FIGURE 15.4. Overlap of orbitals in a photochemical  $[2+2]$  cycloaddition.

On the other hand, the Diels-Alder reaction (a  $[4+2]$  reaction) is allowed, when considered from either direction (Figure 15.3).

These considerations are reversed when the ring closures are photochemically induced since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the  $[2+2]$  reaction is now allowed (Figure 15.4) and the  $[4+2]$  reaction disallowed.

The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, the retro-Diels-Alder reaction is well known, while cleavage of the strained cyclobutanes require more strenuous conditions.<sup>2407</sup>

<sup>2407</sup> For the reactivity of strained cycloalkenes, see Liu, F.; Paton, R.S.; Kim, S.; Liang, Y.; Houk, K.N. *J. Am. Chem. Soc.* **2013**, *135*, 15642.

FIGURE 15.5. Some basis sets.

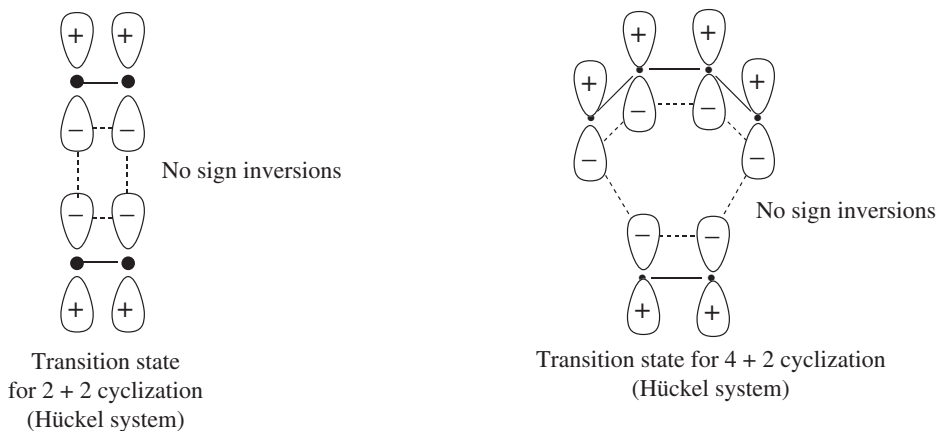

FIGURE 15.6. Transition states illustrating Hückel-Möbius rules for cycloaddition reactions.

The Möbius-Hückel Method<sup>2408</sup> In this method, the orbital symmetry rules are related to the Hückel aromaticity rule discussed in Chapter 2.<sup>2409</sup> Hückel's rule, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of  $4n + 2$  electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle, ground states are not of concern, but the focus is on transition states. In the present method, the molecular orbitals themselves are not examined, but rather it is the  $p$  orbitals before they overlap to form the molecular orbitals that are examined. Such a set of  $p$  orbitals is called a *basis set* (Figure 15.5).

In investigating the possibility of a concerted reaction, the basis sets are put into the position they would occupy in the transition state, as shown in Figure 15.6 for both the [2 + 2] and the [4 + 2] ring closures, looking for *sign inversions*.

In Figure 15.6 there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or an even number* of sign inversions are called *Hückel systems*. Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Figure 15.7).<sup>2410</sup>

<sup>2410</sup> See Hennigar, K.H.R.; Langler, R.F. *Aust. J. Chem.* 2010, 63, 490.

**FIGURE 15.7.** A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper  $180^\circ$  and fastening the ends together.

**FIGURE 15.8.** Transition states of  $[2+2]$  and  $[4+2]$  cyclizations involving other basis sets.

Möbius systems do not enter into either of these reactions, but an example of such a system is shown in **18-28**, part B. Double-twist Möbius aromaticity has been invoked in the Diels-Alder transition state for the reaction of a 5,6-di-*tert*-butyl-substituted decapentaene.<sup>2411</sup>

The rule may then be stated: A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is  $4n + 2$ . A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is  $4n$ . For photochemical reactions these rules are reversed. Since both the  $[4+2]$  and  $[2+2]$  cycloadditions are Hückel systems, the Möbius-Hückel method predicts that the  $[4+2]$  reaction, with 6 electrons, is thermally allowed, but the  $[2+2]$  reaction is not. On the other hand, the  $[2+2]$  reaction is allowed photochemically, while the  $[4+2]$  reaction is forbidden.

Note that both the  $[2+2]$  and  $[4+2]$  transition states are Hückel systems no matter what basis sets were chosen. For example, Figure 15.8 shows other basis sets that might have been chosen. In every case there will be zero or an even number of sign inversions.

Thus, the FMO and the Hückel-Möbius method (and the correlation diagram method as well) lead to the same conclusions: thermal