediate synaptic vesicle fusion.[4] In accordance with this hypothesis, deletion of Munc18-1 (the paralog of *STXBP1*) in mice renders the brain synaptically silent, identifying Munc18-1 (*STXBP1*) as the currently most upstream essential protein in neurotransmitter release.[5] Saitsu et al.[6] first described mutations in this gene in 5 unrelated cases among 13 patients with EIEE with suppression-burst (Ohtahara syndrome) for whom the main causes of EEIE were excluded. Missense mutations, premature termination codons (nonsense mutations) and deletions were reported, leading to the conclusion that the disease is likely due to a haploinsufficiency (loss of function of the mutated copy of the gene) of *STXBP1*.[6,7] Early infantile epileptic encephalopathy 4 is most often associated with neurological signs such as mental retardation, which can be profound, and spastic paraplegia. The rarity of reports on mutations in this gene has to be underlined and raises the question of whether its systematic screening is indicated for patients with mental retardation and EIEE with suppression-burst.

SPTAN1, A NEWLY IDENTIFIED GENE RESPONSIBLE FOR SPORADIC EIEE5

Four patients presenting with early-onset EE with poor attention, severe hypomyelination, and reduction in cerebral white matter (EIEE5; 613477) were reported in 2008. On electroencephalography (EEG), one patient presented with suppression-burst and the other three had hypsarrhythmia. The authors stated that this phenotype could be considered a new clinical condition associated with early-onset West syndrome (WS).[8,9] A de novo 9q33.3-q34.11 microdeletion encompassing the *STXBP1* gene has been detected in one of these patients. Since no mutations of *STXBP1* were found in two of the remaining three patients (one was unavailable) , the authors suspected that another gene within the deletion might contribute to this severe phenotype. *SPTAN1* encoding alpha-II spectrin, which is involved in cell proliferation via arrest at cell cycle phase G1 and in myelination in zebrafish,[10] was localized in the deletion. In the two tested subjects, an in-frame 3 bp deletion and a 6 bp duplication in *SPTAN*, likely resulting in the synthesis of an abnormal protein, were identified at the initial nucleation site of the alpha/beta spectrin heterodimer.[9] *SPTAN1* was further screened in six unrelated individuals with WS and hypomyelination, but no mutations were found. In vitro functional expression studies suggested a dominant-negative effect of the two identified mutations on spectrin heterodimer stability, as well as perturbation of the axon initial segment.

GC1/SLC25A22, a Gene Responsible for Rare Autosomal Recessive (AR) EIEE with a Suppression-Burst Pattern

In Europe, the vast majority of families with an AR disease have a single affected child because of the small number of siblings. However, for rare diseases, consanguinity has to be searched for since it increases the probability of encountering two mutated copies of a gene in the same individual. This was the case for recessive mutations of *GC1* (Glutamate carrier 1; also called *SLC25A22* for solute carrier family 25) identified in patients with EIEE3 (EIEE3; OMIM 6093304). This gene (OMIM 609304) was first mapped on chromosome 11p15.5 in a consanguineous Arab Muslim family from Jerusalem. Patients presented with neonatal intractable

seizures associated with a suppression-burst EEG pattern and hypotonia. Brain atrophy was later diagnosed on a computed tomography (CT) scan (at about 3 years of age).[11] The missense mutation p.Pro206Leu was subsequently identified at the homozygous state in the affected members of this family in the *GC1/SLC25A2* gene, which was located within the candidate genomic region. A second mutation, p.Gly236Trp (G236W), which confirmed the responsibility of the *GC1* gene in this EE, was more recently identified in an Algerian boy also born to related parents with a severe encephalopathy and without any psychomotor acquisition.[12] *GC1/SLC25A22* encodes one of the two mitochondrial glutamate/H^+ symporters, the other being *SLC25A18*.[13] In vitro functional expression assays of G236W-mutated *GC1* cDNA in *Escherichia coli* showed that the mutant protein was correctly inserted into the liposomal membrane but had no functional transport activity, confirming the deleterious effects of the mutation on the protein function.[12]

X-Linked EEs

X-linked heredity is characterized by a difference of phenotype related to gender. The recessive X-linked mode of inheritance is most often characterized by a familial context, with affected males being born to asymptomatic female carriers. The transmission of the mutation by females over several generations leads to isolated affected males. For severe diseases, sporadic cases can also occur by de novo mutation, such as in Duchenne muscular dystrophy, in which one-third of affected males are sporadic cases due to de novo mutations. In dominant X-linked inheritance, heterozygous females can be affected, but generally less severely, in terms of age at onset or prognosis, compared to hemizygous males (i.e., with a single mutated copy of the gene). In some diseases, the presence of the mutations at the hemizygous state in males is even lethal, with the disease consequently being restricted to females. There is also an intermediate condition in which only a small fraction of affected males are born. They usually have a profoundly deleterious disease with a very poor prognosis. All these possibilities will be illustrated in the following examples of X-linked EE.

MUTATIONS IN CDKL5/STK9 CAUSE EE, PREFERENTIALLY IN FEMALES

The *CDKL5/STK9* gene was first incriminated in two unrelated girls with infantile spasm syndrome (ISSX2; OMIM 300672) associated with de novo balanced X-autosome translocations, t(X;7)(p22.3;p15) and t(X;6)(p22.3;q14), respectively. In both cases, the genomic rearrangements disrupted the *CDKL5/STK9* gene.[14] Although *CDKL5/STK9* was submitted to X-inactivation in normal female somatic cells, the expressed protein was not functional in the two patients because of a preferential inactivation of the normal X.[14] Indeed, the inactivation of the translocated X might have diffused to the translocated autosome fragment, leading to a monosomy of the corresponding genomic region, which is lethal.

Mutations in *CDKL5* were later on identified in female patients with atypical Rett syndrome.[15] These patients clearly had some features of Rett syndrome, such as deceleration of head growth, stereotypies, and hand apraxia. In contrast, some signs were absent, such as a period of nearly normal development followed by regression with loss of acquired fine finger skill in early childhood and intensive eye communication, and the characteristic evolution of Rett syndrome on EEG. In the mouse brain, Weaving et al. showed that Cdkl5 expression overlapped with that of Mecp2 (OMIM 300005), which is mutated in the classic Rett syndrome,[16] leading Tao et al. to postulate that these two genes may be involved in a common pathogenic pathway.[15]

The characteristics of the epilepsy associated with *CDKL5* mutations were defined by Bahi-Buisson et al., who showed in a retrospective study of 12 female patients with *CDKL5* mutations that the epilepsy course had three successive stages: Stage I: early epilepsy (onset at 1–10 weeks) with a normal interictal EEG despite frequent convulsive seizures; Stage II: EE with infantile spasms and hypsarrhythmia; stage III: at the age of examination (3–19 years), seven patients were seizure free and six had developed refractory epilepsy with tonic seizures and myoclonia.[17] Moreover, early epilepsy with a normal interictal EEG (stage I)

and severe hypotonia seem to be key clinical features in identifying patients with *CDKL5* mutations.[18]

EES AS PART OF THE PHENOTYPIC SPECTRUM ASSOCIATED WITH ARX MUTATIONS

Mutations in *ARX* were first identified in patients with three different phenotypes, including X-linked lissencephaly with abnormal genitalia (XLAG; OMIM 300215),[19] nonsyndromic X-linked mental retardation (MRX),[20] and X-linked infantile spasms (ISSX; OMIM 308350).[21] The phenotypic spectrum associated with *ARX* mutations includes severe EEs with or without brain malformations. Shoubridge et al. recently reviewed families with *ARX* mutations reported in the literature.[22] Among the 97 families identified, Ohtahara syndrome, X-linked myoclonic epilepsy, and X-linked infantile spasms (WS) were reported in 1, 1, and 12 families, respectively. Other syndromes including seizures were also identified, including Partington syndrome (intellectual disability with dystonic movements, ataxia, and seizures), mental retardation with tonic seizures with dystonia, and infantile epileptic-dyskinetic encephalopathy, in 7, 1, and 4 families, respectively.

The *ARX* gene, which contains five coding exons (GenBank: NM_139058.2: OMIM 300382), maps to Xp22 and encodes a 562 amino acid mature protein, which is expressed predominantly in the fetal and adult brain, testis, skeletal muscle, and pancreas.[23–25] ARX is a paired-type homeobox protein that contains four polyalanine (PolyA) tracts, a homeodomain, and a conserved C-terminal aristaless domain. Male *ARX*-deficient mice have abnormal differentiation and deficient tangential migration of GABAergic (gamma-aminobutyric acid) interneurons in the ganglionic eminence, neocortex, and hippocampus and abnormal testicular differentiation.[19]

All types of mutations—missense, nonsense, insertions, and deletions—have been reported in *ARX*. It is interesting to note that a phenotype–genotype correlation has recently emerged:[22,26] nonmalformative syndromes including EE[27] are mostly due to expansions of polyalanine tracts located in the N-terminal fragment of the protein, whereas syndromes with brain malformations are mostly associated with mutations leading to a premature termination codon (PTC) (nonsense or splice mutations) or deletions encompassing several exons. These mutations lead to a loss of function by haploinsufficiency since the mRNAs with PTC are mainly destroyed in the cells by the nonsense-mediated mRNA decay (NMD) system.[28] Very recently, Kato et al. reported two families, comprising six males with Ohtahara syndrome in two generations, in which frameshift mutations in the terminal exon of the *ARX* gene, Ala524fsX534 and Glu536fsX672, were identified. It is noticeable that the PTC mutations localized in the last exon of genes escape the NMD system and most often cause the synthesis of a truncated protein. Interestingly, two patients developed WS, and one of these later developed Lennox-Gastaut syndrome. The authors concluded that the analysis of *ARX* should be considered in sporadic or familial male patients with Ohtahara syndrome.[29]

SRPX2 IS RESPONSIBLE FOR ROLANDIC SEIZURES WITH SPEECH APRAXIA AND MENTAL RETARDATION

Roll et al. reported a three-generation French family with oral and speech dyspraxia (OSP), rolandic seizures (RS), and mental retardation. Eight individuals had OSP, RS, and mental retardation and three had only OSP and mental retardation without seizures. Epileptic patients had the EEG hallmark of RS (centrotemporal spikes that tend to occur in clusters and are strongly activated during sleep) during the active phase of the epileptic seizures.[30] A whole-genome scan was performed, and the gene was mapped to chromosome Xq. In the 20 cM large candidate interval, a missense mutation, N327S, was identified in the *SRPX2* gene. SRPX2 is a secreted sushi-repeat-containing protein expressed in neurons of the human adult brain, including the rolandic area. The disease-causing mutation resulted in gain of glycosylation of the secreted mutant protein.[30] Roll at al. also described a 12-year-old boy who presented with focal seizures beginning with numbness in the fingers of the right hand and leg and a sudden fall. Neurological examination revealed clonus at both knees and generalized hyperreflexia with an equivocal right plantar response. Neuropsychological examination at age 15 years showed low average to average intellect with weakness in mathematical ability.

The EEG showed left centrotemporal epileptiform activity with a rolandic horizontal dipole. The magnetic resonance imaging (MRI) scan showed bilateral posterior perisylvian polymicrogyria (OMIM 300388), more severe on the left and extending back to involve the parieto-occipital regions. Two of the boy's maternal aunts had mild mental retardation, whereas his mother and another aunt were of normal intelligence. In this family, a second mutation was identified within the first sushi domain of *SRPX2*. These data suggest that *SRPX2* may play a role in the development and/or function of the perisylvian region, which is critical for language and cognitive development. Interestingly, the orthologous *Srpx2* gene is not expressed during murine embryogenesis, suggesting that this gene is involved in the development and functioning of language areas in human cortex.[30]

A GENETICALLY DETERMINED INFANTILE EE: DRAVET SYNDROME (OR SEVERE MYOCLONIC EPILEPSY OF INFANCY)

In contrast to the previously described EE, a large proportion of patients with DS have mutations in known genes, leading to their systematic testing if the clinical context is suggestive.

Clinical Context

Dravet syndrome (DS), previously called *severe myoclonic epilepsy of infancy* (SMEI), is an intractable epileptic syndrome characterized by onset of seizures during the first year of life in a child with normal psychomotor development and no brain damage (the MRI scan is normal at onset). Seizures are clonic or tonic-clonic and may be generalized or unilateral, with either side of the body being involved. They are mainly febrile and often prolonged, resulting in convulsive status epilepticus. Subsequently, children present with myoclonic jerks, absences, and focal seizures. Psychomotor development is delayed from the second year of life, and ataxia may appear. Although these seizures are severe, the interictal EEGs remain free of spikes during the first years of the disorder. However, generalized spike waves with photosensitivity and focal abnormalities occur later on.[31]

De Novo Mutations in *SCN1A* Are the Main Cause of DS

A common genetic predisposition between DS and febrile seizures was first suggested by Benlounis et al..[32] Furthermore, Singh et al. considered DS to be a severe phenotype of the generalized epilepsy with febrile seizures plus (GEFS+) familial context, particularly because of the presence of patients with DS in families with GEFS+ (OMIM 604233).[33] Generalized epilepsy with febrile seizures plus is a variable autosomal dominant epileptic condition that also associates febrile and afebrile seizures. Affected family members present with phenotypes ranging from isolated febrile seizures to various idiopathic generalized epilepsy subtypes (epilepsy with grand mal seizures, childhood absence, or juvenile myoclonic epilepsy) or can remain asymptomatic. The outcome is usually benign, and patients are sensitive to classical antiepileptic treatments.[34] However, family members can occasionally experience focal seizures, be severely affected and/or pharmacoresistant, and even present with DS.[33] This common genetic background was confirmed by Claes et al., who identified seven de novo mutations in *SCN1A*, which had previously been involved in GEFS+,[35] in seven sporadic cases of DS.[36] The vast majority (six of seven) of these mutations led to a premature termination codon.[36] More recent studies have confirmed the high frequency of mutations of *SCN1A* in sporadic DS.[37–42]

DIFFERENT TYPES OF MUTATION IN SCN1A CAUSE DS

All types of mutations have been identified in the coding sequence of the *SCN1A* gene in patients with DS: missense, nonsense, and splice-site mutations, small deletions and insertions. The mutations are located all along the *SCN1A* gene. Missense mutations are the most common mutation type identified (about 40%).[42] The main remaining mutation

types (nonsense, splice-site, and frameshift mutations) introduce PTCs into the mRNA, which are probably recognized and degraded via the NMD system. This hypothesis is compatible with the effects of the other mutation types detected, including alteration of the initiation codon and the microdeletions that delete essential regions of the proteins, introduce PTC, or delete the whole gene in the heterozygous state. Indeed, during the past few years, many techniques have been developed in order to detect genomic rearrangements such as deletions or duplications: quantitative PCR (QPCR),[43] multiplex ligation-dependent probe amplification (MLPA),[44] and microarrays.[45] The analysis of series of patients without point mutations with these methods has identified several heterozygous rearrangements in *SCN1A*, variable in length and breakpoints and ranging from a single exon to the whole gene.[42,46,47] Deletion of the whole gene was the most common rearrangement found, supporting haploinsufficiency as the main molecular mechanism responsible for DS. Analysis of the parents showed that most deletions occurred de novo. The nearby genes comprised in the deletion, including other genes encoding voltage-gated sodium channels (*SCN7A* and *SCN9A*), differed among patients, without evident variability of the phenotype.[42] However, patients with very large deletions could have consistent dysmorphic features, including ear abnormalities, microcephaly, micrognathia, and brachysyndactyly, likely related to the size of the deletion and to deletions of genes other than *SCN1A*.[48]

In spite of many functional studies, it remains unclear how missense mutations can cause a clinical phenotype indistinguishable from that of PTC mutations or whole-gene deletion and why some missense mutations are associated with a severe phenotype, such as DS, and others with pharmaco-sensitive epilepsies, as in GEFS+ families. Kanai et al. suggested a preferential location of the missense mutations leading to DS in the S5 and S6 segments and the S5–S6 intracellular boucle, which together form the "pore" of the Nav1.1 channel.21.[49] Depienne et al. reported that most missense. mutations causing DS affected highly conserved amino acids located in ion-transport sequences and resulted in chemically dissimilar changes in amino acid classes. However, these mutations were not preferentially located in S5–S6 segments, in contrast to the previous report[42] (Fig. 62–2).

The proportion of patients with *SCN1A* mutations is highly variable in reported studies, ranging from 33%[39,50] to 80%–100%.[40,51,52] These discrepancies may be due to the sizes of the series, the methods of screening, and use of different clinical criteria to define DS. Supporting this hypothesis, the proportion of positive patients is higher in DS using strict criteria than in epileptic syndromes closely related to DS including intractable childhood epilepsy with generalized tonic-clonic seizures (ICEGTC) or borderline SMEI (SMEB).[51,53] Considering only the patients with typical DS, approximately 20% of them do not have mutations in *SCN1A*, even when microrearrangements have been excluded.[41,42] In addition,

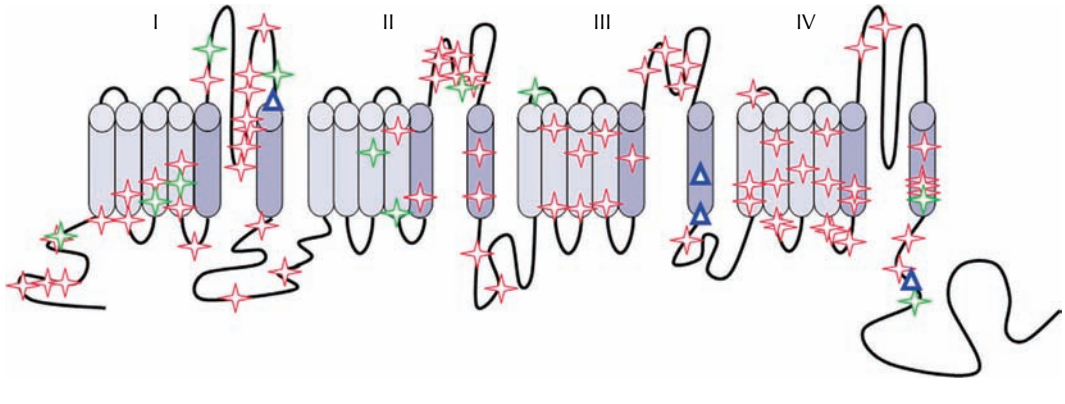

Figure 62–2. Schematic representation of the missense mutations and in-frame deletions in the Nav1.1 protein. Each star represents a missense mutation. Red stars: mutations identified in a single patient; green stars: recurrent mutations; blue triangles: inframe deletions. From ref. 42.

recent studies have established that rare pathogenic mutations in *SCN1A*, some of which are de novo, can also be identified in other infantile EEs, such as cryptogenic generalized epilepsies, cryptogenic focal epilepsies, or infantile spasms.[50,53,54] This extension of the clinical spectrum related to *SCN1A* has called into question the initial concept of DS, because neither clinical nor genetic criteria are sufficient to delimit accurately the various syndromes.

DS IN A FAMILIAL CONTEXT OF EPILEPSY

Few patients with DS have a parent or another relative with a milder epileptic phenotype. Depienne et al. showed that mutations inherited from an asymptomatic or mildly affected parent were identified in 10% of the DS patients. Mosaicism (the mutation is present only in a fraction of germinal [germinal mosaicism] or nongerminal [somatic mosaicism] cells) was the main event associated with inherited *SCN1A* mutations in DS patients (about 70%). Parental mosaicism in DS was not a rare situation since it was found in at least 7% of families with an *SCN1A* mutation. When the level of somatic mosaicism was high, the parent could present with seizures, although he or she was less severely affected than his or her child who carried the mutation in all cells. The clinical status of the mosaic parent appeared to be somehow correlated with the amount of the mutation in his or her blood cells, although this correlation was not strict.[55]

Nevertheless, mosaicism is not the only situation accounting for inherited mutations, as DS can also be encountered in the context of GEFS+ families. In that case, *SCN1A* missense mutations segregating in the family are associated with wide phenotypic variability, with DS at the severe end of the spectrum.[33] Distinguishing mosaicism from de novo constitutional mutations or other situations is of particular concern in disorders that are frequently sporadic, such as DS, in order to give appropriate genetic counseling.[56] The risk of recurrence is, therefore, not null when the mutation is apparently de novo, which should be taken into account for genetic counseling.

A question that remains is whether *SCN1A* neomutations causing DS act through the same pathophysiological mechanisms as mutations found in GEFS+. Basically, mutations associated with clear loss of function are always associated with DS, except in one family recently described by Suls et al., in which a microdeletion of *SCN1A* segregated with a very variable phenotype in a four-generation family.[57] In mosaic patients, the mutations with a loss-of-function effect can be associated with milder phenotypes reminiscent of those seen in GEFS+ if present in only some neurons. Conversely, missense mutations found in GEFS+ are generally associated with mild epileptic phenotypes but can occasionally cause DS. From a mechanistic point of view, it is likely that the pathophysiological pathways are different: de novo mutations would be sufficient to cause DS, whereas missense mutations associated with GEFS+ would not, and additional genetic or nongenetic factors would be necessary to cause DS in the latter case.

DS-Like Syndrome in Females Associated with Mutations in the *PCDH19* Gene

At least 20% of patients with DS are negative for mutations or rearrangements in *SCN1A*. In addition, rare mutations in *GABRG2* have been described in cases of DS belonging to GEFS+ families[58] but were not demonstrated in 29 sporadic cases.[38] These findings suggest that DS could be genetically heterogeneous (i.e., other genes could be involved in DS).

MUTATIONS IN PCDH19 MAINLY AFFECT FEMALES WITH A DS-LIKE SYNDROME

In order to identify new genes responsible for the disorder in *SCN1A* mutation-negative patients, Depienne et al. screened 41 patients with DS for microrearrangements with high-density single nucleotide polymorphism (SNP) microarrays. Interestingly, a hemizygous deletion on chromosome Xq22.1, encompassing the *PCDH19* gene, was identified in one male patient. To confirm that *PCDH19* was responsible for a DS-like syndrome, its coding region was sequenced in 73 additional *SCN1A* mutation-negative patients. Different point mutations (four missense and five truncating mutations) were identified in 11 unrelated female patients (15%). The spectrum

of mutations includes nonsense mutations and small deletions/insertions introducing a frameshift, as well as missense mutations affecting highly conserved amino acids in the protein, predominantly in the extracellular domain, which is presumably involved in cell–cell interaction. These mutations are therefore predicted to result in a loss of function of the mutated allele.[59]

Protocadherin 19 is a 1148 amino acid transmembrane protein belonging to the protocadherin delta2 subclass of the cadherin superfamily, which is highly expressed in neural tissues and at different developmental stages.[60–63] The precise functions of the protein remain unknown. However, delta protocadherins were reported to mediate cell–cell adhesion in vitro and cell sorting in vivo, and could regulate the establishment of neuronal connections during brain development.[64,65]

Patients with *PCDH19* mutations could present with clinical features similar to those of patients with *SCN1A* mutations, including the association of early febrile and afebrile seizures, seizures occurring in clusters, developmental and language delays, behavioral disturbances, and cognitive regression. There were, however, slight but constant differences in the evolution of epilepsy, including fewer polymorphic seizures (in particular, rare myoclonic jerks and atypical absences) in patients with *PCDH19* mutations. These results show that *PCDH19* plays a major role in epileptic encephalopathies, with a clinical spectrum overlapping that of DS.[59]

PCDH19-LINKED EPILEPSIES: AN UNUSUAL MODE OF INHERITANCE

Mutations in *PCDH19* were first reported to cause epilepsy and mental retardation limited to females (EFMR). The clinical features of EFMR, unlike those of DS, are highly variable, even in members of the same family: onset of seizures occurs between 6 and 36 months, and affected females present with a combination of febrile and afebrile seizures of various types and a variable degree of psychomotor delay and cognitive impairment, ranging from mild to severe mental retardation.[66] Dibbens et al. reported *PCDH19* mutations in six large families and one small family with two affected sib pairs.[60] All the patients were family members who were, for the most part, already adults at the time of examination, and appeared socially integrated in that most of them were married and had children.

PCDH19-related EE therefore mainly affects females. In a large series of *PCDH19* mutation-positive index cases in whom inheritance could be assessed, half of the mutations occurred de novo and half were inherited from fathers who were healthy, had no cognitive impairment, and had never had febrile seizures or epilepsy[59] . This heredity is very different from the X-linked mode of inheritance encountered for *ARX* or *CDKL5* mutations since, only the heterozygous females with *PCDH19* mutation are affected, whereas the hemizygous males are asymptomatic and spared (Fig. 62–3).

Several mechanisms have been suggested to account for the unusual mode of inheritance observed in *PCDH19*-linked epilepsy, one of which is cellular interference, a mechanism reminiscent of metabolic interference.[60,67,68] This concept postulates that random inactivation of one X chromosome in mutated females generates tissue mosaicism (i.e., coexistence of *PCDH19*-positive and *PCDH19*-negative cells), which would be pathogenic by altering cell–cell interactions; normal individuals and mutated males, who are homogeneous for *PCDH19*-positive or *PCDH19*-negative cells, respectively, would not develop the disease (Fig. 62–4). The identification of an affected male who was mosaic for the *PCDH19* deletion in his fibroblasts, and therefore had *PCDH19*-positive and *PCDH19*-negative cells in this tissue, strongly supports the hypothesis of cellular interference as the main pathogenic mechanism associated with *PCDH19* mutations.[59]

PROSPECTS AND CONCLUSION

Identification of a Mutation Leads to Genetic Counseling

In the vast majority of EEs, genetic causes are very rare. However, after the most common, nongenetic causes are excluded, it is crucial to perform appropriate genetic analyses, depending on the detailed phenotype of the patient, even if they are time-consuming and costly, since the identification of a mutation raises the possibility of a risk of recurrence in the family. A scrupulous reconstruction of the family

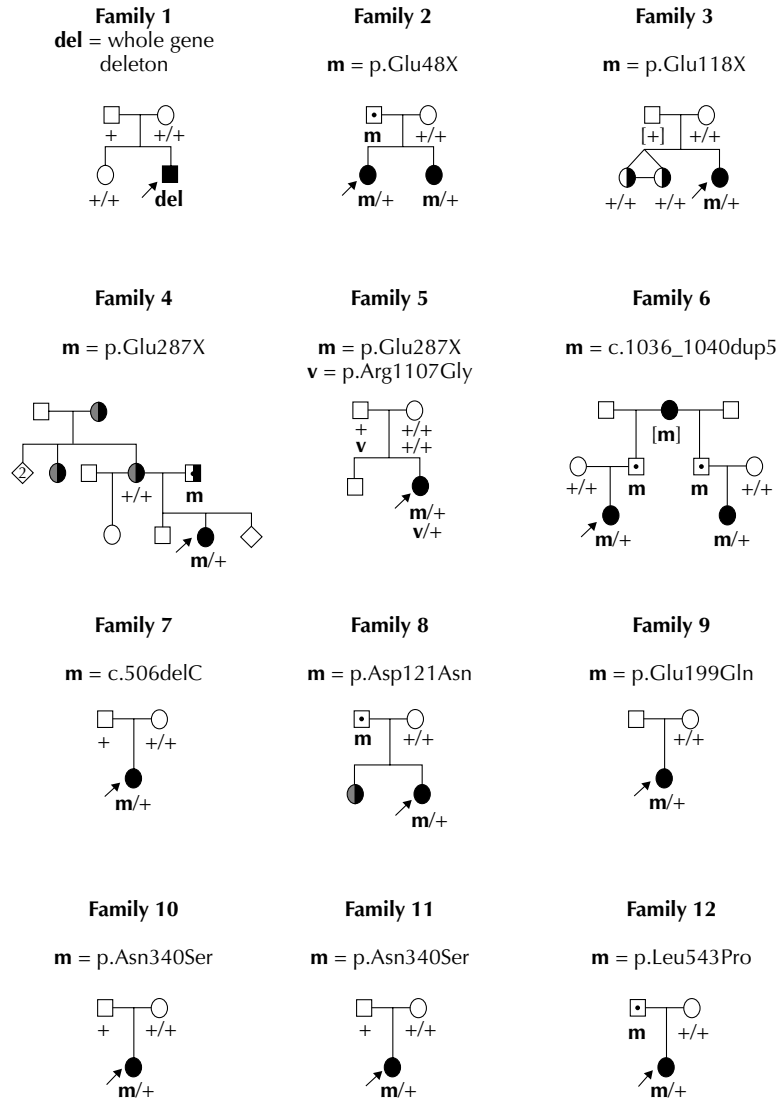

Figure 62–3. Segregation analysis of the *PCDH19* deletion and point mutations in 12 families. del/+, m/+ and v/+ denote individuals heterozygous for the deletion, mutation, or variant, respectively; +/+ denotes individuals carrying homozygous wild-type alleles. Squares represent males, circles females; filled black symbols: patients diagnosed as having DS; right black half: cognitive delay or impairment; left gray half: adolescence-onset idiopathic epilepsy. Dots in the middle of the squares indicate unaffected mutation carriers. The arrows indicate the index cases. From ref. 59.

history has to be made and a pedigree drawn in order to determine the most probable mode of inheritance.

For AR diseases like EIEE3 associated with *GC1* mutations, recurrence in the family is high (25%) and genetic counseling should be provided. The mutation(s) must first be identified in the index case. If the parents are related, we would expect to identify a mutation at the homozygous state. The analysis of the parents' DNA is important to determine whether the mutation is on both copies of the gene in the affected child. However, in some rare cases, only one parent carries the identified mutation, the other having a deletion encompassing the exon bearing the mutation in his or her spouse. If the parents are not related, patients most often have two different mutations in the *GC1* gene; they are then called *compound heterozygotes*. The study of the parents' DNA

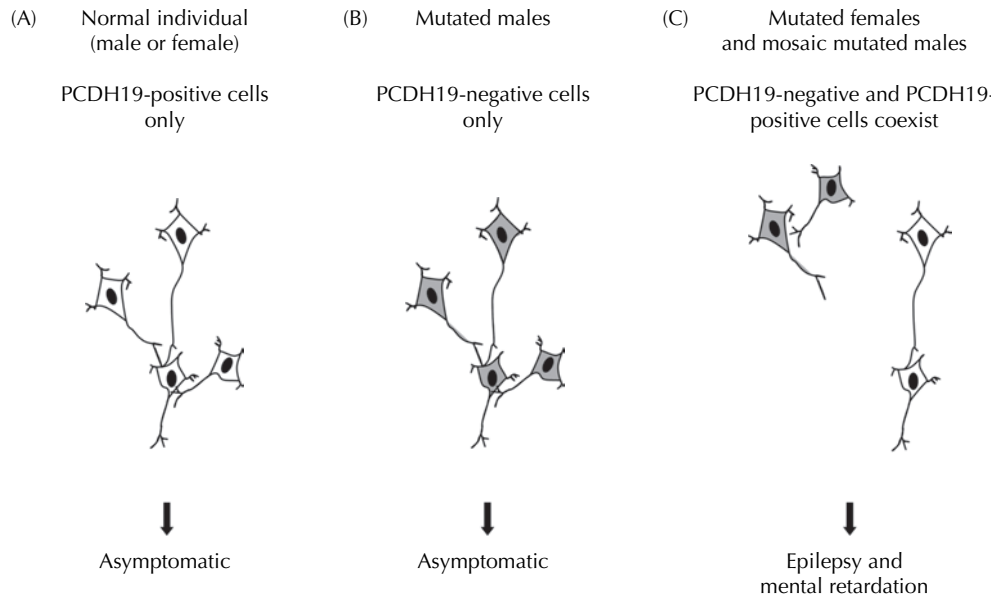

Figure 62–4. Schematic illustration of the cellular interference mechanism associated with *PCDH19* mutations. **A.** In normal individuals characterized by a homogeneous population of *PCDH19*-positive cells, neurons are able to form normal neuronal networks. **B.** In male patients with a *PCDH19* mutation, hemizygosity leads to a homogeneous population of *PCDH19*-negative cells; in this condition, neurons preserve the ability to form normal neuronal networks. This hypothesis implies that there is a compensatory mechanism with the expression of other protocadherins permitting the formation of functional neuronal networks. **C.** In heterozygous mutated females, random X inactivation leads to a functional mosaicism with the coexistence of two *PCDH19*-positive and *PCDH19*-negative cell populations. These two cell populations cause divergent cell sorting and migration (due to attractive or repulsive interactions) and lead to abnormal neuronal networks. Somatic mosaicism in mutated males gives rise to the same pathological situation. The precise mechanisms by which the neuronal networks are altered are still unknown. From ref. 59.

is also used to exclude the possibility that both mutations are on the same copy of the gene. This needs to be verified before a prenatal diagnosis can be proposed.

Several genetically determined EEs are due to de novo mutations, including DS associated with mutations in *SCN1A* or *PCDH19* and early infantile EE due to mutations in *CDKL5/STK9* or *STXBP1*. Genetic counseling in these cases is a very delicate issue since the possibility of germinal mosaicism has to be taken into account. Germinal mosaicism may be suspected in families in certain contexts: (1) the mutation can be detected at a low level in the blood cells' DNA of one parent (the mutation can be detected by direct sequencing when its amount is greater than 20% in DNA from blood cells) or (2) at least two children are affected and carry the same mutation, even if the mutation is not detected in the parent's blood. Importantly, germinal mosaicism or somatic mosaicism undetectable from the blood may be missed in the absence of a second affected child, which means that the possibility of mosaicism should be consider for every sporadic de novo case. The frequency of mosaicism in DS was found to be 7% in a large cohort of patients with *SCN1A* mutations, but this might only be the tip of the iceberg.[55] The risk of recurrence is therefore not null and is difficult to evaluate when the mutation is apparently de novo, which raises the question of prenatal diagnosis in some cases.

The last condition most often concerns autosomal dominant diseases with phenotype variability and is illustrated by the occurrence of DS in families with GEFS+. In this case, the parent with a mild and benign phenotype transmits a *SCN1A* missense mutation to his or her child, who then presents with severe, intractable epilepsy and mental retardation. The occurrence of a DS phenotype has to be related to this mutation but its severity is likely determined by other, as yet unidentified factors, often called *modifying factors*, which can be environmental or genetic. Until these

factors can be identified, the question of the recurrence of this severe phenotype must remain open.

Recent Strategies to Identify New Genes Responsible for EEs

We are only just beginning to appreciate the importance of genetic EE and the consequences of the identification of a mutation in a family in terms of diagnosis and genetic counseling. From a fundamental point of view, the identification of a new gene leads to the deciphering of a new pathological mechanism and may open new therapeutic avenues. Advances in human molecular genetics are revealing the great genetic heterogeneity of infantile EEs and the great variability of their pathological pathways. Moreover, one may suspect that the genes already identified represent only a small fraction of the genes involved in these disorders that can be considered as development disorders. Identifying these genes remains challenging. Nevertheless, the recent technological leap due to the development of next-generation sequencing, allowing the sequencing of the whole genome or coding sequences (exome) of a genome, opens new perspectives not only for monogenic but also polygenic forms of EEs.

IDENTIFYING NEW GENES RESPONSIBLE FOR MONOGENIC FORMS OF EES

Identifying genes in sporadic EEs is difficult since the classical genetic strategies based on the study of large families are not possible. However, alternative genetic approaches are available; they are various and are related to the context of the disease:

1. As for *ARX*, *CDKL5/STK9*, and *SRPX2*, EE can be part of a complex phenotype with or without brain abnormalities. The strategy of screening the responsible gene in series of patients with isolated EE of the same type can be fruitful. Some patients with isolated defined EEs, even if they were rare, had mutations in these genes.
2. The study of GEFS+ and DS highlights the possibility of a gene identification strategy based on the detailed description of syndromes: the occurrence of DS in families with GEFS+ and the high sensitivity to fever in both conditions led to DS being considered as part of the GEFS+ phenotypic spectrum. Claes et al.[36] therefore tested *SCN1A*, which had first been incriminated in GEFS+, as a candidate gene in sporadic patients with DS and identified the first de novo mutations of *SCN1A*.
3. Genomic rearrangements have been identified in most of the genes known to be responsible for infantile EE. Comparative genomic hybridization (CGH) and SNP microarrays have enabled the entire genome to be screened at various resolutions. The detection of a de novo rearrangement in a patient points to a candidate region in which the causative gene is localized. The candidate region often contains several genes, and the involvement of one particular gene needs to be confirmed by the identification of point mutations located in the coding region of this gene in patients with the same phenotype. As we saw in previous sections, this strategy was applied to identify the *SPTAN1* and *CDKL5/STK9* genes. When the rearrangement is inherited from an asymptomatic parent, its causality in the patient's phenotype is more difficult to prove, as it may correspond to a benign copy number variant (CNV) or copy number polymorphism (CNP). However, it cannot be excluded that a recessive mutation in a gene of the region has been transmitted on the undeleted remaining copy by the other parent. Association of an inherited CNV with a phenotype in more than one patient would argue in favor of such an autosomal recessive pathology and lead to the sequencing of candidate genes in the regions concerned.

IDENTIFYING SUSCEPTIBILITY GENES IN POLYGENIC-DETERMINED EES

Since the vast majority of cases of EE are sporadic, the most frequent inheritance of EE is usually thought of as being complex or multifactorial, resulting from the interaction between several genes (susceptibility genes)

and environmental factors. The identification of these genes requires nonparametric analyses (genetic analyses that do not depend on parameters of monogenic diseases as the mode of inheritance, penetrance, rate of phenocopies, etc.). For these analyses, three conditions are needed: (1) a large number of affected individuals (at least several hundred) and a similar number of controls well matched for age, sex, and ethnic background; (2) previous exclusion of monogenic forms; and (3) low genetic heterogeneity of the population (great genetic heterogeneity could mask or dilute the effect of individual susceptibility genes). These conditions are difficult to obtain in EEs, which are rare diseases affecting children (with the problem of constituting a control group) with well-known etiological heterogeneity (Table 62–1). However, such a strategy has already been used, in which Landau-Kleffner syndrome, continuous spike-and-waves during sleep syndrome, benign childhood epilepsy with centrotemporal spikes, and benign rolandic epilepsy were considered to be part of a single continuous spectrum of disorders.[69] The centrotemporal spikes (CTS) were considered to be an endophenotype determined by a common set of susceptibility genes, the different phenotypes being determined by other susceptibility genes and/or environmental factors. A genome-wide study showed a linkage of the CTS endophenotype to 11p13, especially with polymorphic markers in the *ELP4* (Elongator Protein Complex 4) gene.[70] The yeast Elp4 protein is one of the six subunits of *Elongator*. The *Elongator* complex is involved in transcription of several genes that regulate the actin cytoskeleton, cell motility, and migration. These functions are crucial in the nervous system for nerve cell growth cone motility, axon outgrowth and guidance, neuritogenesis, and neuronal migration during development.[71,72] This gene is a good candidate-by-function. It remains to identify functional variants in the vicinity of the *ELP4* gene to confirm its genetic involvement. This strategy could be applied to other clinical or EEG traits.

In conclusion, in the past 10 years, a great amount of genetic data has accumulated, updating our knowledge of the etiologies and pathophysiological mechanisms of infantile EEs. We can expect this chapter to become incomplete in the very next future and hope that all of this basic science will soon open new therapeutic avenues to cure these devastating disorders.

Chapter 63

Developing Models of Aristaless-Related Homeobox Mutations

Eric D. Marsh
Jeffrey A. Golden

INTRODUCTION

Mutations in the Aristaless-related homeobox gene (*ARX*) have been causally linked to a variety of neurological conditions, particularly infantile spasms syndrome. *ARX* is a developmentally regulated homeobox transcription factor with expression both in the ganglionic eminence and in the cortical ventricular zone early in development.[1] Postnatally, the expression pattern is restricted to GABAergic (gamma-aminobutyric acid) neurons in the cortex and basal ganglia. During development, *ARX* functions primarily as a transcriptional repressor[2]: modulating migration and fate specification of interneurons and controlling ventricular zone proliferation. How loss of function of *ARX* leads to an epilepsy phenotype is poorly understood. Three genetically modified mice lines have been generated[3–5] to address this issue. These models each develop epilepsy, and all have changes in interneuron subtype patterns strongly implicating alterations of interneuron development as a cause of epilepsy. Analysis of these models will both further the molecular understanding of the function of *ARX* and allow dissection of the pathophysiological properties of the *ARX*-related epilepsies. This chapter will review the current knowledge of the function of *Arx*, the *Arx* mouse models, and discuss how these models can lead to a better understanding of the role of interneuron loss in the development of epilepsy during early childhood.

During the first few years of life, there exists a spectrum of malignant epileptic disorders. These early epileptic encephalopathies often proceed from one clinical syndrome to another. The named syndromes include early infantile epileptic encephalopathy (Otahara syndrome), severe myoclonic epilepsy of infancy (Dravet syndrome), infantile spasms (West syndrome), Lennox-Gastaut syndrome, and a few others (for review, see ref. 6, as well as various

chapters in this book). Up to the last few years, the etiology of these conditions was unknown for many patients. Recently, a number of genes have been linked to early epileptic encephalopathies, and often a single gene has been found to be responsible for multiple conditions. *ARX* is, to date, one of the genes most commonly associated with these conditions. A sizable literature has accumulated describing mutations in *ARX* that have been reported to cause a variety of neurological disorders, all with epilepsy as a major symptom. *ARX* was first associated with human disease by three groups in 2002.[7–9] The initial descriptions were of three different disorders: X-linked lissencephaly with ambiguous genitalia (XLAG), X-linked mental retardation (XLMR) with epilepsy and spasticity, and X-linked infantile spasms syndrome (ISSX). The finding of a single gene having significant clinical and genetic heterogeneity has led to a considerable amount of research, both clinical and basic science, on this gene. In this chapter, we will introduce the clinical and molecular details of *ARX*, then discuss the molecular mechanisms of the gene and the rodent models of *ARX*-related disease, and end with a discussion of the role of *ARX* in the pathophysiology of the early epileptic encephalopathies.

ARX IN CLINICAL NEUROLOGY

Mutations in the gene *ARX* have been primarily described in boys and generally result in a clinical phenotype with intractable epilepsy as a predominant feature. The mutations can be broadly classified as those resulting in brain malformations and those without brain malformations. The brain malformation syndromes include XLAG,[8,10] Proud syndrome (agenesis of the corpus callosum and ambiguous genitalia),[11] and hydranencephaly with abnormal genitalia[12] (OMIM 300215). The *ARX* disorders without brain malformations include XLMR,[7,9] West syndrome/ISSX,[8,13] Partington syndrome (mental retardation with hand dystonia)[14–16] (OMIM 309510), X-linked myoclonic epilepsy with spasticity and intellectual development (XMESID),[17,18] and Ohtahara/early infantile epileptic encephalopathy syndrome (EIEE),[19–21] as well as other cases with epilepsy, intellectual disability, and dystonia/spasticity as part of the syndrome.[22,23] A number of patients with *ARX* mutations, both with and without clear brain malformations, have also been observed to have cysts within the basal ganglia.[4,12,13] Though not a clear malformation, this is a finding that may be typical in patients with *ARX* mutations.

In females, the only central nervous system (CNS) malformation currently described is agenesis of the corpus callosum (ACC) with or without mental retardation (MR) and seizures.[4,12] Females have also been reported to have infantile spasms, epilepsy, and varying degrees of cognitive dysfunction without clear brain malformation.[4,12,24,25] All of these conditions have been linked to a large number of mutations in the gene. From this large group of mutations and conditions, a number of authors have debated the existence of a clear genotype–phenotype correlation.[12,26,27]

Ostensibly, a clear genotype–phenotype correlation exists between the malformation phenotypes and the nonmalformation phenotypes. Mutations leading to loss of protein function (deletions, nonsense, frameshift, or splice site mutations) or to changes in the homeodomain (for details, see below) lead to malformation syndromes, while missense mutations or expansions of the polyalanine tracts lead to epilepsy phenotypes with normal brain magnetic resonance imaging (MRI) scans.[12] However, this genotype–phenotype correlation breaks down when one looks at the severity of disease in the nonmalformation phenotypes and females.[26] For example, the most common mutation reported (45% of all mutations), the expansion of the second polyalanine tract from 12 to 20 alanines, has been associated with a spectrum of phenotypes ranging from mild MR and seizures to the severe phenotype of Ohtahara syndrome, suggesting greater genotype–phenotype heterogeneity. Another condition in which the genotype–phenotype correlation is less clear is in females with *ARX* mutations. There are mother-daughter and mother-aunt pairs in which one is normal and the other has cognitive disabilities and epilepsy,[4] though this may be due to differences in X-inactivation. Overall, *ARX* mutations result in a spectrum of disorders all with epilepsy as a major phenotype. A degree of genotype–phenotype correlation exists, but other factors, such as familial modifiers or environmental mediators, must exist to explain the variability that does occur.

MOLECULAR BIOLOGY OF *ARX*

What Is *ARX*?

ARX encodes a transcription factor with a role in cortical development. Designated *ARX* in humans and *Arx* in mice, the gene codes for a paired class homeodomain protein and is the vertebrate ortholog to the *Drosophila aristaless* (*al*) gene. *ARX* resides at Xp22.11 and produces a 2.8 kb mRNA with significant homology between human and mouse (89.3% sequence and 95% amino acid homology). The gene encodes a 562 amino acid protein, localized to the nucleus, that functions by binding DNA.[7,28,29] *Arx* is expressed in the developing hypothalamus, thalamus, basal ganglia, and cerebral cortex beginning at embryonic day 8 (E8). In the forebrain, *Arx* is expressed in the anterior neural plate at E8.[7,30] By E10.5, expression is clearly observed in the ventricular zone (VZ) of the dorsal cortex and begins to be seen in the mantle zone of the emerging ganglionic eminences (GE).[30] Ventral telencephalic *Arx* expression is clearly present in the mantle zone of the GE at E12.5.[30] By E14.5 *Arx* protein can be observed in the dorsal VZ, in the intermediate zone (IZ) of the GE, and in scattered cells in the marginal zone (MZ) and dorsal IZ and subventricular zone (SVZ)[7,30,31] (Fig. 63–1A). The ventral expression, at E14.5, has settled into the SVZ of the GE, primarily in proliferating neuroblasts,[30] as determined by colabeling with bromodeoxyuridine (BrdU) staining. *Arx* remains expressed as the cells leave the SVZ to migrate tangentially into the cortex.[8,30,32] The ventral and migratory expression of *Arx* has almost complete overlap with Gad1 (glutamic acid decarboxylase 1) expression.[30] This expression pattern remains until shortly after birth, when the dorsal VZ and GE are no longer present and *Arx* expression in the forebrain is observed only in scattered cells in the cortex and basal ganglia (Fig. 63–1B,C). Colabeling experiments with different interneuron markers have revealed that more than 75% of all interneurons are *Arx* positive.[29–31,33,34] *Arx* is also expressed in the developing pancreas, testis, and muscle. Data from the pancreas suggest an important role of *Arx* in fate determination.[35–37] The role of *ARX* in the brain appears to be more complicated than in the pancreas.

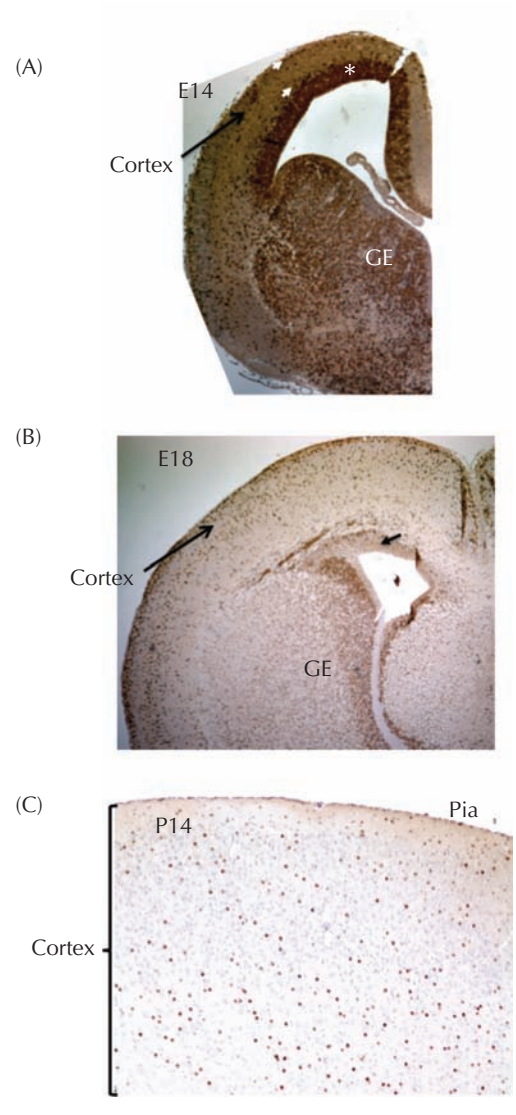

Figure 63–1. Ontogeny of *Arx* protein staining in dorsal neocortex of a wild-type mouse. E14.5, E18.5, and P14 coronal sections are presented. **A.** E14.5 coronal section (4x) with *Arx* staining (dark brown) in the GE and in the dorsal VZ (asterisk). Two trails of migrating *Arx*-positive cells are present in the SVZ/IZ and the MZ (two white arrowheads). **B.** At E18.5, the *Arx* staining is essentially gone from the dorsal VZ (arrow), but it remains in the GE and in cells scattered throughout the cortex. A 4x image is presented. **C.** By postnatal time (P14), staining is present only in scattered cells throughout the cortex. The lighter blue stain is a hematoxylin counterstain for nuclei (magnification 10x). E, embryonic; P, postnatal; GE, ganglionic eminence. All three sections are paraffin-embedded, paraformaldehyde-fixed 6 µm sections. All staining was performed as previously described using an *Arx* antibody (kindly provided by K. Kitamura) and the Vectastain ABC kit as a secondary antibody.[2]

The functional role of *Arx* in the telencephalon is an active area of research. Recent studies suggest that *Arx* is primarily a transcriptional repressor[2,38] and, through this mechanism, has important roles in pallial progenitor cell proliferation, nonradial cell migration of interneurons from the ganglionic eminence, and basal ganglia development.[8,32]

Arx as a Transcriptional Repressor

The Aristaless homeodomain protein in *Drosophila* is a paired related homeobox protein, distinguished by containing a paired homeodomain region, a C-terminal aristaless domain, and an N-terminal octapeptide/engrailed domain.[29,39] The aristaless domain is known to act primarily as a repressor,[40] and the octapeptide domain is believed to be a potent transcriptional repressor.[41] Based on the findings in *Arx* homologues, the transcriptional activity of murine *Arx* has been investigated and also been found to be primarily repressive in nature.[2,38,42] Using a Gal4-reporter assay, the engrailed/octapeptide domain, a region near the C terminus, and the fourth polyalanine tract were found to mediate transcriptional repression.[38,42] The transcriptional repression of the engrailed domain was determined to act via the transducin-like enhancer (TLE) proteins,[38] which are known cofactors for engrailed domain-containing proteins. Indeed, in the same reporter system, introduction of mutations believed to cause XLMR and ISSX reduced repression of the reporter construct[38,42] by decreasing the binding to the TLE elements. *Arx* also functions as a transcriptional promoter, though this is not believed to be as prominent an action of the transcription factor.[2,38] As the data fairly well establish *Arx* as primarily an inhibitor of transcriptional programs, two questions remain: which gene networks are affected, and how does this repression alter normal cortical development?

Attempting to answer these questions, two labs performed mouse whole genome transcriptional arrays followed by bioinformatic analyses to begin to elucidate the downstream targets of *Arx*.[2,43] In these experiments, the ventral telenecephalon, including the GE, developing basal ganglion, and hypothalamic regions were dissected away from the cortex, and their RNA was isolated and hybridized to Affymetrix whole genome transcriptional arrays. Both studies demonstrated that the majority of differentially expressed genes were upregulated in the knockout animals. Many of these were genes previously not (or minimally) expressed in the ventral forebrain, suggesting that *Arx* plays an important role in regionalization and fate determination by suppressing the expression of other transcription factors. The loss of *Arx* also resulted in the decreased expression of a subset of differentially expressed genes, presumably ones that are upregulated by Arx. Some of these latter genes appear to be important in the control of migration and proliferation.[2,43] Together, these experiments confirmed the function of *Arx* as primarily a repressor and began to define the downstream targets of *Arx*-related transcriptional networks that are important in ventral forebrain development.

Role in Interneuron Development

The above studies suggest that *Arx* plays an important role in ventral forebrain development. This is likely for basal ganglia formation, interneuron production, migration, and specification, as well as cholinergic neuronal specification. There is much interest in the interneuron phenotype because of the intractable epilepsy present in most patients with *ARX* mutations. With one of the original three clinical descriptions, a germline knockout of *Arx* was developed and experiments on these animals showed a clear alteration in interneuronal development.[8] The knockout mouse data and other subsequent experiments have confirmed the important role of *Arx* in this developmental process. The expression pattern data described above (e.g., see Fig. 63–1) further corroborate that *Arx* is essential for normal interneuron development.[8,9,30,31] How *Arx* guides interneuronal development is less well understood.

A number of different transcription factors have important roles during interneuron development (for review, see refs. 44 and 45). Early (E8–9) Mash1 expression sets ventral forebrain identity,[46] and subsequent expression of Dlx1/2 is vital for interneuronal fate determination.[47,48] Subsequently, ventral regionalization occurs by the sequential expression of various transcription factors, including Nkx2.1 and Lhx6.1. Accumulating evidence is beginning to place

Arx within this transcriptional network, with *Arx* as a direct target of Dlx1/2[34] by acting through an enhancer element over 12 kB downstream from the end of the coding region. Activation of *Arx* by Dlx1/2 is thought to mediate the Dlx-dependent interneuron migration but not specification of the GABAergic cell fate.[34,49] Loss of *Arx* increases the expression of Gbx1, Lhx6, Dlx2, Nkx2., Magel2, Efb3, and Lmo3 into ventral regions with minimal previous expression[2,32,34] but decreases the expression of Cxcr4 and Bmper.[34] From the results of these experiments, the effect of proper *Arx* expression is the correct specification of ventral areas into regions producing interneurons and subsets of basal ganglia neurons and the appropriate expression of proteins necessary for interneuronal migration (*Cxcr4* and *Ebf3*). The exact mechanisms need to be further elucidated, but a framework for understanding how *Arx* disrupts interneuronal development is now present.

Role in Cortical VZ Development

In contrast to the emerging evidence defining a mechanism of *Arx* action in interneuronal development, much less is known about the role in dorsal cortex during development. *Arx* expression is first observed in the dorsal VZ at E12.5, but by birth (P0), most VZ progenitor cells have matured and have entered the cortex, with resultant loss of *Arx* expression. As stated in the previous sections, all postnatal expression of *Arx* is in interneurons and not in the excitatory cells that are derived from the dorsal VZ. *Arx* expression in the dorsal VZ is under a presumed regulatory element in an ultraconserved region in the 3.5 kB downstream of the *Arx* coding region. The function of *Arx* in the VZ is believed to be in controlling proliferation, and several pieces of evidence support this role. First, humans with *ARX* mutations can develop a form of lissencephaly, with only three thin layers and thickened white matter, suggesting a proliferative defect. Second, germline knockout mice have a thin cortex and a small forebrain.[5,8] Third, the expression in the VZ apparently terminates when the cells enter the SVZ or IZ. Finally, in utero electroporation experiments altering *Arx* levels in the VZ (by a shRNA- or *Arx*-overexpressing vector) described changes in cell cycle time and in the number of cells proliferating in the VZ.[49] These authors showed a lack of cell death, but they could not differentiate between *Arx* involvement in cell cycle timing and proliferation or neuronal differentiation, but they concluded that the role is in cell proliferation and cell cycle timing.[49] Though *Arx* is likely involved in cell proliferation by controlling cell cycle dynamics, the downstream targets for this role and its location within a gene regulatory network in the dorsal cortex are not known. Research into this important area of *Arx* function is ongoing.

Role of Expansion Mutations

A unique feature of *Arx* is the presence of four alanine repeats within the gene. A number of genes are known to contain polyalanine tracts, with the majority acting as transcription factors or having nuclear localization signals in the protein.[50] Polyalanine repeats, unlike the more common/well-known polyglutamine repeats, are shorter, averaging less than 20 alanines, more stable (lacking genetic anticipation), and presumed to cause disease by either protein misfolding or altering the nuclear localization.[50,51] Nine diseases are associated with expansions in these alanine tracts, eight of which are transcription factors and result in developmental disorders similar to those caused by *Arx*. These results led to a series of experiments to determine the effect of different expansions on *Arx* function.[52,53] Expansions in the first polyalanine tract from 16 to 23 alanines resulted in protein aggregations, with two labs finding these protein inclusions in different cellular locations. Our lab reported the presence of intranuclear inclusions,[52] while another lab described cytoplasmic aggregations.[53] Both labs used overexpression experiments in cell culture. It is not clear why the two studies showed a difference in location of the protein aggregates, as both used similar cell lines and culture methods, suggesting that subtle differences in methodology can lead to alterations in protein processing. Importantly, to understand the functional implication of the inclusions, our lab showed increased cell death in HEK cells and both partial reduction in the number of cells with inclusions and partial rescue of the cell death response by overexpressing the heat shock protein HSP-70.[52] Mechanistically, the polyalanine expansion may induce inclusions and

cellular aggregations, not by altering the binding of *Arx* with one potential nuclear import protein, IPO13, but rather due to changes in protein–protein interactions.[53] Finally, the expansions were found to occur in vivo after in utero electroporation.[52] However, inclusions were not observed in the two expansion mouse models that have been recently generated.[3,5] In one expanded mouse model, alterations were reported in cellular localization of the *Arx* protein,[3] partially consistent with some of the cell culture experiments described above.[53]

Recent work has begun to address the issue of mislocalization of *Arx*, though not with the expanded mutation. A few studies have addressed this issue by producing full-length *Arx* cDNA constructs with mutations/disruptions in the nuclear localization sequence (NLS) of *Arx*.[54,55] *Arx* contains at least three NLSs, which are found in the homeodomain or in the 3′ region, and alterations in these sequences cause nuclear or perinuclear protein aggregations. The transport of *Arx* into the nucleus is protein dependent particularly the importin 13 (IPO13)[55] and importin β.[54] The possibility that many *ARX* mutations, both expansions and point mutations, alter ARX binding, inhibiting nuclear import, was tested. Both groups found that the change in cellular localization occurs without affecting binding to nuclear import proteins,[54,55] suggesting that they are purely mistargeted, not altered in protein binding. This work is limited, as there could be alterations in the binding to other *Arx* cofactors, either for nuclear import or DNA binding, and these may lead to the cellular aggregations or nuclear inclusions. Of note, in a single patient with XLAG not due to expansion of the polyalanine tract, no inclusions or aggregations were noted on histopathological exam.[10] This implies that in the more severe mutations, there may be alterations in protein processing and, hence, no aggregations. Further research is needed to fully understand how the protein expansion leads to the *Arx* clinical phenotypes.

ARX MODELS

Since the first description of *Arx*-related disorders, a number of *Arx* mouse models have been developed.[3–5,8,36] These models have led to different insights into the disorders. The first mouse was made by homologous recombination of a lacZ-containing vector into exon 2, producing an *Arx* allele with a premature stop codon[8] and resulting in a truncated protein. These mice died at P0–P2 but were found to have many of the features of XLAG in humans, including a poorly formed small cortex, absent corpus collosum, abnormal tangential migration and differentiation of interneurons, and abnormalities in the male genitalia.[8] There was a severe alteration in interneuron migration, with a delay in onset and loss of all migrating interneurons except for those along the SVZ.[8] These authors also uncovered changes in basal ganglia cell populations. Because of the early lethality of the mice, no behavioral or electrophysiological studies could be performed. Shortly afterward, Collombat and colleagues created a mouse line with targeted knockout of exon 1 and 2 producing a mutant protein with the loss of the first 360 N-terminal amino acids.[36] These mice are born but die by P2, and are smaller and appear dehydrated.[36] The mice were first developed to study the role of *Arx* in pancreatic development, but subsequently they have been used to study both the downstream targets of *Arx* and the alterations in interneurons, basal ganglia, and cholinergic neurons, as described in the preceding sections.[30,32,34,43] As these mice also had perinatal lethality, attributable to loss of glucagon-producing alpha cells, no phenotypic or physiological analysis could be performed. The functional shortcomings of these two mice lines were corrected with a series of five *Arx* model mice lines that were published in 2009.

The latter *Arx* models took two approaches to developing the mice. The first approach, from our lab, used the Cre-Lox system to stop expression of *Arx* in cells expressing Dlx5/6, a transcription factor that is expressed in the majority of developing interneurons within the GE.[4] The Dlx5/6 promoter was chosen to drive the Cre recombinase, as loss of interneurons in patients with *Arx* mutations is believed to be a major contributor to the epilepsy and infantile spasms phenotype.[56] We were, therefore, attempting to prove the hypothesis that interneuron dysfunction is central to the epilepsy phenotype in various brain malformations. Indeed, the conditional knockout (CKO) mice appear to give credence to this view. The adult CKO male mice had faster, higher-voltage electroencephalographic (EEG) tracings with

multifocal spikes reminiscent of a hypsarrhythmic pattern seen in infants.[4] The male mice develop convulsive seizures at P14, the earliest time we were able to assess accurately for the presence of electrographic seizures. The male CKO mice, which live past P14, continue to have seizures and develop an infantile spasms-like seizure type. The development of the spasm phenotype was found more often in the adult animals, most likely due to differences in maturity and neuroanatomy between mice and humans. In addition, we found that approximately half of the female animals also developed seizures at P14 that persisted into adulthood. The loss (or partial loss) of *Arx* reduced the number of calbindin-positive interneurons.[4] Currently, we are determining if there are other interneuronal changes, as well as the developmental time course of this loss. Our approach contrasts with the method of the two other laboratories that recently developed *Arx* models.

The approach taken by these labs was to generate mice with known human mutations associated with disease.[3,5] The Noebels' lab developed a knockin *Arx* mouse with an expansion of the first polyalanine tract, increasing the repeat size from 16 to 23 amino acids.[3] These authors found the animals to have possible behavioral spasms at 7–11 days of age, electroclinical spasms at 14–21 days of age, and then the development of other seizure types (behavioral arrest and motoric seizures) as the animals matured.[3] Behavioral tests on these animals revealed deficits in anxiety, fear conditioning, and social behaviors. Notably, the animals were less anxious and had diminished retention of a conditioned stimulus compared to wild-type mice, suggesting more of an anxiety phenotype rather than diminished ability to learn.[3] The pathological alteration of the *Arx* expansion was regional loss of a population of *Arx*-expressing interneurons. A 50% reduction of *Arx* was found in the hilus of the hippocampus and striatum, and a 68% decrease was discovered in somatosensory and motor cortex, but no change was found in parietal cortex.[3] The authors reported a change in protein localization from nuclear to cytoplasmic, but this contrasts with the other *Arx* expanded mouse, which showed no inclusions or alteration of protein localization.[5] The partial loss of *Arx*-positive interneurons was due primarily to loss of calbindin-positive cells, similar to the changes found in our Dlx5/6 conditional knockout mouse line. There was no loss of neuropeptide Y (NPY) or calretinin-positive cells in the cortex. Finally, the authors reported a loss of calbindin, NPY, and cholinergic neurons in the striatum.[3] Overall, the features of this mouse model were similar to those of the *Arx* CKO model.

The third group, in the Kitamura laboratory, generated three mouse lines. Two were knockins of known pathogenic mutations, both disrupting the homeodomain, but one mutation was associated with the XLAG phenotype and the other with the XLMR phenotype.[5] The third line derived by this group was an expansion of seven alanines to the first polyalanine tract,[5] a line similar to that made by the Noebels' lab. The XLAG mutation mouse line was similar in phenotype to the germline knockout. This mouse was perinatal lethal and had smaller brains, severely diminished numbers of interneurons in the cortex, and a large loss of cholinergic neurons in the striatum.[5] The other two lines were viable and recapitulated aspects of the XLMR or ISSX phenotypes. These two lines both developed spontaneous seizures but of differing severities. Only 10% of XLMR point mutation mice were observed to have a seizure, and no seizures were captured on video EEG in the three mice that were recorded. In contrast, 70% of the expanded mice developed behavior seizures, and all (three of three) mice with EEG recordings developed seizures but no interictal EEG abnormalities.[5] Like the Noebels' lab expansion mice, the two lines were tested for behavioral deficits. Both lines were observed to have impaired motor coordination and increased anxiety. They were also found to learn poorly in both a passive avoidance task and a radial arm task, which tests hippocampal spatial memory.[5] The differences in anxiety and motor phenotypes between the Kitamura and Noebels' expanded mice could be due to the different background strains, C57BL/6J × 129Sv/SvEvBrd mice[3] versus pure C57BL/6J mice,[5] or to other differences with strain generation, suggesting that in humans, genetic background and environmental features may modify the phenotypic expression in patients with the expansion mutation. This is indeed what other authors have proposed for the variability of phenotypes observed in patients with expansions of the first and second polyalanine tracts.[26]

Like the other conditional lines, the two viable lines from the Kitamura lab also had deficiencies in interneuron and striatal neurons. In these animals, interneurons began to migrate at the appropriate time (E12.5) and migrated normally, but reduced numbers of interneurons entered the cortex. Although the total number of interneurons was reduced in postnatal mice, these authors did not find an interneuron subtype-specific difference in either the XLMR or ISSX mutations.[5] This contrasts with what was found in the basal ganglia of these mice. In the striatum, the XLAG mutation resulted in a loss of both radial and tangential migration, whereas the two less severe mutations only altered tangential migration of interneurons into the basal ganglia. Finally, there was a loss of cholinergic neurons in the cortex and basal ganglia, but it was greater in the striatum.[5] Overall, these five mouse lines have a number of similarities but also a few differences. These lines can now be used to attempt to understand how *Arx* alters normal cortical circuitry and how these changed neuronal networks result in an epilepsy phenotype and varying degrees of cognitive dysfunction.

ARX as Disease Mediator

Mutations in *Arx* result in a variety of phenotypes. Two aspects of *Arx* function described in the sections above have both research and clinical implications for the study of *ARX*-related disorders. The first relates to *ARX*'s role in interneuron development. A number of genes can lead to brain malformations, which can be focal or diffuse. In many cases, these malformations present later in life when the child is evaluated for learning issues or for a first seizure. Even in the most severe malformations, such as in lissencephaly, there is variability in the severity of the cognitive disability and the intractable nature of the epilepsy that occurs. In *ARX*-mediated malformations, and in particular, XLAG, the disease is particularly severe. The children often make no developmental progress and have seizures that are not responsive to any treatment. The severity of this disorder, compared to those resulting from other genes that cause lissencephaly or other malformations, has been attributed to the specific loss of interneurons.[56] Kato and Dobyns have used *ARX*-related disorders to designate a new term for a class of neurological diseases called *interneuronopathies*.[56] Other interneuronopathies could be uncovered by screening patients with similar clinical phenotypes for genes either upstream or downstream from *Arx* in the gene regulatory network.

The second aspect of *ARX* activity to have clinical implications is the finding that *Arx* has seemingly very different roles in two regions of the developing forebrain. The fact that *Arx* may control proliferation in the dorsal VZ, but control migration or fate specification in the ventral forebrain, means that altering *Arx* activity throughout the entire brain could have multiple unintended consequences. Therefore, developing a better understanding of how *Arx* functions, and where in the gene regulatory networks of telencephalon development *Arx* acts, is vital to be able to generate therapeutic interventions for patients with *ARX* mutations. In addition, greater understanding of the temporal and spatial regulation of *Arx* expression and function is necessary if future therapeutics are to be designed.

FUTURE DIRECTIONS IN THE STUDY OF *ARX*

Over the last decade, *Arx* has been linked to over 10 overlapping clinical disorders, and a great deal of information regarding the expression pattern, molecular function, and role in cortical development has been generated. This work has answered many questions but inevitably has raised many more. Further study is necessary to understand how different mutations lead to the spectrum of disorders and whether genetic background effect, environment, or changes in the protein due to the mutations are the cause of such variability. Next, a full categorization of the *Arx* involved gene networks is needed, as well as an understanding of how the gene would have differential effects in the ventral and dorsal telecephalon. Another area for future investigation is the role of *Arx* in the postnatal brain. Lastly, consideration of how alteration in interneurons leads to a seizure or cognitive phenotype is warranted, and the four mouse lines are available to study the pathophysiological changes that occur. The next decade will likely yield the answers to many of these questions.

Chapter 64

Haploinsufficiency of *STXBP1* and Ohtahara Syndrome

Hirotomo Saitsu
Mitsuhiro Kato
Naomichi Matsumoto

INTRODUCTION

Ohtahara syndrome (OS), also known as *early infantile epileptic encephalopathy with suppression-burst*, is one of the most severe and earliest forms of epilepsy.[1] It is characterized by early onset of tonic seizures, seizure intractability, characteristic suppression-burst patterns on the electroencephalogram (EEG), and a poor outcome with severe psychomotor retardation.[2,3] Brain malformations, such as cerebral dysgenesis or hemimegalencephaly, are often associated with OS, but cryptogenic or idiopathic OS is found in a subset of OS patients, in whom genetic aberrations might be involved.[4] Although mutations of the *ARX* gene have been found in several male patients with OS,[5–8] the genetic causes are unexplained in most cryptogenic OS cases. We have recently found de novo mutations in *STXBP1* (encoding syntaxin binding protein 1, also known as MUNC18-1) in individuals with cryptogenic OS.[9] Here we present all the mutations in *STXBP1* found to date in OS patients, as well as some evidence of mutations leading to haploinsufficiency.

OHTAHARA SYNDROME

Ohtahara syndrome was first reported as the earliest form of age-dependent epileptic syndromes by Ohtahara et al.[1] It is characterized by early onset of intractable tonic spasms, characteristic suppression-burst patterns on interictal EEG, and a poor outcome with severe psychomotor retardation.[2,3] According to a previous report,[4] all patients have seizure onset within the first 3 months, with the majority

(75%) in the first month. Tonic spasms were observed in all patients. One-third to one-half of patients also had partial seizures, such as erratic focal motor seizures and hemiconvulsions, or asymmetric tonic seizures; however, myoclonic seizures were rare. Hemiconvulsions, tonic seizures, or clonic seizures precede the onset of tonic spasms by 1 to several weeks to in 37.5% of OS patients.[4] Brain malformations, such as cerebral dysgenesis, hemimegalencephaly, porencephaly, and Aicardi syndrome, are often associated with OS, but a significant proportion of patients (31% to 50% of OS cases) remain etiologically unexplained.[2,4] Suppression-burst patterns on interictal EEG consisting of high-voltage activity alternating with nearly flat suppression phases are observed when the patient is both awake and asleep.

Early myoclonic encephalopathy (EME) is another epileptic syndrome showing suppression-burst patterns on EEG.[10] The prevailing initial seizure type is a main difference between OS and EME: tonic seizures in OS and myoclonic seizures in EME.[2,3] However, OS and EME have common features, and it is often difficult to distinguish between them. Homozygous missense mutations of the *SLC25A22* (mitochondrial glutamate carrier 1) gene have been recently found in EME individuals in consanguineous familes.[11,12] Age-dependent evolution is a characteristic feature of both OS and EME: approximately 75% and 40% of OS and EME cases, respectively, transit to West syndrome (WS), usually 3–4 months afterward.[2,3] West syndrome is characterized by tonic spasms with clustering, arrest of psychomotor development, and hypsarrhythmia on EEG. Such transitions suggest a common pathophysiology between OS and WS or between EME and WS. Consistent with this hypothesis, specific mutations of the *ARX* (*aristaless*-related homeobox) gene at Xp22.13, have been recently found in male OS and WS cases.[5–8,13–15]

DE NOVO *STXBP1* MUTATIONS CAUSE OS

Identification of *STXBP1* Mutations in Patients with OS

Through BAC array-based comparative genomic hybridization analysis of patients associated with mental retardation (MR), we found a microdeletion at 9q33.3-q34.11 in a female patient with OS.[9] As the microdeletion occurred de novo, we assumed that a gene within the deletion was responsible for OS. Among the genes mapped within the deletion, the gene encoding syntaxin binding protein 1 (STXBP1) was of particular interest because mouse *Stxbp1* has been shown to be essential for synaptic vesicle release[16] and is specifically expressed in the brains of rodents and humans.[17,18] We therefore analyzed *STXBP1* in 13 unrelated patients with OS. Four heterozygous missense mutations were found at evolutionarily conserved amino acids in three males and one female (Fig. 64–1 and Table 64–1). Three mutations were confirmed as de novo events (paternal DNA was unavailable for one remaining mutation).

STXBP1 Mutation Is a Major Genetic Cause of OS

To delineate the clinical spectrum of patients with *STXBP1* mutations, *STXBP1* was further analyzed in 29 and 54 cases of cryptogenic OS and WS, respectively.[19] No brain malformations were found in any of the cases. Seven novel heterozygous mutations were found in nine OS cases (the same mutation was found in three cases), but none in WS cases (six males and three females; Fig. 64–1 and Table 64–1). The mutations included one missense, one splicing, two frameshift, and three nonsense mutations. A recurrent missense mutation (c.1217G>A, p.R406H) occurred at an evolutionarily conserved amino acid (Fig. 64–1). All the mutations occurred de novo. Collectively, *STXBP1* aberrations account for about one-third of individuals with OS (14 out of 43). These data showed that *STXBP1* mutations are a major genetic cause of cryptogenic OS, but they are not a genetic cause of WS in our Japanese cohort.

Clinical Features of Patients with *STXBP1* Deletion/Mutations

Clinical information from 14 individuals with confirmed *STXBP1* deletion/mutations is summarized in Table 64–1. These persons showed

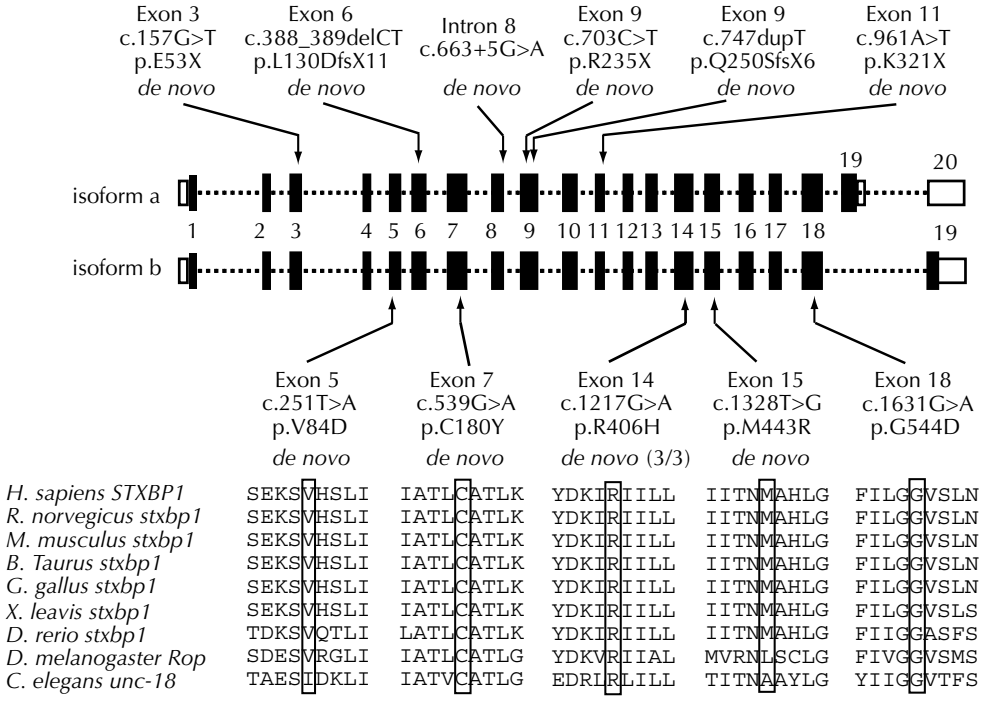

Figure 64–1. Summary of *STXBP1* mutations found in Japanese individuals with OS. Schematic representation of STXBP1, consisting of at most 20 exons (the UTR and the coding region are open and filled rectangles, respectively). There are two isoforms, a (GenBank accession number, NM_003165) with exon 19, and b (NM_001032221) without exon 19 of isoform a. Locations of mutations are indicated by arrows. Eleven different mutations are presented: missense mutations are indicated below the gene scheme, and the other types of mutations are indicated above the gene. Ten mutations in 12 subjects occurred de novo. All missense mutations occurred at evolutionarily conserved amino acids. CLUSTALW (http://align.genome.jp/) was used to align homologs of different species. Adapted from refs. 9 and 19.

distinctive features of OS, such as early-onset seizures including epileptic spasms, suppression-burst pattern on EEG, transition to WS after a few to several months, and severe developmental delay. Epileptic spasms were preceded by other seizure types, including partial seizures in 11 subjects. Transition to WS was observed in 11 subjects with OS. Although seizures were intractable in nine subjects, five subjects responded to medication, such as thyrotropin-releasing hormone (TRH) injection, adrenocorticotropic hormone (ACTH) injection, vitamin B_6, high-dose phenobarbital, and valproic acid. All subjects demonstrated severe psychomotor developmental delay. Brain magnetic resonance imaging (MRI) showed no structural anomalies or hippocampal anomalies but did show some atrophy (Fig. 64–2A). Suppression-burst on interictal EEG was observed in both awake and asleep states (Fig. 64–2B). We gained several insights into the phenotype of *STXBP1* aberrations. Firstly, the age at onset of epileptic spasms is later in subjects with *STXBP1* aberrations than in the 16 original subjects reported by Yamatogi and Ohtahara.[4] Only 27% of the subjects (4/15) in our series had onset of OS within 1 month compared to 75% (12/16) in the series of Yamatogi and Ohtahara. As subjects with *STXBP1* aberrations showed no structural anomalies on brain MRI examination, the onset of epileptic seizures might be affected by associated structural brain abnormalities, which are commonly seen in other reports of OS. Secondly, myoclonic seizures, which are thought to be rarely observed in OS, were occasionally observed (3/14). Myoclonic seizures are the main ictal symptom of EME. These three subjects can be diagnosed as having EME when myoclonic seizures dominate. Thus, *STXBP1* might also be causative for EME, implying a genetic linkage between OS and EME. Another infrequent but interesting finding is that one patient (no. 5) developed vigorous chorea-ballismus

Table 64–1 **Summary of Clinical Features of Subjects with STXBP1 Deletion/Mutations**

Case # Mutation	Initial Symptoms	Onset of Spasms	Transition from Spasms to Other Seizures	Response to Therapy
#1 Deletion	Tonic seizure and oral automatism	2 m	Generalized clonic seizure at 29 m	Seizure free from 5 m after TRH injection
#2 c.1631G>A	Blinking	10 d	No	Seizure free from 3 m
#3 c.539G>A	Tonic seizure with blinking	3 m	No	Intractable, daily
#4 c.1328T>G	Upward gazing and tonic seizure	2 m	Partial seizure at 8 m	Intractable, hourly TRH injection was temporally effective
#5 c.251T>A	Spasms and tonic-clonic seizure	2 m	No	Intractable, daily
#6 c.1217G>A	Generalized convulsions	3 w	No	Intractable, hourly
#7 c.1217G>A	GTCS with upward eye gazing	2 m	Myoclonic seizure at 48 d	Intractable, daily
#8 c.1217G>A	Partial seizures (right hemiconvulsion)	2 m	Tonic seizure to myoclonic seizure	Intractable, daily
#9 c.157G>T	Spasms	2 d	Versive seizure after hypoxia at 2 y	Intractable, daily
#10 c.388_389del	Secondary generalized seizures	2 m	CPS	Seizure free after ACTH or VPA with KBr
#11 c.663+5G>A	Blinking to tonic seizures	1 m	Tonic seizure	Seizure free with VB6 for spasms and ACTH for WS
#12 c.703C>T	Spasms in cluster	1 m	No	Seizure free from 6 m after high-dose PB
#13 c.747dup	Clonic convulsion	31 d	Partial seizure and myoclonic seizures	Intractable, hourly
#14 c.961A>T	Partial seizures	3 w	Partial seizure	Intractable, daily

GTCS, generalized tonic-clonic seizures; CPS, complex partial seizure; TRH, thyrotropin-releasing hormone; ACTH, adrenocorticotropic hormone; VPA, valproic acid; KBr, potassium bromide; VB6, vitamin B_6; PB, phenobarbital; d, day(s); w, week; m, month(s); y, year(s); 0 w, 0 to 6 days; 0 m, 0 to 3 weeks.

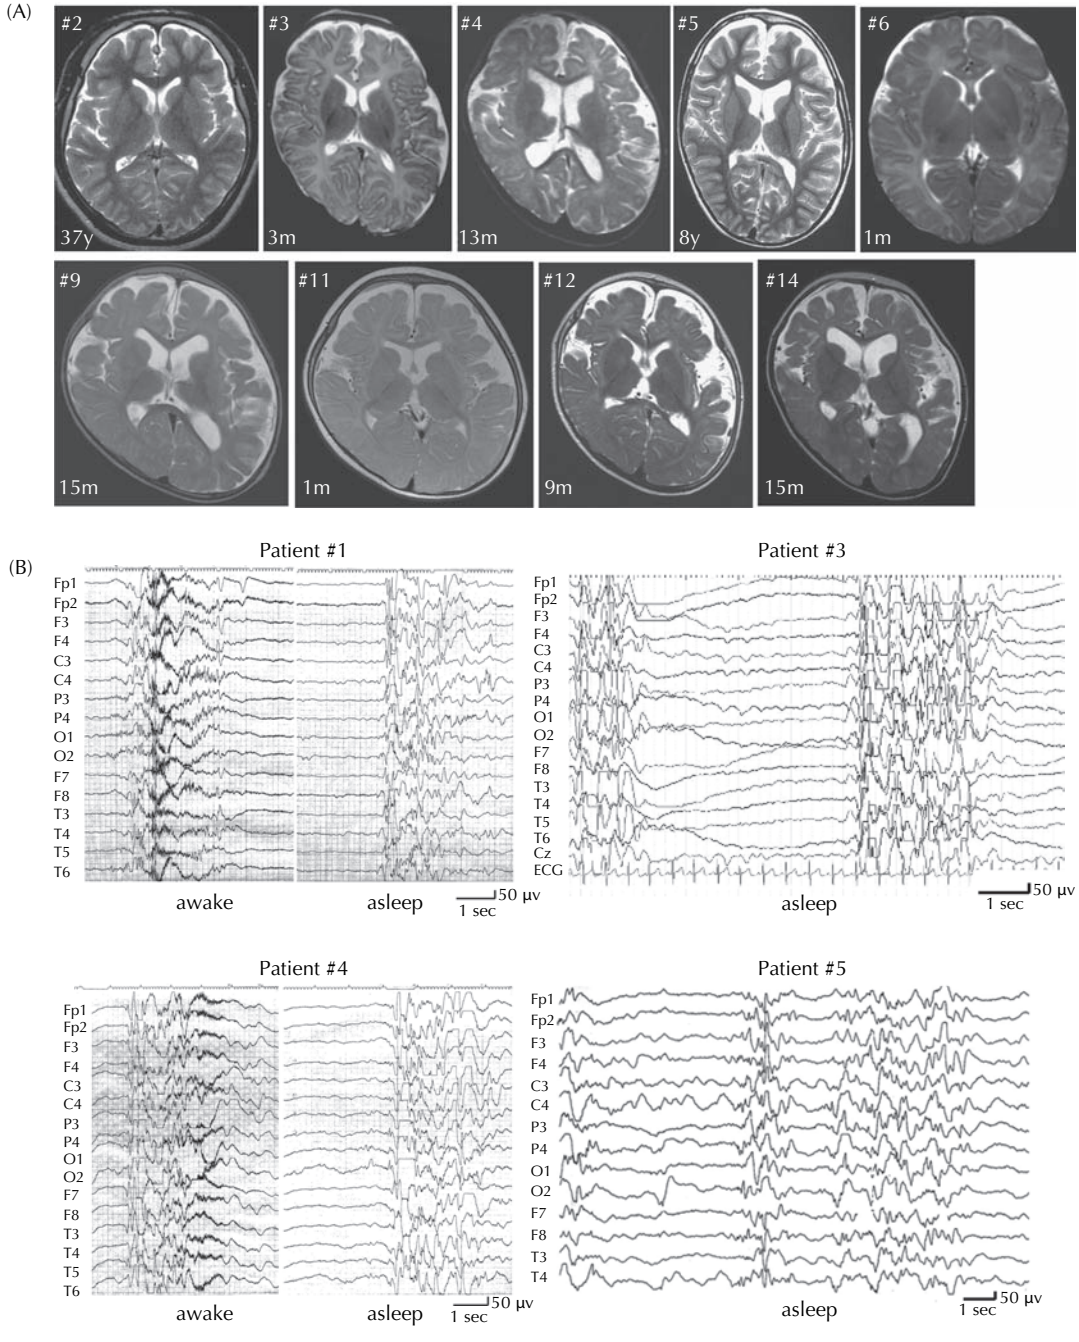

Figure 64–2. Brain MRI scan and EEG of OS patients with *STXBP1* aberrations**. A.** Brain MRI (T2-weighted axial) image through the basal ganglia shows normal brain structure in patients with *STXBP1* mutations. Patient IDs and developmental stages are indicated. Mild dilatation of lateral ventricles is observed in patients #4, #9, #11, and #14, but none shows brain malformation. y, year(s); m, month(s). **B.** Suppression-burst on interictal EEG of patients 1 (at age 2 months), 3 (at 3 months), 4 (at 2 months), and 5 (at 3 months). High-voltage bursts alternating with almost flat suppression phases at an approximately regular rate in both awake and asleep states. Adapted from refs. 9 and 19.

subsequent to OS, suggesting that mutations of *STXBP1* could affect the basal ganglia.[9,20] In terms of the genotype–phenotype relationship, we found no difference in clinical data between seven subjects with missense mutations and seven subjects with microdeletions, premature termination codons, or splicing mutations. This finding is supported by our experimental data that demonstrated both missense mutations and a splicing mutation resulted in haploinsufficiency of *STXBP1*: degradation of STXBP1 proteins containing missense mutations and nonsense-mediated mRNA decay (NMD) associated with aberrantly spliced mRNAs (see below).

MOLECULAR EVIDENCE OF *STXBP1* HAPLOINSUFFICIENCY

Mutant STXBP1 Proteins Are Unstable

All five missense mutations lead to amino acid replacements in the hydrophobic core of STXBP1 and are considered to destabilize the folding architecture. This is especially true for the three mutants (p.V84D, p.G544D, and p.M443R) that have replaced the wild-type (WT) residues with charged residues, which would be predicted to severely disrupt the conformation of STXBP1.[9] In fact, circular dichroism (CD) spectra showed that the helical content of the C180Y mutant is lower (39%) than that of the WT (43%), suggesting that the mutation destabilized the secondary structure of STXBP1[9] (Fig. 64–3A). Moreover, CD melting experiments revealed that the melting temperature (T_m) of the C180Y mutant was about 11 degrees lower than that of the WT (Fig. 64–3B), indicating that the C180Y mutant is much more unstable than the WT. The regulation of synaptic vesicle release by Stxbp1 is mediated in part by binding to Syntaxin-1A as well as directly to the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex, which mediates fusion of vesicles with the target membrane.[21,22] Binding of a mutant protein (p.C180Y) to syntaxin-1A was also significantly impaired, even at 4°C in vitro.[9] Together with the fact that the T_m of the C180Y mutant is close to the physiological temperature of the human body, it is less likely that its functional activity could be retained in the human brain. Other STXBP1 mutants (p.V84D, p.G544D, and p.M443R) tend to form aggregates, and thus sufficient protein for biophysical analyses could not be obtained.

Degradation of Mutant *STXBP1* Proteins

Transient expression of mutant STXBP1 proteins in Neuroblastoma 2A (N2A) cells showed further evidence of *STXBP1* haploinsufficiency. The WT EGFP-STXBP1 was expressed in the cytosolic compartment, but not in the nucleus or plasma membrane, similar to endogenous expression.[9,23] However, in approximately 20% of cells expressing mutant EGFP-STXBP1 (p.V84D, p.C180Y, p.M443R, and p.G544D), intense clusters of fluorescence signals were observed, likely representing protein aggregation.[9] The other 80% of cells showed a diffuse cytosolic protein distribution similar to that expressing the WT, but the signal intensity was much weaker, implying possible protein degradation. Protein degradation of mutant STXBP1 proteins was also confirmed by immunoblotting using an anti-Munc18 antibody[19] (Fig. 64–3C). These experiments suggested that mutant STXBP1 proteins would be aggregated or degraded in neurons, both leading to loss of STXBP1 function.

Degradation of *STXBP1* mRNA with Abnormal Splicing

The splicing, frameshift, and nonsense mutations would produce a premature stop codon; therefore, these mutant mRNAs are likely to be degraded by NMD.[24,25] In fact, NMD associated with abnormal splicing was demonstrated in lymphoblastoid cells derived from a patient harboring a c.663+5G>A mutation. Polymerase chain reaction (PCR) primers designed to amplify exons 7 to 10 amplified a single band (338 bp), corresponding to the WT *STXBP1* allele, using a cDNA template from a control lymphoblastoid cell lines (LCL; Fig. 64–3D). By contrast, a smaller band was detected from the patient's cDNA, in which exon 8 of *STXBP1* was skipped (Fig. 64–3D), resulting in the insertion of nine new amino

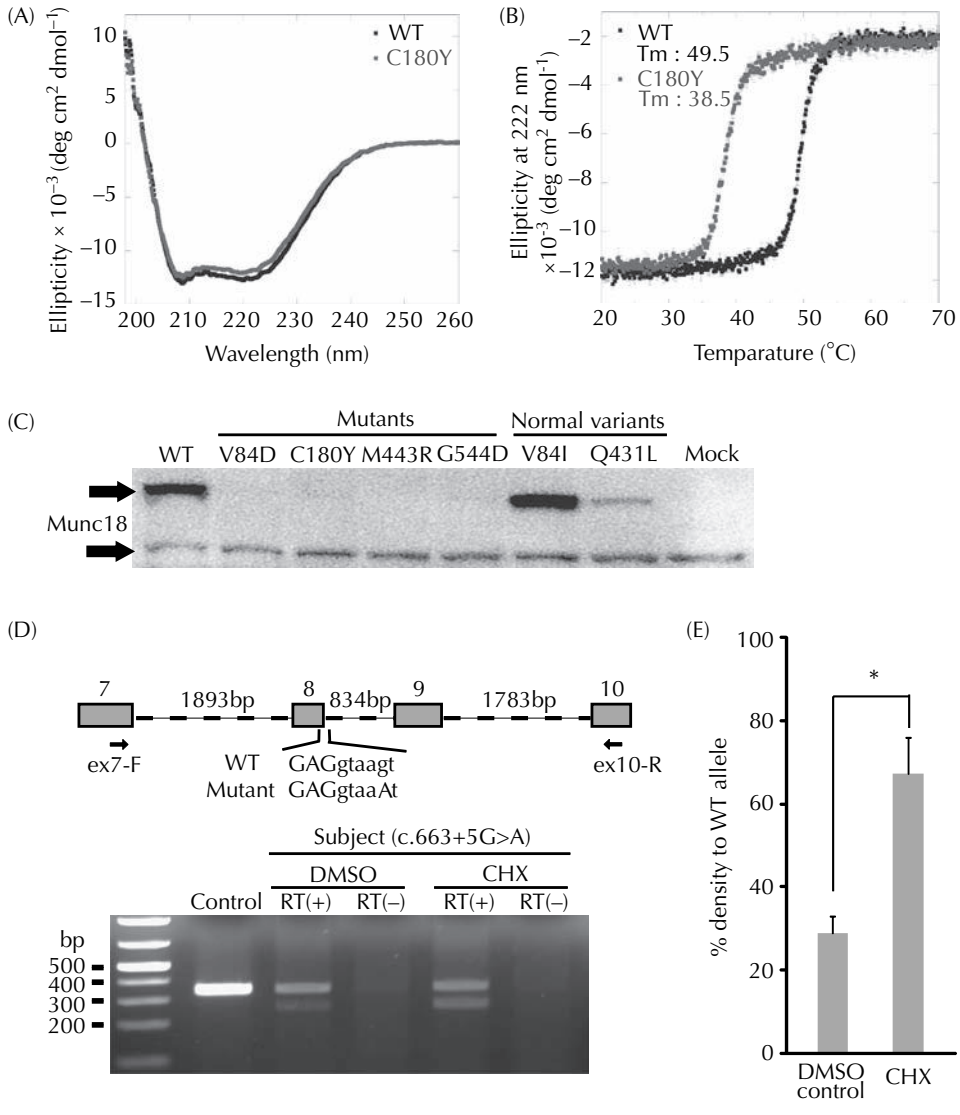

Figure 64–3. Characterization of mutant STXBP1 proteins and mRNAs with aberrant splicing. **A.** Circular dicroism spectra of the WT and C180Y-mutated STXBP1. The C180Y mutation is found to induce a subtle decrease in the helical contents of the STXBP1 structure by comparing the peaks of both proteins at 222 nm, where a large negative ellipticity value indicates a high helical content of the protein. **B.** Circular dicroic melting curves of the STXBP1 WT and C180Y proteins. Values of ellipticity at 222 nm are measured to monitor the thermal unfolding of the proteins. The C180Y mutant became unfolded at a lower temperature compared to the WT. Each dot represents the average of three repeated experiments, with standard deviations depicted as error bars. **C.** Immunoblot analysis of mutant STXBP1 proteins using a monoclonal anti-Munc18 antibody. Upper and lower bands represent EGFP-STXBP1 and endogenous STXBP1 proteins, respectively. Expression of four mutant STXBP1 proteins was not detected, while the WT and two normal variants could be detected. **D.** Top: Schematic representation of the genomic structure from exons 7 to 10 of *STXBP1*. Exons, introns, and primers are shown by boxes, dashed lines, and arrows, respectively. Sequences of exons and introns are presented in uppercase and lowercase, respectively. The mutation in intron 8 is highlighted in bold. Bottom: Reverse transcriptase-PCR analysis of patient 11 with a c.663+5G>A mutation and a normal control. Two PCR products were detected from the patient's cDNA: the upper one is the WT transcript and the lower one is the mutant. Only a single WT amplicon was detected in the control. The mutant amplicon was significantly increased by 30 μM cycloheximide (CHX) treatment compared to dimethyl sulfoxide (DMSO) treatment as a vehicle control. RT (+): with reverse transcriptase, RT (–): without reverse transcriptase as a negative control. **E.** Quantitative analysis of the NMD inhibition by CHX based on the data shown in **D**. **P* = 0.0023 by unpaired Student's *t*-test, two tailed. Averages of three repeated experiments are shown with error bars (s.d). Adapted from refs. 9 and 19.

acids followed by a premature stop codon at position 203. Moreover, the intensity ratio of the mutant compared to the normal band was increased by up to 67% after treatment with 30 μM cycloheximide, which inhibits NMD, compared to a ratio of 29% in the untreated condition (Fig. 64–3D,E). These facts suggest that the mutant mRNA possessing a premature stop codon suffered from degradation by NMD in neurons, resulting in haploinsufficiency.

Considering the degradation of STXBP1 proteins with missense mutations, NMD of mRNAs with premature stop codons and the effects of deletion of STXBP1, we conclude that haploinsufficiency of *STXBP1* causes OS.

HOW WOULD HAPLOINSUFFICIENCY OF *STXBP1* LEAD TO OS?

Impairment of Synaptic Vesicle Release

STXBP1 (*MUNC18-1*) is a member of the evolutionarily conserved Sec1/Munc-18 gene family that acts at specific steps of intracellular membrane transport.[26,27] In mammalian exocytosis, the vesicular SNARE protein, VAMP2 (also known as *synaptobrevin2*), and the target membrane SNARE proteins, Syntaxin-1 and SNAP25, constitute the core fusion machinery that bring two membranes into close apposition to fuse.[22,28] An *Stxbp1* null mutation led to complete loss of neurotransmitter secretion from synaptic vesicles throughout development in mice, though seizures have never been described.[16] Thus, *STXBP1* very likely plays a central role in synaptic vesicle release in coordination with SNARE proteins. The association of mutations of *STXBP1* with OS implies that perturbation of synaptic vesicle release forms part of the genetic basis of epilepsy. To date, the majority of genes associated with epilepsy syndromes are ion channel genes.[29] Synapsin I is a synaptic vesicle protein thought to regulate the kinetics of neurotransmitter release during priming of synaptic vesicles, and a mutation has been identified in a family with X-linked epilepsy and learning difficulties.[30] *STXBP1* is the second synaptic vesicle gene shown to be involved in epilepsy, and this finding will encourage further research into regulation of synaptic vesicle release and its involvement in seizures and related disorders.

Possible Interneuropathy

In *Stxbp1* heterozygous knockout mice, no seizures have been reported, and whole-cell recordings of autaptic glutamatergic or GABAergic (GABA: gamma-aminobutyric acid) neurons showed excitatory and inhibitory postsynaptic currents similar to those of WT littermate neurons upon single depolarizations.[31] However, with repeated stimulation, *Stxbp1*$^{+/-}$ neurons showed impaired synaptic function due to the reduced size and replenishment rate of readily releasable vesicles,[31] suggesting that heterozygous deletion of *Stxbp1* indeed affected synaptic function in mice. Interestingly, the reduction of readily releasable vesicles was more evident in GABAergic neurons than in glutamatergic neurons.[31] It has been reported that *Arx* is expressed in GABAergic interneurons and that *Arx* controls their genesis, migration, and differentiation, as *Arx* knockout mice showed a deficit of GABAergic interneurons.[32] Moreover, neuropathological examination of three patients with X-linked lissencephaly with absent corpus callosum and ambiguous genitalia, caused by *ARX* mutations, has suggested a loss of interneurons.[33] If haploinsufficiency of *STXBP1* affected GABAergic interneurons more severely than glutamatergic neurons in humans, as in mice, a defect in the GABAergic system could be postulated as a common pathophysiology among OS patients with *ARX* or *STXBP1* mutations. Ohtahara syndrome might be designated as a continuum of interneuronopathies.[34,35]

Cell Death of the Brainstem

As brain malformations are often associated with individuals with OS,[2,3] it could be speculated that *STXBP1* mutations would lead to abnormal brain structures directly related to the seizure phenotype of OS. However, we did not observe structural brain anomalies in any of the 14 OS patients with *STXBP1* defects. This is consistent with the findings that mice deleted for *Stxbp1* have normal brain architec-

ture. *Stxbp1* null mice, however, showed extensive cell death of mature neurons in lower brain areas, such as the brainstem; the lower brainstem was almost completely lost by embryonic day 18.[16] This is consistent with the suggestion that tonic seizures in OS might originate from subcortical structures, including the brainstem. Thus, in addition to the impaired synaptic vesicle release, it is possible that *STXBP1* haploinsufficiency leads to OS through microscopically impaired neuronal cell death in lower brain areas.

FUTURE CHALLENGES

Expansion of the Clinical Spectrum of *STXBP1* Mutations

Although OS is the core phenotype of *STXBP1* defects in our Japanese cohort (one-third of OS cases harbored *STXBP1* mutations), Hamdan et al. recently reported that two de novo *STXBP1* mutations, c.1162C>T (p.R388X) and c.169+1G>A, were identified in 2 out of 95 individuals with MR and nonsyndromic epilepsy.[36] According to their report, the two patients never showed the tonic seizures or infantile spasms associated with OS and WS, respectively. The onset of first seizures was at 6 weeks and 2 years of age, respectively. In addition, characteristic EEG patterns, such as suppression-burst or hypsarrhythmia, were never observed in these patients. Thus, the finding by Hamdan et al. indicated that *STXBP1* defects could cause a wide spectrum of clinical epileptic disorders in association with severe MR. Given that defects in synaptic dysfunction have also been implicated in many common neurodevelopmental disorders, such as MR, autism, and schizophrenia,[37,38] the possible involvement of *STXBP1* mutations in such common neurodevelopmental disorders is of interest. Elucidation of the molecular basis of synaptic vesicle processing disturbed by *STXBP1* mutations will allow us to understand not only the pathophysiology of infantile epilepsy, but also many neuropsychiatric conditions that present beyond childhood. The contribution of *STXBP1* mutations to EME also should be clarified, because myoclonic seizures, the characteristic feature of EME, are occasionally observed in 3/14 patients with *STXBP1* mutations.

Animal Model

An animal model is necessary to elucidate the pathophysiology of epilepsy caused by *STXBP1* mutations, including age dependency of seizure type and EEG pattern, and to test potential therapies directed specifically at OS and subsequent WS. The effect of gene dosage alterations of *STXBP1/Stxbp1* might vary between humans and mice: humans might be more susceptible than mice; thus, loss of function of one allele could cause seizures in humans but not in mice. Although it would be challenging to manipulate the gene dosage of *Stxbp1*—for example, in combination with a hypomorphic allele and a null allele—to the level at which mutant mice show a seizure phenotype, the establishment of an animal model will greatly benefit our understanding of the mechanisms of seizures in relation to impaired synaptic function.

Chapter 65

mTOR and Epileptogenesis in Developmental Brain Malformations

Michael Wong
Peter B. Crino

INTRODUCTION

Malformations of cortical development (MCDs) are among the most common causes of epilepsy. While a wide variety of types and classifications of MCDs exists,[1] a subset of focal cortical malformations (FCMs), including tuberous sclerosis complex (TSC), focal cortical dysplasia, ganglioglioma, and hemimegalencephaly, is associated with an especially high incidence of epilepsy and other neurological deficits, such as cognitive dysfunction and autism.[2,3] Epilepsy related to these focal developmental brain malformations is often refractory to medical therapy. Even in patients whose seizures are well controlled with medications, currently available drugs are only symptomatic treatments that help suppress seizures; they have not been demonstrated to have antiepileptogenic or disease-modifying properties in preventing or altering the long-term prognosis of epilepsy. Although epilepsy surgery may eliminate seizures in some medically intractable cases, many patients are not good candidates for surgery or continue to have seizures despite surgical intervention. Thus, novel therapeutic strategies are needed to reduce the burden of seizures and other neurological symptoms caused by MCDs or, ideally, to prevent the development of epilepsy in the first place.

Tuberous sclerosis complex (TSC) is often viewed as a prototypical FCM associated with epilepsy, providing a detailed understanding of the clinical features, the pathological substrates, and now the molecular-genetic pathophysiology of this disease.[4,5] Up to 90% of patients with TSC have epilepsy, most of whom are refractory to seizure medications.[6] The cortical tuber is the pathological hallmark of TSC and is strongly correlated with the neurological manifestations including seizures, cognitive disability, and autism. Cortical tubers are characterized by a focal loss of normal cortical organization or lamination and the presence of a spectrum of abnormal dysmorphic or cytomegalic cell types. Although the mechanisms causing epilepsy in TSC are incompletely understood, a number of cellular and molecular abnormalities have been identified in both tuber and peri-tuber tissue from TSC patients that likely promote epileptogenesis and other neurological deficits in TSC, such as molecular

alterations in neurotransmitter receptors and ion channels, abnormalities in cellular growth and proliferation, and disrupted neuronal circuits (for review, see ref. 3). In addition to TSC, other FCMs, such as focal cortical dysplasia, gangliooglioma, and hemimegalencephaly, exhibit clinical, pathological, and molecular features very similar to those of TSC, which may indicate that common mechanisms of lesion formation and epileptogenesis are shared by these disorders.[2]

Recent exciting scientific discoveries have provided particularly revealing insights into the molecular pathophysiology of TSC and related FCM. In particular, abnormal signaling in the mammalian target of rapamycin (mTOR) pathway occurs in several of these focal brain malformations and may serve as a common trigger for epileptogenesis in these disorders. Furthermore, with the advent of drugs, such as rapamycin, that specifically inhibit the mTOR pathway, the use of mTOR inhibitors may represent a potent therapy for not only treating, but potentially also preventing, epilepsy in TSC and related FCMs. In this chapter, we will review the evidence, from both animal models and clinical studies, that a spectrum of FCM primarily represents disorders of mTOR signaling, or "mTORopathies",[2] that mediate epileptogenesis and other neurological deficits. Several recent comprehensive reviews have addressed the role of mTOR signaling in developmental brain disorders and in the generation of seizures.[7–9]

ANIMAL MODELS OF mTOROPATHIES: FROM YEAST TO MICE

The mammalian target of rapamycin proteins were first discovered in yeast in 1991, identified by genetic screening as the target of the potent immunosuppressant drug, rapamycin.[10] Subsequent studies have found highly conserved TOR analogs in other species, including *Caenorabdis elegans*, *Drosophila*, and mammals. mTOR and its analogs are relatively ubiquitous serine-threonine protein kinases and have been implicated in a large variety of cellular functions, including cellular growth, proliferation, survival/death, and metabolism.[11] On the biochemical level, mTOR integrates input from a number of upstream signaling pathways involved in controlling growth and metabolic requirements, such as the insulin-like growth factor/phosphatidylinositol-3-kinase (PI3K)/Akt and adenosine monophosphate (AMP)-kinase pathways (Fig. 65–1). In turn, two mTOR protein complexes, mTORC1 and mTORC2, modulate a number of downstream proteins, such as p70S6 kinase, ribosomal S6, and 4EBP1 that directly mediate protein synthesis and translation. Recent studies have identified many more mTORC1 substrates that significantly expand the potential cellular repertoire of mTOR signaling. In the brain, mTOR has been implicated in specific functions related to axonal and dendritic growth, synaptic plasticity, and other processes involved in normal brain development.

A potential link between the mTOR pathway and developmental brain malformations was first suggested by the discovery of the function of the genes causing TSC. Two genes, *TSC1* and *TSC2*, that are responsible for TSC and encode the proteins, TSC1 (hamartin) and TSC2 (tuberin), respectively. Importantly, TSC1 and TSC2 bind together and act as a complex to inhibit the mTOR signaling pathway, thus normally preventing excessive cellular growth and proliferation.[12] In human TSC, mutation of either the *TSC1* or *TSC2* gene leads to variable loss of TSC1 or TSC2 function and corresponding hyperactivation of the mTOR pathway. Dysregulated mTOR signaling can certainly explain many of the abnormal cellular and pathological features seen in TSC, such as cytomegalic cells and cellular proliferation, contributing to hamartoma or tumor generation. In addition, given mTOR's role in regulating synaptic plasticity and other fundamental neuronal properties, abnormal mTOR signaling may also contribute to mechanisms of epileptogenesis in TSC.[13]

The involvement of abnormal mTOR signaling in developmental brain anomalies related to epilepsy and other neurological deficits have been investigated in a number of animal models of TSC and related disorders. Several knockout mouse models of TSC, involving inactivation of the *Tsc1* or *Tsc2* gene in neurons, glia, or both, mimic many of the pathological features of TSC, such as neuronal hypertrophy, heterotopic neurons, abnormal myelination, and astrocytosis.[14–17] In addition, these models exhibit some of the cardinal neurological symptoms of TSC, including epilepsy and, in some instances, learning deficits. The role of mTOR

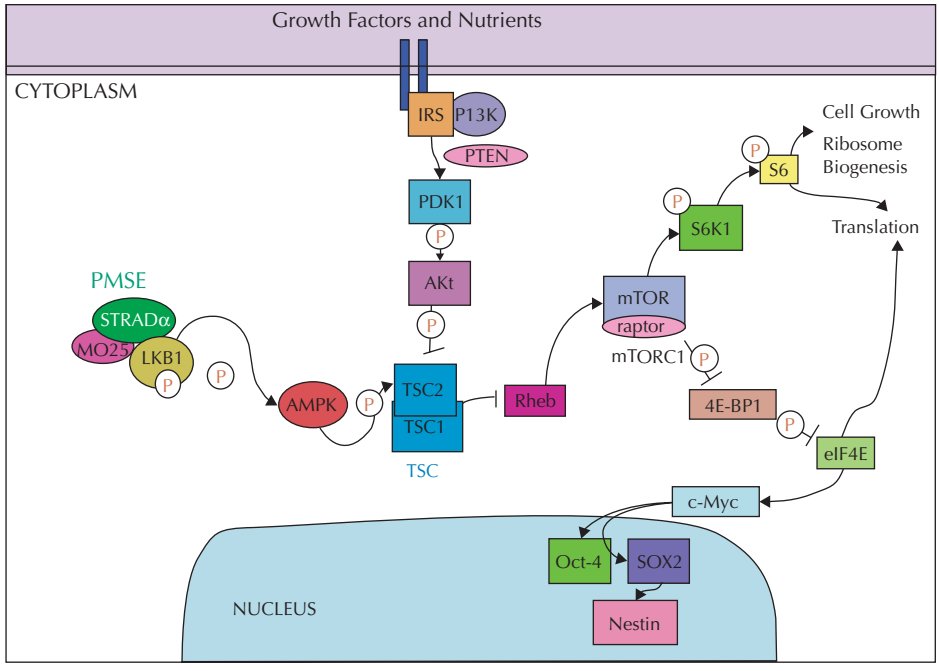

Figure 65–1. The mTOR pathway. Note the key regulatory points, including TSC1, TSC2, PTEN, and LKB1:STRAD. Each provides inhibitory control of mTOR signaling in response to nutrient, growth factor, or energy cues. AMPK, 5' adenosine monophosphate-activated protein kinase; eIF4E, elongation initiation factor 4E; IRS, insulin receptor substrate; mTOR, mammalian target of rapamycin; PDK, phosphoinositide-dependent kinase-1; PI3K, phosphoinositide-3 kinase; PMSE, polyhydramnios, megalencephaly, and symptomatic epilepsy syndrome; PTEN, phosphatase and tensin homolog on chromosome 10; Rheb, Ras homolog enriched in brain; S6, ribosomal protein S6; S6K, ribosomal S6 kinase; TSC1, tuberous sclerosis complex 1 protein; TSC2, tuberous sclerosis complex 2 protein; 4E-BP1, elongation factor 4E binding protein 1.

in mediating most of the neuropathological and neurological symptoms in these TSC mouse models has been established by the reversal of these features by rapamycin.[17–19]

The specific role of the mTOR pathway in causing epileptogenesis has been studied most extensively in a mouse model with conditional inactivation of the *Tsc1* gene in cells expressing glial-fibrillary acidic protein (GFAP), which primarily constitute glia.[14] These *Tsc1*^{GFAP} conditional knockout (CKO) mice appear behaviorally normal for the first few weeks of life but then develop seizures at around 1 month of age, which become progressively more frequent over the following couple of months. Most mice die prematurely, sometimes in an episode of status epilepticus, by 3 months of age. The progressive epilepsy is directly correlated with pathological changes in the brains of *Tsc1*^{GFAP}CKO mice, including megalencephaly, astrogliosis, and neuronal disorganization, especially involving dispersion of the pyramidal cell layers in hippocampus.[14] In addition, molecular and functional changes in astrocytes, such as altered expression of glutamate transporter, potassium channels, and gap junctions, predispose to neuronal hyperexcitability and seizures in *Tsc1*^{GFAP}CKO mice.[20–22] Mammalian TOR signaling is abnormally increased in the brains of *Tsc1*^{GFAP}CKO mice and triggers most of these pathological and molecular changes, as they are mostly reversed by rapamycin.[18] Furthermore, rapamycin administration at an early age that precedes onset of epilepsy can completely prevent the development of seizures in *Tsc1*^{GFAP}CKO mice, indicating an antiepileptogenic effect of mTOR inhibition in this model[18] (Fig. 65–2). Rapamycin treatment after the onset of epilepsy also decreases seizures in already symptomatic *Tsc1*^{GFAP}CKO mice. Notably, however, after rapamycin is discontinued, seizures recur, indicating that continued inhibition of mTOR is necessary to maintain antiepileptogenic efficacy.

In addition to epilepsy, abnormal mTOR signaling has been implicated in causing learning deficits in animal models of TSC. Mice with a heterozygous mutation in the *Tsc2* gene exhibit

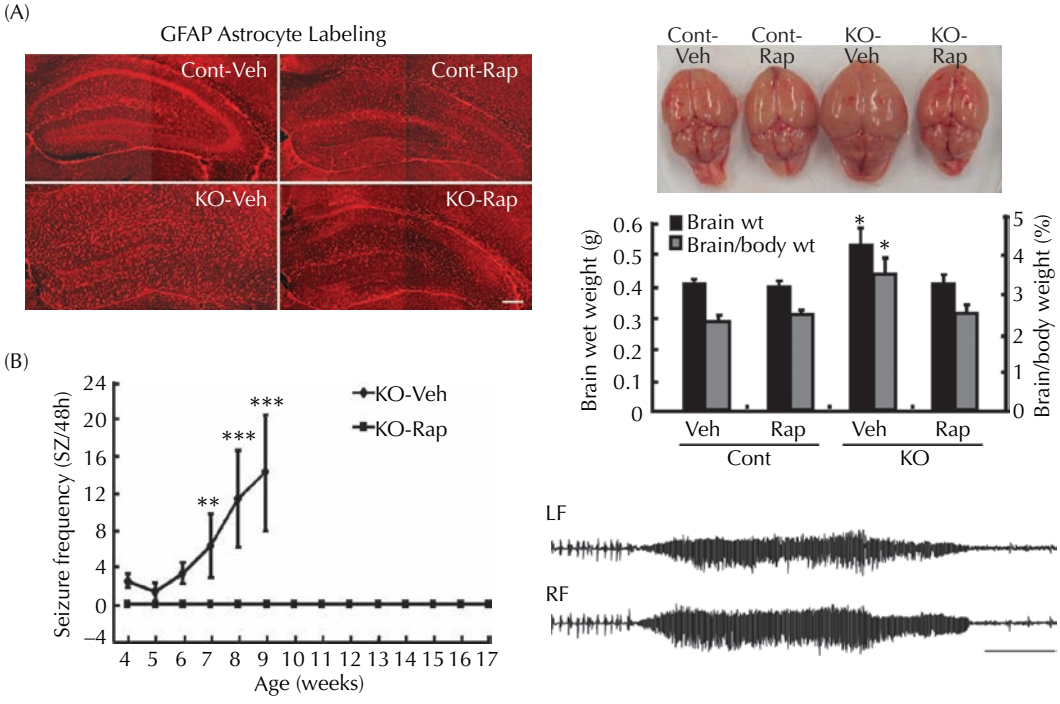

Figure 65–2. The neurological phenotype of a mouse model of TSC is dependent on mTOR and is reversed by mTOR inhibition. **A.** *Tsc1*^{GFAP}CKO mice, involving conditional inactivation of the *Tsc1* gene predominantly in glial cells, exhibit abnormal glial proliferation, as reflected by GFAP staining (left), and a corresponding megencephaly that results from glial proliferation (right). Rapamycin prevents the emergence of the glial proliferation and megencephaly in the *Tsc1*^{GFAP}CKO mice. **B.** *Tsc1*^{GFAP}CKO mice develop seizures (typical ictal EEG trace on the right) at around 4–5 weeks of age, which become progressively more frequent over the following month, with most mice dying prematurely by 2–3 months of age. Rapamycin treatment initiated at 2 weeks of age prior to the onset of seizures blocks the development of epilepsy in these mice. Cont-Veh, control mice treated with vehicle; Cont-Rap, control mice treated with rapamycin; KO-Veh, Tsc1GFAPCKO mice treated with vehicle; KO-rapamycin, Tsc1GFAPCKO mice treated with rapamycin. From ref. 15.

deficits in hippocampal learning, such as spatial learning tasks, in the absence of obvious neuropathological abnormalities or seizures.[17] Rapamycin reverses these learning deficits in these *Tsc2* mutant mice. Remarkably, the beneficial effects of rapamycin are observed after brief treatment of adult mice with already established learning deficits, suggesting that mTOR inhibition could be a potential utility for TSC patients with existing cognitive disabilities.

The role of abnormal mTOR signaling in causing neurological manifestations in animal models of TSC is well established, and the potential benefits of mTOR inhibitors for epilepsy and other neurological deficits are starting to be investigated in TSC patients.[23,24] Interestingly, similar principles and applications of mTOR involvement may be operational in other related developmental or genetic epilepsies. The *PTEN* (phosphatase and tensin homolog deleted on chromosome 10) gene encodes the PTEN protein, which is an inhibitor of the PI3K/Akt pathway upstream from mTOR. Thus, *PTEN* mutations also lead to mTOR hyperactivation and produce several human hamartoma syndromes, including Cowden disease, Lhermitte-Duclos disease, and Proteus syndrome. Mice with *Pten* inactivation in the brain have a number of similarities to models of TSC and have been proposed to represent an animal model of cortical dysplasia.[25] As in the TSC mouse models, rapamycin decreases seizures and associated cellular and pathological abnormalities in the brains of these *Pten*-deficient mice.[25,26] In addition, rapamycin remarkably corrects social deficits in neuronal-specific *Pten* knockout mice suggestive of autistic features.[24] Thus, these findings suggest that mTOR dysregulation may be relevant to neurological manifestations in a variety of animal models of cortical malformations

and that mTOR inhibition could be a potential treatment for a spectrum of TORopathies causing epilepsy and learning deficits.

mTOR ACTIVATION IN HUMAN DEVELOPMENTAL BRAIN DISORDERS

Over the past 6 years, there has been mounting evidence that several distinct FCMs, including tubers in TSC, focal cortical dysplasia (FCD) type IIB (FCDIIB), hemimegalencephaly (HME), and ganglioglioma (GG) may be linked by aberrant activation of the mTOR cascade and constitute a spectrum of disorders known as m*TORopathies.*[2,28–32] The identification of enhanced mTOR cascade activation in human FCM has provided new insight into the pathogenesis of these brain disorders that are variably linked with intractable epilepsy, cognitive disability, and autism. Recently, a new disorder known as polyhydramnios, megalencephaly, symptomatic epilepsy (PMSE) syndrome was identified among the Old Order Mennonite population in Lancaster, Pennsylvania, that results from mutations in the *STRADA* gene[33] and that is characterized by severe epilepsy, profound cognitive disability, and FCM. Interestingly, *STRADA* encodes the novel mTOR regulatory protein, STRADα, and in fact, there is robust evidence of mTOR activation in postmortem brain tissue from PMSE patients.[33,34] Mutations in *PTEN*, which negatively modulates insulin growth factor (IGF), PI3K, PDK, and mTOR signaling, are found in a subset of patients with macrocephaly and autism.[35] Interestingly, the profile of mTOR activation also can be used to distinguish type II FCD from type I FCD, suggesting that mTOR hyperactivation is specific to some but not all FCMs[36] (Fig. 65–3). Thus, mTORopathies encompass a wide range of both rare and common FCMs associated with intractable epilepsy, cognitive disability, and autism that are characterized by abnormal brain architecture. These findings make the compelling case that mTOR inhibition could provide a plausible therapeutic approach to the treatment of neurological features of mTORopathies.

The first studies to demonstrate that the mTOR pathway was activated in FCM assayed the phosphorylation profiles of several downstream mTOR effectors, such as ribosomal S6, S6Kinase, and 4E-BP1 proteins in cortical tubers

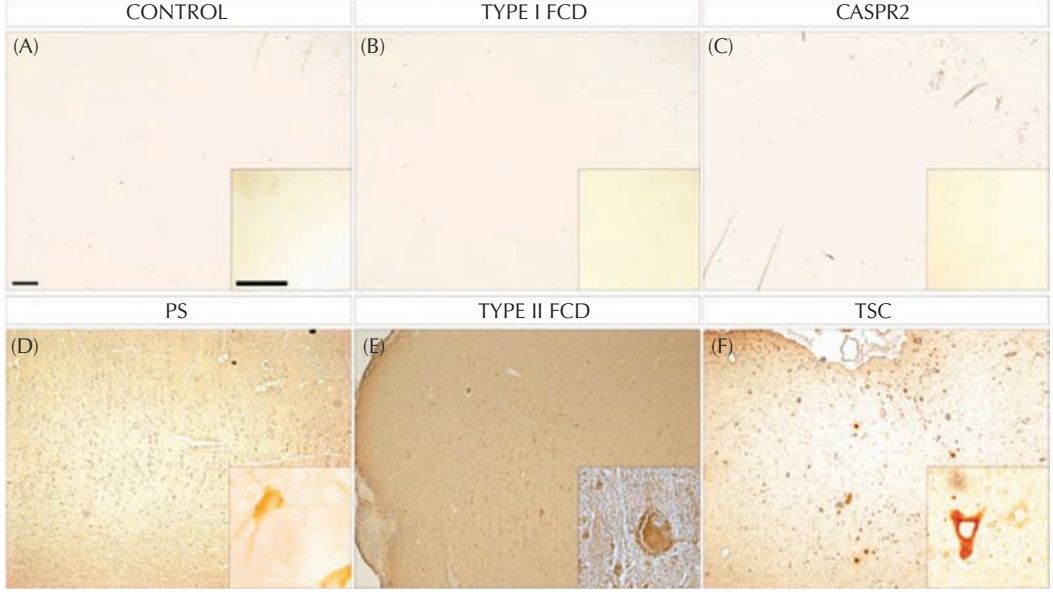

Figure 65–3. A–F. The phosphorylation profile of ribosomal protein S6 distinguishes control tissue and type I FCD from type II FCDs. The CASPR2 mutation is associated with type I FCD. PS, PMSE syndrome. Note the very low levels of phospho-S6 in controls and type I FCD but enhanced levels in type II FCDs.

and FCDs.[28,29] Because the cellular composition of tubers and FCDIIB is similar (e.g., cortical laminar disorganization, cytomegalic cells, and gliosis), it was postulated that there would be a similar activation profile of the mTOR cascade in both malformations. These reports showed that in fact there was cell-specific activation of mTOR in tubers and FCDIIB, evidenced by phosphorylation of ribosomal S6 protein (Ser 235/236) that was most robust in cytomegalic cell types such as balloon cells and large, dysmorphic neurons. These observations were replicated and extended by several other labs.[30] From a pathophysiological perspective, these findings were logical since central known biological roles of mTOR and its downstream target proteins include regulation of cell polarity, establishment and maintenance of cell size, and modulation of neuronal migration. In fact, loss of mTOR inhibition, that is, constitutive mTOR *activation,* leads to disproportionate enhancement of somatic and nuclear size in vitro in cells lacking, for example, Tsc1, Tsc2, or Pten. Subsequent studies demonstrated aberrant phosphorylation of S6K and S6 in balloon cells in HME[28] and atypical ganglion cells found in GG[32] and suggested that the shared pathological characteristics of tubers, FCDIIB, HME, and GG were linked to a core abnormality in mTOR signaling. These findings were relevant because for the first time, a possible pathogenic mechanism for FCDIIB, HME, and GG, sporadic malformations with no known cause, could be reasonably postulated. These data, plus work from preclinical models discussed previously, suggested that hyperactivation of mTOR signaling leads to a marked increase in cell size and invited the compelling and exciting possibility that mTOR inhibition could alter the cellular and clinical phenotypic features of TSC, FCDIIB, HME, and GG.

The evolving role of aberrant mTOR signaling in developmental brain diseases was further supported by the identification of mutations in *STRADA* in PMSE, a devastating autosomal recessive neurodevelopmental disorder characterized by FCM. Analysis of PMSE brain tissue revealed numerous heterotopic cells in the subcortical white matter, as well as cytomegalic cells akin to balloon cells in FCDIIB. Patients with PMSE exhibit macrocephaly, intractable epilepsy, and severe cognitive disability. The causative gene mutation results in loss of function in the STRADα protein, which comprises the heteromeric complex including the kinase LKB1 and its other binding partner, MO25 (see ref. 34 for review). STRADα is a pseudokinase that binds to and activates LKB1 by autophosphorylation. In addition, while LKB1 is mainly found in the nucleus, coexpression of STRADα with LKB1 results in relocalization of both binding partners to the cytoplasm. Cytoplasmic localization of LKB1 has been previously shown to be necessary for LKB1 function—for example, kinase activity toward its downstream targets, such as AMP kinase (AMPK), which becomes activated upon LKB1-mediated phosphorylation of its regulatory activation loop (Thr172). Phosphorylation of TSC2 (Thr1227 and Ser1345) by AMPK leads to direct activation of the heterodimeric TSC2:TSC1 complex. Thus, loss of STRADα function in PMSE leads to loss of AMPK-mediated activation of TSC2 and results in mTOR activation.

The detection of enhanced mTOR pathway signaling provided a rational mechanistic explanation for many of the histopathological similarities between these lesions, including enhanced cell size, cell dysmorphism, and altered cortical lamination. Enhanced cell size may result in part from S6K-mediated phosphorylation of ribosomal protein S6, a component of the 40S ribosomal subunit, and enhanced protein translation, although the precise mechanism leading to enhanced neuronal cell growth is unknown. There is ample evidence in neural and nonneural cell types that altered mTOR signaling leads to changes in actin cytoskeletal arrangement and activation of important structural proteins, such as Rac1 and cdc42, that could lead to changes in cell size and altered cell polarity.[38] It is unclear at what developmental epoch these changes take effect, but in view of the focal nature of FCDIIB, mTOR activation must occur fairly late in cortical development in a restricted number of cells, whereas because HME is an expansive hemispheric malformation, it could be postulated that the activation of mTOR occurs very early in brain development.

A central issue that relates to the pathogenesis of FCM is defining the phenotype of the cells in each lesion subtype. For example, balloon cells in FCDIIB express both glial (glial fibrillary acidic protein [GFAP]) and neuronal (TuJI, NeuN) protein markers, either independently or in combination, suggesting either a mixed lineage, or disordered lineage specification, or

aberrant protein expression.[39] Perhaps more challenging is that in tubers, HME, FCDIIB, and GG, there is robust expression of proteins such as nestin, vimentin, CD133, and Mcm2 that are characteristically expressed in immature cells or even neural stem cells.[40–45] Indeed, proteins such as CD133 and Mcm2 are normally found in stem cells during G1 phase, thus raising the fascinating possibility that balloon cells may be a type of neural stem cell. Recent evidence suggests that balloon cells can be cultured in vitro[36,46] and demonstrates that there is persistent activation of mTOR complex 1 (mTORC1) in vitro. A recent study has shown that proteins that are typically expressed in neural progenitor cells may be linked to mTOR1, such as c-Myc, sex-determining region Y-box 2 (SOX2), and Octamer-4 (Oct-4).[36] SOX2 regulates nestin expression by binding to its enhancer domain, and sustained Oct-4 expression promotes differentiation of nestin-positive neural precursors. Interestingly, differential expression of several stem cell marker proteins such as SOX2, Oct-4, c-Myc, the winged-helix transcription factor forkhead box G1 (FOXG1), Kruppel-like factor 4 (KLF4), Nanog, and sex-determining region Y-box 3 (SOX3) can distinguish between type II and type I FCDs.[36] These findings demonstrate that enhanced mTOR signaling in FCM may explain the profile of protein expression and phenotypic lineage in these cells.

Because single-gene defects associated with TSC and PMSE are linked to aberrant mTOR signaling, the mTOR pathway also provided a rational pathway to examine for candidate mutations in HME, GG, and FCDIIB, which typically occur sporadically without any known familial link or heritability. The prevailing view is that sporadic FCDIIB and HME result from a somatic mutational event that occurs during corticogenesis. A deletion in 15q11–13 has been reported in a single case of sporadic HME and syndromic HME has been reported in association with mutations in *PTEN*,[47] and mutations in LKB1 or B-RAF have been reported in GG.[48] However, the myriad possible genes that could account for these malformations makes identification of a causative mutation a daunting task. In addition, the detection of small or single base pair mutations that are distinct from single nucleotide polymorphisms may be challenging. The phosphorylation profile of the downstream mTOR effectors S6K and S6 provides evidence that the activation of mTOR signaling is enhanced in FCM. However, the mechanism leading to a cortical malformation is unknown e.g., mutation in enhancer or negative regulatory element, post-translational modification, epigenetic silencing, or external/environmental event. To address this question, Schicke and colleagues performed a valuable comparison between FCDII and TSC by examining activated phosphoproteins upstream in the mTOR cascade to determine where activation might be first initiated.[49] These investigators found that the cascade activation was initiated at TSC1:TSC2 in TSC, whereas there was an upstream signaling divergence point at PDK1 that was phosphorylated in FCD but not in TSC. These data suggest that while mTOR activation is initiated by direct loss of inhibitory mTOR control by TSC1:TSC2 in TSC, cascade activation may occur from a more upstream or parallel entry point in FCDIIB. This is currently unknown for GG or HME, although B-RAF mutations may lead to enhanced mTOR signaling. Thus, since HME, GG, and FCDIIB are histopathologically similar to TSC, and since there is a similar profile of mTOR activation in all four lesion types, it seems plausible that candidate gene mutations could be found within the mTOR pathway, such as a loss-of-function mutation in an mTOR inhibitor or a gain-of-function mutation in an mTOR activator. Thus far, however, attempts to screen for mutations in mTORC1 regulatory elements such as *TSC1*, *TSC2*, and *PTEN* have not revealed mutations in DNA extracted from these malformations. One complicating factor is that the heterogeneous pathology of each lesion may suggest that the somatic mutations are confined to particular cell types and, thus, single-cell genetic analysis may be warranted.

A pivotal question is how mTOR activation in FCM can lead to seizures and intractable epilepsy. As discussed above, altered expression of glutamate transporter, potassium channels, and gap junctions in astrocytes in the *Tsc1*^{GFAP}CKO mice are associated with neuronal hyperexcitability and seizures, although the precise mechanisms are unknown. In addition, there is clear evidence that in animal knockout strains, rapamycin can prevent the development of recurrent seizures, although whether this occurs by a reversal of histopathological features or by pharmacological changes in synaptic activity, neurotransmitter release or uptake, or

neuromodulation is not yet known. Analysis of these mechanisms in resected human tissue is challenging, though not impossible, and much work still is needed. Current data suggest that dysmorphic neurons may be important culprits in seizure generation in FCD, whereas balloon cells may be electrically silent.[50] There is clear evidence that expression of excitatory amino acid and $GABA_A$ receptor subunits is altered in TSC, FCD, HME, and GG, but how these changes culminate in recurrent and often intractable seizures is unknown.[51,52] From a molecular perspective, while much has been learned over the past 5 years about upstream control of mTOR activation, there still remains much to understand about the downstream effects of mTOR in neurons and a putative role in hyperexcitability. For example, mTOR governs cellular protein translation via its role in regulation of ribosomal protein synthesis and contributes to the transcription of a variety of genes via modulation of several transcription factors, including c-myc and STAT3. Each of these proteins regulates, in turn, numerous target proteins that are part of the overall mTOR activation response. Thus, it is likely that one or more of these downstream mTOR effectors play an important role in the establishment of cells size or epileptogenesis. Further investigation to define how downstream mTOR effectors can be targeted therapeutically could identify new compounds that, for example, are more effective or less toxic than rapamycin or its analogs.

SUMMARY AND FUTURE COURSE

Studies of both animal models and human brain specimens strongly implicate abnormal mTOR signaling in the pathophysiology of FCM. From a therapeutic standpoint, these findings suggest the exciting possibility that mTOR inhibitors may represent potent and specific treatments for the neurological manifestations of these disorders, including epilepsy. However, despite significant preclinical data, there is currently only anecdotal evidence that rapamycin is efficacious for seizures in human patients with TSC or other TORopathies. In one case report, a 10-year-old girl with TSC experienced a reduction in her seizures with systemic rapamycin therapy,[24] and in clinical trials of rapamycin for astrocytoma and renal tumor growth, some TSC patients have been reported to have decreased seizure frequency as a secondary finding[23]; however, no controlled clinical studies exist testing the benefit of rapamycin for epilepsy in TSC. Furthermore, there have been no reports of early rapamycin treatment preventing or slowing the development or progression of seizures in high-risk, presymptomatic TSC patients before the onset of epilepsy. If rapamycin is shown to be beneficial for seizures, either as antiepileptogenic or symptomatic therapy, several important clinical questions will need to be addressed. First, should rapamycin be used for TSC patients with neurological symptoms only or prophylactically in all TSC patients? The preclinical data suggest that appropriately timed rapamycin therapy could prevent seizures altogether, that is, serve as an antiepileptogenic modification. A particularly tantalizing hope is that rapamycin might yield a highly targeted therapy for infantile spasms in TSC. Thus, should rapamycin be given to TSC infants prophylactically? Once started, how long should rapamycin treatment be continued? Published clinical studies suggest that the benefits of rapapmycin in TSC may be limited to the duration of therapy; thus, one concern is seizure recurrence after cessation of mTOR inhibition. If rapamycin therapy is to be lifelong, then the long-term side effects, such as aphthous oral ulcers, hyperlipidemia, and an enhanced risk of infection, must be anticipated and effectively managed. Particular caution may be warranted with the use of rapamycin in children, given the potential role of mTOR in synaptic plasticity and learning.

There are other critical issues that need to be addressed regarding mTOR cascade activation in TORopathies. First, to date, there have been no reliable biomarker studies to determine whether mTOR pathway activation is a systemic or localized phenomenon in, for example, TSC and FCD. For example, previous studies in the renal transplant literature have demonstrated that changes in the phosphorylation status of p70S6 kinase is a better predictor of rapamycin effect in preventing rejection than a serum rapamycin level.[53] The detection of serum biomarkers for TSC or other TORopathies might provide predictive, prognostic, or diagnostic assays that could be related to seizure onset, seizures recurrence, infantile spasms, or autism. In fact, these markers could result

in improved disease surveillance or treatment protocols. Second, there has been little investigation of how mTOR signaling may differ or vary across individual TSC or FCD patients. One such scenario might be that greater disease severity correlates with increased levels of systemic or organ-specific mTOR activation. Finally, rapamycin therapy could lead to a paradoxical enhancement of mTOR signaling via feedback interactions with Akt and other upstream modulators.[54] Thus, new strategies to modify mTOR signaling may need to be considered as clinical data are analyzed.

Chapter 66

Major Susceptibility Genes for Common Idiopathic Epilepsies

ELP4 in Rolandic Epilepsy and *BRD2* in Juvenile Myoclonic Epilepsy

Deb K. Pal
David A. Greenberg

INTRODUCTION

Clinical observations confirm that the idiopathic epilepsies are neurodevelopmental disorders strongly influenced by genetic factors. Genetic epidemiological studies prove major genetic influences on two common forms of idiopathic epilepsy to be discussed here: rolandic epilepsy (RE) and juvenile myoclonic epilepsy (JME). The common forms of these idiopathic syndromes have a complex genetic inheritance, and this fact complicates the task of finding and elucidating the susceptibility genes as well as proving their pathogenic role. Genetic heterogeneity and phenotype definition are much more serious factors in studying common complex epilepsies than they are in the study of densely affected epilepsy pedigrees showing Mendelian inheritance. In complex disorders, several genes and sometimes environmental factors are believed to contribute to disease etiology; as a result, proving a causative role for any *one* gene, in a genetic model involving multiple genes, can present a challenge.

In this chapter, we first review the methodological issues associated with analyzing complex genetic disorders and then explain the

strategy that we have used in investigating RE and JME. Genome-wide linkage analyses and fine mapping have resulted in the identification of susceptibility genes *ELP4* in RE and *BRD2* in JME. We discuss the evidence in favor of a pathogenic role for each gene and the further steps that are required to establish causality.

THE IDIOPATHIC EPILEPSIES AS NEURODEVELOPMENTAL DISORDERS

Determining the etiology of the common idiopathic epilepsies is a difficult challenge. Although there have been several discoveries of genes involved in rare Mendelian variants of idiopathic epilepsies, for example in autosomal dominant juvenile myoclonic epilepsy[1] and benign familial infantile convulsions (BFIC),[2] mutations in these genes have not been demonstrated in the common forms of epilepsy that show complex, rather than simple Mendelian, inheritance. Further, the phenomenon of heterogeneity, in which similar phenotypes have different genetic etiologies, means that data thought to reflect a single disease may actually refer to diseases of different etiologies. In contrast to the rare Mendelian forms of epilepsy, the common forms have a complex inheritance in which susceptibility likely results from the combination of the interaction of a number of genes, more likely oligogenic (few genes of major effect) rather than polygenic (many genes, each of equal small effect), and there is no evidence for an environmental influence.[3] Many of the gene mutations identified in rare epilepsies are located in ion channel or neurotransmitter subunits, giving rise to the term *channelopathy*, but there is evidence that susceptibility genes influencing common idiopathic epilepsies may be involved in pathways related to neurodevelopment (rather than ion channels).

The hypothesis for a neurodevelopmental origin of common epilepsies derives from three lines of evidence—natural history, neuropathology, and neuroimaging—and is further supported by experimental data outlined later in this chapter. There is increasing recognition of premorbid symptoms in RE. Children with RE are at 2.5 times higher odds of developing a speech sound disorder than the general population and 5.8 times higher odds of developing dyslexia.[4] Speech sound disorder presents in the first 2 years of life, long before the median onset age for seizures, and dyslexia is also recognized at or soon after school entry, usually prior to or around the time of the first seizure. In RE families, these symptoms were reported as epilepsy-associated, but it is evident that their occurrence precedes the onset of seizures, and therefore their sequential onset may indicate a neurodevelopmental pathogenesis of RE. Furthermore, the presence of these same symptoms in relatives of RE patients (who themselves do not have epilepsy) suggests an underlying genetic etiology for these traits related to, but partly independent of, RE itself.[4]

Similar claims for a premorbid or comorbid diathesis have been made for a distinct frontal lobe personality in JME,[5] although this has been debated.[6,7] However, a growing number of neuroimaging studies suggest that JME shows focal brain structural abnormalities[8] associated with specific neuropsychological impairments, and similar findings are emerging from studies of childhood absence epilepsy.[9] Detailed morphometric neuropathological studies in idiopathic generalized epilepsy (IGE) suggest an abnormally increased number of neurons in the molecular layer of the cortex,[10] also described as *microdysgenesis*. These findings have proven hard to replicate owing to the scarcity of biological material. Nonetheless, the pertinence of brain structural abnormalities is further supported by the JME mouse model, discussed below. Taken together, these various lines of evidence suggest that the pathogenesis of idiopathic epilepsies is related to subtle deviations in the normal postnatal development of the brain.

METHODOLOGICAL ISSUES AND EXPERIMENTAL STRATEGIES IN COMMON EPILEPSIES

The experimental approaches available in common epilepsies are somewhat different than those in Mendelian disorders because, in most common epilepsies, there are usually not many affected people in a single kindred. Thus, a single family of a person with a common type of epilepsy does not contain sufficient information

for a genetic study. One way to overcome this limitation is to collect many families with the same phenotype; each family then contributes some genetic information. However, using this strategy, genetic heterogeneity becomes a critical confounder in both genetic association and linkage studies,[11] because signals from different genetic forms of disease may "cancel each other out." An obvious solution would be to separate out possibly different genetic forms on the basis of phenotypic differences. Sometimes, though, there are no obvious phenotypic features to distinguish different genetic forms. Nonetheless, what are often considered minor differences can be exploited to limit potential genetic heterogeneity. For example, generalized tonic-clonic seizures (GTCS) that occur on awakening may be inherited differently from GTCS that occur at random times of the day,[12,13] These studies show that some apparently minor distinguishing features can be feasibly used to stratify datasets to guide gene searches.

Genetic heterogeneity may occur within or between different subpopulations. For example, evidence for linkage to *EJM1* in JME is limited to European origin families and is not found in Hispanic origin or African-American families.[14–17] Another JME locus at 6p12-p11 was found in families from Belize and Mexico.[18] In a third example, GTCS are linked to markers on chromosome 10 in families from India, but no such linkage peak exists in corresponding European datasets.[19] This diversity of findings in genomic geography is increasingly recognized as the norm in international studies of complex disease and likely reflects differing genetic selection pressures on subpopulations in different environments. In epilepsy, the origins of genetic heterogeneity also reflect the multiple genes that contribute to the neural circuits that regulate cortical excitability.

A second complementary approach to overcome genetic heterogeneity is to divide the overall phenotype into simpler traits and then genetically analyze those traits. The success of this approach depends on stringent phenotyping. For example, in IGE, not only do probands have different types of seizures (e.g., absence, generalized tonic-clonic, myoclonic), but also clinically affected family members often have seizure types different from those seen in the proband.[20] By parsing the epilepsy syndrome into separate seizure types, different loci have been identified that lead to shared or distinct influences on the different seizure types in IGE.[21] Thus, *malic enyme 2* (*ME2*) has been identified as a major susceptibility gene common to all forms of IGE,[22] while myoclonic seizures have been mapped to *bromodomain 2* (*BRD2*).[23] Similarly, in RE, probands have combinations of neurodevelopmental traits including speech dyspraxia and dyslexia, while family members without seizures may be affected by the same disorders and/or exhibit centrotemporal sharp waves (CTS) on their electroencephalograms (EEGs). Thus, instead of conducting genetic analysis on a family in which only one person has epilepsy, it is possible to increase the power of genetic analysis by analyzing traits that segregate in more than one family member. Using this strategy, a 4–6 Hz spike-and-wave EEG trait seen in unaffected family members of JME proband families was found, like JME itself, to be influenced by the chromosome 6p21 locus,[15,24] and possibly photosensitivity as well.[25,26] We discovered linkage to the 11p13 region for CTS[27] and showed that speech dyspraxia and CTS share linkage at the same locus.[28] Loci for dyslexia in RE appear to be distinct from those for CTS or speech dyspraxia in RE,[29] adding complexity to the genetic model of the overall phenotype.

Below we review the evidence for the role of *ELP4* in RE and that of *BRD2* in JME.

ELP4 AND RE

Segregation Analysis

Segregation analysis is a method that allows one to test hypotheses about different modes of inheritance. It only has the power to exclude tested modes of inheritance, not to prove conclusively that one mode is correct, and it is often complicated by methodological errors in ascertainment and analysis. Although some attempts were made to estimate the inheritance of CTS and of RE in the past, they were affected by such methodological errors. We designed our study to avoid such errors: we collected 23 probands with RE through unambiguous single ascertainment. Thirty siblings of RE probands in the age range 4–16 years underwent sleep-deprived EEG; observations from those who remained awake were

omitted. Centrotemporal sharp waves were rated as present or absent by two independent observers blinded to the study's hypothesis and the subjects' identities. Twenty-three siblings showed evidence of sleep in their EEG recordings. Eleven of the 23 recordings demonstrated CTS, yielding a corrected segregation ratio of 0.48 (95% CI: 0.27–0.69). The male-to-female ratio of CTS affectedness was approximately equal. The segregation ratio of CTS in RE families is therefore consistent with a highly penetrant autosomal dominant inheritance with an equal sex ratio. Autosomal recessive and X-linked inheritance can be rejected.

Linkage Analysis

Linkage analysis is a method for localizing major effect genes to within several million base pairs. Linkage can be used either to test if a chromosomal region containing a suspected gene is related to disease expression or to do a genome-wide search for disease-related loci. We conducted genome-wide linkage analysis of the CTS trait in 38 U.S. families singly ascertained through a RE proband. In 11 of the families, one additional sibling was known to carry the CTS trait, but the CTS status of individuals younger than 4 years or older than 16 years was unknown because of its age-limited expression. Only markers on chromosome 11 yielded two-point logarithm of the odds (LOD) scores exceeding 3.0. Markers in the region of chromosomal band 11p13 provided strong and compelling evidence for linkage to CTS, with a maximum two-point LOD score of 4.01 and a multipoint LOD score of 4.30. Both European and non-European ancestry families contributed proportionally to the LOD score. Maximization of the LOD score in this region of 11p most often occurred at 95% penetrance, consistent with predictions from segregation analysis. We did not observe significant evidence of linkage at markers previously reported for CTS at 15q14,[30] nor for a rare recessive variant of RE at 16p12–11.2,[31] nor for X-linked rolandic seizures and cognitive deficit.[32] Similarly, we did not find evidence of linkage to 11p13 in an autosomal dominant variant of RE with speech dyspraxia and cognitive impairment.[33]

Association Analysis

Association analysis can show that having a specific allele (variant) at a locus correlates with an increased risk for disease. We designated a 13 cM linkage region at 11p13, encompassing the area in which LOD scores >2.0, as our region of interest for fine mapping. We then tested for association of CTS with single nucleotide polymorphism (SNP) markers distributed across genes in this region. We initially used a *discovery* dataset that included 68 cases and 187 controls group matched for ancestry and gender; 38 of these cases were included in the original linkage screen. In addition to case-control analysis, we used family-based analysis to guard against the potential for positive confounding due to population stratification. We took a pure likelihood approach to the statistical analysis of linkage and association.[34] We then typed additional SNPs around genes that showed compelling evidence of association in the preliminary analysis. In a second, independent, *replication* case-control dataset, we typed a subset of the SNPs in our region of interest. The replication set included 40 RE cases and 120 controls from western Canada; the two datasets were then jointly analyzed.

We discovered a significant association with SNPs in *ELP4* introns 9, 6, and 5, with estimated odds ratios of 1.80–2.04 at these markers (Fig. 66–1). These associations were demonstrated in both family-based analysis and case-control analysis. Joint analysis of the U.S. and Canadian datasets provided confirmation of these associations; the maximum likelihood ratio for association at intron 9 was 589:1 (Fig. 66–2). All associated markers are in linkage disequilibrium with each other (Fig. 66–3), so it is unlikely that they are exerting independent effects. However, none of the associated SNPs are predicted to have deleterious functional consequences, and we therefore resequenced this genomic region to search for a causative variant.

Genomic Resequencing

We resequenced the coding portions, the exon-intron boundaries, and the 50 kb upstream region of the *ELP4* gene in 40 RE probands from the discovery set. The 274 kb *ELP4* gene

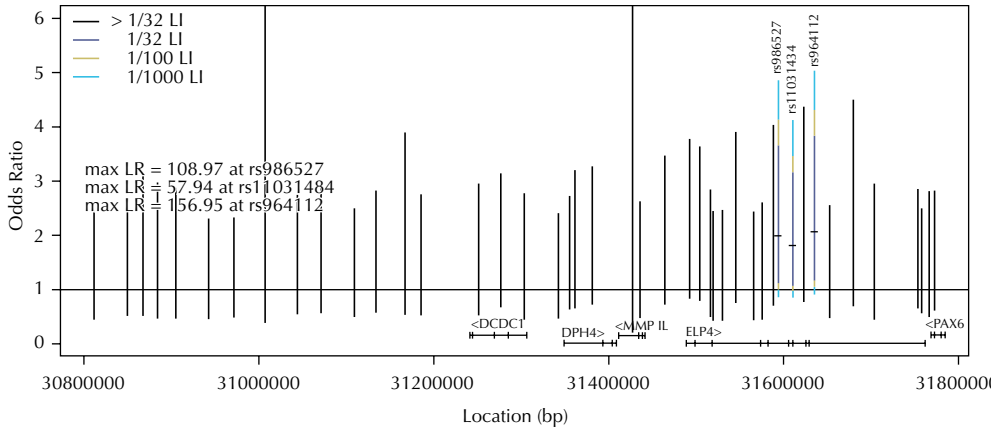

Figure 66–1. Pure likelihood plot of association evidence in a discovery set and in joint analysis of datasets (Fig. 66–2). This pure likelihood analysis plots the odds ratio (OR) on the *y*-axis and the base-pair position on the *x*-axis. Each vertical line represents a likelihood interval (LI) for the OR at a given SNP. The OR 1⁄4 1 line is plotted as a solid black horizontal line for reference. LIs in color are denoted as SNPs of interest, whereas a gray line indicates that the SNP is not of interest because the 1/32 LI for that SNP covers the OR 1⁄4 1 line. The small horizontal tick on each LI is the maximum likelihood estimator for the OR. The portion of the colored LI that covers the OR 1⁄4 1 horizontal line indicates the strength of the association information at that SNP. In particular, if the navy blue portion is above the OR 1⁄4 1 line while the yellow portion of the LI covers the OR 1⁄4 1 line, then the LOD evidence at that SNP is between 1.5 and 2 (i.e., the 1/32 LI does not include the OR 1⁄4 1 value, but the 1/100 LI does); similarly, if both the yellow and navy blue portions are above the OR 1⁄4 1 line but the turquoise portion covers the line, then the LOD evidence is between 2 and 3 (i.e., the 1/100 LI does not include OR 1⁄4 1 as a plausible value but the 1/1000 LI does). The further the colored line is above the OR 1⁄4 1 line, the stronger the association evidence. The max LR for each SNP in color is also provided as text in the plot, providing evidence not only of whether the LOD evidence is between 2 and 3, but also the exact value of the max LR.

is transcribed into a 1584 bp mRNA consisting of 12 exons, a 35 bp 5′untranslated region (5′-UTR), and a 257 bp 3′-UTR. Alternative transcripts have been reported that include or exclude the last two exons. Three previously reported SNP variants were found in these 40 individuals, but the distribution of these SNPs was not different from that found in controls or reference databases.

Summary of Evidence for *ELP4* as a Susceptibility Gene for CTS

Obviously, CTS is a mandatory component of the overall RE phenotype. The sum of our analyses points to CTS as a highly penetrant autosomal dominant trait. We have very strong evidence of a single genome-wide locus at 11p13 influencing the CTS trait. Association evidence unambiguously points to an association with markers in the *ELP4* gene, but not with markers in the *DCDC1*, *DPH4*, *IMMP1L*, or *PAX6* genes under the 11p13 linkage peak. This association evidence is present in family-based analysis, making population stratification an unlikely explanation for the finding, and was also replicated in an independent dataset. However, no obvious coding mutation has been discovered in the *ELP4* gene. There are several possible explanations for this that are yet to be fully explored. First, coding changes are not common in complex diseases, in contrast to the simple loss- or gain-of-function coding mutations found in Mendelian diseases. Hence, the sought-after variant may reside in a regulatory or conserved region of the gene; second, some regulatory regions may be distant from the gene that they regulate, so the causative variant may not be in *ELP4*; third, it is possible that the causative variant lies in another part of the 11p13 linkage region and that the association with *ELP4* represents long-range linkage disequilibrium with the true variant. The search for the causative variant will continue; meanwhile, a coherent evaluation of the evidence should take account of the biological function of potential candidate genes. The relevant information about the role of *Elongator* in the nervous system is presented below.

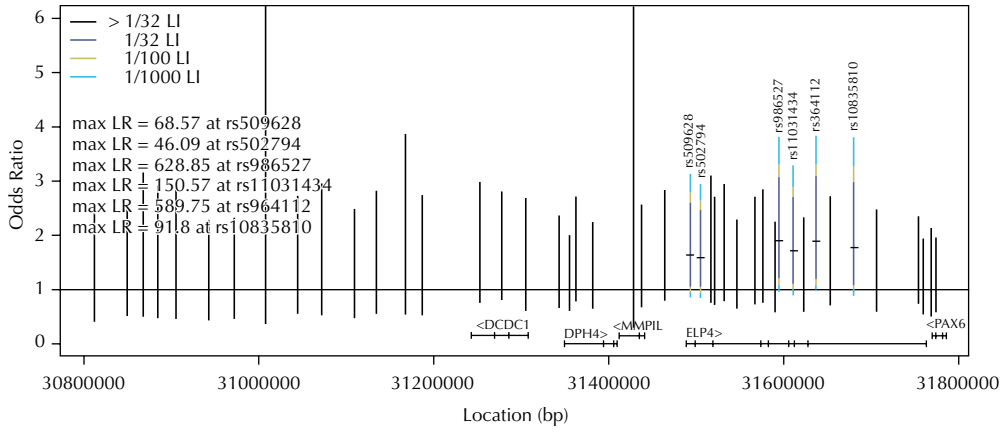

Figure 66–2. Joint analysis of discovery (U.S.) and replication (Canadian) datasets.

Elongator Biology

There is increasing evidence that impairment of the *Elongator* complex may be involved in several different neurological disorders, and this topic has recently been extensively reviewed[35] and is excerpted below. *Elongator* is composed of six subunits (*ELP1–ELP6*). *ELP1* is the main scaffold protein, whereas *ELP3* is the main enzymatic subunit that has histone acetyltransferase activity.[36] *Elongator* is believed to play an important role in the transcriptional elongation of some genes,[37,38] a hypothesis further supported by the observation of transcriptional defects in multiple genes in *ELP1*-depleted cells and mouse embryos.[37,39]

As well as a nuclear function associated with RNA polymerase II and histone H3 acetylation, there is evidence that the *Elongator* complex has a role in tRNA modification in the cytoplasm. Cytoplasmic *ELP1* colocalizes with filamin A in membrane ruffles, and a defective actin cytoskeleton has been reported in *ELP1*-depleted cells, possibly explaining the cell motility defects.[40] Thus, it appears that *Elongator* critically regulates the migration of multiple cell types.

In humans, mutations of the *ELP1* gene on chromosome 9 cause familial dysautonomia (FD) or Riley-Day syndrome.[41] *ELP1* levels are very low in brain tissues of FD patients, and brain neuroimaging abnormalities are

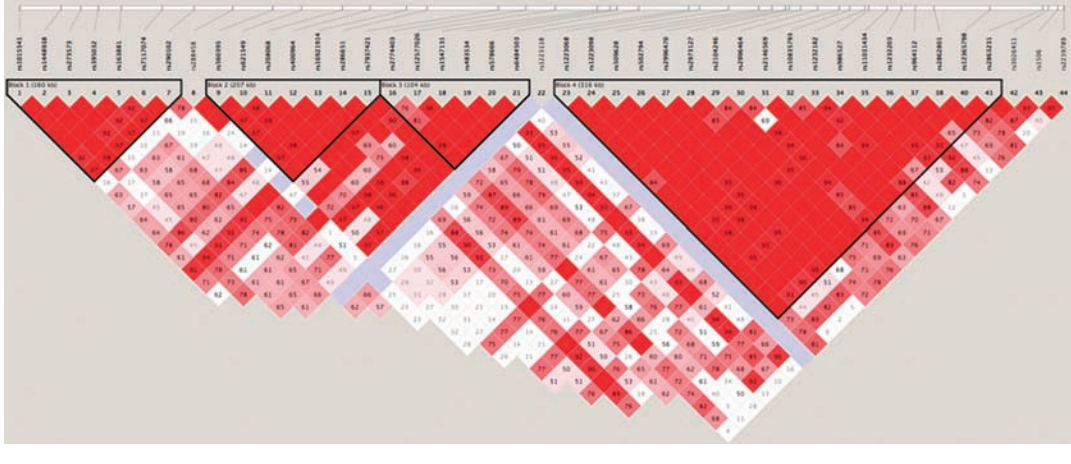

Figure 66–3. Linkage disequilibrium map in the 11p13 region from SNP association data. Block 4 spans the *DPH4, IMMP1L, ELP4,* and *PAX6* genes.

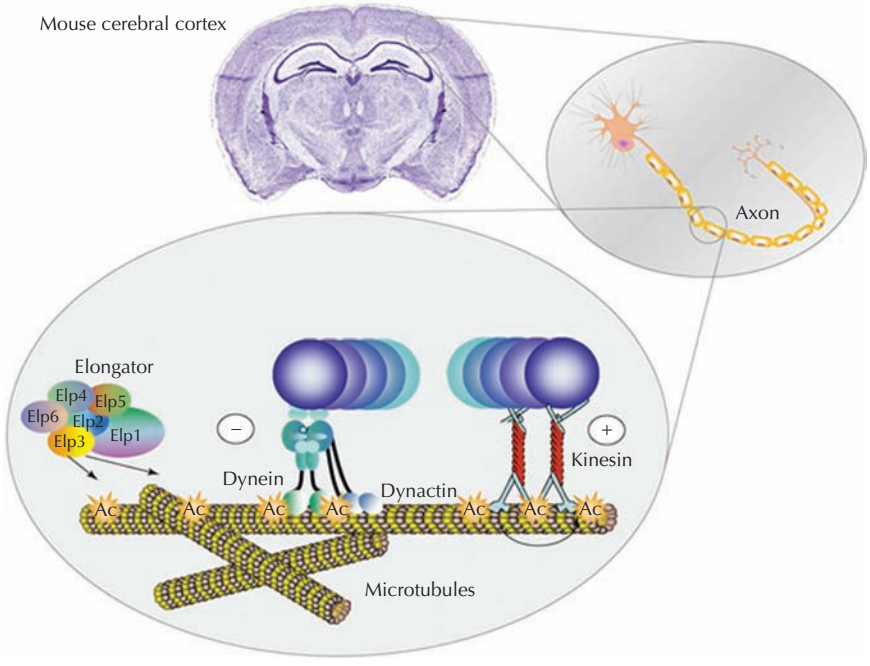

Figure 66–4. A putative role for *Elongator* in the microtubule-dependent transport of cargoes required for the development and/or survival of neurons. *Elongator* catalyzes a-tubulin acetylation via Elp3, a modification that promotes the anchoring of molecular motors and underlies microtubule-dependent trafficking. Two molecular motors anchored to microtubules are illustrated, namely, kinesin and the dynein/dynactin complex, which are involved in the anterograde or retrograde transport of various cargoes (blue circles), respectively. From ref. 35.

reported,[42] as well as EEG abnormalities and seizures.[43] *Elongator* plays an important role in the migration and branching of cerebral cortical projection neurons by promoting the acetylation of alpha-tubulin[44] (Fig. 66–4). Association of *ELP3* variants has been shown with sporadic Amyotrophic Lateral Sclerosis (ALS),[45] and it has been speculated that *Elongator* contributes to the microtubule-dependent trafficking of anti-apoptosis cues in central and peripheral neurons.[35] We speculate that *ELP4* mutations might also partially abrogate *Elongator* function in a regionally and temporally specific manner that results in disruption of neural networks involved in vocal tract function, and with a resulting imbalance of excitatory and inhibitory circuits. We expect the story to become clearer in the near future.

BRD2 AND JME

In discussing our work examining *BRD2* as a gene related to the expression of JME, we must explain why we examined *BRD2* as opposed to any other gene, especially since it had no obvious relationship to our preconceptions about the origins of idiopathic epilepsy in humans. First, it came to our attention when we chose to study JME because the phenotype appeared easy to define; the awakening myoclonic jerks are almost pathognomonic for the condition (when there are no exclusionary symptoms). Second, we could make use of the interictal 4–6 Hz spike-and-wave seen in almost all JME patients as the phenotype because this trait is also seen with increased frequency in clinically unaffected family members.[46,47] This meant that we might be able to use the presence of the EEG trait as the phenotype for the linkage analysis instead of the epilepsy itself, which proved to be a useful approach,[15,47] an approach later confirmed when it led to the discovery that *ELP4* is related to the centrotemporal spikes of RE.[48]

Segregation Analysis

A segregation analysis of JME was able to exclude simple Mendelian modes of inheritance,

even when the 4–6 Hz spike-and-wave trait was used as the phenotype of interest (clinically unaffected family members with the trait were included as "affected").[49] However, the segregation analysis showed that the best fit to the data was a model of inheritance involving two genes, one showing dominant and one showing recessive inheritance. Models in which both loci were dominant or both were recessive did not fit the data as well. Interestingly, two loci later identified as contributing to JME supported that mode of inheritance: linkage analysis identified a dominantly inherited locus at chromosome 6p21, which was eventually identified as *BRD2*, and one on chromosome 18, *ME2*, that indicated recessive inheritance.

Linkage and Association Analysis

Our initial linkage scan revealed the presence of a JME-related locus on chromosome 6p21, a finding confirmed in the dataset of Janz.[14,15] Later, after an entirely new and larger dataset was collected, we were not only able to confirm the linkage again, but the discovery of two families with recombinants allowed us to narrow down the region containing the gene to between the HLA-DQ and HLA-DP loci. Furthermore, the advance in genetic technology allowed us to discover an association of JME, first with a microsatellite marker[17] and later with SNP haplotypes in *BRD2*.[23] Both of these results supported *BRD2* as the gene influencing JME expression. Subsequently, we demonstrated a strong association of *BRD2* variants with JME, with an odds ratio of 6.45.[23]

There are two important points to emphasize. First, these results started with a highly specific phenotype, then used linkage data from entire families to find a locus containing a disease-related gene, and then used association analysis to identify the gene within that locus. No genes were excluded from examination on the basis that they did not fit a preconceived epilepsy mechanism. Second, in the absence of any idea of what the mechanism might be, and confronted with a candidate gene of unknown function and containing no epilepsy-related exonic mutations after sequencing, the problem remained (and remains) one of proving that the gene we found is the gene we are looking for. Up to this point, all the evidence is statistical. In the absence of any idea of how a so-called transcription factor element could lead to a common form of epilepsy, we needed some biological evidence that *BRD2* was somehow involved in expression. This led to our development of the *Brd2* knockout mouse.

Brd2 Knockout Mouse

Our *Brd2* knockout mouse was created using the gene-trap technique,[50] and embryos were raised on a B57Bl/CJ background. We made several observations about mice homozygous for the knockout ($Brd2^{-/-}$):

1. $Brd2^{-/-}$ embryos do not survive past the 13th gestational day (E13).
2. $Brd2^{-/-}$ embryos are considerably smaller than their wild-type $brd2^{+/+}$ or $brd2^{+/-}$ littermates. Figure 66–5 presents a homozygote embryo and a wild-type embryo at E11, showing the much smaller size of the homozygote.
3. The neural tube of the homozygote is not closed, as the arrow in Fig. 66–5 shows.
4. The most obvious effect of a lack of *brd2* during development is on the mouse nervous system. Figure 66–6 shows a wild-type and a $brd2^{-/-}$ mouse in cross section at E11. Note that the brain and spinal cord of the homozygote are severely dysmorphic, with brain development apparently spatially disorganized. Note also how other organs, while smaller than those in the wild type, appear structurally intact.
5. Confirming the apparently major effect of *brd2* mostly on nervous system development, a *brd2* probe showed that *brd2* is expressed mostly in developing nervous tissue. Figure 66–7 shows a wild-type mouse (left) with the densest areas of stain, indicating the greatest expression of *Brd2*, being the nervous system. The $Brd2^{-/-}$ mouse (right) shows no *Brd2* expression.

Thus, from the studies of the $Brd2^{-/-}$ mouse, we can conclude that *Brd2* is not only essential for life, it is a major determinant of brain development and its expression mostly in the brain of developing embryos suggests a critical role, at E13 and earlier, in the nervous system. This immediately raises the question: what is

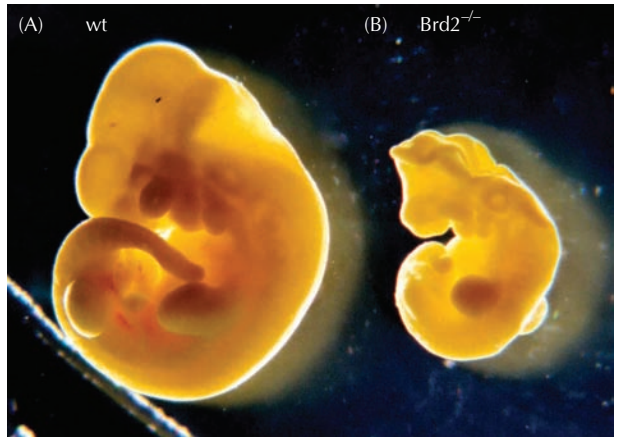

Figure 66–5. Photographs of wild-type (*Brd2*$^{-/-}$, left) and *Brd2*$^{-/-}$ (right) embryos at embryonic day (E) 9.5 of gestation. The mutant embryo is smaller, and the developing neural tube is unfused (arrow). From ref. 50.

the effect of having a deficit, not an absence of, *Brd2*?

The *Brd2*$^{+/-}$ Heterozygote

By all outward appearances, the heterozygote is normal and behaves grossly normally. The question is: are the mice more sensitive to seizures, and is their brain structure normal? We determined that *Brd2*$^{+/-}$ mice are more susceptible to chemically induced seizures than are wild-type mice. We initially used pentylenetetrazole to test seizure susceptibility. The heterozygotes were much more sensitive to the pentylenetetrazole than the wild-type mice, as shown in Fig. 66–8.[51]

These results were confirmed using the seizure-inducing ether, flurothyl (Velisek et al., unpublished data); we also showed that female heterozygote mice are much more sensitive to tonic-clonic seizures than male mice, a finding

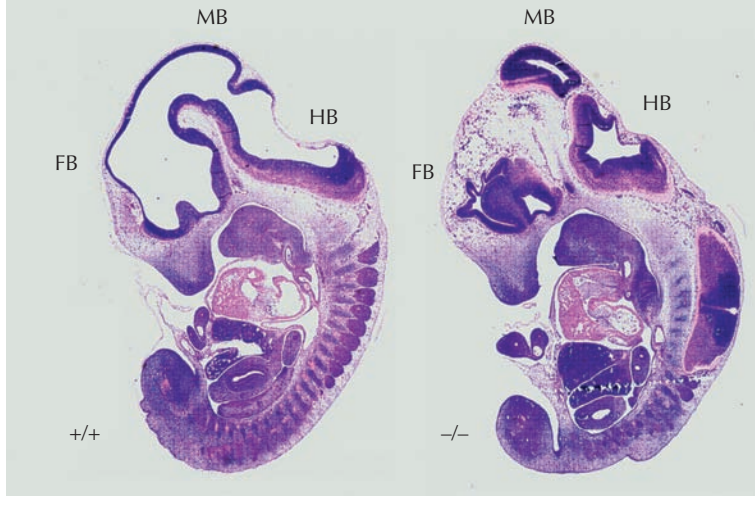

Figure 66–6. Sagittal sections of E11.5 embryos of wild-type and mutant embryos. Grossly normal-appearing heart, lung, and so on, are seen in the mutant, but the brain of the mutant is aberrant. FB, forebrain; MB, midbrain; HB, hindbrain. From ref. 50.

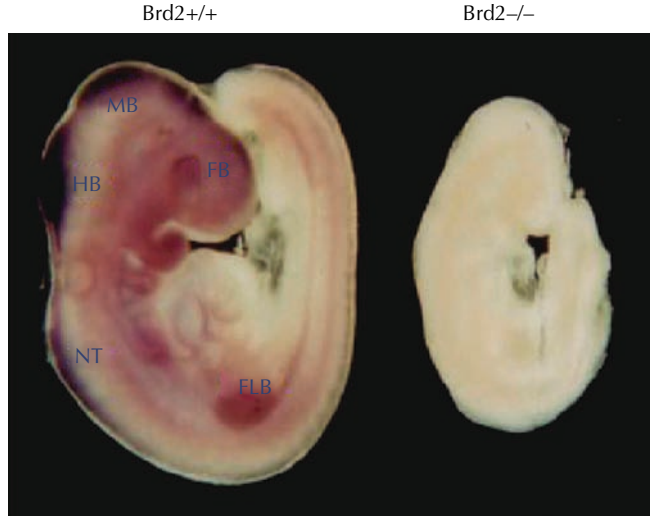

Figure 66–7. Whole-mount in situ hybridization of wild-type and *Brd2* mutant E9.5 embryos using digoxygenin-labeled *Brd2* RNA probes. *Brd2* mRNA is detected in the wild-type developing neural system but is absent in the mutant. FB, forebrain; FLB, forelimb bud; MB, midbrain; HB, hindbrain; NT, neural tube. From ref. 50.

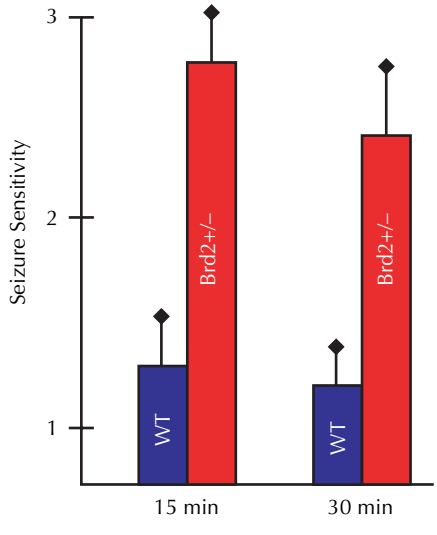

Figure 66–8. Seizure sensitivity to pentylenetetrazol in wild-type and *Brd2*$^{+/-}$ mice. Seizure intensity was scored blind to genotype by four independent observers on a scale of 0–3, where 0 = no change in muscle tone or activity, 1 = mild tremor, 2 = moderate seizure, and 3 = severe seizure. Three of five heterozygotes died following severe convulsion, but all five wild-type animals completely recovered.

perhaps echoing a result found by Pal et al.,[20] in which human females had up to a 12-fold increased risk of seizures in JME families compared to males.

We also found that the brain structures of the *Brd2*$^{+/-}$ mice were subtly abnormal. In the frontal lobes there was up to a 50% deficit of parvalbumin staining interneurons compared to the wild-type mice (Fig. 66–9).

These results were also later confirmed and expanded.[52] Almost all brain areas examined showed varying levels of GABAergic neuron deficit. Taken together with early ultrastructural studies in postmortem human IGE brains,[10] as well as with recent volumetric studies in JME,[8] the corpus of evidence supports a neurodevelopmental origin for common IGE.

The implications of these findings could have a profound effect on our view of the origins of IGE. They imply that, for JME, if not for other IGEs, part of the neural substrate for the epilepsy is a deficit of inhibitory neurons caused by a subtle insufficiency of *BRD2* for JME. This deficit leads to underproduction or abnormal migrations or early apoptosis of such neurons, a deficit that later will lead to epilepsy in the presence of some other, probably subtle, abnormality caused by a second gene or genes.

These results are compelling evidence that *BRD2* is, in fact, the *EJM1* locus on chromosome 6p21. However, mice are not the same as humans. In the absence of human biological material to test the hypothesis that there are fewer GABAergic inhibitory neurons in the brains of JME patients, we must continue to investigate the effects of *Brd2* in mice to discover a definitive connection that will allow us to predict the risk for JME. Identifying the

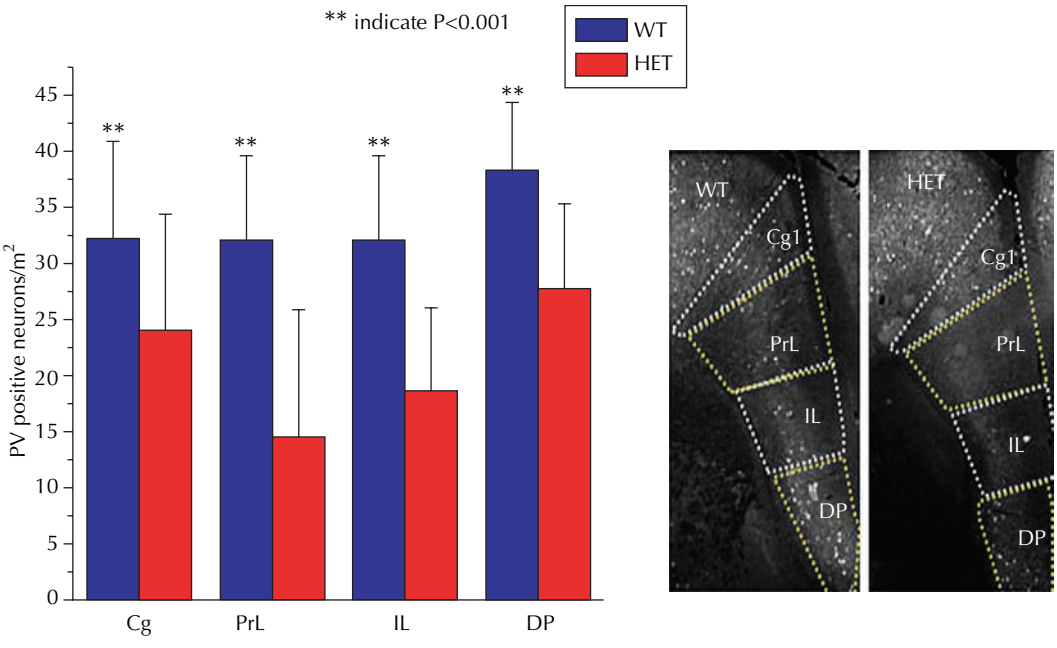

Figure 66–9. Differences in the density of parvalbumin-stained neurons in *Brd2*$^{+/-}$ versus wild-type mice in four brain regions: Cg1, cingulated cortex, area 1; Prl, prelimbic cortex; IL, infralimbic cortex; DP, dorsal peduncular cortex. Densities represent counts from over 100 slices from two *Brd2*$^{+/-}$ and two wild-type mice.

BRD2 JME-related alleles will enable us to do that.

Numerous genes have been identified in densely affected families showing Mendelian inheritance or, like the gene *SCN1A's* role in severe myoclonic epilepsy of infancy, have been shown to play a role in severe epilepsy. However, none of these genes has yet been linked to, associated with, or, by mutation analysis, been shown to play a role in common, genetically complex forms of epilepsy. The results of the RE and JME work on *ELP4* and *BRD2* suggest that common epilepsies are not disorders of a single gene but require several genes for their expression. More important is the suggestion that these disorders result from changes in gene expression that result in subtle changes during development. Investigators studying epilepsy will need to adopt more subtle observational approaches in order to understand these changes.

Juvenile myoclonic epilepsy (JME) is the most frequent form of idiopathic/genetic generalized epilepsy. It accounts for 2%–12% of all epilepsies. The JME symptoms of myoclonias and tonic-clonic convulsions appear in adolescence in an otherwise normal person with normal neurological and cognitive functions.[1] Five percent of these patients, 5% of their affected family members, and 8% of a 252-patient cohort followed for over 20 years have seizures

only when triggered by external factors such as alcohol use, fatigue, menstruation, and sleep deprivation.

To understand the disease mechanisms underlying the stages of susceptibility and epileptogenesis in JME, many have tried to define its complex heritability and identify the genes corresponding to the 15 chromosomal loci so far linked to the disease.[2]

In 2004, Suzuki et al. identified several heterozygous missense mutations in a gene called *EFHC1*[3] in different unrelated families with JME probands. Since then, heterozygous nonsense, deletion frameshift, and novel missense mutations have been identified in various populations from Italy, Austria, and Chile.[4–7] Nine percent of sporadic JME cases detected in families consecutively seen in epilepsy clinics in Mexico and Honduras and 3% of clinic patients from Japan carry mutations in *EFHC1*. This represents the highest number and percentage of mutations found for a JME-causing gene of any population group.[7] The gene encodes a 75 kDa protein with three DM10 domains of unknown function and a single EF-hand motif, a Ca^{2+}-binding domain. The transcript is observed in many cell types of human tissue, including brain (in particular, in ependymal or periventricular cells), but is also best expressed in dividing cells, with the highest levels in lung and testis.[3] It was first proposed that EFHC1 was pro-apoptotic when overexpression in hippocampal neurons in vitro induced apoptotic cell death. This effect was significantly reduced by any of the five mutations associated with JME. Patch-clamp analysis of BHK (baby hamster kidney) cells transfected with $Ca_v2.3$ VDCC (voltage-dependent calcium channel) and EFHC1 showed significantly increased R-type Ca^{2+} currents. So, the pro-apoptotic effect of EFHC1 was assigned to this enhancing effect on Ca^{2+} through $Ca_v2.3$ VDCC.[3]

In 2005, another research group pointed out that EFHC1 is orthologous to Rib72, an axonemal protein of *Chlamydomonas reinhardtii.* They demonstrated that EFHC1 is abundantly expressed in mouse tissues that have motile cilia or flagella, including the brain, and suggested that it plays a role in the intrinsic properties of these organelles.[8]

One of our laboratories previously reported that the subcellular distribution of EFHC1 in different cell lines varied during the cell cycle. In interphase cells, the protein is present in the cytoplasm and nucleus, except for the nucleoli, and is particularly concentrated at the centrosome. During mitosis, EFHC1 is localized at spindle poles of the mitotic spindle and also at the midbody during cytokinesis.[9] These results suggest that EFHC1 could play an important role during cell division, and in particular during brain development, since mRNA expression is higher at embryonic stages than in the adult.[10] More recently, we demonstrated that EFHC1 is a microtubule-associated protein (MAP) playing a key role in neuronal migration.[11] In this chapter, we review these putative roles of Myoclonin 1/EFHC1 during brain development and during adulthood. We posit the hypothesis that JME is a developmental disease involving neuronal migration and synaptic bouton and dendritic morphogenesis.

EFHC1/MYOCLONIN1, A PROTEIN OF UNKNOWN FUNCTION

The *Myoclonin 1/EFHC1* gene is located on chromosome 6 (6p11–12) between markers D6S1960 and D6S11024, spans 72 kb, and contains 11 exons. This gene encodes a protein of 640 amino acids. A domain search identified three tandemly repeated so-called DM10 domains, a motif with unknown function. This protein also contains a single EF-hand, a well-known Ca^{2+}-binding motif, from which it was named EFHC1 for EF-hand Containing 1 (Fig. 67–1). This motif is located at the C terminus between amino acids 578 and 606 and is encoded by a nucleotide sequence present in exon 10. The transcript undergoes alternative splicing in exon 4, resulting in a C-terminally truncated protein, eliminating the EF-hand domain and two DM10 sequences. This last short form therefore only contains 278 amino acids, the first 240 being common with the entire molecule.

The EF-Hand Motif

Krestinger and Nockolds, when exploring the crystal structure of paravalbumin, first described the EF-hand domain.[12] It corresponds to a helix-loop-helix motif, the loop constituted by 12 amino acids, capable of binding Ca^{2+} and

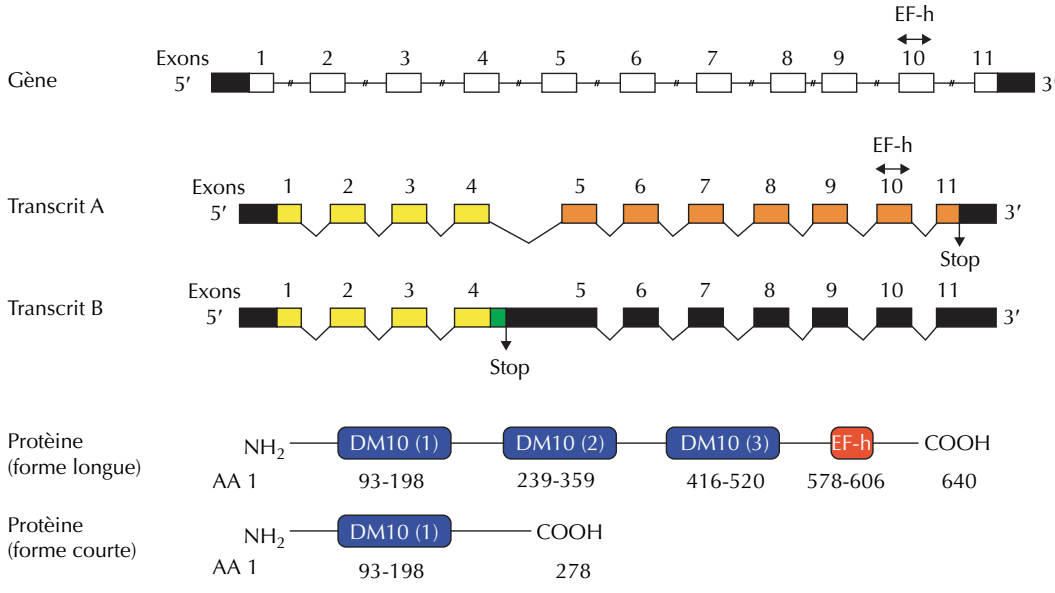

Figure 67–1. Schematic representation of the *EFHC1/Myoclonin1* gene, the long and short forms of the EFHC1 protein, and the different mutations found cosegregated with the JME phenotype.

linking two perpendicular α-helices named E and F (Fig. 67–2). The name *EF-hand* comes from the fact that this motif can be represented with a symbolic right-hand in which the E helix corresponds to the index finger and the F helix to the thumb.[13] The EF-hand proteins belong to the family of Ca^{2+}-binding proteins, which include more than 1000 members classified into 66 different subfamilies. Two groups are distinguished according to their cellular properties: on the one hand, the buffer proteins implicated in the transport and regulation of intracellular calcium concentration (calbindin and calretinin, for instance) and, on the other hand, the calcium sensors that transfer information from calcium influx to specific intracellular molecular pathways (calmodulin, troponin C).[14] Most of the EF-hand proteins, however, contain single or multiple pairs of such helix-loop-helix motifs. They are typically present in globular forms and create a cooperative calcium link between the two motifs, resulting in an increased affinity of the protein for the calcium ion.[15]

At the loop level, the residues in the 1, 3, 5, 7, 9, and 12 positions, also named +X, +Y, +Z, –Y, –X, and –Z, are responsible for binding calcium, forming a geometrical pentagonal bipyramidal structure (Fig. 67–3). The residues +X, +Y, and +Z provide a coordination link, while the residue –Z must provide two of them via the carboxyl groups of its lateral chain. The residue –Y regulates calcium via an oxygen of its principal chain, and the residue –X links calcium indirectly by a molecule of water. The most conserved amino acids of the loop are the aspartate in the +X position and the aspartate or the glutamate in the –Z situation. It is important to note that the EF-hand motif exists in non-canonical positions in which the length or the composition of the calcium binding loop varies, implicating a calcium-binding mechanism with a different system of coordination.[16] The EF-hand domain of EFHC1 is probably one of them, since +Y and –Z residues do not correspond to the consensus sequence of a canonical domain. Moreover, the EFHC1 protein contains only one single EF-hand motif. Therefore, these observations show that EFHC1 is a non-conventional EF-hand protein.

The DM10 Domains

The DM10 domains contain appreciatively 105 residues and are so far of unknown function. The DM10 domains' proteins are found in classes as varied as mammals (human, rat, mouse, dog, cow), fishes (*Tetraodon*, *Danio rerio*), insects (*Anopheles*, *Drosophila*),

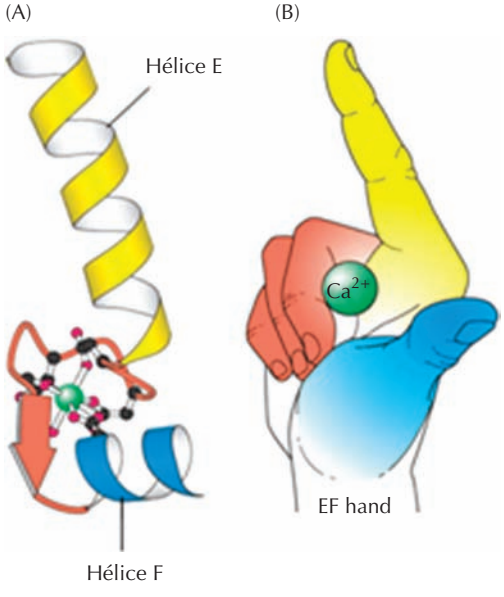

Figure 67–2. The EF-hand domain. **A.** Schematic representation of a EF-hand motif consisting of two helixes, E and F, perpendicularly placed and linked by a Ca^{2+}-binding 12 amino acid sequence. **B.** Symbolic representation of the same motif as a right hand in which the E helix corresponds to the index finger and the F helix corresponds to the thumb.

amphibians (*Xenopus tropicalis*), protists (*Trypanosomia*, *Giardia lamblia*, *Schistosoma japonicum*, *Chlamydomonas reinhardtii*), and nematodes (*C. elegans*). In *Chlamydomonas* and in mammals, these motifs are found in only two types of proteins.[17] The first are type 7 diphosphate nucleoside kinases (NDK7) exhibiting an N-terminal DM10 domain and two catalytic NDK motifs. The NDK catalyze the transfer of the adenosine triphosphate (ATP) terminal gamma-phosphate on the guanosine diphosphate (GDP) to form guanosine triphosphate (GTP) and adenosine diphosphate (ADP). These proteins play crucial roles in cellular proliferation, differentiation, development, and progression of tumors.[18] The second family consists of proteins with three DM10 domains and one C-terminal EF-hand motif, among which one finds EFHC1, its paralog EFHC2, its ortholog Rib72 in *Chlamydomonas* and EFHC1, and EFHC2 in *Drosophila*. In contrast with the NDKs, these proteins do not exhibit any enzymatic activities. Their properties remain to be elucidated; recent findings concerning this family will be reviewed below.

The phylogenetic analysis of these different proteins shows that each of the three DM10 domains is more strongly conserved between the different proteins than among them for the same protein. For instance, the first DM10 domain of EFHC1 is more similar to the first DM10 of Rib72 and EFHC2 compared with the second or third domains of EFHC1.[17] In *Chlamydomonas*, the proteins containing DM10 domains are strongly linked to the flagellar axonema.[19,20] This suggests that these domains could act as flagellar NDK regulators or as specific subunits implicated in axonemal

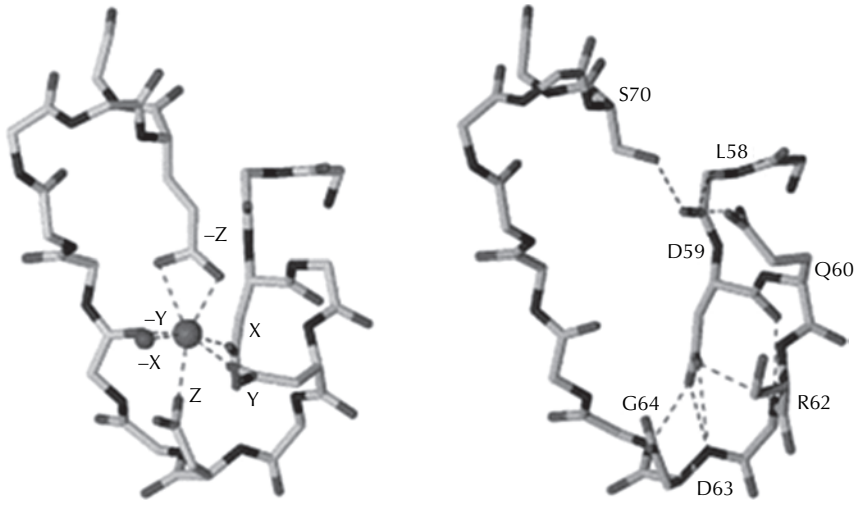

Figure 67–3. Representation of the calcium coordination binding sites by +X, +Y, +Z, -Y, -X, and -Z residues of the EF-hand motif.

assembly or in the localization of these proteins in this structure.[17]

EFHC1/MYOCLONIN1, A WIDELY DISTRIBUTED PROTEIN

So far, the transcript of the Myoclonin 1 has been detected in several structures in various adult and developing tissues or cell models in culture, using either polymerase chain reaction (PCR), Northern blotting, or in situ hybridization.

This last approach, however, produced unconvincing results in determining the presence of the transcript in several tissue, including brain, although PCR on brain tissue samples[21] and cells in culture[9] and Northern blotting from various tissues[3] unequivocally demonstrated its expression. This could indicate a particularly low level of transcription or a fast turnover of the mRNA encoding the Myoclonin1 protein.

Accordingly, using an anti-myoclonin1 polyclonal antibody, the protein EFHC1 has been, in a first approximation, detected by immunohistochemical analyses in several structures of adult mouse brain including hippocampus, cerebellum, cerebral cortex, thalamus, hypothalamus, amygdale, and upper brainstem. In addition, signals were observed in soma and dendrites of both in situ and hippocampal primary culture neurons.[3]

Four years later, however, the same authors[22] created the Efhc1 knockout mouse and, using this null-mutant mouse as a negative control, they found that the signals obtained by the above-mentioned polyclonal antibody remained in the null mutant and that the signals were largely nonspecific. Revisiting the distribution of the protein using a newly generated anti-myoclonin1 monoclonal antibody (yielding more specific myoclonin1 signals in Western blot and immunohistochemical analyses), they showed that myoclonin1 is expressed mainly at cilia on ependymal cells surrounding cerebral ventricles in the postnatal mouse brain. No significant signals were observed in other regions and cell types, including neurons and astrocytes. These observations were, therefore, inconsistent with their previous report. When the authors used a new monoclonal antibody (6A3-mAb) to mouse myoclonin1 and verified its specificity in Western blot and immunohistochemical analyses, using Efhc1-null mice as negative controls, this 6A3-mAb specifically recognized myoclonin1 protein at embryonic choroid plexus and postnatal ependymal cells. However, it should be kept in mind that the sensitivity of these analyses may not be high enough to detect moderate or low levels of myoclonin1 expression in other tissues and cells. In addition, other isoforms of myoclonin1, which the 6A3-mAb cannot recognize, may possibly be expressed in distinct tissues and cells; therefore, further studies are warranted.

We then revisited the distribution and cellular localization of EFHC1 in adult mouse brain[21] studied by immunohistochemistry using a previously well-validated anti-EFHC1 antibody.[8,9] In the adult mouse neocortex, the labeling was present in cells of all cortical layers, particularly in cells resembling pyramidal neurons in cortical layer V and in the piriform cortex. Within the hippocampus, neuronal cells in the CA and the dentate gyrus (DG) regions were stained. Expression was not restricted to the pyramidal cell layer but was also observed in cells located in the striatum oriens, radiatum, and lacunosum-moleculare. At higher magnification, the protein appeared evenly distributed in the cytoplasm. Labeling was also clearly observed in Purkinje cells of the cerebellum and, in particular, in the first-order apical dendrites. In all of these experimental conditions, the immunostaining disappeared or was considerably attenuated after preabsorption of the antibody with purified immunizing peptide.

EFHC1 immunofluorescence, in particular, was clearly observed in cerebellar Purkinje cells with labeling of the soma, the nucleus, and the dendritic arborizations extending throughout the molecular layer. A faint signal was also present in the molecular and granule cell layers. The last one was identified by colabeling using anti-NeuN antibody.

Double immunofluorescence was performed in order to specify the nature of EFHC1-expressing cells in the adult mouse cortex. A count of the number of double- labeled cells indicated that the majority (78%) of EFHC1-positive cells express NeuN and therefore correspond to neurons. In addition, 20% of EFHC1-positive cells express glial fibrillary acidic protein (GFAP) and thus correspond to astrocytes. The labeling was also present in the proximal portion of astrocytic

processes. Another way to illustrate the eventual expression of this gene by neural structures is the use of nerve cell lines in culture. We used this approach extensively and showed clear synthesis of EFHC1 by mouse neuroblastoma cells (N2A cells), as illustrated in the past with HEK-293, HeLa, and COS cell lines.[9] Furthermore, in order to establish how early in culture the *EFHC1* gene was expressed, we investigated its presence in neural stem cells (NSCs). These NSCs were prepared from embryonic mice striata, as previously described.[23] They were allowed to form neurospheres. First, the expression of the *EFHC1* transcript was confirmed by reverse transcriptase-PCR (RT-PCR). Then double immunofluorescence labeling was performed using anti-nestin, a neural stem cell marker, and anti-EFHC1 antibodies. EFHC1 labeling was present in all cells composing neurospheres. Together, these results clearly demonstrate the ability of neuronal cells both in vivo and in vitro to synthesize EFHC1 from the earliest stages of development.

EFHC1/MYOCLONIN1 CALCIUM SIGNALING AND APOPTOSIS

To investigate the functional significance of EFHC1 and its mutants in neurons, Suzuki et al.[22] transfected mouse hippocampal primary culture neurons with enhanced green fluorescent protein (EGFP)-EFHC1 expression constructs. EFHC1-positive neurons had shorter neurites and fewer branches 16 h after transfection and showed signs of neurodegeneration and cell death, including shrinkage of the cell body and fragmentation of processes 48 h after transfection, whereas control cultures seemed to be healthy. Cells transfected with EFHC1 were terminal deoxynucleotidyl deoxyuridine triphosphate nick and labeling (TUNEL)-positive, indicative of apoptosis. Next, Suzuki et al. investigated the effects of EFHC1 mutations on cell survival by counting green fluorescent protein (GFP)-positive surviving cells attached to the dishes at various time points, irrespective of cellular morphologies. The cell-death effect of EFHC1 was substantially reduced by any of the five mutations associated with JME and by the double mutation 229C → A and 662G → A. In contrast, the three coding polymorphisms that were also present in the control population did not affect cell death significantly. Although the number of surviving cells transfected with mutations associated with JME seemed close to that of vector-transfected cells, the cells transfected with mutations associated with JME had unhealthy morphology 48 h after transfection, implying that the mutations did not disrupt EFHC1 function completely. Suzuki et al. also analyzed the effects of EFHC1 isoforms on cell survival. Transfection with a construct-expressing transcript B resulted in moderate cell death, and coexpression of the wild-type transcript and transcript B had intermediate effects. The cellular functions of the protein encoded by transcript B are not known, but the fact that this isoform excludes the mutation 757G → T from its open reading frame suggests that this isoform may not have a large role in the pathogenesis of JME.

As already mentioned, the EF-hand superfamily regulates many aspects of cell function, such as Ca^{2+} buffering in the cytosol, cell proliferation, and signal transduction. In the central nervous system, calmodulin and the related EF-hand containing neuronal Ca^{2+}-sensor proteins have many important roles in neuronal signaling. The basic functional unit consists of a pair of EF-hand motifs, but in the case of human EFHC1, it is not clear if it is present in pairs or not.

Murai et al.[24] reported the first structural and thermodynamic analyses of human EFHC1C-terminus containing the last DM10 domain and the EF-hand motif. The target protein was expressed mainly in soluble form and the purification protocol, including tag removal, was successfully established. The final purified protein demonstrated high stability. The secondary structure was measured by circular dichroism (CD) spectroscopy, showing 34% of α-helices and 17% of β-strands. It was demonstrated that the protein can form dimers in the absence of dithiothreitol (DTT). Tandem mass spectrometry (MS/MS) analysis with the help of the SearchXLinks program suggests that Cys575 participates in intermolecular S–S bond formation. In addition, a dithionitrobenzoic acid (DTNB)assay showed that reduced EFHC1C has only one accessible free thiol per molecule. Isothermal titration calorimetry (ITC) data showed that reduced EFHC1C binds to just one divalent ion (Ca^{2+} or Mg^{2+}), whereas in an oxidized (dimeric) state, EFHC1C has its ion binding site blocked.[24]

To date, it is not clear if EFHC1 is a Ca^{2+}-sensor or a Ca^{2+}-buffer protein. However, full EFHC1 presents 19% identity and 44% similarity with the Ca^{2+} regulator calmodulin, the classical example of an EF-hand protein that suffers conformational changes after ion binding. Additional experiments should be performed in order to better determine the influence of Ca^{2+} or Mg^{2+} binding in the EFHC1 dimerization process. Whether dimerization is a physiological conformation remains to be elucidated.

Because EFHC1 contains a Ca^{2+}-sensing EF-hand motif and because abnormalities of voltage-dependent Ca^{2+} channels (VDCCs) have been described in human and mouse epilepsies, Suzuki et al.[22] investigated whether the observed cell death is due to modulations of VDCCs. Reverse transcriptase-PCR showed that most of the VDCC subtypes were expressed in mouse primary culture neurons, albeit at varied levels. Treatment of EFHC1-transfected primary culture neurons with several antagonists of VDCC subtypes indicated that SNX-482, the antagonist for $Ca_v2.3$, specifically increased the survival rate of EFHC1-positive neurons.

Moreover, patch-clamp analyses of BHK cells stably expressing $Ca_v2.3$ and transiently transfected with EFHC1 showed that EFHC1 substantially increased the R-type Ca^{2+} current generated by $Ca_v2.3$.[3] Cotransfection with constructs expressing P/Q-type VDCC ($Ca_v2.1$) and EFHC1 did not increase Ca^{2+} currents. The effects of EFHC1 on $Ca_v2.3$ were extensive and unique, even when compared with the effects of the auxiliary subunits of the Ca^{2+} channels. These results suggest that EFHC1 enhances Ca^{2+} influx through $Ca_v2.3$ and stimulates programmed cell death.

Mutations associated with JME partly reversed the increase in R-type Ca^{2+} currents by EFHC1. Incomplete reversal of EFHC1-induced Ca^{2+} influx through $Ca_v2.3$ may be responsible for the precarious state of calcium homoeostasis sensitive to the triggering effects of sleep deprivation, fatigue, and alcohol in individuals with JME. The three coding polymorphisms had weaker or no reversal effects, implying that they could be functionally benign or less malignant. Transfection with the transcript B isoform moderately increased the Ca^{2+} current. These results were consistent with those of the cell-death analyses.[3]

EFHC1/MYOCLONIN1 IN MITOSIS AND CELL DIVISION

EFHC1 Colocalizes with Mitotic Spindles

We have shown[9] that the subcellular localization of EFHC1 varied during the cell cycle. The most prominent finding was the association with the mitotic spindle and the midbody. This was observed in different cell lines (HEK293, COS-7, HeLa, NIH3T3, SKNBE) for the overexpressed EGFP-tagged and the endogenous protein. Those results suggest the involvement of EFHC1 in cell division and, in particular, in the organization of the mitotic spindle and the midbody. However, during mitosis, a fraction of EFHC1 remains localized in the cytoplasm, suggesting that only a portion of the protein is recruited by the mitotic apparatus, as is the case for other mitotic apparatus associated proteins.

Colocalization of EFHC1 with α-tubulin was observed at the mitotic spindle, suggesting a possible interaction with microtubules. Such an association was suggested for the *Chlamydomonas* protein Rib72 in flagellar axoneme.[19,20] As the mitotic spindle, axoneme, and cilia are microtubule-based structures, this further supports the hypothesis of a possible interaction of EFHC1 with microtubules.

In nondividing cells, we consistently observed a strong accumulation of EGFP-tagged and endogenous protein in one (occasionally two) perinuclear spot(s). Using anti-γ-tubulin antibody, we identified those spots as centrosomes, suggesting that EFHC1 could be a centrosomal component. This is further supported by the proteomic analysis showing the presence of the *Chlamydomonas* Rib72 in centrioles, a centrosome component.[25] Moreover, the concentration of EFHC1 at spindle poles during mitosis, where centrioles are located, suggests involvement in the functioning and/or organization of the mitotic spindle. Molecular components common to the centrosome and the mitotic spindle have been described.[26–29]

Deletion analyses of EFHC1 demonstrated that its N-terminal portion (construct N92) is required and sufficient for its association with the mitotic spindle and the midbody. In light of our observations made with truncated EFHC1

constructs in mitotic cells, the role of DM10 domains remains unclear.

The association of EFHC1 with the mitotic apparatus and the centrosome constituted at this time a clear, new, and original finding. Correlation between our observations and previous findings, demonstrating the association of the *Chlamydomonas* Rib72 with flagellar axoneme and mRib72-1/Efhc1 with motile cilia and flagella, further supported the concept of EFHC1 interaction with microtubule-based structures. Other axonemal proteins have also been found to be associated with the mitotic spindle and/or the centrosome and vice versa.[25,30–33]

In other respects, our hypothesis of a potential involvement of EFHC1 in cell division is supported by several arguments. It was shown that EFHC1 transcript expression in the mouse brain is higher during embryogenesis, when cell division is prominent, than in the adult brain.[3,10,34] The EFHC1 promoter was also demonstrated to be a putative target of the E2F4 transcription factor,[35] a member of the E2F transcription factor family that plays a crucial role in cell cycle progression and is therefore important in cellular proliferation. Moreover, EFHC1 transcript expression is modulated during the HeLa cell cycle.[36]

EFHC1 Is a Microtubule-Associated Protein (MAP)

To determine more precisely which region of EFHC1 mediates this association, we expressed various EGFP-tagged truncated EFHC1 proteins in HEK293 cells and carried out immunocytochemistry with an antibody to α-tubulin.[11] We found that EGFP-hN45, but not EGFP-hN30, colocalized with the mitotic spindle, suggesting that the first 45-amino-acid region contains a motif that is required for the localization of EFHC1 with the mitotic spindle.

This colocalization prompted us to investigate whether EFHC1 interacts with α- and/or γ-tubulin. Using immunoprecipitation procedures on HEK293 cell lysates, we found that EFHC1 and α-tubulin coprecipitated mutually and that EFHC1 did not interact with γ-tubulin. To determine whether EFHC1 interacts directly with α-tubulin, we used in vitro cosedimentation assays using pure prepolymerized microtubules and different purified glutathione S-transferase (GST)-tagged truncated EFHC1 proteins. We found that GST-hEFHC1 and GST-hN45, but not GST-hN30 and GST, cosedimented with microtubules, indicating that there was a direct interaction between EFHC1 and α-tubulin through the first 45-amino-acid region. This association was not affected by the presence of Ca^{2+}. We therefore estimated the affinity of EFHC1 for microtubules and found an equilibrium dissociation constant of about 1.5 μM, indicating that EFHC1 binds to microtubules with relatively high affinity. Finally, we carried out in vitro tubulin polymerization assays with GST-hEFHC1. We did not detect a substantial change in either the polymerization rate or the nucleation phase in the presence of GST-hEFHC1. This indicates that EFHC1 is not required for the polymerization of microtubules in vitro. It is noteworthy that the region involved in the binding to α-tubulin (i.e., the first 45 amino acids) showed no obvious homology with the microtubule-binding domains (MTBDs) of other known MAPs. Thus, EFHC1 would appear to be a unique MAP, unrelated to conventional previously described MAPs.[11]

EFHC1 Is Required for Mitotic Spindle Organization

In addition to its association with α-tubulin, we found that overexpression of EGFP-hN92, EGFP-hN60, or EGFP-hN45 in HEK293 cells resulted in severe mitotic spindle defects, including monopolar spindle and chromosome alignment failure during metaphase. We quantified their occurrence in cultures overexpressing different EGFP-tagged EFHC1 proteins and found that the percentage of mitotic defects was significantly higher for EGFP-hN92, EGFP-hN60, and EGFP-hN45 compared with EGFP-hEFHC1 or EGFP.

Notably, truncated forms that did not associate with the mitotic spindle did not promote spindle defects, suggesting that binding to microtubules is necessary for this phenotype. EGFP-hDM101, which contains both the N-terminal region and the first DM10 domain, failed to induce mitotic spindle defects. This suggests that at least the first DM10 domain is required for proper EFHC1 function at the

mitotic spindle. Moreover, we observed that monopolar spindles showed an abnormal spherical distribution of chromosomes around a pair of closely and centrally located centrosomes, indicating that the centrosome was duplicated but that there was an insufficient separation to form a bipolar spindle. In the next experiments, we only used the EGFP-hN45 protein, as it produced, in our opinion, the most important phenotype. Using an antibody to the C terminus of EFHC1, we observed that EGFP-hN45 saturated the microtubule's EFHC1 binding sites and, as such, acted as a dominant-negative protein.

Moreover, we transfected HEK293 cells with validated shRNAs and observed a significant increase in the number of disorganized mitotic spindles with the presence of monopolar spindles and misaligned metaphase compared with controls. Expression of rEFHC1, an shRNA-resistant form, rescued the mitotic spindle defects, demonstrating the specificity of the shRNA effect.

Finally, we found that the mitotic index was significantly higher in cultures expressing EGFP-hN45 and hEFHC1 shRNA than in control cultures. In contrast with control cells that were distributed across all mitotic phases, EGFP-hN45- and hEFHC1 shRNA-expressing cells were mostly arrested at prometaphase, with a concomitant decrease in the number of cells in anaphase/telophase and cytokinesis, resulting in subsequent M-phase delay or arrest. Collectively, these results obtained by independent approaches (RNAi and dominant-negative protein) strongly suggest that EFHC1 is involved in mitotic microtubule organization and M-phase progression.[11]

EFHC1 Impairment Induces Microtubule Bundling and Apoptosis

During interphase, EGFP-hN45 and hEFHC1 shRNA expression markedly induced microtubule bundling around the cell periphery. These bundled microtubules were extremely stable and did not depolymerize in the presence of nocodazole. Microtubule bundling was significantly higher in cultures expressing EGFP-hN45 and hEFHC1 shRNA than in those expressing EGFP-hEFHC1, EGFP, or control shRNA. Moreover, using in vitro microtubule bundling assays, we found that GST-hN45, but not GST-hEFHC1 or GST, induced microtubule bundling, indicating that the MTBD of EFHC1 is capable of promoting microtubule bundling formation in vivo and in vitro when expressed alone.

Moreover, in cultures with impaired EFHC1 function, we observed frequent occurrences of nuclear abnormalities such as fragmented and picnotic nuclei, as seen in apoptotic cells. Therefore, we carried out TUNEL assays and found a significant increase of apoptosis in cells overexpressing EGFP-hEFHC1, EGFP-hN45, and hEFHC1 shRNA compared with the EGFP control. Finally, to determine the cell cycle phase distribution of apoptotic cells expressing EGFP or EGFP-hN45, we sorted apoptotic EGFP-positive cells by flow cytometry and carried out cell cycle analysis. We observed a significant enhancement of EGFP-hN45 cells in S and G2/M phases, with a concomitant decrease of cells in the G0/G1 phases compared with EGFP controls, indicating that mitotic spindle defects induced apoptosis.[11]

EFHC1/MYOCLONIN1 AND EARLY NEUROBLAST MIGRATION

EFHC1 Contributes to Radial Migration and Radial Glia Integrity in the Developing Neocortex

On the basis of previous studies reporting higher expression of EFHC1 during brain development,[3,10,34] and on the basis of its key role in cell division, we further investigated the role of EFHC1 in cerebral cortex development by modulating the expression of rEFHC1 in ventricular zone (VZ) cells of the rat developing neocortex using both in utero and ex vivo electroporation (Fig. 67–4). In order to inactivate rEFHC1 functions through RNAi-mediated depletion, we validated the effectiveness of the rEFHC1 shRNA vector by Western blot on extracts from the microdissected ventricular/subventricular zone (VZ/SVZ) after ex vivo electroporation.

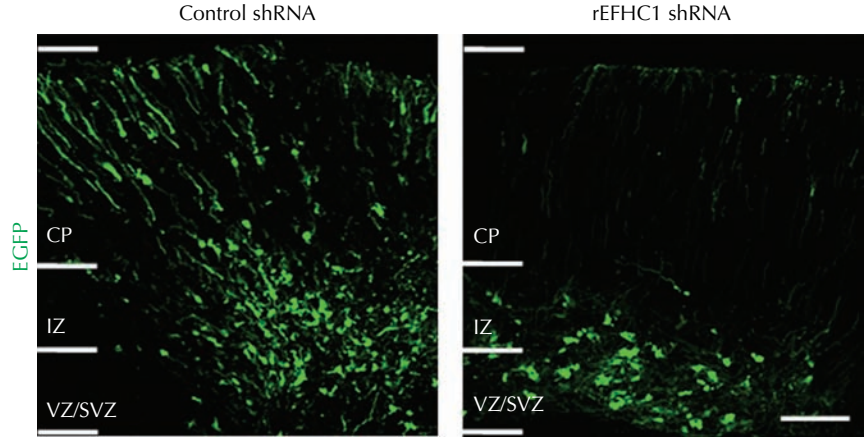

Figure 67–4. Role of EFHC1 in radial neuronal migration. Distribution of EGFP-positive cells (in green) in different cortical regions (VZ/SVZ, IZ, and CP) 4 days after ex vivo electroporation of rat brains at E17 with control shRNA (left) and rEFHC1 shRNA (right) showing significant disruption of neuroblast migration toward the CP when EFHC1 synthesis is invalidated in the cells. Scale bars represent 200 μm (see ref. 11 for more details).

To determine whether EFHC1 influences the radial migration of neocortical neurons in rat neocortex, we examined the position of EGFP$^+$ cells in the VZ/SVZ, intermediate zone (IZ), or cortical plate (CP) 1 and 4 d after ex vivo electroporation at E17 of plasmid encoding Con shRNA, rEFHC1 shRNA, EGFP-hN45, rEFHC1 shRNA, and EGFP-hEFHC1 or EGFP-hEFHC1 alone. On day 1, cells were mostly located within the VZ/SVZ, with no obvious difference in the position of cells in the five different transfected conditions. By day 4, the expression of EGFP-hN45 and rEFHC1 shRNA induced a dramatic disruption of radial migration compared to Con shRNA (Fig. 67–4). In the presence of rEFHC1 shRNA, most of the cells were localized in the VZ/SVZ, whereas few cells reached the CP. RNAi-mediated alteration of radial migration was rescued by the expression of EGFP-hEFHC1, although expression of EGFP-hEFHC1 alone had no significant effect. When electroporated with EGFP-hN45, cells migrated out of the VZ/SVZ but failed to enter the CP and thus accumulated in the IZ. It is interesting to note that similar results have been observed after in utero electroporation of rEFHC1 shRNA (Fig. 67–4). Thus, the impairment of EFHC1 appeared to have a direct effect on radial redistribution to the CP.

Furthermore, immunohistochemistry with anti-brain lipid-binding protein (BLBP) antibody revealed a disruption of extension of radial glial processes with concomitant irregular accumulation of cells strongly stained for BLBP in the VZ/SVZ.

Together, these results indicate a crucial role for EFHC1 in maintaining the integrity of the radial fiber network.

Finally, expression of rEFHC1 shRNA or EGFP-hN45 induced structural disorganization of VZ/SVZ cells; many cells presented an enlarged multipolar morphology and lacked or had only a very short leading process, sometimes not radially oriented. Moreover, we observed the presence of many round-shaped cells with condensed chromosomes, suggesting apoptotic cells. This conclusion was supported by the decreased number of EGFP$^+$ cells in the VZ/SVZ of cortices expressing rEFHC1 shRNA and EGFP-hN45. To test this hypothesis, we performed TUNEL assays and found a significantly increased number of apoptotic cells in brain slices with impaired EFHC1 function.[11]

EFHC1 Is Essential for Mitosis and Cell Cycle Exit of Cortical Progenitor Cells

Since cortical progenitor cell division occurs prior to and is tightly coupled to neuronal migration, we decided to study the influence of EFHC1 on mitosis, proliferation, and cell

cycle exit of cortical progenitors by ex vivo electroporation on E17 rat brains. We analyzed the effect of EGFP-hEFHC1, EGFP-hN45, and rEFHC1 shRNA expression on the spindle mitotic organization of VZ/SVZ cortical progenitors. We observed that both EGFP-hEFHC1 and EGFP-hN45 associated with the mitotic spindle, although EGFP-hN45 and rEFHC1 shRNA induced mitotic spindle defects similar to those observed in vitro (monopolar spindles and misaligned chromosomes at metaphase). To assess whether these abnormalities influence mitotic progression, we performed immunohistochemistry with anti-phospho-Histone H3 (pH3) antibody, a mitotic marker. The mitotic index (the percentage of transfected cells in mitosis) was significantly increased by impairment of EFHC1 function compared to Con shRNA. This accumulation of mitotic cells strongly suggests an M-phase arrest/delay of progenitor cells, as we observed in vitro. Moreover, pH3 immunoreactivity showed ectopic localization of mitotic chromosomes associated with an EFHC1 defect. Whereas most Con shRNA mitotic chromosomes were normally localized along the ventricular lumen, many EFHC1-deficient mitotic chromosomes were found in the region above the ventricular surface.

Furthermore, we explored whether EFHC1 controls the rate of cell cycle exit of cortical progenitors. For this purpose, brains slices were exposed to a short pulse of bromodeoxyuridine (BrdU; 1 h) 24 h after ex vivo electroporation and fixed 24 h later. Triple immunolabeling with antibodies directed against GFP, BrdU, and Ki67 allowed us to establish the cell cycle exit index (the percentage of transfected cells that were exiting the cell cycle within 24 h). We found that the cell cycle exit index was significantly decreased in brains slices expressing rEFHC1 shRNA.

Finally, to quantify the effect of the EFHC1 deficiency on the cortical progenitor population, we determine the percentage of transfected cells expressing Sox2, a progenitor marker, using immunohistochemistry. The fraction of VZ/SVZ cells expressing Sox2 was significantly enhanced by EFHC1 inhibition.

Together, these data suggest that the impairment of EFHC1 function in the developing neocortex interferes with both the cell division and cell cycle exit of cortical progenitors, leading to their accumulation.[11]

EFHC1 Is Required for Locomotion of Postmitotic Neurons

Cortical development is a complex process involving a strictly regulated sequence of neuronal proliferation, differentiation, and migration to specific cell layers.[37] Our results identified an influence of EFHC1 on proliferation and differentiation of cortical progenitors. To investigate the involvement of EFHC1 in radial migration of postmitotic neurons, we performed focal electroporation of plasmid-encoding Con shRNA or rEFHC1 shRNA in the IZ of brain slices at E19 after ex vivo electroporation of red fluorescent protein (RFP) plasmid to label VZ/SVZ progenitors cells. This method allowed us to differentiate progenitors ($EGFP^+/RFP^+$) from postmitotic neurons ($EGFP^+/RFP^-$). We analyzed the cortical scattering of $EGFP^+/RFP^-$ cells 2 days after electroporation using an arbitrary scale divided into 10 bins. Compared to Con shRNA, expression of rEFHC1 shRNA impaired cortical redistribution of postmitotic neurones in the CP, as the majority of cells were located in bins corresponding to the upper IZ, with a concomitant decrease in the number of cells in the CP. In order to confirm these results, we performed ex vivo electroporation at E17 of plasmid-encoding EGFP or EGFP-hN45 under the control of the NeuroD promoter, allowing the expression of protein only in postmitotic neurons. Cortical scattering of $EGFP^+$ cells was analyzed 4 days after electroporation. Compared to EGFP, only a subset of cells had reached the lower CP in brains expressing EGFP-hN45. These results suggest that EFHC1 is also implicated in the locomotion of postmitotic neurons.[11]

EFHC1/MYOCLONIN1, A KEY CILIAR COMPONENT PLAYING A ROLE IN THE FUNCTION OF EPENDYMA

Myoclonin1 is a homolog of P72/Rib72, a flagellar protein of *Chlamydomonas*,[19,20] P72/Rib72 is thought to have important roles in assembly and function of the axoneme. Indeed, it has been shown that Rib72 is an essential component of the flagellar axonemal ribbon (a stable structure formed by protofilaments

of tubulin)[20] that is implicated in calcium-dependent flagellar motility.[19] On the other hand, Rib72 homologs have been observed in organisms containing motile cilia or flagellas, such as humans, mice, sea urchins, and *Drosophila.* Moreover, the mice ortholog of EFHC1 is expressed in many tissues with motile cilia and flagellas, such as lung, testis, and ependymal cells.[8,21,22] Interestingly, in brain, the ependymal cells lining the border of the ventricles are highly ciliated and support, in the adult, a rostral-directed cerebrospinal fluid (CSF) flow pulling along newly forming neuroblasts.[38] One can postulate that a default of EFHC1 highly expressed in these cilia could lead to abnormal migration of newly formed neuroblasts in the adult, modifying the cytoarchitectony of the gabaergic (gamma-aminobutyric acid) cortical interneurons as an epileptogenic mechanism.[17]

Suzuki et al.[22] raise intriguing possibilities that "(choroid) plexusopathy" or "ciliopathy" is the pathological basis of epilepsies caused by the EFHC1 mutations. They found myoclonin1 expression on the hindbrain at the E10 stage and on the choroid plexus at the E14 stage. The surface of choroid plexus is comprised of the choroid epithelium (derived from the same layer of cells that forms the ependymal lining of the ventricles).[39] Since these epithelium cells do not have cilia on the cell surface at the embryonic stages, myoclonin1 might have roles (e.g., CSF secretion) in addition to promoting postnatal ciliary function. Cerebrospinal fluid maintains homeostasis in the extracellular environment of neurons and glial cells.[39]

In 2009, the same authors generated viable *Efhc1*-deficient mice.[40] Most of the mice were normal in outward appearance, and both sexes were found to be fertile. However, the ventricles of the brains were significantly enlarged in the null mutants but not in the heterozygotes. Although the ciliary structure was found to be intact, the ciliary beating frequency was significantly reduced in the null mutants. In adult stages, both the heterozygotes and null mutants developed frequent spontaneous myoclonus. Furthermore, the threshold of seizures induced by pentylenetetrazol was significantly reduced in both heterozygotes and null mutants. These observations seem to further suggest that a decrease or loss of function of myoclonin1 may be the molecular basis for epilepsies caused by *EFHC1* mutations.

THE MAP MYOCLONIN1 IS ESSENTIAL FOR THE NORMAL DEVELOPMENT AND FUNCTION OF THE NEUROMUSCULAR JUNCTION SYNAPSE IN *DROSOPHILA*

Very recently, one of the two *Drosophila* homologs of EFHC1, CG8959, named Defhc1, was functionally characterized.[40a] In agreement with studies in mammalian systems, the investigators found that Defhc1 is capable of binding to microtubules. Transfected Defhc1 distributed both to the cytoplasm and to the nucleus of resting cells, while in dividing cells the protein localized to the mitotic spindle. Defhc1 knockout *Drosophila* displayed normal appearance and behavior. However, the morphology of the neuromuscular junction synapse appeared aberrant, with an increase in the number of satellite boutons, structures that have been regarded as potential ramifications. Defhc1 is capable of binding to microtubules and overlaps in vivo with axonal microtubules. In the neuromuscular junction synapse, disruption of Defhc1 function leads to a decrease in the number of microtubule loops, whose presence correlates with halted bouton division, suggesting that Defhc1 is a negative regulator of this process. The investigators also showed that the increase in satellite boutons requires an intact microtubule cytoskeleton and is accompanied by an increase in spontaneous neurotransmitter release. This important work further shows that loss of Defhc1 induces overgrowth of the dendritic arbor, and in vivo overexpression of Defhc1 in dendritic neurons substantially reduces dendrite elaboration. These results suggest that, at least in this model, Defhc1 functions as an inhibitor of neurite growth by finely tuning microtubule cytoskeleton dynamics. As a corollary, these findings also suggest that the susceptibility stage of EFHC1-dependent JME may result from augmented spontaneous neurotransmitter release due to overgrowth of neuronal processes.

EFHC1 OR MYOCLONIN1 DEFECT CAUSES JME AS A DEVELOPMENTAL DISEASE AFFECTING THE PROPERTIES OF THE MICROTUBULES IN THE NEURONO-GLIAL PROCESSES AND CORTICAL SYNAPTIC FUNCTIONS (MICROTUBULOPATHY)

The works reviewed above all converge to a clear demonstration: *EFHC1* or *Myoclonin 1,* a gene significantly mutated in JME families, is a new MAP. Microtubules affect multiple facets of neuronal development and function, with prominent roles in the growth and maintenance of axons and dendrites[41] but also in the fine tuning of synaptogenesis. Here we will cite some examples from our previously mentioned data supporting the above concept.

As discussed, the mitotic index (the percentage of transfected cells in mitosis) was significantly increased by impairment of EFHC1 function compared to Con shRNA. This accumulation of mitotic cells in VZ/SVZ strongly suggests an M-phase arrest/delay of progenitor cells, as we observed in vitro. The nuclei of the radial glia progenitors (RGPs) perform interkinetic migration along the apico-basal axis in relation to the different phases of the cell cycle. The mitotic cells are located at the border of the ventricular lumen, and the nuclei of the cells in S phase are located in the half basal part of the VZ. The microtubules, the centrosome, and certain MAPs contribute to this important process. It has been shown that the proteins that interact with dynein, lissencephaly 1 (LIS1),and dynactin,[42,43] as well as the centrosomal proteins Cep 120 and TACC,[44] are necessary for the movement of the nuclei from their basal position toward the apical centrosome during the G2 phase. Their dysregulation leads to the occurrence of ectopic cellular divisions. Since EFHC1 appears to be an essential centrosomal MAP, it could play a key role in this mechanism. The nuclei of the EFHC1-depleted cells would then be unable to achieve their G2 phase baso-apical migration, being forced to divide in the basal position and to acquire the basal progenitor phenotype,[45]

Another example concerns the radial glia. These cells play a crucial role during corticogenesis in controlling two important processes of radial migration: somatic translocation and cellular locomotion,[46,47] Defaults in these processes lead to migration defects and disturbances in laminar cortical organization.[48,49] Dynamic regulation of the microtubules by certain MAPS, like MAP1a, MAP4, MAP7, or the tektins, plays a clear role in the extension of the radial glia processes.[50] In addition, the deletion of one of these proteins, doublecortin-like kinase (DCLK), disturbs the cytoarchitectony of the radial glia scaffold.[51] Again, we have shown that invalidation of EFHC1 disrupts the morphology of radial glia organization: the bipolar structure disappears, the cellular extensions are significantly reduced, and sometimes even the radial organization is disrupted. This, in part, can be responsible for the default of migration observed in the postmitotic neuronal progenitors.

The locomotion of these neurons within the VZ is also reduced in cases where EFHC1 is deleted. Migration by locomotion consists of the extension of the anterior process (nucleokinesis) and the retraction of the posterior one. Again, recent studies have shown a key role of lissencephaly 1 (LIS1), dynein, nuclear distribution gene E homolog (A. nidulans)-l (NDEL1), and doublecortin (DCX) in the coupling of the nucleus and centrosome during this phenomenon.[52,53] As a MAP associated with the centrosome, EFHC1 could be implicated in this mechanism. This hypothesis is reinforced by the fact that movement of the nucleus toward the centrosome during interkinetic nuclear migration, nucleokinesis, and locomotion needs the support of the microtubules and the same regulatory proteins.

In summary, all the phenotypes observed with the functional defaults of EFHC1 in the neocortical structures during early brain development mimic those observed with other MAPs, including LIS1, NDEL1, and DCLK. Whether or not these molecules are privileged partners of EFHC1 has still to be determined.

Finally, the *Drosophila* neuromuscular junction synapse has been a useful genetic system in which to assay the role of the microtubule cytoskeleton and model its role in inherited neurological disease. For instance, mutations in the microtubule-interacting protein Futsch (MAP1b) alter synaptic morphology, and VAP-33A regulates synaptic bouton sprouting through interactions with the microtubule cytoskeleton.[54–56] Atypical protein kinase C has been shown to

control bouton formation by regulating the synaptic cytoskeleton,[57] and the hereditary spastic paraplegia genes *spastin* and *spichthyin* regulate synaptic structure and growth through the control of axonal microtubules.[58–61] Furthermore, the *Drosophila fragile X-related* gene has been shown to regulate Futsch/MAP1b, thereby modulating both synaptic architecture and neurotransmission strength.[62]

Microtubules are essential structural components of dendrites as well, and several genes have been reported to influence dendrite growth and arbor expansion through their action on microtubules. For example, *stathmin* regulates dendrite arborization by controlling the dendritic microtubule dynamics,[63] and knockdown of doublecortin, a microtubule-associated protein, in hippocampal neurons results in reduced branching, length, and complexity of the dendrites.[64] Furthermore, Very-(KIND), a KIND domain-containing RasGEF, controls dendrite growth through regulation of microtubule-associated protein 2.[65] Support for an important role of microtubules in regulating dendritic arbor shape has also come from studies in flies demonstrating that in dendritic arborization neurons the Knot transcription factor mediates control of microtubule-based arbor outgrowth by inducing expression of the microtubule-severing protein spastin.[66]

Together, these studies indicate that microtubules play key functions in the control of neurite structure and function, and that mutations perturbing microtubule dynamics are causatively linked with inherited neurological disorders that could therefore be called *microtubulopathies.*

CONCLUSIONS

For the first time, a gene responsible for an idiopathic generalized epilepsy (IGE) has been found to encode a MAP utilizing an unusual MTBD and not an ionic channel. Thus, beside the classical theory of channelopathies causing IGE, our work opens new perspectives in the identification of the precise molecular and cellular mechanisms of IGE, including subtle pathologies of early neuronal migration (microdysgenesis) and/or synaptogenesis. We hypothesize that mutations of *EFHC1* induce subtle neuronal migration or synaptic formation defects that lead to abnormal epileptogenic circuitry during cortical maturation. Eventually, the elucidation of such mechanisms will provide new targets for better pharmacological treatment of epilepsy.

Chapter 68

Progressive Myoclonus Epilepsy of Lafora

José M. Serratosa
Berge A. Minassian
Subramaniam Ganesh

Lafora disease is an autosomal recessive form of progressive myoclonus epilepsy characterized by a severe course that leads to death in 5–10 years in most patients. Patients present with myoclonic, absence, and generalized tonic-clonic seizures at onset, typically at around age 14–15 years. As the disease progresses, difficulties in speech generation and gait as well as cognitive decline appear. Seizures soon become intractable and, due to a rapidly progressing dementia, patients become severely incapacitated and die. Lafora bodies are the characteristic hallmark and consist of an abnormal, poorly branched, intracellular glucose polymer accumulating in many tissues, including heart, skeletal muscle, liver, and brain. They can be observed on optic microscopy as periodic acid–Schiff-positive (PAS+) cytoplasmic inclusions. Lafora bodies thus resemble glycogen with reduced branching, suggesting an alteration in glycogen metabolism as the cause of their accumulation. Since the localization of the first gene for Lafora disease in 1995, major advances have led to a better understanding of the basic mechanisms involved in this adolescent-onset and deadly disease.

MOLECULAR GENETICS AND GENOTYPE–PHENOTYPE CORRELATIONS

Linkage analysis and homozygosity mapping initially localized a major gene for Lafora disease to chromosome 6q24.[1] Subsequently, the first gene, known as *EPM2A,* encoding laforin was identified.[2,3] Mutation analysis has revealed a marked allelic heterogeneity in *EPM2A*. In spite of this remarkable allelic heterogeneity, one mutation, R241stop, was found in approximately 40% of Lafora disease patients in one study of such patients in Spain.[4] This study also suggested that both a founder effect and recurrence contributed to the relatively high prevalence of the R241stop mutation in Spain.

Chan et al.[5] identified a second gene associated with Lafora disease, *NHLRC1* or *EPM2B*,

which encodes malin, a putative E3 ubiquitin ligase with a RING finger domain and six NHL motifs. Malin was found to colocalize with laforin, and it was suggested that the malin-laforin interplay protected against polyglucosan body formation and epilepsy.

Defects in *EPM2A* and *EPM2B* account for more than 95% of cases, and more than 100 mutations have been reported. A study of 77 families with Lafora disease found that 54 (70.1%) had mutations in *EPM2A*, 21 (27.3%) had mutations in *EPM2B*, and 2 (2.6%) had no mutations in either gene. The course of the disease was longer in patients with *EPM2B* mutations compared to patients with *EPM2A* mutations, suggesting that patients with *EPM2B*-associated Lafora disease tend to have a slightly milder clinical course and a slower progression.[6] This finding was also reported in an Italian family with a *EPM2B* mutation and a remarkably slow, mild course and in a series of Italian patients.[7,8] Singh et al. reported similar findings.[9]

In a meta-analysis performed in 2009,[10] nearly 100 distinct mutations were identified in the two genes in over 200 independent Lafora disease families. Nearly half of them were missense mutations, and deletions accounted for one-quarter. The proportion of patients with *EPM2A* and *EPM2B* mutations varies among countries, and whereas in Spain *EPM2A* mutations are more common, in Italy and France *EPM2B* mutations predominate. In India and in the Arab countries, the mutations are distributed evenly.

FUNCTIONAL STUDIES: MECHANISMS OF LAFORA BODY FORMATION AND NEURODEGENERATION

Lafora bodies consist of an abnormal glycogen known *as polyglucosan*, which has a small number of branches and very long chains of glucose. Lafora bodies resemble starch and have low solubility, with a tendency to accumulate. Glycogen is synthesized through the action of glycogen synthase, which is responsible for chain elongation, and glycogen branching enzyme, which is responsible for chain branching. Glycogen is eliminated through digestion by glycogen phosphorylase and glycogen debranching enzyme. Reversible phosphorylation modulates nearly every step of glycogenesis and glycogenolysis. PTG (protein targeting to glycogen) is an indirect activator of glycogen synthase and an indirect inhibitor of both glycogen phosphorylase and glycogen phosphorylase kinase, the enzyme that activates glycogen phosphorylase. PTG performs this reciprocal activation of synthesis and inhibition of breakdown by binding the protein phosphatase-1 (PP1) through its C terminus, binding glycogen, and through a common region in its N terminus binding glycogen synthase, glycogen phosphorylase, or glycogen phosphorylase kinase, thus targeting PP1 to each of these enzymes. PP1 dephosphorylates each of the three enzymes, activating glycogen synthase and inhibiting glycogen phosphorylase and glycogen phosphorylase kinase.[11]

Malin and laforin colocalize in endoplasmic reticulum (ER) and form centrosomal aggregates when treated with proteasomal inhibitors in both neuronal and nonneuronal cells. Laforin/malin aggregates colocalize with γ-tubulin and cause redistribution of α-tubulin. The centrosomal accumulation of malin, possibly with the help of laforin, may enhance the ubiquitination of its substrates and facilitate their efficient degradation by proteasome. Defects in malin or laforin may thus lead to increased levels of misfolded and/or target proteins, which may eventually affect the physiological processes of the neuron. Thus, defects in protein degradation and clearance are likely to be the primary trigger in the physiopathology of Lafora disease.[12]

The first evidence of the possible role of a dysfunction in glycogen synthesis in the accumulation of polyglucosans came from a study of transgenic mice overexpressing glycogen synthase. The authors proposed an imbalance between glycogen synthase and branching enzyme as the mechanism involved in the production of polyglucosan bodies.[13]

Laforin is a protein of 331 amino acids with two domains, a dual-specificity phosphatase domain and a carbohydrate binding domain. Laforin forms part of a multiprotein complex associated with intracellular glycogen particles and is involved in the regulation of glycogen metabolism. Laforin interacts with itself and with PTG, the glycogen targeting regulatory subunit R5 of PP1. R5 is the human homolog of the murine PTG, a protein that acts as

a molecular scaffold assembling PP1 with its substrate, glycogen synthase, at the intracellular glycogen particles. The majority of *EPM2A* missense mutations found in Lafora disease patients result in lack of phosphatase activity, absence of binding to glycogen, and lack of interaction with PTG.[14]

Polyglucosan formation is catalyzed by glycogen synthase, which is activated through dephosphorylation by glycogen-associated PP1. PTG, one of the proteins that target PP1 to glycogen, was removed from laforin knockout mice. This resulted in near-complete disappearance of polyglucosans and in the resolution of neurodegeneration and myoclonic epilepsy. Blocking of PTG could in this way be a form of treatment for Lafora disease.[11]

Malin is a single-subunit E3 ubiquitin (Ub) ligase. Its RING domain is necessary and sufficient to mediate ubiquitination. Additionally, malin interacts with and polyubiquitinates laforin, leading to its degradation. Missense mutations in malin that are present in Lafora disease patients abolish its ability to polyubiquitinate and signal the degradation of laforin. Laforin is thus a physiological substrate of malin.[15]

The laforin-malin complex suppresses glycogen synthesis in neurons, and its malfunction would explain the accumulation of a poorly branched glycogen.[16] Either the abnormal glucose polymer, a malfunction of other pathways where laforin and malin are involved, or both would result in progressive neurodegeneration and epileptic seizures. The laforin-malin complex also downregulates PTG-induced glycogen synthesis through a mechanism involving ubiquitination and degradation of PTG. The interaction between laforin and malin is a regulated process that is modulated by the adenosine monophosphate (AMP)-activated protein kinase (AMPK).[17] Another theory proposes that excessive phosphorylation of glycogen leads to aberrant branching and Lafora body formation.[18]

MOUSE MODELS BEARING ENGINEERED MUTATIONS IN *Epm2A* AND *Epm2B*

To study the pathology of Lafora disease and the functions of laforin, Ganesh et al. disrupted the *Epm2a* gene in mice.[19] At 2 months of age, homozygous null mutants developed widespread degeneration of neurons, most of which occurred in the absence of Lafora bodies. Dying neurons characteristically exhibited swelling in the ER, Golgi network, and mitochondria in the absence of apoptotic bodies or fragmentation of DNA. The Lafora bodies, present both in neuronal and nonneural tissues, were found to be positive for ubiquitin and advanced glycation end products only in neurons, suggesting different pathological consequences for Lafora inclusions in neuronal tissues. The authors concluded that Lafora disease is a primary neurodegenerative disorder that may utilize a nonapoptotic mechanism of cell death.

Disruption of the *Epm2b* gene in mice resulted in viable animals that, by 3 months of age, had accumulated Lafora bodies in the brain and to a lesser extent in heart and skeletal muscle. Analysis of muscle and brain of the *Epm2b*$^{-/-}$ mice by Western blotting indicated no effect on the levels of glycogen synthase, PTG (type 1 phosphatase-targeting subunit), or debranching enzyme, making it unlikely that these proteins are targeted for destruction by malin, as has been proposed. Total laforin protein was increased in the brains of *Epm2b*$^{-/-}$ mice and, most notably, was redistributed from the soluble, low-speed supernatant to the insoluble, low-speed pellet, which now contained 90% of the total laforin. This result correlated with the elevated insolubility of glycogen and glycogen synthase. Because upregulation of laforin cannot explain Lafora body formation, the authors concluded that malin functions to maintain laforin associated with soluble glycogen and that its absence causes sequestration of laforin to an insoluble polysaccharide fraction, where it is functionally inert.[20]

These mouse models permit a clearer understanding of the pathogenic mechanisms involved in Lafora disease in humans and provide tools to unravel the complex mechanisms involved in the formation of Lafora bodies.

In conclusion, major advances have been achieved in the knowledge of the basic mechanisms involved in Lafora disease since the initial molecular genetic studies of 15 years ago. Studies have focused mainly on the mechanisms of Lafora body formation and reveal some clues concerning how neurodegeneration is produced. However, we do not know how the molecular defects found in Lafora disease result in the production of epileptic

seizures: the role of Lafora bodies is still in question, and it may be that the seizures are the consequence of other dysfunctions. The next steps in research on Lafora disease should lead to the development of experimental test systems to define better therapies.

Chapter 69

Progressive Myoclonus Epilepsy

Unverricht-Lundborg Disease and Neuronal Ceroid Lipofuscinoses

Anna-Elina Lehesjoki
Mark Gardiner

UNVERRICHT-LUNDBORG DISEASE

Progressive myoclonus epilepsy of Unverricht-Lundborg type (Unverricht-Lundborg disease; ULD; EPM1) is an autosomal recessive neurodegenerative disorder and the most common single cause of progressive myoclonus epilepsy worldwide.[1] It is enriched in the Finnish population but is also relatively frequent in the western Mediterranean region. EPM1 was previously called *Baltic myoclonus*, *Baltic myoclonic epilepsy*, and *Mediterranean myoclonus*. Following identification of the underlying gene, *CSTB*,[2] and advances in genetic testing, these disorders are now collectively classified as EPM1.

Clinical Features

EPM1 is characterized by onset at 6–16 years, progressive stimulus-sensitive, action-activated myoclonus, and tonic-clonic epileptic seizures.[3] As EPM1 progresses, patients develop ataxia, dysarthria, intentional tremor, and decreased coordination, which reflect widespread neuronal degeneration in the brain. Patients with EPM1show mild intellectual decline over time, but overall their cognitive functions are less impaired than their motor functions. The electroencephalogram (EEG) in EPM1 patients is abnormal, with spontaneous spike-wave discharges, photosensitivity, polyspike discharges during rapid eye movement(REM) sleep, and background slowing.[3,4] The EEG abnormalities

are more pronounced at initial diagnosis, but in general, they diminish as the disease stabilizes. At the time of diagnosis the magnetic resonance imaging (MRI) scan is usually normal. At later stages, atrophy in cortical motor areas, and in pons, medulla, and cerebellar hemispheres, has been reported.[5,6] The limited histopathological findings consist of widespread degenerative changes with no evidence of storage material.

Symptomatic pharmacological and rehabilitative management, including psychosocial support, is the mainstay of EPM1 patients' care.[3] Valproic acid is the first drug of choice, and diminishes both myoclonus and the frequency of tonic-clonic seizures. Clonazepam and piracetam are effective as add-on therapy for myoclonus. Anecdotal evidence exists of the efficacy of levetiracetam, topiramate, and zonisamide, but sodium channel blockers and GABAergic (gamma-aminobutyricacid) drugs should be avoided. With modern antiepileptic medication, the life expectancy of EPM1 patients has gradually increased and is now probably normal. The relative intensity of symptoms and the speed of disease progression vary from one case to another, even within a single family.

The *Cystatin B* Gene and Protein

The *CSTB* gene underlying EPM1 was identified by positional cloning.[2] *CSTB* is alternatively spliced with at least five isoforms of unknown physiological significance, some of which show tissue specificity. The gene has two potential transcription start sites that are located 67 and 78 nucleotides downstream of the dodecamer repeat element in the promoter.

CSTB encodes Cystatin B, a ubiquitously expressed 98 amino acid protein with a molecular weight of approximately 11 kDa. CSTB is a protease inhibitor that inhibits in vitro several lysosomal cysteine proteases, cathepsins, by tight, reversible binding.[7] The main function of cathepsins is nonselective degradation of intracellular proteins, but they also participate in antigen processing and apoptosis.

Cytoplasmic, lysosomal, and nuclear localization has been reported for wild-type CSTB protein in proliferating cells and mainly cytoplasmic localization in differentiated cells,[8] with somewhat conflicting results among different studies, possibly due to the different cellular models and antibodies used. Data suggest that CSTB is attached to the outer side of the lysosomal membrane rather than within the lysosome.[8]

EPM1-Associated *Cystatin B* Gene Mutations

Eleven mutations have been reported to underlie EPM1. The most common mutation is an unstable expansion of a 12-nucleotide dodecamer repeat (5′-CCCCGCCCCGCG-3′) in the promoter region of *CSTB*.[9,10] This is normally polymorphic, with two or three copies present. EPM1-associated alleles have been reported to contain at least 30 repeat copies. The expansion mutation is found in approximately 90% of the disease alleles worldwide and in homozygous form in the majority of patients, especially in populations with a founder effect. No significant correlation between the length of the expanded repeat and the age of onset or disease severity has been reported.

The other EPM1-associated *CSTB* mutations change single amino acids, affect splice sites, or predict truncated proteins. The three reported missense mutations—p.Gly4Arg, p.Gly50Glu, and p.Gln71Pro—are likely to affect the interaction of the CSTB protein with its target cysteine proteases.[8,11] With the exception of the p.Gly4Arg substitution mutation, these mutations have been reported to occur in compound heterozygous form with the repeat expansion.

The expansion mutation causes significant downregulation of *CSTB* mRNA expression, with less than 10% of expression from that in controls.[11] Consequently, CSTB protein expression and its inhibitory activity are also significantly reduced in cells of EPM1 patients. Decreased inhibitory activity of CSTB correlates with enhanced activity of cathepsins B, L, and S in EPM1 patients' cells, providing in vivo evidence for cathepsin regulation by CSTB.[12] Data suggest that reduced CSTB expression is the primary pathological consequence in the majority of EPM1 mutations, with possible exclusion of the amino acid substitution mutations.

When transiently overexpressed in cells, these missense mutant proteins fail to associate

with lysosomes,[8,11] implying an essential role of lysosomal localization for the physiological function of CSTB.

CystatinB-Deficient Mouse Model for EPM1

A mouse model for EPM1 has been generated by targeted disruption of the mouse *Cstb* gene.[13] *Cstb*$^{-/-}$ mice develop myoclonic seizures by 1 month of age and progressive ataxia by 6 months of age and thus recapitulate key clinical features of EPM1. The myoclonic seizures occur during sleep and progress from twitching of isolated muscles to spasms affecting the entire body. Electrocorticogram recordings reveal bilaterally synchronous 4–6Hz repetitive spiking commencing with the myoclonus. No tonic-clonic seizures, photosensitivity, or spike-wave complexes on EEG have been reported. The genetic background has an impact on the clinical outcome, implying that genetic factors influence the phenotype.

The neuropathological hallmark of *Cstb*$^{-/-}$ mice is progressive apoptotic loss of cerebellar granule neurons.[13] There is less marked neuronal apoptosis in the hippocampal formation and entorhinal cortex in young animals and widespread cortical and white matter gliosis in older mice.[13,14] In addition, the superficial neurons of the prosubiculum in the cerebral cortex display prominent cellular atrophy, suggesting that neuronal dysfunction may also contribute to the phenotype. Mutant mice with both seizure-prone and seizure-resistant genetic backgrounds display similar neuropathological changes indicating that neuronal degeneration and loss are consequences of CSTB deficiency independent of seizure events. These data suggest that CSTB has an endogenous neuroprotective role and that EPM1 should be classified as a primary neurodegenerative disorder, with specific neuronal populations affected and with both neuronal death and dysfunction contributing to the phenotype.

Studies of hippocampal slice preparations have revealed hyperexcitability in *Cstb*$^{-/-}$ mice as they responded to afferent stimuli in the CA1 region with multiple population spikes and as kainate perfusion provoked the appearance of epileptic-like activity earlier than in wild-type mice.[15] The density of GABA-positive cells in hippocampus is reduced in *Cstb*$^{-/-}$ mice, and the hyperexcitability may thus be due to loss of inhibition. Moreover, *Cstb*$^{-/-}$ mice have increased susceptibility to kainate-induced seizures, with a shorter latency to seizure onset and more severe seizures compared to wild-type control mice. They also display increased sensitivity to seizure-induced cell death. It has been hypothesized that CSTB acts as a physiological safeguard and that loss of its activity not only triggers hyperexcitability and neurodegeneration, but also makes neurons more susceptible to the prolonged seizure-induced cell death contributing to disease progression in EPM1.[15]

Oxidative Stress in EPM1

A novel function for CSTB in defending cerebellar granule neurons from oxidative stress has been identified.[16] It implies impaired redox homeostasis as a key mechanism by which CSTB deficiency triggers neurodegeneration. Oxidative stress induces CSTB expression in cerebellar granule neurons, and both *Cstb* knockdown in rats and knockout in mice sensitize granule neurons to oxidative stress-induced cell death. The predisposition to oxidative stress in neurons, induced by CSTB deficiency, is mediated by the lysosomal protease Cathepsin B. CSTB deficiency triggers oxidative injury specifically in the cerebellum, leading to diminished antioxidant capacity and elevated lipid peroxidation.[16] Consistent with these findings, cerebellar granule neuron degeneration is reduced in mice deficient in both CSTB and Cathepsin B compared to mice deficient in CSTB only.[17] The double-knockout mice retain myoclonic seizures and ataxia, suggesting that oxidative stress and CSTB may regulate neuronal excitability in EPM1 independently of deregulated Cathepsin B activity.

PRICKLE1 and *SCARB2* Mutations in EPM1-like Patients

Mutations in two genes have been reported in *CSTB* mutation-negative patients presenting with symptoms closely resembling EPM1. A p.Arg104Gln mutation in the *PRICKLE1* gene encoding a protein in the noncanonical (Wnt)

signaling pathway has been described in three possibly related families of Middle Eastern descent.[18] Onset of symptoms is between 5 and 10 years of age, that is, at a slightly younger age than onset in EPM1 patients. The presenting symptom is usually ataxia, with action myoclonus and seizures developing later. Intellect is generally preserved. This disorder was originally named *EPM1B* because of its similarity to EPM1, but it is now referred to as *progressive myoclonus epilepsy with ataxia*.

The second gene harboring mutations in EPM1-like patients is *SCARB2*, which encodes a lysosomal membrane protein. Mutations in *SCARB2* were originally reported in action myoclonus–renal failure syndrome (AMRF).[19] These patients present typically at 15–25 years of age, either with neurological symptoms including tremor, action myoclonus, seizures, and ataxia or with proteinuria that progresses to renal failure. In a subset of patients harboring mutations in *SCARB2* no evidence of renal failure during up to 15 years of follow-up has been observed, implying that mutations in *SCARB2* are an important cause of progressive myoclonus epilepsy cases resembling EPM1 at onset.[20] A missense mutation and five mutations predicting either aberrant splicing or a truncated protein due to a frameshift alteration have been identified in patients with EPM1-like disease. The nature or the location of the mutation in *SCARB2* does not explain the absence of renal features in these patients.

NEURONAL CEROID LIPOFUSCINOSES

The neuronal ceroid lipofuscinoses (NCLs) are a group of inherited neurodegenerative disorders characterized by the accumulation of autofluorescent storage material in neurons and many other cell types. Most are inherited in an autosomal recessive manner and are characterized clinically by epileptic seizures, progressive psychomotor decline, visual failure, and early death.

The NCLs were initially divided into four subtypes according to the age of onset, the clinical phenotype, and the ultrastructure of the storage material. These subtypes, with their eponyms, are infantile NCL (INCL, Haltia-Santavuori), late-infantile NCL (LINCL, Jansky-Bielschowsky), juvenile NCL (Batten, Spielmeyer-Vogt), and adult NCL (Kufs). More recently, several variants of these subtypes, especially of the late-infantile onset, have been characterized, and it has become clear that there is marked locus heterogeneity (mutations in different genes may result in a similar clinical disease phenotype) and allelic heterogeneity (different mutations within the same gene may result in very different clinical disease phenotypes). Estimates of incidence range from 1 in 12,500 to 1 in 100,000.

Eight genes underlying human NCLs have now been identified (*PPT1, TPP1, CLN3, CLN5, CLN6, MFSD8, CLN8*, and *CTSD*), and two are predicted to exist but are not yet isolated (*CLN4, CLN9*).[21] A database of mutations is available (www.ucl.ac.uk/ncl/mutation). In addition, mutations in members of the CLC family of chloride channels and transporters may have a role in NCL, especially *CLCN7, CLCN3*, and *CLCN6*.

Despite much research, including the development of several model organisms for NCLs, the exact biological function of the proteins encoded by NCL genes remains elusive.[22]

They can be usefully divided into the soluble proteins—PPT1, TPP1, CSTD, and CLN5—and the transmembrane proteins coded by *CLN3, CLN6, MFSD8*, and *CLN8*. Although the former have been extensively characterized, their in vivo substrates remain unknown.

Advances in research have enabled diagnosis at the molecular genetic and biochemical levels, and have resulted in prenatal diagnosis and carrier testing availability for many affected families.

Enzyme analysis (for TPP1 and PPT1) and mutation detection for the most common mutations (such as the 1kb deletion in *CLN3*) have become routine and have now replaced more invasive investigations.

There is no specific treatment for the NCLs; the mainstay of treatment is supportive and palliative care. Care is focused on minimizing symptoms, including seizures, behavioral problems, and depression. Antiepilepsy drugs are a mainstay of therapy for the majority of NCL patients. Many promising new therapeutic strategies are presently being investigated, such as chaperone therapy, enzyme replacement therapy, gene therapy, and stem cell therapy. Early diagnosis of

NCL is a key problem, as significant damage occurs between onset of initial symptoms and diagnosis.

CLN1 Disease: *PPT1*

Infantile NCL is caused by mutations in *PPT1*, the gene encoding the enzyme palmitoyl protein thioesterase 1 (PPT1).[23] PPT1 removes fatty acids in covalent linkage to cysteine residues in proteins, ensuring the eventual metabolic disposal of S-acylated cysteine residues during lysosomal degradation. In nonneuronal cells, PPT1 is a soluble lysosomal protein that is targeted to lysosomes through the mannose-6-phosphate pathway. In neuronal cells, it is localized to synaptosomes and synaptic vesicles. Mutations in *PPT1* are associated with granular osmiophilic storage deposits (GRODs) in the cells, where the main components of accumulated protein are the sphingolipid activator proteins (SAPs) A and D.

Over 40 disease-causing mutations distributed throughout the gene have been described in *PPT1*. The most common mutation (c.364A>T) is associated with a founder effect in the Finnish population. This causes disease onset in infancy, as do the majority of the mutations identified.

Early development is normal until 6–18 months, when decreased head growth and developmental retardation appear. Epileptic seizures, hypotonia, ataxia, and visual failure occur, associated with severe brain atrophy and death at 8–15 years. Less severe mutations (missense in peripheral sites) in *PPT1* also cause NCL forms with later onset and protracted progression.

Neurophysiological findings are nonspecific. There is decreased reactivity in EEG to passive eye opening and closing at around the age of 1 year. Sleep spindles are lost by the age of 2 years, and by 3 years the EEG becomes isoelectric. Thalami show markedly decreased signal intensity to the basal ganglia on T2-weighted MR images and increased signal intensity on T1-weighted images even before the clinical disease is apparent. Generalized cerebral and cerebellar atrophy is found by the age of 13 months. Enzyme assay of PPT1 in white cells is the mainstay of diagnosis and has been used for prenatal diagnosis.

CLN2 Disease: *TPP1*

Classical late infantile NCL is caused by mutations in the *TPP1* gene encoding the lysosomal enzyme tripeptidyl peptidase 1 (TPP1).[24] This gene was identified using a proteomics approach to identify the mannose-phosphorylated protein that was missing in brain samples from patients with the disease. TPP1 is a pepstatin-insensitive protease that cleaves tripeptides from the amino termini of polypeptides undergoing degradation. Subunit c of mitochondrial adenosine triphosphate (ATP) synthase, the major protein component of the storage material, particularly in this subtype, is likely to be a substrate. Ultrastructural changes are pure curvilinear membrane-bound lysosmal aggregates.

Over 60 different disease-causing mutations have now been identified in the *TPP1*gene. Two are most common: c.509–1G>C, affecting the splicing of the transcript, and c.622C>T, creating a stop codon (p.Arg208X).

Most mutations in *TPP1* cause classical LINCL. The clinical features usually begin at around the third year of life, with delay of psychomotor development or sudden onset of seizures, which may be generalized tonic-clonic, partial, or often of a severe myoclonic type. Blindness eventually develops due to retinal atrophy. Death usually occurs in mid-childhood. A few of the mutations cause a more protracted or juvenile-onset form of NCL.

The EEG shows characteristic occipital spike responses to slow flash (1–2 Hz) stimulation before the onset of seizures. The electroretinogram is diminished or absent early in the disease even before noticeable visual loss. Severe cerebellar atrophy on MRI is seen at the time of diagnosis. Enzyme assay of TPP1 in white cells is the mainstay of diagnosis.

CLN3 Disease: *CLN3*

Juvenile NCL, the most frequent subtype of the NCLs, is caused by mutations in *CLN3*, which was localized to chromosome 16 by demonstration of linkage to the haptoglobin locus and subsequently identified by a positional cloning strategy.[25] *CLN3* encodes a 438 amino acid transmembrane protein that has been located to various cellular organelles

such as lysosomes, the Golgi complex, and mitochondria.

The function of CLN3 is still unknown, but it is evolutionarily conserved down to yeast, which suggests an important function in eukaryotic cells. Possible roles include maintenance of lysosomal pH homeostasis, inward lysosomal arginine transport, a role in membrane tracking, and an antiapoptotic function. The typical ultrastructural feature is fingerprint profiles.

At least 40 mutations are currently known in *CLN3*. The most common of these is a 1kb deletion (c.462–677del) causing a frameshift after the cysteine residue at position 153 and premature termination. It occurs worldwide but especially in European and North American populations. This mutation is so predominant that most patients are homozygous or at least heterozygous for it. A wide variety of other mutations exist, some of which are associated with a later onset or a more protracted disease course.

Juvenile NCL has a usual age of onset of 4–7 years, with progressive visual failure leading to blindness always occurring first. The ocular pathology is initially a pigmentary retinopathy that may be mistaken for retinitis pigmentosa or cone dystrophy.

Seizures (at a mean age of 10 years) and psychomotor deterioration with behavioral problems follow. The main types of seizures are generalized tonic-clonic seizures, but partial seizures and myoclonic jerks also occur. Seizures tend to increase in frequency and severity, but there is considerable individual variability. In the EEG, progressive background abnormality and an increase in paroxysmal activity are seen.

Extrapyramidal symptoms and signs are noted in about 50% of patients between the ages of 12 and 15 years. Signs include impaired balance, rigidity, hypokinesia, stooped posture, and shuffling gate; tremor is usually mild and inconstant. Death occurs in the second or third decade.

The MRI scan demonstrates variable cerebral and cerebellar atrophy after the age of about 14 years.

Vacuolated lymphocytes visible in the peripheral blood are unique to this form of NCL and are a valuable diagnostic aid. Screening for the 1kb deletion is now widely available as a diagnostic service. The majority (>80%) of children of white Caucasian origin will be homozygous for the common 1kb deletion, and almost all of the rest will be compound heterozygous for the 1kb deletion and another disease-causing mutation that may be unique to the family.

Variant Late Infantile NCLs: *CLN5, CLN6, MFSD8, CLN8*

CLN5 DISEASE

The NCL subtype with mutations in the *CLN5* gene was originally described in the Finnish population and is often referred to as *Finnish variant LI NCL*. The *CLN5* gene was localized to chromosome 13q22 by a genome-wide scan and later identified by a positional cloning strategy.[26] The gene is conserved in vertebrates and encodes a lysosomal glycoprotein with no homology to other known proteins. The function of the CLN5 protein is currently unknown.

Over 25 different disease-causing mutations in *CLN5* have been described. The most common of these, c.1175delAT (p.Tyr392X), presents only in the Finnish population, blocking lysosomal targeting of the mutant protein.

The first disease manifestations include attention deficit and motor clumsiness and usually occur between the ages of 5 and 7 years, later than in the classical form. Thereafter, mental decline and visual failure, myoclonic and tonic-clonic seizures, and ataxia are features of the disease. Specific EEG features include posterior spikes to low-frequency photic stimulation from 7–8 years and giant somatosensory evoked potentials (SEPs). Age of death is between 13 and 21 years.

The MRI scan shows cerebellar atrophy between the ages of 4 and 7 years.

CLN6 DISEASE

A variant late infantile form caused by mutations in the *CLN6* gene is mainly found in the Czech Republic, Croatia, Portugal, Central and South America, and, more rarely, in Central and Northern Europe, Turkey, and the Indian subcontinent. The *CLN6* gene was localized to chromosome 15q21–23 by homozygosity mapping and identified by positional cloning.[27,28] The CLN6 protein has seven transmembrane domains and localizes to the endoplasmic reticulum (ER). It is highly conserved across

vertebrates and has no homology with known proteins; its function is currently unknown.

Over 40 disease-causing mutations have been identified in the *CLN6* gene. One of the two most common of these is a nonsense mutation c.214G>T (p.Glu72X) present in patients of Costa Rican origin.

Ultrastructural deposits include fingerprint, curvilinear, and rectilinear patterns.

Most mutations in *CLN6* cause a clinical phenotype similar to that of classical LINCL with an age of onset between 3 and 5 years, but the range is from 18 months to 8years. Early features may include gait and speech disturbance and epileptic seizures.

CLN7 DISEASE

After a genome-wide scan and homozygosity mapping in nine Turkish families and one Indian family, not linked to any of the known NCL loci, a novel variant LINCL locus was mapped to chromosome 4q28.1-q28.2. Six different mutations were identified in the *MFSD8* gene, which encodes a 518 amino acid membrane protein that belongs to the major facilitator superfamily of transporter proteins.[29] Like the majority of the previously identified NCL proteins, MFSD8 localizes mainly to the lysosomal compartment.

A total of 22 mutations have now been identified in *MFSD8* in patients of various ethnic origins including Italy. A significant group of Roma patients originating from the former Czechoslovakia was shown to bear the c.881C>A (p.Thr294Lys) mutation in *MFSD8*, possibly due to a founder effect. With one exception, these patients presented a phenotype indistinguishable from those of the other variant LINCL forms. In one patient with an in-frame amino acid substitution mutation in *MFSD8*, the disease onset was later and the disease course slower.

CLN8 DISEASE

CLN8 was first identified as a causative gene for Northern epilepsy (also known as *progressive epilepsy with mental retardation*, EPMR) in Finnish patients. Later, recognition of intraneuronal storage material led to this disease being categorized as an NCL. The *CLN8* gene was localized to the short arm of chromosome 8 by linkage analysis and identified by positional cloning.[30] The function of the CLN8 protein is unknown, but it is predicted to be a transmembrane protein with several membrane-spanning domains. In nonneuronal cells, the CLN8 protein is localized to the ER and partially to the ER–Golgi intermediate compartment (ERGIC). In neurons, CLN8 is localized to the ER, but an additional location outside the ER has been suggested in polarized cells. CLN8 has recently been connected to the TRAM-Lag1p-CLN8 (TLC) superfamily of proteins suggested to have a role in biosynthesis, metabolism, and sensing of lipids.

A total of 15 mutations have now been identified, and it is clear that there is allelic heterogeneity with two distinct phenotypes. The most common mutation is c.70C>G (p.Arg24Gly) underlying the EPMR phenotype. The first symptoms in EPMR are epileptic seizures, observed at 5–10 years of age. Two to 5 years after disease onset, patients show progressive mental deterioration and motor and behavioral problems. Additional mutations associated with a variant LINCL phenotype were subsequently identified in Turkish, Israeli, Italian, German, and Pakistani patients, including a novel large deletion in a Turkish family.

CLN10 Disease: *CTSD*

As mutations in the *CSTD* gene had been observed in two naturally occurring animal models for NCL (Swedish Landrace sheep and American bulldogs), *CTSD* was a candidate gene for human NCL. Recently, it was recognized as the causative gene for two separate human NCL phenotypes.

A homozygous duplication (c.764dupA) that creates a premature stop codon at position 255 (p.Tyr255X) results in congenital NCL with absence of CTSD immunostaining in brain.[31] Congenital NCL is the earliest-onset and most aggressive subtype. It presents with extreme brain atrophy, microcephaly, and epilepsy at birth, with death occurring within hours to weeks. In contrast, compound heterozygosity for two missense mutations, with resulting CTSD deficiency, underlies a neurodegenerative phenotype with blindness and psychomotor disability manifesting at an earlyschool age, but no seizures. Ultrastructural features include massive accumulation of GRODs.

The human *CTSD* gene is located on chromosome 11p15.5, contains nine exons, and encodes Cathepsin D, a lysosomal aspartic protease of 412 amino acids that belongs to the pepsin family and is conserved at least down to *Drosophila melanogaster* and *Caenorhabditis elegans*.

CLN4 Disease

The adult-onset form of NCL, Kufs disease, has been assigned the still unidentified gene locus *CLN4*. It is the mildest form of NCL and includes at least two subtypes with an age of onset of about 30 years (range, 10–50 years). The main clinical symptom is dementia. The other clinical features depend on the subtype and include progressive myoclonus epilepsy, ataxia, late pyramidal and extrapyramidal features, behavioral changes, and motor disturbances. There are no ophthalmological abnormalities. The EEG shows generalized fast spike-and-wave discharges with photosensitivity. Diagnosis requires demonstration of ultrastructural changes in skeletal or vascular smooth muscle cells, which may be fingerprint profiles, curvilinear profiles, or GRODs. Both autosomal recessive (most commonly) and dominant inheritance has been reported. Adult-onset NCL can be caused by mutations in the *CLN1* gene, and this may account for some cases.

CLN9 Disease

The most recently reported subtype of NCL was described in two Serbian sisters and two German brothers and is referred to as *CLN9-deficient*, as enzyme screening and sequencing of the coding regions of other NCL genes were negative.[32] The clinical history of these patients was characteristic of juvenile NCL, and curvilinear inclusions, fingerprint profiles, and GRODs were found in neurons, lymphocytes, and conjunctival cells. CLN9-deficient fibroblasts have a distinctive phenotype with rapid growth, increased apoptosis, and diminished levels of ceramide, dihydroceramide, and sphingomyelin. Transfection with *CLN8* but not other NCL genes corrected growth and apoptosis in CLN9-deficient cells. CLN8 is one of the TRAM-Lag1-CLN8 proteins containing a Lag1 motif. The latter imparts dihydroceramide synthase activity to yeast cells, suggesting that the CLN9 protein may be a regulator of dihydroceramide synthase.

SUMMARY

Loss-of-function mutations in *CSTB* are the primary defect in EPM1. In *CSTB* mutation-negative patients, *PRICKLE1* and *SCARB2* should be considered for testing. Lost lysosomal association of CSTB is an important contributing factor to EPM1. CSTB has an endogenous neuroprotective role, with different neuronal populations having different sensitivity to CSTB deficiency. The function of CSTB and the molecular mechanisms of EPM1 remain to be elucidated. Eight genes underlying human NCLs have now been identified: *PPT1*, *TPP1*, *CLN3*, *CLN5*, *CLN6*, *MFSD8*, *CLN8*, and *CSTD*. However, the biological function of the proteins encoded by NCL genes remains elusive, and it is still uncertain whether a common pathway at the molecular level underlies the accumulation of ceroid-lipofuscin. Diagnosis by enzymatic testing or DNA analysis is now available for several subtypes, and new treatment approaches are being developed.

Chapter 70

GABRB3, Epilepsy, and Neurodevelopment

Richard W. Olsen

INTRODUCTION

Three neurodevelopmental disorders—Angelman syndrome (AS), Rett syndrome (RS), and autism spectrum disorders (ASD)—share several clinical features, most notably neurodevelopmental delay and epilepsy. Here, we ask: what common mechanisms do these three neurodevelopmental disorders share that lead to a decline in cognitive development and epilepsy? Based on our observations concerning the genetic regulation of *GABRB3* in childhood absence epilepsy (CAE), we posit that the genetic mutations in these three neurodevelopmental disorders converge on a common disease mechanism involving genetic and epigenetic regulation of *GABRB3*. We first explain the data on human CAE supporting this hypothesis and show that three different point mutations in an alternative signal sequence (exon 1A) and N terminus (exon 2) in *GABRB3* result in hyperglycosylation and decreased gamma-aminobutyric acid (GABA) currents, all of which segregate with CAE. One of the variants of exon 1A, P11S, which is maternally transmitted, links *GABRB3* dysfunction with ASD and provides a possible cause of the seizures in this syndrome. In AS, *GABRB3* deletion contributes to the severe seizure phenotype. Rett syndrome is caused by mutations in MeCp2. Because MeCp2 epigenetically regulates *GABRB3*, reduced expression of *GABRB3* and epilepsy are considered consequences of MeCp2 mutations. We then review the significance of *GABRB3* in embryonic and adult neurogenesis and neuronal development in mammalian brain. We point to a master regulator of neurogenesis, RE1 silencing transcription factor (REST), which binds to repressor element 1 (RE1) in

intron 3 and the 5′ region of *GABRB3*. REST epigenetically regulates tissue and developmental expression of *GABRB3*. Finally, we chart the future challenges and experiments that could prove or disprove our hypothesis that REST and epigenetic regulation are involved in neurogenesis and epileptogenesis of absence seizures.

BACKGROUND

Genomics of *GABRB3*

GABRB3 generates two alternative signal peptide sequences, which are derived from alternative mRNA transcripts (exon 1A and exon 1), along with eight additional exons (exons 2–9). Two different mature polypeptides (NCBI accession number: NM_021912, NM_000814) are produced, each exhibiting a distinct signal peptide sequence with slight variations in residues at the N terminus due to differing cleavage sites.[1]

Exon 1 and exon 1A each can elicit tissue- and temporal-specific expression with the unique signal peptide and N-terminus sequences influencing functions and/or subcellular localization. Both core promoters contain GC-rich regions and are characterized by TATA-less SP1 binding motifs.[1–3] The abundant expression of exon 1A in fetal brain but not adult brain (Fig. 70–1) suggests a role in embryonic neurogenesis, with exon 1 likely contributing to adult brain function. The Human Genome February 2009 (GRCh37/hg19) assembly at the University of California Santa Cruz Genome Browser suggests that additional *GABRB3* sequences are expressed. One isoform found in brain has the first four exons (exons 1A, 1, 2, and 3) truncated, with transcription beginning in intron 3 and extending through exon 9; the other isoform, found in retina, consists of a long mRNA that is transcribed from intron 8 of *GABRA5* and spliced to the short region at the interval between *GABRB3* and *GABRA5* (42 kb upstream from exon 1A) and extending to exon 2 of *GABRB3*. *GABRB3* and *GABRA5* are located in a ~94 kb interval and are transcribed in a head-to-head orientation.[4] The recent reference sequence (NCBI) described four mRNAs of *GABRB3* (variants NM_021912.4, NM_000814.5, NM_001191320.1, NM_001191321.1). Two are truncated mRNAs of *GABRB3* without the first four exons (exons 1A, 1, 2, 3), which have two different lengths of intron 3 added to original variants 1 and 2. However, at present, only two protein sequences of 473 amino acids derived from *GABRB3* have consensus agreement (NP_068712, NP_000805.1).

Thus, *GABRB3* exhibits differing transcription start sites, chromatin accessibility, and histone modification patterns, and/or various splice patterns with stop codons, to produce these two variants. Although some evidence suggests that *GABRB3* is not imprinted, the paternal *GABRB3* gene region has been demonstrated to replicate earlier than maternal replication in

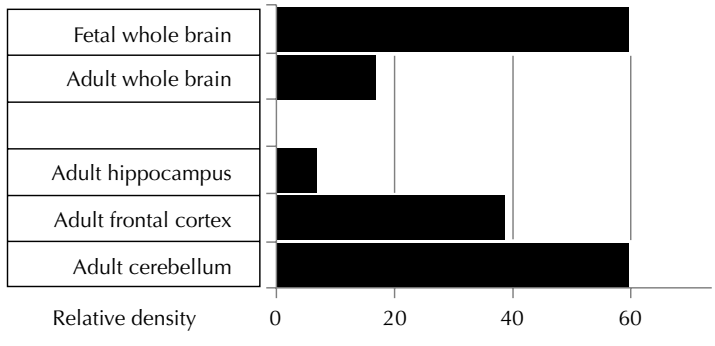

Figure 70–1. Alternative transcripts (*GABRB3* variant 2) of the human $GABA_A$ receptor beta3 subunit detected by RNase protection. The relative RNA content of different sample preparations was assessed by including an antisense riboprobe that was protected by a 152-base segment of the spliced transcript derived from exon 1A and exon 2. The transcript of exon 1A was less abundant than that of exon 1; however, the relative level of alternative transcripts was found to vary among the different brain samples. The transcript of exon 1A was enriched in fetal brain but markedly depleted in adult hippocampus. In frontal cortex and cerebellum, the relative level was similar to that found in adult whole brain. From ref. 3.

T-cell lymphocytes,[5] corresponding with distinct chromatin structure differences between paternal and maternal alleles.[6] This observation suggests paternal expression bias or tissue-specific partial imprinting. In addition, there is evidence that *Gabrb3* expression in brain is not always equivalent between male and female heterozygous mice.[7,8] In a mouse model of AS,[9] maternal-derived heterozygotes for a deletion of the chromosome encompassing *Ube3a* and *Gabrb3* show greater phenotypic correspondence with AS than paternal-derived heterozygotes, consistent with the known imprinting of the disorder; these mice show imprinting in some brain regions, including cerebellum, for *Ube3a* but biallelic expression of *Gabrb3* in the brain regions and ages examined.

GABRB3 in Mammalian Brain Embryogenesis and Adult Neurogenesis

Gamma-aminobutyric acid and $GABA_A$ receptors ($GABA_A$Rs) are the earliest neurotransmitter systems to emerge during development, even prior to glutamatergic synapses. The $GABA_A$Rs mediate excitatory signaling during development and play a significant role in neuronal growth and differentiation.[10,11] The $GABA_A$R β3 subunit mRNA/protein (encoded by *GABRB3*) emerges at embryonic days 14–17 in rat whole brain, and reaches its strongest expression at the perinatal stage, which is 150% of the level expressed in the adult[12] (Fig. 70–2). After birth, the β3 subunit protein decreases to moderate levels in adult cortex while falling rapidly in most thalamic nuclei, except in the reticular thalamic nucleus (NRT), where it remains one of the main components of the $GABA_A$R.[12–14] *GABRB3* therefore plays a significant role in neurodevelopment as well as in adult brain function. By virtue of its location in NRT and cortex, *GABRB3* plays an important role in thalamocortical circuits. As these circuits are essential to sensory processing, it is not surprising that heterozygous disruption of *Gabrb3* in mice would elicit somatosensory disturbances.[8] With *GABRB3* being highly implicated in autism, it is interesting to note that somatosensory disturbances are common to autism.[15]

In adult brain, GABA activates synaptic and extrasynaptic $GABA_A$Rs, producing phasic and tonic inhibitory chloride currents.[16] Opening of chloride conductance channels stabilizes the mature neuron near the resting potential, serving to inhibit neuronal action potentials whether or not the current is hyperpolarizing. Furthermore, $GABA_A$R-mediated chloride conductance can depolarize neural progenitor cells in immature neurons in the adult brain, similar to what occurs in the embryonic nervous system.[10,17] Phasic and tonic $GABA_A$R activity both play an important role in proper regulation of adult neurogenesis within the subventricular zone of the lateral ventricles as well as in the dentate gyrus of the hippocampus.[17]

Recordings of progenitor cells in fresh hippocampal slices from nestin tagged with green fluorescent protein (GFP) mice indicate that these cells receive direct GABAergic inputs, but not glutamatergic inputs, from the hippocampal circuitry. These GABAergic inputs depolarize neuronal progenitor cells, causing an increase in $[Ca^{2+}]_I$, resulting in the induction of expression of NeuroD, a positive regulator of neuronal differentiation. Thus, GABAergic inputs to hippocampal progenitor cells likely promote activity-dependent neuronal differentiation.[18] Since *GABRB3* is one of the main components of $GABA_A$R found in adult hippocampus, *GABRB3* likely contributes

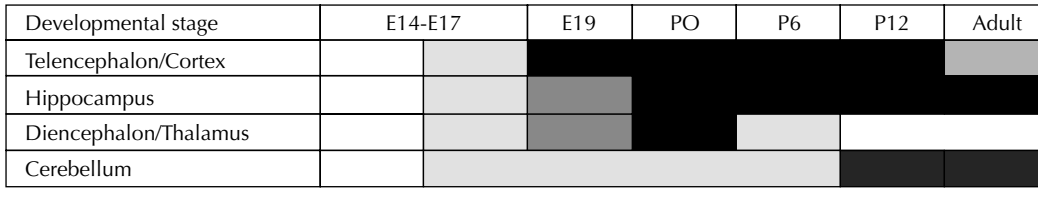

Figure 70–2. Expression level of the $GABA_A$ receptor beta subunit mRNAs in selected regions of embryonic and postnatal rat brain. Black represents a strong signal, dark gray a moderate signal, light gray a weak signal, and white an undetectable signal. From ref. 12.

to these GABAergic inputs. Furthermore, other transcription factors of the basic helix-loop-helix (bHLH) family, to which NeuroD belongs, may likewise be similarly regulated by GABA. *GABRB3* contains NEUROD1 binding motifs within intron 3, as well as a MASH1 binding motif in the 5′ region of exon1A and two NEUROG1 binding motifs in exon 1A (Fig. 70–3). One of the NEUROG1 motifs contains a single nucleotide polymorphism (SNP: rs 25409), which, as described above, we discovered in two CAE families,[1] and is also associated with maternal transmission in autism disorders.[19] This suggests that exon 1A may contain transcription binding sites for essential factors of neurogenesis in addition to its role of encoding a signal peptide. While NEUROD1 regulates neurogenesis,[18,20,21] MASH1 is required for the generation of GABAergic neurons[21,22] and NEUROG1 is required to specify glutamatergic neurons while simultaneously repressing both GABAergic differentiation[23,24] and astrocyte differentiation.[25] Therefore, the SNP rs25409 in the coding sequence may induce malfunction or unbalanced generation of GABAergic and glutamatergic neurons.

The nuclear-localized small modulatory double-stranded RNA (smdsRNA) coding

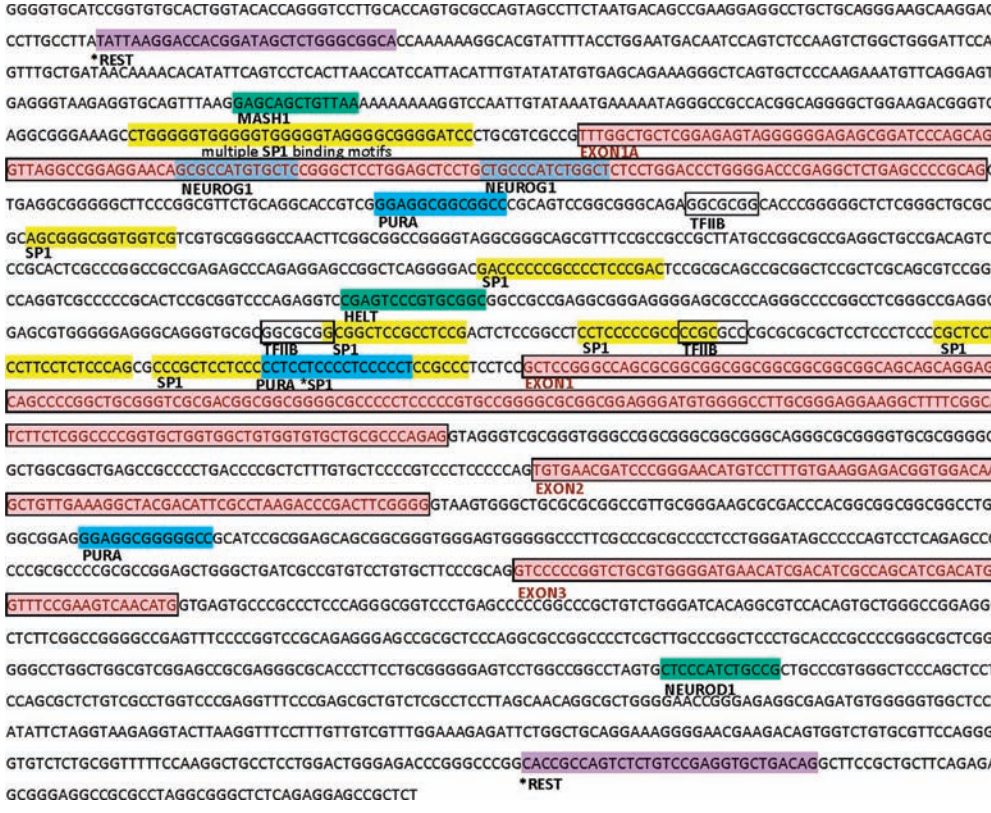

Figure 70–3. Sequence from the 5′ region to intron 3 of human *GABRB3* and predicted transcriptional factor binding motifs. *GABRB3* contains a long intron 3, spanning almost 151 kb. This, along with the first four exons (1A, 1, 2, and 3), represents a GC-rich region of about 1400 bp. Exons are bordered by solid lines. Both signal sequences have multiple SP1 binding sites. The asterisk indicates that the motif is demonstrated by chromatin immunoprecipitation[27] or a gel mobility shift assay with a DNAse I footprinting assay.[3] A Mash binding motif in the 5′ region of exon 1A, a HELT binding motif in intron 1A, two (NEUROG1) binding motifs in the coding region of exon 1A, and a (NEUROD) binding motif in intron 3 are each predicted by the Genomatics MatInspector program 8.0.3 (http://www.genomatics.de). All of these motifs involve GABAergic neuronal determination and differentiation.[20–25] Three predicted PURA motifs in intron 1A, exon 1, and intron 2 are essential for postnatal brain development.[76] The REST binding motif in intron 3 was recognized as two CpG islands by the Methyprimer program (http://www.urogene.org/methprimer/index1.html) and is potentially subject to DNA methylation and MeCP2 binding. This is the same region reported by Hogart et al.[38] as containing MeCP2 binding by chromatin immunoprecipitation.

the RE1-neuron restrictive silencer element (RE1/NRSE) sequence was discovered in hippocampal stem cells and was found to contribute to adult neurogenesis by changing the neuron-restrictive silencer factor (NRSF) from a repressor to an activator for a neuron-specific gene with RE1.[26] Thus, the role of *GABRB3* in adult neurogenesis is promoted by an epigenetic modulator, REST.

Epigenetic Modulation of *GABRB3*

Two NRSF binding motifs are found in *GABRB3*, one about 400 bp upstream from exon 1A and the other within intron 3[27] (Fig. 70–4), both locations corresponding to predicted RE1 sites. The neuron-restrictive silencer factor,, also known as REST, was originally reported as a transcriptional repressor of neuronal differentiation genes in nonneuronal cells and embryonic stem cells.[28] We confirmed the suppression of luciferase promoter activity in a construct containing RE1 in the 5′ region of exon 1A expressed in nonneuronal HEK 293 cells.[2] In contrast, promoter activity was not suppressed in neuron-like NT2 cells.[29]

REST, along with its primary corepressor, CoREST, dynamically recruits cellular cofactors including MeCP2 and other silencing machinery to RE1/NRSE sites to suppress the expression of the target genes, primarily neural genes, by chromatin remodeling.[30] REST not only prevents extraneural expression of target genes but also regulates by repressing the differentiation of neuronal subtypes required for proper tissue differentiation during embryonic development.[28,31,32] REST-mediated regulation of its target genes is not an all-or-none function. It depends on the cellular environment (e.g., intercellular signaling, Ca^{2+} dynamics, cell depolarization) resulting in context-dependent gene repression.[32,33] REST and CoREST can mediate cell type and developmental stage-specific gene repression for protein-coding genes and for several classes of noncoding RNA (ncRNA; e.g., micro RNA and long ncRNAs). The REST and CoREST network is highly integrated with ncRNA and mediates neural gene expression programs including bidirectional feedback.[34,35] REST is an essential epigenetic modulator for neuronal differentiation, homeostasis, and plasticity. Deregulation of REST and ncRNAs are implicated in cancer, neurodegenerative diseases, and neurodevelopmental diseases, including epilepsy.[30,36,37]

Recent studies concluded that REST regulates neurogenesis by reciprocal actions of REST and ncdsRNAs that exhibit RE1 sequence homology; this directly interacts with the REST transcriptional machinery in adult hippocampal neuronal stem cells.[26] The interaction transforms the REST complex into a transcriptional activator, inducing neuronal differentiation. The expression of *GABRB3*, which has two RE1/NRSE sites, is regulated

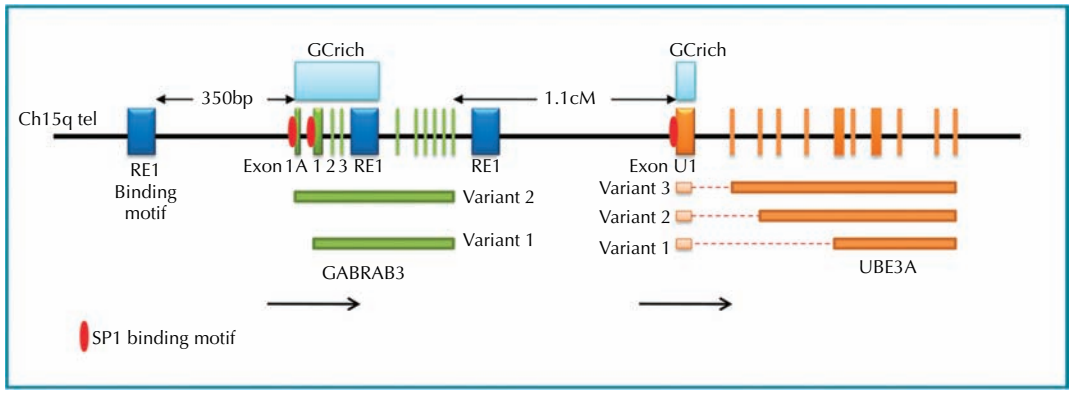

Figure 70–4. Chromosome 15q11.2-q12: *GABRB3* and *UBE3A*. The initial exons of *GABRB3* and *UBE3A* contain SP1 binding motifs in the proximal promoter regions, which are GC-rich regions and are indicated by the light blue painted squares. Green squares indicate exons of *GABRB3* with exon numbers below. Orange squares indicate *UBE3A* exons. Bottom arrows indicate the direction of transcription. Both *GABRB3* and *UBE3A* are transcribed in the same direction. One NRSF binding site lies at 350 bp upstream from exon 1A of *GABRB3*, the second NRSF binding site is in intron 3, and the third NRSF binding site is located 89 kb downstream from *GABRB3* (Quest 2.4 database).

by REST. In addition, Hogart et al.[38] found a MeCP2 binding site in intron 3 of *GABRB3* close to the REST binding site (RE1). MeCP2, a methylated DNA binding protein, is an epigenetic regulator that is required for development and maintenance of neurons.[39] Hogart et al.[38] reported that *GABRB3* expression is biallelic but paternally biased in human prefrontal cortex (Brodmann field 9) via MeCP2 activation of *GABRB3* expression. In other words, REST, which connects with various cofactors including MeCP2, could modulate *GABRB3* expression in age-dependent, tissue-specific development, not only in stem cells, but also in mature neurons through environmental stimulation that could occur throughout life.

NEURODEVELOPMENTAL DISORDERS

GABRB3, Epilepsy, and Autism

Various clinical reports, animal studies, and genetic association and basic molecular studies have provided evidence that *GABRB3* is involved in developmental neurological disorders including epilepsy.[40–46] Three missense mutations (P11S, S15F, G32A) found in an alternative signal peptide and in the N terminus of *GABRB3* segregated with remitting childhood absence epilepsy (rCAE) within four families. Two multiplex and multigenerational families containing eight affected members (Fig. 70–5A) and one proband of a singleton have mutations in an alternative signal peptide. When expressed in vitro, each of the mutations in the signal peptide coding region, exon 1A of *GABRB3,* caused hyperglycosylation of the $GABA_AR$ β3 subunit protein with concurrent reduction in GABA currents.[1] Furthermore, the promoter region of exon 1A of *GABRB3* displayed a significant reduction in promoter activity for a common SNP in the promoter region.[2] We concluded that the functional abnormality resulting from missense mutations, as well as certain combinations of SNPs in multiple regulatory elements in the 5' region and 5′UTR of *GABRB3*, causes reduced expression of *GABRB3* and a concurrent reduction in inhibition, leading to an increase in susceptibility to absence seizures. The CAE disease phenotype exhibits paternal transmission (Fig. 7–5A) of the rare *GABRB3* signal peptide variant (rs 25409: P11S), whereas maternal transmission of the same variant appears to be associated with autism (Fig. 70–5B). The association of phenotype transmission with parental gender suggests that parent-of-origin gene expression is likely occurring in certain brain region(s) within some temporal range (partial imprinting). Further genetic studies are needed to determine conclusively the importance of these rare *GABRB3* variants in CAE and autism.

GABRB3 in Chromosome 15Q11–13, AS, and Prader-Willi Syndrome

GABRB3 is spatially clustered with *GABRA5* and *GABRG3* on chromosome 15q11-q13, with *UBE3A* (ubiquitin protein ligase E3A) lying about 1 cM upstream (centromeric) from *GABRB3*. This region contains a variety of imprinted genes (Fig. 70–6) and exhibits genomic rearrangements at five common breakpoints (BP1–BP5) that often result in deletions and duplications of these genes.[47] Parent-of-origin phenotypes are characteristic of chromosome 15q11-q13 abnormalities. For example, AS,[48] caused by deficiencies of maternal genomic information on chromosome 15q11-q13, exhibits a severe phenotype. In contrast, Prader-Willi syndrome (PWS), resulting from a deficiency of paternal genes from the same region, exhibits a less severe phenotype.[49] The nature of the genomic defect also influences the severity of the phenotype; for instance, a de novo 15q11-q13 deletion on the maternal genome, occurring in 70% of AS cases, is characterized by severe mental retardation, motor dysfunction, and early-onset intractable epilepsy (primarily absences and myoclonic seizures). In contrast, 10% of AS probands exhibit only a mutation in *UBE3A*, also found on chromosome 15q11–13,[49] and are less severely affected than individuals with the full 15q11-q13 deletion. Such patients typically display only mild epilepsy.[50] Recurrence risk and severity of epilepsy also differ according to the genetic type of AS. Minassian et al.[50] suggested that the severe epilepsy in deletion cases of AS appears to be due to the lack of maternal *GABRB3* in addition to the AS gene, *UBE3A*. This is consistent with the epi-

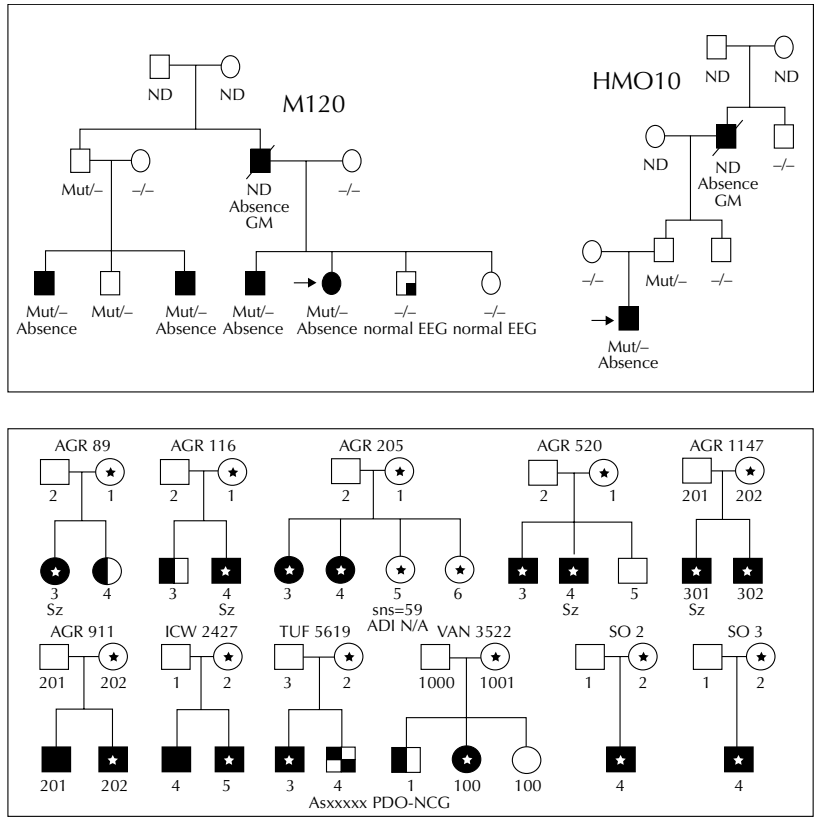

Figure 70–5. Top: Paternally transmitted rs 25409 (P11S) in CAE. The rare variant (dbSNP ID, rs 25409 [P11S]) is segregated in affected persons in two of four families with rCAE probands, as reported.[1] Black circles (female) and squares (males) represent epilepsy-affected probands. Asymptomatic persons who have 3 Hz diffuse bilateral spike-wave complexes or 5 to 6 Hz sharp waves on encephalography are represented by half black circles or squares. From ref. 1. **Bottom:** Maternally transmitted rs 25409 (P11S) in autism. The strictly autism phenotype was shown to be significant in maternal transmission with a genotype relative risk of 6.00 (95% confidence interval 1.62–22.16, $P = 0.007$). Only probands (4 out of 17) with P11S exhibited seizures in this study. One of these probands exhibited paternal transmission, while the other three phenotypes were maternally transmitted. Individuals who meet the criteria for autism on the Autism Diagnostic Interview[19] are represented by completely filled black symbols. Individuals who meet the criteria for ASD1 or ASD2 are represented by half-filled black symbols. ASD1: meets criteria in the Social domain and in either the Communication or Behavior domain. ASD2: meets criteria in the Social and Communication domains or meets criteria in the Social domain and is within 2 points of the Communication domain or meets criteria in the Communication domain and is within 2 points of the Social domain or is within 1 point in both the Social and Communication domains.[77] From ref. 19.

lepsy present in human *GABRB3*[1] and mouse *Gabrb3* mutations.[45] Epilepsy in most AS cases is refractory to medication but shows improvement with age.[51] However, PWS, which results from paternal deletion of the same chromosome 15q11-q13 region, displays a very different phenotype than AS, with mild mental retardation, obesity, and a lower likelihood of epilepsy. Furthermore, Wang et al.[52] reported that 8 of 38 PWS patients (21%) with large deletions of paternal 15q11-q13 genes, including *GABRB3*, had seizures. In contrast, none of the 12 PWS patients without a *GABRB3* deletion had seizures. These differences further support the involvement of *GABRB3* in the epilepsy displayed by these probands.[52] It is also important to note that duplications or micro-deletions of the maternal 15q11-q13 region are one of the more frequently reported observations (~2%) in ASD.[53,54] Interestingly, individuals with paternally derived duplications of 15q11-q13 rarely display autistic symptoms.[55]

The above evidence suggests a significant role for imprinted genes in neurodevelopmental disorders like AS and PWS. Consequently, their control by the imprinting center (IC)

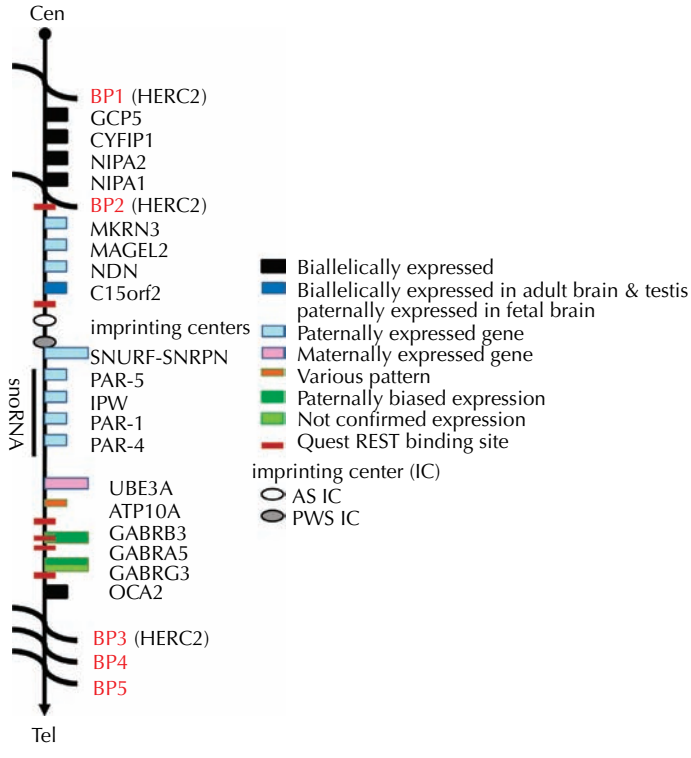

Figure 70–6. Gene order and REST binding sites on chromosome 15q11–13. Chromosome 15 contains segmental duplications and repeated transcribed DNA sequences (i.e., *HERC2* genes) located at the proximal and distal ends of the 15q11-q13 region. The typical deletion of the 15q11-q13 region causes PWS and AS, presumably due to unequal crossing over in meiosis at the breakpoint (BP1–5). Most common deletions extend the region from either of two proximally positioned breakpoints (BP1 or BP2) to a distal breakpoint (BP3). The breakpoint is shown by the curved line. Modified from ref. 78.

on chromosome 15q11-q13 is important. The IC (Fig. 70–6) was originally demonstrated and defined[56,57] by the smallest microdeletion (currently 880 bp) that resulted in a block of resetting the imprint, stabilizing on that chromosome the parental imprint (epigenotype) on which the mutation arose. The IC for AS is located centromeric to the IC for PWS, which includes the first exon of the *SNRPN* gene (Fig. 70–6). None of the paternally imprinted genes (*ZNF127*, *SNRPN*, *PAR-5*, *IPW*, and *PAR-1*), located in the vicinity of the IC, are not expressed when the PWS IC is mutated. By contrast, these same genes are expressed biparentally in mutations of the AS IC. However, these AS probands lack expression of *UBE3A* (the AS gene), located 250–1000 kb distally to the IC. To quote Saitoh et al.,[56] "the paternal chromosome of these PWS (IC mutation) patients carries an ancestral maternal epigenotype, and the maternal chromosome of these AS (IC mutation) patients carries an ancestral paternal epigenotype. The IC therefore functions to reset the maternal and paternal imprints throughout a 2 Mb imprinted domain (in cis) within human chromosome 15q11-q13 during gametogenesis." The two IC sequences presumably also interact in a DNA methylation-regulated manner[57] with proteins and noncoding mRNAs that act in trans with target imprinted genes.[58,59] At this time, the neurological defects in AS are considered to be due primarily to reduced *UBE3A* function needed for inactivation of crucial gene products by ubiquitin-dependent proteasome degradation.[59] Dysfunction of the latter perturbs neuronal growth and development, possibly involving dendritic spine morphology[60] and/or excitatory alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamatergic receptor trafficking.[61] Localization of $GABA_A$ receptors, including the β3 subunit in postmortem AS brain, would be interesting to examine.

GABRB3 and *UBE3A* in Hippocampus

In the hippocampus, *GABRB3* expression levels remain constant throughout maturation and into adulthood. Exon 1 of *GABRB3* is strongly expressed in many regions of adult human brain, including the hippocampus (Fig. 70–2), and initiates transcription by SP1 as well as other transcriptional factor(s).[3] The AS gene, *UBE3A*, located at 1.1 megabase upstream from *GABRB3* in chromosome 15q11.2-q12, is a maternally imprinted gene. Although it has been accepted that *UBE3A* displays maternally imprinted expression in hippocampus, cerebellum, and several lobes of neocortex,[62,63] recent studies utilizing immunoblotting and immunohistochemistry methods found that maternally predominant Ube3a protein expression is not limited to these regions but instead occurs throughout all brain regions.[64]

Three variants of *UBE3A* are transcribed from the same exon in the 5′ region, but different N termini are produced by various splice patterns, including stop codons.[65] The common 5′ region contains a GC- rich region as well as a SP1 binding motif, as predicted by MatInspector software. This suggests that the common ubiquitous transcriptional factor SP1 could transcribe both the *UBE3A* and *GABRB3* genes on the same chromatin at the same time.

UBE3A and *GABRB3* Deficiency with MeCP2 Dysregulation: RS and AS

Angelman syndrome (AS), RS, and ASD each exhibit mental retardation and epilepsy of varying severity as part of their phenotypes. Reduced *GABRB3* in prefrontal cortex is common to these three disorders.[38,46] Rett syndrome, caused by a *MeCP2* mutation, displays deficiency of *GABRB3* and *UBE3A*,[46] even though the genes for *GABRB3* and *UBE3A* are intact. Therefore, MeCP2 deficiency alone can result in reduced *UBE3A* and *GABRB3*. In contrast, the findings in studies of MeCP2-deficient mice were inconsistent,[46,66,67] suggesting that epigenetic regulation that includes RE1 sites is not necessarily the same between humans and mice. Makedonski et al.[68] found that the PWS- imprinting center (PWS-IC) on the maternal allele is normally methylated. This allows MeCP2 to bind and recruit histone deacetylases 1 and 2, which deacetylate histone H3 and histone methyltransferase to methylate H3(K9). This chain of events leads to heterochromatinization and silencing of all paternally expressed genes. However, in the absence of MeCP2, heterochromatin cannot form, allowing an open chromatin structure that is sufficient to transcribe antisense *UBE3A* RNA, thereby reducing *UBE3A* transcription. MeCP2 deficiency in RS can lead to epigenetic aberrations via the IC.[68] REST is degraded by the ubiquitin-proteasome system through SCFbeta-TRCP.[69] UBE3A is therefore hypothesized to degrade REST. Deficient *UBE3A* could then affect expression of *GABRB3* and other neuronal genes through elevated REST/NRSF.

CONCLUSIONS

GABRB3 plays an important role in embryonic/adult neurogenesis and neuronal development in mammalian brain. *GABRB3* is expressed at the embryonic and perinatal stages as well as in childhood brain as a main component of $GABA_A$Rs in most brain regions. This includes many thalamic nuclei that mediate the electroencephalographic spike-wave complex of absence seizures. In adult brain, *GABRB3* is dominantly expressed in the hippocampus and cerebellum but is very low in most parts of the thalamus, the only exception being the nucleus reticularis, where it remains relatively high. *GABRB3* mutations expressed in embryonic and neonatal but not adult thalamic regions of the brain could explain the reduction of seizures in AS and the remission of CAE with age, since CAE remits during puberty, when expression of *GABRB3* diminishes/ceases in most thalamic nuclei.

We suggest that transcript variant 1 and variant 2 of *GABRB3* need to be examined in thalamus and hippocampus as a function of development, in comparison to *UBE3A* expression, in order to establish the significance of *GABRB3* in neurodevelopment and epilepsy. In mouse, such assays of *GABRB3* expression could be performed on animals engineered to produce

a maternal-derived heterozygous deletion of the chromosomal region encompassing both *UBE3A* and *GABRB3*, an animal model of AS.[9]

Future experiments also should consider the epigenetic modulation of REST and MeCP2 in ASD, AS, RS, and CAE. One study[70] has already broadened the view of REST and CoREST action by genome-wide analysis of the binding status of REST and CoREST to various promoters in embryonic mouse forebrain. Expression of REST and CoREST varies in different brain regions and is specific for neuronal subtypes of GABAergic, glutamatergic, and cholinergic neurons. Differential expression of REST and CoREST in brain regions also affects the generation of factors responsible for neuronal diversity, such as homeostasis, cell cycle dynamics, cell viability, stress responses, and epigenetic regulation. REST is likely to have multiple roles, not only in immature neurons but also in mature ones.[70] In situ hybridization analysis in normal brains has already revealed that REST mRNA is highest in adult hippocampus,[71] and REST protein expression studies utilizing mature hippocampal neurons have replicated the in situ hybridization results.[72] Epileptic insults and ischemic changes have also been observed to elevate REST mRNA.[32,71,73]

UBE3A is hypothesized to regulate REST by degradation through the ubiquitin pathway, with altered *GABRB3* expression resulting from maladjustment of REST. When *UBE3A* is mutated, reduced degradation of REST results in excessive REST. When REST acts as a repressor, excessive REST in a developing brain could hypothetically reduce *GABRB3* expression, resulting in cognitive decline and epilepsy. Experiments that would demonstrate the above hypothesis are warranted. The deletion of *UBE3A*, thereby influencing REST, could also lead to a severe phenotype due to inappropriate regulation of a number of other targets, including *GABRB3*, with which REST interacts. Future experiments should also consider whether epigenetic malregulation of *GABRB3* by REST and/or MeCP2 produces the phenotypes of mental retardation and epilepsy even without a *GABRB3* mutation.[74,75] Understanding these epigenetic mechanisms is likely to lead to novel interventions for neurodevelopmental diseases like ASD, AS, RS, and CAE.

Chapter 71

Pathophysiology of Epilepsy in Autism Spectrum Disorders

Carl E. Stafstrom
Paul J. Hagerman
Isaac N. Pessah

INTRODUCTION

Why are seizures so common in children with autism? This relatively straightforward question does not, unfortunately, have a straightforward answer. In this chapter, we explore this question from clinical, pathophysiological, and molecular perspectives, using as examples two genetic disorders that share a high prevalence of autism and epilepsy—fragile X syndrome (FXS) and tuberous sclerosis complex (TSC)—with the hope that understanding the pathophysiology of these monogenic conditions will lead to broader understanding of neural hyperexcitability in other autism syndromes. We conclude by discussing cellular and network dysfunctions that might be amenable to targeted treatments in these disorders, with potential wider applicability to idiopathic autism.

Autism spectrum disorders (ASDs) are neurodevelopmental disorders that share abnormalities in three domains: language development, social interaction, and motor behavior with stereotypies and restricted interests. In this chapter, the term *autism spectrum disorder* encompasses classic childhood autism as originally described by Kanner,[1] Asperger syndrome, and pervasive developmental disorder not otherwise specified. The signs and symptoms of ASD can usually be recognized before age 3 years,[2] although recent evidence of an early, but slow, loss of skills in about three-quarters of the infants who develop ASD is observed by 12 months.[3] Later, some individuals with ASD experience regression of language or behavior (autistic regression), a phenomenon that has been hypothesized to be related to epilepsy or epileptic discharges on the electroencephalogram (EEG).[4] The possibility that subclinical epileptiform discharges can contribute to the spectrum of disability in ASD or lead to regression of language or social skills suggests that the brains of individuals with autism are hyperexcitable.

Clinical aspects of seizures and epilepsy within the autism spectrum have been reviewed in detail.[5–9] Up to 30% of individuals with ASD have epilepsy, and ASD is present in about 30% of patients with epilepsy, though these numbers are approximate due to historical differences in the definition of each condition and to different study methodologies.[10] Risk factors for epilepsy in ASD include mental retardation, motor impairment, symptomatic etiology, and seizure onset either early in life (before 5 years of age) or in adolescence.[9] However, the neurobiology of ASD, as well as the mechanisms responsible for cellular hyperexcitability in ASD, are not well understood and likely involve the interplay of genetic, epigenetic, and environmental contributions.[11–14]

There are several possible relationships between brain development, epilepsy, and ASD (Fig. 71–1).[15] First, ASD and epilepsy might be distinct conditions with no causal relationship; however, this possibility is unlikely in view of the high co-occurrence rate (30%) between the two disorders. Second, a common neurobiological antecedent (e.g., structural or developmental lesions, genetic susceptibilities, and/or environmental insults) might lead to abnormal brain development that results in both epilepsy and ASD. Third, epilepsy could lead to autistic behavior or, conversely, abnormal brain

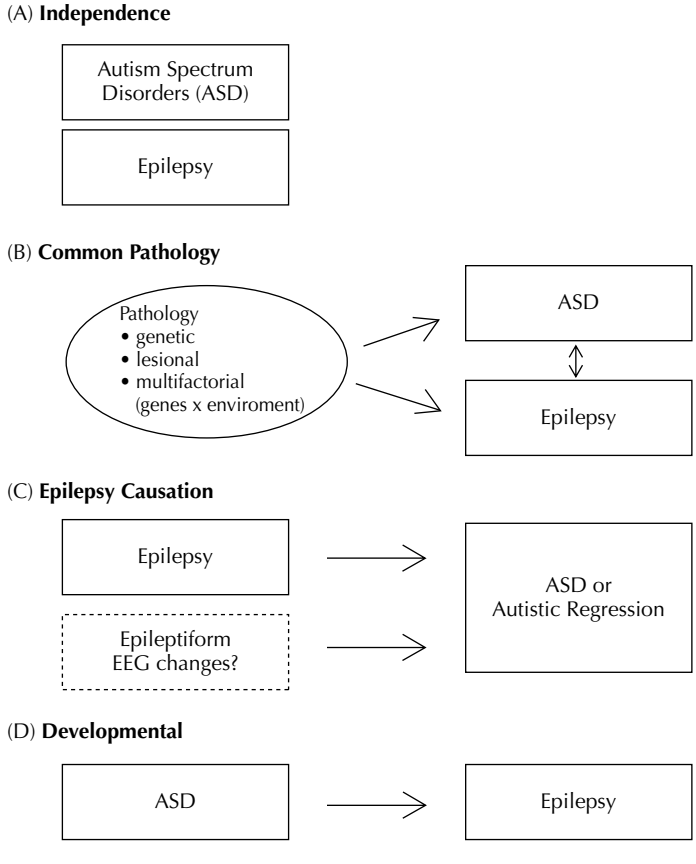

Figure 71–1. Possible relationships between brain development, epilepsy and ASD. **A.** Epilepsy and ASD might be distinct conditions with no causal relationship. This possibility is not likely due to the high comorbidity of these two disorders. **B.** A common neurobiological antecedent (e.g., abnormal brain development, genetic defect) could lead to both epilepsy and ASD. Another possibility is that there is interaction between the pathophysiology of neural circuits underlying established ASD and epilepsy (i.e., at the level of the double-headed arrow). **C.** Epilepsy or epileptogenic EEG changes (the dashed box indicates uncertainty) could lead to ASD. **D.** Conversely, abnormal brain circuitry underlying ASD could predispose the brain to seizures. These relationships are not mutually exclusive or unidirectional, so that mechanisms of epilepsy and ASD are interdependent and targeted therapies for one disorder could benefit the other.

circuitry underlying ASD could predispose the brain to seizures. The second and third possibilities are not mutually exclusive, leading to the hypothesis that mechanisms of epilepsy and ASD are interdependent and that targeted therapies for one condition could ameliorate the impact or severity of the other, as will be discussed in more depth below. The possibility that common developmental mechanisms of epilepsy and ASD exist arises from observations that both disorders, though etiologically heterogeneous, involve abnormal brain plasticity, that is, *dysplasticity* or the ability of neural circuits to function normally with regard to cognitive and social function.[13]

The etiologies of ASD are diverse and can be either idiopathic (nonsyndromic) or secondary to an identifiable underlying medical or genetic disorder (syndromic). The risk of epilepsy is increased in both idiopathic and syndromic forms of ASD, suggesting that there might be common pathophysiological alterations that lower the seizure threshold. Specific medical or genetic/genomic abnormalities have been identified in approximately 20% of ASD cases, though one study reports a 40% diagnostic yield.[16] In the future, the category of "idiopathic" autism might disappear as the molecular and genetic bases of ASD disorder become more fully defined. For now, the existence of known etiologies permits investigation into molecular and physiological aspects of brain function that lead to autistic behaviors.[17] Understanding the pathophysiological mechanisms of increased seizure susceptibility is facilitated by examination of genetic mutations leading to ASD. So far, the results of these studies are weighted toward defects in postsynaptic function and subcellular signaling.[18,19]

While much of idiopathic ASD is likely to be multigenic with complex genetics, a small but increasing proportion of ASD has been identified with specific gene mutations; some single-gene defects are associated with both ASD and seizures.[20] Examples include FXS, caused by mutation of the fragile X mental retardation 1 (*FMR1*) gene, and TSC, due to mutation of the *TSC1* or *TSC2* genes involved in the control of cell growth and differentiation. Other novel mutations with concurrent ASD and epilepsy are rapidly appearing in the literature and are reviewed in detail in elsewhere.[13] Several of these mutations involve genes regulating proteins critical for synapse development (e.g., neuroligins and neurexins)[21] or interneuron function (e.g., aristaless-related homeobox X-linked [*ARX*] gene mutations).[22] Likewise, patients with Rett syndrome, a neurodevelopmental disorder with progressive deterioration of motor skills, language, cognition, and behavior (autism), have a high risk of developing epilepsy.[23] Rett syndrome is due to mutation in the gene encoding methyl-CpG binding protein 2 (*MeCP2*), a transcriptional regulator of numerous genes. Whether genetic mutations associated with syndromic ASD converge on common mechanisms that lead to neuronal hyperexcitability and epilepsy remains to be established.

FRAGILE X SYNDROME

Clinical and Genetic Aspects

Fragile X syndrome is the most common inherited form of cognitive impairment and the leading known monogenic disorder associated with ASD.[24] Using strict diagnostic criteria, 15%–30% of males with FXS have autism.[25] Approximately 20% of children with FXS have seizures, many of which are relatively benign and resolve beyond childhood. Autism in FXS ranges from mild to severe and tends to improve with age.[26,27] Among children with FXS, those with comorbid autism have greater cognitive and verbal impairments than FXS children without autism.[27] Predominant impairments are in the communication domain.[28]

Fragile X syndrome arises when a CGG-repeat tract in the 5′ noncoding region of *FMR1* exceeds 200 repeats (i.e., the "full mutation" range), at which point the gene becomes hypermethylated and transcriptionally silent.[29] The absence of the *FMR1* fragile X mental retardation protein (FMRP) is responsible for the clinical phenotype and physical features, which include prominent ears, long face, high-arched palate, macroorchidism, and hyperextensible finger joints.[30] Approximately 85% of males and 25% of females experience cognitive impairment (IQ <70); nearly all patients have behavioral problems, with males tending to present with attention deficit hyperactivity disorder (ADHD) and aggression, while females are more prone to shyness and social withdrawal.[31] Individuals with CGG expansions in

the premutation range (55–200 CGG repeats) display a range of clinical features, including behavioral and cognitive involvement in children[31–33] and a late-adult-onset neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS).[34] The prevalence of seizures in individuals with the premutation is reported to be in excess of 20%.[35]

The fragile X mental retardation protein is an RNA-binding protein that is believed to have multiple functions, including dendritic transport of various mRNA species[36] and the translational regulation of mRNAs whose protein products are involved in synaptic development, function, and plasticity.[37] Among the known targets of FMRP-coupled translational downregulation are the microtubule-associated protein 1B (MAP1B), which is important for modulating microtubule-coupled growth of dendritic spines and for dendritic arborization,[38] and Arc, which plays a role in the internalization of alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptor subunits, a subtype of ionotropic glutamate receptors.[39]

Seizures occur in 10%–20% of FXS individuals with full mutations.[40–42] Interictal EEG patterns are similar to those seen in benign childhood epilepsy with centrotemporal spikes (rolandic epilepsy). In one study involving 16 children with FXS and epilepsy, 12 children had partial seizures, with 10 of the 12 having an EEG with centrotemporal spikes.[41] In addition, 23% of the children who did not have seizures displayed abnormal EEG patterns, typically centrotemporal spikes. In most children with FXS, seizures are readily controlled and tend to disappear in adolescence. Therefore, there are similarities between epilepsy in individuals with rolandic epilepsy and FXS, and any mechanism postulated to explain epileptogenesis in FXS must account not only for the relatively benign seizure manifestations, but also for their absence in the majority of FXS cases.[43]

Pathophysiology

THE METABOTROPIC GLUTAMATE RECEPTOR THEORY FOR FXS

Numerous animal models and electrophysiological studies have examined the pathogenesis of FXS and the synaptic dysfunction that underlies the hyperexcitability and epileptiform features associated with the disorder. A key advance in the understanding of the molecular basis of FXS was that mice lacking FMRP displayed enhanced long-term depression (LTD) in hippocampal neurons and that this LTD was dependent on protein synthesis.[44,45] Long-term depression is a form of synaptic plasticity that underlies learning and memory, so dysfunctional LTD in FXS could reflect the cognitive deficiencies seen in patients.[46] In this model, LTD could be inhibited by blocking the metabotropic glutamate receptor 5 (mGluR5) with agents such as 2-methyl-6-(phenylethynyl)-pyridine (MPEP). Further, FMRP normally functions to downregulate the translation of proteins, such as Arc, that are involved with the internalization of AMPA receptors from the postsynaptic surface. Thus, in the absence of postsynaptic FMRP, stimulation of mGluR5, either by receptor agonists or presynaptic glutamate release, results in increased postsynaptic protein translation, leading to excess internalization of AMPA receptors and eventual weakening of synaptic transmission (Fig. 71–2). By contrast, premutation-associated disorders (FXTAS, fragile X-associated primary ovarian insufficiency, neurodevelopmental involvement)[47] are not a consequence of FMRP deficiency per se; rather, mounting evidence from both human and animal studies indicates that these premutation-specific disorders are caused by a direct toxic gain of function of the CGG-repeat *FMR1* mRNA.[48,49] Furthermore, reductions in hippocampal volume, activation, and associated memory deficits, as well as reduced amygdala activation[50] and psychopathology,[51] appear much earlier in adulthood than do the symptoms of FXTAS, suggesting that the processes that ultimately will lead to FXTAS may be operating at a much earlier age. The reports of ADHD and ASD in young boys with the premutation also suggest a neurodevelopmental component to the premutation.[33] Recently, low-density hippocampal neuronal cultures from neonatal mice in the premutation range were shown to recapitulate neurodevelopmental and neurodegenerative aspects described in vivo.[52]

The mGluR model accounts for a number of the physical and behavioral features of FXS and predicts several aspects of the phenotype in various animal models, including enhanced seizure activity in an *Fmr1* knockout mouse model with audiogenic seizures.[53–55] One

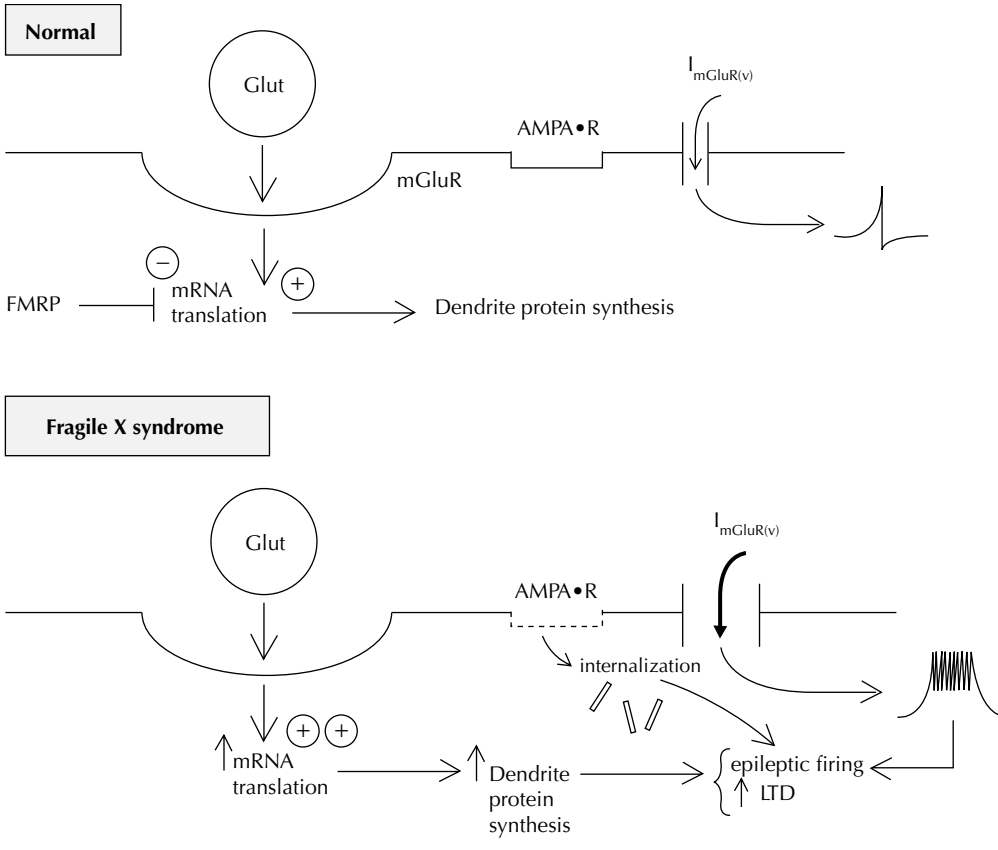

Figure 71–2. Possible mechanisms for seizures in FXS. In the normal case (top), glutamate (Glut) activation of dendritic group I metabotropic receptors (especially mGluR5) enables intracellular gene transcription, leading to translation of dendritic proteins. This process is modulated by FMRP, which keeps protein synthesis in check and prevents synaptic LTD. Activation of group 1 mGluR also activates a phospholipase C β1-dependent, voltage-gated inward current ($I_{mGluR(V)}$), which, under normal conditions, allows hippocampal CA3 neurons to fire in brief bursts (thin curved arrow). In FXS (bottom), with absent FMRP, there is no inhibition of the downstream effects of mGluR activation, leading to excessive protein synthesis, increased LTD, and prolonged $I_{mGluR(V)}$ (thick curved arrow), which can lead to epileptic firing. Internalization of AMPA receptors as a consequence of mGluR activation enhances the tendency toward epileptic firing. The concepts depicted here are derived from the work of several investigators (e.g., refs. 39, 59, 60, 123).

consequence of enhanced protein synthesis in the absence of postsynaptic FMRP in the knockout mouse is increased internalization of AMPA receptors at the postsynaptic surface. The augmented AMPA receptor internalization (a facet of the increased LTD observed in the knockout mouse) no longer requires protein synthesis, suggesting that the elevated protein levels present in the postsynaptic compartment are sufficient to establish the enhanced LTD.[56]

A potential caveat is that agents used in many animal studies, particularly those involving mGluR5 inhibitors (e.g., MPEP) or AMPA-receptor agonists, may have off-target effects that mimic the desired effect. To resolve this uncertainty, *Fmr1* knockout mice were crossed with animals heterozygous for deletion of the *Grm5* gene (50% reduction in mGluR5), thus mimicking drug-induced reductions in mGluR5 activity.[57] The resulting mice, *Fmr1*(–/Y) *Grm5*$^{+/-}$, displayed substantial correction of defects in experience and conditioning (i.e., ocular dominance plasticity and inhibitory avoidance extinction), normalization of dendritic spine density, a return to normal basal protein synthesis, attenuated susceptibility to audiogenic seizures, and rescue from early accelerated growth. These results clearly establish that the enhanced response to stimulation of the mGluR5 receptor plays a critical role in many of the phenotypic characteristics of FXS. Finally, it was shown that kindling promotes

prolonged seizure activity and severe mossy fiber sprouting in the *Fmr1* knockout mouse and that this behavior could be at least partially blocked using either *N*-methyl-d-aspartate (NMDA)-receptor or mGluR5 inhibitors.[58]

EPILEPTOGENIC MECHANISMS IN FXS

While the mGluR theory explains many of the phenotypic features of FXS, altered postsynaptic function arising from the absence of FMRP does not readily explain the central nervous system (CNS) hyperexcitability and seizure susceptibility associated with FXS. However, several recent studies have begun to reveal the connection. A recent investigation provides evidence that a voltage-gated inward current, $I_{mGluR(V)}$, is the cellular basis for the epileptogenic behavior induced by activation of the mGluR5 receptor[59,60] (Fig. 71–2). Specifically, stimulation of mGluR5 by the agonist dihydroxyphenylglycine in mouse hippocampal slices led to prolonged epileptiform discharges that lasted for more than 1 h after washout of the agonist. Moreover, this inward current could be suppressed by inhibitors of downstream signaling pathways that mediate group I mGluR-coupled translation (e.g., tyrosine kinase, extracellular signal-regulated kinase [ERK]1/2).[61,62] Remarkably, glutamate stimulation of glutaminergic synapses did not recapitulate this effect in wild-type mice, whereas $I_{mGluR(V)}$ was activated in hippocampal preparations from *Fmr1* knockout mice. The authors conclude that the induction of $I_{mGluR(V)}$ serves as a form of synaptic plasticity to predispose to epileptogenesis. Thus, activation of mGluR5 at multiple synapses in the absence of FMRP translational control leads to heightened electrical excitability. The carrier of $I_{mGluR(V)}$ is not yet known, though evidence supports one or more of the transient receptor potential canonical (TRPC) channels that mediate Ca^{2+} entry in response to depletion of endoplasmic reticulum Ca^{2+} stores.[63]

Evidence for a connection between the absence of *Fmr1* and epileptogenesis in the knockout mice was extended in a study of neocortical circuits.[64] In agreement with prior observations,[60] the authors documented increased intrinsic excitability in excitatory neurons from *Fmr1* knockout mice. However, there was an imbalance between this excitability and a relatively decreased excitatory drive present at fast-spiking inhibitory neurons. The net result was prolonged neocortical circuit activity (termed the *UP state*) induced by thalamic input. The heightened circuit activity, coupled with less synchronous network inhibition, was proposed as the underlying mechanism that leads to EEG abnormalities and epilepsy in FXS. Thus, the failure to properly modulate the mGluR5 response in the absence of FMRP results in neuronal hyperexcitability, mediated in part by the generation of a voltage-gated inward current, which in turn reduces excitatory input to inhibitory neurons and results in net increased excitability.[65]

ROLE OF GABA RECEPTORS

The increased excitability of hippocampal and neocortical circuits in FXS, due to dysregulation of glutaminergic neurons, can in turn disrupt the normal actions of inhibitory GABAergic neurons. Downregulation of $GABA_A$ receptor (GABR) subunits occurs at both the mRNA and protein levels—a situation that would further increase the excitatory character of limbic and cortical circuits.[66,67] Recently, it was demonstrated that in addition to reductions in $GABA_A$ subunits, there is also lower expression of a number of genes involved in GABA metabolism, including *gad1*, *gat1*, and *gat4,* in the brain of both mouse and *Drosophila* models of FXS.[68]

On a structural level, in the somatosensory cortex of the *Fmr1* knockout mouse, inhibitory circuits were found to be reorganized accompanied by a reduction in the density of GABAergic interneurons.[69] A separate investigation of the function of GABAergic neurons in the subiculum revealed that tonic, but not phasic, $GABA_A$ currents were downregulated in the *Fmr1* knockout mouse relative to wild-type controls.[70] These results were associated with reductions in tonic GABR subunits.

Several classes of pesticides of concern to human environmental health are known to interfere with GABA-mediated neurotransmission because they bind to GABR and block their ability to mediate chloride fluxes. Organochlorine (OC) insecticides that possess polychloroalkane structures are known to bind to GABR in the mammalian brain and potently block their ability to conduct Cl^-, with many having nanomolar affinity for their receptor binding site.[14] Organochlorine insecticides

that are currently being used in the United States include endosulfan, dicofol, and lindane. Because of their chemical stability, global distribution from countries that continue to use these compounds, and their propensity to bioaccumulate, exposure to OC insecticides continues to be a concern for human health. Yet, relatively little is known about their developmental neurotoxicity and the long-term consequences of low-dose exposures.[71] An association between maternal residence near agricultural pesticide applications during key periods of gestation and the development of ASD has been documented.[72] Children of mothers living closest to agricultural fields with the highest endosulfan and dicofol use had a risk factor for autism that was 6.1 times higher than that of mothers not living near agricultural fields. The fact that OC and several newer widely used insecticides impair GABR function suggests that deficiencies in the function of the GABAergic system in the *Fmr1* knockout mouse would further upset the balance between excitatory and inhibitory function in the CNS and may represent a valuable model for studying gene x environment interactions that cause hyperexcitation of the CNS.

Treatment Implications

The growth in knowledge of the pathogenesis of FXS, specifically regarding the linkage between abnormal neural function and epileptogenesis, presents numerous possibilities for targeted interventions.[30,73] Perhaps the most attractive targeted treatment is blockade of the mGluR5 receptor, thus compensating for the absence of downstream control by FMRP. Clinical trials are presently underway with various mGluR5 inhibitors. An open-label single-dose pilot trial in 12 individuals of the mGluR5 agonist, fenobam, demonstrated a reduction in anxiety and hyperactivity, with no significant adverse effects.[74] A second open-label treatment trial of 15 patients assessed the effects of lithium, which reduces mGluR5 activation of downstream processes.[75] There was significant improvement in behavior and verbal memory. Larger clinical trials are needed with both agents.

The GABR subtypes comprise another potential therapeutic target.[76] *Fmr1* mutant *Drosophila* die during development if fed a high-glutamate diet, consistent with the mGluR model of excess activation.[77] The authors exploited this lethal phenotype to screen for small molecules that would rescue the flies and found several, including GABA, that rescued the phenotype, providing additional evidence that GABR agonists might have a beneficial therapeutic effect. Finally, there is substantial evidence that GABR agonists, such as the neurosteroid allopregnanolone and a related analog, ganaxolone, possess significant antiseizure activity.[78]

Other approaches include an open-label trial of minocycline, a metalloproteinase inhibitor that improves dendritic spine morphology in *Fmr1* knockout mice.[79] These and other pharmacological agents will be used singly and in combination to target some of the most troubling behavioral manifestations in FXS.

In summary, epilepsy associated with FXS represents an opportunity to explore mechanisms of hyperexcitability in a disorder for which the molecular pathophysiology is unique and specific.[80] Seizures occurring in conjunction with FXS are generally mild, tend to disappear in childhood, typically respond to anticonvulsant treatment, and are associated with an EEG pattern of centrotemporal spikes. In several respects, the clinical and electrographic aspects of seizures in FXS resemble those of the benign focal epilepsies of childhood. Whether these similarities are coincidental or related mechanistically is an intriguing question for future investigation. The type of (and even need for) antiepileptic therapy for individuals with FXS must be weighed against potential adverse effects, which could be unique in this syndrome. Ideally, pathophysiological insights, as reviewed here, will lead to therapeutic interventions targeted to the specific molecular defects in FXS.

TUBEROUS SCLEROSIS COMPLEX

Clinical and Genetic Aspects

Tuberous sclerosis complex is a multisystem genetic disorder caused by a mutation in the *TSC1* or *TSC2* gene. *TSC1* (on chromosome 9q34) and *TSC2* (on chromosome 16p13) code for proteins (hamartin and tuberin, respectively) that form a dimeric complex that has

guanosine triphosphatase (GTPase) activity and inhibits excessive cell growth and proliferation via the mammalian target of rapamycin (mTOR) signaling pathway.[81] Mutation of either gene causes dysregulation of mTOR, resulting in abnormal cellular proliferation, growth, and differentiation. This leads to the formation of tumors, usually benign, in many organs, including brain, kidney, and heart. Cellular regulation of the mTOR pathway and its dysfunction is discussed briefly below and is elaborated by Wong and Crino (Chapter 65, this volume). Thus, TSC is a malformation of cortical development with a specific genetic basis that leads to a spectrum of neurological disability including multifocal epilepsy, mental retardation, and ASD.[82,83] Here we focus on the relationship between epilepsy and ASD in TSC.

While any organ system can be affected in TSC, the brain is involved extensively. The neuropathological hallmark of TSC is cortical tubers.[84] Tubers are hamartomatous collections of dysplastic cells of both glial and neuronal origin with abnormal morphology, size, orientation, lamination, and cellular connectivity. As such, tubers or nearby extratuberal tissue are extremely epileptogenic, and their extensive and varied cortical localization gives rise to multifocal sites of seizure generation.

In TSC, seizures are very common, affecting 60%–90% of patients.[82,85,86] Seizures in TSC often begin in the first year of life, putting the developing brain at risk for seizure-induced neuroplastic changes.[87] Seizures of any type can be seen, particularly complex partial (related to the multifocal pathology), generalized tonic-clonic, and infantile spasms (IS). Infantile spasms are very common in TSC and are frequently associated with subsequent autism.[88,89] Seizures in TSC are often severe and intractable, with remissions occurring only rarely. In some cases, surgical resection of an offending tuber, especially if performed early in life, can result in seizure reduction and a more favorable developmental profile.[90,91] However, there is a critical need to develop a nonsurgical treatment of TSC that not only reduces seizure occurrence but also prevents epileptogenesis and, by extension, its cognitive and behavioral/autistic sequelae.

About 25%–50% of children with TSC have ASD, with girls and boys affected to a similar degree, in marked contrast to the male predominance in nonsyndromic ASD.[92] The tuber burden (number, extent) and location correlate with the degree of mental retardation, ASD, and seizure predisposition. Tubers located in the temporal lobes are highly correlated with ASD in TSC patients.[89,93] Presumably, disruption of limbic circuitry, perhaps by the hypersynchronous neuronal activity comprising seizures or epileptiform EEG discharges, leads to abnormalities of language development and cognitive processing.[94,95] There is also a high rate of ASD in TSC patients with tubers in the cerebellum.[96] Patients with *TSC2* mutations tend to have earlier onset of ASD and epilepsy, but there is considerable overlap between those with *TSC1* and *TSC2* mutations.[86,97] Although seizures, especially those with onset early in life, are a risk factor for ASD in TSC,[98,99] ASD also occurs in patients with TSC who do not have epilepsy. Therefore, the relationship between seizures and ASD in TSC is complex, with imprecise genotype–phenotype correlation and the potential for modification by epigenetic and environmental factors.[89,100,101] Since epilepsy precedes ASD in many cases of TSC, it is possible that abnormal neural firing alters the development of language and social function.

Pathophysiology

The mTOR protein is a central regulator of cell growth and proliferation.[102] Figure 71–3 depicts some of the molecules involved in this signal transduction pathway. Components of the mTOR pathway are present at synapses and play an important role in synaptic plasticity via regulation of local protein synthesis. Activation of either growth factor receptors or glutamate receptors sets into motion a subcellular signaling cascade that regulates cell growth and differentiation, mediated through the mTOR pathway that is, in turn, regulated by *TSC1* and *TSC2*. A mutation in *TSC1* or *TSC2* prevents mTOR activation, leading to unbridled protein transcription and translation and hence cell growth and proliferation. Upstream regulation of the *TSC1/2* complex and cellular signaling that can bypass *TSC1/2* function (such as the ERK pathway[103]) provides potential pathways for controlling this unchecked cell growth and epileptogenesis. Downstream from mTOR, a variety of kinases and translation factors serve as modulators of cell growth. Nevertheless,

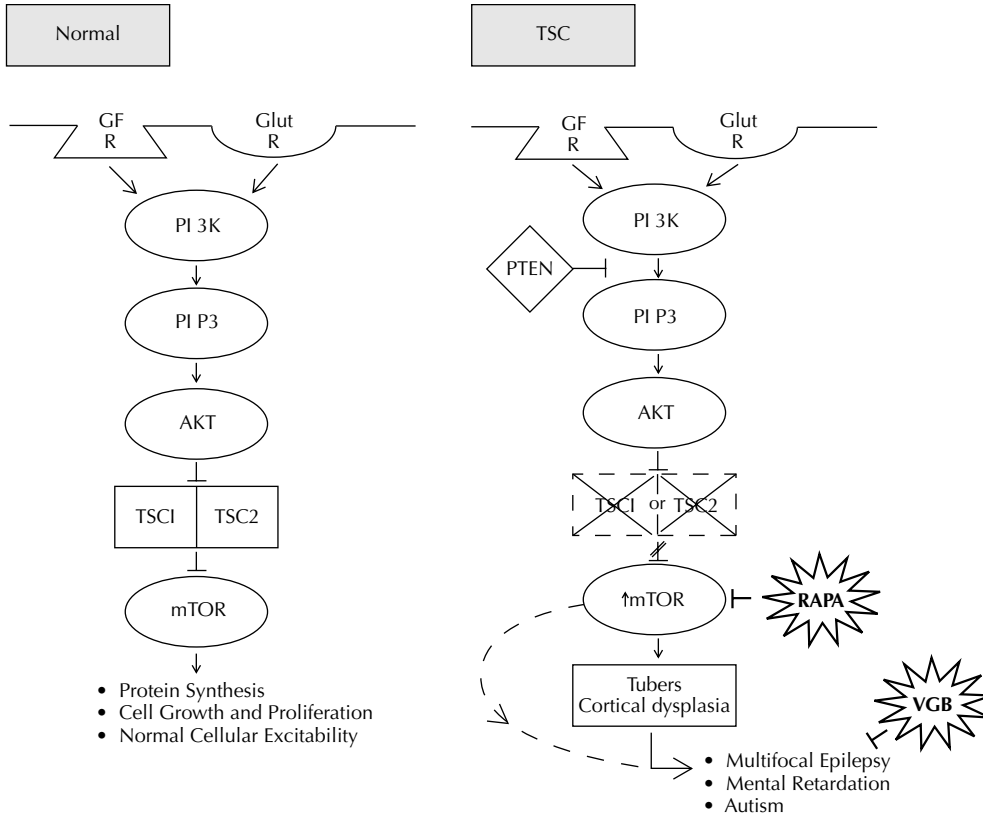

Figure 71–3. Simpified signaling pathway in TSC with possible functional consequences that could lead to increased seizure susceptibility. In the normal situation (left), activation of receptors (R) for growth factors or glutamate leads to an intracellular signaling cascade that limits mTOR activation via the *TSC1* and *TSC2* gene heterodimer. Therefore, protein synthesis is modulated and aberrant cell growth is prevented; likewise, cellular excitability is normal. If *TSC1* or *TSC2* is mutated (right), mTOR is hyperactivated, leading to cellular dysplasia and tuber formation, along with neuronal hyperexcitability, epilepsy, cognitive/behavioral deficits, and autistic symptomatology. It is also possible that epilepsy and ASD can occur independently of dysplasia tubers (dashed arrow). This pathological signaling pathway can be modulated at several points by agents that inhibit mTOR (RAPA) or suppress seizures (VGB). GF, growth factors; Glut, glutamate; R, receptor; PI3K, class I phosphatidylinositol 3-kinase; PIP3, phosphoinositol 3,4,5-triphosphate; AKT, activated tyrosine kinase; TSC, tuberous sclerosis complex; mTOR, mammalian target of rapamycin; PTEN, phosphatase and tensin homolog on chromosome 10; RAPA, rapamycin; VGB, vigabatrin.

it is presently unclear how mTOR dysregulation leads directly to epilepsy or autism susceptibility.

Animal models of TSC afford the opportunity to study pathophysiological consequences of *TSC1* and *TSC2* mutations. The Eker rat is a spontaneous germline mutation in which one *TSC2* allele is inactivated. Eker rats demonstrate defective long-term potentiation (LTP), a form of synaptic plasticity involved in learning and memory; LTP is even more abnormal after seizures in Eker rats.[104,105] Other models have been created by knocking out *TSC1* or *TSC2* in neurons or glia, allowing investigation of the structural, epileptic, and cognitive effects. *TSC2* knockouts have upregulation of the mTOR pathway and abnormal learning and memory.[106] Conditional *TSC1* knockouts have abnormal hippocampal-dependent learning and memory as well as social behaviors, mimicking key autistic features; they demonstrate abnormal cellular architecture and progressive epilepsy as well.[107] Using such models, a variety of pathophysiological findings have been found, including altered glutamate transporters, potassium channels, and gap junctions, all of which are consistent with enhanced excitability (and seizure activity).[108,109] Other factors that alter the excitation/inhibition balance in the TSC brain have also been documented in

favor of excessive excitation, including specific abnormalities of glutamate receptors.[110]

Treatment Implications

Targets for therapeutic intervention in TSC include several components of the mTOR signaling cascade (Fig. 71–3). There is considerable excitement about rapamycin, an inhibitor of mTOR that is already in clinical use as an immunosuppressant, which ameliorates the epileptic and cognitive consequences of TSC.[111] In *TSC1* knockout mice, rapamycin prevents neuronal hypertrophy.[112] Early treatment of *TSC1* knockout mice with rapamycin prevents epileptogenesis, and seizures return if rapamycin is discontinued.[106,113] A case report of a clinical trial with rapamycin in a 10-year-old girl with TSC claims marked seizure reduction without adverse side effects.[114] Obviously, this finding must be expanded in case series. Rapamycin may have utility in acquired epilepsy as well. In a model of temporal lobe epilepsy in mice induced by kainic acid, rapamycin blocked both acute and chronic phases of seizure-induced mTOR activation. It also prevented seizure-induced cell death and reduced subsequent epileptogenesis.[115]

Another strategy in TSC is to suppress seizures with an anticonvulsant drug. Vigabatrin inhibits GABA reuptake into the presynaptic terminal, thus prolonging the availability of GABA to mediate inhibition at its postsynaptic receptors. This agent is particularly useful for treatment of IS in TSC patients, lessening the subsequent risk for epilepsy and autistic/cognitive deficiencies.[116,117] In fact, vigabatrin appears to be uniquely effective for IS in TSC, suggesting that there is some specificity of the drug for the pathophysiological mechanism.

CONCLUSION: IS THERE A CONVERGENT PATHWAY BETWEEN AUTISM AND EPILEPSY?

Returning to the question that opens this chapter, why is epilepsy so common in children with ASD? The heterogeneous etiologies of ASD and epilepsy make it unlikely that a single common mechanism explains seizure predisposition in both disorders, and recent genetic studies point to numerous diverse gene mutations that have autism and epilepsy as joint sequelae.[20] Yet, hints about the pathogenesis of at least some forms of ASD are emerging. First, the majority of mutations focus on the synapse.[17,19] This association is not surprising, as neuronal excitability is governed by the function and dysfunction of synaptic elements such as receptors and their subtypes; neurotransmitters and their synthesis, metabolism, and vesicular release; developmental regulation of cell adhesion; and the ratio of excitation to inhibition as a result of the above factors. Alterations in synaptic plasticity could underlie autistic and cognitive symptoms, especially if selected circuits are involved.

Second, as discussed here, dysfunction in subcellular signaling pathways of diverse conditions (e.g., FXS, TSC) may in fact have common convergence points contributing to pathophysiology, as exemplified by mTOR dysregulation. In dendrites, mTOR is activated by stimulation of mGluR. The reported involvement of the mTOR pathway in FXS emphasizes a potential commonality between FXS and TSC, with a pathophysiological link to abnormal cellular signaling that could lead to ASD. In *Fmr1* knockout mice, the mTOR pathway is upregulated, providing a functional link between mGluR overactivation and abnormal synaptic plasticity.[118] Additional evidence for the mTOR pathway in autism and epilepsy comes from mutations in the tumor suppressor gene *PTEN* (phosphatase and tensin homolog on chromosome 10), which is involved in upstream regulation of mTOR by inhibiting the interaction of phosphatidylinositol 3-kinase (PI3K) and phosphoinositol 3,4,5-triphosphate (PIP3; Fig. 71–3). Conditional knockout of *Pten* in mice results in an increase in mTOR activation and clinical manifestations that include spontaneous seizures and ASD-like symptoms of anxiety and deficiencies in social interaction.[119] Rapamycin treatment rescues all of these neurological deficits.[120]

Third, thinking beyond the synapse to neuronal function on a network scale, both epilepsy and autism involve abnormal synchrony of widespread systems of the brain.[121] Alterations in functional connectivity between brain structures critical for language and social development are also pivotal in the synchronization that occurs in many epilepsy syndromes.[122] Information about the functional pathology

of such systems is just emerging. Unexpected mechanisms may evolve from genetic studies, involving proteins not expected to participate in the control of cognition or cellular excitability. Such molecules are already being linked to ASD and represent additional sites of intervention that give hope for the future.

Chapter 72

Cognitive and Behavioral Comorbidities of Epilepsy

Jonathan K. Kleen
Rod C. Scott
Pierre-Pascal Lenck-Santini
Gregory L. Holmes

Among the comorbidities associated with epilepsy, cognitive and behavioral abnormalities are the most common and severe.[1,2] Mental retardation, learning disabilities, memory impairment, attention deficit hyperactivity disorder, autism, anxiety, and conduct disorders are greatly overrepresented in individuals with epilepsy,[2,3] and the consequences of such comorbidities greatly diminish the patients' quality of life. Indeed, many people with epilepsy, and their families, consider the cognitive and behavioral consequences of seizures to be at least as troubling as the seizures themselves. Cognitive disorders can be found in a wide range of seizure disorders including temporal and frontal lobe epilepsies, primarily generalized idiopathic epilepsies, and epileptic encephalopathies. While our understanding of the mechanisms responsible for epilepsy-related cognitive and behavioral problems lags far behind our knowledge of the mechanism of epilepsy, increased attention has recently been directed to investigating these comorbidities.

When considering the pathophysiological mechanisms of the cognitive and behavioral consequences of epilepsy, it is helpful to distinguish between impairments that are permanent and those that are dynamic, that is, progressive or transient. Permanent deficits originate from a large number of etiologies in epilepsy: trauma, hypoxic-ischemic insults, genetic disorders, mesial temporal sclerosis as a result of status epilepticus, and malformations of cortical development. In addition to causing seizures, these disorders may result in cognitive and behavioral disturbances, with the severity of such disturbances related to the severity of the etiology. While the cognitive and behavioral

issues associated with these brain insults may evolve over time due to maturational and aging changes in the brain, they are relatively fixed and remain attributable to the underlying brain disorder. Only if the underlying cause of epilepsy is remedied do the cognitive and behavioral deficits improve. This aspect of cognitive and behavioral impairments in the context of epilepsy is particularly underinvestigated.

The second type of impairment is dynamic in the sense that the deficits are either happening in stages or transiently affecting the patients. These cognitive and behavioral deficits can occur as a result of the seizures themselves, interictal epileptiform abnormalities, or antiepileptic drug therapy. Although the dynamic impairments can be observed in the absence of the permanent ones, they often contribute together in affecting the patient's quality of life. Understanding how these chronic and dynamic changes influence behavior and cognitive abilities is instrumental to developing therapeutic interventions.

In this chapter, the mechanisms of both permanent and dynamic impairments in cognition and behavior associated with epilepsy will be reviewed. As will be discussed, there is now considerable evidence that the final common pathway for the cognitive and behavioral disturbances is likely through epilepsy-induced altered neuronal signaling resulting in malfunctioning network activity.

MECHANISMS OF PERMANENT DEFICITS IN COGNITION AND BEHAVIOR

It is commonly accepted that the major factor determining the cognitive and behavioral outcomes in epilepsy is the underlying etiology. The cause of the epilepsy determines, to a great degree, the nature and severity of the behavioral and cognitive outcomes. Because these outcomes affect the balance between excitability and inhibition, it can be argued that they also affect the neural function necessary for cognitive processes.

Permanent Cognitive Deficits

Permanent deficits in cognition can be secondary to innate and acquired neurological disorders. Innate causes of epilepsies can be genetic, congenital, or developmental. The epileptic syndromes that they cause often result in severe cognitive impairments. For instance, the channelopathies are a group of genetic disorders caused by disturbed function of ion channel subunits or the proteins that regulate them. The end result of the channelopathies is altered excitability. These disorders include diseases such as Dravet syndrome (Na^{2+} channels), benign familial neonatal convulsions (K^{+} channels), and autosomal dominant nocturnal frontal lobe epilepsy (nicotinic acetylcholine channels). Genetic and congenital diseases induce malformations of brain tissue such as focal cortical dysplasia, tuberous sclerosis, and arteriovenous malformations. Finally, autoimmune factors, such as those involved in Rasmussen's encephalitis, can cause seizures. The cognitive decline witnessed in the first several years following the diagnosis of some of these conditions likely relates to the progressive alterations in neural activity during the developmental period.

Acquired epilepsy etiologies also result in chronic cognitive and behavioral deficits. An example of an acquired insult is status epilepticus (SE), which has been well studied through the use of animal models, producing a chronic condition that reproduces many aspects of the clinical syndrome of temporal lobe epilepsy. Other commonly acquired conditions resulting in epilepsy include head trauma, inflammatory disorders, cerebrovascular insults, and hypoxia-ischemia. In this section, we will use SE as the model for elucidating mechanisms of impaired cognition and behavior.

When studied weeks or months following SE, rats are found to be impaired in spatial memory tasks such as the Morris water maze[4,5] and the radial arm maze.[6,7] The spatial deficits become apparent shortly after SE develops, before spontaneous seizures occur.[8] Deficits in spatial cognition following SE appear to be age dependent. Following SE, very young rats (<2 weeks of age) usually do not show impairments in the water maze task,[9] whereas pubescent and older rats show patterns in this task similar to those of adult rats subjected to SE.

Paralleling this development of cognitive impairment, a number of morphological and physiological changes occur in brain networks as a result of SE. In the adult, neuronal loss becomes apparent in hippocampal fields CA1, CA3, and the dentate hilus,[10,11] with the pattern

of cell loss dependent upon the agent used to induce the initial SE.[12,13] In addition to cell death, prolonged seizures in the adult brain lead to synaptic reorganization, with aberrant growth (sprouting) of granule cell axons (the so-called *mossy fibers*) in the supragranular zone of the fascia and infrapyramidale region of CA3.[14,15] Sprouting and new synapse formation occur in other brain regions as well—notably in the CA1 pyramidal neurons, where it has been shown that newly formed synapses produce more frequent glutamatergic spontaneous synaptic currents.[16] In rat pups, SE produces no cell loss or sprouting in the hippocampus. However, neonatal SE does result in long-standing changes in long-term potentiation (LTP) and depression (LTD),[17] alterations in the subunit configuration of glutamate[17] and gamma-aminobutyric acid (GABA) receptors,[18] and increases in the primary subsynaptic scaffold, PSD-95.[17]

Morphological and physiological alterations following SE are not limited to the hippocampus. The entorhinal cortex, another area deeply involved in cognitive processing, shows a layer-specific loss of neurons and development of aberrant recurrent circuits. Like the hippocampus, the entorhinal cortex shows altered activity after SE as well.[19,20]

In addition to contributing to sporadic generation of seizures, these and other lasting changes in neural circuitry are likely to directly influence the ability of the affected structure to process information normally. For instance, the loss of interneurons during SE[21,22] leads to a loss of inhibition that is not only critical for seizure prevention, but also fundamental for synaptic integration, oscillatory activity, and information processing in general. The relationship between SE-induced network reorganization and cognitive dysfunction is probably best illustrated by single-unit recordings in freely moving rats.

A subset of neurons in the hippocampus called *place cells* elicit action potentials in frequencies that correspond to the animal's location within its environment. Specifically, these hippocampal pyramidal neurons selectively discharge when the animal enters certain locations of the environment, called the cells' *firing fields* (Fig. 72–1). Field location, size, and shape are specific to each cell and each environment, and fields tend to cover the surface of the environment homogeneously when a large number of neurons are being recorded simultaneously. For a given environment, in normal rats, place cell firing patterns remain unchanged, even between exposures separated by months.[23–27]. Since there is a relationship between place cell activity and the ongoing spatial behavior of rats,[28,29] it is believed that such signals provide the animal with a spatial representation in order to navigate efficiently within the environment. These cells provide a very useful surrogate for spatial memory. Adult rats that have experienced SE and have impaired learning in the water maze task have defective place cells.[4,5] Place cells from SE rats have less precise firing fields and less stable firing fields from session to session[4] (Fig. 72–1).

One of the potential mechanisms by which post-SE changes may affectthe cognition and behavior is through alterations of brain oscillations. Seizure-induced changes at the molecular and structural levels, notably through loss of interneurons, are extremely likely to affect the fine tuning of rhythmic activity of large groups of cooperating neurons, as measured by local field potentials. Oscillations in brain structures provide temporal windows that allow local computations, binding cooperating neuronal assemblies for the representation, processing, storage, and retrieval of information. The theta rhythm (4–12 Hz) is critically involved in mnemonic function of the hippocampus.[30,31] Information arriving in the hippocampus during theta oscillations is processed, whereas information arriving in the absence of normal theta activity is believed not to be encoded, or not encoded with the same degree of precision as when theta activity is present.[31–33] Additionally, the phase of theta activity is critical in learning and memory. Tetanic stimulation in CA1 produces LTP when administered at the peak of theta activity and LTD when delivered at the trough.[34] Similarly, gamma oscillations (30–100 Hz) are critical in the processing or perceiving of sensory information,[35,36] consciousness,[37,38] storage of immediate memories,[39–41] and memory recall.[42] Recent work has provided evidence that epileptic rats have alterations in hippocampal theta rhythm magnitude,[8] providing insights into the mechanisms of spatial cognitive defects following SE.

In the hippocampus, pyramidal place cells are characterized not only by their location-specific firing, but also by their precise temporal firing relationship with hippocampal theta oscillations.[5,41,43–45] When the firing field is entered by the rat, place cells will fire

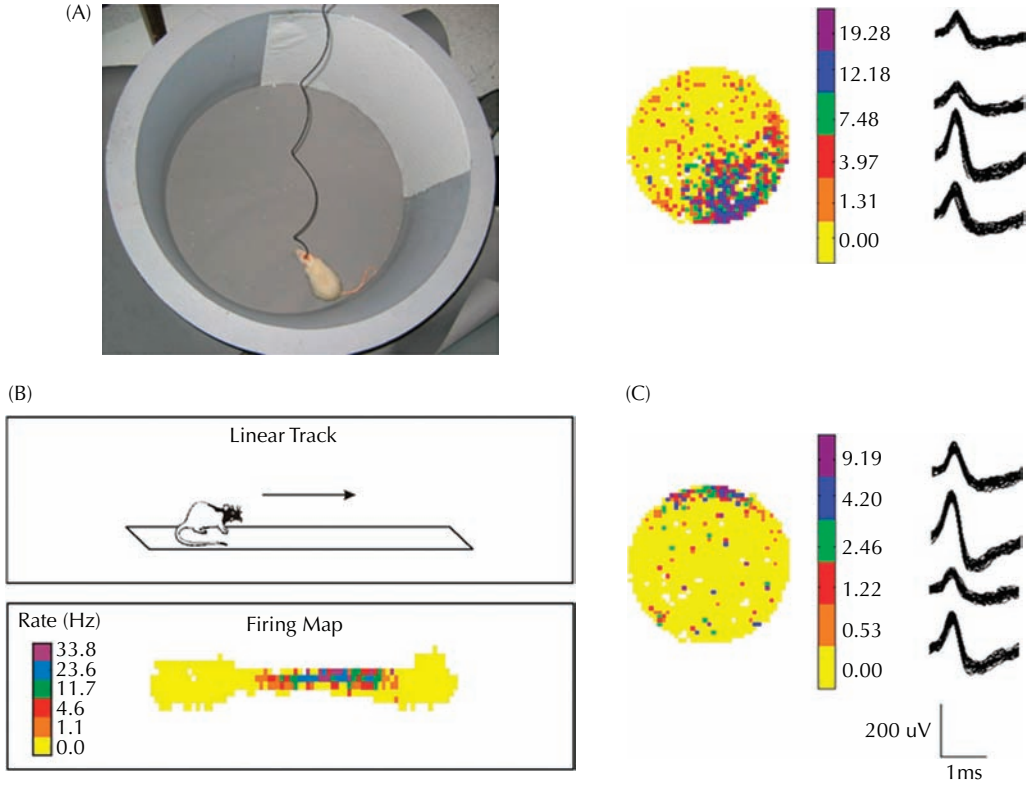

Figure 72–1. Place cell recordings. **A.** Rat in a recording cylinder. The white cue card is placed on the wall of the cylinder to provide orientation for the rat. The environment remains stable from trial to trial. The rat runs about the cylinder chasing food pellets. **B.** Rat on a linear track. The rat runs from one end to the other to obtain a food award. The firing field of a place cell is shown below the track. **C.** Place cells from a rat running in a cylinder. The firing field for the place cell in the upper figure is at around 0500–0600, while the firing field in the lower figure is at 1200. The firing rate was coded in the sequence: yellow, orange, red, green, blue, and purple, from lowest firing rate to highest. The firing rate was zero for yellow pixels. To the right of the firing fields are the complex action potentials recorded using tetrodes. Note the different amplitude of the same action potential in each electrode.

preferentially on the negative phase of the CA1 recorded theta cycle (Fig. 72–2). As the rat crosses the field, the cells fire earlier on successive theta peaks, a phenomenon called *phase precession*.[46,47] Because of this characteristic, two cells with partially overlapping fields will fire at a specific but different phase of the ongoing theta cycle. Their relative firing interval will be constant and directly related to the distance separating their fields. As a result, the sequence of events experienced by the animal, as well as its timing (the rat crossed field A x milliseconds before field B), is encoded: the time difference between A and B is observed on a large time scale (the time it takes to get from field A to field B) and also on the order of tens of milliseconds. The firing sequences of cell assemblies observed in the running time are compressed in a time window short enough to induce LTP-like synaptic changes.[48,49] Using these measurements, a time compression index can be defined, for all possible pairs of cells, as the ratio of two spike-timing measures: (1) the time necessary for the animal to go from one field to the other and (2) the time lag between the spikes of the two corresponding place cells within one theta cycle.[50] Rats subjected to SE have aberrant phase precession and impaired time compression of firing among pairs of neurons,[5] indicating that SE results in impaired temporal coding of information (Fig. 72–3).

Small errors in the timing of neuronal and oscillatory activity can amplify across complex networks and perhaps can even be magnified when synthesized with corresponding cerebral cortical activity.[51] It is likely that such errors are

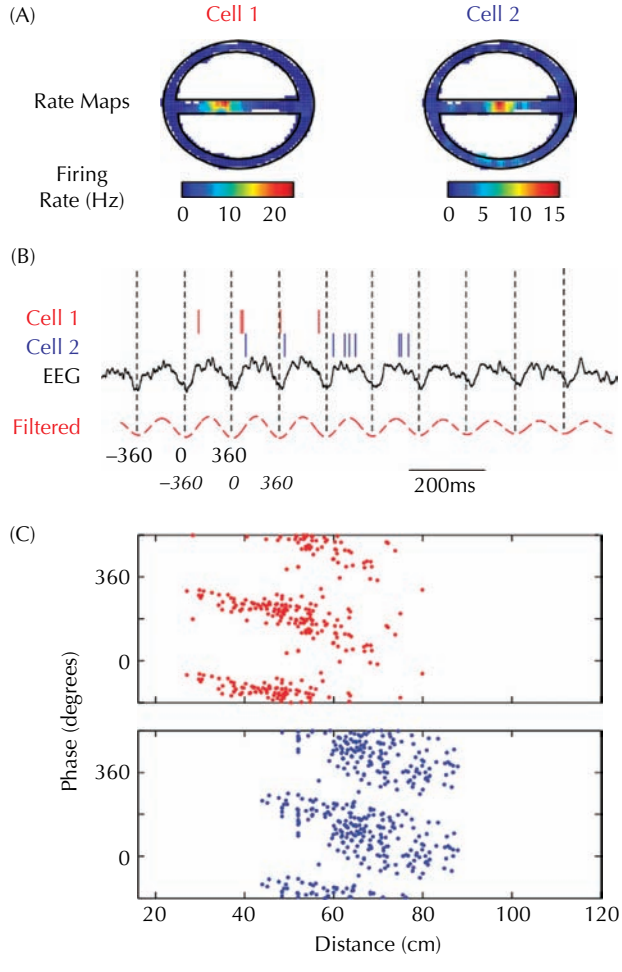

Figure 72–2. Place cell firing and its relationship with the EEG. **A.** Firing rate maps of two cells recorded simultaneously in a rat engaged in a spatial task in a figure 8 maze. Firing activity of the same cells (each vertical bar corresponds to an action potential [AP]) and a simultaneously recorded EEG (black: wideband; red: filtered in the theta band) during a single crossing of the central arm (from left to right). For each cell, as the rat crosses the field, the timing of APs within subsequent theta cycles shifts forward (phase precession). Because the rat enters the field of cell 1 before the field of cell 2, both cells will fire at a different phase on each theta cycle. Within each theta cycle, there is a linear relationship between the time difference of the action potentials of each cell and the distance separating the two fields. Therefore, the cell activation sequence is compressed in a single theta cycle. **B.** Phase/distance plots for the cells represented above. **C.** Each dot corresponds to an action potential. To allow a representation of each cell in relationship to theta activity, each action potential is displayed twice over 360 degrees.

both prominent and perpetual in the chronic epilepsies, and perhaps are even more detrimental in developing animals, in which oscillations drive circuit formation and stabilization.

Permanent Behavioral Deficits

In addition to cognitive abnormalities, chronic epilepsy can produce perpetual behavior problems in both children and adults. Following SE, adult animals become irritable and aggressive on the handling test,[9,52] hyperactive,[9] and anxious.[53] In addition, SE results in impaired socialization; while the animals are more aggressive, irritable, and difficult to handle by experimenters, they display increased passivity toward *an intruder animal* in the home cage intruder test.[7,54] The mechanisms responsible for behavioral changes following SE have not

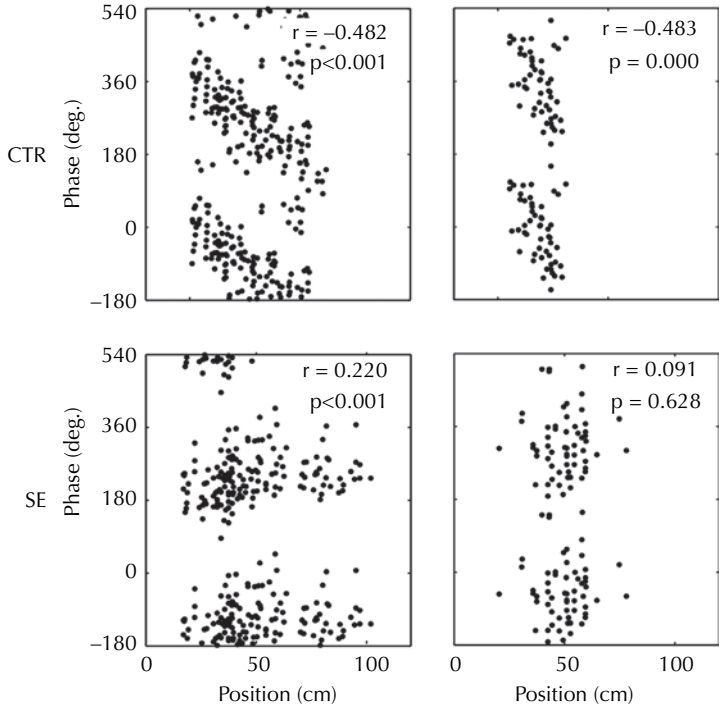

Figure 72–3. Aberrant phase precession in a rat model of epilepsy. Compared to control (CTR) animals, rats with a past history of SE have aberrant phase precession patterns.

been established. However, it is known that SE results in cell loss and synaptic reorganization throughout the behavior-related areas of the brain including the prefrontal cortex, hippocampus, amygdala, and thalamus. While not yet characterized, aberrant signaling changes in these networks likely contribute to these behavioral abnormalities.

MECHANISMS OF DYANAMIC DEFICTS IN COGNITION AND BEHAVIOR

As opposed to permanent deficits in cognition and behavior that are usually attributed to the etiology of the epilepsy, dynamic deficits can also occur. These transient impairments are believed to be caused by the temporary disruption of neural activity patterns. In general, these dynamic cognitive impairments are associated with seizures, epileptiform abnormalities, and the medication used to treat the seizures. While only seizures and interictal epileptiform activity will be discussed here, antiepileptic drug-associated neurobehavioral adverse effects also occur and have been previously reviewed.[55]

Dynamic Deficits Secondary to Seizures

Spontaneous recurrent seizures, a key feature of epilepsy, seriously affect the patient's cognitive ability. In addition to the obvious inabilities during seizures, the postictal state usually corresponds to a period of drastically decreased cognitive ability. After the behavioral symptoms of lethargy and inattention subside, lingering cognitive deficits may persist for minutes to days, depending on the type and severity of the seizure.[56–58]

As an illustration, Lin et al.[59] trained adult rats extensively in the spatial accuracy task, a dry-land analog of the Morris water maze. The authors found a cumulative degradation in spatial performance over 11 days of flurothyl-produced seizures (one per day). However,

the deficits reversed after the seizures were stopped, such that performance returned to baseline. Intriguingly, the rate of learning to an asymptote, the rate of performance decline during one-per-day seizures, and the rate of relearning during the recovery period were all similar. These findings suggest that deficits following a small number of seizures are reversible after a period of time, likely paralleling the return to neurological homeostasis. Similarly, Boukhezra et al.[60] found that generalized seizures following asymptote levels of learning in the Morris water maze task resulted in impaired performance, with the duration of the cognitive deficits exceeding the length of the seizures. Interestingly, the animal's neurological status was a factor in the duration of cognitive impairment following seizures; animals with a prior history of SE had a longer period of impairment following a seizure than animals without such a history.

Zhou et al.[61] assessed the effects of 10 flurothyl-induced seizures in adult rats on LTP and place cell function. Recurrent flurothyl seizures were associated with marked impairment in LTP and a reduction in the frequency of the peak theta power. Compared to baseline recordings, place cell firing patterns following recurrent seizures were significantly less precise, had lower firing rates, and were less stable. Impaired place cell firing was seen as early as after two seizures. Paralleling place cell firing patterns, water maze performance was impaired in animals that underwent a series of seizures. These results demonstrated that significant and long-standing alterations in hippocampal homeostasis occur with relatively brief excitatory events, although the duration of these postictal effects was not measured.

The most commonly provided explanation for the postictal phenomenon is that the prolonged, synchronous neural activity during seizures depletes neurotransmitters and available glucose, which understandably could prevent normal information processing.[62–64]. However, spontaneous seizures are followed by a drastic alteration of place cell firing.[65] After seizures, a marked decrease in the firing rate of action potentials from place cells occurs, whereas interneuron firing is unchanged. In addition, when place cell firing fields persisted or returned, they were aberrant, with reduced coherence and information content. In addition to postictal suppression of firing patterns, seizures lead to the emergence of firing fields in previously silent cells, demonstrating a postictal remapping of the hippocampus. These findings demonstrate that postictal alterations in behavior are not due solely to reduced neuronal firing. Rather, the postictal period is characterized by robust and dynamic changes in cell-firing patterns resulting in the remapping of the hippocampus.

Dynamic Deficits Secondary to Interictal Spikes

In addition to seizures, there is increasing evidence that interictal abnormalities can result in cognitive impairment, though this is much more short-lived than the impairment of the postictal period. Epileptiform abnormalities, including interictal spikes (IIS) or spike-and-wave discharges, represent an aberrant discharge of a large number of neurons near the recording site. These ephemeral events can produce brief disturbances in neural processing, resulting in a phenomenon called *transitory cognitive impairment*.[66] However, they rarely produce overt cognitive or behavioral disturbances.

In a seminal study, Aarts et al.[67] noted that IIS can briefly disrupt neural processes within the brain region where they occur. The authors analyzed the effect of IIS on verbal or nonverbal short-term memory in patients with various epileptic conditions who had no overt clinical manifestations during these discharges, thus targeting the hidden (subclinical) manifestations of IIS. They found that left-hemisphere IIS resulted mainly in verbal task errors, whereas right-hemisphere IIS were associated with errors on the nonverbal task. Electroencephalographic (EEG) discharges interfered mainly when they occurred simultaneously with the presentation of the stimulus, corresponding with the encoding phase of the task. Shewmon and Erwin[68–71] further localized the effect, noting that occipital IIS could disrupt visual perception. A number of ensuing clinical studies demonstrated that IIS in the cortex can result in transitory cognitive impairment.[67–73] One study examined IIS using intracranial electrodes in patients with temporal lobe epilepsy and found transient declines in working memory due to IIS.[74]

To investigate the transient effects of IIS on cognition, Kleen et al.[75] used a within-subject analysis to systematically analyze how IIS might independently affect multiple processes in the hippocampus, a structure critically important for learning and memory and highly prone to IIS in temporal lobe epilepsy. These researchers studied rats that developed chronic IIS following intrahippocampal pilocarpine administration in a hippocampal-dependent operant behavior task, the delayed-match-to-sample. Hippocampal IIS that occurred during memory retrieval strongly impaired performance (Fig. 72–4). However, IIS that occurred during memory encoding or memory maintenance did not affect performance in those trials. Hippocampal IIS also affected response latency, adding approximately 0.48 s to the time taken to respond. Interictal spikes were most harmful if they occurred when hippocampal function was critical, similar to the findings in human studies, showing that cortical spikes are most

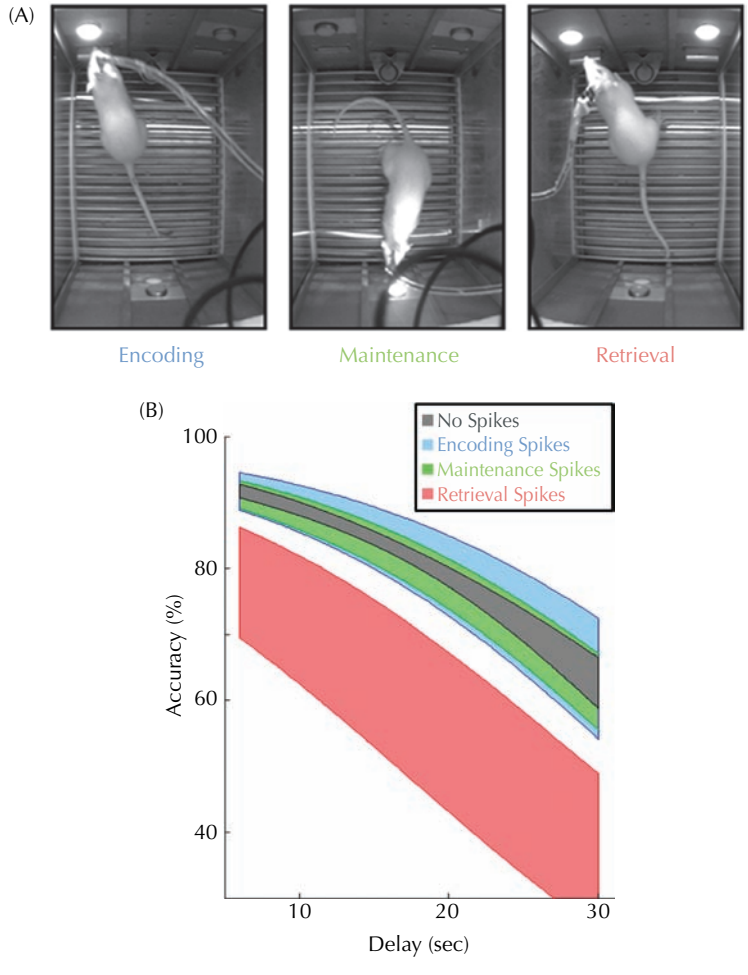

Figure 72–4. Influence of IIS on different memory processes. **A.** Montage of the delayed-match-to-sample task, a useful paradigm for assessing the dynamic influence of IIS on memory. Rats were trained to press a randomly presented lever (e.g., the left lever in this example), then wait for a variable time interval near the opposite wall of the chamber. Subsequently, both levers were presented, and the rat needed to choose the lever it had pressed before. Each trial thereby involved memory encoding, maintenance, and retrieval for accurate performance. **B.** Thousands of trials among five rat trials were separated first by whether an IIS occurred during them and then by the epoch in which the IIS occurred (encoding, maintenance, or retrieval). Accuracy is plotted against the length of the variable interval between lever presses (delay), with longer delays normally producing decreased accuracy. Colored bands of the modeled 95% confidence intervals indicate that IIS during memory retrieval drastically impair memory, while IIS during encoding or maintenance do not.

disruptive during active cortical functioning. It was suggested that the cumulative effects of spikes could therefore impact general cognitive functioning, although this general effect was not seen in this study, supporting the notion that dynamic disruptions in cognition may not be captured by general cognitive testing.

A few studies to date have shed light on the probable cause of IIS-induced transient cognitive disruption. There is a significant and sustained reduction of action potentials in the hippocampus for up to 2 s following a local IIS. Furthermore, when occurring in flurries, IIS can reduce action potential firing for up to 6 s.[76] The response to IIS is cell-dependent; IIS result in decreases in action potential firing after the IIS among interneurons but not among pyramidal (place) cells. In addition to affecting action potentials, the widespread inhibitory wave immediately after IIS can dramatically reduce the power of gamma oscillations and other oscillatory signals in the hippocampus.[77] Since oscillations are intimately linked to ongoing learning and memory functions, this disruption in oscillations likely contributes to cognitive deficits.[75,78]

Transient impairments in cognition are difficult to capture with standard cognitive tests because of several conditions. First, in order to disrupt a particular process, the IIS must incorporate the neural circuits involved in that process, stressing the importance of matching the affected neural substrate with a cognitive test that assesses its intrinsic function. Second, the IIS must occur at a particular moment in cognitive processing when the process is vulnerable to disruption. Third, the process must not be supported significantly by other interconnected structures that might buffer the information and reintroduce it to the affected area once the IIS effects have passed.

Despite these limitations, if the proper cognitive test is utilized and IIS are frequent enough, it is possible to show relations between overall IIS frequency and the degree of cognitive impairment. This accumulation of dynamic effects can thus resemble a chronic cognitive deficit. For example, patients with Landau-Kleffner syndrome gradually develop a high frequency of IIS at a young age, and the degree of their EEG abnormalities is closely related to the auditory agnosia and aphasia most patients eventually experience. These patients may or may not have seizures; thus, the effect seems exclusively related to the EEG abnormalities. Furthermore, improvements in cognition tend to be accompanied by improvements in the EEG.[79]

HOW DYNAMIC DEFICITS MAY BECOME PERMANENT

While a single seizure episode or IIS usually has transient effects on neuronal activity, there are conditions in which their impact may be more detrimental for cognition and behavior. This is the case for recurrent generalized seizures and also for seizures or IIS that occur during critical periods such as sleep or development.

Recurrent Seizures

One of the more popular models for studying recurrent seizures is kindling. Kindling is a dynamic process whereby repeated application of seizure-evoking stimulation produces neuronal changes that result in an enduring enhancement of susceptibility to seizure-evoking stimulation. Since kindling is a gradually acquired process, behavioral tests can be done during the kindling or after the animal has fully kindled. If testing is done during the acquisition of kindling, the investigator can assess behavior before or following the kindling stimulation. If testing occurs after kindling, the investigator can manipulate the time of the testing to determine the duration of any postkindling effect.

Investigators have examined the effect of kindling on spatial memory with the animal being studied after or during kindling using both the radial arm maze and the water maze. The timing of the kindling stimulation determines the type of deficit. If the kindling stimulation is given prior to the learning trial, there is impaired performance,[80–82] whereas kindling immediately after the learning trial impairs retention.[83] Whether kindling has long-term effects on learning is not clear, with some authors finding impairment following hippocampal kindling,[84,85] and others finding no long-standing effects.[81] However, the effects of kindling on spatial memory are not confined solely to electrical kindling. With repetitive

pentylenetetrazole-induced seizures given every other day for 28 days, rats made more reference errors in the radial arm water maze.[86] Genetically epilepsy-prone rats subjected to 66 audiogenic stimulations showed impairment in both the water maze and the T-maze compared to littermates that were handled and placed in the sound chamber but were not stimulated.[87]

The immature brain appears to be particularly prone to developing permanent deficits following early life seizures. Seizures during the first weeks of life result in deficits of spatial cognition in the Morris water maze,[88–93] impairment of auditory discrimination,[94] and altered activity level in the open field.[91] Despite the detrimental effects of early life seizures on cognitive function, recurrent seizures during the first 2 weeks of life do not result in cell loss.[88,90,95] However, early life seizures can result in synaptic reorganization[88,89,96,97] and decreased neurogenesis.[98] Recurrent seizures during development also result in a number of physiological changes including a persistent decrease in GABA currents in the hippocampus[99] and neocortex,[100,101] enhanced excitation in the neocortex,[101] impairment in spike frequency adaptation,[102] marked reductions in afterhyperpolarizing potentials following spike trains,[102] LTP,[91] alterations in theta power,[92] and impaired place cell coherence and stability.[92]

Rats with developmental seizures have also been found to have abnormal hippocampal single-cell firing patterns when studied as adults. Following a series of 100 brief flurothyl-induced seizures during the first weeks of life (P15–P37), rats were found to have impairment in spatial cognition, with poor performance in the water maze and radial arm maze and impaired hippocampal LTP.[92] Similar to rats following SE, these rats had substantial deficits in action potential firing with impaired place cell precision and reduced place cell stability. These results show that recurrent seizures during early development are associated with significant impairment in spatial learning and that these deficits are paralleled by deficits in the hippocampal map.

Recurrent Interictal Spikes

In elegant studies of the striate cortex function in rabbits, IIS were elicited by either penicillin[103,104] or bicuculline[105,106] through focal epidural application. The IIS were elicited for 6–12 h following each drug application, which was given daily from P8–9 up to P24–30. None of the rabbits had behavioral seizures. In single-unit recordings from the lateral geniculate nucleus, superior colliculus, and occipital cortex ipsilateral to the hemisphere with IIS, there was an abnormal distribution of receptive field types, whereas recordings from the contralateral hemisphere were normal. This finding was age-dependent: rabbits with similarly induced IIS during adulthood had normal development of cells, highlighting an additional vulnerability of developmental periods to cumulative IIS effects over time.

Interictal spikes have also been elicited in young rats with flurothyl, an inhaled convulsant.[107] Rat pups were given a low dose of flurothyl for 4 h over 10 days during continuous EEG monitoring. They developed IIS without seizures, while age-matched controls under similar testing conditions showed few IIS. When rats were tested as adults, there was impairment in reference memory in the probe test of the Morris water maze, reference memory impairment in the four-trial radial arm water maze, and impaired LTP. Early-life IIS also resulted in impaired new cell formation and decreased cell counts in the hippocampus, indicating a potential mechanism by which IIS during development can produce cumulative lasting effects in addition to any dynamic disruptions. It appears from these data that IIS, like seizures, during brain development have a cumulative effect on cognitive function.

While not yet fully studied, it is likely that IIS during sleep may contribute to both cognitive and behavioral problems. Sleep is important for memory consolidation, and IIS, when occurring frequently in conditions such as continuous spike-wave sleep, will affect learning and memory.[108] To mimic IIS, Shatskikh et al.[109] implanted a stimulating microelectrode in the ventral hippocampal commissure and a recording microelectrode in the CA1 region of the hippocampus of normal male rats. Spike patterns were induced using a series of electrical pulses to provoke discharges in the hippocampus that resembled naturally occurring IIS in epileptic rats. When the IIS were introduced while the rat was sleeping, performance in the Morris water maze was impaired compared to times when no IIS occurred during sleep. In this study, none of the rats had seizures, indicating

that IIS during sleep have adverse effects in a test of hippocampal memory.

Effect on Behavior

Kindling also affects behavior, with amygdala-kindled animals exhibiting heightened anxiety[110] and enhanced emotionality expressed by elevated anxiety and a defensive attitude toward other animals.[111] Rats kindled in the amygdala and hippocampus explored less in the open field, were more resistant to capture from the open field, and engaged in more open-arm activity in the elevated plus maze,[112,113] classic behavioral signs of increased anxiety in rodent models. Perirhinal cortex kindling also increased anxiety-related behavior in both the elevated plus and open-field mazes and disrupted spontaneous object recognition.[114] Pentylenetetrazol-treated rats have also been shown to have high anxiety levels in the open-field exploratory maze test.[86]

Amygdala kindling also alters social attraction between rats in the open-field test, with kindled rats showing a higher likelihood of remaining in close proximity to a partner rat.[111] Partial kindling of the ventral perforant path in cats produced a lasting increase in the defense response of cats to both rats and conspecific threat howls. In addition, there was a suppression of approach-attack behaviors directed toward rats.[115] Pentylenetetrazol-treated rats also displayed decreased offensive behaviors in the home cage intruder test.[116] Genetically epilepsy-prone rats subjected to repetitive seizures were less active in the open-field activity test, less aggressive in the home cage intruder test, and more irritable and aggressive in the handling test.[87] In a test that mimics depression, the forced swim test, animals receiving repetitive pentylenetetrazole injections were immobile significantly longer than control rats.[86]

CONCLUSIONS

In extrapolating the animal data to individuals with epilepsy, it is helpful to keep in mind that there are two major processes, permanent and dynamic, that can influence cognitive and behavioral outcomes. Permanent deficits are due primarily to the etiology of the epilepsy. Regardless of whether the etiology is innate or acquired, the deficits seen are due to the underlying brain pathology causing the epilepsy. These deficits would occur regardless of the frequency of recurrent seizures. Treating the underlying condition, if possible, may improve the cognitive and behavioral outcomes. Dynamic changes are caused by the seizures or interictal discharges. In the case of dynamic causes of cognitive and behavioral disturbances, there is a window of opportunity for the clinician to intervene by reducing the number of seizures or suppressing the interictal discharges. Failure to do so can convert dynamic changes into permanent ones. This is particularly the case when dealing with seizures and interictal discharges in the developing brain. The challenge for neuroscientists will be to develop safe and effective mechanistically driven therapies to reduce or prevent the dynamic effects of seizures and interictal discharges.

Chapter 73

Migraine and Epilepsy—Shared Mechanisms within the Family of Episodic Disorders

Michael A. Rogawski

INTRODUCTION

In 1906, the British neurologist Sir William R. Gowers delivered a clinical lecture at the National Hospital for the Paralysed and Epileptic, Queen Square, London, in which he pointed out the resemblance between migraine and epilepsy.[1] He argued that migraine is a borderland disease to epilepsy: "near it but not of it." Gowers recognized that migraine and epilepsy often occur together in the same patient and that the two conditions are similar in their "character and nature." In recent years, the association between migraine and epilepsy as comorbid conditions has been confirmed. Moreover, migraine and epilepsy are now recognized to be key members of a large family of episodic disorders that also includes periodic paralyses, cardiac arrhythmias, and episodic movement disorders. Studies of the pathophysiological mechanisms underlying the generation of migraine aura and focal seizures indicate remarkable similarities. The identification of genes responsible for both conditions is perhaps the strongest evidence for shared underlying mechanisms.

Fred Andermann, in the introduction to the book *Migraine and Epilepsy*, published in 1987, proposed the following possible explanations for the comorbidity between migraine and epilepsy: (1) both are common and therefore will co-occur by chance, (2) they are

causally related, with one leading to the other, and (3) there is a shared pathophysiological or genetic basis.[2] In this chapter, I examine the evidence for and against these alternatives, focusing on recent advances in physiology and genetics that support Andermann's third possibility.

COMORBIDITY OF EPILEPSY AND MIGRAINE

Migraine and epilepsy are both common neurological disorders, although migraine is more frequent. Numerous studies have observed an association between the two disorders. Most studies of comorbidity have examined the incidence of migraine in cohorts of subjects with epilepsy. The prevalence of migraine in populations of individuals with epilepsy is estimated at 8%–24%,[3] so that the risk of migraine is approximately twice that in the normal population.[4,5] Recently, the incidence of epilepsy was examined in a large series of children with headache.[3] In this study, children with migraine had a 3.2-fold increased risk of epilepsy compared with those with tension-type headache. Although prior studies have found an association only with migraine with aura,[6] this more recent study observed an increased incidence of epilepsy in subjects with migraine both with aura and without aura. In the majority of cases, epilepsy preceded migraine with aura. Overall, the prevalence of epilepsy in individuals with migraine has been reported to be in the range of 1%–17%, with a median of 5.9%, which is higher than the population prevalence of about 0.5%–1%. There is a small increase in the risk of migraine in those with partial onset seizures compared with generalized onset seizures (relative risk, 1.3).[7] Migraine is particularly frequent in those with epilepsy caused by head trauma, where the relative risk compared with idiopathic or cryptogenic epilepsy is 1.8. The strong association between posttraumatic epilepsy and migraine is believed to occur because head injury is a risk for both conditions.[8]

Apart from the observation that head trauma may lead to both epilepsy and migraine, there are several possible explanations for the general comorbidity between the two conditions. Migraine attacks could be epileptogenic and over time could lead to the development of epilepsy; alternatively, recurrent seizures could lead to the development of migraine. Epidemiological data indicate that these explanations are unlikely.[7,8] If migraine caused epilepsy, for example by inducing brain injury, the incidence of an epilepsy diagnosis should be increased in individuals with preexisting migraine. The epidemiological results demonstrate that there is an excess risk of epilepsy both before and after the onset of migraine, leading to the rejection of the unidirectional causality hypothesis. A similar argument suggests that epilepsy does not lead to the development of migraine.

Do Migraine Attacks Trigger Seizures?

The association between migraine and epilepsy could arise not because migraine attacks are epileptogenic (i.e., cause a permanent change in the brain to an epileptic state), but because migraine attacks may simply trigger seizures. Indeed, in 1960, William G. Lennox and his daughter Margaret A. Lennox, in their book *Epilepsy and Related Disorders*, recognized a condition they termed *migralepsy*, in which "ophthalmic migraine with perhaps nausea and vomiting [is] followed by symptoms characteristic of epilepsy."[9] In recent years, the International Headache Society has included migralepsy in its classification scheme. However, it has been noted that the differentiation of occipital seizures from migraine aura is difficult, leading to the frequent erroneous diagnosis of migralepsy.[10,11] Indeed, a review of the literature suggested that migralepsy is extremely rare.[12] In contrast, occipital seizures are often associated with postictal headache that is often indistinguishable from migraine.[10,13] Therefore, according to Panayiotopoulos,[11] in the majority of cases, occipital epilepsy is the correct diagnosis. An alternative perspective is that there are pathophysiological similarities between migraine and epilepsy that make the sharp distinction between the two disorders artificial. In some cases of occipital epilepsy, migraine mechanisms may come into play, inasmuch as there is an overlapping brain substrate. A particularly extreme example of the concept that shared pathophysiological

mechanisms may underlie migraine and epilepsy in the same patient is familial hemiplegic migraine, discussed in detail below, in which migraine attacks and seizures can occur together.[14] In some instances in familial hemiplegic migraine, true migralepsy occurs in which migraine does trigger a seizure. Also, it should be noted that seizures may be caused by migrainous cerebral infarction or possibly also in basilar artery migraine, although the latter has been disputed.[15]

While triggering of a seizure by migraine is unusual, headache is often associated with seizures. Preictal and ictal headaches occur rarely, but postictal headache is common and may have migraine-like features.[7] Not only does migraine-like postictal headache occur following occipital seizures, it also occurs following generalized tonic-clonic seizures[16] and can also occur following temporal lobe seizures, however, it is less likely following frontal lobe seizures or simple partial seizures.[13] Case reports indicate that postictal headache can respond to sumatriptan.[17] Therefore, it has been proposed that seizures can in some instances trigger trigeminovascular pain mechanisms, as occurs in migraine.

A Hypothesis for Comorbidity

Acknowledging that seizures often trigger headache, which may have migraine-like features, there remains an increased risk of migraine attacks, unassociated with seizures, in persons with epilepsy and vice versa. Given that there is little evidence to support the unilateral causality concept, it might be concluded that shared genetic risk factors are the underlying explanation for the comorbidity. This simple explanation was not supported in the epidemiological study of Ottman and Lipton.[8] Indeed, their result might have been expected from the observation noted above that head trauma is a risk factor for both epilepsy and migraine. Ottman and Lipton therefore discarded the simple genetic risk hypothesis and instead proposed that a state of brain hyperexcitability, which can either be produced by genetic factors or can be acquired (such as in a head injury), increases the risk of both migraine and epilepsy, thus leading to the comorbid association. As discussed below, this concept is supported by a wide range of physiological evidence.

EPISODIC NEUROLOGICAL DISORDERS

Although epilepsy and migraine have distinct clinical manifestations, an important similarity is that they are both episodic disorders in which patients are affected with symptoms sporadically and the interictal interval between the appearance of symptoms is variable; between attacks, affected individuals may be symptom free. Episodic disorders comprise a large group of clinically important conditions that affect excitable tissues in various organs and have diverse outward manifestations that depend upon the organ affected, such as seizures, headache, cardiac arrhythmias, episodic movements, and periodic paralysis.[5] A hallmark of episodic disorders is that they often are due to defects in ion channels or, more generally, ion-translocating transmembrane proteins including Na^+,K^+-ATPase.[18] Paradigmatic of the episodic channelopathies are conditions affecting skeletal muscle that lead to transitory weakness or paralysis, including the periodic paralyses and myotonias. Other well-recognized episodic disorders are the various forms of the long QT syndrome that can cause ventricular tachyarrhythmias and sudden death. In addition to affecting skeletal and cardiac muscles, episodic channelopathies affect the brain. Ryan and Ptáček[18] have defined three broad categories of such episodic disorders: paroxysmal movement disorders (episodic ataxias and paroxysmal dyskinesias), epilepsies, and headache disorders. As episodic disorders, epilepsy and migraine share certain characteristics and a presumption that the underlying pathohysiology relates to alterations in ion channels or ion transporters.

FEATURES THAT CHARACTERIZE EPISODIC DISORDERS

Episodic channelopathies exhibit similar clinical features. The hallmark of all episodic disorders is their paroxysmal nature. A trigger factor of some kind causes the system to assume an

aberrant state that is expressed as an aberrant phenotype. An individual with the disease has a reduced barrier to entry into the aberrant state. In episodic disorders, alterations in the structure of ion channels (more generally, ion transport proteins) decrease the safety margins so that a normally innocuous stressor overcomes homeostatic mechanisms that prevent entry into a pathological state, such as a seizure or migraine attack.[18] This concept implies that unaffected individuals (i.e., individuals who do not enter the aberrant state in the normal course of their daily lives) may enter the aberrant state with sufficient provocation. This is certainly the case for epilepsy and possibly also for migraine. Seizures can be provoked in nonepileptic individuals by head trauma, chemical convulsant agents, electrical stimulation (as in electroconvulsive therapy), or metabolic derangements. Headache can also be provoked by certain chemical agents. For example, glyceryl trinitrate (nitroglycerin) has been known from the time of its discovery to produce intense headache.[19] In addition to the immediate headache that occurs in all individuals, in migraine sufferers glyceryl trinitrate can trigger a delayed headache of greater intensity and with a greater number of migraine-like features than occurs in nonmigrainurs.[20,21] Usually, this is without an aura even in migraineurs who experience an aura, although migraine with a visual aura can be triggered in some cases.[22] Histamine infusion can produce similar effects.[23] Secondary migraine headache can also be triggered in nonmigraineurs by many factors, such as intense physical exercise, head injury, hypoglycemia, chronic renal failure, dialysis, and sickle cell disease.[24]

In addition to being members of the family of episodic disorders and often existing together in the same individual, epilepsy and migraine have other similarities. Seizures and migraine attacks may evolve in four comparable stages, with prodromal symptoms, an aura, an ictus (seizure or headache), and a postdromal or postictal phase. Occasionally, the attacks fail to stop, resulting in status epilepticus or status migrainosus. Although there may be a greater diversity of trigger factors for migraine than for epilepsy, there are a surprisingly large number of similar triggers, such as stress (or letdown from stress), factors related to sleep, photic stimulation, hormonal changes such as those occurring during menstruation, and alcohol or dietary factors. How these factors bring on a migraine attack or epileptic seizures is not well understood. However, there is evidence for enhanced cortical responsiveness to diverse stimuli in migraine as well as in epilepsy, as discussed later in this chapter.

ANTIEPILEPTIC DRUGS IN MIGRAINE

A further similarity between migraine and epilepsy that strongly supports the notion that there are shared underlying mechanisms is that some antiepileptic drugs (AEDs) are useful in both conditions. There is extensive evidence from randomized controlled clinical trials that divalproex sodium (valproate) and topiramate are effective in preventing migraine attacks, and both drugs are approved by the U.S. Food and Drug Administration for this indication.[25] The gabapentinoids gabapentin and pregabalin may also be effective in migraine therapy.[26,27] Other AEDs that have been reported to be useful in migraine prophylaxis are levetiracetam and zonisamide.[28–30] Interestingly, while the limited clinical trial data available do not indicate that lamotrigine reduces the frequency of migraine attacks overall, there is evidence that it may reduce the frequency, duration, and intensity of the migraine aura; in many patients who responded with a reduction in aura, there was a reduction in headache frequency.[31] An effect on aura was also found for the investigational AED tonabersat, which produced a reduction in the number of aura attacks (either isolated aura or aura followed by headache) but not a reduction in the number of migraine headache days.[32] The AEDs reduce neuronal hyperexcitability by various mechanisms.[33] Consequently, these results are consistent with the concept that hyperexcitability is responsible for triggering the aura and the subsequent headache. However, they raise the question of whether, in migraine without aura, different trigger mechanisms may be at play. Some AEDs, including phenytoin, oxcarbazepine, vigabatrin, and clonazepam, are not effective in migraine prophylaxis. Thus, AEDs that primarily act via use-dependent block of voltage-gated sodium channels or that act via GABAergic mechanisms appear to influence

hyperexcitability mechanisms that are not relevant to migraine (perhaps related to the spread of hypersynchronous activity). In any case, it is noteworthy that in both epilepsy and migraine, a proportion of patients are pharmacoresistant (around 30% in both conditions).

CORTICAL SPREADING DEPRESSION

When speaking about migraine in his 1906 lecture on the borderland of epilepsy, Gowers noted, "a peculiar spreading disturbance of the nerve structures is evident."[1] He remarked on the similarity with the Jacksonian march in epilepsy but recognized the different time course in that "The epileptic aura occupies a few seconds," whereas "the premonition of migraine is almost always many minutes, often twenty, in its deliberate course." Gowers' description of the slow spread of the migraine aura is remarkable in that it foreshadows the current view that cortical spreading depression (CSD), a propagating wave of cellular depolarization, is the basis for the aura in migraine and the trigger for the subsequent headache pain.

The phenomenon of CSD was first described by Aristides Leão, who was attempting to develop a model of "experimental epilepsy" by electrically stimulating the cortical surface of the rabbit.[34] Instead, he found that weak electrical (and later mechanical) stimulation elicited a decrease in the spontaneous activity (depression of the electrocorticogram signal) at the stimulated region that slowly spread in all directions at a rate of 3 to 5 mm/min.[34,35] Recovery of the initial pattern of spontaneous activity occurred over 5 to 10 min. Leão found that epileptiform discharges elicited by electrical stimulation, strychnine, or acetylcholine were suppressed by spreading depression. In addition, he noted that various types of discharges occurred in conjunction with the wave of depression, including electrographic events that resembled tonic-clonic seizure discharges. The spreading depression and the tonic-clonic seizure activity involved the same cortical elements. Moreover, Leão ended his classic 1944 paper with the statement "The depression and 'tonic-clonic' activity of experimental cortical epilepsy seem to be closely related phenomena."[35] Although Leão considered the cortical discharges and the suppression of neuronal activity to be independent, Grafstein's subsequent work demonstrated that the depression is actually preceded by neural activation.[36,37] Recording from small, isolated slabs of cortex in *cerveau isolé* (midbrain-transected) cats, Grafstein was able to confirm Leão's observation that spreading depression is associated with a slow negative direct current (DC) shift and depressed neural activity. However, she observed that there is a brief (2–3 s) burst of action potential activity at the initiation of the DC negativity. More recent studies have confirmed the existence of fast, rhythmic discharges in the front of a CSD wave; the discharges are synchronized over considerable distances in the tissue and occur for several seconds before the negative DC shift.[38] Initially, there are subthreshold field oscillations that give rise to a high-frequency (60–70 Hz) burst of populations spikes.

The mechanisms that underlie the initiation and propagation of CSD are still not fully defined. Neurons become silent during the passage of CSD, and recordings from neuronal somata have revealed that the negative DC shift of CSD is associated with collapse of the membrane potential to zero and a severe loss of membrane input resistance.[39] Although neuronal somata become electrically unresponsive during CSD, recent studies indicate that parts of the dendritic tree maintain electrical excitability.[40] The membrane conductances that participate in CSD are not fully defined.[41] Potassium currents, including transient A-type currents, M-type (Kv7/KCNQ) current, and also, to a lesser extent, delayed rectifier current, certainly become activated by the depolarization, leading to large transitory increases in extracellular potassium to 30–60 mM that closely follow the DC shift.[42,43] Ionotropic glutamate receptor channels have also been proposed to play a role. AMPA receptors rapidly desensitize and therefore do not contribute substantially. NMDA receptors are ordinarily blocked by magnesium at resting potential, but the depolarization of CSD is expected to relieve the block. Based on modeling, Makarova et al.[41] have argued that while NMDA receptors do contribute, their contribution is relatively small, particularly since NMDA receptors are inhibited by elevated extracellular potassium concentrations. These authors have proposed that a large, but as yet unidentified, dendritic

conductance is a major determinant of the cellular depolarization in CSD.

The concept that spreading depression is responsible for migraine aura is based on a comparison between the rates of progression of the two phenomena. Most commonly, migraine aura arises in the primary visual cortex and is associated with visual symptoms. The disturbance usually starts at the center of the visual field and propagates to peripheral zones within 10 to 15 min. Function returns to normal within another 10 to 15 min.[44] The rate of development of the visual symptoms suggests that there is a front of hyperactivation in the visual cortex that moves at a speed of approximately 3 mm/min. Milner[45] noted that the speed of propagation of the visual symptoms was the same as that of the wave of spreading depression, leading to the hypothesis that CSD is the physiological basis for the aura. In subjects experiencing somatosensory symptoms, the spread of symptoms along the sensory homunculus occurs at a similar rate.

Numerous neuroimaging studies in humans support the concept that spreading depression-like phenomena in neocortex occur with migraine aura.[46–48] In particular, using functional magnetic resonance imaging, it has been possible to demonstrate slowly propagating neurovascular changes in visual cortex that occur together with visual symptoms in patients experiencing visual aura.[47] Although CSD has been assumed to be relevant only to migraine with aura, there is an increasing body of evidence that CSD-like changes in cerebral blood flow also occur in migraine without aura, providing a unified theory of migraine pathogenesis.[48]

HYPEREXCITABILITY IN CSD AND FOCAL SEIZURES

Given that the propagating wave of CSD is led by oscillatory field activity and the discharge of synchronous field responses,[36,38] it is reasonable to compare the hyperexcitability of CSD with that occurring in a focal seizure discharge. In both cases there is hypersynchronous activity in cortical neural aggregates, although in the case of migraine the current flows are insufficiently broadly distributed spatially to be detected by scalp EEG recordings. Although the way in which CSD generates migraine aura symptoms is poorly understood, the positive symptoms presumably derive from active zones with hypersynchronous activity, whereas negative symptoms (such as scotomas) result from depressed zones; the headache is also generated by depressed cortex. In contrast, in epilepsy, the hypersynchronous activity itself generates the aura and the ictus. The spread of CSD occurs at a stereotypical rate of 3–5 mm/min (50–83 μm/s). In contrast, the spread of epileptiform activity occurs over a wide range of rates that spans three orders of magnitude.[49] Ordinarily, the rate of epileptiform propagation is assumed to be faster than that of CSD. However, in in vitro brain slice models, the speed of propagation depends on the specific model. When synaptic inhibition is reduced (e.g., with $GABA_A$ receptor-blocking agents), neocortical slices exhibit discharges that propagate at a rate of 2–10 mm/s. In contrast, in the low-magnesium model, in which seizures arise as a result of the enhanced activity of NMDA receptors, seizures propagate at rates of approximately 100–250 μm/s, which is in the same range as the rate of propagation of CSD. Similarly, measurements from EEG recordings indicate that human cortical seizures can spread at low or high rates (<200 μm/s to >10,000 μm/s).[49,50] Thus, the rate of propagation of epileptiform discharges that are elicited by unblocking NMDA receptors is similar to that of CSD. Potassium channel blockade with 4-aminopyridine (4-AP) can also induce slowly propagating seizure discharges.[49] These seizures, which are largely due to excessive glutamate-mediated excitatory neurotransmission, are not sensitive to NMDA receptor antagonists but are blocked by AMPA receptor antagonists.[51] Therefore, in general, it appears that epileptiform activity associated with enhanced excitatory neurotransmission propagates at rates comparable to those of CSD, whereas epileptiform activity caused by reduced inhibition propagates much faster.

ROLE OF GLUTAMATE

The evidence presented so far indicates that there are similarities in the physiology of the early stages of the evolution of a migraine attack and a focal epileptic seizure. Both begin with

hypersynchronous activity, and both spread as a wave from the region of detonation. For some types of seizure discharges—specifically, those generated by excessive activation of ionotropic glutamate receptors and where GABAergic inhibition is intact—the rate of spread is similar to that occurring in CSD. Ionotropic glutamate receptors appear to play a special role as a trigger in both instances. Indeed, it has been known since the work of van Harreveld and Fifková in the 1970s that glutamate can trigger CSD.[52] Moreover, in their earliest study, glutamate-induced CSD was found to be inhibited in the presence of high magnesium ion concentrations (10–15 mM). We now know that these concentrations of magnesium are sufficient to block NMDA receptors. Indeed, diverse NMDA receptor antagonists, including MK-801, ketamine, memantine, and 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP), have been shown to inhibit CSD.[53–56] Therefore, NMDA receptors are a critical trigger for CSD. In contrast, AMPA receptor antagonists are generally ineffective.[53] The relative importance of NMDA and AMPA receptors in triggering CSD mimics their relative roles in generating the large DC shift of CSD. The opposite situation applies for most in vitro seizure models, where AMPA receptor antagonists effectively inhibit epileptiform activity but NMDA antagonists do not.[57] An exception is the low-magnesium model associated with excessive activation of NMDA receptors, where NMDA receptor antagonists do abolish the epileptiform discharges.[58]

Given the ability of glutamate to trigger CSD, it has been proposed that glutamate release is responsible for the advancing wave front of CSD. This glutamate could come from neurons, but recently glia have been implicated. At least partial support for this idea is provided by studies showing that NMDA receptor antagonists influence the synchronous prodromal oscillations and raise the threshold required to initiate CSD but do not prevent CSD propagation once initiated.[55] It is concluded that NMDA receptors contribute to but are not essential for the spatial spread of CSD; their role is mainly prior to the massive neuronal depolarization, and they contribute little to this depolarization. In any case, it is interesting to draw a parallel between epileptic activity and CSD/migraine, where fast glutamate-mediated excitation is the inciting event in both instances. In CSD, glia may be a major source of this glutamate. In epilepsy, however, while it had been speculated that glia might release glutamate that generates synchronized epileptic discharges,[59,60] more recent evidence raises doubt.[61] A schematic illustration of the related but distinct pathways leading to an ictal event in migraine and epilepsy is presented in Fig. 73–1. An example of a situation in an experimental model where seizure activity and spreading depression occur in the same brain networks following a triggering event (a brief pulse of potassium) is shown in Fig. 73–2. Ordinarily, seizure and migraine mechanisms are not considered as occurring together. However, the clinical evidence presented in the first part of this chapter suggests that there are many instances, such as migralepsy or more commonly seizure-induced headache, where both mechanisms may come into play.

REQUIREMENT FOR SYNAPTIC TRANSMISSION

An important difference between seizure discharges and CSD is the role of synaptic mechanisms. In most but perhaps not all epilepsy models,[62,63] ictal activity is blocked by the voltage-gated sodium channel blocker tetrodotoxin and therefore appears to require action potential-dependent synaptic transmission (see ref. 61). Inhibitory transmission, which is also tetrodotoxin sensitive, provides an obligatory synchronizing influence.[64] In contrast, while tetrodotoxin may inhibit the triggering of CSD in some situations, it has generally not been found to inhibit CSD propagation.[65–67] Therefore, one hypothesis to explain the difference between the physiology of CSD and focal seizure activity is that in CSD nonsynaptic glutamate release from glia is a major factor, whereas in epileptic discharges synaptic glutamate release from neurons is required. In addition, in epilepsy there is a predominant dependence on AMPA receptors, whereas triggering of CSD is mainly dependent on NMDA receptors.[68] Once CSD is initiated, other channel mechanisms come into play.

CORTICAL HYPERRESPONSIVITY IN MIGRAINE

While it appears that hyperexcitability is critical to seizures and CSD, this does not explain

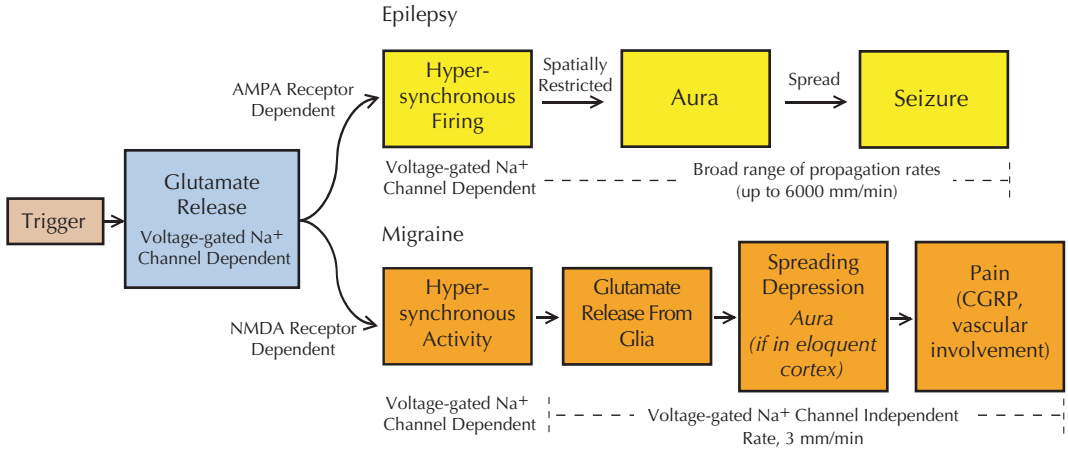

Figure 73–1. chematic illustration of the putative chain of cellular events in the evolution of an epileptic seizure and a migraine attack, highlighting the similarities and differences. In epilepsy, synaptic glutamate release acting through AMPA receptors is a trigger factor and synaptic activity is required (in most instances) for propagation. In migraine, synaptic glutamate acting through NMDA receptors is a trigger factor. Once established, synaptic activity may no longer be necessary and glutamate release from glia is the predominant factor that drives the advancing front of spreading depression. The spreading depression wave triggers the release of mediators that activate the trigeminovascular system, resulting in headache pain. Voltage-gated Na^+ channel dependence (tetrodotoxin sensitivity) implies the involvement of synaptic mechanisms. CGRP, calcitonin gene-related peptide.

the susceptibility of some individuals to clinical attacks of migraine. One possibility is that there is generalized or local cortical hyperresponsivity in susceptible individuals that predisposes to the triggering of attacks. There is a voluminous literature on the sensitivity to sensory stimuli in migraineurs.[69] The techniques that have been used include psychophysical studies; visual, auditory, and somatosensory evoked potentials; magnetoencephalography; and transcranial magnetic stimulation (TMS) of the motor cortex. Although a broad range of results have been obtained, the preponderance of evidence supports the view that there is cortical

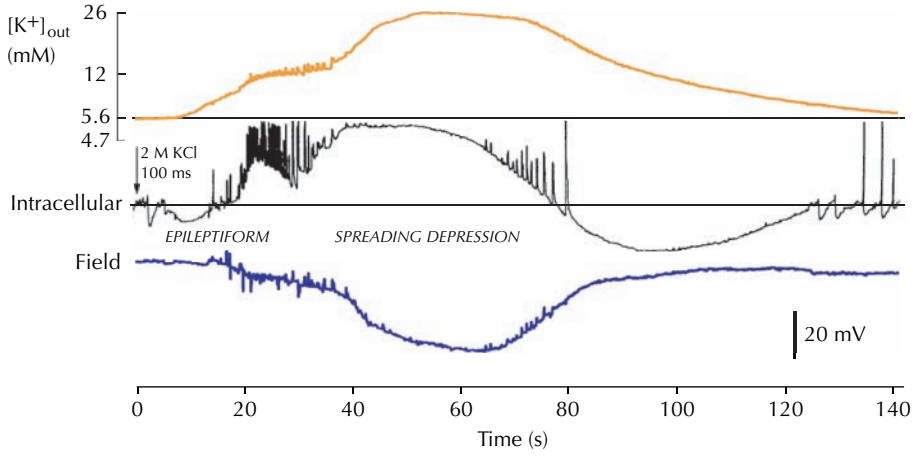

Figure 73–2. Seizure activity and spreading depression can occur together in the same brain substrate. The example shown is from a brain slice recording in the hippocampal CA3 region of a young rabbit. A local micropressure application of 2 M KCl was made at time 0 (arrow). The *top trace* shows the extracellular K^+ level as recorded by an ion-sensitive microelectrode. The *middle trace* is an intracellular recording from a CA3 neuron. The *bottom trace* shows the extracellular field. There is an initial ictal discharge (depolarization and increased action potential generation) followed by full-blown spreading depression with a large negative field potential in conjunction with strong membrane depolarization and a marked increase in extracellular K^+. Adapted from ref. 100.

hypersensitivity to external stimuli in patients with migraine during and between attacks. For example, most but not all studies have shown reduced phosphene thresholds in the visual cortex of migraineurs with TMS.[70] Some studies have found such effects only in subjects who experience migraine with aura, whereas other have found that the visual cortical hyperexcitability extends to subjects who experience migraine without aura.[71,72] Interestingly, the preponderance of TMS data supports the view that untreated patients with generalized epilepsy syndromes also have enhanced cortical excitability.[73]

INSIGHTS FROM GENETICS

Migraine has long been known to have a strong inherited component, but until recently, no accepted linked genetic marker variants have been established for the common forms; a similar lack of information applies to the common forms of epilepsy. Recently, genome-wide association studies have begun to identify genetic variants that confer increased risk for migraine.[74] Some of the variants (such as in the gene for metadherin) have been proposed to influence glutamate signalling although this is still speculative. In contrast, for both migraine and epilepsy, rare Mendelian forms are recognized and single-gene mutations have been identified whose functional implications are better defined. The rare monogenic forms of migraine are of the familial hemiplegic migraine (FHM) subtype. In FHM, attacks typically begin in youth (age range, 5 to 30 years) and include hemiparesis and, in some cases, heminanesthesia, paresthesia, hemianopic visual field disturbances, aphasia, and variable degrees of drowsiness, confusion, or coma. In addition, there is migraine-like unilateral headache that is usually contralateral to the hemparesis. Attacks of nonhemiplegic migraine without aura can occur in FHM patients and family members, which has been interpreted as indicating that FHM is part of the spectrum of migraine.

Calcium Channel

Three different genes cosegregate with FHM. Epilepsy has been reported in all three FHM types. The first to be described was *CACNA1A*, which encodes the pore-forming α_{1A}-subunit ($Ca_V2.1$) of neuronal P/Q-type calcium channels.[75] Mutations in *CACNA1A* account for about one-half of all cases of FHM. In addition to FHM1, mutations in *CACNA1A* are associated with episodic ataxia type 2 (EA2) and spinocerebellar ataxia type 6 (SCA6). All of the 21 FHM1 mutations reported to date produce substitutions of conserved amino acids in important functional regions of the $Ca_V2.1$ channel, including the pore lining and the voltage sensors. Studies in heterologous expression systems show that the FHM1 mutations generally are associated with a gain of function of the channel represented as enhanced channel gating. Different studies have revealed a variety of complex effects on channel inactivation. However, Pietrobon[75] notes that a consistent effect seen in studies of the single-channel properties of human $Ca_V2.1$ channels with FHM1 mutations is enhanced channel-opening probability at a wide range of membrane potentials, mainly due to hyperpolarizing shifts in channel activation. These changes in the biophysical properties of single channels result in greater Ca^{2+} flux through the mutant $Ca_V2.1$ channels, which is confirmed by measurements of whole-cell currents in heterologous expression systems and transfected neurons. In addition, while most FHM1 mutations cause a decreased density of functional channels, in some cases the mutations may cause enhanced channel expression, such as with the S218L mutation, which is associated with a particularly severe form of FHM1.[76] Studies of FHM1 knockin mice carrying two different mutations (R192Q and S218L) have confirmed the gain of function observed with recombinant receptors in heterologous expression systems. The gain of function with the S218L mutation was larger than that with the R192Q mutation in accordance with the more severe phenotype of the S218L mutation.[77,78] R192Q mice exhibit a reduced threshold and an increased velocity of CSD[77]; S218L mice are far more sensitive to CSD. These results provide compelling support for the link between CSD and migraine. The functional consequences of the R192Q mutation were studied in neuronal cultures and brain slices from homozygous R192Q knockin mice.[79] There was a gain of function of excitatory neurotransmission between cortical pyramidal cells and between

pyramidal cells and fast-spiking interneurons manifest as increased synaptic strength due to increased action potential-evoked Ca^{2+} influx through mutant P/Q calcium channels. Overall, the results are consistent with the idea that hemiplegic migraine resulting from the R192Q mutation is due to enhanced cortical excitatory neurotransmission. Indeed, inhibitory neurotransmission mediated by fast-spiking interneurons was unaffected. Despite the altered balance between excitation and inhibition, the R192Q mutation is not associated with seizures. However, a genetic marker association study has indicated that *CACNA1A* is associated with idiopathic generalized epilepsy.[80] Moreover, mutations in homologs of the gene can cause absence-like seizures in rodents.[81,82] Interestingly, in mice with these mutations (*tottering* and *leaner*), there is actually a marked resistance to CSD.[82] Among the FHM types, mutations in *CACNA1A* are least likely to be associated with epilepsy. However, seizures (including seizures occurring during headache) have been reported with some mutations, including S218L[14,76,83] as well as I1710T,[84] where a 14-year-old girl had recurrent FHM episodes with status epilepticus.[85] Childhood absence epilepsy (with generalized tonic-clonic seizures) has been associated with a non-FHM-causing point mutation in *CACNA1A* (C5733T).[86] Therefore, diverse mutations in *CACNA1A* can cause migraine without epilepsy, epilepsy without migraine, or both. The underlying pathophysiological mechanisms of absence epilepsy are distinct from those of partial epilepsy. The evidence presented here for a commonality between epilepsy and migraine does not extend to absence epilepsy. Indeed, absence epilepsy mutations in *CACNA1A* are not associated with FHM, and absence epilepsy mutations in *Cacna1a*, the mouse homolog of *CACNA1A*, not only do not promote CSD but actually markedly inhibit it.[82]

Sodium-Potassium Transporter

The second FHM gene to be described was *ATP1A2*, which encodes the α2 isoform of the main catalytic subunit of Na^+-K^+-ATPase (Na^+-K^+ transporter).[87] Among the forms of FHM, this type has the most frequent association with epilepsy (approximately 20% of families). There have been associations with partial seizures,[88] benign familial infantile convulsions (BFIC),[89] and febrile seizures.[90] Epilepsy and migraine can co-occur in the same mutation carriers[90]; in some cases, seizures occur during migraine attacks, representing true migralepsy.[91] Na^+-K^+-ATPase is a highly conserved membrane protein that is expressed in virtually all cells. There are four different isoforms of the catalytic subunit (α1–α4). The α2 isoform is predominantly expressed in astrocytes and skeletal muscle, although it may be expressed in neurons in early development. Therefore, altered Na^+-K^+-ATPase activity in astrocytes accounts for FHM2. Na^+-K^+-ATPase plays a fundamental role in the maintenance of the resting potential of all cells, including astrocytes. The pump, which transports three Na^+ out of the cell in exchange for the countertransport of two K^+ into the cell, allows extracellular K^+ to be maintained at a low level. In addition, the Na^+ gradient produced by Na^+-K^+-ATPase is required for clearance of extracellular glutamate by astrocytes.[92] Glutamate uptake in astrocytes is mediated by glutamate transporters, predominantly GLAST (L-glutamate/L-aspartate transporter; EAAT1) and GLT-1 (glutamate transporter 1; EAAT2). These transporters are expressed along with Na^+-K^+-ATPase in astrocytic processes surrounding glutamatergic synapses. There is tight functional coupling between the transporters and the pump proteins: the uptake of a glutamate molecule is driven by the entry of three Na^+ (and also one H^+) down the electochemical gradient in exchange for one K^+. Recent evidence indicates that the transporters and Na^+-K^+-ATPase are physically associated in the same protein complex.[93] Impairment in the pump function of Na^+-K^+-ATPase is expected to reduce the ability of astrocytes to remove K^+ that accumulates extracellularly during high-frequency neuronal firing. This in itself would promote hyperexcitability (and seizure activity) and CSD. In addition, elevated external K^+ causes reversal of glutamate transporters, so that intracellular glutamate is released into the extracellular space, which would further enhance excitability and predispose to CSD. The FHM mutations in *ATP1A2*, of which more than 36 have now been described, lead to complete inactivation of the protein in some cases,[94] whereas in other cases there is altered kinetics, altered cation affinity, reduced

membrane trafficking, or reduced protein stability.[92,95,96] Familial hemiplegic migraine 2 is an autosomal dominant condition, and it is likely that FHM2 mutations lead to haploinsufficiency with reduced but not absent Na^+-K^+-ATPase. Indeed, *ATP1A2* knockout mice die at birth but heterozygous animals grow normally.[97] Overall, impairment of astrocytic K^+ and glutamate handing are likely to account for the CSD and seizures in FHM2. To the extent that $\alpha 2$ Na^+-K^+-ATPase is expressed in neurons, the neuronal resting potential may be depolarized, which would also enhance excitability. It is noteworthy that both seizures[98,99] and CSD[66,100] can be produced by pharmacological inhibition of Na^+-K^+-ATPase with ouabain, a nonselective inhibitor of astrocytic and also neuronal Na^+-K^+-ATPase.

Sodium Channel

The third FHM gene is *SCN1A*, which encodes the pore-forming $\alpha 1$ subunit of the neuronal type I voltage-gated sodium channel $Na_v1.1$.[101–103] More than 600 sequence variants of this gene have been identified that have been associated with generalized epilepsy with febrile seizures plus (GEFS+) and severe myoclonic epilepsy of infancy (SMEI). To date, only three mutations have been associated with FHM. The first two to be described (Q1489K and L1649Q) cause pure FHM without epilepsy. More recently, in a multigenerational Portuguese family, the L263V mutation was found to be associated not only with FHM but also with generalized tonic-clonic and complex partial seizures.[103] Family members with the mutation invariably had FHM, and some also exhibited seizures that occurred separately from the migraine attacks.Studies with recombinant human $Na_v1.1$ channels bearing the mutations have demonstrated that the pure FHM mutations Q1489K and L1649Q caused biophysical changes in the Na^+ current that were interpreted as predominantly of the loss-of-function type.[104] In contrast, L263V was interpreted as causing gain of function because it produced delayed entry into and accelerated recovery from fast inactivation and increased persistent current as well as other changes in channel gating.[104] Whether these results, which were obtained with recombinant channels expressed in nonneuronal cells, are relevant to the in vivo situation remains to be determined. However, it has generally been the case that mice with loss-of-function mutations in $Na_v1.1$ have impaired function of GABAergic inhibitory neurons, which leads to enhanced circuit excitability. In cases where there is gain of function in $Na_v1.1$, pathological effects may be mediated by the excessive excitability of principal (glutamatergic) neurons that do express the channel, albeit at lower relative levels than do GABAergic neurons.[105,106] The observation that the gain-of-function L263V mutation is associated with both epilepsy and migraine is consistent with the notion that both disorders are triggered by hyperexcitability. Why attacks are manifest as seizures in some instances and as migraine in others remains to be determined. Different loss-of-function *SCN1A* mutations cause pure epilepsy and pure FHM. This provides an opportunity to determine the factors that account for the tendency of circuit hyperexcitability to transition to seizures in one instance and CSD/migraine in the other.

Familial hemiplegic migraine is distinguished from typical migraine by its autosomal dominant Mendelian inheritance and by various clinical features that are not present in typical migraine. Nevertheless, there are sufficient similarities in headache characteristics and triggers to suggest that an understanding of the pathophysiological basis of FHM can shed light on the underlying mechanisms of the far more frequently encountered nonhemiplegic migraine syndromes. Moreover, nonhemiplegic migraine attacks can occur in FHM. It is remarkable that mutations in certain FHM genes can cause either migraine or epilepsy, or in some cases both, clearly demonstrating a commonality between FHM and epilepsy and supporting the notion that migraine generally, like epilepsy, is a disorder of neuronal hyperexcitability.

CONCLUSIONS

Epilepsy and migraine are both episodic functional disorders in which susceptible brain regions are hyperexcitable and attacks begin with hypersynchronous neuronal firing. In epilepsy, the hypersynchronous activity continues, whereas in migraine with aura (and possibly also in migraine without aura) there is CSD. If

CSD occurs in eloquent cortex, there are associated aura symptoms. pain. In both epilepsy and migraine, leads to the release of mediators that elicit headache pain. In both epilepsy and migraine, ionotropic glutamate receptor activation triggers the hyperexcitability. In epilepsy, AMPA receptors play a predominant role in mediating the generation and spread of seizure activity, whereas in migraine NMDA receptors are dominant in triggering CSD but the nature of the ionic conductance that leads to the massive but transitory neuronal depolarization in CSD is yet to be defined. In epilepsy and migraine, various factors can provoke attacks, but how these factors lead to neuronal hypersynchronous activity and the initiation of an attack is not understood. Evidence from human neurophysiology and functional studies of recombinant ion channels and animals with human FHM mutations supports the view that in migraine, as in epilepsy, excitability thresholds are reduced so that a normally innocuous stressor overcomes homeostatic mechanisms that prevent entry into the pathological state (migraine attack or seizure). Key unanswered questions are why some individuals are susceptible to migraine and others to epileptic seizures, and, in those susceptible to both migraine and seizures, why attacks manifest as one or the other at different times.

Chapter 74

Neurobiology of Depression as a Comorbidity of Epilepsy

Raman Sankar
Andrey Mazarati

In his review on melancholia, Lewis describes Hippocrates as having had the perception that the condition was reciprocally connected to epilepsy.[1] Recent epidemiological studies have supported the notion that depression is more frequent among patients with epilepsy (preceding the diagnosis of epilepsy) than among case controls[2] and that depression is seven times more likely among adults presenting with a new-onset seizure disorder than among controls.[3] Depression has been identified as the most frequent psychiatric comorbidity in patients with epilepsy.[4] Hermann et al. have summarized estimates of the prevalence of lifetime-to-date major depression among patients with epilepsy as ranging from 8% to 48%, with a mean and a median approximating 30%.[5] Hermann and colleagues also stated that psychiatric comorbidities contributed to a lowered health-related quality of life (HRQOL) in epilepsy.[6] Further, their study revealed an association of symptom checklist scores with the chronicity of temporal lobe epilepsy (TLE). Interictal psychiatric symptoms adversely influenced the HRQOL to a greater extent than the frequency, severity, and chronicity of seizures.[7] Consideration of the psychiatric comorbidities in treatment decisions involving drug selection have been reviewed for adult[8] as well as pediatric[9] patients with epilepsy.

Depression in a patient with epilepsy can reflect a neurobiological connection between

the disorders, but can also result in part from socioeconomic factors impacting on epilepsy or due to iatrogenic causes. The iatrogenic causes based on pharmacotherapeutics are reflected in the well-recognized emergence of depression due to barbiturate therapy or an improvement in mood associated with anticonvulsant medications like carbamazepine or lamotrigine.[10–12] A strong case for the neurobiological basis of depression is the finding that patients with the condition seem to be at higher risk for developing epilepsy than controls.[13–15] Another interesting finding regarding depression in human epilepsy is that the involvement of distinct networks may influence the presentation in specific epilepsy syndromes. Altshuler et al.[16] found that patients with seizures of temporal lobe origin were significantly more likely to have a history of depression than those with seizure foci of extratemporal lobe origin and suggested a role for limbic dysfunction in increasing the risk for depression. Piazzini et al.[17] found that while all patients with epilepsy scored higher on depression and anxiety scales than controls, patients with partial epilepsy scored higher than those with generalized epilepsy. Further, those with TLE were affected significantly more than those with frontal lobe epilepsy (FLE).[17]

This relationship regarding depression was confirmed in a cohort of pediatric patients in a study that found a difference between depression and anxiety; depression was more frequent in those with complex partial seizures, while anxiety was more common in childhood absence epilepsy.[18] Other pediatric studies[19,20] were not adequately powered to discern a relationship with the seizure type, but all of the studies failed to find a relationship between seizure frequency and the extent of mood disturbance.[18–20]

In adults with TLE, Gilliam et al.[21] found that while seizure frequency was not a determinant of the extent of depression, the degree of hippocampal dysfunction, as measured by proton magnetic resonance spectroscopy (1H-MRS), was predictive of the severity of depression. Hippocampal functional integrity was assessed by the creatine/*N*-acetyl aspartate (Cr/NAA) ratio. Multiple studies have suggested that depression and anxiety symptoms improved in patients who became seizure-free after temporal lobectomy.[22–24] Interestingly, recovery of Cr/NAA ratios was shown to occur during longitudinal follow-up only in patients who become seizure free.[25,26] The reversal of neuronal metabolic dysfunction suggested by the recovery of the Cr/NAA has a time course consistent with an exponential function with a half-life of 6 months, with 95% recovery achieved by 25 months after surgery.[27] Together, these data support the notion that while short-term seizure frequency does not correlate with the severity of depression, a surgical cure of the epileptic state results in favorable plasticity reflected by improving Cr/NAA scores and mood.

A study that prospectively assessed various quality-of-life measures including anxiety and depression prior to surgery, as well as 2, 12, and 24 months afterward, showed that most of the improvement in anxiety and depression occurred within the first 3 months after surgery and remained stable for up to 24 months.[28] While this outcome does not support the conclusion stated in the previous paragraph, the authors of this study did see a trend toward divergence in long-term outcome between the group that remained in remission from seizures and the one that experienced a relapse.[28]

DEPRESSION IN ANIMAL MODELS OF EPILEPSIES

Animal models of epilepsy allow the study of the emergence of depression-like behaviors, and the accompanying changes in the neurochemical milieu, without the confounding effects of socioeconomic and iatrogenic factors. All of the studies that follow involve rodent models of epilepsy.

In rodents, the state of despair is commonly examined using the forced swim test (FST), which is based on their innate ability to adopt active strategies in the inescapable stressful situation.[29,30] In the FST, animals exhibit two alternating behaviors—active escaping and/or exploring behavior, and relative immobility, when they move only enough to maintain their heads above water and to avoid drowning. The increased immobility time in the FST has been regarded and validated[31] as an indicator of the state of despair. The brain systems underlying this susceptibility to helplessness and

depression have been reviewed[32] and include a dissociated hypothalamic-pituitary-adrenocortical axis, which is discussed further below, and other systems.

The examination of anhedonia in rodents relies on their innate preference for sweets and involves a saccharin consumption test.[33] In this test, healthy subjects, when given access to both tap water and saccharin solution, strongly prefer the latter, whereas animals with experimental depression consume equal amounts of water and saccharin. Loss of the preference for saccharin has been regarded and validated[34] as an indicator of anhedonia.

DEPRESSION IN AN ANIMAL MODEL OF GENETIC ABSENCE EPILEPSY

Spontaneous generalized spike-wave discharges (SWDs) and accompanying staring spells have been found in a number of rodent strains. Of special interest are inbred strains of Wistar rats that develop staring spells and SWDs in the absence of other overt neurological findings such as ataxia, tremor, and other motor system disturbances. These strains include the Genetic Absence Epilepsy Rat from Strasbourg (GAERS) and the Wistar Albino Glaxo/Rijswijk[35] (WAG/Rij), as well as Long Evans rats. The two former strains have been much more studied as models for human absence epilepsy since the SWDs are seen early in life.

A number of behavioral studies have demonstrated despair and anhedonia in the WAG/Rij rat[36] and have been reviewed in detail by Sarkisova and van Luijtelaar.[37] When WAG/Rij rat pups were treated with ethosuximide, an antiabsence agent, beginning at postnatal day 21 for 5 months to prevent the emergence of spontaneous SWDs, as described by Blumenfeld et al.,[38] they exhibited no symptoms of depression-like behavior, in contrast to untreated WAG/Rij animals.[39] The authors did not find an antidepressant effect attributable to ethosuximide in the control Wistar rats, and concluded that early treatment prevented the emergence of SWDs and depression, that is, absence seizures and comorbid behavioral depression-like symptoms.

DEPRESSION IN ANIMAL MODELS OF LIMBIC EPILEPSY

Epileptogenesis in animals after experimental status epilepticus (SE) is often accompanied by significant brain damage, so it is not clear whether the anatomical lesion itself may contribute to behavioral alterations. Behavioral testing can be affected by recurring seizures. It is important to establish whether the epileptic state (increased seizure susceptibility) per se, rather than epileptic seizures and morphological changes, is accompanied by symptoms of depression.

DEPRESSION AFTER KINDLING EPILEPTOGENESIS

Kindling is a model of limbic epilepsy that is characterized by a sustained increase in seizure susceptibility. Kindling is different from post-SE TLE in two major respects: the absence or minimal extent of neuronal injury and the absence of spontaneous recurrent seizures. At the same time, kindled animals exhibit persistent enhanced seizure susceptibility. Hence, kindling appears to be especially suitable for studying the epilepsy-associated depression that results from neuronal plastic changes. A limitation of traditional kindling protocols is that rapid brain and skull growth in developing animals displace electrodes. Lothman and coworkers[40,41] described rapid kindling, which allows the creation of enhanced susceptibility within several hours. We have adapted this approach to evaluating the age-specific and pharmacological properties of epileptogenesis.[42]

In our experiments involving postnatal day 21 (P21) rats,[43] the afterdischarge threshold and duration were detected by applying electrical stimuli consisting of 10 s train duration, 20 Hz, 1 ms pulse duration, square wave monophasic stimuli, starting at 0.2 mA, at 0.1 mA increments, delivered every 10 min. Stimuli were applied to the ventral hippocampus. The rapid kindling procedure, which started 10 min after detecting the afterdischarge, consisted of 84 trains delivered every 5 min using the parameters described above at a current of 0.1 mA over the afterdischarge threshold; the

total procedure duration was 7 h. Sham animals were implanted with electrodes but did not receive kindling stimuli. Behavioral seizures were scored using the following scale: 1: motor arrest and twitching vibrissae; 2: chewing and head bobbing; 3: forelimb clonus; 4: forelimb clonus and rearing; 5: rearing and falling.

The kindled animals as well as the naive and sham animals (implanted with electrodes but not stimulated) underwent behavioral testing 2 and 4 weeks after rapid kindling. Both naive and sham animals showed similar immobility time during the 2- and 4-week recording sessions (Fig. 74–1A). However, the kindled animals spent significantly more time immobile in the tank both 2 weeks after (Fig. 74–1A) and 4 weeks after kindling compared to controls. We further examined whether the immobility time under conditions of FST correlated with the severity of behavioral seizures in response to test stimulations in individual animals. We found a strong positive correlation between the time spent immobile during FST both 2 and 4 weeks after kindling and seizure score both 24 h and 4 weeks after kindling (Fig. 74–1B,C). As shown in Fig. 74–2, the kindled rats demonstrated a loss of preference for saccharin-sweetened water at both 2 and 4 weeks after rapid kindling. Surprisingly, in the sucrose consumption test 4 weeks after kindling, the animals' behavior was reversed—from loss of preference to enhanced preference—even when compared to naive subjects. In contrast to saccharin, sucrose has caloric value. It is

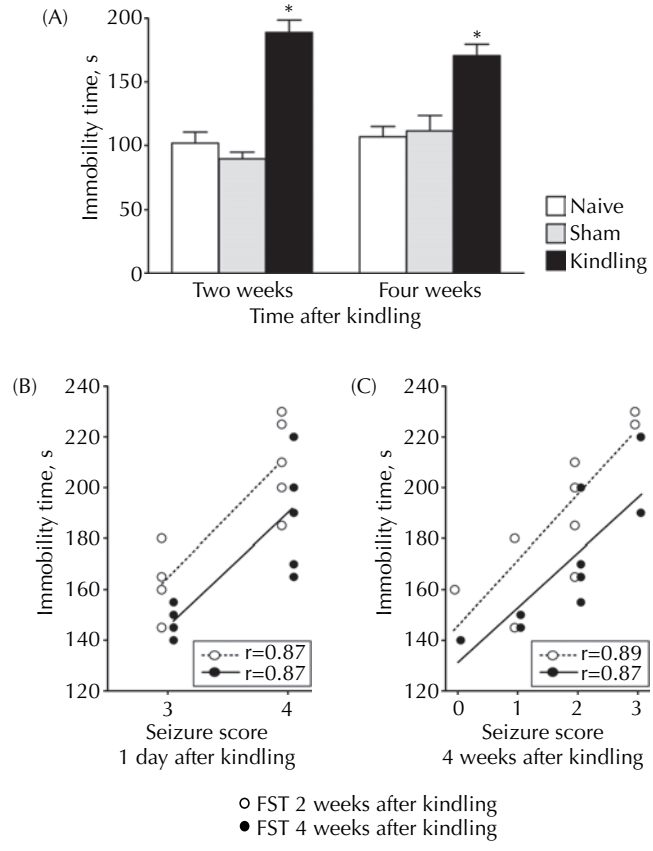

Figure 74–1. The FST before and after rapid kindling. **A.** Mean ± SEM values 2 and 4 weeks after kindling. *$p < 0.05$ versus both naive and sham (one-way ANOVA + Bonferroni test). There were no statistical differences ($p > 0.1$) between the findings at 2 and 4 weeks for any group (paired *t*-test). Seizure scores of individual animals in response to threshold stimulation 1 day (**B**) and 4 weeks (**C**) after kindling are plotted against immobility time in the FST 2 weeks (open circles) and 4 weeks (black circles) after kindling. The coefficient of correlation (*r*), calculated using the Spearman test, is indicated for each dataset; a positive correlation was statistically significant in all cases ($p < 0.05$).

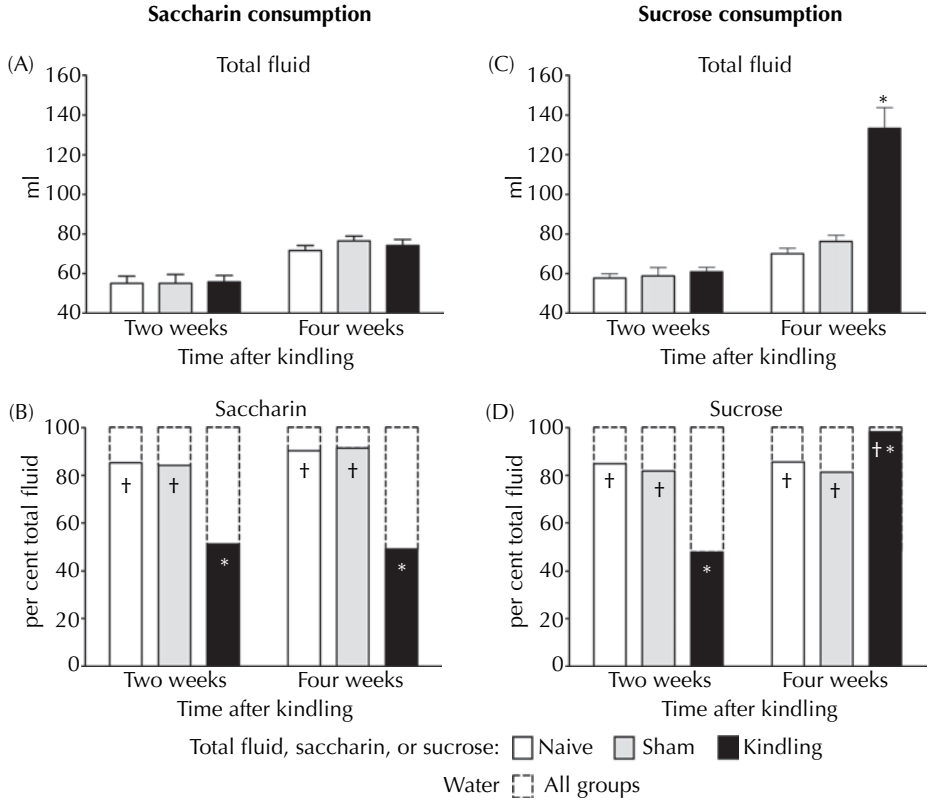

Figure 74–2. Twenty-four-hour saccharin (**A,B**) and sucrose (**C,D**) consumption 2 and 4 weeks after rapid kindling. **A.** No differences were observed at any age in total fluid (tap water + saccharin) intake between control and experimental groups. **B.** Although the naive and sham animals exhibited a strong preference for saccharin versus tap water, the kindled animals exhibited loss of the taste preference for saccharin both 2 and 4 weeks after kindling. **C.** No differences were observed in total fluid (tap water + sucrose) intake between naive and sham animals. However, the total volume of fluid consumed was significantly larger in kindled animals. **D.** Both naive and sham animals preferred sucrose to tap water. Kindled animals did not exhibit a sucrose preference 2 weeks after kindling. However, at 4 weeks, kindled animals consumed significantly more sucrose solution compared with both sham and naive rats. Data in **A** and **C** are presented as means + SEM and those in **B** and **D** as means. $^{*}p < 0.05$ versus both naive and sham rats (one-way ANOVA + Bonferroni test). †$p < 0.05$, percentage of either saccharin or sucrose (bottom bars in the stacks) versus percentage of water (top bars in the stacks, *t*-test).

known that depression can be accompanied by both the loss and the increase of appetite.[44,45]

These data provided evidence that rapid kindling in young animals leads to sustained changes in forced swimming and taste preference tests that can be interpreted as behavioral correlates of depression. In contrast to post-SE epilepsy, kindling is not accompanied by hippocampal sclerosis and spontaneous seizures. Eliminating spontaneous seizures as a variable permits this model to accommodate an important clinical feature of epilepsy-associated depression observed by Attarian et al.,[46] Quigg et al.,[47] and Gilliam et al.[23] Those authors found that the prevalence depression was independent of the degree of seizure control.

Thus, the important findings of our experiments were as follows: (1) the evolution of depression accompanying epileptogenesis can be modeled in young animals and (2) epilepsy-associated depression can be demonstrated in this model without either overt brain injury or ongoing spontaneous seizures. Having established that features of depression can evolve in the absence of brain injury, we decided to extend our observations to a better-established model of rodent epilepsy, one that follows SE induced by lithium-pilocarpine treatment. The latency to the development of spontaneous seizures in this model precludes narrowly defined early developmental aspects of the process.

DEPRESSION ACCOMPANIES EPILEPTOGENESIS FOLLOWING SE

We subjected P35 rats to lithium-pilocarpine-induced SE, a well-studied model of TLE. Four weeks after SE, the animals underwent 1 week of seizure monitoring with continuous electroencephalography (EEG). Subsequently, they underwent physiological interrogations for afterdischarge threshold and duration and were divided into two groups. One group received saline daily for the following 10 days, while the experimental group received daily injections of fluoxetine. After a repetition of the physiological tests, the animals were subjected to the behavioral tests for despair (i.e., FST) and anhedonia (i.e., taste preference for saccharin-sweetened water).

The results confirmed that the post-SE rats had indeed developed increased immobility time in the FST, and they also demonstrated a loss of taste preference for saccharin consumption, as had younger animals subjected to rapid kindling. In our studies, post-SE animals spent a significantly longer time immobile (50% of a total 5 min test duration) compared both with naive rats and with themselves prior to SE (25% of a total test duration), thus suggesting the state of despair. These depression-associated behaviors could not be correlated with the number of seizures and appeared resistant to treatment with the selective serotonin reuptake inhibitor, fluoxetine, despite the adequacy of the fluoxetine treatment regimen in reducing the number of seizures.[48]

EPILEPTOGENESIS IS ACCOMPANIED BY CHANGES IN SEROTONIN TURNOVER AND EVOKED SEROTONIN RELEASE

In our study of depression in post-SE rats, we determined the serotonin (5-hydroxytryptamine, 5-HT) concentration and turnover in the hippocampal tissue using a high-performance liquid chromatography method described previously.[49] In living animals, the evoked release of serotonin upon high-frequency stimulation of the raphe nucleus was determined using fast cyclic voltammetry (FCV).[48] This was accomplished by placing carbon fiber FCV electrodes in the CA1 and CA3 of the hippocampus to provide a ramp current 1 s after raphe stimulation to facilitate the oxidation of the phenolic hydroxyl group in 5-HT released to the quinonoid form; the measured Faradaic peak response provides for quantitative determination of the evoked 5-HT release.

THE EPILEPTIC STATE AFFECTS THE HYPOTHALAMIC-PITUITARY-ADRENOCORTICAL (HPA) AXIS TO PRODUCE EFFECTS ON SEROTONIN RELEASE

We studied the functional state of the HPA axis in our post-SE model of TLE in rats. Young adult animals (45–55 days old) were subjected to lithium-pilocarpine SE and 10-week-long video monitoring beginning 4 weeks after SE. We obtained a basal concentration of plasma corticosterone (CORT) in our rats 3–7 days before and 6–8 weeks after SE. In addition, rats were subjected to challenges with dexamethasone (DEX) and corticotropin releasing hormone (CRH). We were able to conclude that HPA axis dysregulation was present in the post-SE rats by demonstrating that DEX failed to decrease the level of plasma CORT and that exogenously administered CRH led to an increase in the level of CORT.[50] The CRH challenge was added to the conventional DEX test based on the finding of Watson et al.[51] that the DEX/CRH test had higher sensitivity and specificity in a patient population. Care was taken to draw blood samples only from animals that had not experienced a seizure within 6 h prior to specimen collection. In separate experiments, this time period produced CORT levels similar to those at time points separated from the preceding spontaneous seizure by periods of up to 4 days.

In these studies,[50] out of the 16 animals that had undergone SE, spontaneous seizures were observed in 10; however, all of the post-SE animals showed a statistically similar increase in hippocampal excitability that was evident as a lower afterdischarge threshold (ADT) and a longer afterdischarge duration (ADD) compared with controls (data not presented in this chapter); furthermore, unlike the control animals, all post-SE rats developed behavioral seizures in response to the threshold stimulation.

The data shown in Fig. 74–3 demonstrate that the HPA axis dysregulation was similar in rats in which spontaneous seizures were commonly seen and in those with rare or no documented recurrent seizures. This was also the case with regard to the observed immobility time in the FST, reminiscent of our previous observations[48] and those of Gilliam et al.[21] Gilliam and coworkers[21] had shown that in a study of 31 patients with TLE in whom the extent of depression was represented by the Profile of Mood States (POMS) scores and who underwent magnetic resonance spectroscopic imaging (1H-MRSI) to assess the functional state of the hippocampus (Cr]/NAA metabolite ratio maps were derived), hippocampal 1H-MRSI correlated with severity of depression symptoms in TLE rather than with seizure frequency. Likewise, we have found that the HPA axis dysfunction as well as the immobility time in the FST correlated with measures of hippocampal physiology (ADT and ADD) rather than with the frequency of spontaneous seizures.

How does the exaggerated CORT response in post-SE animals influence the serotonergic system? The hippocampus receives serotonergic input from neurons located in median and dorsal raphe nuclei. The release of 5-HT from raphe serotonergic neurons is regulated by a number of intrinsic and external mechanisms.

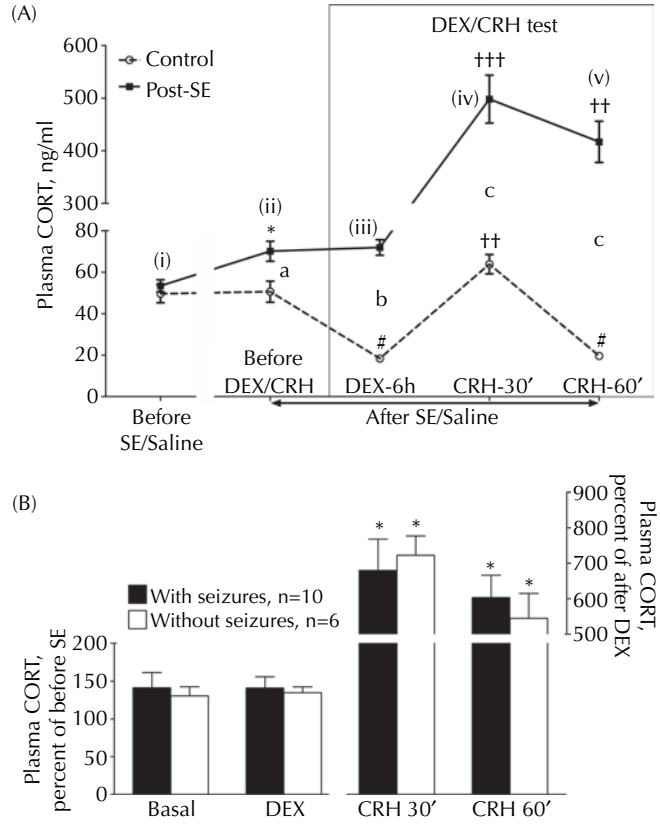

Figure 74–3. Plasma CORT levels in control and post-SE rats under basal conditions and in response to the combined DEX/CRH test. **A.** (i) Basal CORT levels before SE (saline in control rats); (ii) basal CORT levels 6–8 weeks after SE; (iii) CORT levels 6 h after DEX injection; (iv) and (v) CORT levels 30 and 60 min after CRH injection (and 6.5 and 7 h, respectively after DEX injection). Post-SE animals showed an increase in basal CORT level, loss of a response to DEX, and an exacerbated and longer-lasting response to CRH. Data are presented as mean ± SEM. $^{*}p < 0.05$ vs. "Before SE/Saline"; $\#p < 0.01$ vs. "Before DEX/CRH"; $\dagger\dagger p < 0.01$ and $\dagger\dagger\dagger p < 0.001$ vs. "DEX-6 h" (repeated measures ANOVA + Tukey test). $ap < 0.05$; $bp < 0.01$; $cp < 0.001$ for SE vs. Control (Student's *t*-test). **B**. No statistical differences were observed between the subsets of post-SE animals with and without documented spontaneous seizures for both basal CORT concentrations and in response to the combined DEX/CRH test. ($p > 0.05$, Student's *t*-test). $^{*}p < 0.05$ vs. both "Basal" and "DEX" (repeated measures ANOVA + Tukey test). Data are presented as mean ± SEM.

The most efficient mechanism consists of the short feedback autoinhibitory loop that involves somatodendritic 5-HT1A receptors (autoreceptors). The activation of raphe 5-HT1A autoreceptors by locally released serotonin inhibits firing of serotonergic neurons and further neurotransmitter release.[52] Hence, the upregulation of raphe 5-HT1A receptors would be expected to result in compromised raphe-hippocampal serotonergic transmission. In TLE patients with concurrent depression, binding affinity of raphe 5-HT1A receptors was increased, and the increase correlated positively with the severity of depression.[53] Evidence supporting the positive modulation of 5-HT1A receptor function by the glucocorticoid corticosterone exists.[54,55] We found that chronic treatment of post-SE rats with chronic raphe injections of the glucocorticoid receptor antagonist mifepristone or the 5-HT1A antagonist (WAY-100635) could restore evoked 5-HT release, as measured by FCV, as well as reduce immobility time in the FST (unpublished data).

INFLAMMATION CONTRIBUTES TO HPA AXIS DYSREGULATION AND IMPAIRED SEROTONERGIC FUNCTION AND PROLONGS IMMOBILITY TIME IN THE FST

We explored the possible role of hippocampal neuroinflammation and, in particular, enhanced interleukin-1β (IL-1β) signaling. Indeed, activation of hippocampal IL-1β and its receptor has been an established hallmark of TLE in both clinical and experimental settings.[56] Furthermore, IL-1β may lead to depression, conceivably by inducing perturbation in the HPA axis, as suggested by clinical observations and confirmed by experimental studies.[57] In order to evaluate this hypothesis, we subjected animals with post-SE depression to 2 weeks of sustained treatment with a recombinant human interleukin receptor antagonist (IL-1Ra) using osmotic mini-pumps for continuous delivery of the peptide into the hippocampus bilaterally.[58] Experimental animals received IL-1ra, while control animals received either saline or heat-inactivated IL-1Ra (iIL-1Ra). While this treatment had no effect on the behavior of rats that had not undergone SE, in post-SE animals treatment with IL-1Ra restored taste preference in the saccharin consumption test and significant shortening of the immobility time in the FST (Fig. 74–4). Treatment with IL-1Ra

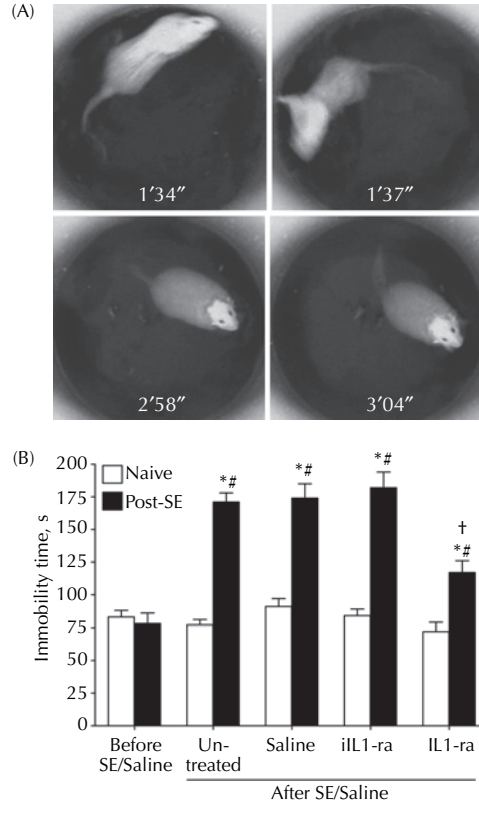

Figure 74–4. Effects of IL-1ra treatment on the forced swimming behavior. **A.** Sample snapshots taken from a prerecorded video during the FST. The time after the start of the test is indicated on each image. Examples of active swimming that reflects active escape strategies are presented at 1 min 34 s and 1 min 37 s. Note the change in the rat's position in the tank, which occurred during the 3 s period, and the fuzziness of images due to the animal's movement. Examples of immobility when animals moved only enough to avoid drowning are presented at 2 min 58 s and 3 min 04 s. Note that the animal's position in the tank did not change during 6 s of recording and that the body is positioned vertically in the water. **B.** Immobility time in naive and post-SE animals: untreated or treated with saline, heat-inactivated IL-1ra (iIL-1ra), or active IL-1ra. Note the increase in the cumulative immobility time in untreated, saline-treated, and iIL-1ratreated post-SE animals and its partial reversal following IL-1ra administration. Data are presented as mean ± SEM. $^{*}p < 0.05$ after SE vs. before SE (repeated measure ANOVA + Newman–Keuls post hoc test); $\#p < 0.05$ post-SE vs. naive; $\dagger p < 0.05$ post-SE IL-1ra vs. post-SE saline (one-way ANOVA + Newman–Keuls post hoc test).

also produced the expected modifications in CORT levels in the DEX/CRH test and partially restored the compromise to evoked serotonin release, as measured by Faradaic currents in the FCV test. These effects were not a consequence of seizure modification, since the frequency of behavioral spontaneous seizures, as assessed by video monitoring, was not altered by the treatment. While hrIL-1Ra can have an anticonvulsant effect,[56] that effect is not seen when it is administered in the manner (dose and site of infusion) used in our experiments.

In our most recent set of experiments,[59] we delved further into aspects of how raphe-hippocampal transmission was affected in the post-SE animals in terms of the presynaptic and postsynaptic 5-HT1A receptors. Tritiated WAY-10065 binding was studied in the raphe and the hippocampus to evaluate receptor numbers, while the functional capacity of the 5-HT1A receptors to activate G-protein was examined using guanosine 5′-O-gamma-thio]triphosphate ([35S]GTPγS) autoradiography.[60] In the dorsal raphe, [3H]WAY-10065 binding was similar in both moderately and severely affected post-SE animals compared to naive animals. However, [35S]GTPγS binding suggested an enhancement in second messenger function. In the hippocampus, [3H]WAY-10065 binding was unaffected in Ammon's horn, while second messenger function showed a diminution when the receptors were activated maximally. Receptor binding was enhanced in the dentate gyrus, where no change in second messenger function was discernible. Administration of mifepristone into the raphe for 1 week improved evoked 5HT-release and mitigated against the impairments in the FST only in those animals that were severely affected. Intrahippocampal mifepristone reduced immobility time in both moderately and severely affected animals.

Based on the studies performed to date, we suggest that the following sequence of events may lead to depression associated with TLE[61] (Fig. 74–5). Chronic epilepsy leads to dysregulation of the HPA axis via several putative mechanisms, one being the activation of hippocampal IL-1β signaling. The enhanced level of circulating glucocorticoids and the hyperactivity of the HPA axis upregulate raphe 5-HT1A

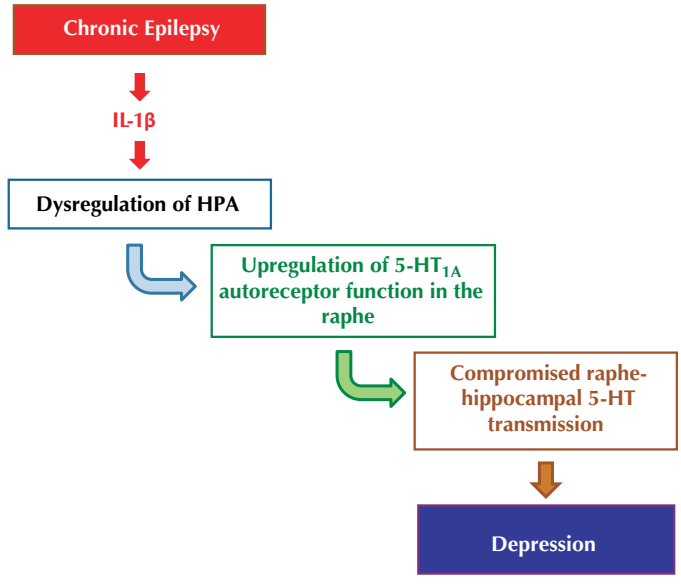

Figure 74–5. Proposed mechanisms of depression as a comorbidity of TLE. Chronic epilepsy leads to dysregulation of the HPA axis[50] via several putative mechanisms, one being activation of IL-1β signaling in the hippocampus.[58] One result of dysregulation of the HPA axis is the upregulation of 5-HT1A somatodendritic receptors in dorsal raphe and subsequent increased autoinhibition of serotonin release in the raphe-hippocampal pathway, as well as changes in the postsynaptic receptors in the hippocampus compromising serotonergic signaling and transuction.[61] Behavioral and biochemical experiments involved the administration of glucocorticoid and 5-HT1A blockers into the raphe of post-SE rats as well as binding studies.[61] The resulting compromised raphe-hippocampal serotonergic transmission[17] leads to behavioral symptoms of depression.[48,50,58]

autoreceptor function and downregulate postsynaptic 5-HT1A receptor function, thus compromising raphe-hippocampal serotonergic transmission. The latter serotonergic deficit leads to the development of clinical symptoms of depression.

CONCLUSIONS

Studies involving an animal model of absence epilepsy suggest that preemptive treatment before the onset of the epileptic syndrome may protect against both the evolution of the epilepsy and the comorbid depressive symptoms. Translation of this concept to humans is difficult at present since we cannot predict with high reliability who will develop the epileptic syndrome and also acquire the comorbidity. Thus, treatment of asymptomatic children with medications that may produce neurobehavioral effects of their own, and may also involve other systemic risks, is not ethically acceptable.

We have demonstrated that symptoms of depression-like behavior can be elicited in rodents upon kindling epileptogenesis, dissociating the emergence of depression from both seizure-related cellular injury and spontaneous seizure frequency. Our studies on limbic epilepsy have focused on the role of raphe-hippocampal serotonergic transmission and how it is influenced by inflammatory signaling by IL-1β and perturbations in the HPA axis.

Clinical depression is a multifactorial and multisymptomatic disorder, and apparently, so is the depression associated with epilepsy. Other lines of experimental evidence involving vagus nerve stimulation suggest that other brain stem nuclei, such as the locus coeruleus and the noradrenergic pathways, may work in partnership with the raphe to ameliorate both epilepsy and depression.[62] Neuropeptide galanin,[63] which is both an anticonvulsant and an antidepressant, also seems to interact with serotonergic and noradrenergic systems at the brainstem.[49,64] Thus, many targets may be relevant for the management of epilepsy and the comorbidity of depression.

Therefore, the validation of the model of comorbidity between epilepsy and depression should continue with examination of other hallmarks of depression and with the investigation of other mechanisms involved. Our studies to date show that the pilocarpine model of epilepsy may be regarded as a model of comorbidity between epilepsy and depression that is useful both for mechanistic studies and as a screening platform for mechanism-driven therapeutic interventions.

Chapter 75

Calcium Channel $\alpha_2\delta$ Subunits in Epilepsy and as Targets for Antiepileptic Drugs

Annette C. Dolphin

Voltage-gated calcium (Ca_V) channels are involved in numerous physiological processes, the most important being muscle contraction, hormone secretion, and synaptic transmission. The pore-forming subunit of Ca_V channels is the $\alpha1$ subunit, and this determines the main biophysical and pharmacological properties of the channels (Fig. 75–1). There are three main subgroups of Ca_V channels, Ca_V1–3. The low-voltage-activated calcium channels (Ca_V3 or T-type channels) appear to be able to function well as monomers. However, the high-voltage activated (HVA) Ca_V1 and Ca_V2 subfamilies are normally heteromeric, with the $\alpha1$ subunit being associated with a $Ca_V\beta$ subunit and an $\alpha_2\delta$ subunit (for reviews see refs. 1–3; Fig. 75–1).

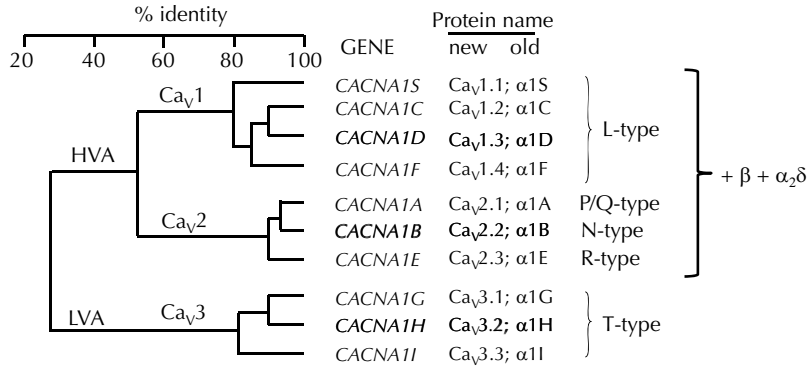

Figure 75–1. Dendrogram showing the similarity of calcium channel α1 subunit genes, with their nomenclature.

Ten mammalian α1 subunits (Fig. 75–1), four β subunits, and four $\alpha_2\delta$ subunits have been cloned. These are described in more detail below.

VOLTAGE-GATED CALCIUM CHANNELS

Discovery of Calcium Channels

A calcium conductance was first identified in crustacean muscle.[4,5] Calcium-dependent action potentials and calcium currents were then investigated in other invertebrate systems[6,7] and subsequently in mammalian systems, first in cardiac Purkinje fibers (e.g., ref. 8), cardiac ventricular cells[9] and subsequently in other excitable cells**.** The identification of 1,4-dihydropyridines (DHPs) and other calcium antagonists as blockers of muscle calcium channels[10] was a major therapeutic advance, but also had the by-product of aiding the isolation of purified Ca_v channels. In skeletal muscle, there is a very high concentration of DHP receptors, representing L-type calcium channels, situated in the T-tubules. Muscle depolarization results in large gating currents but anomalously low calcium flux, which is now explained by the very slow activation of the ionic currents. For this reason, little or no Ca^{2+} passes across the T-tubule membrane during a single action potential. The study of how these skeletal muscle calcium channels are now thought to couple by a direct mechanical process to the release of intracellular Ca^{2+} from the sarcoplasmic reticulum has enhanced our understanding of excitation-contraction coupling in muscle.[11]

Calcium Channel Purification

DHP receptor complexes were first purified from T-tubules because of their relative abundance.[12,13] Three major bands were initially identified: α, β, and γ. Under reducing conditions, the purified skeletal muscle DHP receptor complex was found to contain five components, which were termed α_1 (~175 kDa), α_2 (~150 kDa), β (~54 kDa), δ (17–25 kDa), and γ (~32 kDa), in an approximately stoichiometric ratio. The α1 subunit was shown to bind ^{3}H-DHP ligands, and thus was identified as the pore-forming subunit. In all of the HVA calcium channels in which it has been studied, the $Ca_V\alpha1$ subunit copurifies with a cytoplasmic β subunit ($Ca_V\beta$) and an extracellular $Ca_V\alpha_2$ subunit, which is associated with a membrane-anchored δ subunit.[13–16] In these studies, the association of the $\alpha_2\delta$ subunit with the complex was found to be looser than that of the β subunit.

Calcium Channel Subunit Gene Cloning

Following identification of the α1 subunit as the DHP receptor, by virtue of its ability to bind ^{3}H-azidopine, cloning of its cDNA was accomplished, initially from skeletal muscle,[13] and subsequently from heart, by homology with

the skeletal muscle sequence.[17] Hydropathy analysis indicated that the α_1 subunits have 24 putative transmembrane segments, arranged into four homologous repeated domains, with intracellular linkers and N and C termini. The 10 cloned α_1 subunits all have specialized functions and distributions (Fig. 75–1; for review of nomenclature, see ref. 18). The four members of the Ca_V1 family are all L-type channels, with $Ca_V1.1$ being the skeletal muscle isoform and $Ca_V1.2$ being particularly prevalent in cardiac muscle, whereas the more recently cloned $Ca_V1.3$ and $Ca_V1.4$ are activated at lower voltage thresholds and have a more restricted distribution. All the Ca_V1 family channels are sensitive to the 1,4-DHPs. $Ca_V2.1$ (initially termed α_1A) is the molecular counterpart of P/Q-type calcium channels,[19] and $Ca_V2.2$ or α_1B,[20] is the molecular counterpart of the neuronal N-type calcium channels. $Ca_V2.3$ or α_1E shows more inactivation than the other HVA channels cloned[21] and is thought to contribute to the molecular counterpart of the R-type calcium current. The Ca_V3 group of channels (the molecular counterpart of the T-type channels) are clearly divergent in terms of structure from the HVA channels (for review, see ref. 22).

THE $\alpha_2\delta$ SUBUNITS

$\alpha_2\delta$ Gene Cloning

Four mammalian $\alpha_2\delta$ subunit genes have been cloned; these are skeletal muscle $\alpha_2\delta$-1,[23] $\alpha_2\delta$-2,[24] $\alpha_2\delta$-3,[25] and $\alpha_2\delta$-4.[26] Several other similar genes have been identified[27] but have not yet been shown to function as $\alpha_2\delta$ subunits.

Classical Topology and Posttranslational Processing of $\alpha_2\delta$ Subunits

The topological organization of the $\alpha_2\delta$ protein was first determined for $\alpha_2\delta$-1 and has been thought to be similar in all four $\alpha_2\delta$ subunits that have been cloned (for reviews, see refs. 1 and 2). Biochemical studies on purified skeletal muscle DHP receptors, examined under reducing and nonreducing conditions, showed that the α_2 subunit is disulfide-bonded to the smaller δ subunit.[12,14,28] Following the initial cloning of the gene encoding $\alpha_2\delta$-1 and N-terminal sequencing of the δ peptide, it was realized that α_2 and δ are expressed from the same gene, encoding the $\alpha_2\delta$ preprotein,[29] which is then posttranslationally cleaved into α_2 and δ.[30] by an unknown protease. The α_2 and δ moieties then remain associated by one or more disulfide bonds (Fig. 75–2).

Novel Topology: Evidence That $\alpha_2\delta$ Subunits Can Form GPI-Anchored Proteins

The $\alpha_2\delta$ subunits have an exofacial N terminus, as indicated by the presence of an N-terminal signal sequence, that directs the protein into the lumen of the endoplasmic reticulum, where the signal sequence is cotranslationally cleaved (Fig. 75–2). The $\alpha_2\delta$ subunits were first identified to be type I transmembrane proteins since they also have a C-terminal hydrophobic domain. However, in various proteomic prediction programs, some of these $\alpha_2\delta$ proteins are strongly predicted to be glycosyl-phosphatidylinositol (GPI)-anchored.[31–33] We have now obtained evidence consistent with the hypothesis that both heterologously expressed and endogenous $\alpha_2\delta$ proteins form GPI-anchored rather than transmembrane proteins.[33] All the $\alpha_2\delta$ proteins that we have examined ($\alpha_2\delta$-1, –2, and –3 are substrates for phosphatidyl-inositol phospholipase C enzymes (purified from bacteria or trypanosomes), which act extracellularly, to release both heterologously expressed and endogenous $\alpha_2\delta$ from the plasma membrane. This treatment of cells with these enzymes also inhibits calcium currents in cells in which $\alpha_2\delta$ is expressed.[33]

Structure of $\alpha_2\delta$ Subunits in Calcium Channel Complexes

Very little structural information is available on $\alpha_2\delta$ subunits, although all contain a von Willebrand factor A (VWA) domain[27] and two Cache domains.[34] In general, VWA domains are involved in protein–protein interactions, particularly between extracellular matrix proteins via a metal ion-dependent adhesion site

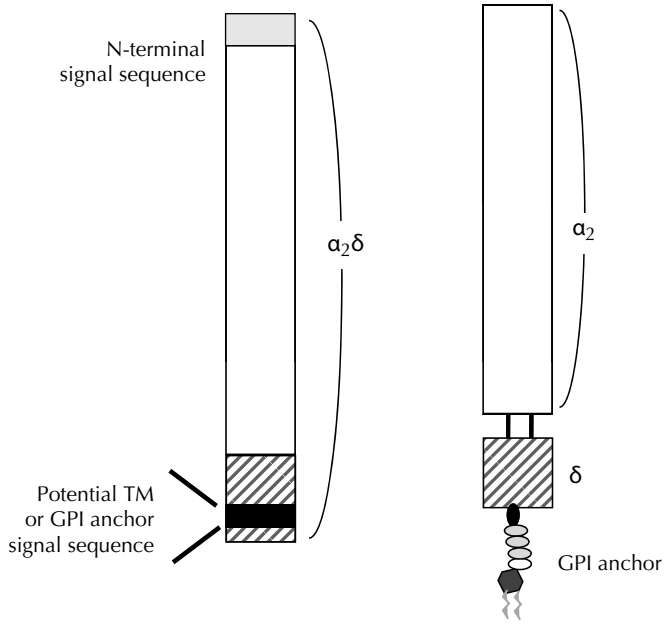

Figure 75–2. Diagram of $\alpha_2\delta$ subunit structure and posttranslational modification.

(MIDAS) motif.[27] We showed that mutation of MIDAS in the VWA domain markedly reduced the functionality of $\alpha_2\delta$ subunits.[35] The VWA domains of $\alpha_2\delta$-2 [35] and $\alpha_2\delta$-1[36] have been subjected to homology modeling, because many template domains are available. The $\alpha_2\delta$ subunit has also been identified in single-particle electron microscopic studies of calcium channel complexes purified from skeletal muscle[37,38] and cardiac muscle.[39]

Function of $\alpha_2\delta$ Subunits in Calcium Channel Complexes

The $\alpha_2\delta$ subunits enhance the forward trafficking of the α1 calcium channel subunits and decrease their turnover at the plasma membrane.[35,40] They also influence the biophysical properties of the channels, increasing the inactivation rate to varying extents. In some studies, hyperpolarization of steady-state inactivation has been observed, as well as an increase in its voltage dependence.[33,35,41] The loss of $\alpha^2\delta$ subunits, as in the naturally occurring $\alpha_2\delta$-2 knockout strains of mice, *ducky* and *ducky*^{2J},[42] results in a reduction in calcium channel currents in Purkinje neurons, where $\alpha_2\delta$-2 is normally strongly expressed. This is accompanied by a marked reduction in both spontaneous and evoked Purkinje cell firing.[43] It was originally mentioned, in several reviews of $\alpha_2\delta$ proteins, that mice in which the more ubiquitously expressed $\alpha_2\delta$-1 is knocked out have a neonatal-lethal phenotype (e.g., refs. 44 and 45). However, a viable $\alpha_2\delta$-1 knockout has recently been published, with a cardiac phenotype, showing reduced cardiac calcium currents and decreased myocardial contractility.[46] The mechanism(s) involved in the function of $\alpha_2\delta$ subunits with respect to calcium channel trafficking and function are still unclear, although we have determined that this process involves their VWA domain.[35] Although the exact site at which the $\alpha_2\delta$ subunits intervene in the calcium channel trafficking process remains to be established, it is assumed that they interact with one or more exofacial domains of the channel α1 subunit. For example, it has been found that the α_2 subunit of $\alpha_2\delta$-1 binds to domain III of $Ca_V1.1$ as one site of interaction.[47,48] Evidence was also obtained previously that the transmembrane segment of δ interacts with α1 subunits.[47,49] However, this needs to be reconsidered in the light of our finding that $\alpha_2\delta$ subunits form GPI-anchored proteins.[33]

Distribution and Function of $\alpha_2\delta$ Proteins in Specific Tissues

SKELETAL MUSCLE

In skeletal muscle T-tubules, $\alpha_2\delta$-1 is found in association with the L-type calcium channel complex including $Ca_V1.1$, β1a, and γ1.[23] In the T-tubule junction with the sarcoplasmic reticulum, the DHP receptors form a characteristic tetrad structure associated with ryanodine receptors on the sarcoplasmic reticulum.[50,51] However, it has been found that although partial loss of $\alpha_2\delta$-1 using small interfering RNA (siRNA) caused a significant increase in the rate of activation of the L-type Ca^{2+} current in myotubes, it had little or no effect on skeletal muscle excitation-contraction coupling.[52] More extensive knockdown, using viral infection of siRNA in myotubes, confirmed the effect on current kinetics but found that the size and spacing of tetradic particles were unaffected by the loss of $\alpha_2\delta$-1, indicating that the visible particles probably represent the α1S ($Ca_V1.1$) subunit.[53] Further, there was a complete loss of excitation-coupled calcium entry during potassium chloride (KCl) depolarization and a more rapid decay of Ca^{2+} transients. However, it was found that $\alpha_2\delta$-1 was not necessary for myotube growth, or for differentiation from myoblasts to form myotubes, or in the expression levels or targeting of $Ca_V1.1$ to the calcium release units apposed to ryanodine receptors.[53] In contrast, another study of developing myocytes showed that $\alpha_2\delta$-1 was concentrated at the ends of the myocytes. In that study, when the expression of $\alpha_2\delta$-1 was reduced with siRNA, migration, attachment and spreading of myoblasts were impaired, while the L-type calcium current remained unaffected.[54]

CARDIAC AND SMOOTH MUSCLE

The $\alpha_2\delta$-1 subunit is strongly expressed in cardiac and smooth muscle and is likely to be the main $\alpha_2\delta$ subunit associated with calcium channels in these tissues.[55,56] It was also found that the $\alpha_2\delta$-4 subunit transcript was expressed in cardiac muscle, although very little $\alpha_2\delta$-4 protein was observed in cardiac tissue.[26]

NERVOUS SYSTEM

The $\alpha_2\delta$-1, $\alpha_2\delta$-2, and $\alpha_2\delta$-3 subunits are widely expressed in brain, with $\alpha_2\delta$-1 being expressed in many neuronal cell types.[57] The $\alpha_2\delta$-1 protein is mainly present in presynaptic terminals, and to a much lower extent in cell bodies under physiological conditions.[58,59] This is illustrated in Fig. 75–3 with respect to the distribution of $\alpha_2\delta$-1 in the hippocampus, where it is clearly absent from the main cell body layers. The expression of $\alpha_2\delta$-1 was also found to be correlated with excitatory rather than inhibitory neurons,[57] and it is strongly expressed in dorsal root ganglion neurons.[59] In contrast, $\alpha_2\delta$-2 expression is more restricted and appears to correlate with GABAergic (gamma-aminobutyric acid) neurons, including cerebellar Purkinje neurons, where it is strongly expressed.[42,57] The $\alpha_2\delta$-3 protein is widely expressed throughout the brain, particularly in the caudate-putamen.[57] In contrast, $\alpha_2\delta$-4 protein is expressed in specific endocrine tissues and at a low level in the brain.[26] It is also expressed in the retina, where its mutation results in a form of night blindness.[60]

Splice Variants of $\alpha_2\delta$ Subunits

It was originally noted that the main $\alpha_2\delta$-1 subunit splice variant expressed in rat brain was different from that in skeletal muscle.[61] Three alternatively spliced regions have been identified from multiple sequence alignments, termed *region A*, *region B*, and *region C*, and five different transcripts consisting of different combinations of these alternatively spliced regions were originally found in mouse brain, skeletal muscle, heart, smooth muscle, and aorta[62] (Fig. 75–4). Other splice variants have been mentioned in abstract form.[63] Differences in the ability of different splice variants to bind ^{3}H-gabapentin have been mentioned in these publications, but it remains unknown whether changes in alternative splicing may correlate with disease states or with the therapeutic efficacy of $\alpha_2\delta$ ligand drugs. A number of splice variants of the other $\alpha_2\delta$ subunits have also been described.[26,64]

Membrane Localization, Trafficking, and Endocytosis of $\alpha_2\delta$ Subunits

Glycosyl-phosphatidylinositol anchoring has major implications for the structure and function

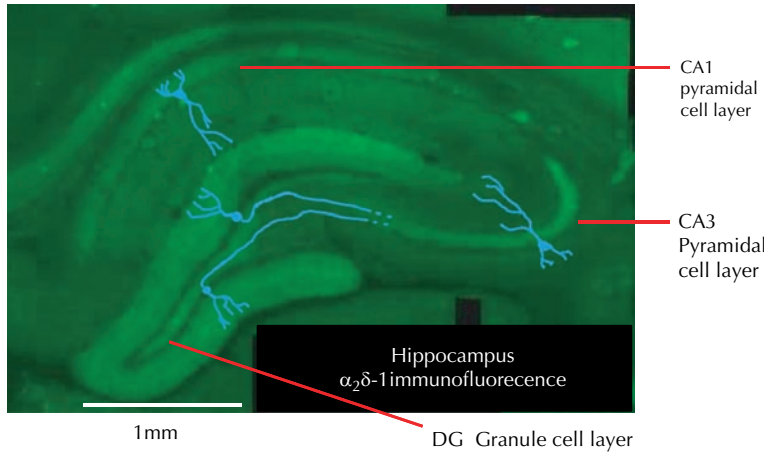

Figure 75–3. Localization of $\alpha_2\delta$-1 in a section of rat hippocampus. The section was 25 μm thick and was prepared and $\alpha_2\delta$-1 was visualized as previously described.[59] Note the lack of $\alpha_2\delta$-1 staining in the hippocampal granule and pyramidal cell body layers. The scale bar is 1 mm.

of $\alpha_2\delta$ proteins, but it also affects their membrane localization and their intracellular trafficking and endocytosis, since these proteins cannot signal across the lipid bilayer to interact directly with sorting proteins.[65,66] Moreover, it explains the marked localization of $\alpha_2\delta$ proteins in a cholesterol-rich detergent-resistant membrane (DRM) fraction, also termed *lipid rafts*, that we have noted previously.[67] Lipid raft localization is shown by many proteins that are GPI-linked to the membrane, for example prion proteins, thy-1, neural cell adhesion molecule (N-CAM), and carcinoembryonic antigen (CEA). Lipid rafts may represent distinct membrane microdomains (for review, see ref. 68), although heterogeneity in the GPI-anchored protein distribution has also been demonstrated,[69] which may be in part a result of variation in the specific chemistry of different GPI anchors.[70] Furthermore, some proteins have both GPI-anchored and transmembrane forms,[71] and our evidence does not yet preclude this possibility for $\alpha_2\delta$ subunits.

Many GPI-anchored proteins are endocytosed by a route involving GPI-enriched early endosomal compartments (GEECs) that is independent of the clathrin pathway.[66,72] The GEECs are cholesterol-rich compartments, and we have recently found that the $\alpha_2\delta$ subunits show constitutive endocytosis.[41,59,73]

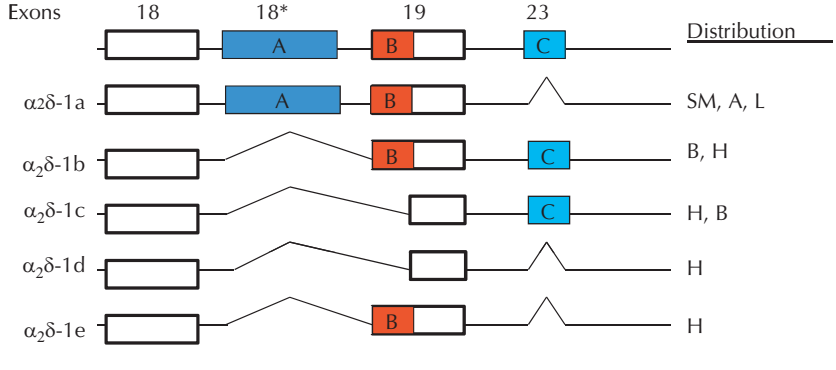

Figure 75–4. Regions of splice variation in $\alpha_2\delta$-1; details are taken from ref. 62. Region A is encoded by a separate exon, here called 18*. Region B is part of exon 19, generated by an alternative splice site. Main tissues showing expression of these splice variants involving regions A, B, and C are given. SM, smooth muscle; A, aorta; L, lung; B, brain; H, heart.

Presynaptic Localization and Transport of $\alpha_2\delta$ Subunits

As described above, $\alpha_2\delta$-1 is mainly associated with terminal fields rather than cell bodies.[58] With regard to $\alpha_2\delta$-3, where similar immunohistochemical studies are lacking, mutations in the *Drosophila* $\alpha_2\delta$-3 subunit have revealed it to be the likely binding partner for the cacophony calcium channel that is involved in presynaptic vesicle release and calcium channel expression at active zones.[74] This suggests that $\alpha_2\delta$-3 has a role in targeting calcium channels to correct presynaptic sites. It has also been found that in *Caenorhabditis. elegans* the $\alpha_2\delta$ subunit (UNC36) is required for the correct presynaptic localization of the Ca_V2 calcium channel (UNC2).[75]

In the peripheral nervous system, $\alpha_2\delta$-1 is strongly expressed in dorsal root ganglion neurons (DRGs), particularly in the small nociceptors.[58,76] We have utilized spinal nerve ligation (SNL) as a rodent model of neuropathic pain to study the distribution of $\alpha_2\delta$-1, following its upregulation in DRGs in vivo as a consequence of SNL.[76] Our results showed that the increase in $\alpha_2\delta$-1 protein occurs in all DRG neuronal subtypes. We also observed an elevation within both myelinated and nonmyelinated DRG axons on the side ipsilateral to the ligation.[76] This increase was rapid, starting on the second day after ligation, in the dorsal roots that terminate in the spinal cord dorsal horn. We also found accumulation of $\alpha_2\delta$-1 proximal to the ligation site—the first direct evidence for $\alpha_2\delta$-1 trafficking toward the periphery.[59] We also observed a large increase in $\alpha_2\delta$-1 immunofluorescence in both the superficial and deeper laminae of the dorsal horn, in accordance with our finding that $\alpha_2\delta$-1 was increased in all DRG neurons.[59] Immunoelectron microscopy showed that the $\alpha_2\delta$-1 protein was predominantly presynaptic, being found on excitatory nerve terminals in the spinal cord. However, some $\alpha_2\delta$-1 immunoparticles were also observed both in endocytic vesicles within dendritic structures and at the dendritic plasma membrane. Our results indicate that $\alpha_2\delta$-1 subunits are trafficked from the site of synthesis to the plasma membrane of the DRG presynaptic terminals. However, the upregulation of $\alpha_2\delta$-1 in damaged sensory neurons in various neuropathic pain models,[59,77] and the fact that the elevated $\alpha_2\delta$-1 is transported not only centrally but also peripherally,[59] suggest that it might affect other processes, such as neuronal regeneration and plasticity, as well as calcium channel trafficking.

Involvement of $\alpha_2\delta$ Subunits in Synaptogenesis and Other Processes

Other roles for $\alpha_2\delta$-1 subunits unrelated to calcium channel function have recently been proposed. One suggestion that $\alpha_2\delta$ subunits may have multiple roles comes from the finding that the genes for both $\alpha_2\delta$-2[24] and $\alpha_2\delta$-3[78] have potentially been implicated in tumor susceptibility and tumor growth. As described above, there is disagreement about whether $\alpha_2\delta$-1 subunits are involved in development and migration of myotubes, separate from their role in the calcium channel complex.[53,54] However, $\alpha_2\delta$ subunits are only loosely associated with calcium channel complexes, and a proportion of $\alpha_2\delta$ subunits can be isolated separately by column chromatography.[79] This supports the possibility that these proteins have other roles.

The $\alpha_2\delta$-1 and $\alpha_2\delta$-3 subunits have also been found to have a role in synaptogenesis, which has been described to be independent of their association with calcium channels.[80,81] The $\alpha_2\delta$-1 protein has been found to be one of the binding partners of the extracellular matrix proteins of the thrombospondin (TSP) family,[80] although TSPs also bind to a number of other proteins and mediate many processes, both in the nervous system and elsewhere.[82] It was also found that $\alpha_2\delta$-1 was required postsynaptically for TSP- and astrocyte-induced synapse formation.[80] This potential postsynaptic function of $\alpha_2\delta$-1 is in contrast to the predominantly presynaptic localization of $\alpha_2\delta$-1 in adult mammalian nervous tissue.[58]

Drosophila $\alpha_2\delta$-3 has also been shown to be required for synaptic stabilization of the *cacophony* calcium channel[74,83] and for synaptogenesis.[81] It is unknown whether it plays a similar role in mammalian brain and whether $\alpha_2\delta$-1 and $\alpha_2\delta$-3 have interchangeable functions.

The $\alpha_2\delta$ Subunits in Disease

EPILEPSIES

We have found that *ducky* and *ducky*^{2J} mice, which show a phenotype of cerebellar ataxia and absence epilepsy,[42,43,84] both have mutations in *cacna2d2.* These mutations both predict the expression of a C-terminally truncated protein, and this protein was detected in *ducky* mice.[84] The ataxic phenotype results primarily from the loss of $\alpha_2\delta$-2 in the cerebellar Purkinje cells, where it is strongly expressed[42] and from which the other $\alpha_2\delta$ subunits are largely absent. Another spontaneous mouse mutation, in *cacna2d2* (*entla*), encodes a mutant form of the $\alpha_2\delta$-2 protein with an intact C terminus. This mutant mouse also shows generalized epilepsy,[85] as does a targeted knockout of *cacna2d2.*[86] These mutations are all recessive, with the heterozygotes showing no significant behavioral effects.[42] To date, no human mutations in $\alpha_2\delta$ subunits have been reported to be associated with epileptic phenotypes.

NEUROPATHIC PAIN

As described above, experimental nerve injury is known to result in an increase in the level of $\alpha_2\delta$-1 mRNA in the damaged sensory neurons (DRGs), shown by in situ hybridization,[87] microarray analysis,[88] and quantitative polymerase chain reaction (PCR).[59] There is a corresponding increase in $\alpha_2\delta$-1 protein in DRGs and spinal cord, as determined by Western blot analysis[77] and immunohistochemistry.[59] Furthermore, $\alpha_2\delta$-1-overexpressing mice show a neuropathic phenotype of hyperalgesia and tactile allodynia in the absence of nerve injury,[89] indicating that $\alpha_2\delta$-1 is instrumental in the excitability of DRG neurons and the expression of neuropathy.

NIGHT BLINDNESS

Mutation in the *CACNA2D4* gene (encoding $\alpha 2\delta$-4 subunits) can lead to dysfunction of photoreceptors, resulting in certain forms of night blindness. A spontaneous mouse mutation and human mutations in this gene have been identified, both showing similar phenotypes of autosomal recessive cone dystrophy and night blindness.[60,90] When the gene encoding $\alpha_2\delta$-4 was cloned, it was suggested that it had limited distribution in certain cell types including pituitary, adrenal gland, colon, and fetal liver.[26] However, Northern blot analysis detected widespread distribution of $\alpha_2\delta$-4 transcripts in mouse tissue.[60] Nevertheless, the phenotype resulting from $\alpha_2\delta$-4 loss or dysfunction appears to be confined to the retina, possibly because of the lack of compensation by other $\alpha_2\delta$ subunits in photoreceptors.

MECHANISM OF ACTION OF THE GABAPENTINOID DRUGS ON $\alpha_2\delta$ SUBUNITS

History of Gabapentinoid Drug Development

Gabapentin (2-[1-(aminomethyl)cyclohexyl] acetic acid) and pregabalin (*S*(+)-3-isobutyl GABA) were synthesized as rigid lipophilic analogs of the inhibitory neurotransmitter GABA, with the intention of mimicking the function of this neurotransmitter and suppressing excitatory neurotransmission.[91] However, despite being shown to be efficacious antiepileptic drugs, both in animal models[92] and in clinical studies (for review, see ref. 45), their mechanism of action remained elusive for many years. No clear binding of these drugs to $GABA_A$ or $GABA_B$ receptors was seen in radioligand binding studies (for review, see ref. 45). Although functional effects of gabapentin attributed to activation of $GABA_B$ receptors were reported,[93] no direct evidence that gabapentin activated $GABA_B$ receptors was obtained.[94,95] There is no evidence from in vivo studies that the antiepileptic or antiallodynic effects of these drugs are produced via $GABA_B$ receptors (for review, see ref. 45). Although pregabalin and gabapentin were found to increase glutamic acid decarboxylase activity in vitro, this only occurred at very high concentrations.[96] Nevertheless, in rats, gabapentin was shown to increase GABA turnover in several brain regions.[97] However, as reviewed recently,[45] neither pregabalin nor gabapentin appears to mimic GABA or enhance the action of GABA pharmacologically, suggesting that direct or indirect effects on GABA receptors do not contribute significantly to their pharmacological actions. Furthermore, pregabalin and

gabapentin did not inhibit GABA transport in vitro, as would be expected of an inhibitor of GABA uptake.[98] However, both gabapentin and pregabalin are zwitterions at neutral pH and utilize the large neutral amino acid transporter *system L* for uptake across cell membranes.[91] This adds a degree of complexity to structure–activity relationships for these compounds.

Effects of Gabapentinoids on Synaptic Transmission and Transmitter Release

Acute inhibitory effects of gabapentinoid drugs on excitatory transmitter release and synaptic transmission have been observed in some but not all *in vitro* systems (reviewed in refs. 2 and 45). Furthermore, there is some indirect evidence that gabapentin increased GABA release.[99] In a study in the trigeminal nucleus, an inhibitory effect of gabapentin was only observed on a component of glutamate release that was enhanced following protein kinase C activation.[100] Of interest, calcium channel insertion into the plasma membrane has been shown to be increased by protein kinase C activation.[101] It is possible that gabapentinoid drugs have differential effects on calcium currents in presynaptic terminals resulting in acute inhibition, or that calcium channel turnover is higher in presynaptic terminals, so that effects on calcium channel trafficking are observed more acutely. Thus, gabapentinoid drugs might act more or less rapidly, depending on the interplay between these different processes. While behavioral therapeutic effects of gabapentinoid drugs may be observed acutely,[102] this is not always the case.[103–105]

Identification of the Gabapentin Receptor in Brain as the $\alpha_2\delta$-1 Subunit

Purification of the ^{3}H-gabapentin binding site from pig brain led to its identification by proteomic methods as the $\alpha_2\delta$-1 subunit of Ca_v channels. N-terminal peptide sequencing of the purified protein gave the sequence EPFPSAVTIK.[79] This was initially very surprising, since these proteins are unrelated to GABA function. However, ^{3}H-gabapentin was shown to bind to purified $\alpha_2\delta$-1 with an affinity of about 13 nM, and expression of recombinant $\alpha_2\delta$-1 revealed it also to bind ^{3}H-gabapentin.[79] This affinity has been shown to vary between 7 and 72 nM, depending on the source and purity of the preparation.[106,107] ^{3}H-gabapentin was also subsequently found to bind to $\alpha_2\delta$-2 with an affinity of 156 nM.[106] The variability in reported affinities may depend on the lipid environment and the state of purification of the $\alpha_2\delta$-1 and $\alpha_2\delta$-2 proteins, as we have found that the affinity of ^{3}H-gabapentin binding to $\alpha_2\delta$ from mouse cerebellum (predominantly $\alpha_2\delta$-2) increases from a K_D of ~385 nM in membranes to ~80 nM in lipid raft preparations.[67] The equivalent values for $\alpha_2\delta$-2 expressed in Cos-7 cells were a K_D of ~470 nM in membranes and ~50 nM in the lipid raft fraction.[67] Others have found that the affinity of ^{3}H-gabapentin binding to $\alpha_2\delta$-1 increases on dialysis of the purified protein, and this was attributed to the removal of a heat-stable factor.[108] This might be a large neutral amino acid, since these were found to compete for binding to $\alpha_2\delta$ subunits,[79] or it might be a more complex molecule. Interestingly, pregabalin was found to be slightly more potent in displacing ^{3}H-gabapentin from $\alpha_2\delta$-2 (70 nM) than from $\alpha_2\delta$-1 (106 nM).[106]

It has recently been shown that the binding of gabapentin and pregabalin to $\alpha_2\delta$-1 subunits is essential for their therapeutic effect in neuropathic pain.[102] In this study, a knockin mouse was generated with a mutation (R217A) that abrogated ^{3}H-gabapentin binding to $\alpha_2\delta$-1. These mice developed neuropathic pain normally in response to chronic constriction injury, but this pain was not sensitive to treatment with the gabapentinoid drugs. Similar studies using these R217A $\alpha_2\delta$-1 mice and mice with the equivalent mutation in $\alpha_2\delta$-2 are urgently needed in the epilepsy field in order to clarify further the mechanism of action of the gabapentinoids as antiepileptic drugs.

Acute and Chronic Effects of Gabapentinoids on Calcium Currents

Some initial studies reported either no effect[109] or small acute inhibitory effects of gabapentin on HVA calcium channel currents in

brain neurons[110] and DRG neurons.[111,112] Furthermore, the inhibitory effect of gabapentin on DRG neurons was observed to be dependent on culture conditions.[111] However, in our studies, we found no reproducible acute effects of gabapentin at 100 μM on Ba^{2+} currents in cerebellar Purkinje neurons, although they contain $\alpha_2\delta$-2 as their main $\alpha_2\delta$ subunit,[67] and no effect of up to 1 mM gabapentin on Ba^{2+} currents in DRG neurons or on transfected cells.[41] It was also reported that there was no effect of gabapentin on calcium channel currents in mouse DRG neurons, although when DRGs from $\alpha_2\delta$-1-overexpressing mice were used, they were sensitive to inhibition by gabapentin.[89]

In a recent study, we showed that chronic application of gabapentin markedly reduced cell surface localization of $\alpha_2\delta$ and α1 subunits, and also calcium channel currents, both in expression systems and in DRG neurons.[41] This effect did not occur when $\alpha_2\delta$ subunits were not expressed or when mutant $\alpha_2\delta$ subunits that do not bind gabapentin were coexpressed,[41] suggesting that gabapentin affects the trafficking function of $\alpha_2\delta$ subunits. Accordingly, we also found that chronic application of pregabalin, at the same time as it alleviated neuropathic pain, markedly reduced the trafficking of $\alpha_2\delta$-1 to presynaptic terminals in vivo, thereby inhibiting the function of presynaptic calcium channels[59]

We have found that gabapentinoid drugs do not affect the constitutive endocytosis of $\alpha_2\delta$-1[59] or $\alpha_2\delta$-2.[113] In contrast, gabapentin inhibits post-Golgi forward trafficking of the $\alpha_2\delta$-2 subunit in a manner that is prevented by dominant-negative Rab11, which disrupts trafficking through the recycling endosome compartment.[113] These findings indicate that gabapentinoid drugs may disrupt the interaction between $\alpha_2\delta$ subunits and sorting proteins in this compartment, and that this may represent a rate-limiting step in calcium channel trafficking.

Furthermore, we have found that the gabapentin analog, pregabalin, reduces the ability of $\alpha_2\delta$-1, upregulated in neuropathic pain, to be trafficked from DRG neurons to presynaptic terminals *in vivo*.[59] Both our *in vivo* and *in vitro* data point to a mechanism of action in which the gabapentinoid drugs would inhibit trafficking of the upregulated $\alpha_2\delta$-1 subunits within DRGs following the development of neuropathic pain, and would therefore inhibit the function of presynaptic calcium channels in the dorsal horn, making this a unique mode of action. The extent of this elevation of $\alpha_2\delta$-1 protein in the dorsal horn but not in the DRGs was significantly reduced by chronic treatment with pregabalin for 8 days following spinal nerve ligation, indicating that pregabalin interferes with the transport of $\alpha_2\delta$-1 to its terminal zones.[59]

Gabapentin and pregabalin are effective treatments for neuropathic pain, including diabetic neuropathy and postherpetic neuralgia, with relatively slow onset of action[45,114] and no effect on acute pain.[115] In several studies, the effects of these drugs were observed, or the response was augmented, only after multiple doses,[59,105,114,115] which might be a result of pharmacokinetics or of a slow mechanism of action. This is compatible with a potential effect of these drugs on calcium channel trafficking.[41,59]

Gabapentin was also reported to disrupt the in vitro interaction between $\alpha_2\delta$-1 and TSPs. In this way it has been found to disrupt synaptogenesis, although it did not affect the stability of preformed synapses.[80] This could have major clinical implications for chronic use of this drug, if confirmed.

CONCLUSIONS AND FUTURE RESEARCH

The $\alpha_2\delta$ proteins are classically known as auxiliary subunits of Ca_v channels, but they may have other functions involving binding to the extracellular matrix. The $\alpha_2\delta$-1 and $\alpha_2\delta$-2 proteins represent the binding sites for the gabapentinoid drugs gabapentin and pregabalin. The $\alpha_2\delta$-1 subunits are strongly upregulated in DRG neurons in experimental models of neuropathic pain, and this protein is trafficked from the cell bodies to the presynaptic terminals in the spinal cord. Several parallels can be drawn between neuropathic pain and epileptic seizures in terms of increased neuronal excitability and the fact that certain drugs are effective in the treatment of both conditions. However, there is, as yet, no evidence that any of the $\alpha_2\delta$ proteins are up- or downregulated in seizure models or following seizure activity. Our evidence suggests that the mechanism of action

of the gabapentinoid drugs in the alleviation of neuropathic pain involves in part an inhibition of $\alpha_2\delta$-1 subunit trafficking and associated calcium channel trafficking. However, these gabapentinoid drugs are also antiepileptic, and evidence suggests that $\alpha_2\delta$-2 may play a role in this disease, at least from rodent studies, since mutations in $\alpha_2\delta$-2, and also its targeted knockout, give rise to epilepsy phenotypes in mice. Nevertheless, there is, as yet, no direct evidence whether either $\alpha_2\delta$-1 or $\alpha_2\delta$-2 is a specific target for the gabapentinoid drugs in the alleviation of epileptic seizures. This will require the examination of whether the antiepileptic efficacy of gabapentinoid drugs is reduced in knockin mice with the point mutations described in $\alpha_2\delta$-1 or $\alpha_2\delta$-2 such that these proteins no longer bind the gabapentinoid drugs.

ACKNOWLEDGMENTS

I would like to thank the MRC and BBSRC for funding, and all the people in my laboratory who have contributed to our work on the $\alpha_2\delta$ subunits.

Chapter 76

Targeting SV2A for Discovery of Antiepileptic Drugs

Rafal M. Kaminski
Michel Gillard
Henrik Klitgaard

Levetiracetam (LEV) is a novel antiepileptic drug (AED) displaying a unique preclinical profile. Despite initial findings showing LEV to be active against audiogenic seizures in mice,[1] later studies failed to show significant activity in classical seizure screening tests such as maximal electroshock (MES) and pentylenetetrazole (PTZ).[2] Interestingly, the same study reported significant seizure protection against fully amygdala-kindled seizures in rats.[2] This unique profile associated with a wide safety margin has also been confirmed in later studies utilizing a range of epilepsy models, including amygdala kindling.[3] Furthermore, LEV significantly inhibited the development of seizure kindling,[4] which may be consistent with its potential antiepileptogenic effect.[5] This unique profile triggered significant interest in unraveling the molecular mechanism of action of LEV. Numerous studies explored the interaction of LEV with mechanisms known to account for the antiseizure activity of established AEDs including GABAergic (gamma-aminobutric acid) and glutamatergic neurotransmission and inhibition of voltage-gated Na^+ and Ca^{2+} channels.[6–8] None of these studies succeeded in identifying any major effects of LEV. In contrast, pioneering studies at UCB more than 15 years ago resulted in the identification of a brain-specific LEV binding site (LBS) for [^{3}H]-LEV that was not shared with any other AED.[9] This breakthrough finding, combined with the later identification of LBS, provided an important rationale to pursue drug discovery efforts aimed at identifying new high-affinity ligands for this novel binding site with antiepileptic properties potentially superior to those of LEV.[10,11] In that context, approximately 12,000 compounds were screened in vitro for binding affinity to LBS; 900 compounds were examined for seizure protection in audiogenic-susceptible mice, and 30 compounds were

characterized broadly in a variety of animal models of seizures and epilepsy. Out of these efforts, two lead candidates, seletracetam and brivaractam, were discovered and underwent clinical testing.[12] Due to a more potent and complete suppression of seizures than provided by LEV in animal models mimicking both partial and generalized seizures, brivaracetam was finally selected for further clinical studies in epilepsy.[13,14] Analysis of the two initial Phase III add-on studies indicated significant efficacy of brivaracetam; however, different results were obtained, depending on patient subpopulations and doses tested (UCB press release, April 28, 2009). Therefore, a confirmatory Phase III program is currently underway. The data accumulated with LEV and brivaracetam support the promise of LBS as a novel target for AED discovery. This highlights the strong interest in pursuing further studies aimed at unraveling the molecular nature and consolidating the validity of LBS as an AED target.

IDENTIFICATION OF SV2A AS THE BINDING TARGET FOR LEV

Our group has demonstrated that LBS is enriched in purified synaptic vesicle fraction. In fact, [^{3}H]ucb 30889, a derivative of LEV, labeled a synaptic vesicle protein with an approximate molecular mass of 90 kDa, which was consistent with the molecular mass of synaptic vesicle protein 2A (SV2A).[15] Binding studies were then performed in brain membranes obtained from SV2A transgenic mice to determine whether SV2A is indeed necessary for LEV binding. We found that [^{3}H]ucb 30889 binds only to membranes from SV2A$^{+/+}$ mice and not to those obtained from SV2A$^{-/-}$ mice.[15] Additional in vitro binding experiments performed in brain membranes confirmed that the B_{max} value for [^{3}H]ucb 30889 is reduced by 50% in SV2A$^{+/-}$ compared to the B_{max} value obtained with brain membranes of their wild-type littermates.[16] These observations were further corroborated by ex vivo binding experiments. Injection of LEV into both SV2A$^{+/+}$ and SV2A$^{+/-}$ mice revealed that that SV2A$^{+/-}$ mice have half of the protein available for binding compared to their wild-type littermates.[16] It should be noted, however, that both the radioligand dissociation constants (K_d) in brain membranes and the inhibitory concentration of 50% (IC_{50}) values of LEV calculated from the ex vivo binding curves were comparable between SV2A$^{+/+}$ and SVA$^{+/-}$ mice, confirming that SV2A binding properties were not modified in transgenic animals.[16] In fact, the binding characteristics of native SV2A in human and rat brain share very similar properties.[17] Furthermore, the binding affinities of several SV2A ligands are also comparable when measured in human brain, in rat brain, and when the recombinant human SV2A protein is expression in Chinese hamster ovary (CHO) cells.[17]

BIOLOGY AND FUNCTION OF SV2

A series of molecular studies described above has led to the identification of SV2A as the molecular correlate of LBS; however, the exact role of this protein in synaptic vesicle cycle and neurotransmitter release still remains elusive. Synaptic vesicle 2 proteins exist as three separate subtypes (SV2A, SV2B, and SV2C) and are an integral part of secretory vesicle membranes localized in different mammalian secretory organs, with the highest expression being observed in the brain.[18–21] Synaptic vesicle 2 proteins have 12 transmembrane domains and are members of the major facilitator superfamily (MFS) of membrane transporters.[18,22] LacY, the prototypic member of the MFS proteins, has been shown to exist under two major conformations, and the transition between these two conformations would allow the transport of lactose.[23] Similar changes in conformation have been proposed for other members of this family of proteins, which also includes neurotransmitter cotransporters.[24] The existence of two major conformations adopted by SV2A proteins in mouse brain was also recently reported by Lynch et al. using protein tomography.[25] One of the conformations has a funnel structure with the opening toward the cytosol, and the second displays a V shape with the opening toward the luminal space. Both conformational states of the protein were present in controls samples and samples treated with LEV, indicating that binding of LEV does not induce an obvious conformational change of SV2A and does not stabilize a specific conformational state of the protein.[25] This apparent lack of effect of LEV on the conformational states of

the SV2A protein may have been hampered by the limitations of the protein tomography technology and its resolution. In that context, as the functional role of SV2A is still largely unknown today, except for its probable involvement in synaptic vesicle cycling and in exo- or endocytosis processes, the downstream consequences of compounds binding to SV2A have not yet been elucidated. One could imagine that upon binding to SV2A, each compound could induce or stabilize a conformational change that would be more or less favorable in terms of function, meaning that compounds could show various degree of intrinsic efficacy. If proven correct, this hypothesis opens the possibility that newer SV2A ligands bearing higher intrinsic efficacy upon binding could either show clinical efficacy at lower levels of SV2A occupancy or even be efficacious in refractory patients.

Synaptic vesicle 2A is the best studied of the three SV2 proteins. To date, the majority of the information about its role in neuronal excitability has been obtained in experiments involving knockout mice.[21,26–29] It appears that SV2A is not crucial for vesicle biogenesis or synaptic function, but instead modulates the exocytosis of transmitter-containing vesicles.[26,28] Mice lacking SV2A are characterized by a decrease in the calcium-dependent exocytotic burst, which is a measure of the availability of neurotransmitter vesicles ready to release their content.[28] Moreover, lack of SV2A results in decreased action potential-dependent neurotransmission, while action potential-independent neurotransmission remains normal.[26,28] Very recent reports seem to confirm the hypothesis that SV2 proteins play an important role in calcium-dependent neurotransmission.[30–32] Other recent data seem to indicate that SV2A also plays a role in structural changes (volume increase) of synaptic vesicles upon loading with glutamate.[33] Finally, SV2A may influence synaptic vesicle priming regulated by binding of adenine nucleotides.[34]

VALIDATION OF SV2A AS A DRUG TARGET FOR AEDS

Affinity–Potency Correlation Studies

A key observation initially suggesting that SV2A is the target site for the principal mechanism of action of LEV was the fact that the anticonvulsant potency of selective SV2A ligands strongly correlated with their in vitro binding affinity. Such correlations between the in vitro affinity of ligands and their potency in inhibiting audiogenic seizures in mice have been documented using SV2A from rat cerebral cortex[9] and human recombinant SV2A expressed in cell lines.[15] Our more recent studies confirmed and extended these initial findings to other animal models of epilepsy, that is, corneal kindling and absence seizures in Genetic Absence Epilepsy Rats from Strasbourg (GAERS).[35] The anticonvulsant potency of SV2A ligands against audiogenic seizures correlated well with their in vitro binding affinity ($r^2 = 0.77$; $p < 0.001$; Fig. 76–1A). Similar correlation ($r^2 = 0.80$; $p < 0.01$) between anticonvulsant activity and SV2A protein in vitro binding was also observed in corneally kindled mice (Fig. 76–1B). Finally, correlation between in vitro SV2A binding and inhibition of spike-wave discharges in GAERS has also been documented ($r^2 = 0.72$; $p < 0.01$; Fig. 76–1C). It is important to note that despite differences in species and epilepsy models, that is, the audiogenic model, corneal kindling, and GAERS, the slopes and intercepts of regression lines were not statistically different. These experiments demonstrated the existence of a strong correlation between SV2A binding affinity and anticonvulsant potency in three distinct preclinical epilepsy models, which reinforced the significance of this molecular target in the mechanism of action of the tested ligands.[35] It also suggested that SV2A-related mechanisms are equally important in protection against seizures irrespective of the model. This was a surprising finding since different mechanisms and brain regions are likely to be involved in the generation of seizure activity observed in these models. Yet, it appears that SV2A protein is essential for neuronal synchronization fundamentally associated with every type of epileptiform activity. Taken together, these data strongly support the notion that targeting SV2A results in an anticonvulsant activity relevant for both partial and generalized epilepsy, and thereby can provide antiepileptic drug candidates with a potential for broad-spectrum clinical efficacy.[35]

Although these correlations were helpful in validating the main target for the anticonvulsant properties of selective SV2A ligands, in vitro data do not take into account individual pharmacokinetic properties of compounds

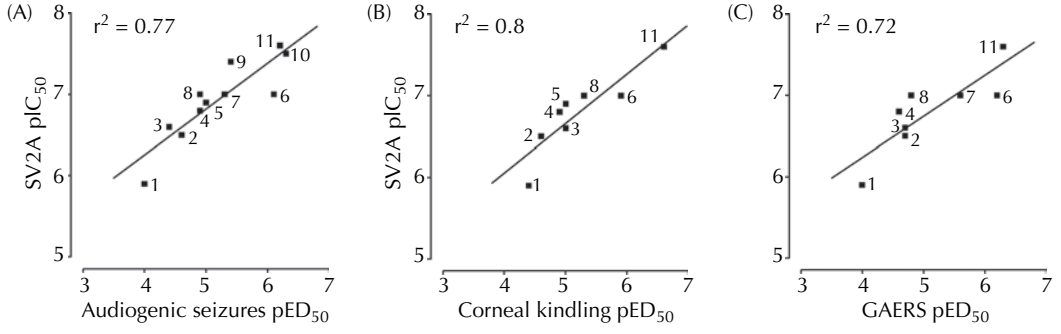

Figure 76–1. Correlation between binding affinity and protective potency of SV2A ligands against convulsive seizures (**A**, audiogenic seizures and **B**, corneal kindling) and (**C**) absence seizures in GAERS rats. Synaptic vesicle protein 2A binding affinities –log IC_{50} (pIC_{50}) were measured in rat brain membranes with the use of [^{3}H]ucb 30889. Antiseizure potencies, based on dose-response studies, are shown as –log ED_{50} (pED_{50}). From ref. 35.

such as protein binding, brain penetration, and metabolism that may affect the concentration of the drug in the compartment of interest and hence binding to its target. The fact that we observed good correlations between in vitro binding and in vivo efficacy indicates that most compounds tested were close structural analogues sharing very similar physicochemical and pharmacokinetic properties. Another major limitation of using in vitro binding data is the inability to predict the level of SV2A occupancy that compounds need to reach in vivo in order to afford seizure protection. To address these issues, we performed ex vivo binding experiments in which binding of compounds with selective affinity for SV2A was measured in vitro in brain homogenates from animals that have been administered the compounds prior to being sacrificed. When corrected for experimental conditions (essentially dilution factors), ex vivo binding data are comparable to in vivo binding data, as shown in Fig. 76–2, where ex vivo and in vivo binding dose-response curves of LEV overlap. The disadvantage of in vivo

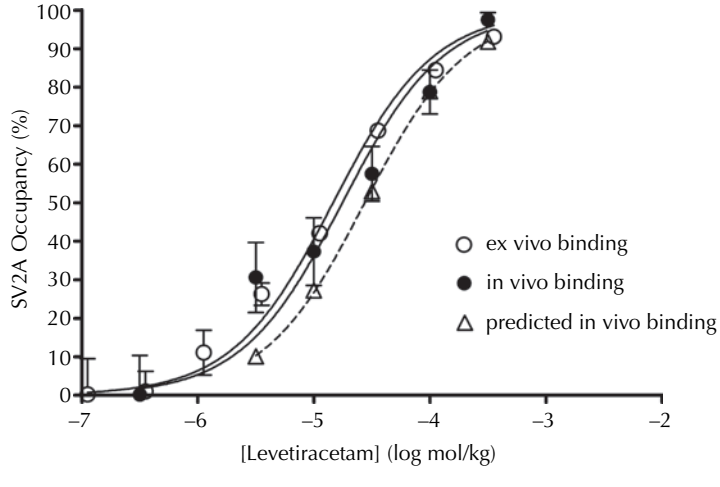

Figure 76–2. Ex vivo and in vivo binding of LEV to SV2A in mouse brain. Increasing doses of LEV were administered intraperitoneally (ip) to mice. The mice were sacrificed 60 min postadministration. For ex vivo binding, the brains were removed and homogenized, and binding using [^{3}H]ucb 30889 was performed as described in Gillard et al.[42] For in vivo binding, [^{3}H] ucb 30889 was injected into the tail vein 5 min prior to sacrifice. The brains were removed, homogenized at 4°C, and quickly filtered to retain the bound radioligand. Synaptic vesicle 2A occupancy of 0% was determined in saline-treated animals, and 100% occupancy was defined by the nonspecific binding measured in the presence of an excess of lLEV (1 mM). Four and six animals per dose were used for ex vivo and in vivo experiments, respectively, and each binding was performed in duplicate or triplicate. Predicted in vivo binding was calculated as explained in the text, taking into account the plasma concentration corrected for protein binding (10%), the brain-to-plasma ratio (0.4), and the affinity of LEV measured at 37°C (8 μM).

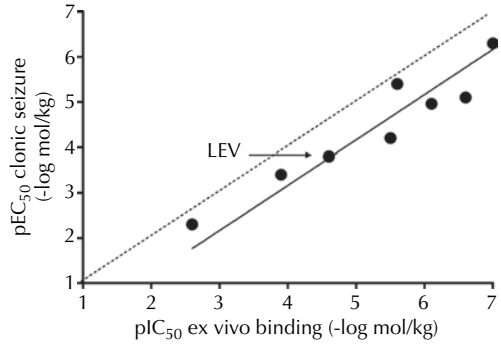

Figure 76–3. Correlation between ex vivo binding affinity and protection against clonic seizures in audiogenic mice. Increasing doses of SV2A ligands were administered ip to mice. The mice were sacrificed 60 min postadministration. The brains were removed and homogenized, and binding using [^{3}H]ucb 30889 was performed as described in Gillard et al.[42] pIC_{50} is the dose of compound leading to 50% of SV2A occupancy ($n = 2$ mice per dose). In parallel experiments, audiogenic seizures were induced by subjecting sound-susceptible mice to a 90 dB, 10 to 20 kHz acoustic stimulus for 30 s. The occurrence of clonic and tonic convulsions was recorded. pED_{50} is the dose leading to 50% protection against clonic seizures ($n = 10$ mice per dose).

compared to ex vivo binding experiments is related to the fact that a substantial amount of radioactive tracer needs to be injected into each animal. Not unexpectedly, we observed a good correlation between SV2A occupancy measured by ex vivo binding and protection against clonic seizures in audiogenic mice, as shown in Fig. 76–3 for a series of compounds. However, it appears quite clear that the doses of compounds needed to occupy 50% of SV2A are generally lower than the doses needed to afford 50% seizure protection ($pIC_{50} > pED_{50}$), that is, high SV2A occupancy is required to provide pharmacological activity (Fig. 76–3).

Anticonvulsant Effects of LEV and Their Relation to SV2A Occupancy

Using the same ex vivo binding approach, we explored the relationship between SV2A occupancy and seizure protection in audiogenic mice as a function of time after single-dose administration. The results obtained with LEV are depicted in Fig. 76–4. We found that the postadministration time needed for LEV to occupy SV2A maximally was well correlated with the time needed for maximal protection against clonic and tonic seizures. Interestingly, protection against the more severe clonic seizures is lost prior to the decrease in protection against tonic seizures. This suggests that lower amounts of SV2A proteins need to be occupied to prevent later-stage less severe (tonic) seizures, while higher occupancy is needed to prevent both forms of seizures (clonic + tonic). We have also accumulated similar data for other SV2A ligands that display a variety of occupancy-protection patterns. Some compounds quickly occupy SV2A and afford maximal protection against seizures faster than LEV, while other compounds display a more rapid decline in occupancy and seizure protection than LEV. This link between SV2A occupancy and efficacy in a time-dependent manner further strengthens the role of SV2A as the relevant target in the mechanism of action of these drugs.

From dose-response and kinetic experiments, as shown in Figs. 76–2 and 76–4, it appears that LEV needs to occupy nearly 90% of SV2A in order to protect against clonic seizures in audiogenic mice. It is also clear that there is a threshold level of occupancy that needs to be reached to afford seizure protection and that minute variations around this threshold are sufficient to prevent or not prevent the occurrence of a seizure. To illustrate this, a group of 10 mice were treated with LEV; 2 h postadministration, 6 mice were protected against sound-elicited clonic seizures and 4 were not. We measured the SV2A occupancy in each mouse and found, quite surprisingly, that the individual SV2A receptor occupancy was nearly identical for all animals. We had expected that in protected mice, the level of SV2A occupancy would be higher than that in nonprotected mice (reflecting interindividual variations due to slight differences in drug administration and/or pharmacokinetics). This might be explained by the fact that a seizure is not a gradual, but rather a binary response, and therefore even small differences in SV2A occupancy might be sufficient to be either above or below the threshold for a seizure to happen. This is in agreement with the rather steep dose-response curves observed for LEV in showing protection against audiogenic[1] or corneally kindled seizures in mice.[36]

To further ascertain whether high occupancy of SV2A is also needed to afford seizure protection in patients, we predicted SV2A occupancy by LEV in the brains of human patients based on affinity and available pharmacokinetic data.

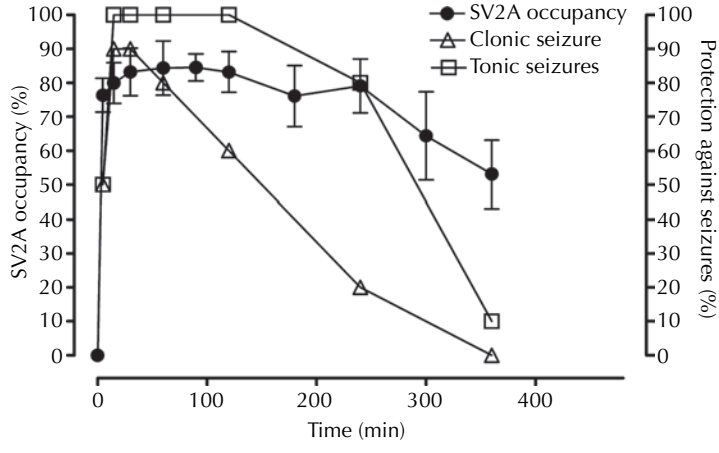

Figure 76–4. Time course of SV2A occupancy and seizure protection in audiogenic mice after a single administration of LEV. A 210 μmol/kg dose of LEV was administered ip. Synaptic vesicle 2A occupancy and protection against tonic and clonic seizures were assessed at several time points after administration. Synaptic vesicle 2A occupancy was measured by ex vivo binding. The mice were sacrificed and the brains were removed and homogenized; binding using [^{3}H]ucb 30889 was performed as described in Gillard et al.[42] Synaptic vesicle 2A occupancy of 0% was determined in saline-treated animals, and 100% occupancy was defined by the nonspecific binding measured in the presence of an excess of LEV (1 mM; $n = 3$ mice per time point). In parallel experiments, audiogenic seizures were induced by subjecting sound-susceptible mice to a 90 dB, 10 to 20 kHz acoustic stimulus for 30 s. The occurrence of clonic and tonic convulsions was recorded ($n = 10$ mice per time point).

We used the following equation describing a single bimolecular interaction between a ligand and a receptor:

[Levetiracetam] refers to the free concentration of LEV in the brain. This was approximated by using total plasma concentrations measured in healthy volunteers and patients (UCB data on file; see ref. 37) corrected for plasma protein binding of 10%.[38] Brain-to-plasma ratios of 0.4 to 1 were considered based on studies in rodents.[39] Ki is the equilibrium dissociation constant (affinity) of LEV for SV2A protein. We took the value of 8 μM that was measured at 37°C in brain tissue. We first validated this approach by predicting, in the same way, the SV2A occupancy in mouse brain 60 min after administration using total plasma concentrations corrected for protein binding, and using a brain-to-plasma ratio of 0.4, as reported for mouse.[39] The predicted SV2A occupancy related to administered dose is shown in Fig. 76–2, and it compares quite satisfactorily with the experimental data obtained from ex vivo and in vivo binding experiments.

The total plasma concentrations of LEV at a clinically active daily dose of 1 g range from 6–8 μg/mL (C_{min}) to 15–20 μg/mL (C_{max}; UCB data on file; see ref. 37). The plasma concentrations have been shown to be linearly proportional to the administered dose[38] and can be adjusted accordingly. Using the above equation and assuming a brain-to-plasma ratio of 1, the predicted SV2A occupancy by LEV in patients varies from 80% to 93% at C_{min} and C_{max} for a 1 g daily dose and from 92% to 98% for a 3 g daily dose. With a less favorable brain-to-plasma ratio of 0.5, the predicted values are 67% (C_{min}) and 87% (C_{max}) for a 1 g daily dose and 86% (C_{min}) and 98% (C_{max}) for a 3 g daily dose. These predicted levels of SV2A occupancy in patients are remarkably close to those measured in animal models of epilepsy at active pharmacological doses and confirm that high SV2A occupancy is needed by current SV2 ligands to afford adequate protection against seizure.

Pharmacology and Phenotyping of SV2A Transgenic Animals in Seizure Models

Direct evidence that the in vivo anticonvulsant activity of LEV is indeed mediated by SV2A has been lacking until recently.[16] Genetically engineered knockout animals, which lack a given drug target, are frequently used to

prove the in vivo selectivity of pharmacological agents and to demonstrate the lack of therapeutic activity in the absence of the molecular target. Similar proof of concept evidence could have been obtained by testing LEV in SV2A$^{-/-}$ homozygous mice. However, these animals suffer from severe seizures starting very early in their development and do not survive beyond 2–3 weeks after birth, which precludes their use in pharmacological in vivo experiments.[26,29] Therefore, we decided to use SV2A$^{+/-}$ mice, which are deficient in the SV2A protein but develop normally after birth. First, we demonstrated by video-electroencephalographic monitoring that SV2A$^{+/-}$ mice do not display any overt epileptic phenotype, but rather show pro-epileptic traits such as decreased seizure thresholds and accelerated kindling development. The pro-epileptic phenotype of SV2A$^{+/-}$ mice was observed in kindling, pilocarpine, kainate, pentylenetetrazol (intravenous) and 6 Hz models, but not in the MES model.[16] Interestingly, the pro-epileptic phenotype of SV2A$^{+/-}$ in a range of different experimental seizure models appeared as a "mirror image" of the unique pharmacological profile of LEV in the same models.[3]

We also demonstrated for the first time a functional involvement of SV2A in mediating the anticonvulsant effect of LEV, which was indeed reduced in SV2A$^{+/-}$ mice.[16] This was illustrated by its failure to produce the same degree of increase in the threshold for induction of 6 Hz seizures in SV2$^{+/-}$ mice as in their wild-type littermates (Fig. 76–5). In contrast, valproate, which has SV2A-unrelated mechanisms of action,[9] produced the same magnitude of threshold increase in both genotypes (Fig. 76–5). We decided to use an unbiased approach for this comparison and ascertain

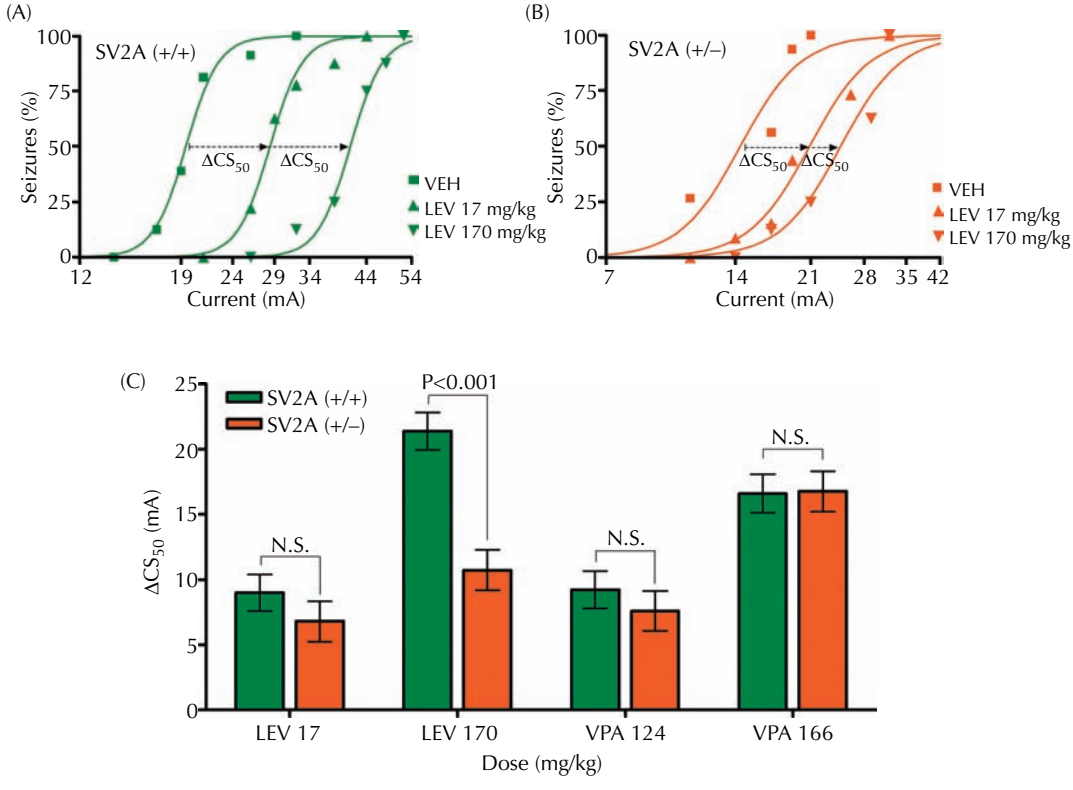

Figure 76–5. Current responses for seizures induced by 6 Hz electrical stimulation after treatment with LEV in SV2A$^{+/+}$ mice (**A**) and SV2A$^{+/-}$ mice (**B**). Points representing the percentage of animals ($n \geq 8$ per group) responding with seizures were used for sigmoidal curve fitting. The CS_{50} value represents the current required to induce convulsions in 50% of animals. **C.** The $\Delta CS_{50s} = [CS_{50\,(DRUG)} — CS_{50\,(SALINE)}] \pm$ SEM value calculated after treatment with two different doses of LEV or valproate (VPA). Values were compared statistically with Student's *t*-test. From ref. 16.

whether the same doses of LEV and valproate would produce the same magnitude of threshold increase for 6 Hz seizures in both $SV2A^{+/+}$ and $SV2A^{+/-}$ mice. Remarkably, this was true only in the case of valproate. A low dose of valproate produced an increase in the threshold for 6 Hz seizures that was comparable between $SV2A^{+/+}$ and $SV2A^{+/-}$ mice (Fig. 76–5). A higher dose of valproate further increased the threshold, which again was almost identical in the two genotypes. Similarly, a low dose of LEV produced comparable increases in the seizure threshold in both genotypes. However, in contrast to valproate, a higher dose of LEV failed to provide an additional threshold increase in the $SV2A^{+/-}$ mice, while the threshold was further increased in $SV2A^{+/+}$ mice. In fact, a higher dose of LEV produced a 50% higher increase in threshold in wild-type mice compared to the increase obtained in $SV2^{+/-}$ mice. It is important to remember that $SV2A^{+/-}$ mice still express 50% of the SV2A protein; thus, occupancy of SV2A by LEV may afford some protection against seizures. Furthermore, $SV2A^{+/-}$ mice have a significantly reduced threshold for 6 Hz seizures, and at lower stimulation currents it might have been somewhat easier to elevate the threshold with the same dose of LEV, which in fact has the same SV2A affinity in both genotypes. The difference in the effects of LEV on the seizure threshold became significant only at the dose that occupied nearly all of the SVA2 binding sites in both genotypes, but since $SV2A^{+/-}$ mice have 50% fewer sites available for LEV binding, the degree of seizure protection was also reduced by approximately 50%.

CHANGES IN SV2A EXPRESSION IN PRECLINICAL MODELS AND HUMAN EPILEPSY

Discovery of SV2A as the binding target for LEV prompted investigations of the potential role of SV2A in the pathophysiology of epilepsy. Van Vliet et al.[40] used immunohistochemistry and Western blot analysis to study SV2A expression patterns during epileptogenesis and chronic epilepsy. Hippocampal samples from autopsy controls, patients who died from status epilepticus, and pharmacoresistant temporal epilepsy (TLE) patients were analyzed. Additionally, SV2A expression was assessed in the hippocampus of rats at different stages of epileptogenesis in a post-status epilepticus model. Remarkable consistency has been observed between human and rat samples. That is, SV2A expression was significantly decreased in the hippocampus of TLE patients with hippocampal sclerosis and also in the mossy fiber terminals during the latent and chronic phases of epileptogenesis in rats.[40] Based on these results, it is not possible to establish a clear cause-effect relationship between reduced expression of SV2A and development of epilepsy, but these data are very consistent with the above-described pro-epileptic phenotype of SV2A-deficnt mice and the accelerated epileptogenesis observed in these animals.[16] Since SV2A is the binding site of LEV and the drug shows reduced efficacy in SV2A-deficient animals,[16] the data of van Vliet et al.[40] may also explain the apparent lack of efficacy of LEV in some patients with TLE. It is conceivable that reduced expression of the target for LEV, namely the SV2A protein, could underlie the cause of nonresponsiveness to the drug in some patients. This hypothesis can be verified by comparison of SV2A expression levels assessed by positron emission tomography (PET) with patients' response or nonresponse to LEV. It is plausible that SV2A expression changes may be responsible for different responses to LEV, because pharmacogenetic studies failed to identify SV2A genetic variants that influence the response to LEV.[41] Future SV2A PET ligands may also allow the study of occupancy–efficacy relationships to allow full translation of the data we have obtained in animal models to human epilepsy.

CONCLUSION

Synaptic vesicle 2A constitutes the unique binding site for LEV and plays an important role in synaptic vesicle function. Affinity–potency correlations in several models of partial and generalized epilepsy indicate that SV2A is a broad-spectrum anticonvulsant target. The anticonvulsant activity of LEV is closely linked with occupancy and availability of SV2A, whereas SV2A deficiency leads to increased seizure vulnerability and accelerated epileptogenesis. Taken together, existing experimental data prove that SV2A plays a crucial role in

mediating the anticonvulsant action of LEV in vivo and indicate that the SV2A protein represents an important and well-validated target for the discovery of novel AEDs. Finally, the finding that SV2A protein is a clinically validated target for epilepsy has triggered further discovery programs exploring the therapeutic potential for SV2A ligands with different binding properties.

Chapter 77

Neurosteroids—Endogenous Regulators of Seizure Susceptibility and Role in the Treatment of Epilepsy

Doodipala Samba Reddy
Michael A. Rogawski

INTRODUCTION

The term *neurosteroid* was coined in 1981 by the French endocrinologist Étienne-Émile Baulieu to refer to steroids that are synthesized de novo in the nervous system from cholesterol independently of the peripheral steroidogenic endocrine glands.[1] Paul and Purdy then characterized *neuroactive steroids* as "natural or synthetic steroids that rapidly alter the excitability of neurons by binding to membrane-bound receptors such as those for inhibitory and (or) excitatory neurotransmitters."[2] This chapter is concerned with the anticonvulsant and antiepileptogenic properties of neurosteroid-related steroid molecules (i.e., related to endogenously synthesized steroids) that meet the Paul and Purdy definition of neuroactive steroids by virtue of their pharmacological actions as positive allosteric modulators of γ-aminobutyric acid A ($GABA_A$) receptors. The effect of these steroids on $GABA_A$ receptors occurs through a direct action on $GABA_A$ receptors and is not related to interactions with classical steroid hormone receptors that regulate gene transcription. Indeed, $GABA_A$ receptor modulatory

neurosteroids are not themselves active at intracellular steroid receptors. We will make scant mention of other endogenous neurosteroids that exert other types of pharmacological actions, such as inhibition of $GABA_A$ receptors or effects on excitatory amino acid receptors (pregnenolone sulfate is an example of such a steroid), although it is conceivable that neurosteroids with such actions could play a role in regulating seizure susceptibility.

It has been known since the 1940s, from the pioneering work of Hans Selye, that naturally occurring steroids such as the ovarian steroid progesterone and the adrenal steroid deoxycorticosterone (DOC) can exert anesthetic and anticonvulsant actions.[3] Recognizing that some steroids could produce such acute central nervous system effects, researchers at the pharmaceutical company Glaxo identified the synthetic steroid alphaxolone as having anesthetic properties. In the early 1970s, alphaxolone was marketed as a component of the intravenous anesthetic agent Althesin, which also included the less potent anesthetic steroid alphadalone acetate, said to increase the solubility of alphaxolone.[4] Several years later, the mechanism of action of alphaxolone was defined: it was found to enhance synaptic inhibition via an action on $GABA_A$ receptors.[5,6] A major advance occurred when naturally occurring metabolites of progesterone and DOC were also found to enhance and directly activate $GABA_A$ receptors.[7] It was speculated that the anesthetic and hypnotic properties of progesterone and DOC known since the time of Selye were due to their conversion in the body to these metabolites, respectively: allopregnanolone (3α-hydroxy-5α-pregnane-20-one) and allotetrahydrodeoxycorticosterone (3α,21-dihydroxy-5α-pregnan-20-one; THDOC). At the time, it was recognized that the enzymes required for the conversion of the steroid hormone precursors to their active A-ring reduced metabolites are present in brain so that part of the synthesis of the $GABA_A$ receptor active steroids could occur locally. Therefore, the neuroactive steroids allopregnanolone and THDOC came to be referred to as *neurosteroids* even though it was not believed at the time that their synthesis occurred independently of peripherally synthesized precursor steroid hormones. We now know that all of the enzymes required for the synthesis of the $GABA_A$ receptor active steroids from cholesterol are present in the brain.[8] It is well recognized that these steroids readily cross the blood-brain barrier. While it is likely that locally synthesized $GABA_A$ receptor active steroids play a role in modulating circuit excitability, there is little information on the relative importance of de novo local synthesis versus peripheral production of either the active $GABA_A$ receptor modulatory steroids (e.g., allopregnanolone or THDOC) or their precursor hormones (e.g., progesterone or DOC), which are converted locally by brain 5α-reductase and 3α-hydroxysteroidoxidoreductase (3α-HSOR). Nevertheless, it is common to refer to $GABA_A$ receptor modulatory steroids such as allopregnanolone and THDOC as neurosteroids, and we will follow that practice here. This chapter reviews the potential roles of such neurosteroids as endogenous modulators of seizure susceptibility and also the more limited evidence that they can, under certain circumstances, influence epileptogenesis (transformation of the brain to an epileptic state). The discussion of these topics serves as a prelude to the main objective of this chapter, which is to review the evidence supporting the utility of exogenously administered neurosteroid-related agents in the treatment of epilepsy.

DIVERSITY OF NEUROSTEROIDS AND THEIR BIOSYNTHESIS

A variety of $GABA_A$ receptor modulatory neurosteroids are known to be synthesized endogenously (Figs. 77–1 and 77–2). The best recognized of these are the pregnane neurosteroids allopregnanolone and THDOC, which are produced via sequential A-ring reduction of the steroid hormones progesterone and its 21-hydroxylated derivative deoxycorticosterone by 5α-reductase and 3α-HSOR isoenzymes. In the periphery, the steroid precursors are mainly synthesized in the gonads, adrenal gland, and feto-placental unit, but as noted above, synthesis of both of these neurosteroids likely occurs in the brain from cholesterol or from peripherally derived intermediates including the steroid hormone precursors. A-ring reduction can also occur in peripheral tissues such as reproductive endocrine tissues, liver, and skin that are rich in the two reducing activities.[8] Since neurosteroids are highly lipophilic and can readily cross the blood-brain barrier, neurosteroids

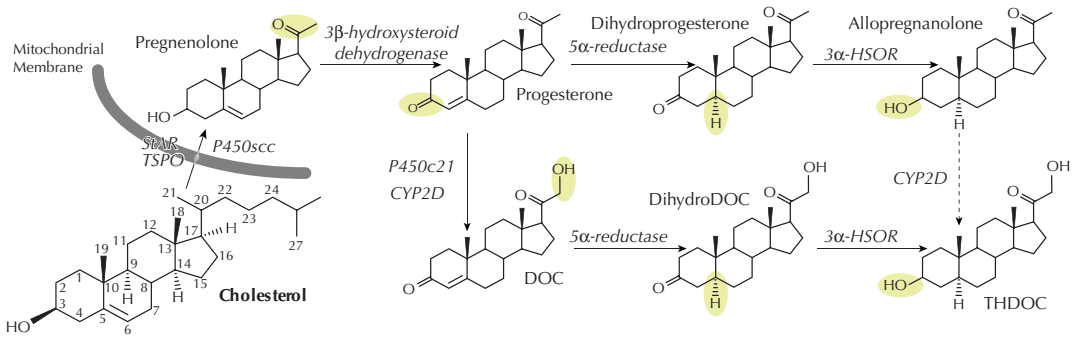

Figure 77–1. Biochemical pathways of neurosteroid biosynthesis. Cholesterol is trafficked by StAR (steroidogenic acute regulatory protein) and TSPO (translocator protein; 18 kDa) to the inner mitochondrial membrane, where it is converted to pregnenolone by P450sc (cytochrome P450 side-chain cleavage). Pregnenolone is the precursor for progesterone that can undergo the two sequential A-ring reduction steps catalyzed by 5α-reductase and 3α-HSOR (3α-hydroxysteroid oxidoreductase) to form the neurosteroid allopregnanolone. Alternatively, in the zona reticulata of the adrenal cortex, P450c21 (cytochrome P450 21-hydroxylase) converts progesterone to DOC (deoxycorticosterone), which is the precursor for the neurosteroid THDOC (allotetrahydrodeoxycorticosterone). In the brain, this reaction appears to be mainly catalyzed by CYP2D isoenzymes, which can also convert allopregnanolone to THDOC.

synthesized in peripheral tissues accumulate in the brain and can influence brain function.

The 5β-isomers of allopregnanolone and THDOC have $GABA_A$ receptor modulatory activity that is only modestly less potent than that of the corresponding 5α-epimers.[9] A steroid 5β-reductase enzyme is distributed widely in vertebrates, including in the gonads, liver, and brain.[10] However, whether progesterone or DOC is a substrate, and the extent to which 5β-reduced epimers of allopregnanolone and THDOC are produced endogenously, is unclear.

The androgenic steroid testosterone differs from progesterone by virtue of a 17-alcohol that replaces the 17-acetyl in progesterone. Testosterone is a substrate for both 5α-reductase and 5β-reductase isoenzymes.

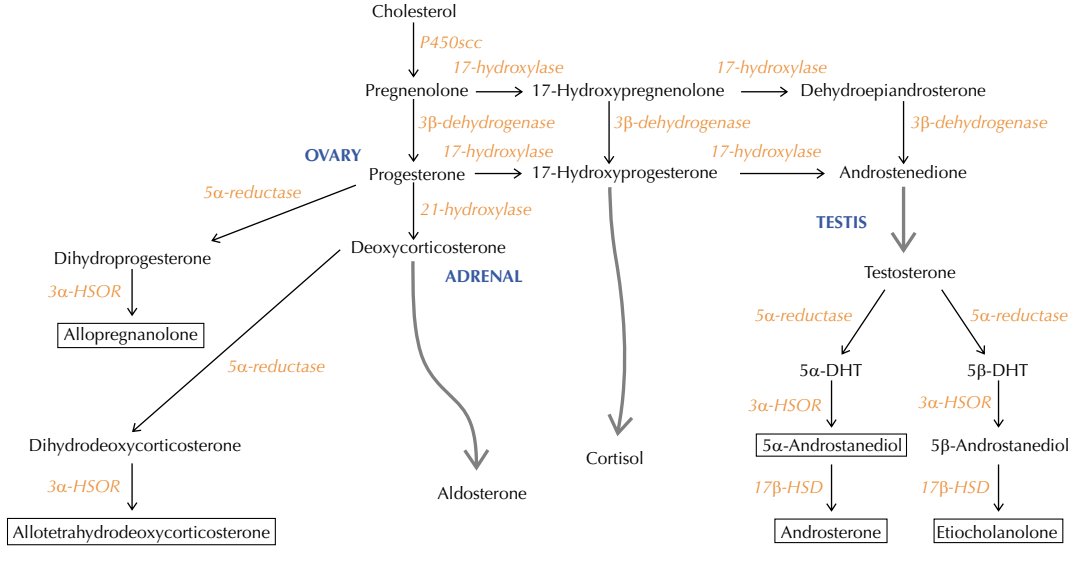

Figure 77–2. General scheme of peripheral steroidogenesis showing side pathways for the production of known neurosteroids. Steroids known to act on $GABA_A$ receptors in a fashion similar to that of the prototypic neurosteroids allopregnanolone and allotetrahydrodeoxycorticosterone are boxed.

The product of 5α-reduction of testosterone, 5α-dihydrotestosterone, is hormonally more active than testosterone itself. However, subsequent 3α-reduction leads to 5α-androstanediol (5α-androstane-3α,17β-diol), which is comparable in potency and efficacy to allopregnanolone as a $GABA_A$ receptor-positive modulator.[11] 5α- and 5β-Androstanediol are further metabolized by 17β-hydroxysteroid dehydrogenase to androsterone and etiocholanolone, respectively, which are considered the major excreted metabolites of testosterone. These compounds and their conjugates are present at high concentrations. Androsterone and etiocholanolone also have $GABA_A$ receptor-positive modulatory activity and represent endogenous neurosteroids.[12] Collectively, the various $GABA_A$ receptor modulatory steroids that lack the pregnane 17β-ethyl moiety, such as 5α-androstanediol, androsterone, and etiocholanolone, can be considered androstane neurosteroids. Finally, substantial amounts of androstenol, the 16-unsaturated form of 5α-androstanediol, are present in mammals, including humans. This compound is considered to be a pheromone that increases sexual receptivity in pigs and possibly other species. Androstenol also is a $GABA_A$ receptor-positive modulator that has similar efficacy but is modestly less potent than allopregnanolone.[13]

PRODUCTION OF NEUROSTEROIDS IN THE BRAIN AND THEIR LOCALIZATION TO PRINCIPAL NEURONS

In addition to peripheral production, it is clear that neurosteroids can be formed from steroid hormone precursors (such as progesterone, DOC, and perhaps testosterone) locally in the brain. 5α-Reductase activity has been identified in both neurons and glial cells in rodent and sheep brain, in regions, such as the neocortex and hippocampus, that are relevant to epilepsy.[14,15] 3α-HSOR is also expressed widely in the brain.[16] In humans, both enzymes have been found in neocortex and hippocampus.[17–19] Thus, it is likely that neurosteroids can be formed from their parent steroid hormone precursors directly in the brain. Steroid precursors readily enter the brain, so pools of peripherally synthesized precursors are available for local neurosteroid biosynthesis. In peripheral tissues 5α-reductase is believed to be the rate-limiting step in the production of neurosteroids because 3α-HSOR is a more ubiquitous enzyme; the same situation likely applies in brain.

It is likely that neurosteroids can be produced locally in brain not only from their steroid hormone precursors but also from more elementary steroid precursors such as cholesterol or pregnenolone. The rate-limiting and initial step in steroidogenesis is the conversion of cholesterol to pregnenolone by the mitochondrial enzyme P450scc (cytochrome P450 cholesterol side-chain cleavage enzyme; CYP11A). Access of cholesterol to P450scc requires StAR (steroidogenic acute regulatory protein), which functions to transfer cholesterol from the outer mitochondrial membrane to the inner membrane where P450scc is located.[20] Translocator protein 18 kD (TSPO), formerly called *peripheral* or *mitochondrial benzodiazepine receptor*, likely functions as a complex with StAR.[21,22] Both proteins are expressed widely in peripheral tissues and in the brain. Activation of TSPO by certain ligands facilitates the intramitochondrial flux of cholesterol and thereby increases the availability of cholesterol to P450scc, enhancing pregnenolone synthesis and ultimately neurosteroid production.[23,24] The observation that TSPO ligands enhance neurosteroid production not only confirms the key role of TSPO in neurosteroidogenesis, but also suggests that such ligands may have therapeutic utility as an alternative to exogenously administered neurosteroids in situations where it is desirable to increase the level of brain neurosteroids.[25]

In addition to P450scc, 3β-hydroxysteroid dehydrogenase, an enzyme required for the conversion of pregnenolone to progesterone, has been demonstrated in the brain.[26] Thus, the enzymes necessary for in situ synthesis of progesterone from cholesterol are present in the brain.

In the adrenal, P450c21 (cytochrome P450 21-hydroxylase) converts progesterone to DOC, which is the precursor for the neurosteroid THDOC. The brain also possesses 21-hydroxylase activity, but it expresses only very small amounts of P450c21 mRNA and protein. It appears that cytochrome P450 2D (CYP2D) isoforms, in particular CYP2D4, present in brain can 21-hydroxylate progesterone to form DOC, which can then be converted to

THDOC.[27] In addition, allopregnanolone itself is a substrate for CYP2D4, so that in brain, allopregnanolone may be converted directly to THDOC. Allopregnanolone and THDOC persist in the brain after adrenalectomy and gonadectomy or after pharmacological suppression of adrenal and gonadal steroid synthesis,[28,29] confirming that these two key neurosteroids can be synthesized independently of peripherally produced steroid hormone precursors. However, the regulatory mechanisms underlying neurosteroid biosynthesis in the brain remain unclear.

In studies with mouse and rat brain, in situ hybridization with mRNA probes to 5α-reductase and 3α-HSOR indicates that the two mRNAs colocalize to glutamatergic principal neurons and not GABAergic inhibitory neurons or glial cells within neocortex, hippocampus, amygdala, and other brain regions.[30] Immunohistochemistry with an antiserum raised against allopregnanolone that also recognizes THDOC confirms that the neurosteroids are concentrated in principal neurons, predominantly in cell bodies and thick dendrites.[31] The highly restricted distribution of neurosteroids to principal neurons suggests that they are mainly derived from local synthesis and not from the circulation, although it is clear that peripheral neurosteroids, as previously noted, readily cross the blood-brain barrier. It is remarkable that brain neurosteroids are localized to the neurons that contain their targets ($GABA_A$ receptors). This observation is consistent with the notion that neurosteroids function in an autocrine fashion in which they reach their targets by lateral membrane diffusion.[32]

NEUROSTEROID MODULATION OF $GABA_A$ RECEPTORS

In electrophysiological studies, allopregnanolone and THDOC at aqueous concentrations in the range 10–1500 nM enhance the activation of $GABA_A$ receptors by GABA.[9,33] At higher concentrations, the steroids directly activate the receptor in the absence of GABA. In addition, like other positive allosteric modulators of $GABA_A$ receptors, neurosteroids exert allosteric effects on these receptors such that there is enhancement of the binding of [^{3}H]flunitrazepam, a benzodiazepine receptor agonist, and [^{3}H]muscimol, a specific GABA-site agonist, as well as inhibition of the binding of [^{35}S]*t*-butylbicycloorthobenzoate (TBPS), a cage convulsant and noncompetitive $GABA_A$ receptor antagonist.[34,35] Neurosteroid enhancement of $GABA_A$ receptors occurs through increases in both channel open frequency and channel open duration.[36–38] Thus, neurosteroids greatly enhance the probability of $GABA_A$ receptor chloride channel opening, thereby enhancing $GABA_A$ receptor-mediated inhibition.

The effects of neurosteroids on $GABA_A$ receptors occur by binding to discrete sites on the receptor-channel complex that are located within the transmembrane domains of the α and β subunits.[38] The binding sites for neurosteroids are distinct from the recognition sites for GABA, benzodiazepines, and barbiturates. Although the exact location of neurosteroid binding has not been mapped, it has been proposed that there are two distinct sites for neurosteroids that act as positive modulators: one for allosteric enhancement of GABA and another for direct activation of the receptor.[37,38] Using site-directed mutagenesis, it has been shown that a highly conserved glutamine at position 241 in the M1 domain (toward the intracellular side) of the α subunit plays a key role in neurosteroid modulation of GABA responses and is believed to contribute to the binding site for modulation.[39] Additional nearby residues in the M4 domain of the same α subunit (tyrosine 410 and asparagines 407, which are located more toward the extracellular side) have also been proposed to contribute to the binding site. Other investigators have found that mutations in serine 240 and tryptophan 245 of the α subunit interfere with neurosteroid potentiation.[40] Studies with structurally diverse steroids have led to the conclusion that the steroid binding pocket on the α subunit is more correctly viewed as a *hydrophobic surface* that can accommodate steroid molecules of different structures.[40] Direct activation of the receptor, in contrast, has been proposed to be due to binding at a site on the interface between β and α subunits formed by a threonine at position 236 in the α subunit and a tyrosine at position 284 in the β subunit.[38] However, more recent models of

the $GABA_A$ receptor have questioned whether these residues reside at the β subunit–α subunit interface.[41] A photo-incorporable analog of the anesthetic etomidate appears to bind at the interface, but binding of this ligand is not competitively inhibited by neurosteroids.[41] In fact, neurosteroids (at concentrations that produce direct receptor activation) enhance binding, presumably due to allosteric effects transmitted upon interaction with a different site on the receptor. The newer topology models do not bring into proximity the residues in the β and α subunits proposed to constitute the site for direct activation. Therefore, at present, the location of this site is uncertain.

A range of steroid structures have activity as positive modulators of $GABA_A$ receptors in line with the hydrophobic surface binding site model. Nevertheless, there are certain strict structural requirements for neurosteroid-positive modulation. A hydrogen bond-donating 3α-hydroxy group on the steroid A-ring and a hydrogen bond-accepting group (typically a keto moiety) on the D-ring at either C20 of the pregnane steroid side chain or C17 of the androstane ring system are critical for positive modulatory activity at $GABA_A$ receptors.[37,42] The orientation of the C5 hydrogen group only modestly influences potency.[9]

Studies with recombinant $GABA_A$ receptor isoforms indicate that neurosteroids act on most subunit combinations.[37,43] This distinguishes neurosteroids from benzodiazepines, which only act on $GABA_A$ receptors that contain γ2 subunits and do not contain α4 or α6 subunits. In general, the specific α subunit type may influence neurosteroid efficacy, whereas the γ subunit type may affect both the efficacy and potency of neurosteroid modulation.[37]

GABA is a relatively low-efficacy agonist of $GABA_A$ receptors in which the δ subunit replaces the more common γ2 subunit, even though it binds with high affinity to such δ-subunit-containing receptors.[44] Neurosteroids therefore have an opportunity to markedly enhance the current generated by δ-subunit-containing $GABA_A$ receptors even in the presence of saturating GABA concentrations. Consequently, $GABA_A$ receptors that contain the δ subunit are highly sensitive to neurosteroid-induced potentiation of GABA responses,[45,46] and mice lacking δ subunits show drastically reduced sensitivity to neurosteroids.[47–49] $GABA_A$ receptors containing δ subunits exhibit low desensitization, and they are located nonsynaptically (perisynaptically/extrasynaptically) since the γ2 subunit is required for synaptic targeting. These properties cause them to be prime candidates for mediating *tonic* $GABA_A$ receptor current that is activated by ambient concentrations of GABA in the extracellular space. Ambient GABA is believed to result from spillover of synaptically released GABA; concentrations would increase with high levels of activity of GABAergic interneurons, as occurs during seizures. Tonic $GABA_A$ receptor current causes a steady inhibition of neurons and reduces their excitability. Neurosteroids could therefore have a general role in setting the level of excitability and might specifically potentiate tonic inhibition during seizures when ambient GABA may rise. Overall, the robust effect of neurosteroids is likely to be due to their action on both synaptic and perisynaptic/extrasynaptic $GABA_A$ receptors.

Although neurosteroids are viewed as high-potency modulators of $GABA_A$ receptors since they are effective at concentrations in the mid-nanomolar to low-micromolar range in aqueous solution, recent studies indicate that neurosteroid binding to the $GABA_A$ receptor is actually of low affinity (K_d, ~1 mM).[32] The high effective potency of neurosteroids results from partitioning of the lipophilic steroids within the plasma membrane, such that the concentrations presented to the receptor are orders of magnitude greater. Neurosteroids access the $GABA_A$ receptor from the lipophilic plasma membrane. The nonspecific accumulation and removal of the neurosteroids from the membrane are the major factors determining the rates of neurosteroid action when applied to cells via aqueous solution; rates of binding and unbinding to the receptor are only secondary factors.[50] It is noteworthy that intracellular delivery through the plasma membrane is compatible with the autocrine mechanism discussed above, in which the neurosteroids act on the $GABA_A$ receptors in the same neurons in which they are produced.

As noted, at high concentrations (>10 μM), neurosteroids can directly activate $GABA_A$ receptor channels in the absence of GABA.[9,51,52] In this respect, neurosteroids resemble barbiturates but not benzodiazepines.[53] Given the high concentrations required, whether direct

actions are relevant to the role of endogenous neurosteroids or to the pharmacological actions of exogenously administered neurosteroid-related agents is not well understood.

ANTICONVULSANT AND ANTIEPILEPTOGENIC EFFECTS OF NEUROSTEROIDS

Exogenously administered neurosteroids, like other agents that act as positive $GABA_A$ receptor modulators, exhibit broad-spectrum anticonvulsant effects in diverse rodent seizure models. They protect against seizures induced by $GABA_A$ receptor antagonists including pentylenetetrazol (PTZ) and bicuculline, and they are effective against pilocarpine-induced limbic seizures and seizures in kindled animals.[9,54–57] However, neurosteroids may exacerbate generalized absence seizures.[58,59] The potencies of neurosteroids in models where they confer seizure protection vary largely in accordance with their activities as positive allosteric modulators of $GABA_A$ receptors. Thus, allopregnanolone has roughly equal potency to THDOC, but androstanediol, androsterone, and etiocholanolone are somewhat less potent.[12,60,61] Like other anticonvulsant agents that act on $GABA_A$ receptors, neurosteroids are inactive or only weakly active against electrically induced tonic extension seizures elicited according to the maximal electroshock (MES) protocol that is widely used for drug screening. However, they are active in the 6 Hz model in mice in which limbic-like seizures are induced by electrical stimulation of lower frequency and longer duration than in the MES test.[62] In general, neurosteroids have comparable potencies in the 6 Hz and PTZ models. Neurosteroids are also highly effective in suppressing seizures due to withdrawal of $GABA_A$ receptor modulator drugs including neurosteroids and benzodiazepines (diazepam), and also due to other types of agents such as ethanol, which may act in part through $GABA_A$ receptors.[63–65] In contrast to benzodiazepines, where utility in the chronic treatment of epilepsy is limited by tolerance, anticonvulsant tolerance is not obtained with neurosteroids.[66,67] Thus, neurosteroids have the potential to be used in the chronic treatment of epilepsy, and this has been borne out in clinical trials (see below). The mechanisms responsible for tolerance to benzodiazepines are not known. However, factors such as uncoupling of the allosteric linkage between the GABA and benzodiazepine sites and changes in receptor subunit turnover with switching of subunits may be contributing mechanisms.[68] Neurosteroids do not act on the benzodiazepine site of $GABA_A$ receptors, and they are able to modulate all isoforms of $GABA_A$ receptors, even those that contain benzodiazepine-insensitive $\alpha 4$ and $\alpha 6$ subunits or do not include the obligatory $\gamma 2$ subunit required for benzodiazepine sensitivity. Thus, it is clear that neurosteroids can act on $GABA_A$ receptors where the proposed benzodiazepine tolerance mechanisms have been invoked. Surprisingly, while chronic neurosteroid exposure does not lead to anticonvulsant tolerance, chronic neurosteroid exposure does lead to tolerance to benzodiazepines.[67] Thus, it appears that the same plastic changes that underlie benzodiazepine tolerance are brought into play by chronic neurosteroid exposure. However, neurosteroids, acting at distinct sites on $GABA_A$ receptors and exhibiting effects on the full range of $GABA_A$ receptor isoforms, do not exhibit anticonvulsant tolerance.

The sulfated neurosteroids pregnenolone sulfate and dehydroepiandosterone sulfate, which act as $GABA_A$ receptor antagonists, are pro-convulsant when administered at high doses into the brain, producing seizures and status epilepticus.[69,70] Compelling evidence that such steroids exist endogenously in the brain is lacking, and in any case it is unlikely that they exist at sufficiently high concentrations to exert pro-convulsant effects, so the physiological relevance is unclear. However, it is known that the seizure-facilitating effects of these steroids can be blocked by coadministration of allopregnanolone or other neurosteroids that positively modulate $GABA_A$ receptors.[71]

In addition to anticonvulsant activity, there is some limited evidence that endogenous neurosteroids play a role in regulating epileptogenesis.[72–74] Following pilocarpine-induced status epilepticus in the rat, the neurosteroidogenic enzyme P450scc is upregulated for several weeks, suggesting that neurosteroidogenesis may be increased. Ordinarily, rats develop spontaneous recurrent seizures following a latent period of similar duration to the period during which P450scc is elevated. Inhibiting neurosteroid synthesis with

finasteride accelerated the onset of spontaneous recurrent seizures, suggesting that endogenous neurosteroids play a role in restraining epileptogenesis or at least that they inhibit the expression of seizures. Exogenous treatment with neurosteroids or with progesterone, which serves as a precursor for neurosteroid synthesis, has also been reported to delay the occurrence of epileptogenesis in some situations.[75] In fact, progesterone may impair epileptogenesis in kindling models, even at doses that do not affect seizure expression.[76,77] If endogenous neurosteroids can be confirmed as endogenous regulators of epileptogenesis, neurosteroids themselves or modulators of neurosteroid disposition could potentially have disease-modifying therapeutic activity.

ROLE OF ENDOGENOUS NEUROSTEROIDS IN THE MODULATION OF SEIZURES

Endogenous neurosteroids may play a role in the physiological regulation of seizure susceptibility in individuals with epilepsy. We will discuss several such situations: catamenial epilepsy, stress, temporal lobe epilepsy, and alcohol withdrawal. However, it is noteworthy that there is no evidence that alterations in neurosteroid levels in the absence of preexisting epilepsy can induce epileptogenesis.

Neurosteroids in Catamenial Epilepsy

Catamenial epilepsy, the cyclical occurrence of seizure exacerbations during particular phases of the menstrual cycle in women with preexisting epilepsy, is a specific form of pharmacoresistant epilepsy. Catamenial seizure exacerbations affect up to 70% of women of childbearing age with epilepsy.[78–80] Although there are several forms of catamenial epilepsy, neurosteroids have been implicated only in the seizure exacerbations that occur in the most common situation, which is when women with normal menstrual cycles experience seizure exacerbations in the perimenstrual period. It is hypothesized that withdrawal of progesterone-derived neurosteroids leads to enhanced brain excitability predisposing to seizures.

During the menstrual cycle, circulating progesterone levels are low in the follicular phase but rise in the midluteal phase for about 10 to 11 days before declining in the late luteal phase. Circulating allopregnanolone levels parallel those of its parent progesterone.[81] Circulating THDOC levels also fluctuate during the menstrual cycle, with higher levels in the luteal phase.[81] Overall, the serum levels of THDOC are lower than those of allopregnanolone, so THDOC is likely to be less relevant to catamenial epilepsy, although it could contribute. An important unanswered question is whether the local brain synthesis of neurosteroids also fluctuates.

In addition to withdrawal of the anticonvulsant effects of neurosteroids in association with the fall in progesterone at the time of menstruation, plasticity in $GABA_A$ receptors, the targets of neurosteroid action, could also play a role in the enhanced brain excitability that is presumed to underlie the increase in seizure susceptibility in perimenstrual catamenial epilepsy. The precise changes in brain $GABA_A$ receptor subunit expression occurring during the human menstrual cycle have not been determined. However, it is now well recognized that prolonged exposure to allopregnanolone in rats causes increased expression of the $\alpha 4$ $GABA_A$ receptor subunit in hippocampus, resulting in decreased benzodiazepine sensitivity of $GABA_A$ receptor currents.[82,83] Although $\alpha 4$ can coassemble with $\gamma 2$ to form synaptic $GABA_A$ receptors, it preferentially coassembles with δ to form nonsynaptic (perisynaptic/extrasynaptic) $GABA_A$ receptors. Treatment of rats with allopregnanolone results in transient increased expression of the δ subunit in hippocampus and increased benzodiazepine-insensitive tonic current.[84,85] Progesterone also increases δ subunit expression, likely as a result of conversion to allopregnanolone. The relevance of the increased δ subunit expression for catamenial epilepsy is unclear, as δ subunit increases may be transitory and followed by *reduced* expression with chronic exposures, as in pregnancy or in the prolonged luteal phase of the human menstrual cycle. Therefore, an important consequence of the incorporation of the normally low-abundance $\alpha 4$ subunit into synaptic $GABA_A$ receptors is that synaptic currents generated by these receptors have accelerated decay kinetics, so that there is less total charge transfer, which results in

reduced inhibition.[86] $GABA_A$ receptor-modulating neurosteroids cause a prolongation of the decay of GABA-mediated synaptic currents. Consequently, in the presence of high levels of allopregnanolone during the luteal phase, the acceleration due to α4 substitution is balanced. However, when neurosteroids are withdrawn at the time of menstruation, synaptic inhibition is diminished from normal, resulting in enhanced excitability, which, among other effects, predisposes to seizures. Indeed, chronic exposure to neurosteroids also is accompanied by downregulation of δ subunit expression and perisynaptic/extrasynaptic $GABA_A$ receptors.[84] This change is believed to be a compensatory mechanism, which would avoid excessive sedation caused by high neurosteroid levels acting on sensitive δ subunit-containing $GABA_A$ receptors. At the time of neurosteroid withdrawal, δ subunit expression rapidly recovers. However, if recovery is not sufficiently fast, there could be an enhancement of excitability due to a reduction in tonic inhibition mediated by perisynaptic/extrasynaptic $GABA_A$ receptors in the relative absence of neurosteroids.

A rodent model has been developed to simulate the hormonal changes that are believed to be relevant to perimenstrual catamenial epilepsy.[87,88] Rodents have a 4 to 5 day estrous cycle, and studies of fluctuations in seizure susceptibility in cycling female rodents have not led to results that are relevant to the human menstrual cycle. In order to provide a model that more closely mimics the human situation, a condition of pseudopregnancy was induced in rats by sequential gonadotropin treatment. This resulted in prolonged high circulating levels of estrogen and progesterone similar to those that occur in the luteal phase of the 28 day human menstrual cycle. Then, to simulate the withdrawal of allopregnanolone that occurs in conjunction with the fall in progesterone levels at the time of menstruation, the animals were treated with finasteride 11 days after the initiation of gonadotropin treatment.

The neurosteroid withdrawal model of catamenial epilepsy was used to investigate therapies for perimenstrual catamenial epilepsy.[63,89] A key result is that conventional antiepileptic drugs, including benzodiazepines and valproate, have reduced potency in protecting against seizures during the period of enhanced seizure susceptibility following neurosteroid withdrawal. This pharmacoresistance seems to mimic the situation in women with catamenial epilepsy in which breakthrough seizures occur despite treatment with antiepileptic drugs. In contrast to the results with conventional antiepileptic drugs, neurosteroids, including allopregnanolone, THDOC, and their 5β-isomers, were found to have enhanced activity in the perimenstrual catamenial epilepsy model.[63] This suggested a "neurosteroid replacement" approach to treat catamenial seizure exacerbations.[88] A neurosteroid could be administered in a "pulse" prior to menstruation and then withdrawn or continuously administered throughout the month. While intermittent administration at the time of increased seizure vulnerability is rational, continuous administration would avoid withdrawal of the therapeutic agent, which itself could predispose to seizures. This factor, as well as the practical difficulty many women experience in predicting the time of their menstrual periods, suggests that continuous administration is preferred. The neurosteroid would be administered at low doses to avoid sedative side effects. Such low doses are expected to contribute little anticonvulsant activity during most of the menstrual cycle. Patients would still require treatment with conventional antiepileptic medications. However, during the period of enhanced seizure susceptibility at the time of menstruation, the increased potency of the neurosteroid would confer protection against perimenstrual seizure exacerbations. It is noteworthy that while the anticonvulsant activity of neurosteroids increases in conjunction with neurosteroid withdrawal, there is no corresponding increase in side effects (mainly sedation), at least as assessed by a measure of motor impairment.[88] Therefore, enhanced side effects, which would negate the potential of the therapeutic approach, would not be expected to occur.

To determine whether the enhanced activity of neurosteroids is due to pharmacokinetic or pharmacodynamic factors, brain and plasma levels of the neurosteroid ganaxolone (3α-hydroxy-3β-methyl-5α-pregnan-20-one, discussed below) were determined with a liquid chromatography-mass spectrometric method. Control and neurosteroid withdrawn animals received a single dose of ganaxolone (7 mg/kg, subcutaneously), resulting in an elevation in PTZ threshold that peaked at 30 min and returned to baseline at 120–180 min. Ganaxolone caused a markedly greater (1.8-fold) elevation of the PTZ threshold in the withdrawn animals than in controls,

indicating a greater sensitivity to the anticonvulsant effects of ganaxolone. Surprisingly, plasma and brain ganaxolone levels were reduced in withdrawn animals (69% of control levels). Adjusting for the reduced brain levels, the pharmacodynamic sensitivity to ganaxolone was enhanced 2.3-fold in the withdrawn animals compared with controls. There was a significant increase in clearance (CL) of ganaxolone in the withdrawn animals, which accounts for the reduced plasma and brain levels. Ganaxolone levels reached a peak more slowly in brain ($T_{max\text{-}brain}$, ~30 min) than in plasma ($T_{max\text{-}plasma}$, ~15 min); the $T_{max\text{-}brain}$ value corresponds with the peak elevation in seizure threshold. These studies confirmed the enhanced anticonvulsant activity of ganaxolone in the rat model of catamenial epilepsy. The enhanced activity occurs in the face of decreased plasma and brain ganaxolone levels, indicating a marked increase in pharmacodynamic sensitivity.

Recently, studies have been conducted with the catamenial epilepsy model in female rats that experienced a prolonged bout of status epilepticus induced by lithium-pilocarpine treatment, resulting in a chronic epileptic state with spontaneous recurrent seizures.[90] Epileptic animals in the catamenial epilepsy model exhibited about six seizures per day, each lasting approximately 1 min. When neurosteroids were withdrawn by treatment with finasteride, an enormous (more than 10-fold) increase in seizure frequency was observed. In contrast, finasteride did not induce seizures in normal animals. However, it did induce an increase in seizures in epileptic rats that were not treated with gonadotropins, albeit of smaller magnitude than that in the pseudopregnant animals. The observation that inhibition of the synthesis of endogenous neurosteroids in nonepileptic animals did not lead to seizures indicates that neurosteroid reductions are not epileptogenic. This is consistent with the observation that finasteride does not cause seizures in humans who do not have epilepsy. Finasteride is used clinically for the treatment of benign prostatic hypertrophy and male pattern hair loss. Seizures have not been reported as an adverse effect of the drug. While it is clear that finasteride does not provoke seizures in the general population, there are no prospective studies to determine whether inhibition of 5α-reductase by finasteride influences seizure susceptibility in individuals with epilepsy. There is a single anecdotal report of a woman with epilepsy taking finasteride for male pattern baldness who experienced an increase in seizure frequency and severity in association with finasteride use.[91] The doses of finasteride used clinically are in the range of 1–5 mg/day, which are far less than the doses of 30–100 mg/kg used in rats to inhibit brain neurosteroid synthesis. Furthermore, in humans, finasteride is selective for the type 2 5α-reductase isoform and is less active on the type 1 enzyme that is the isoform predominantly present in the brain. This selectivity is not observed with the rat enzymes. In sum, finasteride, as administered clinically in humans, probably does not block neurosteroidogenesis sufficiently to influence seizure susceptibility under most circumstances. Also, individuals with congenital 5α-reductase deficiency, caused by a mutation in the 5α-reductase type 2 gene (a condition with ambiguous genitalia), do not exhibit epilepsy. While neurosteroid reduction by itself does not lead to epilepsy, it is apparent that endogenous neurosteroids do modulate seizure susceptibility in epileptic animals.

Although it has been assumed that the effect of finasteride on seizure susceptibility is mediated through inhibition of peripheral neurosteroidogenesis, ovariectomized epileptic animals also exhibited large increases in seizure frequency following finasteride treatment, indicating that a major effect of the drug may be to influence neurosteroid synthesis in the brain.[90] Whatever the site of action of finasteride, treatment with exogenous allopregnanolone was found to rapidly terminate the finasteride-induced exacerbation of seizures, providing additional evidence that the increase in seizure frequency is due to a finasteride-induced reduction in neurosteroids and not some other action of the drug. More importantly, it supports the concept that neurosteroid replacement may be useful in the treatment of seizures associated with neurosteroid fluctuations, such as catamenial epilepsy. In catamenial epilepsy, breakthrough seizures occur despite treatment with antiepileptic drugs. Previous studies (reviewed in ref. 88) and the new results from Lawrence et al.[90] support the potential of neurosteroids as a novel treatment approach for these pharmacoresistant seizures.

Although neurosteroids seems to be the most direct approach to the treatment of catamenial

epilepsy, only limited anecdotal data are available to support their use.[92] No neurosteroid is currently approved. In contrast, two open-label trials have shown that adjunctive progesterone therapy produces significant reductions in seizure occurrence.[93] It is recommended that the hormone be administered during the entire second half of the menstrual cycle and tapered gradually, as it is believed that abrupt discontinuation can result in rebound seizure exacerbation. Enthusiasm for the use of progesterone in the treatment of catamenial epilepsy has been tempered by the lack of data from adequately controlled clinical trials. A multicenter prospective controlled trial of 3 months of supplemental progesterone in 462 women, 294 who were randomized 2:1 to progesterone or placebo, has been completed. While the overall response to progesterone was no greater than to placebo in women with or without catamenial epilepsy, as the magnitude of a woman's perimenstrual seizure exacerbation increased there was a correlated increase in the response to progesterone but not to placebo, suggesting that some women may benefit.[93a] Progesterone therapy in women may cause hormonal effects such as breakthrough vaginal bleeding and breast tenderness as well as weight gain, sedation, and emotional depression. Neurosteroids, such as ganaxolone, have not been associated with such side effects and may ultimately prove to be superior as a treatment approach.

Neurosteroids and Stress-Induced Seizure Fluctuations

The availability of neurosteroids is increased during physiological stress. Stress results in the hypothalamic release of corticotropin-releasing hormone (CRH), which liberates adrenocorticotropic hormone (ACTH) from the anterior pituitary. Along with cortisol, ACTH also enhances the synthesis of adrenal DOC,[94,95] which is released into the circulation and can serve as a precursor for synthesis of the neurosteroid DOC (Fig. 77–1). In contrast to allopregnanolone, which is present in the brain even after adrenalectomy and gonadectomy, THDOC appears to be derived nearly exclusively from adrenal sources.[96] Plasma and brain levels of THDOC and allopregnanolone rise rapidly following acute stress.[52,97] Acute stressors such as swimming, foot shock, or carbon dioxide exposure elicit an increase in allopregnanolone and THDOC concentrations in plasma and in brain.[98,99] Plasma levels of THDOC normally fluctuate between 1 and 5 nM, but increase to 15–30 nM following acute stress and might reach 40–60 nM during pregnancy.[97,100] In contrast, allopregnanolone levels during the third trimester of pregnancy typically reach 70–160 nM and have been measured as high as 220 nM.[101]

Stress-induced neurosteroids have been demonstrated to elevate the seizure threshold.[52] Stress-induced seizure protection could be due to circulating neurosteroids synthesized in peripheral tissues or to those produced locally in the brain. However, the effects of swim stress-induced increases in seizure threshold and THDOC levels in rats were abolished in adrenalectomized animals, implicating adrenal-derived THDOC. Despite stress-induced seizure protection in animals,[52,102] patients and clinicians are not likely to recognize a reduction in seizure frequency associated with stress. Indeed, stress has been reported to trigger seizure activity in persons with epilepsy.[103,104] During stressful episodes adrenal hormone levels are expected to fluctuate, and it may simply be the withdrawal of THDOC during such fluctuations that is associated with seizure provocation. Alternatively, other unidentified hormonal factors with proconvulsant activity may be responsible for stress-induced increases in seizures. However, chronic stress of the type experienced by patients with epilepsy likely has different endocrinological consequences than acute stress. The effects on seizures of fluctuations in neurosteroid levels in chronic stress remain to be studied.

Neurosteroids in Temporal Lobe Epilepsy

Sexual and reproductive dysfunction are common among persons with epilepsy.[105] In particular, men with temporal lobe epilepsy (TLE) often have diminished libido and sexual potency that is associated with low testosterone levels.[106–108] This hypogonadal state has been attributed to the effects of certain hepatic enzyme-inducing antiepileptic drugs, or alternatively—given the extensive connections between temporal lobe structures such as the amygdala and hypothalamic nuclei that

govern the production and secretion of gonadotropin releasing hormone—to suppression of the hypothalamic-pituitary-gonadal axis by limbic seizures. There is evidence that serum androgen levels normalize after temporal lobe surgery that results in successful seizure control but not in patients who continue to have seizures, supporting the view that seizures are responsible for the hypoandrongenic state.[109] Testosterone, as noted previously, is a precursor for at least three neurosteroids with anticonvulsant properties: 5α-androstanediol, androsterone, and etiocholanolone.[11,12,110,111] There is evidence that serum levels of at least two of these steroids (androsterone and etiocholanolone) are reduced in men with epilepsy compared with control subjects.[106] It is conceivable that reduced levels of such anticonvulsant neurosteroids lead to an enhanced propensity for seizures and that neurosteroid replacement might be a useful therapeutic approach.

Certain biological factors in TLE may influence the sensitivity to endogenous neurosteroids and could have an impact on the efficacy of exogenous neurosteroids used in epilepsy therapy. Studies in a status epilepticus model of TLE have shown a striking reduction in δ subunit-containing $GABA_A$ receptors in the dentate gyrus,[112,113] suggesting that neurosteroid effects on nonsynaptic $GABA_A$ receptors may be reduced. In addition, in dentate gyrus granule cells, neurosteroid modulation of synaptic currents is diminished and α4 subunit-containing receptors are present at synapses.[114] All of these changes may facilitate seizures in epileptic animals but may reduce the efficacy of endogenous neurosteroids. The expression of neurosteroidogenic enzymes such as P450scc[73] and 3α-HSOR[17,19] appears to be elevated in the hippocampus in animals and human subjects affected by TLE. If local neurosteroidogenesis is enhanced, this may counteract in part the epileptogenesis-induced changes. However, the effect of withdrawal of neurosteroids, as might occur in catamenial epilepsy or with stress, could be enhanced.

Neurosteroids and Alcohol Withdrawal Seizures

Systemic administration of moderate doses (1–2.5 g/kg) of ethanol causes increases in plasma and brain neurosteroids that may contribute to many of the behavioral effects of ethanol in rodents.[115] This effect of ethanol is believed to be due to activation of the hypothalamic-pituitary-adrenal axis. As is the case in the catamenial epilepsy model, chronic ethanol-induced elevations in neurosteroids lead to an enhancement in the anticonvulsant actions of the neurosteroids allopregnanolone and THDOC.[116] These effects are associated with increases in the sensitivity of $GABA_A$ receptors to neurosteroids.[115] Endogenous neurosteroids may protect against ethanol withdrawal seizures. However, ethanol induction of allopregnanolone is diminished in tolerant and dependent animals. Reduced availability of allopregnanolone under such circumstances may be a factor that predisposes to alcohol withdrawal seizures. As is the case with catamenial epilepsy, neurosteroid replacement could conceivably be useful in the treatment of alcohol withdrawal seizures, given that current pharmacological approaches are not entirely satisfactory.[117]

GANAXOLONE AS A NOVEL NEUROSTEROID-BASED ANTIEPILEPTIC DRUG

Ganaxolone, the synthetic 3β-methyl derivative of allopregnanolone,[118] is the only neurosteroid that has been evaluated for the treatment of epilepsy in humans.[75,119] Allopregnanolne itself has been administered to humans at low doses intravenously (0.05–0.09 mg/kg) and found to be largely free of side effects except for sedation.[120,121] However, it has been proposed that allopregnanolone can undergo back conversion by 3α-HSOR isoenzymes to a hormonally active intermediate (dihydroprogesterone).[122] The 3β-methyl substituent of ganaxolone eliminates this back conversion, potentially avoiding hormonal side effects. Other than this theoretical advantage, ganaxolone has pharmacological properties similar to those of the natural neurosteroid from which it is derived.

Preclinical Studies

Ganaxolone has protective activity in diverse rodent seizure models, including clonic seizures induced by the chemoconvulsants pentylenetetrazol, bicuculline, flurothyl,

t-butylbicycloorthobenzoate, and aminophylline; limbic seizures in the 6 Hz model; amygdala- and cocaine-kindled seizures; and corneal kindled seizures (Table 77–1).[62,67,123–126] In chronically treated rats, tolerance does not occur to the anticonvulsant activity of ganaxolone.[67] In addition, a recent study in female amygdala-kindled mice demonstrated suppression of behavioral and electrographic seizures with a median effective dose (ED_{50}) of 6.6 mg/kg.[127]

Animal pharmacokinetic studies have found that ganaxolone has a large steady-state volume of distribution (6.5, 7.0, 19.5, and 3.5 L/kg in mice, rats, rabbits, and dogs, respectively), indicating that it distributes extensively into tissues.[75] Studies with radioactive ganaxolone in rats have found that ganaxolone (and its metabolites) are concentrated in tissues including the brain (brain-to-plasma concentration ratio between 5 and 10). Ganaxalone is highly bound to human plasma proteins (>99%). It is extensively metabolized to at least 16 different compounds; the primary metabolite is 16α-hydroxyganaxolone, which likely results from the action of CYP3A4. This primary metabolite is inactive in the PTZ seizure model and is 25-fold weaker than ganaxolone in inhibiting [^{35}S]TBPS binding. Ganaxolone is a CYP3A4 autoinducer in rodents but not in dogs or humans; chronic exposure to high doses in female rats does cause liver hypertrophy. Metabolites of ganaxolone are eliminated in the urine (13%–23%) and feces (65%–76%) in rats and dogs; the corresponding values in male healthy volunteers are 25% and 69%, respectively. Because of its aqueous insolubility, orally administered ganaxolone is poorly absorbed. To provide more consistent bioavailability, the steroid has been administered as a submicron particulate suspension and in a proprietary solid formulation.

Animal safety studies have demonstrated little evidence of target organ or systemic toxicity with either single-dose or multiple-dose ganaxolone treatment. In studies on pre- and postnatal development in mice, rats, and dogs, ganaxolone did not affect fetal implantation, viability, or growth and development from birth to weaning and was not teratogenic. Genotoxicity tests have not demonstrated any mutagenic or clastogenic potential for ganaxolone. Oral administration of ganaxolone to conscious dogs at a dose of 10 mg/kg did not reveal changes in cardiovascular hemodynamics.

Clinical Safety and Efficacy Studies

Over the past decade, ganaxolone has been studied in various clinical trials to assess its efficacy and safety in the treatment of epilepsy. More than 900 subjects have received the drug at doses of up to 1875 mg/day in adults and up to 54 mg/kg/day in children in Phase 1 normal volunteer studies, epilepsy trials, and also clinical trials for migraine. Single oral doses of 50–1600 mg in healthy volunteers results in peak plasma concentrations of 14 to as high as 460 ng/mL. Overall, the drug is safe and well tolerated. The most common side effect is

Table 77–1 **Anticonvulsant Profile of Ganaxolone in Mouse Seizure Models**

Seizure Model	ED_{50} Value (mg/kg)	Reference
Pentylenetetrazol	3.5 (2.1–5.8)	Reddy and Rogawski[67]
Pentylenetetrazol kindling	4.1 (2.7–6.4)	Gasior et al.[125]
Bicuculline	4.6 (3.2–6.8)	Carter et al.[118]
Flurothyl	5.0 (ND)	Liptáková et al.[123]
6 Hz	6.3 (4.0–9.8)	Kaminski et al.[62]
Amygdala kindling	6.6 (5.1–9.7)	Reddy and Rogawski[127]
t-Butylbicycloorthobenzoate	11.7 (8.8–15.7)	Carter et al.[118]
Aminophylline	11.5 (8.1–16.3)	Carter et al.[118]
Cocaine kindling	17.0 (ND)	Kaminski et al.[126]
Maximal electroshock	29.7 (25.3–34.8)	Carter et al.[118]
N-methyl-D-aspartate	>30 (ND)	Carter et al.[118]
Strychnine	>40 (ND)	Carter et al.[118]

Numbers in parentheses are 95% confidence intervals. ND, not determined. ED_{50} is the dose estimated to produce seizure protection in 50% of mice. The ED_{50} value in the rotarod test of motor toxicity in mice was 33.4 (30.9–39.4) mg/kg.[118]

reversible dose-related sedation. One epilepsy trial used the inpatient presurgical study design in adults with partial seizures.[128] A second study was an open-label, add-on trial in pediatric patients with a history of infantile spasms.[129] A third study was an open-label nonrandomized, dose-escalation add-on trial in highly refractory pediatric and adolescent patients; three patients in this study were followed in an extension phase over 3.5 years.[130] As discussed previously, there is limited anecdotal information supporting the efficacy of ganaxolone in the treatment of catamenial seizure exacerbations.[92] Recently, a double-blind, randomized, placebo-controlled study was completed in adults with partial seizures.[75] A separate trial was completed in infants with spasms. In this study, there was no clear statistically significant treatment effect, although some subjects did appear to demonstrate a treatment-related reduction in spasm clusters as assessed by 24 h video-electroencephalographic recordings.

The adult trial included 147 subjects (100 females, 47 males), aged 18 to 69 years, with partial-onset seizures with or without secondary generalization who were refractory to conventional antiepileptic drugs. Subjects were randomized in a 2:1 ratio to ganaxolone (1500 mg/day in three divided doses) or placebo. Ganaxolone treatment produced an 18% decrease in mean weekly seizure frequency compared with a 2% increase for placebo over the 10 week treatment period ($p = .025$). Responder rates (proportions of subjects with greater than 50% reduction in seizures during the maintenance phase) were 26% for the ganaxolone group versus 13% for the placebo group. Results from the open-label extension phase indicated that ganaxolone maintains its efficacy over time. Adverse events reported by at least 5% of patients, and at least twice as common in the ganaxolone group compared to the placebo group, were dizziness, fatigue (both 16% versus 8%), and somnolence (13% versus 2%). Seven percent of the subjects in the ganaxolone treatment group and 6% of those in the placebo group discontinued treatment due to adverse events.

CONCLUSIONS

Neurosteroids are endogenous modulators of neural excitability that are believed to have a role in the regulation of seizure susceptibility in the setting of preexisting epilepsy. Menstrual and stress-related fluctuations in seizures may in part be related to changes in brain neurosteroid levels. In addition, men with TLE who have suppression of the hypothalamic-pituitary-gonadal axis may have a reduction in testosterone-derived neurosteroids that could worsen seizures.

Treatment with exogenously administered natural neurosteroids or synthetic analogs such as ganaxolone may be beneficial to treat partial seizures. Further studies are required to determine if neurosteroid replacement is a useful therapeutic approach for seizure exacerbations related to endogenous neurosteroid fluctuations, such as in catamenial epilepsy and stress. In the future, agents that influence the endogenous synthesis of neurosteroids, such as TSPO ligands, may find utility as an alternative to neurosteroids themselves in the treatment of epilepsy.[24,131]

Chapter 78

Mechanisms of Ketogenic Diet Action

Susan A. Masino
Jong M. Rho

INTRODUCTION

The ketogenic diet (KD) is a high-fat, low-carbohydrate, adequate-protein diet that has been employed as a treatment for medically refractory epilepsy for over 90 years.[1] This alternative therapy was originally designed to mimic the biochemical changes associated with fasting, a treatment reported anecdotally over millennia to control seizure activity. The hallmark features of KD treatment are the production of ketone bodies (principally β-hydroxybutyrate, acetoacetate, and acetone)—products of fatty acid oxidation in the liver—and reduced blood glucose levels (Fig. 78–1). Ketone bodies provide an alternative substrate to glucose for energy utilization and, in the developing brain, also constitute essential building blocks for the biosynthesis of cell membranes and lipids.

Throughout much of the past century, the popularity of the KD waxed and waned. Initial enthusiasm was fueled by dramatic success rates, reported entirely in uncontrolled studies, but the KD was quickly supplanted by new antiepileptic drugs (such as phenytoin) that became available in the 1930s. Clinicians found it more convenient to administer a drug than to supervise a regimen requiring scrupulous attention to foodstuffs and avoidance of anti-ketogenic carbohydrates. Notwithstanding the prolonged stigma of being a fad therapy and one without a credible scientific basis, the KD experienced a major resurgence in the late 1990s, mostly as a consequence of serendipitous media attention and the continued failure of even newer antiepileptic drugs to offer significantly enhanced clinical efficacy.

Today, the KD is acknowledged as a proven therapy for epilepsy.[2] The growing number of clinical KD treatment centers throughout the world serves as a testament to the notion that irrespective of cultural and ethnic differences that define dietary and nutritional practices, a fundamental shift from carbohydrate-based

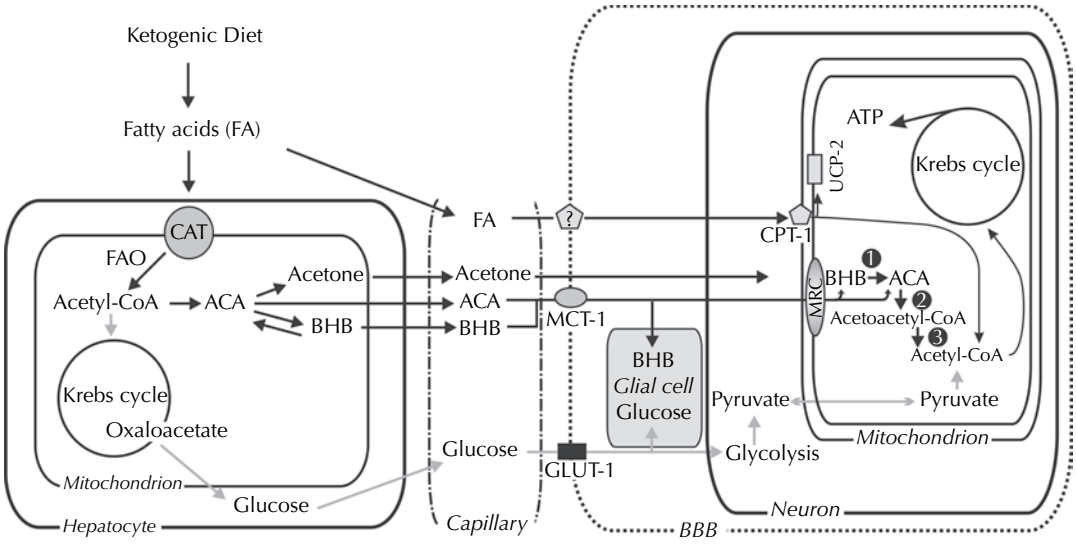

Figure 78–1. Metabolic pathways involved in KD treatment. In the liver, fatty acids are ordinarily converted into acetyl-coenzyme A (acetyl-CoA), which enters the tricarboxylic acid (TCA) cycle. When fatty acid levels are elevated and exceed the metabolic capacity of the TCA cycle, acetyl-CoA is shunted to ketogenesis. Two acetyl-CoAs can combine through a thiolase enzyme to produce acetoacetyl-CoA, which is a precursor for the synthesis of acetoacetate (ACA) and β-hydroxybutyrate (BHB). Acetone, the other major ketone body, is produced primarily from spontaneous decarboxylation of ACA and can be eliminated as a volatile substrate through the lungs and kidneys. In the blood, ACA and BHB are transported from the vascular lumen to the brain interstitial space, and to both glia and neurons, by monocarboxylic acid transporters (MCTs). Monocarboxylate transporter-1 is the principal carrier localized to the vascular endothelium. Within neurons, both ACA and BHB are transported directly into mitochondria and then converted to acetyl-CoA through several enzymatic steps. β-Hydroxybutyrate is converted to ACA through D-β-hydroxybutyrate dehydrogenase, and ACA undergoes subsequent conversion to acetoacetyl-CoA through a succinyl-CoA transferase enzyme. Finally, acetoacetyl-CoA-thiolase converts acetoacetyl-CoA to two acetyl-CoA moieties that then enter the TCA cycle. consumption to fatty acid oxidation results in similar clinical effects. Despite such widespread use of the KD, surprisingly little is understood about its underlying mechanisms of action. This may be due to the inherently complex interplay between the network dynamics of the human brain (particularly in the disease state and during development) and the myriad biochemical and physiological changes evoked by consumption of dietary substrates. It has not been straightforward to determine cause-and-effect relationships in this bewildering context, and one cannot be certain whether specific molecular and cellular alterations observed are relevant or simply represent epiphenomena. This knowledge gap has hindered efforts to develop improved or simplified treatments (such as a "KD in a pill"[3]) that obviate the strict adherence to protocol that the KD requires. However, research efforts have been intensifying over the past decade, and recent investigations have provided new insights and molecular targets.

Herein we outline the most prominent mechanisms underlying KD action. We introduce these mechanisms chronologically as they were proposed, integrate these ideas with more recent findings, and examine the evidence for the broad neuroprotective properties of the KD; these properties, if validated, would highlight the clinical potential of the KD as a broadly encompassing disease-modifying intervention.[4–7] Whether the cellular mechanisms responsible for the clinical utility of the KD for human epilepsies are identical to those observed in animal models, or whether they overlap with the mechanisms that afford clinical benefits for other neurological conditions,

remains to be determined. An integration of older and newer ideas regarding the underlying mechanisms of KDs might represent the ideal scientific strategy to eventually unlock the secrets of this metabolism-based therapy.

HISTORICAL AND CLINICAL PERSPECTIVES

Early Hypotheses of KD Action

Initial studies into the mechanisms underlying KD action focused on concepts of acidosis, dehydration, and increased ketone concentrations—largely because these were the readily apparent ideas stemming from clinical implementation and observations.[8] Mild dehydration was postulated as necessary, possibly to maximize concentrations of ketones that were believed to provide anti-convulsant effects. As discussed later, however, peripheral ketone concentrations alone (whether measured in urine or in blood) are not tightly correlated with seizure control, and there is no evidence that dehydration or fluid restriction is necessary for clinical efficacy.[9] Nonetheless, because ketone metabolism generates protons and pH-lowering metabolic products, decreased pH (i.e., acidosis) was also considered initially to be a key aspect of the KD. However, there is no clear evidence that a KD significantly lowers brain pH, let alone that a decrease in pH-however small—may be associated with its anti-convulsant activity.[10]

Despite these negative results, however, it is possible that the KD may induce dynamic and differential pH changes in local microdomains; this possibility has yet to be assayed during KD treatment. Indeed, local compartments have been shown to exhibit differential pH regulation during neuronal activity,[11,12] and recent work has highlighted novel pH-related anti-convulsant mechanisms. For example, acidosis in vivo reduced seizure activity via activation of a depolarizing acid-sensing ion channel 1a (ASIC1a) localized to hippocampal interneurons.[13] Other studies showed that decreased intracellular pH during periods of increased neuronal excitability releases adenosine and decreases excitatory synaptic transmission and bursting in in vitro hippocampal slices.[14] Thus, pH-related mechanisms may offer new prospects for anti-convulsant therapies, and techniques enabling higher-resolution studies of pH dynamics in vivo and within neuron-glia microdomains may resolve permanently whether the KD acts in part by changing pH-which can influence proton-sensitive ion channels such as *N*-methyl-D-aspartate (NMDA) receptors[15,16] and specific gamma-aminobutyric acid A ($GABA_A$) receptor isoforms.[17–19]

Clinical Insights

From decades of clinical experience, it is been observed that almost any diet resulting in ketonemia and/or reduced blood glucose levels can produce an anti-convulsant effect. Comparable clinical efficacy has been seen using KDs comprised of either long-chain triglycerides (LCTs)[20,21] or medium-chain triglycerides (MCTs).[22–25] Within the last decade, two additional variations of these KDs have emerged[26]: the modified Atkins diet (MAD)[27–30] and the low-glycemic index treatment (LGIT).[31–33] The former allows for more liberal carbohydrate consumption and does not significantly restrict protein intake compared to the classic KD, whereas the latter was developed to mirror reduced glucose levels during KD treatment, and as such is based on a fundamental adherence to foods with low glycemic indices. The glycemic index is a value that describes the extent to which a carbohydrate is absorbed and elevates blood glucose, and lower indices correlate with slower insulin responses compared to glucose. Interestingly, LGIT does not induce the prominent ketosis seen with classic KDs and the Atkins diet.

Thus, at present, there are three primary dietary therapies for epilepsy: the traditional KD (a variation of which is the MCT diet), the MAD, and the LGIT. All three diets have been increasingly studied and are being used currently for both children and adults in centers worldwide. Importantly, available evidence indicates that dietary composition per se does not appear to affect the anti-convulsant efficacy of the diet as long as there is a degree of sustained ketosis and/or calorie restriction.[34–39] And although there are patients with epilepsy who respond dramatically within days of initiating the KD, maximum efficacy is not generally achieved for several days or weeks after initiation, suggesting that longer-term adaptive

Table 78–1 **Ketogenic Diet: Clinical Correlates and Experimental Observations**

	Clinical Correlate	Observation in Animal Models
Seizure type	KD is effective against many seizure types and epilepsy syndromes	KD is effective in models employing a wide variety of seizure paradigms
Age range	Children extract and utilize ketones from blood more efficiently than older individuals	Younger animals respond better to the KD
Caloric restriction	Associated with seizure reduction	Increases the seizure threshold
Diet type	Classic and MCT KDs are equally efficacious	Classic and MCT diets both increase the seizure threshold
Ketosis	Ketosis is necessary but not sufficient for seizure control	A threshold level of ketosis is necessary but not sufficient to explain antiseizure effects
Fat	Practical concerns limit the ketogenic ratio; possible role of fat chain length and degree of saturation (e.g., PUFAs)	Improved efficacy with higher ketogenic ratios; uncertain if the type of fat is a critical variable
Latency to KD effectiveness	Seizures may be seen during the prediet fast or after a latency of days to weeks	Several days
Reversal of protective effect when KD is discontinued	Rapid (hours)	Rapid (hours)

Abbreviations: KD, ketogenic diet; MCT, medium-chain triglycerides; PUFAs, polyunsaturated fatty acids.

metabolic and/or genetic mechanisms may be recruited.[40] These adaptations are likely generalized throughout the epileptic brain, irrespective of the underlying pathology or the genetic predisposition to seizures, because the KD is an effective treatment for diverse epileptic conditions.[41,42] Table 78–1 provides a general context for the subsequent discussion, comparing and contrasting key parameters observed clinically and in experimental models.

ANIMAL MODELS

Acute Models

The bulk of the existing experimental literature pertaining to the KD involves studies in which various high-fat treatments are implemented prior to acute provocation with either electrical or chemoconvulsant stimulation in rodents. In these studies, animal diets have modeled the classic LCT diet and conform closely to either a 4:1 or approximately a 6:1 ketogenic ratio of fats to carbohydrates plus protein (by weight). In general, irrespective of the precise dietary formulation—as long as ketosis is seen, reflecting a shift from primarily glycolysis to intermediary metabolism—anti-convulsant effects have been observed. Indeed, whether seizures are provoked by corneal electroshock, hydration electroshock, maximal electroshock, pentylenetetrazol (PTZ), bicuculline, semicarbazide, kainate, flurothyl, or 6 Hz stimulation, chronic pretreatment with a KD appears to render anticonvulsant effects.[43–53] It should be noted that the KD is not anti-convulsant in all acute animal models, particularly in mice,[54–56] and its effects may be of limited duration[44] or can even exacerbate (maximal) seizures.[37,46,47,57,58] But while such results may raise concerns for the validity of the studies as a whole, one must recall that the KD is not universally effective in patients with medically refractory epilepsy.[20,21,41]

Further complicating interpretation of the animal literature, the highly variable methodologies used (e.g., use of calorie restriction, age at initiation and duration of therapy, dietary ratios and formulations, timing of treatment, mode of seizure induction) have made cross-comparisons nearly impossible.[59,60] Regarding observations in rodent models, the anticonvulsant efficacy of 4:1 or 6:1 KDs may be

confounded by the fact that they did not control for intake of vitamins, minerals, and antioxidants. Highlighting this cautionary note, when a balanced KD was utilized in the PTZ, kainate, or flurothyl models, anti-convulsant efficacy was not actually observed.[55] Thus, acute animal studies highlight a number of problems with these experimental approaches and have challenged our ability to directly translate animal research to the human epileptic condition.

Chronic Animal Models

Published animal studies, in attempting to replicate the clinical experience, suggest that dietary effects in controlling brain excitability extend beyond species boundaries, but they have done little to enhance our knowledge of underlying mechanisms of action. Rather, they raise more issues and highlight the necessity of investigating KD effects in a more clinically relevant model—namely, a chronic model characterized by early-onset, medically refractory epilepsy that is responsive to a clinically validated formulation of the KD.[61] That said, it is also important to recognize that species differences, particularly with regard to fatty acid metabolism and blood-brain-barrier properties, may dictate incongruency of experimental results.

Muller-Schwarze and colleagues[62] provided the first evidence that a KD can retard epileptogenesis in a chronic animal model. In this study, rats were first subjected to kainate-induced status epilepticus and then treated with a KD. Seizure frequency and duration, recorded after the latent period, were both significantly lower in the KD-treated group compared to controls. Further, there was a significant reduction in the extent of mossy fiber sprouting in the KD-fed group. In another model of chronic epilepsy, the KD was shown to prolong the lifespan in succinic semialdehyde dehydrogenase (SSADH)-deficient (*Aldh5a1*$^{-/-}$) mice, which are characterized by GABA deficiency, recurrent seizures, and early demise.[63] Interestingly, KD treatment restored spontaneous inhibitory synaptic currents to control levels, effects that were later attributed to an increase in the number of mitochondria in hippocampus, as well as a restoration of reduced hippocampal adenosine triphosphate (ATP) levels compared to controls.[64]

Comparable to induced models, the KD has also been shown to be effective in genetically determined epilepsy models. The EL mouse is a seizure-susceptible inbred strain believed to represent a model of multifactorial idiopathic partial epilepsy with secondary generalization.[65] Environmental stimulation such as repetitive handling can induce seizures in EL mice and facilitate epileptogenesis beginning at postnatal day 30 (P30). Generalized seizures generally manifest by the second postnatal month and persist throughout life.[66] When mice were fed a 4.75:1 KD formula over a 10-week period, seizure susceptibility scores were significantly reduced compared to those of controls after 3 weeks, but this difference disappeared by week 7.[67] These transient results were similar to those reported earlier in the kindling model.[44]

More recently, effects of a 6.3:1 KD were investigated in *Kcna1*-null mice lacking the gene encoding the delayed rectifier potassium channel α subunit, Kv1.1. The frequency of spontaneous recurrent seizures was significantly reduced in KD-fed mice compared to wild types.[68] This observation is of particular interest due to the facts that (1) *Kcna1*-null mice exhibit progressive histological changes in the hippocampus similar to those observed in human epileptic tissues and in many animal models of temporal lobe epilepsy[69] and (2) the *Kcna1* gene is one of only a few epilepsy genes in a developmental animal model that has a homologue in a human epileptic condition.[70,71]

MECHANISTIC STUDIES IN THE EARLY RENAISSANCE ERA

Ultimately, to produce anti-convulsant effects, the KD must reduce neuronal excitability and/or synchrony. The essential currency of neuronal excitability—both normal and aberrant—is the complex array of primarily voltage-gated and ligand-gated ion channels that determine the firing properties of neurons and mediate synaptic transmission. At present, there appear to be at least six important mechanisms through which the currently available antiepileptic drugs exert their anti-convulsant action,[72–74] and the vast majority of molecular targets are ion channels and transporters localized to plasmalemmal membranes. In this

light, a fundamental question pertaining to KD effects at the cellular and molecular levels has been whether any of the metabolic substrates (e.g., ketone bodies) elaborated by this non-pharmacological intervention can interact with ion channels known to regulate neuronal excitability. Broadly speaking, this does not appear to be the case. Given this tantalizing situation, there has been intense recent interest in how metabolic changes induced by a KD translate in a causal manner into a reduction in neuronal excitability and/or synchrony. Most of the postulated mechanisms discussed below are considered in the context of multiple lines of evidence, from human data as well as in vivo and in vitro model systems.

Ketone Bodies

Perhaps the most obvious and potentially most important clinical observation pertaining to the mechanistic underpinnings of the KD is the prominent ketonemia seen in patients. At face value, it would seem to be a relatively straightforward matter to establish a cause-and-effect relationship between the degree of ketonemia and seizure control. Further, it should be no surprise that since the 1930s, researchers have asked time and again whether ketone bodies might themselves exert anti-convulsant effects.[49,75–78] Despite intense scrutiny, this matter remains unresolved. It is well known that seizure control gradually improves within the first few weeks of initiating the KD, as serum ketone levels steadily increase. Interestingly, seizure control can be lost abruptly when ketosis is broken, usually through ingestion of carbohydrates,[22] again implicating ketone body action. Further, blood β-hydroxybutyrate (BHB) levels can appear to correlate directly with seizure control in children placed on a KD,[20,21,79] but the relationship is inconsistent.[41] The threshold BHB level for seizure control appears to be a blood concentration of 4 mmol/L for children successfully maintained on the KD for 3 or 6 months,[79] and investigators have used such clinical observations to model KD conditions in both animal models and in vitro studies. In general, blood levels are better correlated with seizure control than urinary levels; the latter are obtained through dipstick assessments that grossly reflect only acetoacetate levels.[79,80]

Keith first reported that acetoacetate (ACA) protected against thujone-induced seizures in rabbits,[75] an observation that was later confirmed in an audiogenic seizure-susceptible mouse model.[49] Later, Likhodii and colleagues provided direct evidence that acetone could block induced seizures in multiple animal models of seizures and epileptogenesis.[76] They demonstrated that acetone, when injected intraperitoneally, yielded plasma and cerebrospinal fluid (CSF) concentrations consistent with doses used to suppress seizures. In support of this, clinical investigators found that acetone was detectable in the brains of fully controlled KD-treated epileptic patients using proton magnetic resonance spectroscopy and was estimated to be present in concentrations of approximately 0.7 mM.[81] Curiously, while in vivo experiments have demonstrated the acute anticonvulsant properties of ACA and acetone, there are as yet no convincing data indicating that the major ketone body, BHB, can exert similar effects. Intriguingly, however, recent work suggests that metabolizing BHB rather than glucose reduces the availability of glutamate, which could then contribute to anticonvulsant and potentially neuroprotective effects.[82]

Considering the other ketone bodies, the link between ACA and acetone is particularly tight; ACA is spontaneously decarboxylated to acetone, and as such, it was speculated that ACA's acute anticonvulsant effects might be due to immediate conversion to acetone and subsequently to its many downstream derivatives.[83] But more recent work has clearly demonstrated that the anticonvulsant activity of acetone is not dependent upon its metabolites,[84] so the exact mechanism of acetone's rather broad-spectrum anticonvulsant activity remains unknown. It has been proposed that S-D-lactoylglutathione, an intermediate of acetone metabolism, might activate voltage-gated potassium channels and thereby hyperpolarize the neuronal cell membrane,[85] but there is as yet no direct evidence. And there is yet another report that acetone and BHB enhanced inhibitory glycine receptors, whereas BHB alone was able to enhance $GABA_A$ receptor-mediated currents—but all of these actions were observed at highly supratherapeutic (i.e., anesthetic) concentrations, not seen during KD treatment.[86]

Investigations involving potential anticonvulsant compounds would not be complete

without the use of cellular electrophysiological techniques, and thus it was of interest whether ketone bodies would affect any of the principal ion channels that are the primary targets of clinically used antiepileptic drugs. Surprisingly, such studies were initiated little more than a decade ago. Thio and colleagues[87] reported that acute application of low millimolar concentrations of BHB or ACA did not affect synaptic transmission in normal rat hippocampus and did not affect $GABA_A$ receptors, ionotropic glutamate receptors, or voltage-gated sodium channels over a wide concentration range (300 μM to 10 mM). The fact that ACA was ineffective in their hands was indeed surprising, especially given its clear anti-convulsant effects when administered in vivo.[49,76]

Recently, however, Ma and colleagues[77] found that BHB and ACA—at physiological concentrations—reduced the spontaneous firing of GABAergic neurons in rat substantia nigra pars reticulata (SNr; a subcortical structure that influences seizure propagation) by opening cellular membrane-bound, ATP-sensitive potassium (K_{ATP}) channels. K_{ATP} channels, a type of inwardly rectifying potassium channel (Kir6) that is activated when intracellular ATP levels fall, were long considered logical candidates for linking metabolic changes to cellular membrane excitability.[88] Despite the intuitive appeal of this observation, an inherent discrepancy remains to be reconciled. Consistently, studies have shown that the KD can increase levels of ATP and other bioenergetic substrates through enhanced mitochondrial respiration.[89–93] Because high ATP levels block K_{ATP} channel activity, it is unclear how opening of these channels is achieved by infusion of ketone bodies in the SNr.

Yet another intriguing link between ketone bodies and neuronal excitability was recently reported. Juge and colleagues demonstrated that ACA inhibits vesicular glutamate transporters (VGLUTs), which are required for exocytotic release of the excitatory neurotransmitter glutamate, specifically by competing with an anion-dependent regulatory site on presynaptic vesicles.[78] These investigators demonstrated that ACA decreased the quantal size of excitatory neurotransmission at hippocampal synapses, and suppressed glutamate release and seizures evoked by the convulsant 4-aminopyridine in rats. This novel finding may be a plausible explanation for the acute in vivo effects of ACA observed nearly eight decades earlier,[75] but ACA is reported to have other actions as well, notably on mitochondria.[92,94] The other caveat is that ACA is highly unstable and undergoes spontaneous decarboxylation to acetone, which may have other actions. Further, in the presence of BHB dehydrogenase, ACA is interconverted to the major ketone body BHB. Thus, it appears that seemingly straightforward metabolic substrates are players in a more complex arena.

In summary, the available evidence thus far fails to strongly support a primary mechanistic role for ketone bodies in the clinical efficacy of the KD, as no compelling molecular target has been identified and linked to attenuation of spontaneous seizures in a chronic epilepsy model. At this juncture, it is unlikely that there is only one relevant action of any of the primary ketone bodies on neuronal activity. If ketones are indeed fundamentally required for the anticonvulsant efficacy of the KD, they are more likely contributory to other parallel (and possibly synergistic) effects of the diet. Of the various hypotheses proposed, the most likely candidate mechanisms are membrane hyperpolarization through activation of potassium channels, increased GABAergic neurotransmission, or a reduction in vesicular glutamate release. Ketones have been shown to reduce brain glucose consumption,[95] and reduced glucose is another key hallmark of a KD discussed in more detail below.

Age Dependence of Ketone Utilization

Multiple studies and anecdotal observations have suggested that the KD is most effective in immature animals or infants and children,[34,45,54,58,96] perhaps due to greater fatty acid oxidation of breast milk (which is high in fats), more efficient extraction of ketone bodies from the blood, and an early age-dependent surge in the expression of the monocarboxylic acid transporters, MCT1 and MCT2.[97,98] If indeed the degree of ketonemia is a major determinant of seizure control, one would predict that younger patients would respond better than older ones. Clinical studies to date tend to support this notion, although it is becoming clearer that adolescents and adult patients with

epilepsy also benefit from KD treatment[99,100] In addition, there is abundant laboratory evidence suggesting that the anticonvulsant effects of KDs are not age-dependent.[40]

There is recent controversy involving ketone bodies aimed straight at the heart of a scientific dogma—that is, the notion that GABA-mediated responses in the early developing brain are excitatory, not inhibitory.[101,102] Zilberter and colleagues reported that the addition of ketones and other metabolic substrates such as lactate to artificial cerebrospinal fluid (aCSF)—which traditionally contains glucose as the sole energy substrate—resulted in an age-dependent hyperpolarizing shift of the GABA reversal potential in both hippocampus and neocortex and a significant reduction in the generation of giant depolarizing potentials (GDPs), which have long been regarded as the hallmark of spontaneous neonatal network activity in vitro.[103,104] This striking finding suggests that in the immature brain, GABAergic neurotransmission might actually be inhibitory in situ, as there is a greater preponderance of energy substrates (such as ketone bodies, lactate, and pyruvate) than at later ages.[105–107] However, these provocative findings have quickly been challenged by other groups who found that (1) the depolarizing GABA action in neonatal hippocampal slices is not due to deficiencies in energy metabolism[108] and (2) physiological plasma concentrations of BHB, lactate, and pyruvate failed to affect the depolarizing actions of GABA in immature rat pups (P4–7), and only nonphysiological concentrations of pyruvate (5 mM) reduced the driving force for $GABA_A$ receptor-mediated currents and blocked GDPs.[109] Clearly, while this controversy remains unsettled at present, the general notion that bioenergetic substrates may exert profound cellular electrophysiological effects is becoming increasingly appreciated.

GABAergic Inhibition

An enduring hypothesis regarding the mechanisms of KD action involves enhancement of GABA-mediated inhibition. Facilitation of GABAergic neurotransmission has long been accepted as a critical mechanism of action for a variety of clinically effective antiepileptic drugs, and thus there is an intrinsic appeal to invoking this mechanism. With respect to ketone bodies, however, $GABA_A$ receptors do not appear to be the primary targets in this regard. Indirect evidence comes from acute animal studies in which the KD is found to be most effective against seizures evoked by the GABAergic antagonists (i.e., PTZ, bicuculline, picrotoxin and gamma-butyrolactone), whereas it fails to block acute seizures provoked by kainic acid, strychnine (a glycine receptor antagonist), and maximal electroshock (MES; involving voltage-dependent sodium channels).[48]

More direct evidence comes from electrophysiological recordings conducted in vivo, demonstrating that the KD increased paired-pulse inhibition and elevated the maximal dentate activation threshold in rats, consistent with an elevated seizure threshold via enhancement of GABAergic inhibition.[37] In a related study, caloric restriction—which results in mild ketosis—enhanced the expression of both isoforms of glutamic acid decarboxylase (GAD65 and GAD67, the biosynthetic enzymes for GABA) in the tectum, cerebellum, and temporal cortex of rats, suggesting increased GABA levels.[110] However, increased GAD expression might actually reflect decreased GABA production,[111–113] so the ramifications of these findings to neuronal inhibition remain unclear.

At a neurochemical level, Yudkoff and colleagues have proposed that in the ketotic state, a major shift in brain amino acid handling results in a reduction of aspartate relative to glutamate (the precursor to GABA synthesis) and a shift in the equilibrium of the aspartate aminotransferase reaction.[114–117] This adaptation in the metabolism of the excitatory neurotransmitter glutamate (i.e., a decrease in the rate of glutamate transamination to aspartate) would be predicted to increase the rate of glutamate decarboxylation to GABA, the major inhibitory neurotransmitter, because more glutamate would be available for the synthesis of both GABA and glutamine.[114,115,118] An increase in brain GABA levels would then be expected to dampen seizure activity (Fig. 78–2). But is there any evidence that the KD increases GABA levels in seizure-prone areas of the brain? The experimental data thus far are inconsistent or are reflective of changes outside of critical areas such as the hippocampus, thalamus, and neocortex.[10,91,114,119] Two clinical studies have reported significant increases in GABA levels following KD treatment,[120,121] however, further substantiating this view. More recent work

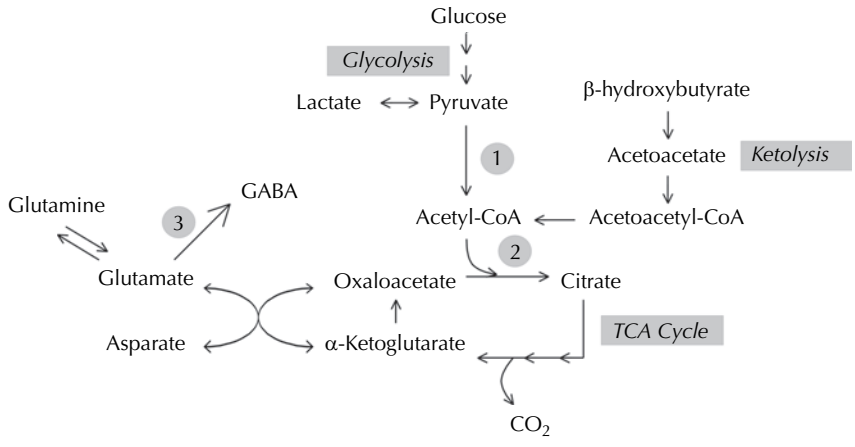

Figure 78–2. The metabolic interrelationships between brain metabolism of glutamate, ketone bodies, and glucose. In ketosis, 3-OH-butyrate (β-hydroxybutyrate) and acetoacetate contribute heavily to brain energy needs. A variable fraction of pyruvate (**1**) is ordinarily converted to acetyl-CoA via pyruvate dehydrogenase. In contrast, all ketone bodies generate acetyl-CoA, which enters the TCA cycle via the citrate synthetase pathway (**2**). This step involves the consumption of oxaloacetate, which is necessary for the transamination of glutamate to aspartate. Oxaloacetate is then less available as a reactant of the aspartate aminotransferase pathway, which couples the glutamate-aspartate interchange via transamination to the metabolism of glucose through the TCA cycle. Less glutamate is converted to aspartate, and thus more glutamate is available for synthesis of GABA (**3**) through glutamic acid decarboxylase (GAD). Adapted from Yudkoff M, Daiken Y, Nissim, I, Nissim I. The ketogenic diet: interactions with brain amino acid handling. In: Stafstrom CE, Rho JM, eds. *Epilepsy and the Ketogenic Diet*. Totowa, NJ: Humana Press; 2004:186.

has demonstrated that BHB decreases GABA degradation and thus could increase the available pool of GABA.[122] Collectively, whereas both laboratory and clinical data support a role for increases in GABA levels and presumably increased inhibition via GABA receptors as a potential mechanism underlying KD action, it remains unclear why a KD can be effective in stopping seizures in patients who have failed to respond to GABAergic drugs.

Norepinephrine and Neuropeptides

One of the more intriguing observations regarding KD action involves the noradrenergic system. Several lines of evidence support the notion that increases in noradrenergic tone result in anticonvulsant activity. For example, norepinephrine (NE) reuptake inhibitors prevent seizures in genetically epilepsy-prone rats (GEPRs),[123] agonists of noradrenergic receptors are generally anticonvulsant,[124] and ablation of the locus coeruleus (the origin of both ascending and descending noradrenergic innervation) contributes to the ontogeny of self-sustaining status epilepticus (SSSE) in rats.[125] Along these lines, it is of significant interest that mice lacking the ability to produce NE (i.e., dopamine β-hydroxylase-deficient mice) do not exhibit increased resistance to flurothyl seizures when treated with a KD,[126] whereas similar treatment renders protective effects in control wild types. These data indicate that NE is required for the anticonvulsant effect of KD, at least in the flurothyl seizure threshold model. It was later shown that a KD increased basal NE levels in hippocampus nearly two-fold,[124] further supporting this mechanistic hypothesis. Increased NE release would also be predicted to promote co-release of anticonvulsant orexigenic peptides such as neuropeptide Y (NPY) and galanin.[124] However, there was is no evidence for enhanced transcription of either of these peptides in the brain after KD treatment, suggesting that neither NPY nor galanin contributes significantly to the anticonvulsant actions of a KD.[127]

Another peptide potentially important in mediating KD effects is leptin, an endogenous substrate that helps regulate energy homeostasis. Leptin is part of the hormonal system that limits energy intake and expenditure and is intimately involved in appetite regulation.[128] Less appreciated, however, is the fact that it can exert modulatory effects on neuronal

excitability and suppress seizure activity.[129,130] In an important translational study, leptin was shown to attenuate focal or generalized seizures in rodents, possibly through alteration of alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA) receptor-mediated synaptic transmission.[131] Since the KD causes a rise in leptin levels,[132] it is possible that the KD's mechanism, at least in part, may relate to a leptin-associated reduction in synaptic excitability.

Polyunsaturated Fatty Acids

Of the various fats that constitute KDs, polyunsaturated fatty acids (PUFAs) have received by far the most attention. Docosahexaenoic acid (DHA, C22:6ω3), arachidonic acid (AA, C20:4ω6), and eicosapentaenoic acid (EPA, C20:5ω3) are the main PUFAs believed to profoundly affect cardiovascular function and health. It is well known that PUFAs can directly inhibit voltage-gated sodium channels and L-type calcium channels[133–135] and can activate certain classes of potassium channels.[136,137] Further, DHA and EPA have been shown to decrease neuronal excitability and bursting in hippocampus.[138]

Intriguingly, there is clinical evidence that the KD elevates key PUFA levels in the blood.[139] In this study—in which each patient served as his or her own control—AA increased 1.6- to 2.9-fold, DHA increased 1.5- to 4.0-fold, and the rise in total serum AA correlated with improved seizure control. A later thought-provoking study revealed that CSF taken from epileptic patients on the KD promoted opening of voltage-gated Shaker-type potassium channels expressed in *Xenopus* oocytes, and these authors surmised that the DHA, EPA, and linoleic acid might be responsible for this effect.[140]

Laboratory investigations linking PUFAs to KD action appear discordant. Several studies have found that PUFAs are anticonvulsant in rodents,[133,137,141–143] yet other published investigations report no such effects.[144,145] Interestingly, KDs with widely differing effects on tissue lipids and fatty acid profiles can confer similar degrees of seizure protection,[146] suggesting that specific fatty acids might not be the key mediators of the KD's clinical effects. This latter study is consistent with the notion that a general metabolic shift toward fatty acid oxidation is a fundamental requirement.

Clinical studies are similarly inconclusive. One early study of five patients found that dietary supplementation with a "PUFA spread" (specifically, 5 gm of 65% omega-3 PUFAs once daily) suppressed seizures in those who tolerated the treatment.[147] Later, a randomized, placebo-controlled study involving a larger sample size failed to find similar effects when a PUFA supplement consisting of EPA plus DHA (2.2 mg/day in a 3:2 ratio) was administered over a 12-week treatment period.[148] Another study found no correlation between changes in fatty acid levels and seizure response when a KD was supplemented with omega-3 fatty acids in 25 children with epilepsy.[149] More recently, a retrospective analysis revealed that AA levels were significantly decreased in epileptic patients treated successfully with the KD compared to nonresponders.[150] Although it would be reasonable to dismiss the PUFA hypothesis given the clinical data thus far, it is likely that a proper controlled trial design has yet to be implemented. Further, while there are a number of clinical research variables that were not considered, factors such as PUFA load, duration of treatment, and, potentially, degree of ketosis might be highly important in demonstrating significant effects.

There are a few additional aspects of PUFA biology worth mentioning. Polyunsaturated fatty acids are natural activators of fatty acid receptors, specifically peroxisome proliferator-activated receptors (PPARs), and there is evidence that activation of brain-localized PPARs can influence seizure activity.[151–153] In this regard, PPARα could act as both a sensor and an effector of KD action.[154] Further, nuclear translocation of activated PPARs inhibits pro-inflammatory transcription factors,[151] and, as inflammation is increasingly recognized as a core contributor to seizures and epileptogenesis,[155] a KD (or a similar metabolic formulation) might constitute a rational treatment approach.[156]

METABOLIC MECHANISMS

The earliest demonstration that the KD enhances energy substrates was provided by DeVivo and colleagues,[119] who showed significant increases in brain bioenergetic substrates such

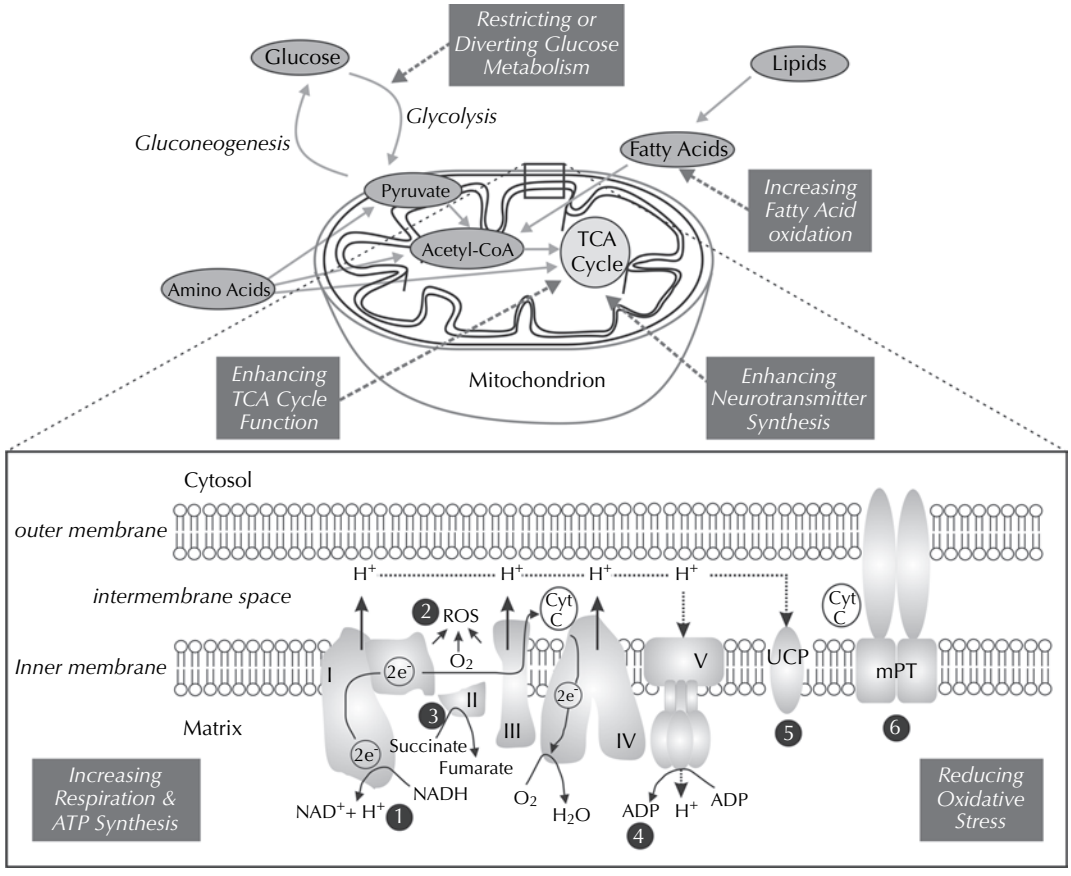
as ATP, creatine, and phosphocreatine in normal adult rats fed a high-fat, low-carbohydrate diet for 3 weeks. The metabolic data examined in this study indicated an overall increase in the cerebral energy reserve and energy charge that the authors believed could account for the neuronal stability that accompanied the chronic ketosis. A later study confirmed the elevation in brain adenine nucleotides as a consequence of KD treatment.[157] However, the most compelling demonstration that the KD profoundly affects energy metabolism was provided by Bough and colleagues, who used microarray and electron microscopic techniques to examine patterns of gene expression in the hippocampus of rats fed either a KD or a control diet.[91] They quantified a robust upregulation of transcripts encoding metabolism enzymes and mitochondrial proteins and an increased number of mitochondrial profiles. Importantly, and consistent with increased energy reserves, hippocampal slices from KD-fed animals were highly resistant to the metabolic stress induced by low-glucose conditions. Additional studies support the beneficial effects of a KD on mitochondrial energy metabolism.[64,158] Figure 78–3 highlights some of the effects of the KD on mitochondrial function.

As intriguing as these studies are, how exactly would enhanced energy reserves lead to a stabilization of synaptic functioning, membrane potential, and diminished seizure activity? One interpretation of the neuronal consequences of these bioenergetic changes is that neurons are better able to maintain ionic gradients and the resting membrane potential and thus resist depolarizing influences. The most likely way this stabilization is accomplished is through the Na^+/K^+ adenosine triphosphatase (ATPase) pump; specifically, KD-induced elevations in ATP concentrations might enhance and/or prolong the activation of the Na^+/K^+-ATPase, perhaps via an increase in the delta-G′ of ATP hydrolysis.[159] To date, however, there are no published studies directly testing this sodium-pump hypothesis in epileptic brain.

There is an alternative and complementary hypothesis linking increased energy substrate availability with membrane hyperpolarization. Kawamura and colleagues evaluated the electrophysiological effects of reduced glucose (a consistent finding in patients successfully treated with the KD) in CA3 hippocampal pyramidal neurons—importantly, under conditions of adequate or enhanced ATP levels, but without the addition of ketone bodies—using whole-cell recording techniques.[160] These investigators found that glucose restriction led to ATP release through pannexin hemichannels localized on CA3 neurons. The increased extracellular ATP, upon rapid degradation by ectonucleotidases to adenosine, resulted in activation of adenosine A_1 receptors that were shown to be coupled to opening of plasmalemmal K_{ATP} channels. This study highlights a novel mechanism of metabolic autocrine regulation, involving close cooperation among pannexin hemichannels, adenosine receptors, and K_{ATP} channels, and provides an elegant connection to an earlier study demonstrating ketone-mediated attenuation of spontaneous neuronal discharge in SNr.[77] It should be noted that the potential contribution of adenosine is plausible, given the well-substantiated role of this endogenous purine in suppressing cellular excitability.[161] Consistent with the involvement of adenosine, this latter group recently found evidence that the KD suppresses electrographic seizures in vivo in mice with spontaneous seizures through a mechanism involving A_1 receptors.[162]

It is important to note that the observation that reduced glucose might contribute to seizure control is not recent. Caloric restriction in rodents was shown to reduce seizure susceptibility, and lowered levels of blood glucose correlated with inhibition of epileptogenesis in a genetic model.[35,163] When the interplay of glucose levels and ketosis is examined, metabolic control theory would argue that glucose restriction might be more important than ketonemia.[164] Clinically, the link between blood glucose levels and seizure control has yet to be proven, and skepticism regarding relative hypoglycemia as the major contributor to KD action is supported by the incongruency of animal data.[165]

Another potentially important consequence of reduced glucose has been highlighted by the use of 2-deoxy-D-glucose (2DG), a glucose analog that inhibits glycolysis by blocking phosphoglucose isomerase. 2-Deoxy-D-glucose has been shown to be a potent anti-convulsant and antiepileptic agent in several animal models, including kindling, audiogenic seizures in Fring's mice, and 6 Hz corneal stimulation,[6,166] as well as in vitro,[6] and decreases synaptic transmission via adenosine in vitro.[167] The acute effects



Electron Transport and Oxidative Phosphorylation

Figure 78–3. Major changes in important biochemical pathways reported to exert anti-convulsant and antiepileptogenic effects in experimental models (*shadowed boxes*; also see text). *Below*: Putative interactions between mitochondrial respiratory complexes (MRCs) and KD-related metabolites. First ❶, either acetoacetate (ACA) or β-hydroxybutyrate (BHB) can oxidize the NADH couple. Second ❷, ketone bodies (KB) can decrease mitochondrial reactive oxygen species (ROS) generation. Third ❸, KB can protect neurons against MRC I and II inhibitors. Also, the KD elevates the seizure threshold in epileptic patients with impaired MRC function. Fourth ❹, either the KD or KB can enhance ATP production. Fifth ❺, fatty acids can activate mitochondrial uncoupling proteins (UCPs). Finally ❻, KB can elevate the threshold for mitochondrial permeability transition (mPT) activation. The bulk of experimental evidence supports the hypothesis that activation of mitochondrial K_{ATP} (mKATP) channels decreases ROS formation, likely by diminishing the proton-motive force ($\Delta\psi$) across the mitochondrial inner membrane (via transmembrane flux of potassium), and subsequently attenuating electron flux across the MRC, in a manner similar to mitochondrial uncoupling. Cyt C, cytochrome c.

of 2DG may be mediated through a number of different downstream mechanisms, but one intriguing possibility is a decrease in the endogenous phosphorylation of $GABA_A$ receptors (which renders them dysfunctional) by the glycolytic enzyme glyceradeldehyde-3-phosphate dehydrogenase.[168,169] Perhaps the most compelling effect of 2DG in the kindling model is decreasing the expression of brain-derived neurotrophic factor (BDNF) and its principal receptor, neurotrophic tyrosine kinase receptor, type 2 TrkB, via induction of the transcription factor NRSF (neuron restrictive silencing factor), a master negative regulator of neuronal genes.[166] This fascinating study reveals a biochemical interruption of glycolysis that can result in downstream physicochemical modulation of transcription, yielding a powerful effect in retarding epileptogenesis.

While glucose inhibition may exert pleiotropic effects in animal seizure models, similar anticonvulsant actions have been achieved by diversion of glucose to the pentose phosphate pathway (PPP). Fructose-1,6-diphosphate (FDP), a glycolytic intermediate, has been shown to exert acute anticonvulsant activity in

several seizure models in adult rats including kainate, pilocarpine, PTZ, and kindling.[170,171] Indeed, FDP was more effective as an anticonvulsant than 2DG, KD, or valproate in these studies. The precise mechanisms through which FDP produces anticonvulsant effects remain unclear, but it is conceivable that this substrate may exert an antioxidant action because the reduced nicotinamide adenine dinucleotide phosphate (NADPH) generated through the PPP reduces glutathione.[172]

Another fascinating dietary approach to epilepsy treatment is based on the observation that seizures cause a deficiency in tricarboxylic acid cycle (TCA) intermediates (especially α-ketoglutarate and oxaloacetate). It has been hypothesized that "refilling" these deficient compounds (a process called *anaplerosis*) might oppose seizure generation. In support of this idea, the anaplerotic substrate triheptanoin was recently studied in both acute and chronic seizure models.[173] Mice fed triheptanoin exhibited delayed development of corneal kindled seizures, and triheptanoin feeding increased the PTZ seizure threshold in chronically epileptic mice that had undergone status epilepticus 3 weeks before PTZ testing.[173] Therefore, like 2DG, anaplerotic compounds appear to alter both acute and chronic seizure susceptibility. Anaplerosis represents a novel approach that expands the potential metabolic modifications that could be anticonvulsant or antiepileptic. Taken together, results from studies of KDs, 2DG, FDP, and anaplerosis suggest that shifts in the activity of certain metabolic pathways might be exploited to develop novel treatments for epilepsy.

KD AND NEUROPROTECTION

While a detailed discussion of the expanding literature on the neuroprotective properties of the KD is beyond the scope of this chapter, a brief discussion is warranted, as such actions are intimately related to epileptogenesis and seizure propensity. Further, the neuroprotective potential of the KD is increasingly being explored in a number of neurological disorders (see below). The reader is referred to recent reviews for more details on this subject.[4,174–176]

Ketone bodies and PUFAs—metabolic substrates that are both elevated in epileptic patients treated with the KD—have been shown to exert neuroprotective activity in neurodegenerative conditions associated with impaired mitochondrial function.[175] Ketone bodies appear not only to raise ATP levels in seizure-prone areas such as hippocampus,[177] but also diminish reactive oxygen species (ROS) production through increases in reduced nicotinamide adenine dinucleotide (NADH) oxidation[92] and inhibition of mitochondrial permeability transition.[178]

Other than their effects on voltage-gated ion channels, PUFAs—through induction of PPARα and its co-activator PGC-1 (peroxisome proliferator-activated receptor γ coactivator-1)—induce the expression of mitochondrial uncoupling proteins (UCPs), which are homodimers spanning the inner mitochondrial membrane that enable a proton leak from the intermembrane space to the mitochondrial matrix. The net effect of this action is to reduce ATP synthesis, reduce calcium influx into the mitochondrial matrix, dissipate heat, and reduce ROS production.[179,180] The protective consequences of UCP activation have been detailed in a number of published reports.[180] One study demonstrated that dietary enhancement of UCP expression and function in immature rats protected against kainate-induced excitotoxicity, most likely by decreasing ROS generation.[181] Further work demonstrated that mice maintained on a high-fat KD demonstrated an increase in the hippocampal expression and activity of all three brain-localized mitochondrial UCPs (UCP2, UCP4, and UCP5) and exhibited a significant reduction in ROS generation in mitochondria isolated from the same brain region.[90] Thus, it appears that a prominent neuroprotective mechanism of KD action involves a reduction in mitochondrial free radical production, which would decrease oxidative stress and potentially neuronal injury.

FUTURE DIRECTIONS

To date, research efforts aimed at elucidating the mechanisms of KD action have not yielded simple answers. It is becoming increasingly apparent that the relevant mechanisms are likely diverse and operate in a coordinated and potentially synergistic fashion. The ongoing quest is challenged by the inherent difficulties in understanding neuronal network activity, let alone metabolism in the context of disease

states, and importantly, in the intact patient or animal. Despite these issues, the research reviewed herein provides a clearer link between metabolism and neuronal excitability and further validates the emerging field of neurometabolism, especially as it relates to epilepsy.

Based on the foregoing discussion, there are broader clinical implications posed by the KD. As the mechanisms underlying the neuroprotective activity of the KD are fundamental to many disease processes, it should be no surprise that diet can profoundly influence brain function and, in a growing number of instances, exert protective and potentially disease-modifying effects.[4,175,182] As examples, the KD (or various formulations of its key metabolic substrates) have been found to ameliorate a range of clinical disorders and/or experimental models such as autism and Rett syndrome,[183,184] pain and inflammation,[185] traumatic brain injury,[186–188] neurodegenerative diseases such as Alzheimer's and Parkinson's diseases,[189,190] brain cancer,[191–193] prostate cancer,[194] diabetes,[195,196] and obesity.[197] It should be noted that some of these disorders are comorbid with each other, thus presenting the opportunity to help ameliorate multiple diseases with a single therapy.

Of the many potential uses of the KD, brain cancer is perhaps one of the most compelling targets given the rising interest in identifying metabolic targets for intervention.[198] The theoretical basis for using the KD to treat cancer is that tumorigenesis relies heavily on glucose, whereas normal cells retain metabolic flexibility and can use ketones for fuel.[192,198,199] A calorically restricted KD or other glycolysis-limiting treatment forces higher ketone production, putting maximal stress on the tumor cells and minimal stress on the normal cells.[191,192,198] Paradoxically, some aspects of the current standard of care for brain cancer may support tumor growth.[200]

Neurodegenerative diseases are universally associated not only with mitochondrial dysfunction but also with inflammation, and inflammation is a hallmark of virtually every chronic disease process throughout the body. In addition to reducing pain and inflammation,[185] the KD appears to enhance motor and cognitive functioning in a model of multiple sclerosis.[201] Further evidence is provided by recent reports of the KD mitigating 1-methyl-4-phenyl-1, 2,3,6-tetrahydropyridine (MPTP)-induced neurotoxicity and microglial activation,[190] as well as encephalopathy and seizures in some forms of fever-induced epilepsy.[202] Ultimately, reducing inflammation could be one of the most important disease-modifying effects of a KD.

In addition to inflammation, disrupted sleep and circadian rhythms are common comorbidities with many diseases. Recent evidence in humans and in animal models shows that a KD can improve sleep in children with epilepsy[203] and circadian rhythmicity in epileptic *Kcna1*-null mice.[68] It is well known that circadian rhythm disruption is associated with epilepsy, psychiatric disorders, and the prevalent metabolic syndrome.[204–207] Normalization of circadian rhythms alone could yield enormous clinical benefits.[208]

CONCLUSIONS

The evidence for a KD as a successful epilepsy treatment is clear. Multiple retrospective, multi-center, and randomized prospective studies document consistent and significant clinical benefits. The true efficacy of dietary treatments for epilepsy may be underestimated, as the KD is rarely used as a first-line therapy. Certainly, by the time the KD is initiated to thwart medically refractory epilepsy, in some instances the severity of the epileptic condition may be too difficult to overcome. But remarkably, the KD works in the majority of patients who failed to respond to numerous antiepileptic drugs. A detailed understanding of key KD mechanisms could offer a meaningful adjuvant or ultimately the development of a "diet in a pill."[3] But while clinical applications of metabolism-based therapy appear to

(BDNF) and TrkB signaling in brain. As activation of TrkB pathways by BDNF has been shown to promote hyperexcitability and kindling, these potential KD-induced effects would be expected to limit the symptom (seizures) as well as epileptogenesis. Boxed variables depict findings described from KD studies; up (↑) or down (↓) arrows indicate the direction of the relationship between variables as a result of KD treatment. Dashed lines are used to clarify linkages and are not meant to suggest either magnitude or relative importance compared to solid lines. Figure 78–4. Hypothetical pathways leading to the anti-convulsant effects of the KD. Elevated free fatty acids (FFA) lead to chronic ketosis and increased concentrations of polyunsaturated fatty acids (PUFAs) in the brain. Chronic ketosis is predicted to lead to increased levels of acetone; this might activate K_{2P} channels to hyperpolarize neurons and limit neuronal excitability. Chronic ketosis is also anticipated to modify the tricarboxcylic acid (TCA) cycle, as would the presence of anaplerotic substrates such as triheptanoin. This would increase glutamate and, subsequently, GABA synthesis in brain. Among several direct inhibitory actions, PUFAs boost the activity of brain-specific uncoupling proteins (UCPs). This is expected to limit ROS generation, neuronal dysfunction, and resultant neurodegeneration. Acting via the nuclear transcription factor peroxisome proliferator-activated receptor-α (PPARα) and its coactivator peroxisome proliferator-activated receptor γ coactivator-1 (PGC-1α), PUFAs would induce the expression of UCPs and coordinately upregulate several dozen genes related to oxidative energy metabolism. Expression of PPARα is inversely correlated with interleukin 1β (IL-1β) cytokine expression; given the role of IL-1β in hyperexcitability and seizure generation, diminished expression of IL-β cytokines during KD treatment could lead to improved seizure control. Ultimately, PUFAs would stimulate mitochondrial biogenesis. Mitochondrial biogenesis is predicted to increase adenosine triphosphate (ATP) production capacity and enhance energy reserves, leading to stabilized synaptic function and improved seizure control. In particular, an elevated phosphocreatine:creatine (PCr:Cr) energy-reserve ratio is predicted to enhance GABAergic output, perhaps in conjunction with the ketosis-induced elevated GABA production, leading to diminished hyperexcitability. Reduced glucose coupled with elevated FFA is proposed to reduce glycolytic flux during KD, which would further be feedback inhibited by high concentrations of citrate and ATP produced during KD treatment. This would activate metabolic K_{ATP} channels. Ketones may also directly activate K_{ATP} channels. Reduced glucose alone, under conditions of adequate or enhanced energy levels, activates pannexin hemichannels on CA3 pyramidal neurons, releasing ATP into the extracellular space; ATP is converted via ectonucleotidases to adenosine, which subsequently activates adenosine receptors (A_1R). Activation of A_1R is also coupled to K_{ATP} channels. Ultimately, opening of K_{ATP} channels would hyperpolarize neurons and diminish neuronal excitability to contribute to the anti-convulsant (and perhaps neuroprotective) actions of the KD. Increased leptin, seen with KD treatment, can reduce glucose levels and inhibit AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate) receptor-mediated synaptic excitation. Reduced glucose is also expected to downregulate brain-derived neurotrophic factor

(*continues on page 1016*)

be growing rapidly, there is a continuing need to develop modified diet formulations with improved efficacy and tolerability (as well as palatability) and to identify new pharmacological targets for drug discovery.

It is often stated that no single mechanism is likely to explain the clinical effects of antiepileptic drugs, and certainly the same could be said for the KD. The challenge of finding key mediators of KD action is made even more difficult by the intrinsic complexity of metabolic activity within neurons and glia, which, to be relevant to the epileptic condition, must be interpreted at network levels. In this chapter, we have reviewed a number of seemingly disparate variables proposed to collectively exert anti-convulsant (and potentially neuroprotective) effects. The important interrelationships are summarized in Fig. 78–4. The fact that a fundamental modification in diet can have such profound therapeutic effects on neurological disease underscores the importance of elucidating the mechanisms of KD action. In summary, mounting interest in and insight into the mechanisms of KD action have laid a promising foundation for metabolic therapy as an emerging strategy for neurological disorders.

Chapter 79

Deep Brain Stimulation for Epilepsy

Animal Models

Kevin D. Graber
Robert S. Fisher

Epilepsy afflicts approximately 50 million individuals globally.[1] Approximately 40% of patients with symptomatic epilepsy continue to have seizures despite aggressive medical therapy,[2] and about one-third are less than satisfied with their antiepileptic medicine.[3] Surgical resection of the epileptogenic zone is an option for only a minority of patients.[4] Thus, there is great need for new and better treatments for various epilepsy syndromes. A recent clinical trial showed electrical stimulation of the anterior nucleus of the thalamus to be effective in refractory patients with partial and secondarily generalized seizures.[5] Clinical trials have proceeded with only limited understanding of the basic mechanisms of brain stimulation. The most suitable animal models to use can be disputed, and occasionally the results are contradictory. The outcome depends exquisitely upon detailed parameters of stimulation and other unknown factors.

Electrical brain stimulation in laboratory animals dates to the 1860s, with the discovery of involuntary motor phenomena in dogs with acute focal currents applied to the cortical surface.[6] Early studies of high-intensity stimulation of motor cortices of monkeys and dogs produced repetitive movements reminiscent of epileptic seizures.[7] Much earlier work over the last century focused on behavioral effects of brain stimulation in animals. An early dramatic presentation of the effects of chronically implanted electrodes involved stopping a charging bull via a remotely controlled caudate and internal capsule stimulation.[8,9] There is a dichotomy between brain stimulation and epilepsy; kindling, a popular model for generation of an epileptogenic focus in laboratory rodents,

involves application of repetitive stimulation typically to limbic circuits, which results in increasing excitability and eventual spontaneous seizures.[10] Although initially epilepsy was thought to be simply pathological learning of a neuronal circuit, extensive studies have demonstrated that the specific stimulation protocols necessary to generate an epileptic focus act in the context of some neuronal injury, axonal changes, synaptogenesis, and receptor changes dependent on *N*-methyl-D-aspartate (NMDA) receptor-mediated activity (see ref. 11 for review). By contrast, this chapter will deal with antiepileptic effects of deep brain stimulation via implantation of electrodes to various regions in laboratory animals, including the cerebellum, locus coeruleus, substantia nigra, caudate, hippocampus, hypothalamus, subthalamus, centromedian thalamus, anterior nucleus of the thalamus, and, while not necessarily "deep brain," cortex. Sites are separated into those that may be part of a wider epileptic network or have a gating effect versus those that constitute the potential seizure focus; however, it should be understood that this is a loose categorization, as epileptogenic zones are perhaps not strictly demarcated and may involve networks of neurons with long projections separated in space.[11]

POTENTIAL MECHANISMS OF ACTION

At the level of an individual nerve fiber, electrical stimulation effects are predictable, but predictability is generally lost when neuronal tissue is stimulated. The fields of distribution of current can only be estimated, and effects cannot be classified simply as excitatory or inhibitory. Stimulation may inhibit inhibitory pathways and may either synchronize or desynchronize the networks participating in seizure generation.[12] Stimulation may have one effect near the electrode and the opposite or a different effect at more distant locations. An applied electrical field in a hippocampal slice produces an increase in extracellular potassium, a negative direct current (DC) shift, depolarization block of sodium channels, and inhibition of penicillin-induced bursting.[13] Acute inhibition of seizures by stimulation is different from either inhibition of seizures in chronic animal models or prevention of epileptogenesis. One clinical puzzle has been the observation of increasing efficacy of nerve stimulation against seizures over time. Laboratory studies show that growth factors increase with stimulation[14] and that stimulation can generate synapses.[15]

Since effects of brain stimulation on seizures cannot be predicted from first principles, much of the little that we do know comes from empirical experiments on in vitro tissue, laboratory animals, or limited numbers of clinical trials. Animal experimentation is of value in proportion to the relevance of the model to the clinical disease. It is important to be clear about whether a treatment is being tested on a model of acute seizures or of spontaneously recurring seizures, such as those of epilepsy. Multiple possible parameters and sites of stimulation also make it difficult to compare and contrast studies in this area. In the following section, we review laboratory studies by site in the nervous system. Clinical reviews may be found elsewhere.[16]

SITES OF STIMULATION: MODULATION OF THE NETWORK

Cerebellum

Intrinsic cerebellar lesions themselves do not seem to generate epileptic seizures, but the cerebellum was an early target for stimulation studies with mixed results. Although a role for modulating epileptic seizures is poorly understood, output from cerebellar cortex inhibits the deep cerebellar nuclei, which have wide projections. The most radical related approach, cerebellectomy, in rodents reduced hindlimb extension following maximal electroshock-induced seizures but had little effect on the threshold for chemically induced convulsions,[17] suggesting the potential for a differential effect of reducing focal seizures but not attenuating diffuse seizures. However, the effect may be highly model dependent, as rodent cerebellectomy enhanced cortical focal hyperexcitability following penicillin injection.[18] On this backdrop, electrical stimulation studies have likewise produced somewhat contradictory data.

Early studies in anesthetized cats show that high-frequency stimulation at 300 Hz, 40 V for 60 s to the paramedian lobule could abort seizures induced by cortical[19] or hippocampal stimulation.[20] Stimulation of the cerebellar cortex and fastigial nucleus was effective, although no systematic evaluation of various stimulation parameters was initially pursued. Dorsal midline cerebellar stimulation was also reported to be effective in reducing the hyperexcitability produced by cobalt injection into anesthetized feline hippocampus.[21] Hutton and colleagues[22] reported that cerebellar stimulation of anesthetized cats reduced spiking or focal penicillin-induced seizures when applied to the vermis and focally to right paramedian lobules, but deep nuclear stimulation (dentate, fastigial, and interpositus) was ineffective, while widespread stimulation across the cerebellar surface worsened seizures. Babb and colleagues[23] reported similar findings, noting that dentate nuclear stimulation worsened seizures. Dow and colleagues[24] reported that both superficial and deep high-frequency cerebellar stimulation reduced chronic cobalt-induced seizures in freely behaving rats. Low-frequency (10 Hz, 1.5 ms, biphasic 3–4 V) stimulation of rabbit cerebellar cortex (simplex or ansiform lobes) reduced seizure activity generated with intravenous pentylenetetrazole (PTZ) or frontal lobe electrical stimulation, similar to the effects of phenytoin and phenobarbital.[25] In this study, 8 and 12 Hz stimulation was less effective and 6 Hz was ineffective. By contrast, more recent studies in freely behaving rats reported that stimulation of the uvula and nodulus at low frequencies (10–12 Hz, 0.5 ms pulse duration, for 4 to 7 s trains) worsened penicillin-induced epileptiform discharges in rats, while higher-frequency stimulation (100–300 Hz, 0.25 ms pulse duration, for 4 to 7 s trains) was beneficial.[26]

Early studies in monkeys were not promising, and deep nuclear stimulation had no measurable effect on cobalt-induced seizures.[27] Hemmy and colleagues[28] found no benefit of 4–100 Hz (1 ms, 10 mA) superficial lateral cerebellar and dentate nuclear stimulation in awake macaques with electrically induced cortical seizures. Some parameters of chronic cerebellar stimulation in rhesus monkeys caused neuronal damage.[29]

Many early studies do not use statistics and simply report examples of findings. Details of the parameters of stimulation often are lacking. Some studies show efficacy and others do not. Stimulation of midline cerebellar cortex and of deep cerebellar nuclei, which are inhibited by cerebellar cortex, both have shown efficacy or lack thereof in different circumstances. Not all studies have been included; see Krauss and Koubeissi[30] and Fountas and colleagues[31] for additional reviews.[32]

There has been interest in cerebellar stimulation for seizure control in humans, although placement of electrodes in the posterior fossa increases the potential for grave consequences associated with hemorrhage, should there be complications with placement. Hematoma after 5 years of implantation has been also reported.[33] Pilot clinical trials were reportedly effective (e.g., Cooper and colleagues[34]), while blinded studies involving small numbers of subjects produced variable results.[35–37]

Basal Ganglia

CAUDATE

Early studies of caudate stimulation found enhancement of hippocampal afterdischarges in rabbit.[38] Administration of pulses at 5–300 Hz of 1–2 ms duration for 10–400 s into various caudate regions caused synchronous changes in dorsal hippocampal electrodes and increased afterdischarges from hippocampal stimulation following caudate stimulation. However, prolonged caudate stimulation reduced evoked hippocampal activity. Electrical stimulation of feline caudate, concomitant with cholinesterase inhibition focally in caudate, caused cortical seizures.[39] Longer trains of caudate stimulation in the cat were effective against seizures induced by topical penicillin in hippocampus or by atropine treatment.[40] Trains of 10 Hz lasting for 180 s and 25 Hz stimulation for 90 s reduced spike frequency, with a greater effect produced by trains of longer duration. Other investigators also found similar results—reduced epileptiform discharges with feline stimulation—with hippocampal penicillin.[41] Trains of 1 ms at 0.5 Hz for 60 s into cat caudate suppressed seizure activity induced by cortical cobalt if stimulation was started during an interictal period; however, no effect was observed if stimulation was applied during ictal discharges.[42] Psatta[43]

studied 1 to 3 s, 0.3 ms pulses at 5–100 Hz in feline caudate with chronic cobalt-induced neocortical epileptogenic foci. They reported that low-frequency stimulation worked better than high-frequency stimulation and abruptly stopped interictal spiking, but occasionally it provoked focal cortical discharges. Others found that 400 Hz feline caudate stimulation reduced spikes from penicillin-induced foci better than did stimulation at several thalamic targets, with return of spiking following cessation of stimuli. There was greater efficacy with several minutes of stimulation, although "very active foci" were driven by prolonged stimulation.[44]

In monkey, continuous stimulation of the caudate head inhibited seizures from alumina gel on cortex,[45] but there was a rebound effect when stimulation was stopped. A small clinical series reported reduced frequency of seizures with 4–8 Hz caudate stimulation[46]; however, additional studies are necessary to clarify the potential benefits. In summary, animal studies of caudate stimulation have reported both pro- and antiseizure effects, depending on the model, the parameters of stimulation, and whether there was a rebound increase in seizures when stimulation stopped.

SUBSTANTIA NIGRA

It has been suggested that GABAergic (gamma-aminobutyric acid receptor mediated) projections from the pars reticulata of the substantia nigra (SNr) may be one site of action for GABA-mediated antiseizure medications[47] in addition to local inhibitory effects. Substantia nigra pars reticulata projections also appear to influence the kindling threshold.[48] Six 0.1 ms pulses at 100 Hz into rat SNr increased afterdischarges in hippocampal dentate gyrus evoked by perforant path stimulation.[49] However, stimulation of SNr in rats generally inhibited seizures provoked by 3-aminopyridine, including decreased propagation, duration, and occurrence of runs, although effects were more marked with lower-frequency seizures, as some high-frequency seizure patterns worsened.[50] Stimulation of the SNr reduced cortical spikes in the feline generalized penicillin model by 80% in contrast to a 19% reduction with stimulation of the substantia nigra pars compacta.[51] In the rat flurothyl model, 130 Hz unilateral and bilateral posterior SNr stimulation was efficacious against clonic but not clonic-tonic seizures in 2-month-old rats, but anterior SNr stimulation was ineffective.[52] In this same study with 2-week-old rats, bilateral stimulation was effective anywhere in the SNr against both seizure types but unilateral stimulation was ineffective, suggesting age-dependent effects. Stimulation of the SNr reduced acquisition of rat amygdala kindling,[53,54] suggesting a possible effect on epileptogenesis. In Genetic Absence Epilepsy Rats from Strasbourg (GAERS rats), Feddersen and associates more recently report that isolated 60 Hz, 60 μs pulse width bilateral SNr stimulation for 5 s was optimal in suppressing individual seizures but that chronic stimulation overall worsened seizures.[55] In summary, stimulation of the SNr has shown both pro- and antiseizure effects in different models and parameters. Concern about movement side effects in patients may also limit any potential clinical utility.

SUBTHALAMIC NUCLEUS

The subthalamic nucleus (STN) has been the target of numerous studies for the treatment of tremor and other movement disorders (see refs. 56 and 57 for recent reviews). In a detailed and controlled study, Lado and colleagues[58] studied the effects of bilateral STN stimulation on the flurothyl seizure thresholds in rats, using pulses of 30–60 μs duration, titrated to a level just below threshold for a non-seizure-related motor response. In this model, clonic seizures occurred at a lower threshold than did tonic-clonic seizures; 130 Hz stimulation reduced seizures by increasing the clonic seizure threshold 28%, but it only slightly increased the threshold for tonic-clonic seizures. Stimulation at 260 Hz had no significant effect on either seizure type, while 800 Hz stimulation increased seizures, reducing the threshold for tonic-clonic seizures 16%, with a tendency to reduce the threshold of clonic seizures. Stimulation of the STN was shown to interrupt spike-wave discharges in GAERS rats,[59] although there had been criticism that the effects may be nonspecific, as various external stimuli can produce the same response.[60] In summary, STN stimulation affects motor control above a certain threshold, and the influence on seizures appears to be variable.

Brainstem

LOCUS COERULEUS

Vagus nerve stimulation is an accepted palliative but effective treatment for medically refractory epilepsy.[61] Norepinephrine released from locus coeruleus (LC) projections may affect the seizure threshold, and LC circuitry has been proposed to be important for efficacy of vagus nerve stimulation for clinical epilepsy.[62] There has been a small number of investigations of LC stimulation in animal models. Trains of up to 1–2 min of 50–200 Hz rectangular constant current pulses (20–200 μs duration modified by 0.01 μF in series capacitor), delivered via monopolar electrodes placed in the vicinity of the LC and grounded to occipital bone, suppressed but sometimes only reduced PTZ-induced epileptiform discharges in young rats.[63] Unilateral stimulation had bilateral suppressive effects. In the penicillin model of focal epilepsy, bipolar stimulation at 1–200 Hz (biphasic current, 0.1–0.5 ms per phase) in rat LC also suppressed epileptiform activity in proportion to its frequency and intensity, with pharmacological manipulations suggesting that the effects were mediated by the alpha-1 adrenoreceptor.[64] Others have suggested effects at beta adrenoreceptors.[65] Similar results were found with cobalt-induced seizure foci in rats,[66] although the effects in all studies were limited to the seconds during and immediately following stimulation. Longer-term effects have been proposed with delayed amygdala kindling via LC stimulation.[67] A few patients have been implanted with LC stimulation electrodes for spasticity and epilepsy; however, the numbers are too small to draw significant conclusions.[68]

RAPHE NUCLEI

The dorsal raphe nucleus provides strong serotonergic input to forebrain, amygdala, and hypothalamus. Sensitivity to inhibitory inputs changes following amygdala kindling.[69] An older study found increased hyperexcitability with stimulation of this region in rats.[70] Based on pharmacological manipulations, it has been suggested that noxious tactile stimuli can abort seizures in some rodent models via serotonergic inputs from the raphe nuclei.[71] Although understudied, there are no good data suggesting any antiseizure effect of the dorsal raphe nucleus with electrical stimulation. The medial raphe nucleus (superior central nucleus) is also rich in neurons containing serotonin. Bipolar 8 Hz stimulation (1 ms pulses) of rat median raphe nucleus for 1 h reduced the severity of PTZ-induced seizures in rats, as well as those induced by amygdala stimulation following full kindling.[72] At present, there is insufficient evidence to promote clinical studies in these nuclei, and some animal studies support a pro-epileptic effect in some circumstances.

NUCLEUS OF THE SOLITARY TRACT

Receiving afferents from the vagus nerve, the nucleus of the solitary tract may also potentially mediate effects of vagus nerve stimulation for epilepsy.[61,73] The neurons from the nucleus of the solitary tract send afferents to amygdala, hypothalamus, and elsewhere. Hypothetically, direct stimulation might provide a mechanism to avoid side effects such as changes in voice with vagus nerve stimulation and/or could potentially increase potency. One group has reported that 0.5 ms pulses at 30 Hz for 1 min four times a day reduced seizure severity in amygdala-kindled cats.[74] Similar stimulation patterns applied more frequently to the feline nucleus of the solitary tract have been suggested to be antiepileptogenic based on delayed kindling in this model.[75] However, effects at this brainstem site have not been widely studied, and mechanisms of any potential benefit have not been elucidated. Without strong evidence of superior efficacy, it is unclear why placement of a brainstem electrode in any specific target would be a preferable treatment to vagus nerve stimulation unless other side effects could be avoided.

Hypothalamus

Hypothalamic circuits may be important for certain epilepsies, most obviously with the less common syndrome of hypothalamic hamartoma.[76] While there is no suitable animal model of this specific syndrome, in the broader scheme hypothalamic connections may play a role in many seizures via the classical circuit of Papez, linking the mammillary bodies of posterior hypothalamus to anterior thalamus,

cingulate, entorhinal cortex, and hippocampus. Low-frequency hypothalamic stimulation in rats was initially found to be pro-convulsive,[77] although antecedent stimulation with subconvulsant currents sometimes appeared to convey resistance to the occurrence of seizures with suprathreshold stimulation.[78] Cullen and Goddard reported that intermittent chronic stimulation of various hypothalamic locations in rats resulted in amygdala kindling.[79] However, others reported that 5 s of 60 Hz sinusoidal bipolar stimulation of the posterior-lateral hypothalamus of rats reduced behavioral convulsions induced by carbachol injections into the amygdala.[80] More rigorous studies employing 100 Hz stimulation of mammillary bodies of the posterior hypothalamus increased the PTZ seizure threshold in rats, likely related to disruption of mammillothalamic connections[81] (see the discussion of the thalamus below). In a very small clinical series of posterior medial hypothalamic stimulation in patients for pain syndromes and behavior, there is anecdotal mention of a 50% reduction of seizures in two patients[82]; however, overall experience with hypothalamic stimulation is too limited to draw strong conclusions. This target may not be desirable in human due to consequences of hemorrhage in this region with electrode implantation.

Thalamus

ANTERIOR NUCLEUS OF THE THALAMUS

The anterior nucleus of the thalamus (ANT) has been categorized with the so-called midline thalamus and the nonspecific thalamus, structures considered to have associative functions rather than direct sensorimotor relay functions.[83] In the 1940s and 1950s, Dempsey and Morison[84] showed that thalamic stimulation could produce waxing and waning cortical electroencephalographic (EEG) potentials called *recruiting rhythms*. Jasper and Droogleever-Fortuyn[85] suggested a role for nonspecific thalamus in primary and secondarily generalized epilepsies and showed that 3 Hz thalamic stimulation in young cats can produce a spike-wave. More recently, the midline thalamus in rat, although not necessarily the ANT, has been shown to demonstrate electrophysiological changes early during temporal lobe seizures.[86] Figure 79–1 shows a correlation of epileptiform activity between ANT and neocortex during a PTZ-induced seizure in a rat. Spectral coherence of the EEG in neocortex and ANT during a seizure exceeds that of neocortex and posterior thalamus.[87]

The ANT is part of the so-called circuit of Papez, which is believed to be involved in memory, emotionality, and epilepsy. In this circuit, hippocampal outflow via the fornix travels to the mammillary bodies of the posterior hypothalamus. Mammillary neurons give rise to the mammillothalamic tract to the ANT, and from there to the mesial frontal cingulate cortex, and via the cingulum bundle back to the entorhinal cortex and hippocampus. Stimulation of the ANT would therefore be expected to influence oligosynaptically both the superior-mesial frontal cortex and the mesial temporal cortex. These regions are intimately involved in the pathoanatomy of refractory epilepsy.

Autoradiography of the brain in guinea pigs made to have seizures with the convulsant drug PTZ demonstrated marked activation of mammillary bodies, the anterior thalamus, and the mammillothalamic tract connecting them.[88–91] Cutting the tract increases the threshold for

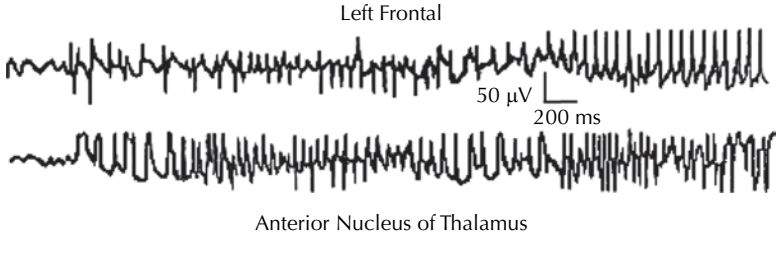

Figure 79–1. Simultaneous EEG recordings from a left frontal cortex bone screw (top trace) and an ANT depth wire (bottom trace) in a rat treated with PTZ. Epileptiform potentials can be seen at both sites and are attenuated (see text) by thalamic electrical stimulation. The EEG tracings were retraced in places for clarity of display.

inducing seizures.[92] Mirski and Fisher[81] used 100 Hz electrical stimulation of mammillary bodies to induce a temporary disruption of the mammillothalamic connections. During times of stimulation, the amount of PTZ required to provoke seizures doubled. The possibility that high-frequency stimulation of mammillary bodies was acting as a local inhibitory stimulus was supported by similar effects produced by injecting the GABAergic drug, muscimol, into posterior hypothalamus during PTZ-induced seizures.[93] Status epilepticus produced by systemic pilocarpine could be delayed two- to threefold, but not prevented, by cannula injection of 160 μmol muscimol bilaterally into the ANT.[94]

The posterior hypothalamus could be a relatively high-risk target for electrode implantation, since local hemorrhage could result in Korsakoff's encephalopathy. The next way station on the circuit of Papez, the ANT, might be a more attractive implantation target. Electrical stimulation of the ANT at frequencies of 100 Hz in rats inhibited PTZ-induced seizures.[95] Stimulation at rates of fewer than Hz was ineffective. High-frequency stimulation delayed the onset of pilocarpine-induced status epilepticus, whereas bilateral ANT lesions delayed seizure onset[96] or prevented status epilepticus.[97] Unilateral stimulation, unilateral lesions, or stimulation initiated after the onset of status epilepticus all were ineffective.

Stimulation of the ANT in a chronic epilepsy model produced by kainic acid injected into rat amygdala[98] decreased the number of total and secondarily generalized seizures. Rearing, falling, and forelimb clonus, associated with seizure spread, were more suppressed than limbic system behaviors such as sniffing, searching, and salivation. Seizures decreased significantly with unilateral lesions of the ANT but were further reduced with bilateral lesions. Stimulation reduced corticothalamic metabolic consumption of glucose, but there was less reduction in temporal regions. Similar reductions of seizures and widespread glucose utilization were seen with seizures induced by kainic acid injection into the rat left sensorimotor cortex.[99]

Several investigations have not documented any efficacy of ANT stimulation in seizure or epilepsy models. A study by Lado[100] of ANT stimulation in a kainic acid-induced chronic epilepsy model in the rat resulted in increased seizure frequency. Another study[101] failed to find any benefit of 100 Hz intermittent ANT stimulation against PTZ-induced seizures, even though benefit could be seen with stimulation in other brain regions. Stimulation of the ANT delayed the acute onset of seizures produced by pilocarpine,[96] but stimulation failed to reduce the number of chronically recurrent seizures after a bout of pilocarpine-induced status epilepticus.[102] The reasons for these differing results are unclear; however, dependence of efficacy upon exact stimulation parameters and experimental conditions was shown earlier by the study of Mirski and colleagues,[95] in which some stimulation parameters induced cortical spike-wave discharges and behavioral activity arrest and others inhibited seizures. No study of electrical stimulation of ANT has documented the anatomical extent of the stimulation effects and how changes in parameters of stimulation might involve different neuronal networks.

How ANT stimulation might inhibit seizures is unknown, but studies have evaluated the release of two neurotransmitters, histamine and serotonin, in relation to efficacy of stimulation. Electrical stimulation of the histaminergic tuberomammillary nucleus delayed and shortened PTZ-induced seizures in rats.[103] The serotonin (HT) metabolite, 5-hydroxyindoleacetic acid (5-HIAA), increases regionally in rat ANT during PTZ-induced seizures.[101] Since ANT is enriched with 5HT-7 receptor subtypes, Mirski and colleagues[104] used a selective 5HT-7 agonist, 5-carboxamidotryptamine, dialyzed into ANT to inhibit PTZ-induced seizures. Rats given control injections had PTZ-induced seizures at a latency of 3120 ± 770 s. Stimulation of ANT at 100 Hz, 150 mA, 0.1 ms pulse duration beginning 40 min prior to PTZ infusion delayed seizure onset to 5018 ± 1100 s ($p < 0.01$). Dialysis of 5-carboxamidotryptamine increased the latency to 4247 ± 528 s ($p < 0.05$). Glutamate, GABA, adenosine, and other neurotransmitters or neuromodulators might play a role in the mechanism of ANT stimulation, but their specific effects have not been elucidated in experiments.

In summary, ANT is a participant in several models of seizures. Lesions, local injection of muscimol, and high-frequency electrical stimulation can inhibit seizures in several chemoconvulsant models, although not all experiments find efficacy. A large, randomized clinical trial

of ANT in patients with refractory partial or secondarily generalized seizures did document efficacy,[5] so further investigation into the mechanisms of stimulation at this nucleus is likely to be clinically relevant.

CENTROMEDIAN NUCLEUS

Other midline thalamic structures can influence seizures in animal models.[105] Injection of $GABA_A$ and $GABA_B$ receptor antagonists into the rodent centromedian nucleus (CM) of the thalamus facilitates some seizure types[106]; however, good animal studies with stimulation are largely lacking. In a controlled pilot study of CM stimulation in seven patients, Fisher and colleagues found a nonsignificant 30% reduction in overall seizure frequency.[107] Nevertheless, the CM of the thalamus has been a further target of considerable clinical interest.[108]

NUCLEUS RETICULARIS THALAMI

A single report suggests that stimulation of the reticular nucleus of rodent thalamus attenuates hippocampal kindling.[109] The reticular nuclei are shells surrounding other thalamic nuclei. They are believed to be critical for widespread network synchrony and important in the physiology of absence seizures and potentially other seizures.[110] However, brain stimulation of this structure has not been sufficiently studied.

SITES OF STIMULATION: THE SEIZURE FOCUS

Hippocampus and Amygdala

The mesial temporal structures are important in the pathophysiology of many clinical focal epilepsies. A popular model for the generation of an epileptogenic focus in laboratory rodents, kindling, involves application of repetitive stimulation to the hippocampus, amygdala, or other limbic structures.[10] Pro- or antiseizure effects appear to depend on the details of stimulation; however, in contrast to studies of many possible targets, these experiments typically deal with current injection directly into the epileptogenic region. Laboratory studies have used both in vitro slice and whole animal models. In rodent hippocampal slices, epileptiform discharges in CA1 provoked with bicuculline, primarily blocking $GABA_A$-mediated inhibition, can be rapidly attenuated with 100 Hz stimulation to Schaeffer collaterals, but the effect is temporary.[111] Stimulation in these studies at 1 Hz had a more persistent effect, possibly mediated by NMDA receptor activity. Albensi and colleagues[112] studied a range of stimulation parameters affecting epileptiform discharges induced by low magnesium, suggesting that 0.5 and 1 Hz for up to 5 min were optimal, although stimulation up 50 Hz was also suppressive; the authors noted that there was no continuum of efficacy from slow to rapid parameters. Although these types of manipulations may provide a platform to better understand some of the mechanisms by which stimulation can abort seizures, truly long-term effects can only be studied in whole animal models. On this note, similar stimulation frequencies of 1 and 50 Hz applied to the hippocampal dentate gyrus or to the entorhinal cortex of behaving rats reduced interictal spikes transiently but did not reduce seizures.[113]

Contralateral rat hilar stimulation reduced the effect of perforant path stimulation-induced population discharges in hippocampal dentate gyrus.[114] In some cases, antiseizure stimulation worked to prevent later seizures, but at the cost of provoking an initial seizure. Early studies of "antecedent" amydgala[115] or hippocampal[116] stimulation to fully kindled rats demonstrated a reduced seizure rate with "test" pulses intended to evoke seizures, although the antecedent current also typically evoked seizures, leaving unanswered the question of whether the effect was due to the applied current or to ictal aftereffects. However, Shao and Valenstein[117] reported success in blocking evocable seizures (at barely suprathreshold parameters) for a week in fully kindled rats after administration of subthreshold constant 60 Hz sinusoidal 1 s current bursts in trains (6 s interpulse interval) using gradually increasing intensities, delivered to the same amydgala electrodes used for kindling and recording. Low-frequency amygdala stimulation of 1 Hz was reported to provide a "quenching" stimulus slowing or arresting the kindling process, later to be attributed to a 5–15 μA direct current leakage of the stimulation.[118] However, more recent studies also report that 1 Hz stimulation of the hippocampus delayed the effects of kindling, suggesting antiepileptogenic properties.[119] Low-frequency stimulation of the perforant path to the hippocampus slowed the kindling process if given immediately after the stimulation for

kindling.[120] High-frequency stimulation also can be effective. Ten days of hippocampal stimulation at 130 Hz increased the afterdischarge threshold in previously kindled rats.[121]

Implantation of electrodes has made kindling a convenient method for creating seizures in many studies, which facilitates additional studies of potential antiseizure stimulation parameters. But given that electrical stimulation drives the processes responsible for epileptogenesis in the kindling model, it is unclear if attempts at *antiseizure* manipulations bring about separate antiepileptic/antiepileptogenic pathways or simply modify the early and intermediate effects of the kindling stimuli. Both 1 and 50 Hz rostral hippocampal and perforant path stimulation trains lasting for 10 min to 2 h reduced interictal epileptiform discharges for 30–60 min in the dentate gyrus of epileptic rats following kainic acid-induced status epilepticus, but there was no measurable effect on the spontaneous seizure rate and no long-term benefit.[113] Nevertheless, Velasco and colleagues[122] and Boon and colleagues[123] found high-frequency hippocampal stimulation to be effective in unblinded pilot patient trials. A small blinded crossover trial of hippocampal stimulation in epilepsy was negative.[124]

Piriform and Entorhinal Cortex

The entorhinal cortex provides strong feedforward excitation to the hippocampus, with strong hippocampal afferents also originating in the piriform cortex in many species, circuits likely involved with limbic epilepsy.[125–127] Because of their mesial temporal location in human anatomy, we have grouped these structures with other epileptogenic foci, possibly a bit tenuous in classification. Stimulation of these parahippocampal structures within certain parameters is also epileptogenic,[128] similar, albeit with varying thresholds, to kindling elsewhere in limbic circuits.[129] Low-frequency stimulation of the central piriform[130,131] and entorhinal[132] cortices has been reported to delay rodent amygdala kindling; however, the relevance of this finding to other epilepsies is uncertain.

Neocortex

Chronically undercut and partially isolated neocortical islands were originally made and studied in cats and monkeys, becoming progressively more hyperexcitable after a latent period of 2–3 weeks in this model.[133,134] Spontaneous epileptiform discharges spread from the area of isolation to adjacent and contralateral cortices and persisted for at least a year,[135,136] a relatively focal model of posttraumatic epileptogenesis and deafferentation. There is a suggestion that focal electrical stimulation may be antiepileptogenic in the undercut feline marginal gyrus.[137] Using an array of dural electrodes placed about 3 mm apart, Rutledge and colleagues[137] applied 20 daily 2 s trains of 50 Hz, 1 ms pulses at 0.6–1 mA, subthreshold for afterdischarges, spaced 1 min apart, for 1 week and starting 1 week postinjury (6 weeks in two animals). At least 1 week following electrical stimulation, 80% of control animals demonstrated evocable epileptiform afterdischarge runs, in contrast to 18% of the stimulation group. In more recent decades, this model has been adapted to rodents for in vitro slice physiology studies. Supramaximal or rapid stimulation acutely also attenuates hyperexcitability in rodent neocortical slices in this model, hypothetically from recruitment of more intense inhibition.[138] However, the mechanisms of direct cortical electrical stimulation have not been explored in this model.

Many studies of direct electrical stimulation of an epileptogenic focus have drawn largely from the human experience. Penfield and Jasper reported that stimulation of exposed cortex flattened the EEG of epileptic patients.[139] There are also examples of electrical stimulation applied through implanted intracranial electrodes both starting and stopping EEG seizures.[140,141] Clinical trials have been performed with direct responsive neurostimulation of a cortical epileptogenic focus based upon analysis of the ongoing EEG.[142] Trials were preceded by safety and feasibility studies of the implanted device in Suffolk sheep using surface cortical and hippocampal depth electrodes with 30 min of stimulation (50 Hz, 2.5 mA, 300 μs phase duration, biphasic) daily; however, limited data are only available in abstract form,[143,144] and the results of planned histological studies are currently unavailable.

LIMITATIONS OF ANIMAL STUDIES

Clinical trials in patients ideally should be based upon a solid foundation of laboratory

experimentation documenting the basis for a therapeutic effect and the optimal parameters for producing such an effect. Neurostimulation for epilepsy, in contrast, often has moved in reverse, from pilot studies in patients back to the laboratory for validation and modification of stimulation methods. Some degree of public hysteria about the possibilities for "mind control" and other ethical controversies several decades ago surrounding brain stimulation may have steered some scientists away from the field in the past.[9]

Some reports are problematic. Many early studies report empirical examples of changes in epileptiform patterns without the use of statistics, and some parameters of stimulation are not mentioned. Often studies do not provide information about equipment calibration or examples of raw stimulation patterns that may test the limits of safety, particularly for older equipment; leakage currents and other technical issues may contribute to the findings.[118] Small differences in parameters can invoke very different neuronal networks with different effects. Spatial and volumetric differences between the human brain and the small rodent brain, differences in electrode size, and numbers of contacts all may produce significant differences in electrical fields, altering the outcome. Most studies are empirical and do not answer many questions concerning the mechanisms of deep brain stimulation, which should be the true strength of laboratory research.

All animal models of epilepsy have inherent limitations. Conclusions from laboratory work extend only as far as the models reflect human epilepsy in the clinical setting. In contrast to clinical experience, seizures in a large number of animal models can be manipulated by external stimuli, such as sound, novel environments, and tactile stimulation (see ref. 145), leaving some uncertainty about the specific effects of localized stimulation in behaving animals. The chronicity of animal studies is often short in comparison to potential treatment of patients lasting for years, resulting in some uncertainty about the long-term risks of prolonged stimulation with concern about potential for kindling (depending on the site and nature of stimulation), gliosis, or neuronal damage.[29] But in contrast to worsening, the pivotal trial of ANT stimulation revealed a trend toward clinical improvement over months,[5] similar to latent improvement with vagus nerve stimulation.[61] Thus, despite their limitations, rigorous laboratory studies have the potential to provide insight into the cellular mechanisms of antiseizure effects of deep brain stimulation that may guide future clinical improvements.

CONCLUSIONS

Studies of deep brain stimulation in laboratory models of seizures and epilepsy are invaluable for understanding the mechanisms of stimulation and for identifying the best targets and parameters of stimulation. Unfortunately, existing laboratory studies of brain stimulation in epilepsy models present an incomplete and often contradictory picture (Table 79–1). Some efficacy for deep brain stimulation has been documented in labora-

Table 79–1 **Examples of Diversity of Effects of Brain Stimulation in Animal Models***

Site of Stimulation	Result		
	Anti-seizure	No effect	Pro-seizure
Cerebellum	Both deep nuclear and superficial in multiple models in cat, rabbit, rat	Monkeys with deep nuclear or superficial stimulation (cobalt and electrically induced seizures) Deep nuclear stimulation in cat, (penicillin model)	Dentate nucleus stimulation in cat (cobalt model) Superficial stimulation in rat, cat (penicillin model)

(*continued*)

Table 79–1 **(Continued)**

Site of Stimulation	Result		
	Anti-seizure	**No effect**	**Pro-seizure**
Caudate	Cat, some circumstances (focal penicillin, atropine, cobalt models) Monkey (alumina cream model)		Enhance evoked hippocampal discharges in rabbit. Robust seizures in cat worsened (penicillin model) Rebound effect in monkey after stimulation stopped (alumina cream model)
Substantia Nigra pars reticulate (see text for differences of unilateral vs. bilateral stimulation)	Rat (3-aminopyridine model) Cat (penicillin model) Rat (flurothyl model)	Older rat, tonic clonic seizures (flurothyl model)	Rats (evoked hippocampal discharges) Rat (GAERS)
Subthalamic Nucleus	Rat (flurothyl model) Rat (GAERS)	Rat (flurothyl model)	
Brainstem	Locus Coeruleus, rat (PTZ, penicillin, delayed kindling) Median raphe nucleus, rat (PTZ, kindled) Nucleus of the Solitary Tract, kindled cat, delayed kindling in cat		Dorsal raphe nucleus, rat (kindled)
Hypothalamus	Rat (focal carbachol, PTZ models)		Low-frequency stimulation, rat.
Anterior Nucleus of Thalamus	Rat (PTZ, hippocampal kainic acid, pilocarpine)	Low-frequency stimulation, rat (PTZ)	Rat (Kainic acid)
Hippocampus/ Amygdala	Some parameters of rodent hippocampal slice stimulation (bicuculline, low magnesium in vitro models) Rat, some parameters of stimulation (kindling, perforant path stimulation)	Rodent hippocampal slices-some stimulation suppresses spikes, not seizures.	Kindling and evoked seizures in multiple species
Piriform Cortex	Rat (delayed kindling with low-frequency stimulation)		Kindling in rodents
Neocortex	Possible antiepileptogenic in cat (undercut model) Rodent brain slice		Evoked seizures in multiple species/models

tory models involving the cerebellar cortex, caudate, hypothalamus, subthalamus, centromedian and midline thalamus, anterior thalamus, hippocampus, and neocortex. However, many studies are empiric in nature and mechanisms, and our understanding of the optimal parameters remains incomplete. Pivotal clinical trials with the ANT and responsive neural stimulation of the hippocampus and neocortex have been effective in reducing seizures. These recent successes in clinical studies may give more impetus to laboratory investigations, which in turn will potentially further our clinical practice.

Chapter 80

Animal Models for Evaluating Antiepileptogenesis

H. Steve White

INTRODUCTION

Since the first White House-initiated CURE conference in March 2000, the epilepsy research community has placed greater emphasis on finding a cure for epilepsy. Supported by the National Institutes of Health, Citizen's United for Research in Epilepsy (CURE), the Epilepsy Therapy Development Project, the American Epilepsy Society, the Epilepsy Foundation of America, and the pharmaceutical industry, this multifaceted approach has led to several important advances that include (*1*) *a greater understanding of the pathophysiology of epilepsy at the molecular and genetic levels;* (*2*) *the search for surrogate markers of the epileptogenic process;* (*3*) *the development and utilization of model systems (animal and human) for evaluating novel therapeutic approaches; and* (*4*) *productive discussions and collaborations within the scientific, regulatory, and pharmaceutical communities.*

The need to find a therapy that will prevent or delay the development of epilepsy in the susceptible individual is evident, and many of the required tools have already been developed. Nonetheless, there are many practical challenges and hurdles at both the preclinical and clinical levels that must be overcome before a cure can be developed. Prior to embarking on a clinical trial, there should be some evidence that a hypothetical therapy is effective in one or more animal models of epileptogenesis. However, unlike the animal models routinely employed in the search for novel anticonvulsant compounds, the animal models of epileptogenesis that are currently available have not been validated clinically. Unfortunately, clinical validation will not be provided until the first truly antiepileptic or disease-modifying therapy has been found to be effective in an appropriately designed clinical trial. With this in mind, it is still unknown what preclinical evidence of efficacy would be required before one would be

willing to embark on an expensive clinical trial that involves a path not yet paved by past experience. Nevertheless, the scientific community should not be discouraged from pursing this approach but should clearly be aware of the limitations of the existing models and employ caution when designing preclinical studies and interpreting the results obtained.

ANIMAL MODELS OF ACQUIRED EPILEPSY

There are a number of experimental animal models that could be used to test a potential disease-modifying or antiepileptogenic therapy. These include several models of acquired epilepsy (Table 80–1) and an expanding number of genetic models that possess a known mutation found to be associated with a particular genetic form of human epilepsy.[1,2] The models of acquired epilepsy listed in Table 80–1 involve an initial insult followed by a variable latent period that often culminates in the evolution of recurrent, spontaneous seizure activity or, at the very least, measurable hyperexcitability at some later time. In this regard, many of the animal models of epileptogenesis that have been described in recent years recapitulate several of the features of human epilepsy. The use of these and other emerging models will likely play an important role in the discovery of novel treatment strategies for the individual at risk of developing epilepsy as a result of a brain insult or genetic susceptibility. Moreover, their use can help guide clinical trials once an ideal clinical candidate has been identified.

The rodent models of epileptogenesis that have been most often employed in epilepsy research include kindling and status epilepticus (SE).[3] As summarized in Table 80–1, other models of epileptogenesis that have been developed over the years include the tetanus toxin model of partial epilepsy, the neonatal hypoxia-ischemia model of hypoxic-ischemic injury, the neonatal hyperpyrexia model of febrile seizures, models of infantile spasms (IS), models of cortical dysplasia, and models of traumatic brain injury (TBI). Each of these rodent models displays varying degrees of cell loss, synaptic reorganization, network hyperexcitability, and a latent period that is followed by the expression of an altered seizure threshold or the development of spontaneous seizures or spasms in the case of IS, that is, the hallmark of epilepsy. As such, they embody some of the important characteristics of a model of acquired epilepsy.[4] A comprehensive review of all of the models listed in Table 80–1 is beyond the scope of this chapter, and the reader is encouraged to review the primary literature cited within. The remainder of this chapter will review the salient points and utility of the kindling, SE, and TBI models of acquired epilepsy and discuss an emerging model of viral encephalitis wherein the central administration of Theiler's virus to C57BL/6 mice results in acute symptomatic seizures followed by latent hyperexcitability and the development of recurrent spontaneous seizures. Importantly, each of these models has a clear clinical correlate wherein therapies identified at the preclinical level could be quickly translated to the human population at risk for developing epilepsy. As such, they offer something unique for the investigator interested in evaluating a proposed antiepileptogenic therapy.

Kindling

Kindling is the process originally described by Goddard and colleagues[5] whereby an electrical stimulus typically delivered to a limbic brain structure sufficient to evoke a limited afterdischarge duration (ADD) is, with repetition over time, able to evoke an electrographic afterdischarge that is capable of spreading and initiating a generalized convulsive seizure. The change in responsiveness that occurs during kindling acquisition is permanent, and although it is not usually associated with spontaneous seizures, it is associated with a reduced seizure threshold. The fully kindled animal model is routinely employed in the search for novel therapies for the patient with complex partial seizures with secondary generalization. Indeed, the pharmacological profile of the fully kindled animal supports the validity of this model for drug screening (see Loscher and Brandt,[3] Smith et al.,[68] and Bialer and White[69] for review and references).

The process by which an initially subconvulsive stimulation becomes convulsive has provided the experimental epilepsy community with a valuable platform to study the neurobiological substrates that underlie the

Table 80–1 **Animal Models of Epileptogenesis**

Experimental Model	Neuropathology Present	Chronic Hyper-excitability	Latent Period	Spontaneous Seizures	Selected References
Kindling (amygdala, hippocampal, corneal)	Yes	Yes	No	No[a]	5–10
Post-status epilepticus (bicuculline, kainic acid, pilocarpine ± Li^+, electrical models of self-sustaining status, cobalt-homocysteine, fluorothyl)	Yes; age-dependent variability	Yes	Yes (days, weeks, to months)	Yes; marked age-dependent variability	11–26
Tetanus toxin	Yes	Yes	Yes	Yes, but may remit	27–29
Traumatic brain injury					
Cortical undercut	Yes	Yes	Yes	Yes	30–35
Ferric chloride	Yes	Yes	Yes	Yes	36
Fluid percussion	Yes	Yes	Yes	Yes	37–44
Neonatal hypoxia-ischemia	Yes	Yes	Yes	Yes	45–51

epileptogenic process. Unfortunately, the extent to which the acquisition of kindling reflects human epileptogenesis, and the validity of the kindled animal for studying the antiepileptogenic or disease-modifying potential of a novel therapeutic, are still debated (see Loscher and Brandt[3] for review and discussion). For example, most of the studies that use kindled rats do not employ animals that display spontaneous seizures. This is important because it is highly unlikely that the neuropathological alterations at the synaptic and network levels are the same in the rat with an altered threshold as those in an animal that displays spontaneous seizures; as such, the therapies that might be found to be disease-modifying in one model would likely differ from those effective in the other. These and other issues surrounding the validity of the kindled rat as a true model of human epilepsy are nicely summarized in a 2010 review by Loscher and Brandt.[3]

A number of changes at the molecular and structural levels have been associated with kindling. Studies of hippocampal cellular pathology and electrophysiology during the kindling process suggest a role for mossy fiber sprouting involving an increased recurrent excitatory action on both dentate cell dendrites and GABAergic (gamma-aminobutyric acid) interneurons and alterations in the function of GABAergic synapses and glutamatergic synapses within the dentate gyrus and hilar regions.[70–72] The degree to which these changes are causative or represent an epiphenomena of the kindling process is not known, but they do provide some insight into the pathophysiology associated with kindling.

In the kindling model, an intervention study most often assesses the effect of an intervention on limbic or cortical ADD or quantifies the number of stimulations required to reach a particular Racine seizure score;[73,74] for example, does a particular intervention reduce the ADD or delay the time required to reach a grade 5 Racine seizure?

Choosing the appropriate timing for therapeutic intervention in the kindling model is problematic. Conventionally, drugs have been given 0.5 to 2 h prior to the kindling stimulus. When the drug under investigation possesses anticonvulsant activity, interpretation of the results from an intervention study can be complicated. Insult modification; that is, decreasing the duration of the ADD or decreasing the seizure severity through a drug's inherent anticonvulsant action can be easily confused with antiepileptogenesis. Thus, any study that sets out to modify or prevent kindling acquisition needs to be carefully considered and the results interpreted with this caveat in mind. Of the numerous studies that have employed the kindled rat as the test subject to evaluate the antiepileptogenic effect of a number of antiseizure drugs and *N*-methyl-D-aspartate (NMDA) antagonists, the only drugs found to reliably retard kindling acquisition using a treatment paradigm that was designed to separate the anticonvulsant effect from any potential disease-modifying effect of the treatment were levetiracetam,[75,76] phenobarbital,[77,78] and valproate.[77] As discussed by Loscher and Brandt,[3] the time- and labor-intensive nature of the kindled rat is not ideal for even medium- throughput screening of potential antiepileptogenic or disease-modifying treatments. To address this issue, Mazarati and colleagues[79–84] have been actively characterizing the rapid hippocampal kindling model originally described by Lothman et al.[85] as a viable alternative for drug screening. In contrast to the days to weeks that are required to fully kindle an adult rat using the traditional kindling paradigm, they have demonstrated that the kindling process can be contracted to several hours using the rapid hippocampal kindling protocol.[79–84] They have evaluated a number of traditional and investigational antiepileptic drugs (AEDs) using this model and demonstrated that it has potential utility as a high-throughput screening tool for the early evaluation of potential antiepileptogenic or disease-modifying therapies. Moreover, they have demonstrated that the effect of any given drug treatment can be age-dependent.[84] These effects suggest that there are likely to be age-dependent changes in the targets and that the window of treatment opportunity will be different, depending on the age of the patient at the time of a particular brain insult. As discussed above, the kindling model has some limitations, and any findings suggestive of a disease-modifying effect will certainly require confirmation in one or more models of epileptogenesis.

Status Epilepticus

Status epilepticus is a medical emergency that requires prompt recognition and aggressive

treatment. Status epilepticus is not a disease; it is a manifestation of an underlying central nervous system (CNS) insult or systemic pathology that affects CNS function. Status epilepticus results when there is a failure of those inherent factors that would normally function to stop seizures.

Although many people will survive an episode of SE with no, or only limited, untoward effects, SE is life-threatening and is often associated with long-term neurological sequelae that include an elevated risk for developing epilepsy and substantial cognitive decline (see ref. 86 for review and references). The high morbidity and mortality associated with convulsive SE underlie the importance of early recognition and aggressive treatment. Although controversial, nonconvulsive SE[87] is also associated with high morbidity and mortality.

The chemoconvulsant and electrical post-SE models of temporal lobe epilepsy (TLE) that have emerged over the last three decades (Table 80–1) involve prolonged seizure activity within the limbic system sufficient to induce some focal hippocampal damage that is followed, after a latent period of days, weeks, or months, by the appearance of spontaneous limbic seizures.[12,13,18,22,24,25,88–90] In this regard, post-SE models reproduce the clinical features of acquired epilepsy; such as a brain insult that is followed by a variable latent period before spontaneous seizures emerge. As in patients with epilepsy, the seizure frequency of a rodent with epilepsy can also be age-dependent and quite variable, and seizures are often clustered. Variability in seizure frequency and seizure clustering have the disadvantage that seizure monitoring and quantification are technically challenging and require dedicated commitment to rigorous video-electroencephalographic (EEG) monitoring (see below).

Not all models of SE are created equally; the extent of damage to hippocampal and extrahippocampal structures, as well as the length of the latent period, vary greatly among the various SE models. To this point, Sloviter and colleagues have described a model wherein prolonged hippocampal excitation in awake rats results in classic hippocampal sclerosis in the absence of convulsive SE.[22] In two separate models, these investigators were able to demonstrate that a single episode of clinically cryptic excitation without evidence of convulsive seizure activity produced classic hippocampal sclerosis that was followed by the emergence of spontaneous hippocampal-onset seizures. Their results suggest that epileptogenic insults may involve prolonged excitation that can go undetected at the time of the initial insult. This is not to say that models of convulsive SE lack value in therapy discovery, but the availability of an animal model that mimics human patterns of limited pathology with hippocampal-onset seizures that displays minimal variability and lethality and does not require exposure to chemoconvulsant drugs is a potentially important advance. For example, being able to tightly and reproducibly control the outcome in terms of both pathology and seizure origin should lead to a greater understanding of the relationship between neuronal loss, subclinical focal events, and those network processes that contribute to the expression of clinical seizures. As the authors suggest, such a model should help to elucidate the mechanisms that convert focal seizures into clinical seizures and facilitate the development of strategies that might prolong the latent period indefinitely (see ref. 22 for further discussion).

Traumatic Brain Injury

Traumatic brain injury (TBI) is a well-appreciated risk factor for epilepsy.[91,92] *Traumatic brain injury* refers to any biomechanically induced damage to the brain. The greater the initial severity, the higher the risk for developing epilepsy.[91] Traumatic brain injury is a common cause of acquired epilepsy; for example, it accounts for up to 20% of all symptomatic epilepsies and 6% of all epilepsies.[93] In the United States, TBI is also the most common cause of death and disability in persons under 45 years of age and is particularly prevalent in young adult men; the male:female ratio is 2:1 or 3:1 (see ref. 94 for review and references). Causes of TBI include motor vehicle accidents, falls, sports-related concussions, assaults, gunshot wounds, and military-related injuries. Depending on the severity of the insult, TBI can be associated with both early (within the first 7 days postinjury) and late posttraumatic seizures (those occurring after the first 7 days postinjury). The distinction is important because the pathophysiological substrate underlying early versus late seizures and

the onset of epilepsy is thought to be different and as such implies that there could be different therapeutic approaches, depending on the time frame in which an intervention therapy is initiated.[94]

From a pathophysiological perspective, early posttraumatic seizures (PTS) are associated with changes in ion (Na^+, K^+, and Ca^{2+}) flux, glutamate release, spreading depression-like state, secondary injury, metabolic dysfunction, oxidative stress/heme toxicity, inflammation, acute cell death, altered connectivity, excitation, and inhibition. In addition to altered excitatory and inhibitory neurotransmission, late PTS and posttraumatic epilepsy, have been associated with aberrant sprouting, changes in neurotrophin (e.g., brain-derived neurotrophic factor [BDNF]) expression, synaptic structural changes, delayed cell death, chronic inflammatory changes, and progressive disconnection.[94]

Thus, the availability of an animal model of TBI that recapitulates many of the features of trauma-induced human epilepsy could be used for the early identification of neuroprotective and/or disease-modifying therapies that can be quickly transferred to human clinical trials. As summarized in Table 80–1, a number of models of TBI have been described over the last four decades. Collectively, they have all provided a greater understanding of the pathophysiology of PTS and trauma-induced epilepsy.[94]

In recent years, the rostral parasagittal fluid percussion injury (rpFPI) model has been extensively characterized at the electrographic, phenotypic, histological, and pharmacological levels.[37–40,95,96] As early as 2 weeks after FPI delivered to the rostral parasagittal convexity, animals display subtle ictal behaviors that include motion arrest, posturing, and automatisms that are coincident with epileptiform electrographic discharges. Cross-correlograms obtained by analysis of the behavior of the animals while blinded to the electrocorticogram (ECoG) suggest that epileptiform ECoG events as short as ~1 s may satisfy the definition of clinical seizure.[39] However, seizures appearing in the early weeks after FPI present with a wide range of durations, most commonly lasting for 2–15 s but sometimes up to 6 min, and then progress in duration over time postinjury.[40,95] Similar progression is also observed in the frequency of the seizures, severity of the ictal behavior, and underlying pathology.[37,38] A remarkable feature of posttraumatic epilepsy (PTE) induced by rpFPI in the rat is that it presents with both neocortical and subcortical seizures, just as human PTE does.[97,98]

Although debated,[99,100] the results obtained in the rpFPI model support the authors' hypothesis that the focal electrographic and clinical events observed following rpFPI mimic human simple partial and complex partial seizures.[39,95] Furthermore, their results support the earlier hypothesis that chronically recurring spontaneous partial seizures with subtle manifestations occur in patients long before a diagnosis of epilepsy is made.[89,101] If this is true, early and aggressive use of emerging seizure detection technologies following TBI to explore the presence of subtle seizures seems warranted. Minimizing their occurrence and spread could, as suggested previously,[22] facilitate the development of strategies that might prolong the latent period indefinitely.

Viral Encephalitis

The precise mechanisms that underlie the development of epilepsy following an insult to the brain have yet to be clearly defined. Nevertheless, it is becoming increasingly apparent that inflammation plays an important role in some of the damage and reorganization observed following a variety of brain insults including hypoxia/ischemia, SE, TBI, and others.[102] A number of studies have demonstrated that inflammatory cytokines such as interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and IL-6 can contribute to both acute excitability of neurons and chronic molecular changes that can contribute to the development of epilepsy.[103] Inflammatory cytokines have been shown to increase blood-brain-barrier (BBB) permeability, decrease the seizure threshold, increase expression of the drug transporter protein P-glycoprotein (Pgp), and epileptogenesis.[104–106] Interleukin-1β can increase the permeability of the BBB to immunoglobulin G (IgG) and albumin, which can trigger an immune response.[104] Albumin, which is taken up by astrocytes, impairs astrocytic function and reduces the ability to clear extracellular glutamate. The ability of astrocytes to regulate extracellular ion homeostasis can also be impaired. Both of these effects can contribute to an acute lowering of the seizure threshold and an imbalance between excitation

and inhibition.[103] Moreover, overexpression of inflammatory cytokines can have long-term consequences for brain excitability by inducing structural and functional changes in glial and neuronal networks. For example, IL-1β can activate mitogen-activated protein kinases and (NF-κB)-dependent pathways.[102,103] The resultant transcription of genes can lead to the modification of ion channels and thus contribute to long-term hyperexcitability and epileptogenesis.

Therapies that target inflammatory processes could have a profound effect on both acute seizure susceptibility and the development of epilepsy following an acute insult to the brain.[102,103,107,108] Having an animal model that mimics much of the pathology of CNS inflammation would provide an important platform to study epileptogenesis resulting from inflammatory insults.

Viral infection of the CNS can lead to long-term neurological defects, including an increased risk for the development of epilepsy.[102,103] Common viral infections that have been associated with clinical seizures include human immunodeficiency virus (HIV), West Nile virus, measles, and human herpes simplex virus-6 (HHV6), a virus that infects nearly everyone by 3 years of age.[109,110] Human herpes simplex virus-6 has been found in astrocytes obtained from resected tissue from patients with medial temporal lobe epilepsy, a severe seizure disorder that is often resistant to treatment with existing therapies.[111,112] Furthermore, acute viral infections have been associated with SE[113] and the subsequent development of severe epilepsy in children,[114] including IS,[115] a particularly difficult-to-treat form of epilepsy. Thus, there is an emerging body of data that suggests that the limbic system is compromised in some forms of viral-induced encephalitis and that these patients are at increased risk for developing pharmacoresistent epilepsy.

Until recently, viral infections that lead to epilepsy have been difficult to address experimentally because, despite the fact that acute viral infection of rabbits, rats, and mice is associated with seizures,[116–119] infected animals either die from the acute viral encephalitis or, if they do not die, they do not go on to develop spontaneous recurrent seizures.

In contrast to herpes simplex virus encephalitis and Borna disease virus, mice inoculated with Daniels strain of Theiler's murine encephalomyelitis virus (TMEV) survive the initial infection and a high percentage ultimately develop recurrent seizure activity.[62] Theiler's murine encephalomyelitis virus is a positive-sense, single-stranded RNA picornavirus that naturally infects mice and can lead to chronic demyelinating disease in SJL mice[59,60,63] and acute behavioral seizures that resolve within a few days in C57BL/6 mice.[60] Mice that exhibit acute seizures following TMEV infection display substantially reduced thresholds to electrically evoked seizures months after the infection has cleared and after the acute seizures have resolved.[63] Of those mice that were observed to have acute symptomatic seizures postinoculation (p.i.) and were monitored continuously using video-EEG) monitoring for 1 week at 4 weeks p.i., 1 month at 16 weeks p.i., and 1 month again at 28 weeks p.i., 64%, 57%, and 40%, respectively, were observed to display spontaneous electrographic seizures that correlated with behavioral seizures lasting between 45 and 66 s[62] (Fig. 80–1). Moreover, 100% of these mice displayed abnormal brief epileptiform discharges that were associated with behavioral arrest.[62] Infected mice exhibiting acute seizures also exhibit profound temporal lobe sclerosis.[62]

Gene array experiments performed on tissue from TMEV-infected animals have shown dramatic increases in mRNA expression of TNF-α,[59] a cytokine recently linked to homeostatic synaptic scaling,[120–123] thus providing a putative direct link between a virus-initiated immune response and general neural circuit excitability.[59] Consistent with this observation, Fujinami and colleagues have shown that TNF-αR1 knockout mice infected with TMEV experienced fewer behavioral seizures than control C57BL/6 mice.[59] Collectively, these results suggest that TMEV infection in C57BL/6 mice represents a unique "hit-and-run" model of encephalitis-induced TLE that can be used to investigate the mechanisms underlying virus-induced acute symptomatic seizures, epileptogenesis, and epilepsy and serve as a novel model for therapy discovery.

Other Models of Acquired Epilepsy

As summarized in Table 80–1, a number of other models of acquired epilepsy have been proposed over the years. These include, but are not limited to, the tetanus toxin model of partial epilepsy, the neonatal hypoxia-ischemia

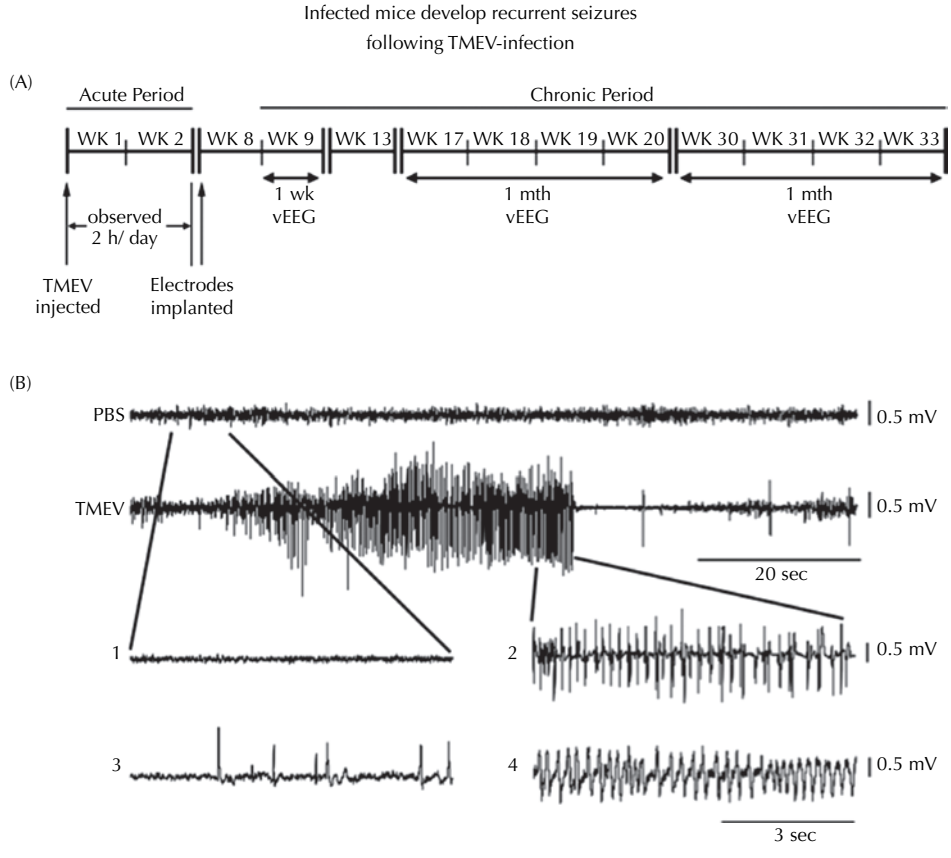

Figure 80–1. Chronology of procedures and representative seizures in epileptic TMEV-infected mice. **A.** Timeline of procedures. Animals were monitored with video-EEG at three different time points during the chronic period: 2 months p.i. for 1 week ($n = 14$), 4 months p.i. for 1 month ($n = 7$), and 7 months p.i. for 1 month ($n = 5$). **B.** Representative EEG traces showing baseline activity in a control (phosphate buffered saline [PBS]-injected] mouse (top trace) compared to high-frequency, high-amplitude, and rhythmic activity recorded during a Stage 5 seizure at 4 months p.i. Seizures were similar to those observed during the acute infection.[63] In the expanded traces (1–4), epileptiform activity associated with behavioral arrest (3) or no behavioral arrest (4) is present in TMEV mice but not in PBS mice (1). Activity observed during a Stage 5 seizure is expanded for comparison (2). From ref. 62.

model of hypoxic-ischemic injury, the neonatal hyperpyrexia model of febrile seizures, several models of IS, and models of cortical dysplasia. Each of these models display several phenotypic, histological, and electrophysiological similarities to their human counterpart and are likely to provide a framework for evaluating proposed antiepileptogenic and/or disease-modifying therapies.

Genetic Models: Unrealized Potential for Therapy Discovery

A number of genetic mouse models have been described in recent years that possess many of the features of human genetic epilepsy resulting from a specific defect in a particular receptor or voltage-gated ion channel. These have provided a wealth of information regarding the underpinnings of epileptogenesis and epilepsy at the molecular and genetic levels. For example, two excellent examples of animal models that have emerged from knowledge of human genetic mutations are the various mouse models that contain mutations in Nav1.1[124] and Kv7.2/7.3[125] genes. These mice recapitulate many of the phenotypic and pharmacological features of human severe myoclonic epilepsy of infancy (SMEI) and benign familial neonatal convulsions (BFNC), respectively. What is yet to be fully appreciated is the degree to which these and other emerging genetic mouse

models will aid in the identification and validation of novel targets for the treatment and prevention of epilepsy.

The Wistar Albino Glaxo Rat from Kijswijk (WAG/Rij), like the Genetic Absence Epileptic Rat from Strasbourg (GAERS), is an excellent model of human absence epilepsy.[126] In a novel experimental approach, Blumenfeld and colleagues demonstrated that early treatment with ethosuximide from postnatal day 21 through 5 months of age blocked changes in the expression of ion channels Nav1.1, Nav1.6, and (HCN1) normally associated with the onset and expression of spike-wave seizures in the WAG/Rij rat model of absence epilepsy.[127] Furthermore, they observed that early treatment was associated with prolonged suppression of seizures long after ethosuximide treatment was discontinued. This study does not show that ethosuximide prevented the development of epilepsy; however, it provides supportive information suggesting that early intervention with ethosuximide has the potential for disease modification and represents how innovative and strategic approaches can advance our efforts to identify novel therapies for the prevention of epilepsy.

CHALLENGES IN CHARACTERIZING THE ANTIEPILEPTOGENIC POTENTIAL OF AN INVESTIGATIONAL THERAPY

Conducting an intervention study with any one of the available models that display recurrent spontaneous seizures has its limitations.[128] Outcome measures include time to first seizure, seizure frequency, and severity of seizures at various time intervals postinsult and postintervention. As discussed above, there is substantial variability among individual animals in the latent period between their initial insult and the development of spontaneous seizures. Before declaring that a therapy is antiepileptogenic, the investigator is almost certainly obligated to conduct months of continuous video-EEG recording in order to ensure that a seizure was not missed due to a lapse in monitoring or due to the fact that seizures in animals, like those in humans, often cluster and could be easily missed by intermittent monitoring. Monitoring 24 h/day is clearly optimal, as intermittent sampling protocols are likely to introduce errors and underestimate the seizure frequency, particularly if seizures are clustered. Similarly, the optimal duration for monitoring may be 6 to12 months, but shorter periods are clearly more practical. It is important to note that it is always much easier to conclude that an animal has epilepsy than to conclude that an intervention prevented epileptogenesis. With that said, limited intermittent monitoring over the course of several weeks could serve to screen for potential antiepileptic drugs that could subsequently be submitted to more extensive and rigorous monitoring described above.

Another important issue that has to be considered when interpreting results from a positive intervention study is the possibility that the therapy itself decreased the insult-induced seizure severity and/or its duration.[128] This is not to imply that such a therapy would not be important; however, it becomes difficult under these conditions to separate the acute anticonvulsant effect of a therapy from its purported antiepileptogenic effects.

There have been a number of attempts to prevent the development of epilepsy in one or more of the available models (see ref. 3). Unfortunately, the results of these attempts have been somewhat disappointing and/or inconclusive given the caveats surrounding the study design and/or the seizure-monitoring protocol employed. Nonetheless, each of these studies has been extremely useful in setting the stage for further investigations and providing useful information regarding potential mechanisms underlying epileptogenesis for further hypothesis testing. The results obtained have been encouraging in that that they suggest that early treatment after an insult may offer some therapeutic benefit in terms of disease modification. These and other issues continue to be discussed, as the outcome of any intervention study is highly dependent on the question being asked and the extent to which a particular model mirrors the human condition being studied. Unfortunately, until the first antiepileptogenic or disease-modifying therapy is introduced, questions regarding the clinical validity of any animal model of epileptogenesis will remain.

The ability to prevent the development of epilepsy in the susceptible individual represents the holy grail of epilepsy research; however, preventing the cognitive decline and the

emergence of other debilitating comorbidities associated with epilepsy would represent a significant step forward for the patient with epilepsy. To this end, employing the currently available models to evaluate the cognition-sparing potential of a new therapy could provide the patient with an improved quality of life in the near term while the search for a cure continues.

CONCLUSIONS

The current approach to AED discovery is effective for identifying drugs that are useful for the symptomatic treatment of seizures. However, it would be naive to believe that therapies identified through this process would be useful for preventing or modifying the development of epilepsy in the susceptible person. A greater understanding of the pathophysiology of acquired epilepsy at the molecular and genetic levels will likely lead to the development of a new therapeutic approach that reaches beyond the symptomatic treatment of epilepsy to modify the progression or, dare we suggest, prevent the development of epilepsy in the susceptible patient. The realization of such a possibility will necessitate a change in our current AED discovery approach. Significant progress in our understanding of the factors that contribute to human epileptogenesis has been made in recent years. These advances have been made possible largely by the development and characterization of genetic-, insult-, and age-specific animal models of epileptogenesis and secondary neuronal hyperexcitability. The true validation of a given model of epileptogenesis requires the development of an effective therapy that prevents or delays the development of epilepsy or secondary hyperexcitability in the human condition and has activity that was predicted by preclinical testing. As we gain additional insight into the molecular biology and genetics of the acquired and genetic epilepsies, the day may come when new therapies that target the epileptogenic process will be developed.

Chapter 81

Strategies for Antiepileptogenesis

Antiepileptic Drugs versus Novel Approaches Evaluated in Post–Status Epilepticus Models of Temporal Lobe Epilepsy

Wolfgang Löscher

Epileptogenesis, that is, the process leading to epilepsy, is a common sequel of brain insults such as head trauma, cerebrovascular disease, brain tumors, neurosurgical procedures, neurodegenerative conditions, status epilepticus (SE), and complex febrile seizures.[1–3] Following such brain insults, there is a cascade of morphological and functional changes in the injured area over months to years before the occurrence of spontaneous recurrent seizures, that is, the hallmark of epilepsy (Fig. 81–1). This latent ("silent") period may offer a therapeutic window for the prevention of epileptogenesis and the subsequent development of unprovoked seizures and epilepsy.[2]

MOST ANTIEPILEPTIC DRUGS ARE NOT ANTIEPILEPTOGENIC

Based on the concept of a window of opportunity in which an appropriate treatment will stop the epileptogenic process induced by a brain insult, several clinical trials have been carried out to evaluate whether prolonged prophylactic administration of an antiepileptic (anticonvulsant, anti-ictal, anti-seizure) drug (AED) prevents the development of epilepsy after head trauma. However, in such clinical trials, administration of conventional AEDs such as phenytoin, phenobarbital, carbamazepine, or valproate following acute brain insults has thus far failed to prevent epileptogenesis.[4–6]

A similar lack of antiepileptogenic effects of clinically established AEDs has been found in most experimental studies, using post-SE rat models of temporal lobe epilepsy (TLE; Table 81–1). Post-SE models of TLE, in which SE is induced by sustained electrical stimulation of hippocampus or amygdala or by systemic administration of convulsants such as pilocarpine or kainate, display most of the major features of mesial TLE, that is, (1) neuropathological changes reminiscent of mesiotemporal sclerosis, (2) recurrent spontaneous seizures,

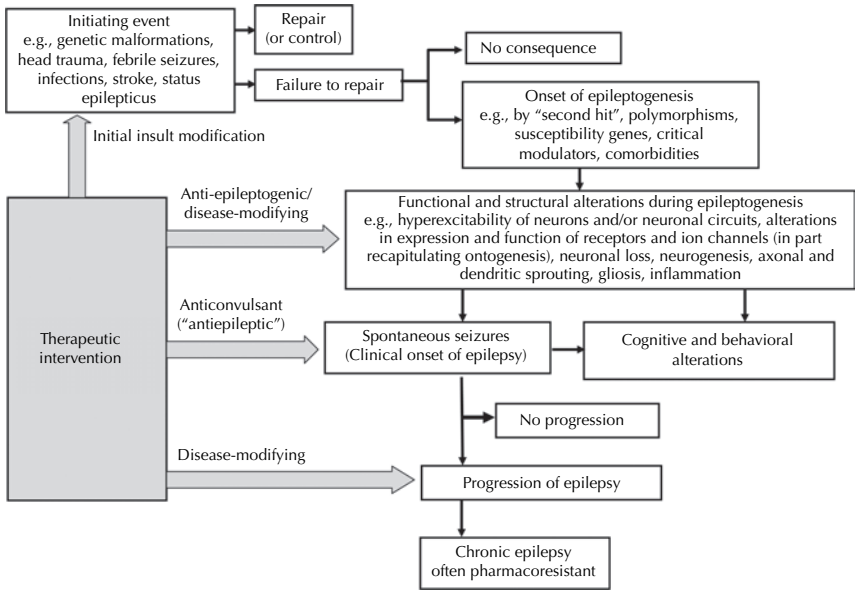

Figure 81–1. Steps in the development and progression of temporal lobe epilepsy and possible therapeutic interventions. The term *epileptogenesis* includes processes that take place before the first spontaneous seizure occurs to render the brain susceptible to spontaneous recurrent seizures and processes that intensify seizures and make them more refractory to therapy (progression). The concept illustrated in the figure is based on both experimental and clinical data. Adapted from Löscher[47] and Löscher et al.[48]

and (3) behavioral and cognitive changes associated with epilepsy.[7] Typically, depending on the severity and duration of SE, the spontaneous seizures first occur after a latent period following the SE of about 1–4 weeks, that is, the period of epileptogenesis (Figs. 81–1 and 81–2). In Table 81–1, only studies in which drugs were administered *after* onset of SE are shown. In various other studies, not included in this review, drugs were given *prior* to induction of SE, which may attenuate the severity or shorten the duration of SE and thereby reduce the long-term consequences of the brain insult. However, only a drug capable of preventing epilepsy *after* an initial insult such as SE would be clinically relevant.[8] A schematic illustration of drug testing in post-SE models of TLE, as used in our group, is shown in Fig. 81–2.

Antiepileptogenesis versus Disease Modification versus Initial Insult Modification

With respect to the lack of any antiepileptogenic or disease-modifying effect of most AEDs in most studies in post-SE models of TLE (Table 81–1), there are at least two critical issues. First, is it at all possible to prevent or modify epileptogenesis by a pharmacological treatment after SE? And, second, is there a critical time window in which to achieve such an effect after SE? When reviewing the literature in this respect, it is important to differentiate between drug effects resulting from *initial insult modification* and effects representing *true* antiepileptogenic or neuroprotective drug efficacy.[8,9] Initial insult modification means that the long-term consequences of the insult can be diminished by reducing the severity or duration of the initial brain insult, such as SE. This has, for instance, been demonstrated by reducing the duration of SE by phenobarbital, the *N*-methyl-D-aspartate (NMDA) antagonist MK-801 (dizocilpine), pregabalin, or diazepam in SE models in rats,[10–12] thus substantiating that early termination of SE is a powerful means for preventing or limiting its consequences.[13] In post-SE models of TLE with electrical SE induction, a SE duration of at least 3 h is needed to induce epileptogenesis in the majority of rats, so that any reduction of this duration by AEDs will result in a modification of

Table 81–1 **Prophylactic Effects of Treatment with Clinically Used Antiepileptic Drugs on the Long-Term Consequences of SE in Rats**

Drug	Model (Induction of SE)	Consequences of Drug Treatment				Reference
		Incidence of SRS	Frequency, Severity, or Duration of SRS	Neurodegeneration	Impairment of Learning and Memory	
Carbamazepine	Kainate	No effect	↓	↓ (hippocampus)	N.D.	Capella and Lemos[49]
Carbamazepine	Pilocarpine (in hippocampus)	N.D.	N.D.	↓ (CA1, CA3, hilus)	↓	Cunha et al.[41]
Carisbamate	Lithium-pilocarpine	N.D.	↓	↓ (CA1, PC, EC, amygdala, thalamus)	N.D.	Francois et al.[50] (A)

Table 81–1 **Prophylactic Effects of Treatment with Clinically Used Antiepileptic Drugs on the Long-Term Consequences of SE in Rats (Continued)**

Drug	Model (Induction of SE)	Consequences of Drug Treatment				Reference
		Incidence of SRS	Frequency, Severity, or Duration of SRS	Neurodegeneration	Impairment of Learning and Memory	
Phenytoin	Pilocarpine (in hippocampus)	N.D.	N.D.	↓ (CA1, CA3, hilus)	↓	Cunha et al.[41]
Pregabalin*	Lithium-pilocarpine	N.D.	N.D.	↓ (PC, EC)	N.D.	André et al.[11]*
Retigabine	Kainate	N.D	N.D	No effect	N.D	Ebert et al.[61]
Topiramate	Hippocampal stimulation	N.D.	N.D.	↓ (CA1, CA3, hilus)	N.D.	Niebauer and Gruenthal[62]
Topiramate	Pilocarpine	↓ (3–6 months after SE)	N.D.	↓ (CA1)	N.D.	DeLorenzo et al.[63] (A)
Topiramate	Lithium-pilocarpine	No effect	No effect	↓ (CA1, CA3)	N.D.	Rigoulot et al.[64]
Topiramate (plus diazepam)	Lithium-pilocarpine	No effect	No effect	↓ (CA1, hilus)	N.D.	Francois et al.[65]
Topiramate	Pilocarpine	N.D.	N.D.	↓ (CA1, CA3)	↓	Frisch et al.[66]
Topiramate	Lithium-pilocarpine	N.D.	N.D.	No effect (hippocampus)	(↓)	Shatskikh et al.[67]
Valproate	Kainate	↓ (during taper)	↓ (during taper)	↓ (CA1)	↓	Bolanos et al.[60]
Valproate	Amygdala stimulation	No effect	No effect	↓ (hippocampus and hilus)	No effect	Brandt et al.[15]
Valproate	Kainate	N.D.	N.D.	No effect (hippocampus and hilus)	↓	Jessberger et al.[68]
Vigabatrin*	Lithium-pilocarpine	No effect	No effect	↓ (CA1, CA3, and hilus)	N.D.	André et al.[69]*
Vigabatrin	Amygdala stimulation	No effect	No effect	No effect	No effect	Halonen et al.[70]

Notes: Only studies in which treatment started *after* onset of SE are included. A prophlylactic (beneficial) effect is indicated by "↓." Studies in which treatment effects were due to initial insult modification (i.e., reduction of SE duration or severity) rather than an antiepileptogenic effect are indicated by an asterisk (see text for discussion). Studies that are only available as abstracts are indicated by "A."

Abbreviations: EC, entorhinal cortex; N.D., not determined; PC, piriform cortex; SRS, spontaneous recurrent seizures.

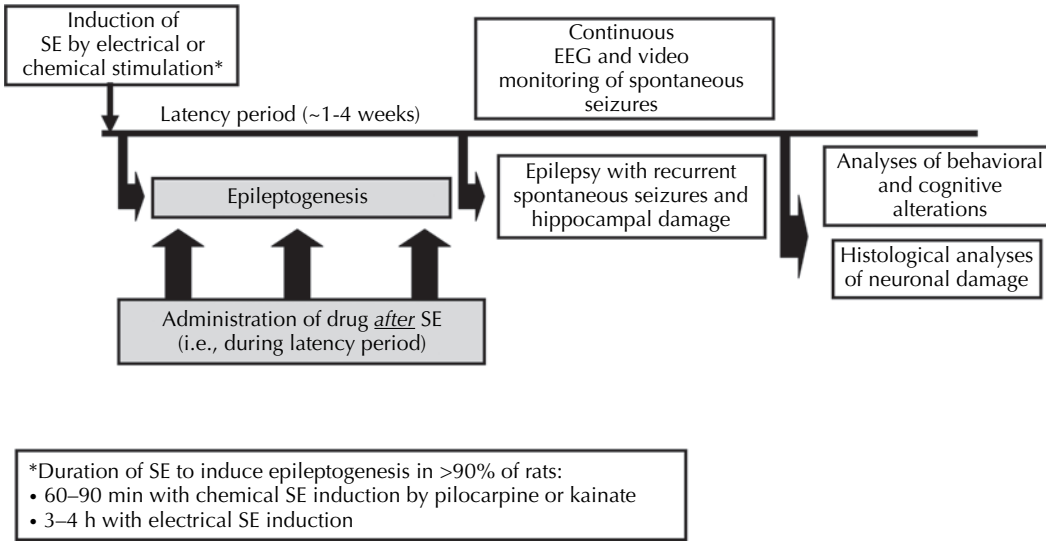

Figure 81–2. Schematic illustration of an experimental protocol to evaluate antiepileptogenic (or disease-modifying) drug effects by prophylactic drug treatment *after* SE.

the long-term consequences of the SE in such a way that fewer rats develop epilepsy or that the epilepsy that develops is milder.[2,8,9] Thus, in such SE models, the antiepileptogenic or neuroprotective potential of a drug should be tested by administering this drug *after* an SE of at least 3 h duration.[8] In chemical models of SE, such as the pilocarpine or kainate model, the critical duration of SE for induction of epileptogenesis and brain damage is considerably shorter, that is, about 60–90 min.[8] There are numerous studies that tested AEDs *after* such critical duration of SE for effects on epileptogenesis, brain damage, and/or behavioral and cognitive alterations in rats (Table 81–1). However, to our knowledge, there is no incontrovertible evidence supporting the idea that AEDs administered during the latent period following SE prevent the development of epilepsy, although some studies indicated that development of epilepsy may be delayed or the severity of spontaneous seizures may be reduced by such treatment (Table 81–1).

The ultimate goal of any prophylactic drug treatment after a brain insult such as SE is prevention of spontaneous recurrent seizures, that is, a true antiepileptogenic effect. However, alternative goals would be that the spontaneous seizures, if not prevented, are less frequent, less severe, and less resistant to AED treatment. Furthermore, any beneficial effect on the neuronal damage developing after brain insults or the cognitive and behavioral disturbances associated with epilepsy would be desirable. In this respect, it is important to note that several AEDs exerted neuroprotective effects when administered after SE (Table 81–1). At least in part, this neuroprotective effect was associated with positive effects on memory impairment or psychopathology. However, these data also indicate that protecting neurons from death is not sufficient for preventing the development of spontaneous seizures after brain insults, that is, for antiepileptogenic therapy.

NOVEL APPROACHES FOR ANTIEPILEPTOGENESIS

It is likely that antiepileptogenic drugs, if they exist, will have mechanisms of action distinct from those of traditional AEDs, as the molecular mechanisms underlying epileptogenesis and ictogenesis probably differ. Thus, a rational strategy for discovery of antiepileptogenic drugs would be testing of experimental compounds that interfere with one or several of the mechanisms underlying epileptogenesis (Fig. 81–1).

Neuroprotective Drugs

Because hippocampal damage has long been thought to be critically involved in the development of TLE, one potential strategy is administration of neuroprotective drugs after a brain insult (Table 81–2). For instance, we found that a single administration of a low dose (0.1 mg/kg) of the NMDA antagonist MK-801 after a kainate-induced SE of 90 min was capable of preventing most of the brain damage occurring in this model, but this treatment did not prevent the development of spontaneous seizures.[14] A similar finding was obtained more recently by starting prolonged treatment with valproate after 4 h of an electrically induced SE, which completely prevented any hippocampal damage, including cell loss in the hilus, but did not prevent development of spontaneous seizures.[15] These data thus substantiate the findings with MK-801 that an epileptogenic cascade, resulting in altered network excitability, may be triggered by SE, even in the absence of discernible neuronal injury in the hippocampal formation. Interestingly, although treatment with valproate after SE did not exert an antiepileptogenic effect, it did prevent most of the behavioral alterations developing after SE in rats.[15] We are currently evaluating the optimal therapeutic window and dosage protocol for these effects of valproate. Our data indicate that hippocampal damage is not critically involved in the development of spontaneous recurrent seizures but does play a major role in the psychopathology associated with epilepsy. We currently prove this hypothesis by experiments with the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) antagonist NS-1209, which has been shown to exert pronounced neuroprotective effects when administered after SE in rats (Table 81–2).

Anti-inflammatory Drugs

Another rational strategy for preventing or reducing the long-term consequences of brain insults is anti-inflammation. There is accumulating evidence that different types of brain insults, including SE, induce inflammatory processes in the brain that may critically contribute to epileptogenesis.[16] Thus, SE provoked experimentally in rodents triggers a prominent inflammatory response in brain areas recruited in the onset and propagation of epileptic activity.[16,17] This seizure-induced brain inflammation involves both the brain resident cells, such as glia and neurons, and cells of the peripheral innate immune systems such as granulocytes and macrophages, and shares molecules and pathways also activated by systemic infection, such as the Toll-like receptor signaling.[16] Various pro-inflammatory mediators are induced by SE in the brain, including cytokines such as interleukin (IL)-1ß, IL-6 or tumor necrosis factor-α (TNF-α), complement, and cyclooxygenase-2 (COX-2), which is responsible for generation of postaglandins from arachidonic acid.[16] Increase of these pro-inflammatory mediators is thought to be involved in impairment of blood-brain barrier function, neurodegeneration, and the neuronal hyperexcitability developing after SE.[16,17] Based on this hypothesis, Jung et al.[18] administered the COX-2 inhibitor, celecoxib, after a pilocarpine-induced SE in rats (Table 81–2). Compared to vehicle-treated controls, treatment with celecoxib prevented neuronal damage in the hippocampus and reduced the incidence and frequency of spontaneous recurrent seizures, that is, a true antiepileptogenic effect. This important finding prompted us to perform a similar study with the more selective COX-2 inhibitor, parecoxib. Parecoxib was administered twice daily at a rate of 10 mg/kg over 18 days, starting immediately after a pilocarpine-induced SE of 90 min duration. This treatment reduced hippocampal damage and the impairment of learning and memory in the Morris water maze test but did not prevent the development of spontaneous seizures, although seizures were less severe compared to those of controls.[19] Thus, anti-inflammation by COX-2 inhibition appears to constitute an interesting novel approach for disease modification after brain insults such as SE. However, a recent study with the COX-2 inhibitor SC58236 did not find any disease-modifying or neuroprotective effect when rats were treated after an electrically induced SE.[20] The most likely explanation for this different outcome of studies with prophylactic administration of COX-2 inhibitors after SE is the duration of the initial brain insult. Jung et al.[18] terminated SE after

Table 81–2 **Prophylactic Effects of Treatment with Various Drug Categories on the Long-Term Consequences of SE in Rats**

Drug	Model (Induction of SE)	Consequences of Drug Treatment				Reference
		Incidence of SRS	Frequency, Severity, or Duration of SRS	Neurodegeneration	Impairment of Learning and Memory	
Neuroprotective						
Ketamin* (NMDA antagonist)	Pilocarpine	↓ (K15)	N.D.	↓ (Ca1, Ca3) (K15 > K120)	↓ (K15 > K120)	Hort et al.[71]*
Ketamin	Pilocarpine (in hippocampus)	N.D.	N.D.	↓ (CA1, CA3, hilus)	↓	Cunha et al.[41]
MK-801* (NMDA antagonist)	Hippocampus stimulation	↓ (only for the 1 and 2 h after SE onset groups)	N.D.	N.D.	N.D.	Prasad et al.[10]*
MK-801	Kainate	No effect	No effect	↓ (CA1, CA3, PC, thalamus)	N.D.	Brandt et al.[14]
MK-801	Lithium-pilocarpine	N.D.	N.D.	↓ (CA1, CA3, PC, SN)	N.D.	Bankstahl et al.[72]
NS1209* (AMPA antagonist)	Amygdala stimulation	N.D.	N.D.	↓ (hippocampus)	N.D.	Pitkänen et al.[73]*
DEVD (caspase-3 inhibitor)	Kainate	N.D.	N.D.	No effect (hippocampus)	N.D.	Ebert et al.[61]
z-DEVD-fmk (caspase-3 inhibitor)	Amygdala stimulation	↓ (at 8–11 weeks post-SE)	No effect	↓ (CA3 and hilus)	No effect	Narkilahti et al.[74]
Anti-inflammatory						
Celecoxib (COX-2 inhibitor)	Lithium-pilocarpine	↓	↓	↓ (CA1, CA3, hilus)	N.D.	Jung et al.[18]
SC58236 (COX-2 inhibitor)	Hippocampus stimulation	No effect	No effect	No effect (hilus)	N.D.	Holtman et al.[20]
Parecoxib	Lithium-pilocarpine	No effect	↓	↓ (CA1, PC)	(↓)	Polascheck et al.[19]
Neuromodulators						
Atipamezole (α_2 antagonist)	Amygdala stimulation	No effect	↓	↓ (hilus)	No effect	Pitkänen et al.[22]
Rimonabant (CB1 antagonist)	Kainate	No effect	No effect	N.D.	N.D.	Pouliot et al.[25] (A)
Bumetanide	Lithium-Pilocarpine	No effect	No effect	No effect	N.D.	Brandt et al.[40]
Bumetanide + phenobarbital	Lithium-Pilocarpine	No effect	↓	No effect (?)	N.D.	Brandt et al.[40]

Notes: Only studies in which treatment started *after* onset of SE are included. A prophlylactic (beneficial) effect is indicated by "↓." Studies in which treatment effects were due to initial insult modification (i.e., reduction of SE duration or severity) rather than an anti-epileptogenic effect are indicated by an asterisk (see text for discussion). Studies that are only available as abstracts are indicated by "A."
Abbreviations: CB1, cannabinoid receptor 1; DEVD, a small peptide caspase-3 inhibitor with the amino acid sequence Asp-Glu-Val-Asp; N.D., not determined; PC, piriform cortex; SN, substantia nigra; SRS, spontaneous recurrent seizures.

60 min by diazepam and we did so after 90 min by diazepam, whereas Holtman et al.[20] terminated SE after 4 h by isoflurane anesthesia. However, SE was only transiently interrupted by anesthesia and continued for several more hours thereafter, resulting in a total SE duration of about 9–10 h.[20] Holtman et al.[20] suggested that the long duration of SE interfered with the outcome of COX-2 inhibition that started within this period. Thus, such technical details are very important when comparing studies on prophylactic drug treatment after SE.

Neuronal Modulators

A third rational strategy for preventing or modifying epileptogenesis and its consequences is to counteract the development of neuronal hyperexcitability after brain insults (Table 81–2). Interestingly, a number of studies have shown that different central nervous system (CNS)-stimulating drugs, including the adenosine antagonist caffeine, the α2 receptor antagonist atipamezole, and the cannabinoid (CB)-1 receptor antagonist rimobanant (SR141716A) exert neuromodulatory and/or antiepileptogenic and neuroprotective effects in epilepsy models[21–24] (but see Pouliot et al.[25]). Paradoxically, all of these compounds exert proconvulsant activity in normal animals, so that brain insults such as SE seem to change the pharmacology of these compounds. This is obviously a consequence of the molecular reorganization that develops after brain insults, resulting in alterations in the subunit composition and expression of receptors and ion channels and, thus, in their functions and pharmacology.[26–28] Furthermore, brain insults seem to induce a shift from adult to neonatal receptor and ion channel functions, indicating that epileptogenesis recapitulates ontogenesis.[29,30] Such a shift in GABAergic (gamma-aminobutyric acid) response polarity from hyperpolarizing to depolarizing has been described in human epileptic neurons recorded in the subiculum of hippocampal slices obtained from resections in patients suffering from mesial TLE.[31] This shift is thought to be a result of increased intraneuronal Cl^- levels caused by increased neuronal expression of the Na^+-K^+-$2Cl^-$ co-transporter NKCC1, an inwardly directed transporter that facilitates the accumulation of intracellular Cl^-, and downregulation of the K^+-Cl^- co-transporter KCC2, an outwardly directed transporter.[29,30,32,33] Upregulation of NKCC1 and downregulation of KCC2 in the hippocampus have been described both in patients with TLE and in the kindling and pilocarpine models of TLE.[33–39] This prompted us to evaluate whether inhibition of NKCC1 after SE affects the development of epilepsy in rats.[40] The diuretic bumetanide was used for these experiments, administered either alone or in combination with phenobarbital. Because bumetanide is very rapidly eliminated by rats and does not penetrate very well into the brain, various dosing protocols of bumetanide were evaluated in our experiments. Our data did not indicate any beneficial effects of bumetanide alone, but a combination of bumetanide and phenobarbital retarded development of epilepsy and reduced the frequency of spontaneous seizures (Table 81–2). However, this effect was not significantly different from that of treatment with phenobarbital alone. We are currently testing various pro-drugs of bumetanide to enhance its penetration into the brain of adult rats and mice. Furthermore, based on the observations with pro-convulsant drugs (Table 81–2), we have started experiments in which we administer the GABA receptor antagonist pentylenetetrazole at subconvulsant doses after SE to examine whether this treatment modifies epileptogenesis.

CONCLUSIONS

Novel drugs that interfere with epileptogenic processes may (1) prevent seizures (ultimate goal), (2) reduce the frequency, duration, or severity of seizures (disease modification), (3) prevent or reduce neurodegeneration, or (4) prevent or reduce the behavioral and cognitive alterations associated with epilepsy. New promising data with neuroprotective, anti-inflammatory, and neuromodulatory drugs seem to indicate that these goals are not unrealistic. However, because of the numerous pathological alterations that occur simultaneously during the epileptogenic cascade (Fig. 81–1), it will most certainly not be possible to halt epileptogenesis by targeting only one of these processes. Instead, cocktails of drugs that target different epileptogenic alterations should be

administered after brain insults, and we have started to explore this strategy. Furthermore, the models used to test potential antiepileptogenic agents should be modified to enhance the chance for identifying such agents. For instance, instead of inducing SE by systemic administration of kainate or pilocarpine, focal (e.g., intrahippocampal) injection of these convulsants may provide a more realistic scenario of TLE without the widespread brain damage and high mortality associated with conventional routes of administration. The recent study by Cunha et al.,[41] in which several drugs were tested for neuroprotective effects when given after SE induced by intrahippocampal pilocarpine, illustrates that the drug effects obtained in this model differ strikingly from the respective effects in models in which SE is induced by systemic injection of pilocarpine (Tables 81–1 and 81–2). Furthermore, the search for antiepileptogenic drugs should not rely solely on post-SE models of TLE; other approaches, including genetic animal models of epilepsy, should be included. In this respect, it is interesting to note that levetiracetam, which we reported to retard amygdala kindling,[42] failed to prevent development of spontaneous seizures after SE (Table 81–1) but more recently was found to exert antiepileptogenic or disease-modifying effects in spontaneously epileptic rats,[43,44] indicating that studies on kindling acquisition may be more predictive for such effects than data from SE models. The laboratory findings with levetiracetam prompted a clinical trial in which this AED will be examined for antiepileptogenic effects in patients with traumatic brain injury.[3] Based on experimental data indicating antiepileptogenic or disease-modifying effects of topiramate (Table 81–1), another clinical trial will determine whether topiramate decreases the risk of posttraumatic epilepsy.[3] Ultimately, only clinical trials can determine whether a drug possesses antiepileptogenic or disease-modifying potential. However, defining the clinical paradigm and selecting appropriate outcomes to detect such potential effects present challenges to clinicians studying the antiepileptogenic or neuroprotective properties of drugs.[45,46] Achieving a better understanding of the process of epileptogenesis, improved testing treatments that demonstrate antiepileptogenic effects in the laboratory, and performing thorough preclinical and clinical evaluations before attempting definitive trials should greatly improve the chance of identifying ways to prevent epilepsy after brain insults, providing the ultimate cure for this condition.[6]

Chapter 82

Neonatal Seizures and Neuronal Transmembrane Ion Transport

Kristopher T. Kahle
Kevin J. Staley

Chloride is the primary permeant anion in the mammalian nervous system, and the regulation of its flux across cell membranes is important for a diversity of neurophysiological processes. Neurons carefully adjust the intracellular level of chloride to ensure the proper electrical response to the amino acid neurotransmitter gamma-aminobutyric acid (GABA), which binds ligand-gated $GABA_A$ receptors that operate chloride channels. In adult neurons, the level of intracellular chloride is low and the reversal potential for chloride currents is near the neuron's resting membrane potential. Minor changes in the intracellular chloride concentration can significantly affect the strength, and even polarity, of GABAergic neurotransmission.

In addition to setting the direction of $GABA_A$ receptor-mediated currents, the intracellular chloride concentration is an important osmotic determinant of cell volume. Neurons, glia, and most other cells in the brain alter their cellular chloride concentration to defend their cell volume against fluctuations of extracellular osmolality and/or intracellular solute content—perturbations that can imperil their structural integrity. Neuronal chloride homeostasis is thus a balancing act between volume regulation and GABA signaling.

In the nervous system, the intracellular chloride concentration is set, in part, by the chloride-importing Na-K-2Cl cotransporter NKCC1, in concert with several different chloride-extruding K-Cl cotransporters. These related cation-chloride cotransporters (CCCs) are all members of the *SLC12* gene family.

This book chapter will discuss recent work that has provided insight into the role of

NKCC1 in fostering excitatory GABAergic neurotransmission in the immature brain and how the pharmacological inhibition of NKCC1 might hold promise for the treatment of neonatal seizures.

THE EFFECTS OF GABA ARE LAREGLY DETERMINED BY THE INTRACELLULAR CONCENTRATION OF CHLORIDE

Gamma-aminobutyric acid is the main *inhibitory* neurotransmitter in the adult cortex, where its activity is essential for maintaining appropriate electrical activity by balancing inputs that are triggered by excitatory neurotransmitters like glutamate. In contrast, in the neonatal cortex, GABA is an *excitatory* neurotransmitter. There, it plays an important role in neuronal development and the activity-dependent wiring of circuits by triggering the depolarizing inputs that underlie large-scale spontaneous electrical activity.[1]

In neurons, GABA acts by binding to $GABA_A$ receptors, which function as ligand-gated chloride channels. Gama-aminobutyric acid triggers conformational changes in these receptors that facilitate the passive inflow or outflow of chloride ions, depending on the cell's equilibrium potential for chloride (E_{Cl}). $[Cl^-]_i$ is a key determinant of the neuronal response to GABA. When $[Cl^-]_i$ is high, such that E_{Cl} is positive relative to the neuron's membrane potential (V_m), the opening of chloride channels by $GABA_A$-receptor activation results in chloride efflux, which consequently depolarizes the neuron. When $[Cl^-]_i$ is low, such that E_{Cl} is negative relative to the neuron's V_m, activation of the $GABA_A$ receptor results in chloride influx, leading to hyperpolarization of the neuron. Depolarization increases the chance that the neuron will fire an action potential, whereas hyperpolarization is associated with a decreased chance of its firing an action potential. Therefore, high neuronal chloride concentrations are generally considered to subserve GABA-mediated excitation and low concentrations to facilitate GABA-mediated inhibition. There are, however, exceptions to these considerations (such as shunting inhibition mediated by depolarizing conductances and action potentials triggered by conductances that are activated by membrane hyperpolarization), so it is sometimes preferable to assay the net effect of endogenously released GABA based on the rate of action potentials in the neural network rather than extrapolate from the effect of GABA on membrane potential.[2]

The differential action (excitatory versus inhibitory) of GABA in the neonate and adult central nervous systems is likely due to a difference in the $[Cl^-]_i$ of immature versus mature neurons.[3] Compared to mature adult neurons, $[Cl^-]_i$ is about 20–40 mM *higher* in immature neonatal neurons, a difference that is sufficient to shift the action of GABA from inhibition to excitation, because the electrochemical driving force for chloride drives the flux of this anion out of the cell when GABA channels are opened. $[Cl^-]_i$ is determined in part by the Na-K-Cl cotransporter NKCC1, which mediates chloride transport into the cell,[4] and the K-Cl cotransporter KCC2,[5] which mediates chloride transport out of the cell. NKCC1 and KCC2 are related members of the *SLC12A* electroneutral cation-chloride cotransporter gene family.

NKCC1 AND KCC2 ARE ESSENTIAL CATION-CHLORIDE COTRANSPORTERS IN THE NERVOUS SYSTEM

The CCCs are targets of some of the most common drugs in medicine—the loop and thiazide diuretics—and are mutated in several inherited human diseases.[6] The CCCs are intrinsic membrane proteins that transport chloride ions, together with sodium and/or potassium ions, across the plasma membranes. The stoichiometric coupling and directionality of their translocated ions result in an electroneutral, secondarily active transport process driven energetically by transmembrane sodium and potassium gradients established by the Na^+-K^+-adenosine triphosphatase (ATPase).

Defined by their sensitivity to pharmacological inhibitors, stoichiometry of transported ions, and phylogeny, the CCCs are divided into two main branches. Given the large electrochemically favorable inward gradient for sodium, the sodium-coupled CCC branch that comprises the Na-(K)-Cl cotransporters (NCC, NKCC1, and NKCC2) loads chloride ions into the cell to raise $[Cl^-]_i$ above its electrochemical

equilibrium. Conversely, by coupling chloride transport to the outward gradient for potassium, the potassium-coupled CCC branch, comprised of four different K-Cl cotransporters (KCC1, KCC2, KCC3, and KCC4), primarily transports chloride ions out of the cell, reducing $[Cl^-]_i$ below its electrochemical equilibrium. The relative activities of these mediators of chloride influx and efflux determine the level of $[Cl^-]_i$ in numerous cell types, and consequently play key roles in the regulation of neuronal excitability, the homeostasis of cellular volume, and the transepithelial transport of salt, potassium, and water.

Consistent with the opposing directionality of the chloride they transport, the Na-K-Cl and K-Cl cotransporters exhibit reciprocal regulation by volume- and chloride-sensitive serine-threonine phosphorylation/dephosphorylation events.[7] Cell swelling (triggered by extracellular hypotonicity), high intracellular levels of chloride, and protein phosphatases (by promoting cotransporter dephosphorylation) stimulate the K-Cl cotransporters but inhibit NKCC1, thereby decreasing $[Cl^-]_i$. Conversely, cell shrinkage (triggered by extracellular hypertonicity), low intracellular chloride, and protein phosphatase inhibitors (by promoting cotransporter phosphorylation) activate NKCC1 and inhibit the K-Cl cotransporters, resulting in increased $[Cl^-]_i$.

NKCC1 is expressed early in development in neurons and glia in the cerebrum and cerebellum, as well as in the spinal cord, peripheral nervous system, and cerebral vascular endothelial cells in adults.[8] The expression of KCC2 is restricted to mature neurons in the retina, cortex, cerebellum, and the dorsal horn of the spinal cord.[9]

The WNK (With No K, i.e. lysine) kinases, members of which are mutated in a inherited syndrome of human hypertension,[10] and also a hereditary sensory and autonomic neuropathy,[11] along with the Ste20p-related Proline Alanine-rich Kinase (SPAK) and oxidative stress-responsive kinase-1 (OSR1),[12] are now thought to be the long-sought chloride/volume-sensitive regulatory kinases of the Na-K-Cl and K-Cl cotransporters.[13] Protein phosphorylation is likely the predominant mechanism by which acute, dynamic modulation of CCC function takes place; regulation of gene transcription and protein degradation are mechanisms by which the activity of the CCCs can be modulated over a less rapid time scale.

A DEVELOPMENTAL SWITCH IN NKCC1:KCC2 EXPRESSION RENDERS GABA HYPERPOLARIZING DURING NEURONAL DEVELOPMENT

A developmental switch in neuronal chloride gradients underlies the maturation of GABAergic signaling from excitatory to inhibitory.[14,15] Before synaptic transmission is established, GABA plays an important role in neuronal growth, development, and the activity-dependent wiring of circuits by triggering the excitatory inputs that underlie large-scale spontaneous electrical activity in the neonatal central and peripheral nervous systems.[1,16–18] In contrast to its action in the adult, during this early time period GABA is an excitatory neurotransmitter due to a relatively higher level of intraneuronal chloride, such that GABA triggers an outward flux of chloride that leads to membrane depolarization.[14,19] As discussed above, this depolarization can generate action potentials, as well as directly activate voltage-dependent calcium channels and indirectly activate *N*-methyl-D-aspartate (NMDA) receptors by removing the obstructive block of magnesium ions from the receptor pore. The subsequent GABA-induced elevations of intracellular calcium promote neuronal survival and differentiation, and are important for the genesis and maintenance of synaptic connections.[16] However, during later stages of development, excitatory GABAergic inputs are replaced by inhibitory GABAergic inputs.[19] A shift in the relative predominance of neuronal KCC2 to NKCC1 activity is now considered to be the mechanism that underlies the excitatory-to-inhibitory developmental transition of GABAergic signaling.

Influx of chloride into neurons is mediated largely by Na–K–2Cl cotransport via NKCC1. In embryonic and early postnatal life, neurons show robust expression of NKCC1 but minimal expression of KCC2.[20] This predominance of inward-directed chloride transport increases the $[Cl^-]_i$, resulting in a positive E_{Cl} relative to the V_m of the neuron, so that GABA stimulates an outward-directed chloride current that triggers neuronal depolarization and excitation. Sustained block of excitatory GABAergic signaling during development by persistent pharmacological inhibition or genetic disruption

of NKCC1 results in a lack of morphological maturation of cortical neurons, fewer mature spinal neurons, reduced dendritic arborization, disrupted motor activity, fewer motor neurons and interneurons, a reduction in the elaboration of axonal tracts, and smaller brains and spinal cords.[8,21]

Efflux of chloride out of neurons is mediated largely by the K–Cl cotransporter KCC2. In many species, this cotransporter is expressed at very low levels at birth.[19] In rat hippocampal and neocortical pyramidal neurons, a negative shift in the GABA reversal potential (E_{GABA}) is paralleled by a robust increase in KCC2 expression near the end of the second postnatal week.[14] Dzhala et al. demonstrated that KCC2 expression in the human neocortex begins to increase at 40 weeks after conception.[22] This increase in KCC2 expression, accompanied by a concurrent downregulation of NKCC1 expression, results in the dominance of chloride efflux over chloride influx, which decreases $[Cl^-]_i$ such that E_{Cl} is negative relative to the neuron's V_m, thereby rendering GABAergic signals hyperpolarizing.[14] *Kcc2*$^{-/-}$ mice have seizures and die at birth, in part owing to malfunction of the respiratory center.[23]

Gamma-aminobutyric acid itself, by acting as a self-limiting trophic factor, might promote this GABAergic switch by triggering specific intracellular cascades that upregulate KCC2 gene expression.[15] Recent work suggests that another regulatory factor might be cholinergic signaling. Spontaneous cholinergic activity, by triggering calcium-signaling cascades that upregulate KCC2 downstream of the acetylcholine nicotinic receptor, has been shown to be important for the GABAergic excitation-to-inhibition transition.[17] Synergistic with the newly established inhibitory GABAergic signaling, cholinergic signaling then triggers later events of neuronal development.

Both bumetanide and furosemide, well-known loop diuretics, are capable of inhibiting the cation-chloride cotransporters in vitro and in vivo.[24,25] Bumetanide has an approximately 500-fold greater affinity for NKCC1 (inhibition constant [K_i] of approximately 0.1 μM) than for KCC2 (K_i of approximately 25–50 μM). Furosemide inhibits NKCC1 and KCC2 with equal potency (K_i of approximately 25–50 μM). Therefore, at low at low doses (2–10 μM), bumetanide is a relatively specific inhibitor of NKCC1. The accumulation of bumetanide in the central nervous system after systemic administration has not been directly measured, but the drug's high lipid:water partition coefficient, its documented anticonvulsant effects in both animals and humans in vivo, and the developmental effects of chronic systemically administered bumetanide suggest that the drug is able to cross the blood-brain barrier.[8,26,27]

THE ROLE OF NKCC1-DEPENDENT CHLORIDE ACCUMULATION IN NEONATAL SEIZURES

Neonatal seizures, or epileptic episodes suffered by infants in the first 28 days of life, occur in 1% to 2% of patients in neonatal intensive care units and are the most common manifestation of an acute neurological disorder in newborn infants.[28] Most commonly caused by hypoxic-ischemic encephalopathy, hemorrhage, or cerebral infarction, the presence of neonatal seizures often portends severe neurological dysfunction later in life, with high rates of adult epilepsy and long-term cognitive and motor deficits in survivors. In animal models, neonatal seizures have been shown to be injurious to the development of the brain, inducing synaptic reorganization, altering synaptic plasticity, and priming cortical neurons to increased damage from seizures sustained later in life. Thus, the prompt diagnosis and successful treatment of neonatal seizures are important for improving the long-term neurological outcome.

While seizure activity in adults is usually clinically obvious and the electroencephalogram (EEG) reflects coordinated seizure activity, diagnosing seizures in neonates is difficult because seizures are often behaviorally subtle and the EEG typically demonstrates a multifocal process.[29,30] Nonetheless, seizures in neonates are currently diagnosed by EEG, with a discharge duration of 10 s (versus 3 s in older age groups) required to diagnose an electrographic seizure. However, because EEGs are not immediately available in many neonatal intensive care units, the initial diagnosis and treatment of seizures are often based on clinical assessment alone, and EEGs are performed *after* the administration of antiepileptic drugs. Unfortunately, it is all too common for electrographic seizures to persist in encephalopathic

neonates even when antiepileptic drug levels are "therapeutic."[31]

Conventional antiepileptic drugs have limited utility in treating neonatal seizures. Barbiturates and benzodiazepines, $GABA_A$ receptor agonists that are efficacious for treating adult seizures, are currently among the first-line drugs for neonatal seizures; however, they are often ineffective and have been shown to actually have the potential to increase seizure activity in the immature brain.[32] Phenytoin has been used with similarly limited success.[33] Barbiturates and benzodiazepines have also been known to produce a phenomenon termed *electroclinical dissociation* in neonates, whereby the overt clinical manifestations of seizures (e.g., convulsions) are inhibited but EEG-documented cortical seizure activity is either unaffected or exacerbated.[34] This insidious effect of the GABA agonists has the potential for great harm, as it provides physicians with a false impression that seizures are under control, while cortical seizure activity—and its potentially detrimental effects—rages on.

There have been few prospective studies or randomized, controlled trials of the antiepileptic drugs that are currently used to treat neonatal seizures.[32] To date, the only randomized trial of antiepileptic drugs for the treatment of neonatal seizures compared the current first-line drugs, phenobarbital to phenytoin.[33] In this study, the majority of neonates had asphyxia, infarction, or hemorrhage as the etiology of their seizures. Complete control of electrographic seizures was achieved with either drug in only ~25% of neonates whose seizure frequency was increasing. Seizure control was achieved in another 15% of newborns when both agents were used concurrently. Preliminary studies of antiepileptic drugs other than phenobarbital and phenytoin have shown only modest efficacy in smaller cohorts of neonates, though sufficiently powered randomized trials are needed to demonstrate conclusively whether any of these drugs are truly effective.[32] The lack of evidence-based treatment recommendations, coupled with the paucity of data regarding the underlying pathophysiology of neonatal seizures, has made their current management far from optimal.

Increasing synaptic excitation and/or decreasing synaptic inhibition can cause neurons to become hyperactive. Because neurons harbor a multiplicity of connections with other neurons, the electrical firing of even a small population of hyperexcitable neurons, when synchronized, can progressively entrain larger neural networks until seizures ensue. In neonates, while GABA-mediated excitation plays a role in neuronal development, it also renders the developing brain particularly susceptible to seizures. In the adult cortex, excitatory glutaminergic signaling is balanced by inhibitory GABAergic signaling. However, in the brain-injured neonate, the additional depolarization due to $GABA_A$ receptor activation likely adds to the excitation already initiated by glutamate neurotransmission to tip the balance of excitation/inhibition toward excessive excitation and a propensity to seizure activity. Experimentally, GABA-mediated excitation has been shown to support epileptogenesis in the developing hippocampus and also to decrease the seizure threshold of neonates.[22,35,36] The excitatory nature of GABA signaling in immature neurons also explains why GABA agonists like barbiturates and benzodiazepines are often ineffective in reducing neonatal seizures and can even exacerbate seizure activity. Clearly, new antiepileptic treatment strategies are needed for neonatal seizures.

Because the elevated $[Cl^-]_i$ of immature neurons is due to robust activity of NKCC1, this cotransporter is currently being explored as a target for novel anticonvulsant strategies for neonatal seizures. In theory, inhibition of NKCC1, by reducing $[Cl^-]_i$, could reduce the GABA-mediated excitation of immature neonatal neurons or even possibly convert the GABA response to inhibitory.

Dzhala et al. were the first to test this hypothesis in a recent seminal paper.[22] Previous groups had established that NKCC1 expression in rats is highest in cortical neurons during the first postnatal week, begins to decrease at postnatal day 14 (P14), and then drops to the low levels that are found in adults (reviewed in ref. 37). Conversely, the expression of KCC2 is minimal at birth in rat cortical neurons, is low during the first postnatal week, and then attains an expression level at P14 that is comparable to that of adults. Dzhala et al. demonstrated that a similar expression pattern is present in the human cortex, with high NKCC1 and low KCC2 expression during the neonatal time period and before the end of the first year of life—a time scale not different from that of the rat when adjusted for the greater length of time

required for the development of the human cortex relative to the rodent brain. These data supported the hypothesis that, similar to the situation in the rat, GABA is excitatory in immature human cortical neurons, and neonates may be susceptible to seizures due to the excitatory effects of GABA during development. Because NKCC1 is known to establish the elevated levels of $[Cl^-]_i$ that underlie excitatory GABAergic signaling in immature neurons, these data predicted that bumetanide, an inhibitor of NKCC1, might be an effective treatment for neonatal seizures.[22]

This hypothesis was tested in a series of elegant in vitro and in vivo physiological studies.[22] NKCC1 blockade by bumetanide inhibited cortical seizure activity in neonatal rats both in vitro and in vivo, and this inhibition was observed at doses that have already been extensively tested in human neonates in diuresis studies. Specifically, pharmacological inhibition of NKCC1 by bumetanide (1) produced a negative shift in E_{GABA}, (2) inhibited GABA-dependent synchronous excitatory activity in the immature hippocampus, (3) suppressed interictal and ictal-like activity in immature hippocampal slices in vitro, and (4) attenuated kainate-induced seizure activity in vivo in neonatal rats. These anticonvulsant effects of bumetanide were shown to be specific, as they (1) were achieved at low doses that selectively block NKCC1, (2) were blocked by antagonists of the $GABA_A$ receptor (indicating that bumetanide is acting through a $GABA_A$ receptor-associated signaling pathway), (3) did not affect epileptiform activity in brain slices from *NKCC1*$^{-/-}$ mice (indicating that inhibition of NKCC1 is the mechanism by which bumetanide exerts its GABA-dependent anticonvulsant effects), and (4) did not depress epileptiform activity in mature neurons (where the expression of NKCC1 is less than 10% of that in neonatal tissue).[22]

Given these promising findings, it seemed reasonable to combine bumetanide, which blocks the excitatory effect of GABA in immature neurons by decreasing $[Cl^-]_i$, with phenobarbital, a GABA agonist that opens $GABA_A$ receptor-associated chloride channels. Theoretically, such an increase in GABA-mediated conductance in neurons already targeted by bumetanide would serve to increase shunting inhibition and maximize the anticonvulsant power of the GABA system.

The efficacy of bumetanide, in combination with the GABA-enhancing anticonvulsant phenobarbital, was tested for the treatment of recurrent tonic-clonic epileptiform activity in the intact immature hippocampus in vitro.[35] In this study, a low-magnesium model of neonatal seizures in the intact immature hippocampal formation in vitro was employed. Such a model has the benefits of not altering the energy gradient for NKCC1-mediated cation-chloride transport, as well as preserving longitudinal intrahippocampal connections. Recurrent seizures were induced in the intact hippocampal preparation by a continuous 5 h exposure to low-magnesium solution, and the anticonvulsant efficacy of phenobarbital, bumetanide, and the combination of these drugs was then studied. While phenobarbital failed to abolish or depress recurrent seizures in 70% of immature hippocampi, phenobarbital *in combination with bumetanide* abolished seizures in 70% of immature hippocampi and significantly reduced the frequency, duration, and power of seizures in the remaining 30% of immature hippocampi. Taken together, the results of these in vitro and in vivo studies suggested that bumetanide, alone or in combination with other drugs such as phenobarbital, might be useful in the treatment of neonatal seizures in humans.[22,35]

Electrographic neonatal seizures frequently have no clinical manifestations, a phenomenon referred to as *electroclinical dissociation* or *uncoupling*.[29,30] Phenobarbital, an allosteric modulator of $GABA_A$ receptors, is the drug of choice for treating neonatal seizures. Video-EEG studies have demonstrated that phenobarbital inhibits electrographic seizure activity much less effectively than clinically apparent convulsive activity. This differential efficacy exacerbates electroclinical dissociation so that the incidence of electroclinical dissociation in neonates is 80% after anticonvulsive treatment.[29,38] The ontogeny of KCC2 mRNA expression follows a caudal-rostral pattern. Spinal cord and subcortical neurons begin to express KCC2 early during embryogenesis, while KCC2 expression in cortical neurons increases after birth.[8,9] These expression patterns of NKCC1 and KCC2 suggests that at birth, GABA should have a more inhibitory effect in spinal and subcortical neurons compared to cortical neurons, but there is no direct

evidence for a differential effect of GABA on cortical versus subcortical structures.

To gain insight into the mechanisms of electroclinical dissociation and its exacerbation by phenobarbital, Glykys et al.[39] tested the hypotheses that the neocortex and subcortical structures have different $[Cl^-]_i$ during postnatal development using the genetically expressed Cl-sensitive dual-wavelength fluorescent protein Clomeleon. They then tested whether these regions have oppositely directed responses to $GABA_A$ receptor agonists and phenobarbital, and whether bumetanide, an NKCC1 blocker, preferentially alters the responses to GABA in cortical areas expressing high levels of NKCC1. Experiments revealed that (1) $[Cl^-]_i$ varies substantially between neighboring neurons in both the developing thalamus and neocortex, but the average $[Cl^-]_i$ is significantly lower in thalamic versus cortical neurons; (2) phenobarbital is an effective anticonvulsant in the thalamus but not in the neocortex due to a net inhibitory effect of GABA in the thalamus but an excitatory effect in the neocortex; and (3) the combination of bumetanide and phenobarbital is effective in decreasing epileptiform activity in the neocortex, while it is not different from phenobarbital alone in the thalamus. These results supported the idea that caudal-rostral $[Cl^-]_i$ maturation determines neuronal responses to GABA, and therefore the effects of allosteric modulators of GABA receptor function, and supported the hypothesis that differences in $[Cl^-]_i$ comprise a candidate mechanism of electroclinical dissociation of neonatal seizures and the exacerbation of dissociation by GABAergic anticonvulsants.[39]

Dzhala et al. considered the possibility that *activity-dependent*, NKCC1-dependent changes in E_{GABA} help determine the time course of neonatal seizures, explaining the substantial variations in the efficacy of GABAergic anticonvulsants in different reported experimental settings.[36] This hypothesis is of considerable clinical importance because it provides an additional impetus for immediate and aggressive treatment of neonatal seizures: the more seizures that occur, the more E_{GABA} will shift, and the lower the probability that the seizures will respond to available anticonvulsants such as phenobarbital, particularly during the crescendo phase of neonatal seizures.[33] A corollary of this hypothesis is that, by blocking NKCC1, bumetanide should prevent or reduce the seizure-induced shift in E_{GABA}, potentially ameliorating the crescendo pattern of neonatal seizures. Finally, enhancement of the efficacy of GABAergic anticonvulsants by bumetanide should increase with the duration of the previous seizure activity.

These hypotheses were tested in whole hippocampal preparations from neonatal rats and CLM-1 mice expressing Clomeleon.[36] Recurrent seizures were shown to increase progressively the intracellular chloride concentration $[Cl^-]_i$ assayed by Clomeleon imaging and invert the net effect of $GABA_A$ receptor activation from inhibition to excitation assayed by the frequency of action potentials and intracellular Ca^{2+} transients. These changes correlated with increasing frequency of seizure-like events and reduction in phenobarbital efficacy. Bumetanide inhibited seizure-induced neuronal chloride accumulation and the consequent facilitation of recurrent seizures. Together, these results suggest that seizure activity leads to $[Cl^-]_i$ accumulation, thereby increasing the probability of subsequent seizures and providing a potential mechanism for the early crescendo phase of neonatal seizures.[36]

TARGETING NKCC1 AND OTHER CCCS AS AN ANTIEPILEPTIC STRATEGY

At low concentrations (2–10 μM), bumetanide is a specific inhibitor of NKCC1 and has well-established pharmacokinetic and pharmacodynamic properties in adult humans with few side effects (reviewed in ref. 40). Because the expression patterns of NKCC1 during development are similar in the human and rat cortex, bumetanide might be useful for the treatment of seizures in human neonates. Bumetanide has been extensively used in both healthy and critically ill human term and preterm infants to treat fluid volume overload due to cardiac and/or pulmonary disease, with few side effects other than minor electrolyte imbalances, so extrapolation from these studies might help guide the design of any potential pilot studies or clinical trials.[26] However, it will be important to investigate whether the pharmacokinetics of bumetanide are altered by any of the

underlying diseases that are responsible for triggering seizures in neonates, because many term newborns with refractory seizures have hypoxic-ischemic encephalopathy from perinatal asphyxia, which is often accompanied by multiorgan dysfunction (including hepatic and renal failure); such organ dysfunction can dramatically affect drug metabolism.

Perhaps the best new treatment strategy for neonatal seizures, and one that could be easily tested, is a combination regimen that would include bumetanide with a barbiturate like phenobarbital. In the neonatal rat brain, phenobarbital has been rendered a more effective anticonvulsant by coadministering it with bumetanide, which reverses the chloride gradient in immature neurons to a level such that $GABA_A$ receptor potentiation by phenobarbital results in synaptic inhibition. If such a trial were to take place, neonates with persistent seizures despite an initial loading dose of phenobarbital (the current standard of care) could be offered bumetanide along with the second dose of phenobarbital. Continuous EEG monitoring of patients could then be used to determine whether bumetanide reduces seizures compared with controls (i.e., those neonates treated with phenobarbital alone). Pilot studies of the efficacy of bumetanide, administered with phenobarbital, for the treatment of neonatal seizures, are now underway (FDA IND #101690; see http://www.cureepilepsy.org/research/current.asp).

The combination of bumetanide and a barbiturate should obviate the need to use the high doses of barbiturate or benzodiazepine that have been associated with significant side effects, such as apoptotic neurodegeneration in the developing brain and late cognitive/behavioral impairment.[4,5,22] Moreover, because of bumetanide's long-standing safe use in newborns as a diuretic, the low doses that are required to inhibit NKCC1 are not anticipated to produce short- or long-term side effects. However, caution must be exercised as work proceeds, and studies should be done to determine any potential side effects of inhibiting NKCC1 in the neonatal nervous system, since GABA-mediated excitation is important for neuronal development.[1] To date, bumetanide-mediated inhibition of NKCC1 in the brain, for periods of time that would far exceed the duration that would be used for the treatment of neonatal seizures, has been shown to have few developmental side effects. These modest but measurable side effects must be weighed against the well-known detrimental effects of persistent seizures in the immature brain on cortical development and the absence of knowledge regarding the developmental effects of NKCC1 inhibition in the setting of such seizures. Recently, bumetanide treatment was reported to decrease seizure duration and frequency in a 6-week-old baby girl with anticonvulsant-resistant status epilepticus secondary to meningitis.[41]

Brain-derived neurotrophic factor (BDNF), released upon seizure-like activity, causes downregulation of KCC2 that results in a decreased chloride extrusion capacity of neurons that propagates further seizure episodes.[42] Because inhibition of BDNF action via blockage of the TrkB receptor reverses depolarizing shifts in E_{GABA}, inhibitors of TrkB, by increasing the endogenous expression of KCC2, might help treat different seizure syndromes. Additionally, targeting the volume/chloride-sensitive regulatory kinases of the CCCs, the WNKs or SPAK/OSR1, might have utility. The role of these kinases in the mammalian nervous system is only beginning to be explored; however, in vitro experiments in mammalian cells and in vivo experiments in lower organisms suggest that these serine-threonine kinases—initially characterized in the kidney—might prove relevant to the physiology and pathophysiology of neuronal chloride transport, GABA signaling, and the origin and treatment of seizures.

SUMMARY

The incidence of seizures is higher in the immediate postnatal period than at any other age. The presence of seizures during this time period is a powerful predictor of long-term cognitive and developmental impairment. Electrographic neonatal seizures are notoriously resistant to phenobarbital and other allosteric modulators of ionotropic $GABA_A$ receptors, making their treatment difficult with the existing antiepileptic agents. Better drugs could be designed with an improved understanding of the pathophysiology underlying seizure activity in neonates and their resistance to GABAergic anticonvulsants (Fig. 82–1). The opening of $GABA_A$ receptors gates a transmembrane current that

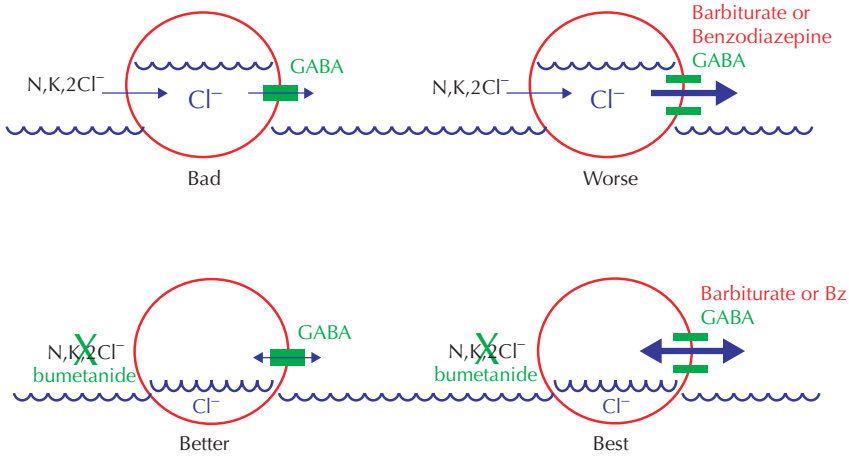

Figure 82–1. Anticonvulsant strategies for neonatal seizures. Top left: NKCC1 accumulates intracellular Cl^- in immature neurons. Neurons with high intracellular Cl^- levels will lose negatively charged chloride ions when GABA binds to $GABA_A$ receptors, opening a channel that is selectively permeable to anions. This loss of negative charge depolarizes neurons and may initiate excitatory processes such as action potentials and calcium waves. Top right: Allosteric modulators of the $GABA_A$ receptor such as anticonvulsant barbiturates and benzodiazepines increase the open probability of the anion channel, resulting in increased Cl^- efflux, increased depolarization, and increased probability of initiating frankly excitatory processes. Bottom left: Blocking NKCC1 is a better anticonvulsant strategy, because it blocks Cl^- accumulation and the net loss of Cl^- when the $GABA_A$ receptor channel opens. Although the neuron is not hyperpolarized by $GABA_A$ receptor activations, membrane conductance is increased, reducing the probability of initiating action potentials or calcium waves. Bottom right: the best anticonvulsant strategy may be to block NKCC1, thereby removing chloride accumulation and increasing the open probability of the $GABA_A$ receptor. This maximizes the increase in membrane conductance initiated by GABA binding and minimizes Cl^- loss that might otherwise initiate action potentials.

is carried by anions. The current's direction and effect (excitation or inhibition) depend on the neuron's resting membrane potential (RMP) and its relation to the reversal potential for GABA (E_{GABA}), which is primarily determined by the intracellular concentration of chloride $[Cl^-]_i$. If E_{GABA} is negative relative to the RMP, GABA will trigger Cl^- influx, membrane hyperpolarization, and neuronal inhibition; if E_{GABA} is positive relative to the RMP, GABA can trigger Cl^- efflux, membrane depolarization, and neuronal excitation. Relative to adult neurons, the $[Cl^-]_i$ of neurons in the cortex of seizing neonates is about 30 mM higher due to robust activity of the chloride-importing, bumetanide-sensitive Na-K-2Cl cotransporter NKCC1 and low activity of the chloride-exporting K-Cl cotransporter KCC2. An ontological switch from NKCC1 to KCC2 activity at around 2 weeks postnatally underlies the switch from excitatory to inhibitory GABA neurotransmission due to a reversal of Cl^- gradients in neocortical neurons. Though important for neuronal development and synaptogenesis, the excitatory actions of GABA in neonates lower the seizure threshold and might explain the poor EEG response to GABAergic anticonvulsants such as phenobarbital and benzodiazepines in this age group. Recent studies show that bumetanide, a diuretic that inhibits NKCC1, modulates Cl^- transport sufficiently to cause a more negative E_{GABA} in immature neurons, rendering the widely used antiepileptic drug phenobarbital effective in neonatal rats. This demonstration of rational anticonvulsant polypharmacy in animals has served as the basis for two double-blind, randomized, placebo-controlled multicenter trials testing the efficacy of phenobarbital and bumetanide in the treatment of neonatal seizures.

Chapter 83

Antiepileptogenesis, Plasticity of AED Targets, Drug Resistance, and Targeting the Immature Brain

Heinz Beck
Yoel Yaari

INTRODUCTION

The cellular basis of epileptic seizures consists of high-frequency, synchronized discharges of neuronal ensembles. The ultimate goal of all antiepileptic therapies is to prevent the occurrence of such episodes or to substantially attenuate their severity. To this end, a multitude of antiepileptic compounds have been developed that are currently in clinical use. However, seizures remain uncontrolled by carefully monitored drug treatment in a substantial portion (~30%) of epilepsy patients. Therefore, a better understanding of the mode of action of different antiepileptic drugs is mandatory, along with an improved understanding of why these compounds fail in some epilepsy patients, with the ultimate goal of developing new therapeutic avenues.

So far, two hypotheses have been advanced to account for the cellular basis of pharmacoresistance in chronic epilepsy. The first hypothesis proposes that pharmacoresistance involves an upregulation of multidrug transporters at

the blood-brain barrier. This upregulation limits the access of antiepileptic drugs to the brain parenchyma and therefore leads to a reduced drug concentration at the respective drug target. Because multidrug transporter proteins are of central importance to this hypothesis, it has been termed the *transporter hypothesis*. The second hypothesis contends that the molecular targets of antiepileptic drugs are modified in chronic epilepsy. Consequently, they are less sensitive to these compounds. This hypothesis has been named the *target hypothesis*.[1,2] Clearly, these two hypotheses are not mutually exclusive. Rather, the underlying mechanisms may coexist and perhaps even act in synergy. The subject of this chapter is the target hypothesis. We describe the molecular mechanisms that alter the targets of antiepileptic drugs and how these mechanisms may interact with altered drug transporter function to cause pharmacoresistance.

DEFINING DRUG TARGETS

In general, antiepileptic drug targets are proteins involved in neuronal function that mediate a reduction in excitability after binding the antiepileptic drug at clinically relevant concentrations. A plethora of drug targets has been identified in central neurons (see Table 83–1). Most of these targets are neurotransmitter receptors or voltage-gated ion channels. A comprehensive review of the different ion channel types that are affected by antiepileptic drugs is beyond the scope of this review. However, a number of classes of ion channels are particularly prominent targets.

Sodium Channels

Voltage-gated sodium channels are implicated in the mode of action of a large number of common antiepileptic drugs, such as phenytoin, carbamazepine, valproate, lamotrigine, lacosamide, and eslicarbazepine.[3–5] These channels are found in all excitable cells and are capable of extremely rapid channel gating that mediates millisecond-scale physiological processes.[6] They open rapidly upon membrane depolarization, causing the upstroke of the action potential, and subsequently undergo fast inactivation, thus contributing to its downstroke. Upon repolarization of the cell membrane, sodium channels recover from inactivation with a complex time course. In many cells, however, a noninactivating, persistent component of the sodium current is also observed in addition to the rapidly inactivating component. This current component activates even during subthreshold depolarizations and therefore is important in controlling subthreshold activity. Both the transient and persistent components of the sodium current are potently inhibited by antiepileptic drugs, such as phenytoin, carbamazepine, and lamotrigine, in addition to other drugs. A characteristic effect of most of these sodium channel blockers is that they preferentially bind to channels that have entered an inactivated state following depolarization of the cell. In addition, a second major mechanism is that the recovery from depolarization-induced inactivation is prolonged by many antiepileptic drugs.[4,5] These two effects together explain why these drugs preferentially block repetitive high-frequency neuronal activity and long-lasting depolarizations, both of which typically occur during epileptic seizures.

Calcium Channels

Voltage-gated calcium channels are also targets for numerous antiepileptic drugs. Central nervous system (CNS) neurons express multiple types of calcium channels, which can be separated into two classes based on their biophysical properties, namely, high-threshold and low-threshold calcium channels.[7] A number of antiepileptic drugs have been shown to inhibit high-threshold calcium channels in native neurons at high therapeutic concentrations,[8–10] and this has been proposed to inhibit neurotransmitter release via a reduction of presynaptic action potential-induced calcium increases.[11] Some antiepileptic drugs potently inhibit low-threshold (also known as *T-type*) calcium channels, which are expressed in postsynaptic compartments,[12–14] and powerfully control postsynaptic excitability and the propensity to generate burst discharges.[15] Intriguingly, the antiepileptic drug gabapentin has been shown to exhibit strong and specific binding to the accessory calcium channel $\alpha 2\delta$ subunit,[16] but this binding seems to have no effect on the

functional properties of the channel complex, suggesting that gabapentin binding to these subunits exerts effects that are not dependent on calcium channel modulation.[17]

HCN Channels

Hyperpolarization-activated, cyclic nucleotide-gated (HCN) cation channels, responsible for generating the so called H-current, are cation-permeable channels that are activated by hyperpolarization and deactivate upon depolarization of the membrane potential.[18,19] H-currents modulate membrane resistance and resting potential, and can mediate pacemaker activity in some types of neurons due to their particular biophysical properties.[19] H-currents, and their corresponding HCN channel subunits, appear to be located mainly in dendrites.[20–22] Accordingly, they potently modify dendritic integration of excitatory input.[22,23] Interestingly, dendritic H-currents are potentiated by application of the antiepileptic drugs lamotrigine or gabapentin.[24,25] Thus, H-currents appear to be dendritic antiepileptic drug targets.

$GABA_A$ Receptors

A further group of antiepileptic drugs seems to exert its main effects via an increase in synaptic inhibition. Gamma-aminobutyric acid (GABA) is the predominant inhibitory neurotransmitter in the adult brain. The ionotropic $GABA_A$ receptor, which conducts chloride upon the binding of GABA, is an important target for antiepileptic drugs. Gamma-aminobutyric acid A receptor-active drugs include direct modulators such as benzodiazepines and barbiturates, which increase the $GABA_A$ receptor-mediated chloride currents via allosteric modulation.[26] A number of additional antiepileptic drugs indirectly enhance $GABA_A$ receptor-mediated action by inhibiting the reuptake of GABA or its catabolism. This class of compounds includes tiagabine and vigabatrin. Tiagabine inhibits the high-affinity GABA transporter

GAT1 that normally terminates synaptic action of GABA via rapid uptake into astrocytes, whereas vigabatrin is a GABA analog that inhibits GABA transaminase, one of the main GABA-degrading enzymes in the brain. Both compounds are capable of causing large elevations in brain GABA levels.

Glutamate Receptors

A number of newer antiepileptic drugs exert their action primarily or in part by reducing the activity of excitatory neurotransmitter receptors, namely, glutamate receptors. Felbamate exerts complex effects on the *N*-methyl-D-aspartate (NMDA) receptor, perhaps by interacting with the modulatory glycine-binding site of this receptor.[27–30] Some of the effects of felbamate have been shown to be dependent upon NMDA receptor subunit composition.[31,32] Topiramate,[33] as well as a number of compounds currently in clinical trials,[34] have been shown to reduce excitatory synaptic transmission via an inhibition of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors.

Presynaptic Proteins

Recently, the presynaptic vesicle protein SV2A has been identified as a target for the antiepileptic levetiracetam. More intriguingly, SV2A seems to be the only high-affinity receptor for levetiracetam in the rodent brain.[35] The SV2A protein is a vesicular component of the complex presynaptic release machinery and inhibits presynaptic neurotransmitter release in a use-dependent manner. Studies in knockout mice have suggested that SV2A is involved in regulating the release probability of quiescent neurons, either via protein interactions that facilitate vesicle priming or inhibit depriming or by transporting a protein involved in priming.[36–39] However, the precise effects of levetiracetam binding to SV2A, and how this in turn affects neurotransmitter release, are still unknown.

Unconventional Drug Targets

It should be emphasized that many of the antiepileptic drugs discussed so far show multiple modes of action. It is also very probable that the list of drug targets will have to be expanded. Research on drug targets has hitherto focused on voltage-gated or neurotransmitter-gated receptor ion channels, which are the most easily investigated drug targets in a quantitative manner. Studies of alternative drug targets that control processes on a slower time scale (e.g., neuroendocrine processes or neuronal structural and functional plasticity) have been conducted more rarely, likely because they are more technically demanding and labor intensive. One intriguing study has identified the calcium channel subunit α2δ-1 as a receptor for thrombospondin.[17] Thrombospondin is an astrocyte-secreted protein that promotes synaptogenesis via an α2δ-1 interaction. Intriguingly, gabapentin antagonizes thrombospondin binding to α2δ-1 and powerfully inhibits excitatory synapse formation in vitro and in vivo.[17] These findings were the first to identify a specific drug target that may act by inhibiting pathological structural plasticity. It should also be noted that studies concerning mechanisms of antiepileptic drug action and refractoriness have so far focused mostly on drug targets in neurons while neglecting many putative targets in glia. Glial function may also be affected by common antiepileptic drugs.[40]

ALTERED PHARMACOLOGY AND MOLECULAR PLASTICITY OF DRUG TARGETS IN CHRONIC EPILEPSY

In a number of cases, our knowledge of the cellular mechanisms of action of antiepileptic drugs has fueled studies aimed at finding whether these drug actions are altered in chronically epileptic tissue. Indeed, many drug targets undergo plastic changes on the molecular level in epilepsy models and probably also in human epilepsy. In this section, we will summarize what is known about epilepsy-associated modifications of drug targets.

Altered Pharmacology of Voltage-Gated Sodium Channels

Reduced activity of the antiepileptic drug carbamazepine on the transient sodium current in

dentate granule cells of the hippocampus has been shown in vitro, both in patients with pharmacoresistant epilepsy and in the pilocarpine model of temporal lobe epilepsy. This loss of activity was selective for the use-dependent or frequency-dependent sodium channel blocking effects of carbamazepine; other effects of this drug were not altered.[41] A similar but weaker effect was seen in pyramidal cells in the CA1 subregion of the hippocampus.[42] Intriguingly, in the pilocarpine model, phenytoin showed a similar but much less pronounced loss of its use- and voltage-dependent sodium channel blocking activity. In contrast, the use- and voltage-dependent blocking effects of lamotrigine and valproate were unchanged.[43] Likewise, data from both epilepsy patients and the kindling models of epilepsy suggest that valproate's effects on Na^+ channels are unaltered in epileptic tissue.[44,45]

These data indicate that the molecular mechanisms of pharmacoresistance likely are drug specific, so that changes in sodium channel properties affecting the efficacy of one antiepileptic drug, such as carbamazepine, are less relevant for other drugs interacting with the same channel.

The molecular mechanisms leading to the selective loss of use-dependent sodium channel block by carbamazepine, while other actions of carbamazepine on these channels remain untouched, are completely unclear. One potential molecular mechanism is downregulation of accessory β subunits shown to occur in epilepsy models.[46,47] However, this mechanism is unlikely to be relevant, because mice lacking either β^1 or β^2 subunits display undiminished use- and frequency-dependent block of sodium channels by carbamazepine.[48] A number of additional changes in the subunit composition of sodium channels have been discovered in epilepsy that may account for the reduced efficacy of carbamazepine.[49] Further possibilities are alternative splicing of sodium channels or the reexpression of neonatal isoforms of sodium channels.[50] In addition, posttranscriptional changes in sodium channel properties may alter the sensitivity of drug targets. For instance, there is evidence that phosphorylation of sodium channels alters the efficacy of some antiepileptic drugs in suppressing the persistent sodium current component.[51]

Loss of ion channel drug sensitivity occurs not only in the pilocarpine model of chronic epilepsy. A diminished effect of carbamazepine has also been observed on the steady-state inactivation properties of Na^+ channels in CA1 neurons from kindled animals.[45]

Plasticity of Calcium Channels: Emergence of a Novel Drug Target?

The altered expression of calcium channels and their functional consequences have been studied extensively in chronic epilepsy. So far, these studies have yielded no clear evidence of altered Ca^{2+} channel pharmacology in chronic epilepsy or of the formation of pharmacoinsensitive channels. However, in the pilocarpine model of epilepsy, the T-type calcium current was shown to be upregulated in CA1 pyramidal cells, at least during the early stage of epileptogenesis, causing the conversion of these ordinarily regularly firing neurons into aberrantly burst-firing neurons.[52,53] An upregulation of T-type calcium current was shown to result from a transcriptional upregulation of $Ca_v3.2$ calcium channel subunits and was critical for the development of the epileptic condition.[54] This finding suggests that $Ca_v3.2$ may constitute a novel drug target that emerges during epileptogenesis. However, studies so far have yielded no clear evidence of altered calcium channel pharmacology or of the formation of pharmacoresistant calcium channels in chronic epilepsy.

Plasticity of H-Current Expression: Loss of a Drug Target?

In chronic epilepsy, dramatic changes in the magnitude of dendritic H-currents, and expression of the underlying HCN subunits, particularly in pyramidal cells, have been reported in chronic epilepsy models.[55–57] Given that HCN channels are likely a major target in the antiepileptic action of lamotrigine and gabapentin, it is tempting to speculate that their downregulation causes pharmacoresistance to these drugs.

Altered Subunit Composition of $GABA_A$ Receptors

An enormous diversity of $GABA_A$ receptors has been reported in the CNS, reflecting the fact that in each receptor at least three different subunits are present, deriving from one of

eight structurally distinct and genetically distinct families.[58,59] An elegant study by Brooks-Kayal et al. has shown that $GABA_A$ receptor subunit composition is specifically altered in epilepsy models, and that this alteration is associated with reduced activity of $GABA_A$ receptor agonists.[60] Whether these changes are pertinent for pharmacoresistance to antiepileptic drugs acting on GABAergic inhibition remains to be explored. It is noteworthy that neither the efficacy of GABA uptake nor the sensitivity of the GABA transporter GAT-1 to tiagabine is altered in chronic experimental epilepsy.[61]

Increasing evidence suggests that the actions of GABA in epileptic brain tissue, as in immature brain, are not strictly inhibitory.[62] For instance, in the epileptic human subiculum, $GABA_A$ receptor activation in a subset of principal neurons causes depolarization rather than the ordinary hyperpolarization of the membrane potential.[63,64] This change in GABA action is caused by the altered expression of chloride transporters, leading to the intracellular accumulation of chloride.[65] Depolarizing GABAergic action in subsets of neurons would be expected to strongly reduce the antiepileptic activity of drugs acting on synaptic inhibition and thus may contribute to pharmacoresistance. This consideration illustrates a more general point: changes in drug targets have to be considered within the context of other epilepsy-related cellular changes.

RELATIONSHIP BETWEEN CHANGES IN ANTIEPILEPTIC DRUG TARGETS AND IN VIVO PHARMACORESISTANCE

What is the relationship of changes in specific drug targets to the pharmacoresistance observed either in epilepsy patients or in animal models of chronic epilepsy? Addressing this question requires investigators first to assess the antiepileptic efficacy of a drug in vivo in chronic epilepsy models and then to compare it to the drug's efficacy in modifying its putative target. This approach has been implemented in only a few studies. One study used kindled rats separated into two groups, one responsive and the other unresponsive to phenytoin.[66] In these groups, gross differences in the sensitivity of transient sodium currents to suppression by phenytoin were not found.[67] Further studies are needed to compare the two groups with respect to phenytoin's use-dependent sodium current block and its effect on the persistent sodium current. Nevertheless, this experimental approach, which involves comparing the pharmacosensitivity of putative antiepileptic drug targets in pharmacoresponsive versus pharmacoresistent epileptic animals, likely will lead to a better understanding of pharmacoresistance.[68]

A similar approach has been applied in studies of hippocampal tissue resected from carbamazepine-treated epileptic patients separated into pharmacoresistant and pharmacoresponsive groups. Interestingly, the use-dependent block of sodium currents by carbamazepine was evident in CA1 pyramidal cells in the responsive group but not in the resistant group.[41] Furthermore, epileptiform activity induced acutely was strongly inhibited by carbamazepine in hippocampal slices from the responsive group but not in slices from the resistant group.[41,69] Because changes in the blood-brain barrier cannot contribute to pharmacoresistance in these in vitro slice experiments, these findings support the presence of a target mechanism for pharmacoresistance.

RELATIONSHIP BETWEEN THE TARGET AND TRANSPORTER HYPOTHESES OF PHARMACORESISTANCE

Functionally relevant changes in antiepileptic drug targets, as well as in multidrug transporters, occur in chronic epilepsy.[2] To define the relative impact of these two mechanisms for each individual antiepileptic drug is of obvious therapeutic relevance. In the case of carbamazepine, for instance, a target mechanism is well established in human and experimental epilepsy.[41,69] On the other hand, recent studies have revealed that carbamazepine is not transported by numerous human multidrug transporters, including P-glycoprotein and multidrug resistance-associated proteins MRP1, MRP2, and MRP5.[70–72] These results suggest that a target mechanism of pharmacoresistance may be dominant in the case of carbamazepine. On the other hand, a number of other antiepileptic drugs are excellent substrates for the human multidrug transporter

Table 83–2 **Relative Importance of Target and Transporter Mechanisms**

	Transported by Human Multidrug Transporters				Target Mechanism: Reduction of Use-or Voltage-Dependent Block in Epilepsy Models
	MRP1	MRP2	MRP5	PGP	
Carbamazepine	–	–	–	–	Dentate gyrus: +++ [41,69] CA1: +, smaller effects[42]
Phenytoin	–	–	–	+	Dentate gyrus: +, small effects[43] CA1: +, small effects[42]
Lamotrigine	–	–	–	+	Dentate gyrus: no change in use-dependent block, only impaired tonic block[43]
Valproic acid	–	–	–	–	– [43,44,45]

Notes: MRP1, MRP2, MRP5, and PGP denote types of multidrug transporters. The data given for drug transporters (left side of the table) are based on results described for human multidrug transporters.[70–74]

P-glycoprotein 1 (PGP1).[71,73] In the case of phenytoin or lamotrigine, which are transported efficiently by PGP1,[71] target changes in drug sensitivity seem to be less pronounced than for carbamazepine.[42,43,67] These data support the notion that potentially pharmacoresistent mechanisms, and the predominance of either target or transporter mechanisms, have to be evaluated individually for each antiepileptic drug (see Table 83–2).

The therapeutic relevance of these considerations to pharmacoresistent epilepsy is underscored by the fact that a large number of increasingly selective inhibitors exist for multidrug transporters. Comedication of antiepileptic drugs with such compounds may overcome pharmacoresistance, provided that the antiepileptic drug is a substrate of the multidrug transporter and that upregulation of the transporter contributes importantly to pharmacoresistance to this drug. If a dominant target mechanism exists, the efforts to overcome pharmacoresistance should be aimed at designing novel compounds that act on the modified drug targets in the epileptic brain. Thus, a comprehensive understanding of the dominant mechanisms underlying pharmacoresistance to each antiepileptic drug will be required to develop strategies toward new therapeutic options.

Chapter 84

Drug Resistance

Jan A. Gorter
Heidrun Potschka

INTRODUCTION

Drug resistance poses a major challenge to the therapeutic management of epilepsy patients. Multiple studies have explored the epidemiological factors and mechanisms of drug resistance in order to increase knowledge and provide a basis for optimized therapeutic protocols and strategies. However, the lack of a common definition of clinical drug resistance hampers the comparison of data. Therefore, it is a major step forward that a task force of the International League against Epilepsy has recently proposed a definition.[1] According to this task force, drug resistance may be defined as failure of adequate drug trials of two tolerated and appropriately chosen and used antiepileptic drug (AED) schedules (whether as monotherapy or in combination) to achieve freedom from seizures. The proposal is consistent with the clinical observation that therapeutic success is unlikely when these conditions are met.[2] The task force emphasized that the definition should be considered as work in progress; therefore, clinicians are encouraged to test and apply the definition and provide feedback.

In individual patients, the time course of drug resistance can differ significantly. Whereas seizure control might never be achieved in some patients, others might initially respond and then develop drug resistance, or might exhibit alternate phases with seizures being controlled and uncontrolled.[3] Moreover, seizure activity can be uncontrolled in the initial phase but become controlled with ongoing treatment. Long-term studies indicate that many patients with intractable seizures exhibit drug resistance from the onset of treatment.

A large number of seizures before treatment onset are generally considered a major predictor of a poor outcome of drug therapy. Mohanraj and Brodie[2] also explored seizure density as a parameter and found that the greater the number of seizures before treatment, the higher the risk of drug resistance. Based on these data, seizure density seems to be an even more significant predictive factor than the overall number of pretreatment seizures. Considering the epidemiological data, Rogawski and Johnson[4] proposed the *intrinsic severity hypothesis*, which suggests that common neurobiological factors contribute to both

epilepsy severity and drug refractoriness (see below). Further factors that are discussed as clinical predictors of drug resistance include a family history of epilepsy, prior febrile convulsions, seizure clusters, traumatic brain injury, and psychiatric comorbidities, particularly depression.[5]

Therapeutic management of patients with drug-resistant epilepsy can include nonpharmacological approaches such as epilepsy surgery, vagal nerve stimulation, or a ketogenic diet. Recent data suggest that although the number of responders might be low, it is also worthwhile to test further AEDs in patients who have been classified as drug resistant based on two or more drug trials.[6] The authors emphasize that no matter how many AED therapies have failed, there is always hope for meaningful seizure remission in this population.

Research efforts have been made to elucidate specific mechanisms of drug resistance. The identification of these mechanisms might provide a basis for the future design and development of novel pharmacological approaches to overcome resistance.

MECHANISMS OF DRUG RESISTANCE

The two main hypotheses concerning a mechanism for pharmacoresistant epilepsy, which have attracted the most attention over the past 15 years, are the *target hypothesis* and the *drug transporter hypothesis* (Fig. 84–1). The target hypothesis posits that the AED fails to act because of a molecular alteration of its target. The transporter hypothesis posits that the AED fails to reach its target in sufficient concentration because of overexpressed drug transporters at the blood-brain barrier. As mentioned above, another hypothesis that has been put forward recently is the *intrinsic severity hypothesis*.[4]

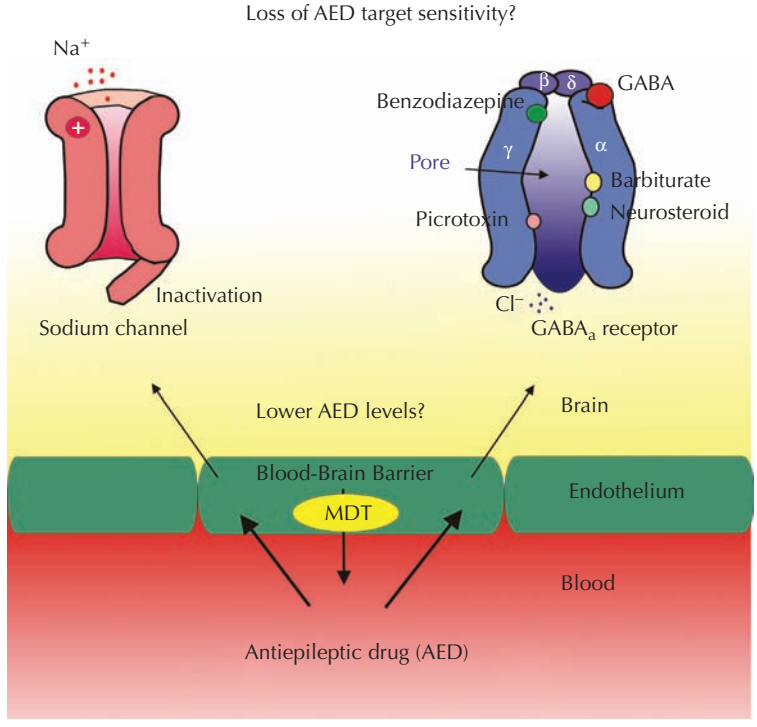

Figure 84–1. Schematic representation of the drug transporter hypothesis and the target hypothesis. MDT illustrates the multidrug transporter proteins on the luminal site of the endothelial cells. Overexpression of MDT in epilepsy leads to reduced AED levels at the targets. The $GABA_A$ receptor, with its multiple binding sites, and the sodium channels are examples of two important targets for AEDs. Changes of AED binding sites can alter its sensitivity. Both lack of AED availability at the target and altered target sensitivity to the AED may play a role in drug resistance. Adapted from ref. 59.

Although the neurobiological mechanisms are still elusive, the authors propose that some of the factors related to the severity of the disease also cause drug resistance. Below, we discuss these hypotheses separately in more detail.

Target Hypothesis

The main targets of the current AEDs are voltage-gated ion channels and neurotransmitter receptors.[7] Carbamazepine, phenytoin, valproate, oxcarbazepine, lamotrigine, rufinamide, zonisamide, lacosamide, and topiramate act mainly on voltage-gated sodium channels, although some of these drugs also act partially on other channels. Other AEDs act mainly on voltage-gated calcium channels (e.g., gabapentin, pregabalin, ethosuximide). Barbiturates, benzodiazepines, valproate, tiagabine, and vigabatrin are AEDs that amplify inhibitory gamma-aminobutyric acid (GABA) action. Specific potassium channel subunits and glutamate receptor (subunits) are also potential targets, and AEDs for some of these targets are just recently marketed (e.g., retigabine) or cautiously used in more severe syndromes (e.g., felbamate). More unconventional targets are enzymes (e.g., GABA transaminase, inhibited by vigabatrin, and carbonic anhydrase, inhibited by acetazolamide) and the synaptic vesicle protein SV2A (the binding site for levetiracetam and related compounds). The target hypothesis implies that molecular changes in AED targets, whether intrinsic (e.g., polymorphisms) or acquired (e.g., by the disease process, seizures, drugs, etc.), may lead to reduced sensitivity to AEDs.

The voltage-dependent sodium channels are the most intensively studied targets. The first studies that addressed changes in sodium channel function and reduced AED sensitivity in the remaining CA1 neurons of epileptic rats and of epilepsy patients were reported by Wadman and colleagues.[8,9] Beck and colleagues extended these studies and reported reduced carbamazepine and phenytoin sensitivity to sodium channels in hippocampal dentate neurons in the pilocarpine model for temporal lobe epilepsy (TLE) as well as in hippocampal neurons of tissue from TLE patients obtained after surgical resection.[10,11] Antiepileptic drugs like carbamazepine act by shifting the voltage dependency of the steady-state inactivation in a more hyperpolarized direction and by producing a use-dependent block. In tissue of epileptic rats as well as in tissue of carbamazepine-resistant patients, carbamazepine loses its ability to shift this voltage dependency in a more hyperpolarized direction; the use-dependent block by carbamazepine is also diminished. Lack of a cellular response to carbamazepine was particularly evident in a group of patients who were also unresponsive to carbamazepine, while a small group of patients who still responded to carbamazepine also still showed a cellular response to carbamazepine in vitro.[10]

Most of the changes reported above may have developed over time as part of the epileptogenic process and may have involved changes in transcription or RNA processing (e.g., alternative splicing). A change in subunit gene expression can be obtained rapidly. For instance, increased expression of a neonatal splice variant of rNav1.2/rNav1.3 was detected within 4 h after electrically induced status epilepticus (SE) in rats.[12] However, although a change in sodium channel properties has been detected after electrically induced SE,[13] it has not been determined whether this change is related to this neonatal channel function with altered sensitivity to AEDs. Phosphorylation can also alter the AED sensitivity of targets. Changes in the topiramate sensitivity of sodium channels have been detected after protein kinase C activation in rat cortical neurons, suggesting that phosphorylation may limit the effect of this AED on the persistent fraction of the sodium current.[14]

There are significant cell-specific changes in $GABA_A$ receptor subunit expression after epileptic insults induced by kindling stimulations, by electrically or pharmacologically induced SE, and in TLE patients with hippocampal sclerosis. A clear example of the changes in subunit expression and their effects on drug sensitivity has been shown in dentate granule cells after pilocarpine-induced SE; decreased sensitivity to benzodiazepines was detected after $GABA_A$ receptor activation,[15] which appeared to be related to alterations in subunit expression.[16] Reduced benzodiazepine sensitivity was detected within hours after electrically induced SE in rats. However, this was not believed to be caused by transcriptional changes but was attributed to GABA receptor subunit trafficking away from the membrane into the cytoplasm.[17]

The aforementioned studies are examples of changes in target function due to modification of the target itself. However, target function could also be altered by changes in the ion environment caused by ion transporters. For instance, a number of studies have shown that expression of the sodium-potassium chloride cotransporter (NKCC1) is increased in a subset of neurons obtained from epileptic patients and epileptic animals.[18,19] This transporter, whose expression is also increased during early development, is responsible for an increase in intracellular chloride, which leads to a depolarizing effect of GABA (or GABA agonists). These insights may lead to clinical trials using drugs that inhibit the function of NKCC1, so that the hyperpolarizing action of GABA will be obtained or restored.[20]

SV2A, the binding site for levetiracetam, is significantly changed after SE and in tissue of patients with hippocampal sclerosis. Cell-specific downregulation of SV2A expression has been observed, with significant permanent downregulation in the mossy fibers of the dentate gyrus of post-SE rats and of patients with hippocampal sclerosis.[21] Whether this has consequences for the action or the efficacy of levetiracetam needs to be determined.

Most of the experimental studies mentioned above have described AED effects in cells measured in in vitro slice preparations and obtained from epileptic or control animals. Whether AEDs were effective in the same animals was not tested. Only one study related to the target hypothesis has been performed in responder versus nonresponder rats with spontaneous seizures.[22] Therefore, our insights would benefit if, in future studies, more experiments are designed in which the effects of the AED are tested on cellular responses in epileptic animals in which it is known whether or not seizures can be controlled by AEDs. Also, most studies have mainly investigated the effects of a few first-generation AEDs on cellular responses in patients who suffer from TLE (or in TLE animal models). Future studies should also test cellular responses of newer AEDs in animal models that mimic not only TLE but also other epilepsy syndromes (e.g., the rat methylazoxymethanol model of cortical dysplasia, the 6 Hz psychomotor model of partial epilepsies, or traumatic brain injury epilepsy models[23]) and take advantage of resected tissue that becomes available from pharmacoresistant epilepsy syndromes other than TLE.

Although the data above provide support for the target hypothesis, some issues remain unresolved. For instance, although carbamazepine sensitivity is altered in epileptic tissue compared to control tissue (which in human studies is often obtained from cortex), sensitivity to phenytoin is less affected, while sensitivity to lamotrigine is hardly changed.[11] This is surprising, considering the fact the voltage-gated sodium channels are the main, although not the exclusive, target of these AEDs. This also suggests that the target hypothesis cannot describe the only mechanism explaining drug resistance; other mechanisms also play a role. One such alternative mechanism is proposed by the drug transporter hypothesis.

Drug Transporter Hypothesis

The fact that pharmacoresistant epilepsy patients are resistant to a broad range of AEDs with different mechanisms of action suggests that nonspecific mechanisms contribute to drug resistance. By analogy with cancer research, where drug resistance to chemotherapy is also a huge problem, the drug transporter hypothesis has been proposed for pharmacoresistant epilepsy. This hypothesis states that drug resistance is caused by overexpression of multidrug transporters that prevent therapeutic drugs from entering the brain in sufficient concentrations.[24]

The best-known drug transporters at the blood-brain barrier are members of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter superfamily. The multidrug transporters (MDTs) that are present at the blood-brain barrier normally prevent the entrance of many different lipophilic toxic compounds or xenobiotics from blood to brain by an active (ATP-driven) efflux mechanism. Their presence is important and necessary in order to protect the brain, but it is not very useful when one needs to get drugs into the brain for therapeutic purposes. Of the many different known drug transporters, P-glycoprotein (P-gp; ABCB1) is the most intensively studied, followed by multidrug resistance-related proteins

(MRPs, ABCC1–5) and breast cancer-related protein (BCRP; ABCG2). P-glycoprotein, MRP1, MRP2, MRP5, and BCRP are reported to be present at the luminal site of endothelial cells and are therefore in a position to extrude their substrates back into the bloodstream.

The study of Tishler et al.[25] led to the formulation of the drug transporter hypothesis for epilepsy. These authors reported increased expression of P-glycoprotein on brain capillaries and perivascular astrocytes in epileptic tissue. Numerous studies have confirmed this finding not only in tissue of patients with hippocampal sclerosis but also in epilepsies associated with cortical malformations. There is now general agreement that drug transporters such as P-gp, MRP1, MRP2, MRP5, and BCRP are overexpressed in brain tissue of patients with a pharmacoresistant epilepsy syndrome as well as in different epilepsy animal models (reviewed in ref. 24). P-glycoprotein overexpression can be detected within 1 day after SE, but it does not appear to play a role in reduced AED efficacy during SE.[26]

In comparison with anticancer drugs, AEDs are much weaker substrates for the drug transporters. Therefore, AED transport may be detected only when the transporters are overexpressed. There is ample evidence that increased expression of drug transporters correlates negatively with brain levels of several major AEDs in epileptic animals. One study in epileptic patients reports a negative correlation between P-gp expression and the brain concentration of an active metabolite of oxcarbamazepine.[27]

Pharmacological P-gp inhibition in rats or absence of P-gp by genetic deletion of *mdr1a/b* in mice led to increased brain levels of phenytoin, carbamazepine, phenobarbital, lamotrigine, and felbamate.[28,29] A study with MRP2-deficient rats indicates that phenytoin, but not carbamazepine, lamotrigine, and phenobarbital, is a substrate for MRP2.[30] Great skepticism concerning the relevance of drug transporters for pharmacoresistant epilepsy in humans arose, however, when it was reported that human P-gp did not transport major AEDs such as phenytoin, carbamazepine, or levetiracetam.[31] However, this doubt was refuted by subsequent studies by the same authors and others who tested AED transport in more sensitive screening assays. Using these transport assays, it has been shown that major AEDs, including phenytoin, lamotrigine, levetiracetam, and phenobarbital (but not carbamazepine), can be transported by human P-gp transfected in kidney cell lines.[32] This was confirmed for phenytoin transport in brain capillary endothelial cells from AED-resistant patients and controls.[33] Transport measurements in cell lines transfected with human MRP1, MRP2, or MRP5 revealed that none of these drugs were transported by these MRPs.[34] The authors acknowledge, however, that in vitro assays may produce false-negative results and suggest that the potential role of MRPs should be further investigated in vivo, including positron emission tomography (PET) studies with labeled MRP and P-gp substrates.

More support for a role of multidrug transporters in pharmacoresistant epilepsy came from two proof-of-principle studies in chronic epileptic rats in which brain AED concentrations were increased and seizure control was obtained when P-gp was inhibited with the selective P-gp inhibitor tariquidar.[35,36] In the study of van Vliet et al.,[36] therapeutic doses of phenytoin were used for 7 days in rats that had developed epilepsy with frequent daily seizures after electrically induced SE. Phenytoin treatment alone produced only a slight reduction in daily seizure frequency. However, almost complete seizure control was observed when phenytoin was administered together with tariquidar. Unfortunately, this control was present for only 3–4 days, after which seizure frequency increased again to pretreatment levels, despite the fact that brain phenytoin levels were higher than the levels in control rats. Loscher and colleagues performed similar proof-of-principle experiments in a rat post-SE model.[35] They used phenobarbital as the AED and discriminated between rats that responded to phenobarbital and those that did not. In previous experiments, these rats were characterized by low and high endothelial P-gp expression, respectively. [37] The nonresponders became responsive to phenobarbital when tariquidar was coadministered. Thus, although these findings clearly showed that inhibition of P-gp improves AED action and produces complete seizure control (which is not obtained with the AED alone), the temporary effects that were observed with phenytoin in the study of van Vliet et al.[36] may indicate that other factors can come into play, reducing the efficacy of phenytoin once again. One such mechanism might

be related to the development of tolerance to the AED.[38]

Despite quite convincing indications from animal studies that drug transporters play a role in pharmacoresistant epilepsy, clinical proof is still lacking. In this respect, PET studies in pharmacoresistant patients using specific transporter inhibitors are needed to provide more definite evidence of the clinical relevance of this putative mechanism.

Drug transporters are regulated in a complex manner and by different processes, including oxidative stress and inflammation.[39] Ligand-activated nuclear receptors, β-amyloid, glutamate, and elements of the innate immune response can regulate drug transporter expression. In relation to epilepsy, the immune response and glutamate are particularly relevant since they both play a crucial role in the epileptogenic process. The role of inflammation as a regulator of drug transporters is very complex and may be dose-, model-, and time-dependent. Both increases and decreases in drug transporter expression on endothelial cells have been reported, depending on the timing of the activation of specific inflammatory pathways. While increased expression of P-gp is evident after an ischemic insult and in a variety of epilepsy syndromes (that are associated with inflammation), decreased P-gp expression has been observed in endothelial cells of multiple sclerosis patients and in the animal model for this disease.[40] It has been shown that glutamate increases P-gp expression in endothelial cells via *N*-methyl-D-aspartate (NMDA) receptor activation and cyclo-oxygenase-2 (COX-2) activation.[41] This opens the possibility of targeting COX-2 in order to regulate P-gp expression in epileptic patients.

There are several other proposed mechanisms of drug resistance that have been less intensively investigated or that may be more closely related to the specific properties of the AED. Like overexpression of drug transporters, interaction between the AED and serum proteins can lead to reduced AED levels near the target (Table 84–1). This can occur during brain edema and was recently put forward as the *protein-binding hypothesis* of drug resistance.[42] The idea behind this hypothesis is that plasma proteins penetrate into the brain because of disturbance of blood-brain barrier integrity. As a consequence, enhanced protein binding in the brain extracellular space might decrease free concentrations of AEDs with a high protein-binding rate. Disease-related structural alterations, such as tumors and scars, can also form physical barriers that may prevent the AED from reaching its target and contribute to drug resistance. Other important factors are metabolic or pharmacokinetic tolerance induced by AED-metabolizing enzymes. This is mainly a problem for the older AEDs. The development of pharmacodynamic or functional tolerance that is due to adaptation of AED targets (e.g., by loss of receptor sensitivity) may be another reason for failure of drug treatment. This has been shown experimentally for all AEDs that lose activity during prolonged treatment.[38]

Intrinsic Severity Hypothesis

As mentioned above, Rogawski and Johnson have recently proposed the intrinsic severity hypothesis,[4] which incorporates the intriguing epidemiological finding that a higher seizure frequency in the early phase of epilepsy before treatment increases the risk of drug resistance. An essential point of this hypothesis is that common neurobiological factors may underlie both epilepsy severity and drug resistance. The general concept of this hypothesis is that seizures that are easily triggered can result in frequent seizures that may be difficult to suppress. The neurobiological or molecular factors are still unknown, but one could speculate that they include changes of targets and alterations of network properties (e.g., via elimination of cellular elements and/or abnormal network plasticity) that lead to unstable neuronal networks, making it impossible to control seizures with the currently available AEDs. Although this is an attractive hypothesis, Schmidt and Loscher[42] have pointed out that it also has weak points: despite the fact that high seizure frequency in patients is often associated with drug resistance, a subgroup of patients can become seizure-free after a change in medication. Moreover, there are patients who start with only few seizures and become pharmacoresistant.[43] As a consequence, future research needs to determine the neurobiological factors that critically affect the severity of the disease. The studies should be based on the definition of common measures that provide a basis for scoring epilepsy severity.

Table 84–1 **Overview of Mechanistic Hypotheses, Their Limitations, and Putative Implications**

	Hypotheses		
	Target	**Transporter**	**Protein Binding**
Experimental evidence from rodent epilepsy models	Loss or reduction of drug resistance	Expression correlates with drug sensitivity Modulation of transporters improves AED efficacy	Relevance not yet demonstrated in an epilepsy model
Clinical evidence	Limited evidence from a small number of patients	Expression levels ↑ but functional relevance not proven	Protein extravasation demonstrated, but impact not proven
Major limitations	Alterations in one target do not explain broad drug resistance	Controversial data on transport of AEDs	Only of relevance for older AEDs with high rates of protein binding
Implications for therapy or drug development	Develop AEDs with affinity to altered target sites or to novel targets	Select/develop AEDs that are not transporter substrates Modulate transporter function Prevent transporter induction By-pass transporters.	As already done for other reasons: select AEDs with low protein binding Prevent disturbance of blood-brain barrier function
Identification in patients	Development of radiolabeled ligands with affinity sensitive to molecular alterations	Analyze brain kinetics of radiolabeled transporter substrates	Image protein extravasation

NOVEL APPROACHES TO OVERCOME DRUG RESISTANCE

Ongoing efforts to elucidate the mechanisms of drug resistance raise the question of whether increasing knowledge might provide a basis for future drug development and novel therapeutic strategies (Figure 84–2). The target hypothesis implicates that drug development should consider the molecular and functional alterations occurring in promising target sites. Based on precise identification of these changes, it should be possible to develop in vitro screening tests for an affinity of developmental compounds to altered target sites. This would allow the selection of advantageous compounds at early stages of drug development. Moreover, the target hypothesis points to the fact that the use of chronic epilepsy models during in vivo testing is of particular importance. In acute models with seizure elicitation, naive mice do not exhibit alterations in target sites. A major problem is that chronic epilepsy models characterized by disease-associated molecular and cellular alterations are generally elaborate and time-consuming to use. Thus, recommendations based on the target hypothesis pose a major challenge to the choice of initial in vivo screening models used as gatekeepers in the selection of promising compounds.[23]

The implications of the protein-binding hypothesis for drug development have been considered during the last decades. In order to avoid drug interactions, compounds have been selected that exhibit a low protein-binding rate. This is reflected by the pharmacokinetic characteristics of the majority of second- and third-generation AEDs. Therefore, protein binding following protein extravasation into the brain extracellular space is an issue for older AEDs. Since further support for the relevance of protein binding in the extracellular space of the epileptic brain has been obtained, future strategies might aim to maintain the integrity of the blood-brain barrier despite the occurrence of seizure activity. Anti-inflammatory drugs such

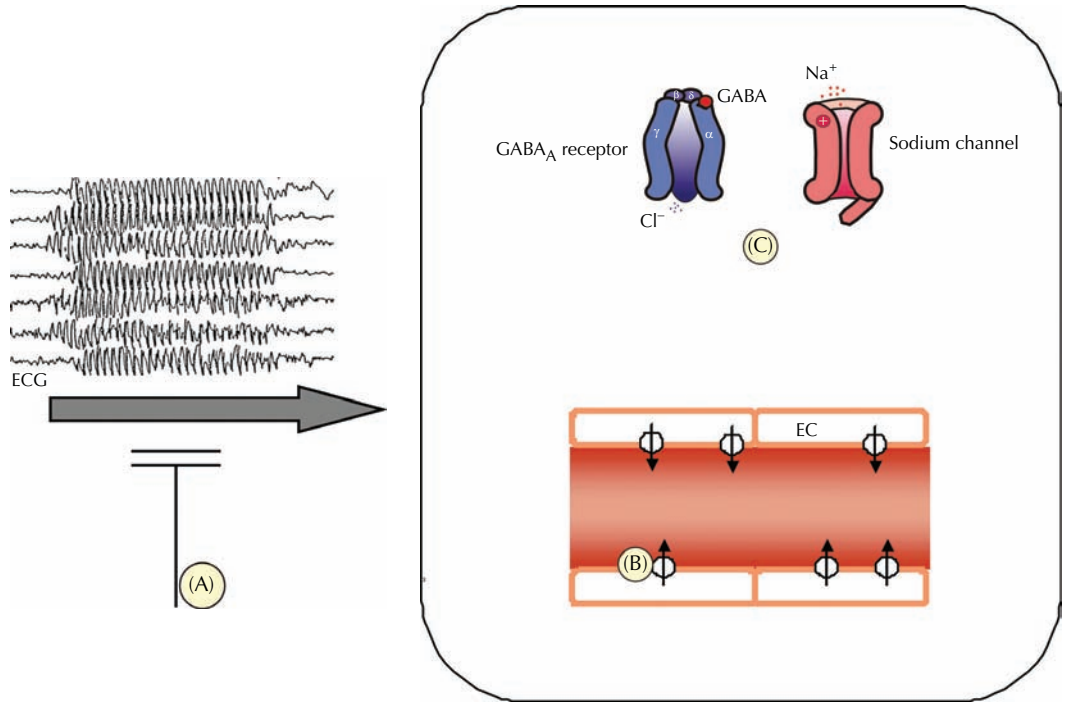

Figure 84–2. Implications of mechanistic hypotheses for drug development or strategies to overcome resistance. **A.** Mechanisms of resistance might be acquired as a consequence of seizure activity (indicated by the arrow and the EEG high-amplitude spiking pattern). As a novel approach, acquired alterations such as target alterations, transporter overexpression, and blood-brain barrier disruption can be prevented by interference with involved molecular and signaling events. **B.** Transporter-mediated resistance might be targeted by inhibiting or bypassing transporters. **C.** The target hypothesis suggests development of AEDs tailored for altered target sites or novel targets. EC, endothelial cells.

as steroids have been suggested as therapeutic add-on options with the ability to repair or protect the blood-brain barrier.[44]

The transporter hypothesis has different implications for drug development and therapy. In general, the developmental process of central nervous system drugs already includes testing whether compounds are efflux transporter substrates. However, a series of in vitro analyses suggests that determining the substrate specificities of highly lipophilic compounds such as AEDs involves particular requirements for the sensitivity of the transport assay used. Thus, care should be taken to integrate sensitive assays into the screening process. Add-on strategies might aim to modulate transporter function or to prevent induction of transporter expression. As already described, experimental proof of principle has been obtained in acute and chronic epilepsy models demonstrating that the addition of P-gp modulators enhances the anticonvulsant efficacy of AEDs and can even help to overcome drug resistance.[35,36] The use of transporter modulators that reduce the transport capacity in a competitive or noncompetitive manner requires careful safety considerations. Efflux transporters such as P-gp serve important protective functions. Through their activity in biological barriers, excretory organs, and hematopoietic cells, they significantly limit the exposure of sensitive tissues and cells to harmful xenobiotics. For instance, evidence exists that low expression of P-gp predisposes to Alzheimer's disease, Parkinson's disease, and inflammatory bowel disease. Long-term pharmacological inhibition of P-gp might be associated with comparable risks. Thus, translational development should consider transient phases of add-on therapy.

Progress has been made in the identification of key signaling factors upregulating P-gp in the epileptic brain.[45] Seizure-associated induction of P-gp has been prevented by targeting these key factors, including COX-2 inhibitors and

prostaglandin E2 (PGE_2) receptor type 1 (EP1) antagonists.[46–48] More importantly, COX-2 inhibition increased the brain penetration rate of phenytoin and restored pharmacosensitivity to phenobarbital in chronic epileptic rats.[49] As these preventive strategies have been proven to keep P-gp expression at control levels, targeting P-gp upregulation will not interfere with basal transport function. However, the specific side effects of compounds targeting arachidonic acid signaling need to be taken into consideration.

Bypassing overexpressed efflux transporters might be another option. Approaches might include nanoparticle encapsulation of AEDs and invasive strategies involving intracerebral drug administration.

Any strategy that aims to overcome one of the suggested mechanisms of resistance has several challenges. First, the paucity or lack of convincing clinical support demands further efforts to explore the clinical relevance of specific resistance mechanisms. Moreover, drug resistance has generally been considered a multifactorial problem. Therefore, it remains questionable whether overcoming one selected mechanism is sufficient to restore pharmacosensitivity in patients. In this context, clinical studies also need to explore whether specific mechanisms might predominate in a subgroup of patients.

APPROACHES TO IDENTIFY RESISTANCE MECHANISMS IN PATIENTS

Evaluation of the clinical relevance of a suggested mechanism of drug resistance would benefit significantly from the availability of tools to study the alterations in individual patients. Pharmacogenetic analyses might be helpful in the identification of intrinsic mechanisms of drug resistance.[50] The presence of genetic differences in drug targets might affect the affinity and efficacy of AEDs. Considering voltage-gated sodium channels as one of the major targets of AEDs, it is of specific interest that a single nucleotide polymorphism (SNP) has been identified in the *SCN1A* gene that, by affecting the splicing of the gene, might alter the functional properties of the Na^+ channel. In an initial analysis of a large cohort of patients from the United Kingdom, the SNP proved to be associated with the maximal prescribed dose of the AEDs carbamazepine and phenytoin.[51] However, studies in a Chinese patient population, as well as a replication study in a European cohort, failed to detect a respective association.[52,53] Thus, the clinical relevance of this SNP remains questionable.

An association between the assembly of the pentameric $GABA_A$ receptor and its sensitivity to the agonist zolpidem was reported several years ago. Based on these data, it has been suggested that functional polymorphisms at sites that regulate the expression of $GABA_A$ receptor subunits might affect drug responsiveness.[54] Further research is necessary to explore the pharmacogenetic relevance of the described polymorphisms.

Many AEDs act by multiple mechanisms, representing one of the major challenges in efforts to identify a link between a selected polymorphism in one drug target and drug responsiveness. This problem is considered a major cause of the failure to reproduce an association in replication studies.

Considering the putative differences in brain penetration of AEDs, several groups have performed association studies analyzing a link between polymorphisms in the P-gp-encoding gene *ABCB1* and resistance to treatment.[54,55] Evidence exists that the most intensely analyzed SNP located in exon 27 (C3435T) is associated with altered protein expression rates, although this SNP does not affect the amino acid sequence. Single nucleotide polymorphisms that are in linkage disequilibrium with the C3435T SNP have been suggested to mediate the functional consequences. An initial study indicated an association between the C3435T polymorphism and resistance to multiple AEDs. Since then, a series of studies has supported this link, but a number of other studies failed to confirm the association.[54,56]

Controversial data might be related to differences in inclusion criteria. Among other factors, the failure to focus on AEDs that are transported by P-gp should be considered as a major limitation in some of the studies. Inconsistencies in the outcome might also reflect the complexity of drug resistance mechanisms. Even the focus on P-gp as one transporter might require much more complex considerations. Experimental data indicate that overexpression of this transporter in the epileptic brain is an acquired

phenomenon occurring as a consequence of seizure activity. Therefore, differences between responders and nonresponders might lie in regulatory mechanisms. Thus, genetic analyses need to include regulatory sequences that control *ABCB1* expression as well as the different signaling factors driving P-gp expression during seizures. Given these issues, investigators are unlikely to obtain explicit and reproducible results from analyses of SNPs in the *ABCB1* coding sequence.

Imaging techniques might allow a more direct evaluation of intrinsic or acquired mechanisms of resistance. Although a series of PET tracers proved to be affected by P-gp, the vast majority of studies so far have used the [^{11}C]-labeled (R)-enantiomer of verapamil. Using this radiotracer, a pilot PET study in epileptic patients revealed evidence of asymmetries in R-[^{11}C] verapamil distribution in homologous brain regions located ipsilateral and contralateral to the seizure focus.[57] The failure to reach significance was attributed to the small sample size of the study. Explicit conclusions obviously need to await the completion of more comprehensive studies.

Progress has been made in the optimization of sensitive techniques in that the reversal of P-gp function can also be monitored when a P-gp substrate radiotracer is combined with a P-gp modulator such as tariquidar.[58] Subsequent PET scanning using a radiotracer with and without pretreatment with a P-gp inhibitor will probably allow an even more precise determination of P-gp function when analyzing the difference in tracer kinetics between both scans.

Evaluation of the transport function of further efflux transporters at the blood-brain barrier is currently hampered by the lack of excellent tracer candidates. With regard to the target hypothesis, it might be worthwhile to develop radioligands with an affinity sensitive to target variations. Such tracers might allow evaluation of the predominant variant in individual patients.

SUMMARY

Despite the ongoing development of novel AEDs, drug resistance remains a major problem in the clinical management of epilepsy patients. Thus, strategies to break new grounds in the development of novel AEDs or alternative therapeutic approaches are urgently needed. Based on epidemiological data as well as experimental studies, several hypotheses have been proposed to explain the phenomenon of drug resistance. These hypotheses suggest specific implications for future drug development and clinical therapeutic management. However, clinical evidence for the drug resistance mechanisms is still limited. Therefore, novel tools to study putative resistance mechanisms in individual patients are needed. New techniques might also guide individualized therapeutic decisions in the future.

Chapter 85

Neural Stem Cell Therapy for Temporal Lobe Epilepsy

Ashok K. Shetty

Temporal lobe epilepsy (TLE), one of the common types of epilepsy, is characterized by multiple hippocampal abnormalities. These include a substantial reduction in the numbers of different subclasses of inhibitory gamma-amino butyric acid-positive (GABAergic) interneurons, aberrant synaptic reorganization, hippocampal hyperexcitability due to an increase in the overall excitatory tone vis-à-vis the inhibitory function, spontaneous recurrent seizures [SRS]) originating mostly from the hippocampus, and impairments in hippocampal-dependent cognitive function and mood.[1–10] Although regular treatment with the antiepileptic drugs (AEDs) has been found to be useful for controlling seizures in many patients, ~35% of people with TLE have chronic seizures that are resistant to AEDs.[2,11,12] Furthermore, AED therapy is associated with side effects, and most TLE patients have learning and memory impairments and depression that are not alleviated with AED therapy.[4,5,13–18] From the above perspectives, alternative therapies that have the potential for easing the frequency and intensity of SRS, learning and memory impairments, and depression in TLE are needed.

Cell transplantation strategies have received significant attention as an alternative therapy for TLE in preclinical studies.[19–26] This is because these approaches have promise for restraining epileptogenesis as well as preventing TLE development and cognitive and mood dysfunction when applied shortly after an initial precipitating hippocampal injury resulting from status epilepticus (SE), head injury, or stroke. Cell therapy may also be useful for restraining seizures and reversing cognitive and mood dysfunction when applied after the onset of TLE. Neural stem cells (NSCs) are one of the donor cell candidates considered for grafting in the domain of cell-based therapy for TLE. Neural stem cells are attractive as donor cells

for grafting in TLE because these cells can be expanded in culture for extended periods from diverse sources such as the fetal, postnatal, and adult brain, human embryonic stem (ES) cells, and human induced pluripotent stem (iPS) cells.[27–36] The promise of NSC grafting therapy for restraining SRS in TLE stems particularly from their ability to migrate extensively into different regions of the hippocampus and produce significant numbers of neurons synthesizing the inhibitory neurotransmitter GABA and astrocytes secreting the anticonvulsant factors such as the glial cell-derived neurotrophic factor (GDNF).[37–39] Moreover, the NSC grafting approach is also expected to ease the cognitive and mood dysfunction observed in TLE, as these cells can secrete a multitude of neurotrophic factors that are known to enhance both endogenous NSC proliferation and overall hippocampal neurogenesis,[40] one of the substrates important for maintaining the hippocampal-dependent cognitive functions and mood.[41–45]

The major objective of this chapter is to evaluate the contemporary knowledge and to put forward perspectives concerning the NSC grafting therapy for TLE. Since the efficiency of grafting of neural progenitors obtained from the fetal brain or ES cells are covered in other chapters in this book, this chapter is deliberately confined to studies on the efficacy of NSC grafts in TLE prototypes. The first section will focus on the prospects for preventing or minimizing SRS using NSC grafting procedures that are performed shortly after the initial precipitating injury (IPI), such as SE or a direct excitotoxic lesion. The second section will consider the promise of NSC grafting therapy for restraining seizures and easing cognitive dysfunction when applied shortly after or at prolonged periods after the onset of SE- or kindling- induced TLE. Several critical issues that need to be resolved before initiating the clinical application of NSC grafting therapy for TLE are also discussed.

EFFICACY OF THE NSC GRAFTING STRATEGY FOR PREVENTING EPILEPTOGENESIS AND/OR CHRONIC EPILEPSY AFTER HIPPOCAMPAL INJURY

Several studies have investigated the efficacy of NSC grafts for restraining seizures in different models of TLE through quantification of SRS or spontaneous spike activity via intermittent behavioral observations or/and electroencephalographic (EEG) recordings over a period of time after NSC grafting. In these studies, the effects of NSC grafts placed into hippocampi at early time points after the injury mediated by an excitotoxic lesion or SE were examined.

Effects of Adult Subventricular Zone NSC Grafts in a Unilateral Hippocampal Injury Model

Jing and colleagues[46] expanded NSCs obtained from the adult subventricular zone (SVZ) in culture as neurospheres and transplanted a suspension of neurosphere cells into the rat hippocampus 1 week after a hippocampal injury inflicted through a unilateral intracerebroventricular (ICV) administration of a small dose of kainic acid (KA). They examined the effects of NSC grafts on spontaneous spike activity using EEG recordings for 3 weeks after grafting.

DONOR CELLS AND THE TLE PROTOTYPE

The SVZ is one of the neurogenic regions in the adult brain where stem cells persist throughout life and produce neuroblasts that migrate normally into the olfactory bulb and differentiate mostly into interneurons.[31] Neural stem cells from both postnatal and adult SVZ can be expanded in culture for prolonged periods without losing their self-renewal and multipotent properties.[34,47–49] Upon differentiation, these NSCs have the ability to give rise to substantial numbers of GABAergic neurons, astrocytes, and oligodendrocytes. The prototype induced through a unilateral ICV KA administration is considered a relatively milder model of TLE, as neurodegeneration (characterized by a substantial loss of hippocampal CA3 pyramidal neurons and dentate hilar neurons), inflammation, aberrant neurogenesis, and hyperexcitability are mostly restricted to the hippocampus ipsilateral to the area of KA administration.[50–57] Additionally, the overall SRS after a unilateral ICV KA-induced hippocampal injury are much fewer and occur much later after the injury in this model in comparison to SE models of TLE.[55]

EFFECTS OF SVZ-NSC GRAFTING ON ABNORMAL SPIKE ACTIVITY AND HOST HIPPOCAMPAL INTERNEURONS

The abnormal spike frequencies in the injured hippocampus obtained through EEG recordings did not differ between the KA-treated rats that received NSC grafts and the KA-treated rats that received nonspecific grafts such as fibroblasts in the first week after grafting. However, in the second and third weeks after grafting, the KA-treated rats receiving NSC grafts displayed reduced frequencies of abnormal spikes in comparison to the KA-treated rats receiving nonspecific grafts, suggesting that NSC grafts are capable of decelerating the process of epileptogenesis. However, the major limitation of this study is that the effects of NSC grafts on SRS were not determined. Histological analyses revealed the survival of graft-derived cells and also their differentiation into glial fibrillary acidic protein positive (GFAP+) astrocytes and neuron-specific nuclear antigen positive (NeuN+) mature neurons. Interestingly, the frequency of abnormal spikes was found to be negatively correlated with the number of surviving graft-derived cells, suggesting that a reduced frequency of abnormal spikes in grafted animals is linked to the presence of graft-derived cells. The mechanisms underlying this phenomenon are yet to be determined. Additionally, the differentiation of graft-derived cells into GABAergic interneurons was not evaluated in this study. Analyses of the injured host hippocampi that received NSC grafts revealed improved survival of subclasses of host GABAergic interneurons and reduced aberrant sprouting of mossy fibers into the dentate molecular layer. As reductions in the number of GABAergic interneurons and aberrant mossy fiber sprouting are both hallmarks of TLE and are believed to contribute to the enhanced excitatory tone in the chronically epileptic hippocampus, the above results suggested that NSC grafting shortly after injury exerts an antiepileptogenic effect on the injured hippocampus.

Effects of Intravenous Administration of Human NSCs in a Pilocarpine Prototype of TLE

A study by Chu et al.[58] examined the efficacy of intravenous administration of beta galactosidase-encoded human NSCs on SRS in a pilocarpine model of TLE in rats. Administration of NSCs was performed just 1 day after the induction of SE. At 28–35 days after SE, 87% of the rats that did not receive NSCs (epilepsy-only group) exhibited SRS. In contrast, only 13% of the rats that received NSCs after SE displayed SRS. The severity of SRS was also diminished in rats receiving NSCs in comparison to the epilepsy-only group. Analyses of the field excitatory postsynaptic potentials (fEPSPs) in the CA1 region through stimulation of the CA3 Schaffer collaterals revealed that, in animals that received NSC grafts, fEPSPs were smaller than their counterparts in the epilepsy-only group. Histological analyses of the brains of rats that received intravenous administration of β gal$^+$ NSCs 6 weeks postadministration revealed the presence of β gal$^+$ cells in multiple regions of the brain, which included the hippocampal CA1 and CA3 subfields, the dentate hilus, the subiculum, amygdala, and piriform cortex. Investigation of the phenotypes of β gal$^+$ cells demonstrated that only a few cells derived from NSCs expressed markers of mature neurons. A fraction of β gal$^+$ cells coexpressed markers of interneurons such as GABA and parvalbumin (PV) in the hippocampus and the piriform cortex, suggesting that the cells derived from NSCs differentiate into GABA-synthesizing cells. A few cells derived from NSCs also expressed GFAP (presumably astrocytes or undifferentiated NSCs). These results suggested that NSCs have the ability to differentiate into GABA-synthesizing cells following engrafting into the injured hippocampus. It is possible that introduction of these new GABA-synthesizing cells into the inhibitory circuitry of the injured hippocampus decreased overall neuronal excitability and resulted in considerable suppression of SRS after SE. However, this mechanism needs to be confirmed in future studies.

Effects of Hippocampal NSC Grafts in an SE Model

A recent study investigated the efficacy of grafting of NSCs expanded from the fetal hippocampi into hippocampi of adult rats 1 week after the induction of SE for preventing or minimizing the SRS that typically occur several months after SE.[37]

DONOR CELLS FOR GRAFTING AND THE TLE PROTOTYPE

Neural stem cells were expanded from the embryonic day 19 (E19) hippocampi in vitro as neurospheres,[30] and the neurosphere cells were labeled via the addition of chlorodeoxyuridine (CldU; a thymidine analog and cell birth-dating marker) to the stem cell proliferation medium. The hippocampus is another region in the developing brain and the adult brain rich in NSCs. Neural stem cells from the fetal, postnatal, and adult hippocampi can be expanded in culture for prolonged periods.[28,30,59–61] Upon differentiation, these NSCs have the ability to give rise to all three central nervous system (CNS) phenotypes and GABAergic neurons. For grafting, neurospheres were triturated gently, and the resulting suspension of neurosphere cells was treated with differentiation factors such as fibroblast growth factor-2 (FGF-2) and brain-derived neurotrophic factor (BDNF) and transplanted into hippocampi of adult rats 7 days after the induction of SE. Status epilepticus was induced via graded injections of the KA,[62,63] and the KA-induced continuous acute seizure activity (i.e., SE) was terminated 3 h after the onset through an injection of diazepam (5 mg/kg body weight). Since virtually all rats treated with KA as described above typically develop SRS (or chronic TLE) 3–4 months after SE,[62] this is an excellent model to test the efficacy of NSC grafts for seizure suppression.

EFFECTS OF HIPPOCAMPAL NSC GRAFTS ON SRS

Graft-mediated beneficial effects on the frequency and intensity of SRS were quantified at 4–6 months postgrafting through intermittent behavioral observations (4 h per session, two sessions per week for 3 months). To authenticate the direct effects of hippocampal NSC grafts on SRS, seizure data were compared with those from another group of rats that underwent SE and sham surgery (involving injections of the culture medium instead of the hippocampal NSC grafts) 1 week post-SE. This comparison clearly revealed considerably diminished frequency and intensity of SRS in the rats that received hippocampal NSC grafts after SE in comparison to those that received sham-grafting surgery after SE (82%–90% reduction in all seizures and 89%–93% reduction in stage 5 seizures; $p < .01$). Thus, the beneficial effects in terms of the frequency and intensity of SRS observed with hippocampal NSC grafting in this SE model appeared specific to the presence of NSC-derived cells, as the animals that received sham-grafting surgery did not exhibit these beneficial changes.

Additional analyses of the SRS and high-amplitude spikes were done at 6 months postgrafting using continuous EEG recordings for 4 days in comparison to two age-matched control groups (i.e., rats receiving dead NSC grafts after SE or rats receiving no grafts after SE).[64] These analyses also demonstrated that grafting of hippocampal NSCs into hippocampi of rats 1 week post-SE considerably diminishes the frequency of SRS (53%–63% reduction; $p < 0.001$) and the total numbers of high-amplitude spikes (40%–55% reduction; $p < 0.05$) in the chronic phase after SE in comparison to control groups.[64] Histological analyses revealed an extensive migration of NSC graft-derived cells into different regions of the hippocampus. The overall yield of graft-derived cells was equivalent to ~50% of the injected cells. Phenotypic analyses of graft-derived cells revealed the ability of hippocampal NSCs to give rise to mature neurons (including the differentiation of ~15% of cells into GABAergic neurons) and mature astrocytes following grafting into the epileptic hippocampus.[64] Hippocampal NSC grafting also appeared to have a neuroprotective effect on the survival of host interneurons positive for neuropeptide Y (NPY) and PV. This neuroprotective effect, as well as the addition of new GABAergic neurons, could be the mechanism underlying the suppression of SRS in this grafting model. Overall, this study, using both behavioral observations and EEG recordings, indicated that grafting of hippocampal NSCs into adult hippocampi shortly after SE is an excellent strategy for greatly restraining SE-induced chronic epilepsy for prolonged periods. The seizure-suppressing effect demonstrated with grafting of hippocampal NSCs in this study is relevant for the future clinical application of NSC grafting for restraining TLE development after a hippocampal injury due to acute seizures, SE, stroke, or head injury.

EFFICACY OF NSC GRAFTING FOR EASING CHRONIC TLE

Application of NSC grafts at early time points after the injury or insult, using TLE models as described above, is useful for unraveling the antiepileptogenic effects of NSC grafts and for developing a pretreatment strategy that prevents or diminishes the development of chronic epilepsy after an injury to the hippocampus. However, such studies are not relevant for treating patients who are already suffering from chronic TLE. As patients with intractable epilepsy are the most likely candidates for NSC grafting therapy among the epilepsy patient population as an alternative to hippocampal resection, it is vital that studies are performed in prototypes where animals are epileptic at the time of grafting. As seizures in TLE originate mainly from the hippocampus and are associated with cognitive impairments and reduced hippocampal neurogenesis, it is also important to examine the effects of grafting NSCs into hippocampi of animals that are not only chronically epileptic but also have cognitive impairments at the time of grafting. The following section discusses findings from NSC grafting studies in rats that exhibited SRS and/or cognitive impairments at the time of grafting.

Effects of NSC Grafts in an SE-Induced Chronic Epilepsy Model

A recent study in our laboratory ascertained whether grafting of NSCs that are capable of adding new GABAergic interneurons and GDNF-expressing astrocytes to the epileptic hippocampus restrains SRS in chronic TLE.[39] In this study, NSCs expanded in vitro from the embryonic medial ganglionic eminence (MGE) were grafted bilaterally into hippocampi of adult rats exhibiting chronic TLE with cognitive impairments for prolonged periods to ascertain the efficacy of such grafts for treating chronic TLE.

PREPARATION AND PROPERTIES OF DONOR NSCS

For preparation of donor NSCs, MGEs of E14 fetuses were dissected, dissociated, and expanded as neurospheres in an NSC proliferation medium containing the birth-dating marker CldU. The reasons for choosing MGE-NSCs for grafting in this study are based on the fact that the MGE is the source of most hippocampal GABAergic interneurons in the developing brain and the observation that GABAergic interneurons derived from primary MGE cells display the ability for both functional integration and increasing the extent of inhibition when grafted into the normal postnatal brain.[65] For grafting, the MGE-NSC-derived neurospheres were dissociated and a suspension of neurosphere cells was prepared. Parallel differentiation cultures of neurosphere cells were also performed, which revealed the ability of MGE-derived neurosphere cells to differentiate into all three CNS phenotypes. Additionally, 15% of NSC-derived cells differentiated into GABAergic neurons in culture.[39] Figure 85–1 illustrates examples of the beta-III tubulin positive (TuJ-1+) and GABAergic neurons derived from the MGE-NSCs.

CHARACTERISTICS OF CHRONICALLY EPILEPTIC RATS USED FOR THE GRAFTING STUDY

Chronically epileptic rats used in this study were generated using a KA-induced SE.[63] Since the extent of SRS varies among animals, a group of age-matched chronically epileptic rats exhibiting a similar extent of SRS were chosen from a larger pool of animals that were chronically epileptic for ~12 months. In addition, all chronically epileptic animals chosen for grafting were also examined with a water maze test to confirm the spatial learning and memory impairments in these rats at the time of grafting. These rats were grafted with MGE-NSCs, with each rat receiving four grafts per hippocampus (80,000 live cells per graft). In order to exclude the effects of grafting surgery on SRS, sham-grafting surgery was performed in an additional group of rats exhibiting a similar extent of SRS.

EFFICACY OF MGE-DERIVED NSC GRAFTS FOR EASING SRS

Grafting of MGE-NSCs greatly reduced not only the frequency but also the duration and severity of SRS[39] (Fig. 85–2). At 3 months

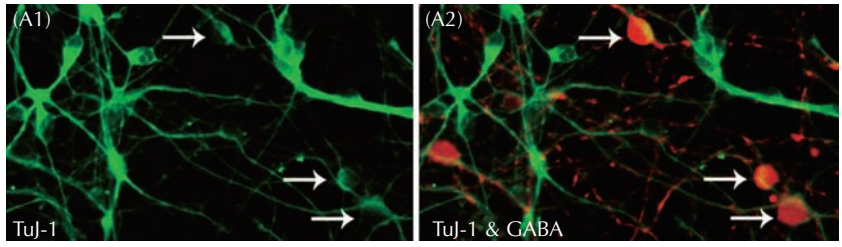

Figure 85–1. A significant fraction of the MGE-NSCs differentiate into TujJ-1+ neurons and GABA+ neurons in culture. The figure shows examples of TujJ-1+ neurons and GABA+ neurons from an MGE-NSC culture after 8 days of incubation in a differentiation medium. Arrows denote the TuJ-1+ neurons that express GABA. From ref. 39.

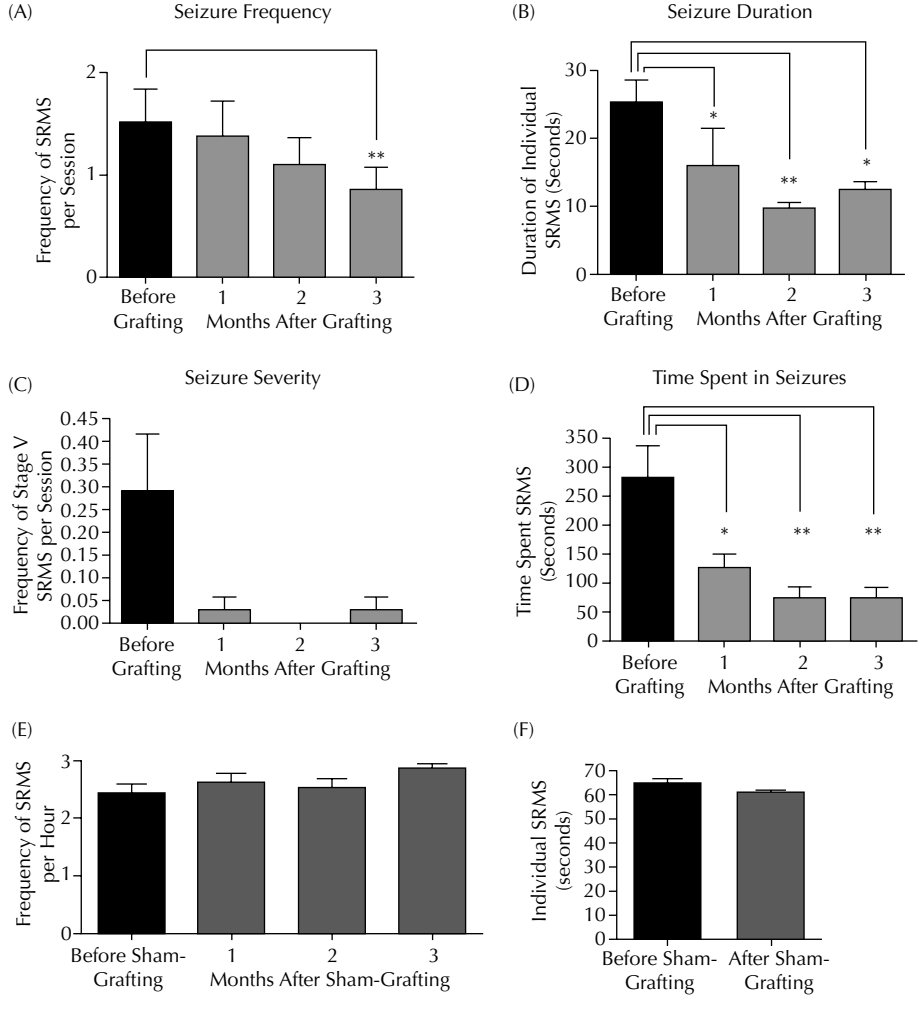

Figure 85–2. The MGE-NSC grafting procedure considerably eases spontaneous recurrent motor seizures (SRMS) in chronically epileptic rats. The *y*-axis in bar charts **A** and **C** denotes the average number of seizures per session (4 h block) of observation. Note that MGE-NSC grafting considerably decreases the seizure frequency (**A**), the duration of individual seizures (**B**), the severity of seizures (**C**), and the total time spent in seizures (**D**). $^{*}p < .05$; $^{**}p < .01$. The bar charts in **E** and **F** show the average seizure frequency and the average seizure duration in chronically epileptic animals that received the sham-grafting surgery. The sham-grafting surgery did not alter the seizure frequency or the seizure duration in chronically epileptic rats. From ref. 39.

postgrafting, the overall decreases were 43% for the frequency of SRS, 51% for the duration of individual SRS, and 90% for the frequency of stage 5 seizures (the most severe form of SRS). In addition, there was a 74% decrease in the total time in seizures during the third month after grafting. Sham-grafting surgery had no effect on chronic epilepsy, however, as the animals in this group displayed no decrease in either seizure frequency or duration of individual SRS.[39]

SURVIVAL AND DIFFERENTIATION OF MGE-NSC GRAFTS IN THE CHRONICALLY EPILEPTIC HIPPOCAMPUS

Analyses of brain tissues with immunostaining for CldU (the marker used for identifying graft-derived cells in this study) revealed the presence of graft-derived cells in hippocampi after 3 months of grafting. Graft-derived cells migrated extensively into different layers of the CA3 subfield and the lateral regions of the CA1 and dentate gyrus subfields throughout the antero-posterior axis of the hippocampus[39] (Fig. 85–3). However, graft-derived cells were only occasionally observed in the dentate subgranular zone and the granule cell layer. Quantification of the total number of graft-derived cells demonstrated a yield that was equivalent to 28% of injected cells or ~81,536 cells per hippocampus. Furthermore, the grafted MGE-NSCs differentiated into the NeuN+ neurons, the GABA+ interneurons (Fig. 85–4), the (S-100β+) mature astrocytes, and the neuron-glia chondritin sulfate proteoglycan 2 positive (NG2+) oligodendrocyte progenitors. Extrapolation of the yield of graft-derived cells with percentages of different cell types suggested that MGE-NSC grafting resulted in the addition of over 10,000 new neurons, 46,000 new astrocytes, 2000 new oligodendrocyte progenitors, and 8000 new GABAergic neurons into each hippocampus of chronically epileptic rats. A substantial fraction (~50%) of cells derived from the MGE-NSC grafts also expressed GDNF, which morphologically appeared to be astrocytes. Considering the overall yield of graft-derived cells, this amounted to the addition of over 40,000 new GDNF+ cells into the each hippocampus of epileptic rats.[39]

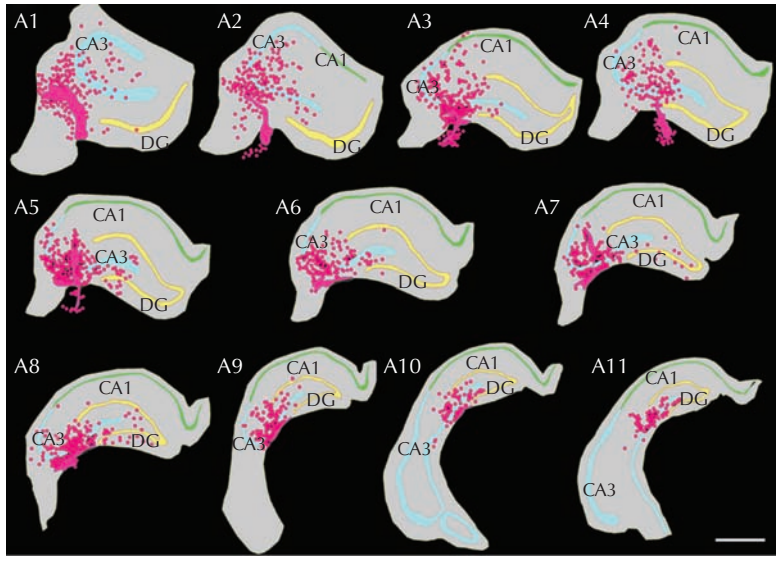

Figure 85–3. Cells derived from the MGE-NSC grafts migrate extensively in the chronically epileptic hippocampus. The figures illustrate the location of transplants and the transplant-derived cells (shown in pink based on the donor cell marker CldU+ immunoreactivity) with respect to the hippocampal cell layers and the subfields in a chronically epileptic rat after 3 months of grafting. These tracings, performed using Neurolucida software (Microbrightfield Inc.), represent every tenth 30 μm thick section through a chronically epileptic hippocampus that received four MGE-NSC grafts. Note that the grafts and graft-derived cells were located mostly in the CA3 subfield and the lateral ends of the CA1 subfield and the dentate gyrus. The core of transplants partially projected ventrally into the thalamus at certain levels. Scale bar, A1–A11, 1000 μm. From ref. 39.

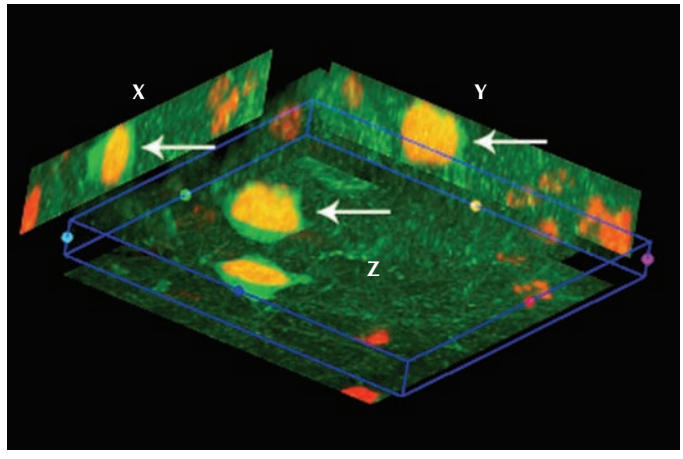

Figure 85–4. A fraction of the cells derived from the MGE-NSC grafts differentiate into GABA-positive neurons in the chronically epileptic hippocampus. The figure illustrates a three-dimensional view of (in X, Y, Z planes) a GABAergic neuron (indicated by arrows) derived from an MGE-NSC graft. This neuron was visualized through dual immunofluorescence for CldU (a birth-dating marker used for the donor MGE-NSCs) and GABA (a marker of inhibitory neurons) followed by Z-section and three-dimensional analyses in a confocal microscope.

EFFECTS OF MGE-NSC GRAFTING ON HOST HIPPOCAMPAL GDNF EXPRESSION

This study demonstrated that the vast majority of astrocytes (≥86%) in all subfields of the intact hippocampus of naive rats express the anticonvulsant protein GDNF but a substantially smaller percentage of astrocytes (≤42%) express GDNF in the hippocampus of chronically epileptic rats. Interestingly, MGE-NSC grafting into the hippocampus restored GDNF expression (Fig. 85–5), as ≥76% of S-100β+ astrocytes in the hippocampus of rats that received MGE-NSC grafts expressed GDNF.

POTENTIAL MECHANISMS OF NSC GRAFT-MEDIATED SUPPRESSION OF SRS

While this study did not investigate the precise mechanisms underlying the NSC graft- mediated suppression of SRS in chronically epileptic rats, correlative observations suggested two potential mechanisms. One pertains to the addition of over 8000 new GABAergic neurons per hippocampus through NSC grafting. This addition is clearly significant, considering the extent of GABAergic interneuron loss and loss of the functional inhibition observed in TLE,[1,6,7,9,50,51] as well as the observation that grafting of cells that release only GABA can also facilitate transient antiseizure effects.[23,25,66–68] Based on these observations, it is possible that the antiseizure effect is a consequence of an increase in the GABA concentration mediated by the GABAergic neurons derived from the NSC grafts. It is also possible that the inhibitory synaptic integration of graft-derived GABAergic neurons on hippocampal principal excitatory neurons underlies the seizure suppression demonstrated in this study. This is because the overall suppression of SRS was improved over the 3-month postgrafting period, a sizable number of graft-derived GABAergic neurons survived for 3 months, and previous studies have shown that axons of GABAergic neurons derived from the MGE precursor cell grafts integrate with the host brain and increase the level of inhibition.[65,69] Nevertheless, electrophysiological and electron microscopic studies are needed to confirm the synaptic integration of NSC graft-derived GABAergic neurons. The second potential mechanism is related to the addition of over 40,000 GDNF+ cells per hippocampus and restoration of GDNF expression in the host hippocampal astrocytes with MGE-NSC grafting because of the anticonvulsant property of GDNF noted in models of TLE.[70,71] Thus, suppression of SRS by NSC grafts in this study appeared to be due to both addition of GABAergic neurons and GDNF-secreting

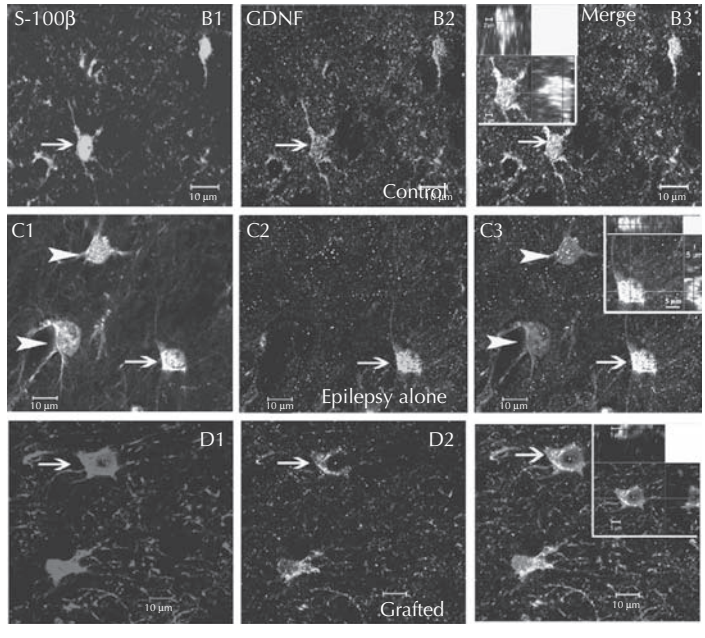

Figure 85–5. The MGE-NSC grafting into the chronically epileptic hippocampus restores the expression of GDNF in the host hippocampal astrocytes. Figures **B1–D3** show confocal microscopic images of S-100β+ hippocampal astrocytes that exhibit GDNF expression in an age-matched control rat (**B1–B3**), a rat with chronic epilepsy alone (**C1–C3**), and a chronically epileptic rat that received MGE-NSC grafts (**D1–D3**). The insets in **B3**, **C3**, and **D3** show orthogonal views of cells that are indicated by arrows in **B1** and **B2**, **C1** and **C2**, and **D1** and **D2**, respectively.. Note that these cells are positive for both S-100β and GDNF. Arrowheads in **C1** and **C3** denote S-100β+ astrocytes that lack GDNF expression in the epilepsy-alone group. Scale bar, 10 μm. From ref. 39.

cells and restoration of GDNF expression in the host hippocampal astrocytes.

EFFICACY OF MGE-NSC GRAFTS FOR EASING LEARNING AND MEMORY DYSFUNCTION IN CHRONICALLY EPILEPTIC RATS

Evaluation of chronically epileptic rats prior to grafting with a water maze test had revealed the existence of impairments in learning and memory function in comparison to age-matched control rats. In the second water maze test performed 2 months postgrafting, their posttransplantation learning and memory scores were not improved in comparison to their pretransplantation scores. Thus, transplantation of the MGE-NSC grafts did not reverse the hippocampal-dependent spatial learning and memory deficits in chronically epileptic rats. Considering the importance of neurogenesis for hippocampal-dependent learning and memory function,[42–45] the failure to reverse the cognitive dysfunction likely reflects the inability of the grafts to enhance the hippocampal neurogenesis that almost shuts down in chronic epilepsy.[55,72] Indeed, no effects of MGE-NSC grafting on neurogenesis were observed when the chronically epileptic rats were examined after 3 months of grafting. Lack of graft-mediated effects on neurogenesis might be attributable to insufficient engrafting of the graft-derived NSCs into the neurogenic niche of the dentate gyrus. Another reason for the lack of improvement in cognitive function is that the MGE-NSC grafts did not give rise to CA1 or CA3 pyramidal neurons to restore the neuron loss in CA1 and CA3 cell layers. Restoration of the cognitive pathways might require grafting of NSCs that are capable of engrafting substantially into the neurogenic region of the dentate gyrus[40] and/or cells that have the ability to differentiate into hippocampal pyramidal neurons and restore the damaged CA1-CA3 circuitry.[6,8,19,20,21]

Overall, this study provided novel evidence that MGE-NSC grafting into the hippocampus is an effective approach for suppressing SRS

in chronic TLE. The limitation of this study is that continuous EEG recordings were not performed to ascertain all of the SRS occurring in the postgrafting observation period, which is necessary in future NSC grafting studies using chronic epilepsy models to advance this therapy for TLE patients.

Effects of NSC Grafts in Suppressing SRS in a Kindling Model

Shindo and colleagues examined the efficacy of transplantation of NSCs generated from mouse ES cells into the hippocampus of kindled epileptic mice for suppressing SRS.[38]

DONOR CELLS FOR GRAFTING AND THE ANIMAL MODEL

Pluripotent mouse ES cells were first grown into aggregates of cells called *embryoid bodies* (EBs). Following this, NSCs derived from EBs were selectively expanded in serum-free defined media containing FGF-2 to generate neurospheres. The neurospheres were then dissociated into single cells and used for grafting. The host epileptic rats were prepared using the amygdala kindling paradigm.[38] This comprised implantation of electrodes into the left amygdala followed by electrical stimulation of the left amygdala (twice daily) with a biphasic square wave pulse and evaluation of the induced seizures using a modified Racine scale.[38] The stimulation was continued until animals displayed stage V seizures. The animals exhibiting stage V seizures were then used for intrahippocampal grafting of the NSCs (one transplant to the left hippocampus comprising 400,000 live cells).

EFFECTS OF ES CELL-DERIVED NSC GRAFTS ON SRS

Evaluation of SRS 6 weeks after grafting through behavioral observations revealed partial recovery from seizures in all animals that received NSC grafts.[38] Recovery was, however, manifested only in terms of reduction in the intensity of seizures (i.e., from stage V to stage III/IV seizures) but was significant in comparison to recovery in the sham-operated (i.e., culture media- injected) rats exhibiting stage V seizures during the same time period. Qualitative immunohistochemical analyses of the transplanted NSCs 6 weeks postgrafting revealed some differentiation of the graft-derived cells into neurons, including neurons that were positive for the GABA-synthesizing enzyme glutamic acid decarboxylase-67 (GAD-67).[38] Overall, this study suggested that NSCs derived from ES cells are also efficacious for restraining SRS in a TLE model. However, the limitations of this study include the brief intermittent analyses of SRS (i.e., only at 2, 4, and 6 weeks after grafting), the lack of EEG recordings to document all (electrographic as well as behavioral) SRS occurring during the entire postgrafting observation period, and the lack of quantitative correlation between the phenotype of the NSC graft-derived cells (such as cells positive for GAD-67) and SRS.

CONCLUSIONS AND FUTURE DIRECTIONS

Neural stem cell grafting into the hippocampus shortly after the initial precipitating injury has shown considerable beneficial effects in terms of restraining injury- or SE-induced epileptogenesis and SRS in animal models of TLE.[37,46,58,64] However, the beneficial effects of such early grafting strategies for preventing the injury-induced cognitive dysfunction and depression have not been ascertained so far. Grafting of NSCs has also shown considerable efficacy for restraining SRS when applied shortly or at prolonged periods after the onset of TLE.[38,39] While the precise mechanisms underlying NSC graft-mediated seizure suppression are yet to be determined, correlative analyses point to the addition of substantial numbers of GABAergic neurons and GDNF-secreting cells into the epileptic host hippocampus and restoration of GDNF in host hippocampal astrocytes by NSC grafts.[39]

Nonetheless, additional rigorous studies are needed prior to the clinical application of NSC grafts for treating TLE. First, it is vital to study human NSCs such as those derived from fetal, postnatal, and adult brain tissues, human ES cells, or human iPS cells for their ability to survive for a long time and their ability to give rise to substantial numbers of GABAergic neurons and/or GDNF-secreting astrocytes after being

grafted into the hippocampus in animal models of chronic TLE. Second, it is important to rigorously assess the ability of NSC grafts to give rise to subclasses of interneurons that exhibit substantial depletions in number in the chronically epileptic hippocampus (such as those positive for NPY, somatostatin, and PV). Third, it will be useful to determine whether or not the appropriate synaptic integration of NSC graft-derived GABAergic neurons underlies seizure suppression in chronically epileptic prototypes. Fourth, as strategies that suppress SRS (e.g., increased inhibition) may not necessarily improve cognitive function and mood in chronic epilepsy,[39] it will be important to examine the efficacy of combination strategies such as grafting of NSCs into the hippocampi with systemic administration of neurogenesis-enhancing factors such as antidepressants, neurotrophic factors, antioxidants, or dietary supplements. In addition, studies will be needed for developing strategies that both increase the overall yield of NSC graft-derived GABAergic neurons and GDNF-secreting cells and also promote the engraftment of graft-derived NSCs into the dentate subgranular zone to restore the greatly attenuated hippocampal neurogenesis observed in chronic epilepsy.

Chapter 86

Embryonic Stem Cell Therapy for Intractable Epilepsy

Janice R. Naegele
Mohan C. Vemuri
Lorenz Studer

Envisioning a world in which humans are able to regenerate severed limbs, rewire neural pathways, and enhance sensory perception has been a mainstay of science fiction novels and movies for decades. While human limb regeneration is still not possible, remarkable developments in the fields of stem cell biology and neuroscience are leading the way for stem cell-based therapies to amend brain and spinal cord damage and repair sensory organs. In this chapter, we discuss recent efforts to derive neural stem cells from embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) and their applications to treating conditions such as temporal lobe epilepsy (TLE) and neurodegenerative diseases.

Information about the spatiotemporal patterns of transcription factor expression in the developing nervous system suggests that the major classes of neurons in the brain and spinal cord become specified by combinatorial codes of transcription factors. Studies aimed at directing pluripotent stem cells toward neural fates have utilized this information to monitor the differentiation of ESCs and iPSCs into neural progenitors. There are several examples in which sufficient advances in production of clinical-grade cells have led to clinical trials for neurological disorders. Geron initiated the first clinical trial with transplanted human ESC-derived glial progenitors for repairing spinal cord injuries in paraplegic patients (http://www.geron.com/). Due

to financial constraints however, the company halted the trial and withdrew from the field of stem cell therapy. A second clinical trial with retinal grafts of human ESC (hESC)-derived retinal pigment epithelial cells will establish whether blindness caused by macular degeneration is treatable by this approach. In both cases, the cell-based therapies were extensively validated in animal models of the disorders. Systematic studies of the fates and functional properties of neurons and glia derived from ESCs and iPSCs in experimental models of epilepsy are still in their infancy. Relatively few studies have evaluated the efficacy of transplanting different cell types for seizure control in epilepsy.

MIGHT STEM CELL THERAPIES BE EFFECTIVE FOR CONTROLLING SEIZURES IN EPILEPSY?

Spontaneous seizures in patients may induce changes in gene expression and trigger widespread inflammation. It is not well understood how these and other seizure-induced changes in the brain will influence the survival, differentiation, or integration of transplanted neural precursors. Therefore, stem cell cures for complex and heterogeneous neurological disorders such as TLE may be years in the future.

Mesial temporal lobe epilepsy (MTLE) is often acquired after prolonged status epilepticus caused by prolonged high fever, a brain tumor, stroke, or traumatic brain injury, but it is also found in patients diagnosed with Alzheimer's disease. Following the initial brain injury, neural plasticity is thought to lead to an imbalance between synaptic excitation and inhibition in the dentate gyrus, abetting epileptogenesis.[1] Magnetic resonance imaging studies show that hippocampal atrophy is common in patients with childhood-onset MTLE,[2] and seizures in childhood are associated with cognitive decline.[3,4] Partial complex epilepsy involving the mesial temporal lobes can be difficult to control with anticonvulsant medications, and the high doses that are often required can cause debilitating cognitive side effects and toxicity. Surgical resection of hippocampus or severing the corpus callosum are alternative therapeutic interventions that may be beneficial for eliminating the seizure focus or reducing the spread of seizures,[5] but hippocampal resection can only be used in MTLE patients with a well-defined and unilateral seizure focus. When pharmacological and surgical approaches are not feasible, stem cell therapies might be an alternative; these therapies also offer the additional potential for cell replacement and neural circuit repair. The availability of hESCs and strategies for directing their differentiation toward specific types of forebrain neurons and glia is beginning to offer hope that a stem cell cure may be on the horizon for treating hippocampal sclerosis in some forms of acquired epilepsy.[6,7]

REPAIRING DYSFUNCTIONAL NEURAL CIRCUITRY IN TLE

Epileptogenesis refers to cellular and molecular changes occurring during the latent period after an initial insult or seizure, when the brain rewires and becomes prone to spontaneous seizures. Epileptogenesis is hypothesized to be caused by disruption of the normal balance between inhibitory and excitatory connections within limbic circuits.[8] One hypothetical mechanism in epileptogenesis is the loss of GABAergic (gamma-aminobutyric acid) interneurons and inhibitory synapses with granule cells after an initial precipitating injury. Gamma-aminobutyric acid is the principal inhibitory neurotransmitter in the adult neocortex and hippocampus, where it constrains the spread of neuronal excitation. The GABA-producing interneurons also modulate and integrate information in the cortex and hippocampus by synchronizing cortical oscillations underlying brain function and preventing the development of hyperexcitability and epileptiform activity. Two of the hallmark neuropathological changes in patients with MTLE resulting from traumatic brain injury or prolonged febrile seizures are reduced numbers of hilar interneurons and mossy cells in the dentate gyrus.[2,9,10]

In experimental MTLE in adult rodents, prolonged seizures or head injury can lead to hyperexcitability of granule neurons[11] and deficits in functional subclasses of GABAergic interneurons that coexpress neuropeptide Y or somatostatin.[12–14] These observations have spurred efforts to repair damaged neural circuits with GABAergic neuron precursors generated from ESCs or fetal neural progenitor cells (NPCs), as discussed below.

In both the neocortex and hippocampus, inhibitory cells also regulate networks of synaptically interconnected excitatory pyramidal neurons. Due to recurrent networks of excitatory connections, "runaway excitation" and prolonged burst firing of pyramidal neurons can result when synaptic inhibition is reduced. It has been proposed that prolonged status epilepticus impairs the efficacy of inhibitory GABAergic synaptic transmission onto granule neurons,[15] caused by dysregulation of $GABA_A$ receptors.[16,17] In addition, recent studies in the pilocarpine model suggest that despite a significant loss of hilar GABAergic interneurons, a compensatory response in the residual hippocampal interneurons causes them to hypertrophy, resulting in a net increase in GABAergic synapses in the inner molecular layer of the dentate gyrus.[18] Failure of these new connections to regulate dentate granule neuron hyperexcitability further supports the hypothesis that inhibitory synaptic transmission becomes dysfunctional in some forms of acquired MTLE.[18,19] Developmental disorders affecting the specification and migration of GABAergic interneurons in neocortical and hippocampal regions have also been shown to cause abnormal neuronal firing properties and spontaneous seizures.[20–24]

Taken together, the evidence from human neuroimaging data, postmortem histological studies of tissue from MTLE patients, and experimental models in rodents supports the idea that defective inhibitory neurotransmission in the hippocampus is a key factor in epileptogenesis and recurrent spontaneous seizures. As the above examples show, however, effective cell replacement in acquired forms of MTLE is likely to require extensive integration of specific functional types of GABAergic neurons into the dentate gyrus and correction of some of the other deficits in limbic circuits that underlie epileptogenesis.

In addition to requiring selective cell replacement in MTLE, effective therapies may need to address activity-dependent changes in gene expression induced by seizure activity that alter patterns of granule cell neurogenesis in the dentate gyrus.[25] Spontaneous recurrent seizures in MTLE are also associated with sprouting of mossy fibers from granule neurons, creating new excitatory synaptic connections in the inner molecular layer of the dentate gyrus.[26–28] While the exact mechanisms remain unclear, aberrant migration of the new neurons and abnormal axonal and dendritic growth of granule neurons contribute to network dysfunction in MTLE.[25, 29–31]

Glial cell involvement in chronic epilepsy is another feature adding to the complexity of the cellular and molecular changes. Glial cells are an important source of the anticonvulsant molecule adenosine, and augmenting adenosine levels has a powerful anticonvulsant effect.[32–35] However, glial cells also produce proinflammatory molecules that contribute to hyperexcitability. Taken together, these studies implicate multiple cell types and pathophysiological processes in acquired focal TLE. Even with the advent of new methods for replacing specific types of neurons and glia in the brain by stem cell therapy, treatment strategies may need to be devised that incorporate multiple approaches to correct the defects, including gene therapy, neuroprotection, and dietary modifications such as the ketogenic diet.

STEM CELLS FOR NEURODEGENERATION AND EPILEPSY

Fetal neural precursor cells (NPCs), adult neural stem cells, mesenchymal stem cells (MSCs), cord blood cells, ESCs, and iPSCs are all being tested for therapeutic effects in experimental models of neurodegenerative diseases and epilepsy. By definition, neural stem cells are self-renewing and can generate neurons or glial cells through asymmetric cell division.

Recent studies demonstrate that stem cells exist not only in the developing embryo, but also in the adult body and brain. The discovery and isolation of neural stem cells from the fetal and adult nervous system has shown that they retain the potential to generate the three major cell types in the central nervous system, namely, neurons, astrocytes, and oligodendrocytes. Once the molecules that govern stem cell self-renewal were identified, it became possible to harvest neural stem cells from the fetal or adult nervous system, expand their populations as neurospheres in vitro, or transplant them directly after removal from fetal brains. To date, significantly more progress has been made in examining the efficacy of grafts derived from fetal progenitors or

genetically modified cell lines, compared to neural stem cells derived from ESCs or iPSCs, for suppressing seizures in experimental models of TLE, ion channel mutations, or developmental disorders of interneurons associated with spontaneous seizures.[36–41]

Classification systems for the different brain-specific stem cells are still evolving.[42] Populations of neural stem cells in the adult nervous system reside within a specialized stem cell niche surrounding the lateral ventricles called the *subependymal zone*. Another specialized niche is the *subgranular zone* of the dentate gyrus, but here the stem cells are defined as progenitors, because separate populations appear to give rise to neurons or glial cells and have very limited self-renewal capacity.

In tissues of the adult body, stem cells are hard to find, but they do exist. An advantage of patient-derived stem cells is that they may be used for autologous transplants, reducing complications caused by immune incompatibility and transplant rejection.[43,44] Increasingly, neural stem cells derived from patients with genetic disorders of the nervous system are being studied in vitro to gain insights into basic disease mechanisms and for drug discovery. However, limited availability of human fetal tissue precludes widespread use of fetal neural stem cells for most clinical or biotechnology applications. To circumvent this problem, protocols have been developed to improve the yield of fetal or adult neural stem cells from the brain by propagating them as neurosphere-forming cells. While rarely tumorigenic when transplanted into the brain, propagation of human NPCs (hNPCs) in culture may select for chromosomal aneuploidy; therefore, cytogenetic screening of hNPCs is necessary prior to their use in clinical applications.[45]

PLURIPOTENT STEM CELLS

The pluripotent stem cells derived from the inner cell mass of human or mouse blastocyst have the capacity to generate all tissue types of the embryo and these cells have been used to generate ESCs. Protocols for differentiating ESCs into neural stem cells in vitro have been developed for adherent ESC lines, as well as those that require an initial stage of growth as embryoid bodies. They were shown to undergo extensive migration and integration after transplantation into the developing rodent brain.[46–48] The three main in vitro approaches for generating neural stem cells from ESCs include the formation of embryoid bodies, growth of neural stem cells in monolayer cultures on feeder layers in the presence of growth factors such as fibroblast growth factor-2 (FGF-2), or neurosphere cultures grown in the presence of defined growth factors. The challenge has been to obtain neural stem cells that can be patterned with regional identities upon differentiation into specific neural and glial types. Rapid progress toward this goal has been aided by identification of the transcriptional codes that specify functionally distinct subsets of neurons at different levels of the developing nervous system.

Although deriving neural stem cells from human ESCs (hESCs) requires more specialized conditions than fresh dissection of fetal neural stem cells from the embryo, the difficulty of obtaining fetal tissue presents an even larger obstacle for clinical applications. One of the biggest challenges in hESC research has been to obtain consistent batches of stem cells with regional and laminar identities. Recent modifications to culture conditions resulted in the growth of mESC- and hESC-derived neural stem cells into neural tube-like rosette structures.[49] As these neural rosettes grow, they recapitulate some notable features of the growing neural tube. Symmetrical mitotic divisions characterize the early-stage rosettes, without forming postmitotic neurons. There is a close temporal link between the neural rosette stage and its potential for neural patterning, similar to that of the neural tube. As neural rosettes develop into late-stage rosettes, they divide asymmetrically, producing neurons and glia that migrate away and differentiate. At this stage, radial glial-like progenitors appear in the rosettes and show interkinetic nuclear migration, similar to that of radial glial cells of the neural tube. They also have apical end feet that form a structure similar to the center of the neural tube. Human ESC-derived neural stem cells have been found to develop laminated structures with distinctive cell populations in the different layers reminiscent of the cerebral cortex. As shown in Fig. 86–1, human H9 pluripotent stem cells can be differentiated into neural stem cells in adherent cultures. These cells are beyond the neural rosette stage and

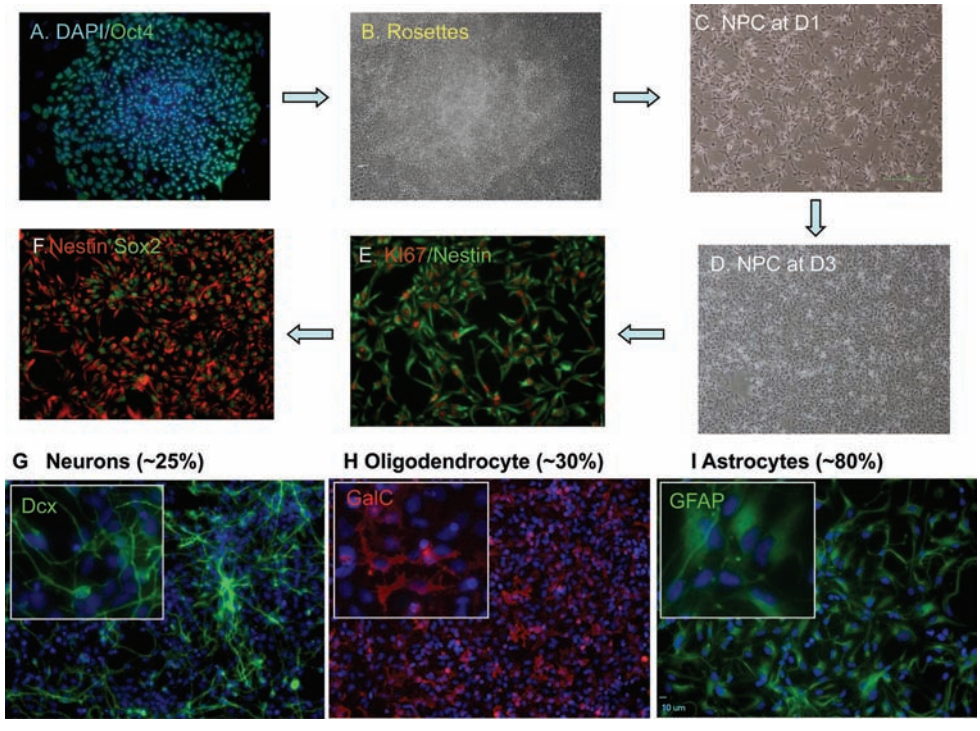

Figure 86–1. Neural induction of hESCs to neural stem cells followed by differentiation into neuronal and glial lineages. Human ESCs (H9) are pluripotent and able to differentiate into all derivatives of the three primary germ layers: ectoderm, endoderm, and mesoderm. Pluripotency is typically indicated by the expression of the transcription factor Oct-4 (octamer-binding transcription factor **4**). **A.** Embryoid body formation and subsequent adherent culture of embryoid bodies to generate neural rosettes. **B.** Phase contrast images (10x) of GIBCO® hNSCs cultured in StemPro® NSC SFM (Serum-free media) at day 1 (**C**) and at day 3 (**D**) after thawing. Fluorescence images (20x) of GIBCO® hNSCs that were cultured in StemPro® NSC SFM for three passages and then allowed to differentiate into neurons, oligodendrocytes, or astrocytes. The cells were stained with antibodies recognizing a marker of cellular proliferation: Ki67 (red) in combination with the neural stem cell markers nestin (green, **E**) or with nestin (red) and SRY (sex determining region Y)-box 2 (SOX2) green, **F**). Upon directed differentiation, NSC types may be further distinguished based on their expression of the immature neuronal marker Dcx (doublecortin; green, **G**), the oligodendrocyte marker GalC (galactosylceramidase; red, **H**), or the astrocyte intermediate filament protein GFAP (glial fibrillary acidic protein: green, **I**). Nuclei are identified by staining with the dye DAPI (4′,6-diamidino-2-phenylindole; blue).

can be readily patterned toward a wide range of neural and glial fates. Studies have also shown that transplanted ESC-derived human or mouse NPCs migrate in the rodent brain after transplantation into the cerebral cortex or hippocampus and differentiate in a region-specific manner.[41,46,50] It is not known whether these cells can provide long-term seizure suppression or neuroprotection in TLE.

INDUCED PLURIPOTENT STEM CELLS

Induced pluripotent stem cells (iPSCs) are genetically reprogrammed adult cells that exhibit a pluripotent stem cell-like state like that of hESCs. Induced pluripotent stem cells may be derived by several different methods that induce select gene expression to confer pluripotency.[51–53] Functionally distinct types of neurons have been generated from iPSCs, and studies are now examining their ability to migrate and successfully modify symptoms of neurological disease.[54–56] One of the advantages of studying iPSC-derived neurons from patients with epilepsy is the possibility of gaining insights at the cellular level into how a particular genetic mutation affects neuronal excitability, migration, dendritic or axonal differentiation, or synapse formation. This approach is now being used to study iPSCs from patients with inherited forms of epilepsy. These cells may also be

quite useful for screening anticonvulsant drugs. Based on their cellular responses to different drug compounds, more effective anticonvulsant drugs can be selected and then administered to individual patients.

DIRECTED DIFFERENTIATION OF ESCS AND IPSCS

Recent advances in directing the fates of hESCs and iPSCs toward neural cell types that have relevance to TLE have utilized defined media conditions, reporter genes, or bacterial artificial chromosomes to select for neural stem cells with GABAergic fates.[50,57] For example, transcriptional codes for specifying GABAergic interneuron subtypes have been identified,[58,59] and this information has been used to direct ESC-derived NPCs to differentiate into GABAergic interneurons.[60] In one study, floating stem cell aggregates were first generated to obtain neural progenitors with a transgene, *Lhx6-GFP* (*Lim homeobox6-green fluorescent protein*). These were then grown on adherent substrates in the presence of growth factors and the signaling molecule sonic hedgehog to obtain ventral telencephalon neural progenitors. By harvesting the neural precursors at this stage, they were able to use the fluorescent transgene in fluorescence-activated cell sorting (FACS) to identify and prospectively isolate the *Lhx6*-expressing GABAergic progenitors prior to transplantation.[60] When the isolated interneuron precursors were then transplanted into the developing mouse brain, they differentiated into functionally defined types of interneurons and exhibited mature electrophysiological properties. Studies are now beginning to test systematically whether transplants of interneuron progenitors obtained with similar protocols have disease-modifying effects in experimental models of temporal lobe epilepsy.

BACTERIAL ARTIFICIAL CHROMOSOME TRANSGENESIS

Another powerful approach is to force the differentiation of hESC-derived neural stem cells toward particular neural fates by introducing bacterial artificial chromosomes (BAC) into the cells. This approach, called *BAC transgenesis*, is a novel tool to define and isolate different neural and glial lineages from ESCs.[61–63] This approach has used the GENSAT library of BACs, which have been engineered to express GFP under the control of key genes related to neural development. To obtain stable BAC transgenesis in hESCs, the cells had to be dissociated into single-cell suspensions using enzymatic digestion and an inhibitor of the Rho-associated kinase. This relatively simple step provided a substantial improvement in survival and cloning efficiency. The BACS were then nucleofected into the dissociated hESCs and selected for antibiotic resistance to obtain hESCs with different GFP transgenes that reported differentiation into motor neuron or dopamine neuron fates.

CLINICAL GRADE PLURIPOTENT STEM CELLS IN XENO- AND FEEDER-FREE CULTURE SYSTEMS

Successful stem cell therapies for central nervous system (CNS) diseases require large-scale production of neural stem cells from hESCs or iPSCs. In addition, such neural stem cells should be nontransformed and well characterized, with adequate bioprocess controls such as safety, sterility, and traceability. These cells, upon transplantation, should differentiate into appropriate target cell types, survive in diseased CNS tissue, and integrate with the existing neural network to improve the functional efficacy and clinical outcome.

A variety of protocols and cell culture conditions have been reported for the generation, expansion, and differentiation of neural stem cells from hESCs. A typical induction protocol from hESCs to human neural stem cells is shown in a schematic diagram (Fig. 86–1), and this can be achieved either by spontaneous or directed differentiation methods.[64–66] Some of the earliest protocols used serum-free culture conditions with either N2 or B27 neural supplements, but the process was not robust enough for reproducibility and scalability and neural induction efficiency was low (0.2% hESC to hNPC) with spontaneous differentiation.[67] Higher efficiency for neural induction was achieved by adding retinoic acid,[68] medium conditioned with stromal cells,[69] or bone morphogenetic protein (BMP) pathway inhibitors.[70]

For human cell therapy, however, using animal serum in the media, stromal feeder cells derived from animals, cocultures, or preconditioned media is incompatible because animal cell- and serum-free conditions are necessary. Guidelines for the manufacture of biologics have been developed and codified under chemistry and manufacturing controls (CMC) and good manufacturing practices (GMP). Deriving the first hESC line with these properties for clinical applications was an important advance.[71] It was necessary to demonstrate the ability to obtain pure populations of long-term self-renewing rosette-type hESC-derived neural stem cells that exhibited extensive self-renewal, clonogenicity, and stable neurogenesis upon transplantation.[72] Recently, an hESC line was generated that has the capacity to produce dopaminergic precursors in completely xeno-free cultures using four steps for producing functional dopaminergic neurons for clinical purposes.[73] Neurons generated by this process were shown to survive in experimental animal models of Parkinson's disease. A third important advance was the development of an efficient method to generate hNSCs from hESC or induced pluripotent stem cells by a combined blockade of SMAD (the SMAD proteins are homologs of two proteins, the drosophila protein, mothers against decapentaplegic (MAD) and the *Caenorhabditis elegans* protein SMA and the name is a combination of these two homologs) signaling with Noggin and a small molecule, SB431542, to achieve full neural conversion. This method is regulatory compliant, as it obviates the need for intermediary steps of generating embryoid bodies, the use of stromal feeders, and even the isolation of rosette structures.[74] The commercial availability of expandable populations of neural stem cells with stable phenotype marker expression will facilitate efforts to produce neural stem cells under xeno-free culture conditions for epilepsy research and clinical applications.

TRANSPLANT STUDIES OF FETAL NEURAL STEM CELLS FOR SEIZURE SUPPRESSION IN EXPERIMENTAL MODELS

Neural stem cells and fetal NPCs have been transplanted into a variety of experimental models of neurological disorders including ischemic stroke, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis, spinal cord injury, and epilepsy.[40,41,50,75–83]

Evidence from experimental studies in several models of TLE in rodents has provided proof of concept that fetal neural stem cell transplants or cell lines genetically engineered to release GABA at multiple sites in the brain reduce seizure severity and/or frequency.[36,84–92] Studies with fetal cell transplants showed reduction of abnormal electrical discharges in the hippocampus or substantia nigra. Moreover, when GABAergic NPCs from the embryonic medial ganglionic eminence were transplanted into the forebrains of young mice, they showed widespread migration across the hippocampus and neocortex. The grafted cells differentiated into distinct types of GABAergic interneurons, functionally integrated, and increased the inhibitory tone in the host cortex and hippocampus.[37] These studies serve as proof of concept that increasing the number of forebrain GABAergic neurons in several different models of epilepsy can not only raise seizure thresholds in genetic models but also suppress recurrent spontaneous seizures in acquired MTLE. Studies employing fetal neural stem cells are described in detail in additional chapters in this volume (Chapters 85 and 87).

CHALLENGES IN CELL THERAPY APPROACHES TO TREAT EPILEPSY

While there are several advantages of stem cell-based therapies over gene therapy and other traditional approaches for treating epilepsy, significant technical hurdles still impede cell therapy for treating epilepsy. Unlike other tissues of the body, the nervous system has a limited capacity for self-repair because mature neurons cannot regenerate, and despite the presence of neural stem cells in the adult brain, their ability to respond to injury is limited. Improving the efficacy of stem cell therapies for replacing neurons or glial cell types destroyed by damage or disease is an extremely active area of investigation. To be successful, grafts of stem cells and their differentiated derivatives in the epileptic brain must not only survive for long periods of time, they must also migrate to the appropriate sites, integrate, and

establish the correct types of synaptic connections with the host brain. The importance of this last point is underscored by studies showing that seizures induce the genesis of ectopically positioned neurons from endogenous neural stem populations, and these ectopic neurons can contribute to increased excitability and epileptogenesis.[29,93]

Immune incompatibility between the donor and host is one of the more formidable problems in the field of cell replacement therapy. Currently, cell therapies based on fetal cell transplants require that patients receiving fetal stem cells also take immunosuppressive drugs to prevent rejection of fetal cell grafts.[40] Autologous stem cell grafts, in which the patient is also the stem cell donor, may help overcome the problem of graft rejection. Another major hurdle for ESC-based therapy is that the risk of tumor formation is high because these cells are pluripotent and mitotically active. To address this problem, hESCs cells have been engineered with suicide genes to allow elimination if the transplanted cells proliferate excessively or form tumors.[94]

CONCLUSIONS AND THE PATH FORWARD

Testing the feasibility of ESC-derived neurons for seizure suppression and hippocampal sclerosis in epilepsy will require a better understanding of how seizures alter the environment of the brain. Activity-dependent changes in the expression of a large number of genes have been found in experimental models of epilepsy. Additionally, even brief seizures may cause epigenetic changes that alter gene expression. Evidence for host brain influences on transplanted neural stem cells suggests that these local changes in the brain's milieu may be powerful influences on stem cell survival and migration after transplantation.

To achieve further advances in stem cell therapies for epilepsy, it will be necessary to improve the ability to track the transplanted cells after transplantation in the human brain. It will also be necessary to achieve long-term survival of transplants, circumvent the immunological problem of graft rejection, and tailor therapies for individual patients. The development of protocols for directing iPSCs into particular cell fates is one way to remove immunological barriers, since these cells can be generated from the patient's skin and offer the possibility of being transplanted back into the same patient. Lastly, before moving into the clinic, it will be necessary to produce clinical-grade human pluripotent cell-derived neural stem cells that differentiate into particular classes of GABAergic interneurons or other cell types that are injured in epilepsy.

With further new technological advances in the field of stem cell biology, cell therapies to treat neurological disorders such as epilepsy may soon become feasible. Stem cell transplants that employ NPCs for subclasses of GABAergic interneurons show great promise for controlling "runaway" excitation in the brain and spontaneous seizures in acquired forms of TLE. However, further studies are needed in a range of translational models of TLE to determine whether hESC- or iPSC-derived neurons transplanted into the hippocampus have the capacity to survive over the long term, form synapses with their appropriate synaptic targets, and regulate pyramidal and granule neuron hyperexcitability without causing adverse neurological side effects.

Chapter 87

Cell Therapy Using GABAergic Neural Progenitors

Stewart A. Anderson
Scott C. Baraban

EMBRYONIC ORIGIN OF CORTICAL INTERNEURONS

Pioneering work in the late 1990s confirmed the concept that neurons arising in the ganglionic eminences of the ventral subpallium of the telencephalon migrate in a tangential manner to developing neocortex, hippocampus, and olfactory bulb, where they generate gamma-aminobutyric acid (GABA)-containing interneurons.[1–3] These cells are thought to arise from two primary, and transient, embryonic structures known as the *medial* and *caudal ganglionic eminences* (MGE and CGE, respectively).[4,5] Seminal studies of interneuron migration in explants[6,7] and in vivo fate mapping[8,9] revealed distinct subtypes of cortical interneurons that arise from each of these two locations. The MGE mainly gives rise to two neurochemically defined subgroups, those that express the calcium binding protein parvalbumin (PV) and those that express the neuropeptide somastostatin[10,11]; the CGE gives rise to vertically oriented calretinin- and vasoactive intestinal peptide (VIP)-expressing interneurons,[10,11] as well as neuropeptide Y (NPY)- and reelin-expressing neurogliaform subclasses.[12,13] Within these neurochemically defined subgroups, there are numerous interneuron subtypes defined by combinations of neurochemical, physiological, and axon-targeting criteria.[14]

Genetically engineered mice lacking transcription factors expressed in these embryonic regions (e.g., *Dlx1* or *Mash1*) lack interneurons confirming a ventral telencephalic origin for these cells and, relevant to this volume, demonstrate that the consequence of interneuron deficiency is often epilepsy. For example, inactivation of a homeobox transcription factor, *Dlx1*, resulted in mutant mice featuring an age-dependent loss of somatostatin$^+$, NPY$^+$, and calretinin$^+$ interneurons (identified through immunohistochemical and in situ hybridization studies), with a subsequent reduction in cortical/hippocampal inhibition (evaluated in acute slice experiments) and spontaneous electrographic

seizures (assessed in video-electroencephalographic [EEG] recordings).[15] Late-onset epilepsy in these *Dlx1* mutants, and another mouse with subtype-specific reductions in cortical interneuron density, that is, the *uPAR*$^{-/-}$ mouse[16] provide strong support for the hypothesis that correct interneuron number and function plays a key antiepileptic role in the adult central nervous system (CNS). Decreased numbers of PV^{+} and NPY^{+} interneurons also correlate with increased seizure susceptibility in a recently described neuropilin-2 knockout mouse,[17] and genetic manipulation of the Aristaless-related homeobox gene (*ARX*) in mice results in a reduction of cortical calbindin-positive interneurons and a variety of seizure phenotypes.[18,19] Taken together, these discoveries and the identification of an epileptic phenotype in children with *ARX* mutations (and reduced cortical interneuron function) have prompted a new *interneuronopathy* epilepsy designation.[20]

TRANSPLANTATION OF MGE PRECURSOR CELLS

Grafted neural progenitors can produce functionally integrated neurons, even after host neurogenesis is complete, and in brain areas outside traditional neurogenic regions. For example, progenitors derived from fetal midbrain integrate into host striatum as dopaminergic neurons, and immortalized neural progenitors (RN33B) transplanted into cortex or hippocampus of neonatal rats differentiate into cells with the morphological features of pyramidal neurons.[21] In electrophysiological studies, these cells can generate action potentials and receive excitatory or inhibitory input from neighboring cells. Using grafted embryonic stem (ES) cells expressing green fluorescent protein (GFP) and voltage-clamp analysis of postsynaptic currents, Wernig et al.[22] confirmed synapse formation between host and donor neurons. These studies, though elegant in design and buttressed by anatomical data indicating synapse formation onto GFP cells, failed to examine synaptic integration in the opposite direction—for example, from donor neuron to host brain. Additionally, large tumors were noted in most animals receiving ES-GFP cell grafts. Embryonic stem cell-derived neural progenitor cells transplanted into hippocampus also display a "marked tendency" to form tumors[23] or appear as "clumps" or "clusters" of cells with mixed lineage near the transplant site.[24,25] Although a promising alternative to currently available drug therapies, functional integration of these ES-derived cells within the host brain is probably quite limited.

Immature neurons arising from the embryonic MGE, in stark contrast to ES-derived cell lines, exhibit a unique ability to migrate widely in host brain following early postnatal transplantation.[7] Medial ganglionic eminence-derived cells express neuronal markers such as NeuN and Hu[24] but exhibit only limited, or no, expression of nonneuronal markers such as glial fibrillary acidic protein, vimentin, or Olig-2.[7,26–29] Transplanted MGE cells are also immune-negative for tyrosine hydroxylase, choline acetyltransferase, calcium/calmodulin-dependent (CaM) kinase IIα or the neuronal glutamate transporter excitatory amino acid carrier-1. Consistent with lineage tracing and fate-mapping studies, nearly all MGE-derived neurons in the host brain are GABAergic and stain with antibodies to GABA or GAD67. Subpopulations of MGE-derived interneurons can be double-labeled with antibodies to PV, somatostatin, NPY, and calretinin. Most importantly, MGE-derived neurons can migrate up to 5 mm from the injection site and show signs of synapse formation in electron micrographic studies.[7,29,30] These anatomical findings suggest that MGE-derived cells could be a source of new, and functionally integrated, interneurons in the host brain. In vitro electrophysiology studies using GFP-labeled, MGE-derived interneurons confirmed that these cells exhibit intrinsic membrane and active firing properties that would classify them as mature interneurons following transplantation.[26,27,30] Moreover, as direct evidence that these cells can integrate functionally and influence GABA-mediated inhibition in the host brain, slice electrophysiology studies consistently show an increase in synaptic[26,28,30] and extrasynaptic inhibition[30] in regions of the host brain containing MGE-derived GFP^{+} interneurons.

CELL THERAPY USING TRANSPLANTED MGE PRECURSOR CELLS

Epilepsy can be a devastating neurological condition characterized by unpredictable

abnormal electrical discharges (seizures) that can result in various combinations of uncontrolled motor output, loss of consciousness, and sometimes death. Nearly 3 million Americans suffer from some form of epilepsy, it has long been recognized that loss (or reduction) of GABA-mediated inhibition can be a contributing factor, and available antiepileptic drugs (including those that target GABAergic signaling pathways) are not effective in approximately one-third of these patients. Cell therapy could offer an alternative treatment option. One critical advantage of a transplantation strategy over conventional antiepileptic drug therapy is that cell treatments can be locally restricted, whereas drugs have widespread and systemic adverse effects. What will be critical to the success of this therapy is the type of neuron that is generated. Early attempts at establishing a cell-based therapy for epilepsy used fetal noradrenergic neurons that were grafted bilaterally to the hippocampus of adult rats following chemical lesioning of the central catecholamine pathway.[31,32] However, the adrenergic cell grafts did not suppress kindling-induced seizure discharge in nonlesioned animals, nor did they suppress seizures when grafted postkindling. Fetal catecholamine-releasing cell grafts were shown to be only moderately effective at suppressing seizure-like activity in a variety of animal models.[33,34] Grafting fetal serotonergic or cholinergic neurons was shown to suppress seizures in epilepsy-prone animals in which these signaling pathways were lesioned.[35,36] Because inhibition is a key deficit in epilepsy, several early attempts to enhance GABA-mediated inhibition have been tried: (1) grafting fetal "GABAergic" neurons putatively derived from the rat embryonic ganglionic eminence (no immunohistochemical confirmation of the cell type was performed) only produced modest effects that were similar to those observed with control cell grafts from the sciatic nerve[37]; (2) grafts of fetal GABA-rich cells into substantia nigra produced transient effects on afterdischarge activity in kindled rats[38,39]; and (3) grafting of an immortalized cortical cell line engineered to produce GABA also produced only a modest suppression of afterdischarge activity.[39,40] Though encouraging, none of these studies demonstrated the ability to selectively generate interneurons that migrate, function, and integrate into host brain in a manner similar to that of the endogenous interneuron cell population.

Although interneuron dysfunction can be a feature of the epileptic brain, and although GABA-enhancing or GABA-mimetic antiepileptic drugs are already in widespread clinical use, a strategy to modify host brain circuitry by exploiting the embryonic source of these cells (i.e., MGE) has only recently been explored. Using rat embryonic day 14 (E14) fetal tissue to generate putative MGE neural stem cells (NSCs) for in vivo grafting into the hippocampus of rats made chronically epileptic by the intraperitoneal injection of kainic acid, Shetty and coworkers reported a reduction in behaviorally monitored seizure frequency and duration.[41] Although it was suggested that increased numbers of new GABAergic interneurons were responsible for the observed suppression of seizure behavior, only 10% of graft-derived cells were immunoreactive for GABA in these studies and whether subdissection of embryonic MGE was performed prior to the derivation of NSC neurospheres was not explicitly described. A more promising study by Zipancic and coworkers[28] described transplantation of E12.5 embryonic MGE progenitor cells into the hippocampus of adult mice 1 week after ablation of a subpopulation of GABAergic interneurons using a neurotoxic saporin conjugated to substance P (SSP-Sap). Gamma-aminobutyric acid-mediated inhibition, shown to be decreased in voltage-clamp recordings of miniature and spontaneous inhibitory postsynaptic currents from hippocampal slices prepared from SSP-Sap mice, was restored to normal levels following MGE transplantation. In additional studies, MGE-grafted SSP-Sap mice were found to be less sensitive to pentylenetetrazole (PTZ)-induced seizures than age-matched SSP-Sap control mice. We also used mouse embryonic MGE progenitor cell transplantations in our attempts to develop an interneuron-based cell therapy for epilepsy. First, we examined the thresholds for induction of seizure activity in wild-type CD1 mice. To induce seizures, we chose the pilocarpine model, as activity is triggered by cholinergic mechanisms and is sensitive to endogenous GABA tone.[42] Acute pilocarpine administration induces ictal and interictal discharge activity in electrographic recordings (Fig. 87–1A), which is correlated with a sequence of behavioral alterations that include akinesia, ataxic lurching, and facial automatisms (Stage II), progressing to tonic-clonic motor seizures (Stage III). Following brief concentration-response

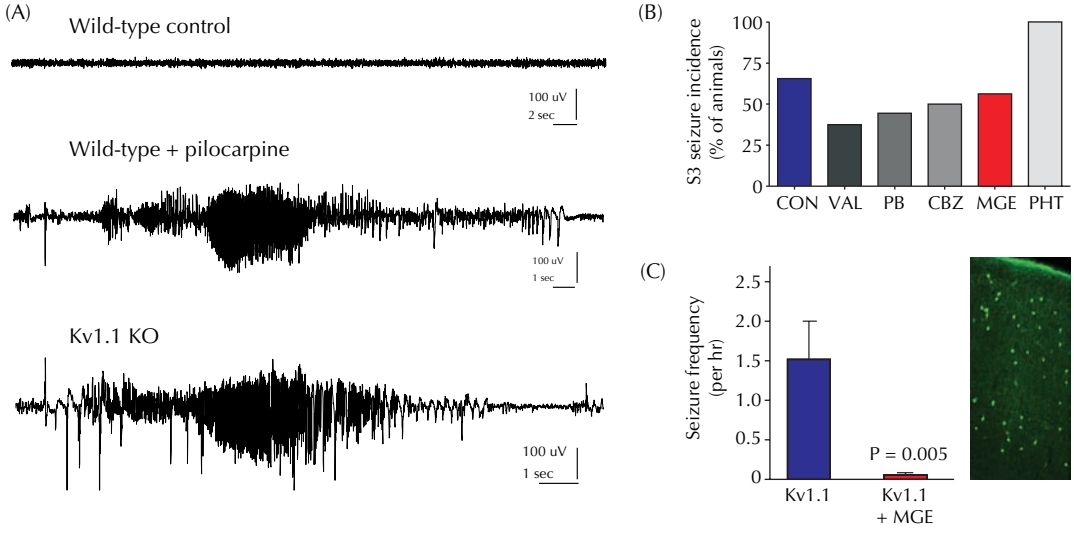

Figure 87–1. Medial ganglionic eminence cell therapy for epilepsy. **A.** Sample EEG traces from a wild-type CD1 mouse (top), a CD1 mouse injected with 300 mg/kg pilocarpine (middle), and a Kv1.1$^{-/-}$ mouse (bottom); seizures are observed as high-frequency, large-amplitude events with durations greater than 45 s. **B.** Plot of the percentage of mice scored as reaching a Stage III seizure in response to pilocarpine. CON, control ($n = 18$); VAL, valproate ($n = 8$); PB, phenobarbital ($n = 9$); CBZ, carbamazepine ($n = 8$); MGE, medial ganglionic eminence ($n = 16$; red bars); PHT, phenytoin ($n = 8$). **C.** Plot of the seizure frequency (measured as EEG-verified seizures per hour) for Kv1.1$^{-/-}$ mice receiving sham surgery or dead cells ($n = 8$) and Kv1.1$^{-/-}$ mice receiving MGE grafts at P2 ($n = 8$). Coronal section of neocortex showing the distribution and spread of MGE-derived GFP-positive neurons in the host brain (inset at the right); the section is approximately 900 mm caudal to the injection site.

studies, a pilocarpine concentration (300 mg/kg, intraperitonal) was chosen that elicits Stage III seizures in approximately 70% of control mice. As an initial demonstration of "seizure protection" conferred by MGE cell grafts, only 55% of grafted mice were observed to exhibit pilocarpine-induced Stage III seizures at 45 days after transplantation; in all grafted animals post hoc immunohistochemistry was used to confirm the presence of at least 40,000 MGE-GFP cells in cortex. To place the MGE graft "protection" data in a therapeutic context, we also preadministered three conventional antiepileptic drugs (AEDs) and measured pilocarpine-induced Stage III seizure incidence. Interestingly, MGE grafts conferred protection that was comparable to that of available AEDs and was clearly superior to at least one, phenytoin (Fig. 87–1B). Next, we tested our early MGE transplantation strategy in Kv.1.1 null mice that mimic a human form of epilepsy associated with mutation of the *Kv1.1/Kcna1* channel. These mice exhibited a spontaneous seizure frequency of at least one tonic-clonic seizure per hour and were shown to be predisposed to sudden unexplained death in epilepsy (SUDEP).[43–45] Medial ganglionic eminence grafts dramatically reduced the frequency of electrographic seizures (Fig. 87–1C) in Kv1.1-deficient mice and when rare electrographic seizure events did occur in grafted animals, they were reduced in duration by over 50%.[30]

POTENTIAL SOURCES OF MGE-LIKE INTERNEURON PRECURSORS

The studies described above provide exciting evidence that interneuron transplantation could become a new therapy for medication-resistant seizures. However, this point begs the obvious question: where would "MGE cells" for such therapy come from? Recently, mouse and human ES cells have been differentiated into ventral telencephalic progenitors that give rise to GABA+ cells.[46–48] One approach is to initially use signaling pathway inhibitors to allow ES cells to take what appears to be, at least for human cells, their default fate of telencephalic, multipotent progenitors.[47,49,50] The progenitors are then ventralized to subcortical fates with

the morphogen Sonic Hedgehog.[48,51] Induced pluripotent stem cells (iPSCs), which are generated by the dedifferentiation of somatic, mitotic cells such as fibroblasts, also default to a telencephalic-like progenitor stage[52] and thus should also be amenable to ventralization into MGE-like progenitors of GABA-producing neurons. Conceivably, the latter approach would permit the generation of interneurons from a patient's own somatic cells.

CONCLUSION

While the above studies demonstrate the feasibility of generating progenitors of GABA+ telencephalic neurons from mouse and human stem cells, none of them determined whether putative MGE-derived cortical interneurons were being generated. This issue is critical since the vast majority of subcortical telencephalic neurons are GABAergic, including several large classes of projection neurons. To achieve this goal, promoter elements from the *Lhx6* gene have been used to generate a mouse ES cell line that, following differentiation to ventral telencephalic progenitors, expresses GFP in putative postmitotic cortical interneuron precursors.[53] Green fluorescent protein-positive cells from this line migrate extensively after transplantation into neocortex, express markers such as PV or somatostatin that define cortical interneuron subgroups, and express intrinsic firing properties typical of these subgroups—for example, critical features of MGE-derived progenitors harvested from the mouse embryo. Promoter elements that impart MGE expression of *Lhx6* downstream of the interneuron fate-determining gene *Nkx2.1* are highly conserved between mice and humans, increasing the likelihood that the same or similar reporter constructs could also be used to isolate cortical interneuron precursors from telencephalon-directed cultures of human ES cells or IPSCs. However, even if this particular approach is successful in generating putative human interneurons, a major challenge will be proving this point, since either very long-term cultures or xenographic transplants with long-term survival will be needed due to the extended period of maturation of cortical interneurons in humans. Of course, it will then be necessary to demonstrate that these integrated cell lines are capable of suppressing spontaneous seizure activity. These caveats aside, the prospect of developing a new cell-based therapy based on transplantation of GABA progenitor cells is an exciting one and clearly merits further study.

Chapter 88

Reversing Disorders of Neuronal Migration and Differentiation in Animal Models

Jean-Bernard Manent
Joseph J. LoTurco

The developing brain has a remarkable capacity for plasticity at both the structural and functional levels. For example, lesions and traumatic injury in the developing rodent neocortex can often be difficult to detect later in life[1,2] and can even trigger new neurogenesis.[3] Similarly, activity-dependent synaptic plasticity is greatest early in development.[4–7] The high degree of plasticity in the developing brain suggests the possibility that after an initially detected disrupted developmental pattern, one that could predispose to seizures, it may be possible to restore a normal developmental state by reactivating appropriate developmental processes to reduce or even prevent the development of seizures.

In this chapter, we review results from animal models that begin to provide evidence that genetically based developmental abnormalities leading to epilepsy can be reversed by reactivating developmental programs. The abnormalities reversed include disruptions in neuronal migration and differentiation. Moreover, molecular genetic and pharmacological interventions in animal models have been shown to reduce morphological disruptions, seizures, and associated behavioral impairments. Significant challenges remain, particularly with respect to translating the approaches used in animal models into viable human therapies. However, the diversity of both the methods used and the disruptions successfully targeted to date should encourage future research and therapy development in this area.

REVERSAL OF A MODEL OF SUBCORTICAL BAND HETEROTOPIA

Disorders in neuronal migration cause aberrations in the normal patterns of cellular

architecture, including alterations in lamination of the neocortex.[8,9] The term *neuronal migration disorder* (NMD) has come to encompass a number of syndromes, including lissencepahly and subcortical band heterotopia. Alterations that occur in cytoarchitecture and structure in NMD are diverse in terms of type and severity.[10] Disruptions range from subtle, only seen with microscopic analysis in isolated regions, to major disruptions covering large regions of the brain and easily apparent with magnetic resonance imaging (MRI). Genetic studies have now revealed many gene mutations that cause syndromes associated with disorders in neuronal migration and abnormal development of the human neocortex.[9,11] Studies focusing on the functions of the products of these genes have, in turn, revealed proteins and pathways required for distinct stages in neocortical development.[10]

Neuronal migration disorder has come to include a variety of early developmental disruptions that may cause displacement of neurons from the typical pattern. It is, however, important to appreciate that the actual underlying disruption that causes NMD may not be a direct deficit in the process of neuronal motility or migration during development. For example, changes in cell proliferation, cell death, cellular differentiation, or cellular adhesion can all cause disruptions in normal cellular patterns of the neocortex. Changes in any of these may alter the movements and ultimate positioning of neurons by blocking or changing physical pathways, or by altering a pattern of cellular growth, without causing any direct change in an immature neuron's intrinsic ability to move or migrate. Nevertheless, mispositioned neurons, independent of how they became mispositioned, could theoretically be repositioned by reactivating a neuronal migration program in those neurons.

Subcortical band heterotopia (SBH) and lissencephaly are both caused by defective neuronal migration during fetal brain development. Subcortical band heteropia is associated with mild to moderate mental retardation and intractable epilepsy in most patients.[12,13] The majority of individuals with SBH are females with mutations in the X-linked gene doublecortin (*DCX*) that encodes a microtubule-binding protein essential to neuronal migration.[14,15] *DCX* mutations in males usually cause anterior lissencephaly, but SBH associated with *DCX* mutations has also been described rarely in males.[16]

Subcortical band heterotopia is the type of malformation that is most clearly a direct consequence of stalled migration in the developing neocortex [17]. In its extreme form, a large band of cells can form a separate mass of gray matter throughout cortex, and the presence of such a large SBH has been referred to as *double cortex syndrome*.[17] During the formation of SBH malformations, many neurons fail to migrate through the intermediate zone and into normally forming cortical lamina, becoming embedded within what will become the white matter of neocortex. With enhanced MRI imaging methods the identification of small, potentially benign areas of SBH has increased, and small SBH-like aggegates of cells are often a feature of type I focal cortical dysplasias.[18–20]

Heterotopia of any type in which subsets of neurons and glia occupy abnormal positions, while others migrate and pattern normally within the same area, suggests a degree of somatic mosaicism in neuronal migration disorders. How such mosaicism occurs is clear for two X-linked genetic causes of heterotopia: periventricular heterotopia and SBH. Heterozygous mutation in the *DCX* gene in females is the most common cause of SBH.[21,22] Random X-inactivation in somatic cells naturally creates a cellular mosaic. Heterozygous *DCX* mutations combined with X-inactivation result in some cells with an active copy of the mutant gene, and these cells fail to migrate into normotopic cortex [14,23]. Somatic mosaicism may also occur from somatic mutations in early stages of embryonic development, creating a mixture of cells with functional and nonfunctional copies of genes essential to migration. Evidence for this type of mosaic pattern has been found by genotyping hair follicles in some SBH cases and finding a mosaic pattern of *DCX* or *LIS1* mutation[24,25]. Such somatic mosaicism in *DCX* mutations can be a cause of SBH in males.[26] Because many, and often most, neurons attain a normal position in mosaic disruptions of neuronal migration, the general substrates necessary for neuronal migration, radial glia and neurons, may be sufficiently intact to guide additional migration if stalled cells could be reactivated to migrate.

The clinical features of SBH show a wide range of severity, but typical deficits are mental retardation with a high incidence of seizures.[27–29]

Importantly for the prospects of reversing the neurological effects of heterotopia, the size of SBH is correlated with the severity.[27,28] The primary reasons for a range in the size of SBH in different cases may be due to the natural variation of random X-inactivation or the specific causative *DCX* mutation, with some mutations causing larger malformations than others. Some milder mutations can even cause SBH in males in which lissencepahly is the typical result. Some migrating cortical neurons may be able to migrate normally even with a defective copy of the *DCX* gene.

Although SBH malformations do not form in mouse genetic models of *Dcx* loss of function,[30,31] Bai and colleagues showed that a rat model for SBH can be generated efficiently by knocking down *Dcx* expression with in utero RNA interference (RNAi). RNA interference targeting of *Dcx* expression in a subset of migrating neurons caused a mosaic of migratory arrest, and *Dcx*-deficient neurons formed the core of an SBH.[32] This model accurately reproduces the main genetic and anatomical features of the human disease, and is also associated with aberrant network activities[33] and spontaneous seizures in the animal model.[34]

Subcortical band heterotopia formation in the RNAi model was shown to be prevented with concurrent expression of *Dcx* in the rat fetus.[35] Manent and colleagues further tested whether delayed reexpression of *Dcx* in already formed SBH after birth could restimulate a developmental program that would lead to SBH regression.[36] Temporal control of *Dcx* reexpression was obtained using a system of drug-inducible DNA plasmid expression vectors that allowed conditional expression of *Dcx* upon injection of 4-hydroxy-tamoxifen (4-OHT). Strikingly, reexpressing *Dcx* stimulated neuronal migration in aberrantly positioned neurons stalled in SBH, leading to both SBH regression and relocation of neurons to their correct laminar destination in the cortex (Fig. 88–1A–D). Moreover, whereas animals with SBH were more sensitive to the induction of seizures by convulsants (Fig. 88–1E,F), animals with regressed SBH showed levels of sensitivity to convulsants no different from those seen in malformation-free controls (Fig. 88–1E,F). Morphological rescue in terms of reduction of the SBH had a critical period and was restricted to early postnatal ages. Restarting migration was no longer possible by the middle of the second postnatal week in the rat model. These observations presented the first proof of concept that neuronal migration disorders may eventually be treatable by molecular or pharmacological interventions aimed at restarting migration to reduce malformations and the neuronal hyperexcitability associated with their presence. The Manent et al. study also suggested that such interventions, at least for migration disorders, may have a critical period to be most effective.

Significant challenges remain for restarting migration caused by deficiencies in *Dcx*, including extending the window for reinitiating migration to later developmental periods and applying gene delivery approaches that do not require fetal surgery. The Manent et al. study examined a relatively narrow period of reactivation and did not extend observations after reexpression of *DCX* to periods longer than 3 weeks. In addition, several *DCX*-interacting proteins, including *LIS1*, are required for migration, and if these decrease in expression or function as well, then they may also need to be reexpressed to restart migration in stalled cells.

PHARMACOLOGICAL RESCUE IN A MODEL OF LISSENCEPHALY

Classical lissencephaly in human patients is caused primarily by mutations in either the *DCX* or *LIS1* genes.[21,37–41] Miller-Dieker syndrome is a severe neurodevelopmental disorder that involves lissencephaly as well as other disruptions in central nervous system (CNS) structure. The syndrome is caused by deletions or translocations involving the short arm of chromosome 17 and heterozygous mutations of at least the two genes *LIS1* and *YWHAE*. Isolated lissencepahly (iLIS), without all the defining features of Miller-Dieker syndrome, can be caused by mutation in *LIS1* alone. Miller-Dieker syndrome is characterized by pachygyria[42] and, compared to X-linked lissencepahly (XLIS), caused typically by mutations in *DCX*, has a greater degree of agyria in posterior and occipital regions of the cortex.[43,44] Miller-Dieker syndrome is also associated with enlarged ventricles, hypoplasia of the corpus callosum, and hypoplasia of the cerebral peduncles and cerebral pyramids, further adding to the severity of the neural disruption. Miller-Dieker syndrome and iLIS

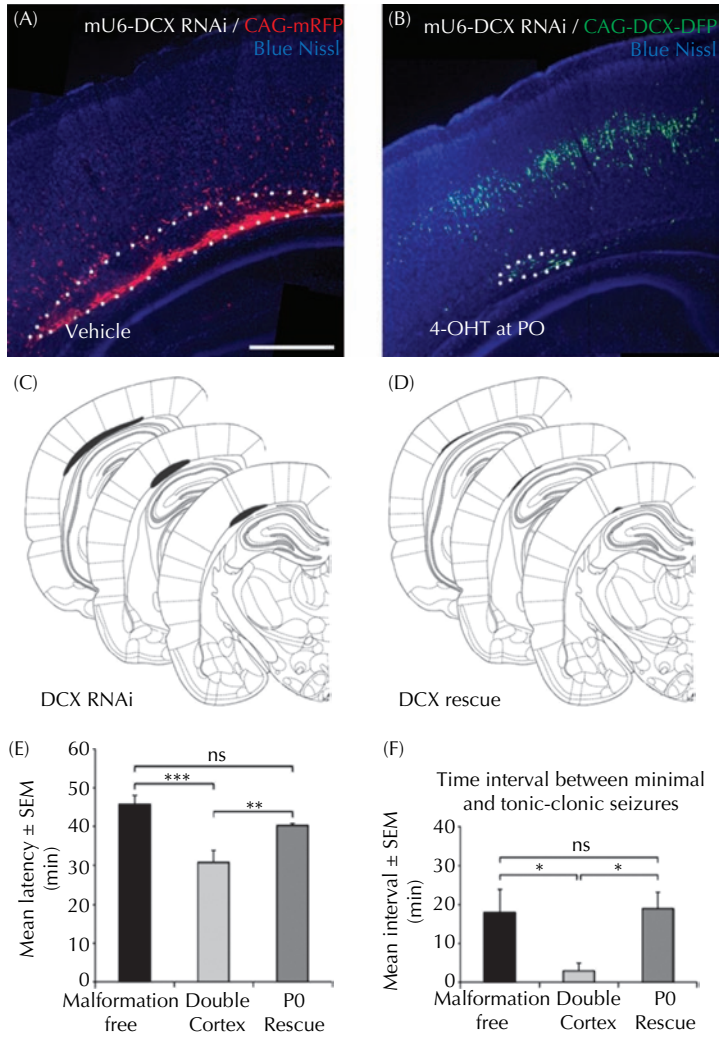

Figure 88–1. Rescue by reexpression of *Dcx* of SBH in a rat model of NMD. **A.** Subcortical band heterotopia is indicated by the dotted line and aggregates of monomeric red fluorescent protein (mRFP)-labeled (red) neurons just below the normatopic neocortex. The SBH was created by RNAi against *Dcx*. **B.** Greatly reduced SBH in a brain in which *Dcx* was reexpressed. Green fluorescent protein was used to mark the cells manipulated in **B**, and red fluorescent protein was used to mark the cells in **A. C,D.** Serial section reconstruction of SBH remaining in a control brain, an RNAi- alone brain (**C**), and a *Dcx* rescue brain in which *Dcx* was reexpressed after birth (**D**). **E,F.** *Dcx* reexpression at P0 (P0 rescue) restored the response to a ramped dosage of the convulsant PTZ to levels similar to those of malformation-free animals. This was seen both in the latency to the first induced seizure (**E**) and in the time interval between minimal seizure signs and the first generalized tonic-clonic seizure episode. Adapted from ref. 36.

patients show severe to profound mental retardation and early-onset seizures that may lead to intractable epilepsy. Seizures start early in life, near birth to 4 months of age,[45] and there is a significantly shortened lifespan.[46] The clinical severity of lissencepahly, like that of SBH, correlates with anatomical measures of morphological and neurodevelopmental disruption and genetic mutation.[47]

The *LIS1* gene, also known as *PAFAH1B*, codes for a protein initially described as a subunit in the enzyme for processing platelet activating factor (PAF). It was the first gene to be shown to be involved in lissencephaly when mutated.[38] Its role in neuronal migration has not been found to be linked to PAF activity; instead, it functions primarily in neurodevelopment through interactions with

dynein, microtubules, 14–3-3 epsilon protein, and nudel protein. The genetic evidence for Miller-Dieker syndrome and the protein interaction evidence for *LIS1* and *YWHAE* are consistent.[48] In addition, *LIS1-NDEL1* interaction plays a well-conserved role throughout biology in the movement of nuclei within cells.[49]

Heterozygous loss of *Lis1* function in mutant mice, as in humans, causes migration disruptions that result in disorganized lamination of the neocortex, hippocampus, and olfactory bulb[41] and epilepsy. Inspired by the finding that *LIS1* is degraded by calpain-dependent proteolysis, Yamada and colleagues[50] tested whether inhibition of calpains could increase *LIS1* protein abundance and effectively bring the expression levels of the heterozygous mutant back to wild-type levels, and if so, reverse the developmental disruptions. Yamada et al. showed that either treatment with calpain inhibitors or knockdown of calpain expression by small interfering RNA (siRNA) improved the abnormal cellular phenotype caused by heterozygous loss of *Lis1* in cell culture. They also showed that treatment with calpain inhibitors rescued migration of $Lis1^{+/-}$ cerebellar granule neurons from heterozygous mutant mice in an in vitro migration assay. These in vitro observations were followed by experiments in which calpain inhibitors were administered to pregnant $Lis1^{+/-}$ mice during embryonic corticogenesis. Remarkably, both pharmacological inhibition and knockdown of calpain in vivo rescued defective neuronal migration and abnormal cortical and hippocampal layering in heterozygous mutant pups ($Lis1^{+/-}$) born to treated mothers. Therefore, pharmacologically increasing Lis1 protein abundance normalized neurogenesis, and neuronal migration by blocking Lis1 protein degradation was sufficient to partially reverse the neuro-morphological deficit.[50,51] Pharmacological restoration of Lis1 protein levels by inhibition of calpain also ameliorated behavioral symptoms in $Lis1^{+/-}$ mice.[50,51] Whereas untreated $Lis1^{+/-}$ mice displayed abnormal motor behavior, $Lis1^{+/-}$ mice embryonicaly treated with calpain inhibitors showed significant levels of improvement in motor function. Considering the potential to reverse developmental insults even after birth, as revealed in the *DCX* reexpression experiments, it would be interesting to test whether calpain inhibition after the onset of early migration disruption phenotypes in neonatal animals can rescue the migration alterations in $Lis^{+/-}$ mutants. In addition, normalization of neural excitatability and the seizure risk in this model has not yet been fully characterized, but considering the nearly complete rescue of motor behaviors by calpain inhibition, seizures are also likely to be ameliorated.

REVERSAL OF NEURODEVELOPMENTAL DISRUPTION BEYOND NEURONAL MIGRATION DISORDERS

Molecular rescue of neurodevelopmental disorders after the onset of neurological and neuromorphological changes is not restricted to the two examples of NMD described above. Several experiments involving rodent models of Rett syndrome, caused by mutations in the gene *MECP2* and models of tuberous sclerosis complex (TSC) have been used to test both molecular genetic and pharmacological rescue of neurodevelopmental disorders. The late rescue of genetically based neurodevelopmental disorders may therefore be a general phenomenon, not restricted to disorders of neuronal migration.

Genetic Rescue of Rett Syndrome

Luikenhuis and colleagues[52] engineered a transgenic mouse strain (*Tau-Mecp2* knock-in) such that *Mecp2* expression was placed under the control of the Tau promoter to drive neuron-specific embryonic expression of *Mecp2* in mutant animals. Unlike *Mecp2-null* mutant mice that displayed reduced weight and brain size and exhibited impaired locomotor and exploratory activity, offspring of *Mecp2-null* mice mated to *Tau-Mecp2* mice were indistinguishable from wild-type animals and displayed no Rett syndrome-like symptoms. These observations indicated that reexpressing *Mecp2* in *Mecp2*-deficient neurons was sufficient to reverse Rett syndrome-associated developmental impairments.

Reexpression of *Mecp2* later in development as a means to prevent the Rett phenotype was tested in a study by Giacometti and colleagues.[53] A mouse was produced carrying

a conditional "*Mecp2* rescue transgene" engineered so that the *Mecp2* coding sequence was placed downstream of a lox-Stop-lox (LSL) cassette. These *LSL Mecp2* mice were then crossed with *Mecp2-null* mutants to generate animals carrying the *Mecp2-null* allele as well as the conditional "rescue" construct. In order to test whether *Mecp2* reexpression at late embryonic and postnatal ages could ameliorate the Rett syndrome-like phenotype, the investigators crossed *LSL Mecp2;Mecp2-null* double mutants with Cre-expressing transgenic mouse lines to induce reexpression of *Mecp2* in the brain at either early embryonic or postnatal periods in development. Whereas *Mecp2-null* mice developed Rett syndrome-associated symptoms and died early, mice in which *Mecp2* expression was reintroduced at embryonic ages displayed significantly delayed behavioral alterations and an increased lifespan. Similarly, mice in which *Mecp2* expression was reintroduced at early or even late postnatal ages displayed significant improvements including an increased lifespan. Reexpressing *Mecp2* at presymptomatic postnatal ages positively affected the course of the disease and significantly ameliorated Rett syndrome-like symptoms. Guy and colleagues[54] used a slightly different strategy. They created a mouse in which the endogenous *Mecp2* gene was silenced by insertion of a LSL cassette that could be conditionally deleted using Cre-mediated excision to activate the gene later in development. This mouse was crossed with a mouse carrying a tamoxifen-activatable Cre transgene so that the endogenous *Mecp2* gene in the offspring could be reactivated upon tamoxifen-induced deletion of the LSL cassette. In this model, when an active copy of *Mecp2* was restored in males at an age after which they exhibited advanced symptoms, the animals significantly improved their behavioral scores and had an increased lifespan.[54] Similarly, in postnatal female mice with advanced behavioral symptoms, a significant reversal of both behavioral and electrophysiological deficits associated with the Rett syndrome-like phenotype was observed when an active copy of the *Mecp2* gene was activated. Together, these reexpression studies in different Rett syndrome models indicate that the neurological deficits associated with *Mecp2* deficiency can be reversed by reintroduction of the gene even after the appearance of the first developmental deficits.

Pharmacological Rescue of TSC

Mutations in the *Tsc1* or *Tsc2* genes cause TSC and result in hyperactivatation of the mammalian target of rapamycin (mTOR) pathway.[55,56] Several research groups hypothesized that treating TSC model animals with the mTOR inhibitor rapamycin or its derivates could lead to phenotypic ameliorations.[57] Zeng et al. first investigated this issue in the astrocyte-specific TSC mouse model by administering rapamycin at presymptomatic or symptomatic stages of the disease in mice with mutated conditional alleles of *Tsc1*.[57] Rapamycin treatment prevented the development of seizures and significantly increased the lifespan of conditional *Tsc1* mutant mice. Remarkably, late rapamycin treatment in already symptomatic animals also decreased seizures and improved survival. Moreover, both early and late treatment resulted in reduced morphological signs of decreased *Tsc* function, including astrogliosis and disorganization in hippocampal lamination. In similar experiments, Meikle and colleagues carried out experiments in the neuron-specific TSC mouse model[58] and administered rapamycin or 40-O-(2-hydroxyethyl)-rapamycin (RAD001, also called *SDZ RAD* or *everolimus*) to postnatal day (7–9 (P7–9) animals for up to 100 days. Whereas *Tsc1*$^{\text{null-neuron}}$ mice displayed hyperactivity, postural and behavioral abnormalities, poor weight gain, and development of seizures and died at P33, both rapamycin- and RAD001-treated mice showed clinical improvement. Postural and behavioral abnormalities, weight gain, and survival were significantly improved in long-term treated animals, as well as in animals in which treatment was stopped after 30 days. Moreover, some histopathological improvement was obtained, including reduced neuronal hypertrophy and increased myelination.[58] Disorganized cortical lamination, abnormal cortical neurons, dendritic orientation, and reduced spine density remained unchanged. Interestingly, some histopathological amelioration was transient and progressively reversed after cessation of drug treatment, while major clinical benefits persisted for several weeks after the treatment was stopped.

Models of *Tsc2* loss can also be rescued with rapamycin. Ehninger and colleagues administered rapamycin to adult *Tsc2*$^{+/-}$ mice and observed a remarkable restoration of impaired spatial learning deficits, context discrimination,

and an abnormal late-phase long-term potentiation (LTP) threshold.[59] Importantly, learning and memory deficits were ameliorated even after brief rapamycin treatment periods. In the same study, the authors treated heterozygous neuron-specific *Tsc1*^{null} mice with a similar rapamycin regimen. Whereas *Tsc1*$^{null\text{-}neuron}$ mice displayed severe brain abnormalities such as macrocephaly, neuronal hypertrophy, and astrogliosis and exhibited neurological impairments, after rapamycin treatment mice showed significantly improved motor behavior, an increased lifespan, and decreased brain size.[59] This suggests that rescue for some phenotypes in TSC models does not depend upon reversal of morphological developmental defects.

The tumor suppressor gene *PTEN* (phosphatase and tensin homolog on chromosome 10) is a negative regulator of the mTOR signaling pathway, and *PTEN* mutations have been identified in several clinical disorders grouped as *PTEN*-hamartoma tumor syndromes.[60] Ljungberg and colleagues analyzed *Pten*^{loxP}; *GFAP-Cre* mice (referred to as *NS-PTEN* mice in their study) and observed that these animals display widespread neurodevelopmental abnormalities.[61] In addition to the presence of enlarged cortical, hippocampal, and cerebellar structures, detailed analysis of Pten immunolabeling revealed the presence of significant numbers of Pten-negative glutamatergic neurons with abnormal hypermorphic morphology in the neocortex. Moreover, the mTOR pathway was found to be hyperactive in these neocortical neurons, consistent with the previously described role of Pten in this pathway. As previously shown by Kwon et al., *NS-PTEN* mice after a few weeks of age exhibited mainly subclinical spontaneous epileptiform activity that often evolved to tonic-clonic seizures.[62] Altogether, these observations led Ljungberg and colleagues to propose that *NS-PTEN* mice could be considered as a model of focal cortical dysplasia (FCD), recapitulating some physiopathological aspects of the human disease, namely, hypermorphic cortical neurons and spontaneous epileptic manifestations. Similar to a previous study, the authors hypothesized that treating animals with the mTOR inhibitor rapamycin could restore mTOR activity. Indeed, after 2 weeks of treatment with rapamycin, they found a significant decrease in mTOR activity and reduced hypertrophy of neurons. As dysregulated mTOR activity was found in patients with FCD, hemimegalencephaly, and TSC, the authors concluded that modulating mTOR activity in such patients may help to control seizures resistant to AED therapy and/or epilepsy surgery.[61] The results also suggest that FCDs that result from developmental disruption in an earlier developmental period can be ameliorated in terms of both neuroanatomical abnormality and seizures.[61] This serves as another dramatic example of an intervention after a malformation or developmental disruption reversing in part the developmental abnormality.

SUMMARY AND FUTURE CHALLENGES

Reactivation of migration in molecularly and genetically defined models of NMDs, SBH, and lissencepahly can reduce the morphological and behavioral impairments associated with these NMDs in animal models. Future studies must now extend these approaches to other neurodevelopmental disorders, including NMD caused by mutations in genes other than *Lis1* and *Dcx,* as well as migration disruption caused by environmental insults or trauma. In addition, alternative pharmacological and molecular approaches that may be more amenable to human therapy than the ones used so far need to be tested in animal models.

Gene therapy approaches, both viral and virus-free, have advanced significantly in the past several years.[63–66] For example, adeno-associated virus technologies have approached a level where genes can be reintroduced safely into primates.[63,64] Different serotypes effectively create stable transgenesis with little or no toxicity in neurons and glia. Similarly, nonviral liposomal-mediated transgenesis has progressed rapidly and has been shown to be successful in treating animal models of neurological disease.[63,64] These two technologies should now be tested in neurodevelopmental models to attempt to genetically reactivate developmental pathways and genes in a way that does not require the use of specialized genetic models that allow for conditional gene expression. Alternatives to gene therapy should also be tested in neurodevelopmental disorders. Indeed, as already shown for inhibition of calpain in *Lis1* mutants and rapamycin

treatment in TSC models, it is possible to overcome impaired developmental pathways either directly or indirectly. Specific small molecule screens might be successful in identifying novel agents to enhance pathways impaired by loss of specific genes.

Chapter 89

Gene Therapy of Focal-Onset Epilepsy Using Adeno-Associated Virus Vector-Mediated Overexpression of Neuropeptide Y

Francesco M. Noè
Andreas T. Sørensen
Merab Kokaia
Annamaria Vezzani

Although various new antiepileptic drugs (AEDs) with diverse mechanisms of action have been developed in the last 15 years with improved tolerability and pharmacokinetic properties,[1,2] there has been relatively little improvement in their ability to control pharmacoresistant epilepsies compared to traditional AEDs. Thus, about 30% of patients with epilepsy still have seizures that are resistant to available AEDs. Drug-resistant epileptic patients are considered for surgical resection of the epileptic focus: this invasive procedure, however, is suitable only for a minority of them and results in complete control of epilepsy (seizure freedom without AEDs) in about 30% to 50% of cases, according to a 5- to 10-year follow-up study.[3] Additionally, most AEDs provide symptomatic suppression of seizures without apparently interfering with the mechanisms involved in the epileptic process.[4,5] Currently, AEDs mainly target neurotransmitter receptors, mechanisms of neurotransmitter release or reuptake, or ion channels.[1] There is therefore an urgent need to find novel treatment strategies, particularly for the most refractory forms, such as temporal lobe epilepsy (TLE).[4,6]

As an alternative approach to pharmacotherapy, preclinical studies in models of seizures

and epilepsy are addressing the possibility of suppressing seizures by inducing the overexpression of neuromodulatory molecules in the area(s) of seizure origin or propagation. This may be achieved using gene therapy that has been developed, and clinically applied, in other neurological disorders.[7–12] The intent of experimental studies is to establish the proof-of-concept evidence that gene therapy may be envisioned as a novel therapeutic approach to control drug-resistant seizures in focal-onset epilepsies.

GENE THERAPY IN THE CENTRAL NERVOUS SYSTEM AND THE CHOICE OF TOOLS FOR GENE DELIVERY

Gene manipulation in the central nervous system (CNS) encounters specific problems related to the presence of the blood-brain barrier, which is impermeable to many xenobiotics (including carriers that may be used to deliver the therapeutic gene into the brain). Furthermore, gene therapy must target cells in a defined brain area with a specific function relevant to epilepsy. Finally, most cells in the CNS are postmitotic and therefore inadequate for gene transduction with vectors requiring DNA integration.

Neurotropic adeno-associated viral (AAV) vectors are the tool of choice for gene delivery into brain tissue and consequent neuron transfection. These vectors can efficiently express single or multiple transgenes together with a wide range of regulatory elements; they are nonpathogenic and appear to be innocuous for normal brain physiology.[13,14] For these reasons, AAV is considered a safe vector for gene transfer and has been used in various clinical trials (see http://www.clinicaltrials.gov).

For gene therapy purpose, recombinant (r)AAV vectors are used[15,16] in which all viral genes encoding wild-type viral proteins are removed to avoid viral replication and reduce toxicity and immunogenicity while permitting the insertion of therapeutic genes with a length of up to 4.7 kb.

There are several serotypes of rAAV that can be used for gene transfer in the CNS, each of them possessing a distinct cellular tropism that depends on the expression of cell membrane receptors that can mediate vector transport inside the cells: heparan sulfate proteoglycans are the main receptors for AAV serotype 2; AAV serotype 1 binds to α2,3 and α2,6 sialic acids, which are present on N-linked glycoproteins. This evidence suggests that it is possible to use different serotypes, or even modify the capsid composition of the viral vector, for targeting specific cell populations. Moreover, it is possible to use specific promoters or other regulatory elements[17] to generate cell- and tissue-specific gene expression.

Gene therapy techniques in epilepsy are designed to successflully transfer a putative therapeutic gene, and its related protein, into the ictogenic brain area(s) and express them, thus permitting long-term CNS expression of neuromodulatory molecules with potential anticonvulsive, neuroprotective, and antiepileptogenic properties. Two main approaches have been developed for the transfer of a specific gene into the CNS: the ex vivo approach, consisting of in vitro genetic modifications of cells that are then transferred into the brain to provide a source of release of the therapeutic molecule, and the in vivo approach that allows direct transgene transfection in the brain using viral vectors or systemic delivery of the genes using strategies that favor their brain penetration, such as immunoliposomes.[18,19] Up to now, in vivo direct brain gene transfer has been used more frequently for introducing genes into postmitotic cells such as neurons and to promote long-term expression of the related proteins.[20]

There is a wide range of potential therapeutic targets that could modulate neuronal activity in vivo and inhibit hyperexcitability. The selection of the appropriate therapeutic gene is one crucial aspect of gene therapy for epilepsy.

GENE THERAPY: THE CHOICE OF THE THERAPEUTIC GENE

So far, therapeutic genes have been used to decrease the effect of excitatory neurotransmitters (e.g., using antisense sequences against *N*-methyl-D-aspartate [NMDA] receptor subunit 1),[21] to increase inhibitory neurotransmission (e.g., gamma-aminobutyric acid A [$GABA_A$] receptor subunit α-1, glutamic acid decarboxylase 65 [GAD65], adenosine kinase),[22–24] and to

enhance the release of neurotrophic factors, such as glial cell-derived neurotrophic factor (GDNF),[25] brain-derived neurotrophic factor (BDNF), and fibroblast growth factor (FGF),[26] or neuropeptides with anticonvulsant properties such as galanin[27,28] and neuropeptide Y (NPY).[29,30]

Recent studies have focused on endogenous neuropeptides with neuroprotective and neuromodulatory functions. Indeed, in contrast to classical neurotransmitters, neuropeptides are preferentially released by neurons during high-frequency neuronal activity, such as during seizures, while they do not appear to contribute significantly to synaptic transmission in physiological conditions,[31–33] thus reducing the chances of ensuing side effects by targeting these systems.

THE FOCUS ON NPY

Both galanin and NPY are peptides with powerful anticonvulsant properties in various experimental models of seizures.[34,35] Both peptides inhibit glutamate release, via different mechanisms, and this effect appears to be mainly responsible for their anticonvulsant actions.[29,36] Gene therapy approaches using either galanin or NPY as transgenes have been developed to reduce seizures. In this chapter, we will focus on preclinical studies related to NPY overexpression mediated by AAV vectors.

Changes in the Endogenous NPY System during Seizures

Overexpression of NPY in the hippocampus and temporal cortex has been described in several models of seizures and in human brain tissue from TLE patients. [29,37,38]
In the hippocampus, seizure-induced NPY overexpression occurs both in interneurons, where NPY is physiologically colocalized mainly with GABA and/or somatostatin, and ectopically in granule cells of the dentate gyrus and in CA1 pyramidal neurons.[35] The changes in peptide expression are concomitant with modifications in NPY receptor subtypes (i.e., Y2 receptors are increased on presynaptic glutamatergic terminals, whereas Y1 receptors are decreased on granule cell dendrites) and are accompanied by increased NPY release,[29,35,39,40] thus suggesting that NPY-mediated neurotransmission is altered in the epileptic tissue. A similar pattern of NPY changes was reported in patients with intractable TLE,[38] except for the long-lasting ectopic expression of NPY in granule cells and their mossy fibers, typically observed in seizure models but lacking in human epileptic tissue.[29]

The anticonvulsant effect of NPY is mainly ascribed to its release from hippocampal GABAergic interneurons, as well as from glutamatergic mossy fibers terminals. Acting on presynaptic Y2 receptors localized on glutamatergic terminals, NPY inhibits glutamate release,[41,42] thus reducing the excitability of the trisynaptic pathway of the hippocampal formation.[42,43] One main action of NPY is to block the synchronization of granule cell discharge, thus inhibiting epileptiform activity dependent on the recurrent collaterals of mossy fibers.[40,44] Y5 receptors in granule cells of the dentate gyrus and in pyramidal cell layers may also contribute to NPY inhibitory actions,[45,46] although this possibility has been challenged in in vitro and in vivo studies.[47,48]

In experimental models of seizures, intracerebral administration of NPY[29] or Y2/Y5 receptor agonists[49–51] resulted in strong anticonvulsant effects[37] (Table 89–1). Accordingly, the susceptibility to seizure was decreased in transgenic rats overexpressing NPY in CA1 pyramidal neurons,[52] whereas mice with NPY or Y2 gene deletion were more susceptible to seizures.[48,53] Moreover, NPY suppressed epileptiform activity and attenuated excitatory responses in dentate granule cells evoked by perforant path stimulation in brain tissue surgically resected from medically intractable TLE patients.[54]

These findings suggest that increased NPY-mediated neurotrasmission during seizures represents a homeostatic mechanism to counteract hyperexcitability. Moreover, anticonvulsant effects can be achieved by increasing endogenous NPY actions by pharmacological or genetic manipulation.

GENE THERAPY WITH NPY IN SEIZURE MODELS

AAV-Mediated NPY Overexpression

To study the expression of the NPY transgene in the CNS using gene therapy approaches, the

Table 89–1 **Anticonvulsant Effects of NPY Injected in Rodent Seizure Models**

human pre-pro-NPY cDNA sequence has been cloned into a highly purified recombinant rAAV vector. Rat and human NPY cDNAs have a remarkable degree of homology (about 75% in the translated region) and are identical in their amino acid sequence in the mature form.[61] Recombinant rAAV vectors with different serotypes have been tested in rats in order to develop the most suitable vector for clinical application: a nonimmunogenic and nontoxic vector able to transfect hippocampal neurons and to express NPY long-term at sufficiently high levels and in a releasable form.

Serotype 2 (rAAV2), chimeric serotype 1/2 (rAAV1/2), and serotype 1 (rAAV1) vectors have been used in different sets of experiments. The rAAV2-NPY vector increased peptide expression in hilar interneurons only,[62] while chimeric rAAV1/2 (expressing capsid surface proteins of both serotype 1 and serotype 2) and rAAV1-NPY vectors mediated more widespread expression, including granule cells and their mossy fibers, and pyramidal cells in the hippocampus and the subiculum.[62,63]

Two different promoters have been tested on the backbone of serotype 2 plasmid, namely, neuron-specific enolase (NSE) and cytomegalovirus (CMV)-chicken β-actin (CBA) promoters. The neuron-specific enolase promoter leads primarily to expression of gene products in neurons, providing a good level of specificity; CBA is a very powerful promoter that provides higher levels of protein expression in neurons for at least 18 months postinjection.[64]

Using the NSE promoter, the hippocampal injection of rAAV2-NSE-NPY vector induced transgene expression for about 1.5 mm around the injection site. Using the chimeric rAAV1/2-NSE-NPY vector, or the CBA promoter coupled to chimeric or to AAV1 serotypes (rAAV1/2-CBA and rAAV1-CBA-NPY vectors), a larger spread of the transgene was obtained (i.e., about 2.5 mm around the injection site).[62,63] Moreover, NPY immunoreactivity was increased to the greatest extent in neurons for at least 6 months using the CBA promoter (unpublished data).

High-performance liquid chromatography (HPLC) analysis demonstrated that NPY encoded by transduced neurons elutes with the synthetic rat peptide.[30] In situ hybridization analysis of mRNA sequence specific for the vector genome, as well as peptide immunohistochemistry, showed that NPY expression was confined to neurons within the hippocampal formation and did not spread outside the injected hippocampus, except for its axonal transport to synaptic terminals in the contralateral hemisphere.[62,63] Neurochemical experiments in hippocampal slices from rAAV-NPY-injected rats showed that NPY is released by neurons only under high potassium chloride (KCl) depolarization (about 10-fold more than control slices), and in vivo electrophysiology confirmed that transduced NPY is released by high-frequency stimulation.[30,33] Overexpression of NPY was associated with decreased levels of Y1 receptors likely due to peptide-induced

internalization,[65] while the levels of Y2 receptors were unchanged.[30]

Anticonvulsant Effects Mediated by Transgene NPY

Hippocampal rAAV-mediated NPY overexpression in rats was associated with powerful anticonvulsant effects in various rat models of seizures and epilepsy (Table 89–2). The first study was carried out in a rat model of acute focal seizures induced by intrahippocampal administration of kainic acid: the overexpression of NPY was driven by the NSE promoter, resulting in 50% or 75% seizure reduction when the serotype 2 or chimeric serotype 1/2 vector, respectively, was used.[62] Thus, the greater levels of NPY produced with the chimeric vector provided more effective seizure control. When the CBA promoter and the chimeric rAAV1/2 or rAAV1 vector were used, the number of focal seizures was also significantly reduced.[63] Total focal seizure duration was decreased in all experimental settings, up to 70% in rats injected with the serotype 1 vector. Moreover, status epilepticus induced by intraventricular injection of kainic acid in rats could not be evoked in rats injected with the rAAV1/2-NSE-NPY vector. Thus, continuous epileptic activity recorded electroencephalographically in the hippocampus and in the overlying cortex was precluded in NPY-overexpressing rats, as well as clonic motor seizures that were instead observed in control animals.[62] These findings showed that NPY overexpression results in reduction of focal seizure activity and anticipates a role for this peptide in reducing seizure generalization as well, as subsequently demonstrated in kindling and using systemic administration of chemoconvulsants.[33,62,66,67]

To address the antiepileptogenic potential of this gene therapy approach, we used the rapid hippocampal kindling model; rats injected with the rAAV1/2-NSE-NPY vector showed a significant delay in acquisition of generalized seizures, a significant increase in the threshold current for inducing a local afterdischarge, and a decrease in afterdischarge duration.[33,62] A subsequent study supported and extended these findings[66] by demonstrating that rAAV-mediated overexpression of NPY13–36, a peptide fragment that activates Y2 receptors, in the rat piriform cortex attenuates generalized limbic seizures induced by systemic kainate. In this set of experiments, the authors used a rAAV vector construct that included insertion of the secretion signal sequence of fibronectin, which promotes the *constitutive release* of the encoded peptide, as opposed to the *regulated release* mediated by the above-described vectors.

The inhibitory effects mediated by NPY overexpression on status epilepticus and the associated motor seizures, as well as on kindling progression, demonstrate a prominent reduction of seizure generalization.

Importantly, rAAV-NPY-based gene therapy was reported to be effective in reducing spontaneous recurrent limbic seizures when injected in the hippocampus of chronic epileptic rats mimicking TLE.[30] The increased NPY levels resulted in a significant decrease in spontaneous seizures frequency compared to preinjection baseline levels. Moreover, rAAV-NPY-injected rats showed a reduction in the symptomatic progression of the disease (i.e., no increase in seizure frequency and reduced behavioral seizure severity over time) compared to control epileptic rats, thus suggesting a disease-modifying effect. Disease progression is typical of this epilepsy model,[68] and is also described in TLE patients who do not respond adequately to AEDs and are eventually evaluated for surgical resection of the seizure focus.[69] Since the NPY transgene could not be switched off in these sets of experiments, it remains unresolved if NPY overexpression results in genuine disease-modifying effects or if the suppression of seizure progression was due mainly to the peptide's anticonvulsant properties.[70]

As noted in acute seizure models, the extent of seizure reduction provided by the rAAV-NPY vector in chronic epileptic rats correlated positively with the extent of NPY overexpression in the hippocampus.[30] A significant inverse correlation was found between hippocampal NPY levels and seizure progression, indicating that the NPY level within the epileptic focus is a key factor determining the antiepileptic efficacy of this approach.

GENE THERAPY: ANY ADVERSE EFFECTS?

Gene therapy approaches may encounter great difficulties related both to the invasiveness of

Table 89–2 **Effects of rAAV-NPY Vectors Injection in Rat Models of Seizures and Epilepsy**

Vector	Injection site	Seizure Model	Effects	References
rAAV2-NSE-NPY	Intrahippocampal	Kainic acid (intrahippocampal)	↑ Onset ↓ 50% number of seizures ↓ 50% time in seizures	62
rAAV1/2-NSE-NPY	Intrahippocampal	Kainic acid (intrahippocampal)	↑ Onset ↓ 75% number of seizures ↓ 75% time in seizures	62
		Kainic acid (intracerebroventricular)	↑ Onset No SE	62
		Electrical kindling	↑ 40% treshold current ↑ number of stimuli to generalized seizures ↓ number of generalized seizures ↓ Afterdischarge duration	33,62,67
rAAV1/2-CBA-NPY	Intrahippocampal	Kainic acid (intrahippocampal)	↓ 35% number of seizures ↓ 40% time in seizures	63
		Epilepsy	↓ Spontaneous seizures frequency ↓ number of generalized seizures ↓ Seizure progression	30
rAAV1-CBA-NPY	Intrahippocampal	Kainic acid Intrahippocampal	↓ 55% number of seizures ↓ 70% time in seizures	63
rAAV1/2-CBA-(FIB)NPY	Piriform Cortex	Kainic acid intraperitoneal	No generalized seizures	66

the intervention and to the specific targeting of the brain region; moreover, toxic effects may arise due to the injection of the vector that might induce an inflammatory response in brain tissue or trigger immune host reactions to capsid proteins or to the gene product. The possible occurrence of these effects should be carefully considered since brain inflammatory molecules may exacerbate seizures[71] and the presence of antibodies against the vector could affect its ability to transfect neurons, resulting in decreased or impaired efficacy of gene therapy.[72–74] These considerations have been recently addressed in studies in which normal rats were injected in the hippocampus with the rAAV1-CBA-NPY vector,[63] which appears to be suitable for clinical application.[75–77] Light microscopy showed lack of a local reaction to the vector injection except for nonspecific damage due to needle insertion, which was similar in vehicle-injected rats. Neutralizing serum antibodies against the serotype 1 AAV vector were not detected except in one rat, which, however, showed increased transgene expression and was significantly protected from seizures.

Another factor that should be considered is the pleiotropic effects of NPY, since this neuropeptide is involved in several physiological functions, including cognition, anxiety, and motor activity.[39,78–82] The hippocampus plays a significant role in the processing of spatial information and memory and, in association with the amygdala, in anxiety behavior. Thus, NPY overexpression in the hippocampus could result in anxiolytic-like effects, impairment of spatial memory, and reduction of long-term potentiation (LTP).[83–85] In this regard, we showed that rats injected with rAAV1/2-NPY using the NSE promoter in the CA1 area of the septal hippocampus had impaired LTP.[85] Long-term potentiation is a process that depends on high-frequency neuronal activity and thus can be affected by the release of NPY from transfected neurons: indeed, NPY may suppress LTP in CA1 by inhibiting voltage-gated Ca^{2+} channels via Y2 receptors, thus reducing glutamate release.[41,42,85] Rats also exhibited a transient learning deficit[33] suggesting a delayed process of learning. Interestingly, in subsequent studies,[30,63] no learning deficits were observed in naive rats injected into the hippocampus with rAAV-NPY vectors containing the CBA promoter. These different results likely depend on the hippocampal region where NPY was overexpressed, namely, the septal pole in the first study and both the septal and temporal poles in the second study. Thus, the effects of NPY on cognition depend on the hippocampal region where the peptide levels are increased.[86,87] Another possible explanation involves the use of different promoters, that is, NSE or CBA, which might have preferentially induced transgene expression in distinct neuronal populations (see also ref. 21), thus resulting in different functional outcomes. In this respect, it is possible that interneurons and GABAergic transmission could be affected by NPY overexpression. Interneurons contribute to oscillatory network activity arising during information and memory processing of the hippocampus; therefore, changes in their afferent synapses induced by NPY may alter memory function. In support of this possibility, it has been shown recently that both inhibitory and excitatory afferent transmission on cholecystokinin-expressing basket cells, a subclass of GABAergic interneurons residing in the hilus granule cell border, was changed by exogenous NPY via Y2 receptors activation.[88] Whether viral overexpression of NPY induces similar effects, and the physiological implications of NPY-induced modulation of hippocampal interneurons, are still unknown, but it could be an alternative explanation for the differential effect on memory behavior observed in naive rats.

It is noteworthy that cognitive function is often compromised in epileptic patients;[89,90] thus, one should test it to determine if the gene therapy approach could exacerbate this condition. Recent findings have demonstrated that the attenuation of LTP found in hyperexcitable kindled rats is not further compromised by NPY overexpression[67] (Fig. 89–1), thus suggesting that seizure-induced cognitive impairment may not be worsened by rAAV-NPY treatment. Overexpression of NPY in the hippocampus does not appear to alter basal synaptic transmission in both naive and hyperexcitable kindled rats, and only minor changes in the short-term synaptic plasticity of excitatory glutamatergic synapses have been observed.[33,67]

Finally, no behavioral impairments were observed in naive rats injected intrahippocampally with rAAV1-CBA-NPY vector[63] when they were tested for anxiety and motor functions.[79]

These data suggest that rAAV-NPY gene therapy might be safe and well tolerated, although

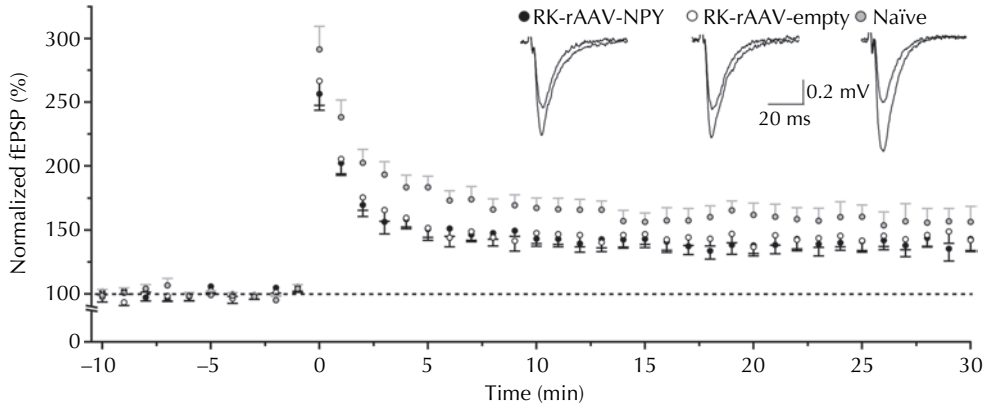

Figure 89–1. Long-term potentiation (LTP) is attenuated by rAAV-NPY treatment but is not further compromised in hyperexcitable kindled rats. Electrophysiological field recordings were obtained in slices from adult male rats after they were injected with rAAV-NPY (NSE promoter and serotype 1/2) or rAAV-empty vector and exposed to rapid kindling (RK). Stable field excitatory postsynaptic potentials (fEPSPs) were acquired as a baseline before high-frequency stimulation, delivered at 100 Hz for 1 s, was applied to slices (at 0 min) to induce LTP. Long-term potentiation was significantly and equally compromised in slices from RK-rAAV-NPY and RK-rAAV-empty animals compared to slices from non kindled naive animals (repeated measures ANOVA [$p < .05$] and the Mann-Whitney test [$p < .001$]). Initial slopes of fEPSPs are normalized to average baseline values and plotted against time (average of four fEPSPs per minute) for RK-rAAV-NPY (n = 11 slices, 7 rats), RK-rAAV-empty (n = 11 slices, 9 rats), and naive (n = 10 slices, 7 rats) groups. Data are shown as mean ± SEM. Representative fEPSPs (average of four traces) acquired during baseline and 20 min after high-frequency stimulation for each group. Modified from ref. 67.

these conditions should be further studied in the context of the epileptic pathology.

CONCLUSION

Focal-onset drug-resistant epilepsy, such as TLE, is potentially eligible for gene therapy since the therapeutic gene can be delivered into a specific epileptogenic brain area, thus obtaining local and sustained release of a therapeutic molecule. Recombinant AAV vectors have already been used in clinical trials for neurological disorders, with encouraging results, for example, in patients with Parkinson's disease.[7]

Experimental findings in rat models of seizures and epilepsy provide proof-of-principle evidence that the transfer of a gene expressing an endogenous anticonvulsant peptide in chronic epileptic tissue may offer a novel therapeutic intervention to control seizures.

However, further development of gene therapy strategies is still needed, such as improving gene delivery methods (i.e., brain targeting of the transgene using systemic delivery[91]), using inducible gene expression regulation, which would allow the transgene to be switched off when required,[92] and studying in greater depth the safety profile and possible side effects of gene therapy in epileptic conditions.

A protocol for a Phase 1 clinical trial based on rAAV-NPY is under consideration at the U.S. Food and Drug Administration (http://www4.od.nih.gov/oba/RAC/meetings/Sept2004/RACagenda092304.pdf): the target population is mesial TLE patients with pharmacoresistant chronic seizures who are candidates for surgical resection of the epileptogenic focus. If this alternative treatment strategy undergoes successful clinical trials, it will open new avenues for the treatment of seizures that offer potential cures rather than focusing on the symptoms.

Chapter 90

Adenosine Augmentation Therapy

Detlev Boison

The ribonucleoside adenosine is based on the purine base adenine, which was most likely already present on the prebiotic primitive Earth.[1] Being the core molecule of the energy metabolite adenosine-5′-triphosphate (ATP) as well as being an integral component of both DNA and RNA, adenosine likely played an important role in early evolution as an ideally positioned negative feedback regulator to adjust cellular activity (DNA, RNA) to available energy supplies (ATP). Adenosine has therefore evolved as an important modulator of function in brain, but also in heart, skeletal muscle, kidney, and adipose tissue, in the sense of a "retaliatory metabolite" that protects the cell against excessive external stimulation.[2]

Adenosine was first recognized as an endogenous modulator of neuronal excitability in 1980.[3] Today it is well recognized that adenosine exerts potent anticonvulsant[4] and neuroprotective[5] functions in brain that are largely mediated via the activation of pre- and postsynaptic G protein-coupled adenosine A_1 receptors (A_1Rs) providing presynaptic inhibition and stabilization of the postsynaptic membrane potential, respectively.[6,7] Furthermore, a rise in endogenous adenosine has been documented during ongoing seizure activity in patients with epilepsy,[8] and adenosine has consequently been identified as an endogenous mediator of seizure arrest and postictal refractoriness.[8,9] In addition, A_1Rs, which are the dominant receptor subtype in the limbic system, are crucial in preventing the spread of seizures,[10] and lack of the receptor is associated with spontaneous electrographic seizures[11] and with increased susceptibility to seizure-[11] or trauma-[12] induced mortality. Apart from the direct role of A_1Rs in regulating the susceptibility to seizures, stimulatory A_{2A}Rs, which in brain have their highest expression levels in striatum, appear to be involved in the regulation of several pathways thought to be implicated in epileptogenesis. Notably, A_{2A}Rs interact directly with various transmitter systems to modulate both inflammatory and cognitive processes.[13,14]

Clinical evidence, in particular the widespread use of the adenosine receptor antagonist theophylline as a bronchodilator, suggests that methylxanthines can cause seizures in patients without known underlying epilepsy.[15] Conversely, pharmacological activation of A_1Rs

provides effective seizure control in animal models,[16] albeit accompanied by significant, largely cardiovascular, side effects that are common after systemic use of adenosinergic drugs.[17] Importantly, pharmacological activation of A_1Rs effectively suppressed seizures in mice that were resistant to treatment with conventional antiepileptic drugs (AEDs).[18] Despite 30 years of research on adenosine and epilepsy, only the recent advent of novel molecular tools has led to the discovery of adenosine-related pathogenetic mechanisms in epilepsy and the translation of those findings into novel therapeutic approaches.

ADENOSINE DYSFUNCTION IN EPILEPSY

Although astrogliosis is a pathological hallmark of the epileptic brain, the important role of astrocytes in the control of neuronal excitability has only recently been appreciated.[19,20] Via the formation of tripartite synapses, astrocytes control synaptic transmission and neurovascular coupling.[21] Importantly, purinergic[22] as well as glutamatergic[23] signaling from astrocytes was shown to influence neuronal networks, and an astrocytic basis of epilepsy has been proposed.[23]

Astrocytes and Adenosine Kinase Are Key Regulators of Synaptic Adenosine

Synaptic levels of adenosine are largely controlled by an astrocyte-based adenosine cycle.[6,24] The major source of synaptic adenosine is its precursor, ATP, which can be released by astrocytes via regulated vesicular transport[22] or via hemichannels.[25] Once in the synaptic cleft, ATP is rapidly degraded into adenosine by a cascade of ectonucleotidases.[26] Proof that the astrocytic release of ATP plays a crucial role in regulating neuronal excitability via adenosine was provided using inducible transgenic mice that express a dominant-negative *N*-methylmaleimide-sensitive fusion protein receptor (SNARE) domain selectively in astrocytes to block the astrocytic release of ATP. Using these mice, it was shown that by releasing ATP, which accumulated as adenosine, astrocytes tonically suppressed synaptic transmission.[22] In contrast to classical neurotransmitters, which are removed from the extracellular space via specific energy-driven reuptake transporters, astrocyte membranes contain two types of equilibrative transporters for adenosine that rapidly equilibrate extra- and intracellular levels of adenosine.[27] Due to the lack of a classical transporter-regulated reuptake system for adenosine, the intracellular astrocyte-specific enzyme adenosine kinase (ADK) has likely adopted the role of a metabolic reuptake system for adenosine. Thus, by phosphorylation of adenosine into 5′-adenosine monophosphate (AMP), ADK drives the influx of adenosine into the astrocyte, thereby reducing the concentration of synaptic adenosine.[6,24,28] The notion that ADK is the key enzyme for the regulation of ambient adenosine in brain is further supported by the following evidence: (1) In adult brain, ADK expression is restricted to astrocytes.[29] (2) Inhibition of ADK in hippocampal slices increases endogenous adenosine and depresses neuronal firing, whereas inhibition of ADA has no effect.[30] (3) Pharmacological inhibition of ADK suppresses seizures in models of epilepsy.[31] (4) Genetic disruption of ADK induces an increase in adenosine.[32–35] (5) Overexpression of ADK triggers seizures by reducing ambient adenosine.[36] (6) A substrate cycle between AMP and adenosine, which involves ADK and 5′-nucleotidase, enables minor changes in ADK activity to translate rapidly into major changes in adenosine.[37]

ADK Is a Target for Seizure Prediction and Prevention

The crucial role of ADK in regulating the synaptic availability of adenosine and thus neuronal excitability has led to the proposal of the *adenosine kinase hypothesis of epileptogenesis*.[24] In an acute response to injury to the brain, a surge in micromolar levels of adenosine is triggered[38] that is further potentiated by acute downregulation of ADK during the first hours after experimental stroke[39] or status epilepticus.[40]

The acute injury-induced surge of adenosine increases the neuroprotective tone during the

first hours following an insult to the brain and seems to be a ubiquitous endogenous protective mechanism.[24] However, this acute surge in adenosine is also able to trigger several downstream pathways that can all contribute to the initiation of epileptogenesis. Several downstream mechanisms can be influenced by an acute surge of adenosine: Adenosine is an important modulator of inflammation.[41] Activation of A_1 as well as A_{2A} receptors triggers the proliferation of microglial cells.[42] In addition, adenosine A_{2A} receptor activation promotes inflammatory responses that are specific to the central nervous system (CNS).[43] Furthermore, increased levels of adenosine can induce downregulation of A_1Rs but upregulation of A_{2A}Rs on astrocytes.[44] Increased occupancy of astrocytic A_{2A}Rs was shown to increase astrocyte proliferation and activation.[45,46] Therefore, any injury-induced surge in adenosine can be a direct trigger for subsequent astrogliosis.

Based on the mechanisms discussed above, it is not surprising that astrogliosis is a common pathological consequence of different types of brain injury, such as status epilepticus, trauma, or stroke, but is also a common pathological hallmark of a variety of neurodegenerative and neuropsychiatric disorders, including Alzheimer's disease and autism (Fig. 90–1). As will be discussed in more detail below, astrogliosis is accompanied by overexpression of ADK, thereby inducing focal adenosine deficiency and spontaneous electrographic seizures. Adenosine deficiency can also explain a wide spectrum of comorbidities that are common in epilepsy or after brain injury (Fig. 90–1). Evidence that ADK, expressed by astrocytes, is a key molecular link between astrogliosis and neuronal dysfunction in epilepsy has been obtained in seizure models as well as through genetic and pharmacological approaches.

EVIDENCE FROM SEIZURE MODELS

Temporal lobe epilepsy is characterized by a complex pathophysiology including mossy fiber sprouting, granule cell dispersion, neuronal cell loss, ectopic neurons, and astrogliosis. Given this complex situation, it is almost impossible to attribute specific cause-effect relationships between those pathological changes and the development of seizures. To dissect out the specific contribution of astrogliosis to seizure generation, a mouse model was created that isolates astrogliosis from other components of the epileptogenic cascade.[47] In this model, a single unilateral injection of the excitotoxin kainic acid (KA) into the basolateral amygdala triggers status epilepticus that is terminated after 30 min with an intravenous infusion of lorazepam. This manipulation results in neuronal cell loss that is restricted to the ipsilateral CA3 area of the hippocampal formation.[47] The induced acute injury constitutes a trigger for subsequent epileptogenesis, and 3 weeks after KA injection the ipsilateral CA3 is characterized

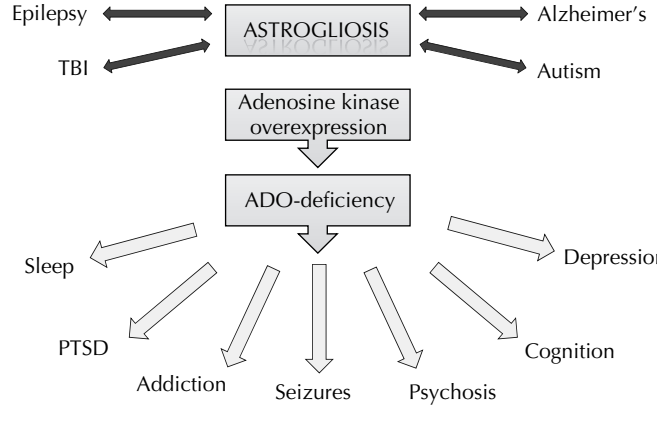

Figure 90–1. Astrogliosis and adenosine deficiency link diverse pathologies with co-morbidities. Astrogliosis—a common pathological hallmark of conditions as diverse as epilepsy, traumatic brain injury (TBI), Alzheimer's disease, and autism—is accompanied, at least in several models, with overexpression of ADK and resulting adenosine deficiency. Adenosine deficiency can likely explain several comorbidities between the conditions shown above, including sleep disorders, posttraumatic stress disorder (PTSD), addiction, seizures, psychosis, cognitive impairment, and depression.

by prominent astrogliosis and overexpression of ADK.[47] Remarkably frequent spontaneous electrographic seizures (approximately four seizures per hour, with a duration of 20 s per seizure) result that are restricted to the ipsilateral CA3.[47] These findings demonstrate spatial colocalization of astrogliosis, overexpressed ADK, and spontaneous seizures, and document that astrogliosis and/or overexpression of ADK per se, in the absence of any other component of the epileptogenic cascade, is sufficient to trigger seizures. Remarkably, during epileptogenesis in this model, astrogliosis, overexpression of ADK, and the first emergence of spontaneous seizures also coincide temporally at around day 12 following the KA injection, further highlighting the possible causal relationship between these events.[11]

EVIDENCE FROM GENETIC APPROACHES

The seizure model described above does not allow determination of whether astrogliosis or overexpression of ADK is required for seizure generation. To address this question, transgenic mice were engineered with global brain-wide overexpression of an *Adk*-transgene in addition to deletion of the endogenous *Adk* gene (Adk-tg mice). These animals are characterized by spontaneous hippocampal seizures in the absence of astrogliosis or any other histopathological alterations.[11] These data demonstrate that overexpression of ADK in the absence of any histopathological alteration usually associated with an epileptic brain is sufficient to trigger seizures. More recently, an injection of an adeno-associated virus (AAV) overexpressing a cDNA of *Adk* selectively in astrocytes was shown to trigger the same type of spontaneous seizures in otherwise healthy wild-type mice, whereas the injection of an AAV expressing an *Adk* antisense construct into the CA3 of Adk-tg mice was able to abolish almost completely spontaneous seizures in those animals.[48] Together these data define ADK as a rational target for therapeutic intervention.

EVIDENCE FROM PHARMACOLOGICAL APPROACHES

The identification of overexpressed ADK and the resulting adenosine deficiency as a major inducer of seizures implies that adenosine augmentation therapies (AATs) should be highly effective in seizure suppression. Indeed, adenosine A_1R agonists effectively inhibit neuronal activity, suppress seizures,[49] and have been the subject of intense drug development efforts.[50,51] Although A_1R agonists are effective in a variety of models, including one of pharmacoresistant epilepsy,[18] the systemic application of those drugs leads to profound cardiovascular and sedative side effects.[52] Sedative side effects of systemic adenosine augmentation can best be explained by the sleep-promoting effects of A_1R activation.[53] Since any type of injury or stress to the brain leads to an increase in endogenous adenosine,[8,38,54] agents (e.g., the ADK inhibitor ABT-702[55,56]) that amplify this site- and event-specific increase in adenosine could provide antiseizure activity comparable to that of adenosine receptor agonists.[31,57] Consequently, pharmacological inhibition of ADK is effective in inhibiting epileptic seizures,[31,40] with an improved therapeutic window compared to A_1R agonists.[58] However, systemic ADK inhibitors might not be a long-term therapeutic option for epilepsy due to their interference with methionine metabolism in liver[59,60] and the risk of brain hemorrhage.[61,62]

FOCAL ADENOSINE AUGMENTATION

Rationale for Focal Drug Delivery Approaches in Epilepsy

Side effects of systemic adenosine augmentation can most effectively be avoided by focal treatment approaches. In general, spatially restricted therapies are considered to be safe and feasible alternatives for systemic drug use, and given the focal nature of many epilepsies, focal interventions might be preferable.[63] The identification of neurochemical deficits that are specific for an epileptogenic focus provide a direct rationale for focal intervention (Fig. 90–2). Endogenous "AEDs" such as gamma-aminobutyric acid (GABA),[64–66] adenosine,[67–69] galanin,[70–72] or neuropeptide Y (NPY)[73,74] are therefore logical candidates for therapeutic intervention. Tools for focal drug delivery have been reviewed recently[75–78]

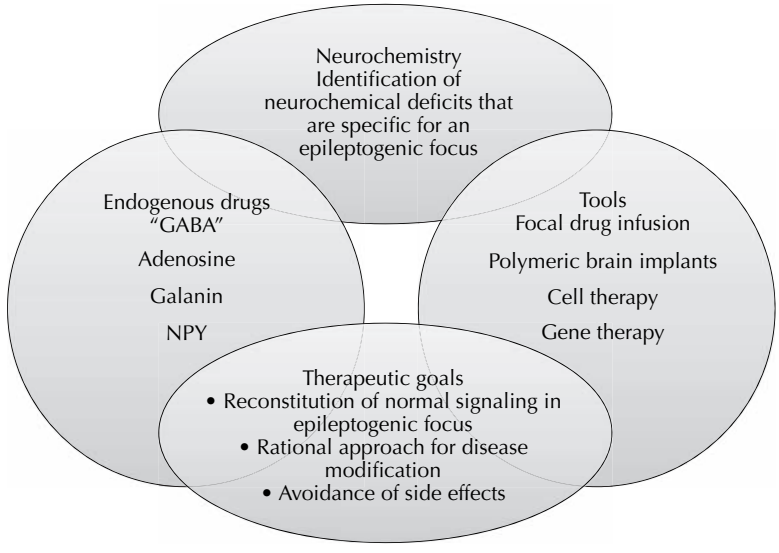

Figure 90–2. Rationale for local drug delivery in epilepsy.

and include polymeric brain implants,[79,80] cell therapy,[81–84] and gene therapy.[85–87] In contrast to conventional systemically used AEDs, the rational focal use of endogenous anticonvulsants is uniquely posed to reconstitute normal signaling within an epileptogenic focus and thereby not only to suppress seizures but also to affect disease progression in the absence of systemic side effects (Fig. 90–2). As outlined above, manipulation of ADK and focal adenosine augmentation are considered to be an effective and rational strategy for epilepsy therapy.

Molecular Approaches to Induce Adenosine Augmentation

The most effective strategy to increase levels of ambient adenosine is disruption of metabolic adenosine clearance. Pharmacologically, it has been demonstrated that inhibition of ADK is more effective in raising adenosine levels and in enhancing presynaptic inhibition than blockade of adenosine deaminase (ADA).[30] Likewise, engineered fibroblasts lacking ADK released 2.3 times more adenosine compared to fibroblasts lacking ADA.[35] Consequently, ADK is an effective target to induce cellular adenosine release. Two molecular strategies have been used to augment the adenosine system: (1) gene targeting to disrupt the endogenous *Adk* gene[34] and (2) RNA interference (RNAi) to knock down ADK expression.[88]

Using a gene-targeting construct to disrupt the endogenous *Adk* gene by homologous recombination in murine embryonic stem cells (ESCs) and subsequent biochemical selection for ADK deficiency, ESCs were isolated with a biallelic disruption of their endogenous *Adk* gene.[34] Upon directed differentiation in vitro into either neuronal or glial cell populations, the ADK-deficient cells released up to 40 ng adenosine per hour per 10^5 cells, an amount considered to be of therapeutic relevance. To induce therapeutic adenosine release in adult stem cells, an RNAi approach was used to induce a knockdown of ADK in human mesenchymal stem cells (hMSCs). This was achieved by constructing a lentivirus expressing an artificial micro-RNA directed against ADK. Transduction of hMSCs with the virus yielded cell populations in which ADK expression was reduced by up to 80%; this manipulation resulted in a release of about 1 ng adenosine per hour per 10^5 cells.[32] Control cells, transduced with a lentivirus expressing a scrambled control sequence, did not release detectable amounts of adenosine. These results demonstrate that although complete genetic disruption of the *Adk* gene is more effective in inducing adenosine release, RNAi-based strategies can effectively be used to engineer stem cells to release adenosine.

Seizure Suppression and Prevention by Focal Adenosine Augmentation

PROOF OF PRINCIPLE

The first proof of principle that focal adenosine augmentation might be effective for seizure control was demonstrated in the rat kindling model. Synthetic ethylene vinyl acetate copolymers were engineered to release approximately 20 to 50 ng adenosine per day.[89] Individual polymers were implanted into the lateral brain ventricles of rats that had been kindled in the hippocampus. Recipients of adenosine-releasing polymers were characterized by a strong reduction of stage 5 seizures for at least 7 days and by a reduction of epileptiform electrical afterdischarges for up to 3 days. In line with a transient delivery of adenosine, the antiepileptic effects gradually decreased and were no longer evident 2 weeks after polymer implantation. Control implants loaded with BSA failed to display any therapeutic effects. This was the first published demonstration that a focal release of adenosine in doses of 20 to 50 ng adenosine per day can suppress epileptic seizures.[89] Subsequently, robust but transient seizure suppression in kindled rats was demonstrated using intraventricular implants of encapsulated fibroblasts engineered to release adenosine.[35] The proof of principle that focal adenosine delivery can be of therapeutic benefit was further validated by an independent research group using intracranial adenosine injections in a rat seizure model.[69]

STEM CELL-BASED ADENOSINE DELIVERY

In the adult brain the subgranular zone of the hippocampal formation, as well as the subventricular zone, contain primitive cell sources and stem cells capable of repairing the injured brain.[90] Therefore, stem cell therapies are a logical choice for regeneration and repair of the epileptic hippocampal formation. While stem cell-derived brain implants may indeed repair the injured hippocampus in epilepsy and may be of therapeutic value by modifying circuitry through synaptic interactions,[91] stem cell-based brain implants may also exert direct anticonvulsant activity via the paracrine release of adenosine.[92] Based on the therapeutic efficacy of paracrine adenosine delivery,[35,92] stem cell-based adenosine delivery can be achieved effectively by injecting the cells into the infrahippocampal fissure of rodents, thereby avoiding interference with hippocampal circuitry.[93] Infrahippocampal implants of neural precursor cells derived from murine or human ESCs as well as hMSCs survive within the infrahippocampal fissure for at least several weeks.[32,47,93–95]

Infrahippocampal implants of adenosine-releasing stem cells provided potent seizure control in several experimental paradigms: (1) Embryonic stem cell-derived neural precursor cells injected into rats prior to the onset of kindling provided robust suppression of kindling epileptogenesis.[93] (2) The same cells injected after intra-amygdaloid KA-induced status epilepticus in mice prevented the development of spontaneous seizures 3 weeks after the injury, a time point when recipients of control cells had developed recurrent electrographic CA3 seizures at the rate of about four seizures per hour[47]; remarkably, the animals with the adenosine-releasing implants were characterized by significantly reduced astrogliosis and almost normal expression levels of ADK. Together, these data suggest a novel disease-modifying and possibly antiepileptogenic effect of focal adenosine augmentation.[47] (3) Adenosine-releasing hMSC implants were demonstrated to provide neuroprotective as well as antiepileptic effects in the mouse intra-amygdaloid KA model of CA3-restricted epileptogenesis[32,95]; however, due to 40 times lower amounts of released adenosine, these effects were less profound compared to those observed in ESC recipients.

SILK-BASED ADENOSINE DELIVERY

Although stem cell-based adenosine delivery yielded robust antiepileptic and possibly antiepileptogenic effects in two different models of epilepsy, those approaches still seem far from future clinical implementation. To provide a platform for rapid clinical implementation of focal adenosine augmentation, the natural biopolymer silk was recently evaluated for the therapeutic delivery of adenosine.[79,96] Purified silk fibroin presents a unique option for therapeutic adenosine delivery, as it is biocompatible and biodegrades slowly.[97] Degradation kinetics can be regulated to allow control of release from weeks to years.[97] Both silk as well

as adenosine are approved by the U.S. Food and Drug Administration (FDA), and the frequent use of silk sutures in brain confirms the feasibility of implanting silk biomaterials into brain.

In the first therapeutic silk-based adenosine delivery approach, a hierarchically structured silk-based implant was engineered with target release rates of 0, 40, 200, and 1000 ng adenosine per day.[79] The devices were implanted into the infrahippocampal fissure of rats prior to the onset of electrical kindling. It was demonstrated that focal adenosine release from silk-based polymers dose-dependently retarded kindling epileptogenesis. Importantly, recipients of polymers releasing a target dose of 1000 ng adenosine per day did not display any behavioral seizures during the time period of active adenosine release, whereas control rats experienced convulsions during the same period. As soon as adenosine release from the polymers began to wear off, seizures gradually reappeared with progressive intensity.[79]

Likewise, when implanted after completion of kindling into fully kindled rats (reproducible stage 4 to 5 seizures), implants engineered to release 1000 ng adenosine for a defined time period of 10 days effectively suppressed seizures for 10 days in fully kindled rats. After expiration of adenosine release from the polymers, stage 4 to 5 seizures recurred.[98] To assess the potential antiepileptogenic effect of focal adenosine delivery, unilateral (ipsilateral to the side of kindling) implantations with the same adenosine-releasing or control polymers were performed prior to the onset of kindling. All animals received a total of 30 kindling stimulations between days 4 and 8 after polymer implantation. This treatment resulted in stable stage 5 seizure expression in control animals, whereas seizure stages in adenosine-treated animals did not progress beyond stage 1. The lack of convulsive seizures in the adenosine group can be attributed either to the antiepileptogenic effects of focal adenosine delivery or merely to seizure suppression by adenosine (masking potential antiepileptogenic effects). To distinguish between the two possibilities, kindling was discontinued to allow expiration of adenosine release from the polymers. On day 18, kindling was resumed. Whereas control animals continued with generalized stage 5 seizures, animals from the adenosine group resumed kindling at stage 0 to 1, indicating that epileptogenesis was indeed suppressed during the time period of active adenosine delivery.[98] Pharmacological control experiments with the adenosine A_1 receptor antagonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) further corroborated the disease-modifying effects of focal adenosine delivery: Whereas a dose of 1 mg/kg DPCPX had no effects in nonkindled control animals, DPCPX restored stage 5 seizures in fully kindled rats that were protected from transient adenosine delivery.[35] Importantly, DPCPX did not trigger seizures in kindled animals that received adenosine-releasing implants prior to the onset of kindling, a result that further substantiated a possible antiepileptogenic effect of focal adenosine delivery.[98]

Together these studies document the therapeutic potential of silk-based adenosine delivery, capitalizing on a biopolymer that fulfills crucial requirements for future clinical application, such as biocompatibility, delivery of defined doses of adenosine, safety, and therapeutic efficacy in a widely used preclinical model. Although the polymer design used in this study[79] precluded long-term applications due to adenosine depletion over a period of 2 weeks, the system would nevertheless be suitable for initial short-term clinical safety and feasibility trials.

CHALLENGES AND IMPACT

Data from the acute and chronic models of epilepsy discussed above suggest that focal AATs may combine anticonvulsive, neuroprotective, and possibly antiepileptogenic properties. The conceptual rationale for focal AAT development differs from that of classical AED development. Since current AED development follows largely a *neuro*centric concept, it is unlikely that the development of new AEDs acting on similar neuronal targets will lead to any significant improvement in antiepileptic therapy. In contrast, augmentation of adenosine as an upstream modulator of several downstream pathways is uniquely suited to affect neuronal excitability on the network level and therefore constitutes a new pharmacological principle that has not yet been exploited in clinical epilepsy therapy. In addition, adenosine is an *endogenous* anticonvulsant and therefore is subject to physiological clearance. Rather

Therapy	Benefits	Limitations
Stem cell-based AAT	• Paracrine release of adenosine • Additional benefit of network repair? • Widespread delivery possible • Cell injection possible	• Long-term effectiveness/viability? • Control of network interactions? • Immunosuppresion if not autologous cell source
Polymer-based AAT	• Release of defined doses • Release by defined kinetics • Precise local restriction • Safety	• Invasive surgical procedure • Local effects/limitatin to focal epilepsies • Long-term effectiveness

Figure 90–3. Benefits and limitations of stem cell-based or silk polymer-based AATs.

than leading to toxic accumulations of adenosine, adenosine augmentation is likely to restore adenosinergic equilibrium, thereby avoiding undue side effects.

The stem cell-based and silk-based focal AAT approaches discussed here have distinctive benefits and limitations that are summarized in Fig. 90–3. Before focal AATs can move into the clinical realm, several issues need to be resolved. These include but are not limited to (1) determination of the median effective doses (ED_{50}s) and median toxic doses (TD_{50}s) and the respective therapeutic index; (2) differentiation of antiepileptic efficacy in mechanistically different animal models; (3) determination of appropriate time points for therapeutic intervention; (4) determination of appropriate therapeutic target populations (e.g., temporal lobe epilepsy vs. cortical dysplasia); and (5) demonstration of long-term efficacy.

Adenosine augmentation therapies rationally utilize the brain's endogenous adenosine-based seizure-control system, thereby presenting significant therapeutic potential for epilepsy. Adenosine is already FDA-approved for the treatment of supraventricular tachycardia and has been used in intrathecal infusions in Phase 1 clinical trials for the treatment of chronic pain.[99] Based on their relative safety profile, focal AATs, in particular those involving silk-based adenosine delivery, could rapidly be translated from animal studies to clinical trials. One possibility for first safety and feasibility studies could be the infusion of adenosine into an epileptic temporal lobe during its surgical removal. When coupled to synchronous electroencephalographic recordings, a proof of principle could be established that adenosine is effective in pharmacoresistant human epilepsy. Given the potential disease-modifying effects of focal AAT, the implantation of a bio-resorbable adenosine-releasing silk polymer into an epileptogenic brain region could eventually provide lasting benefit even after expiration of adenosine delivery. To make the best possible use of those disease-modifying effects, it is of benefit to use a carrier system that can degrade with time without having any long-lasting residual impacts.
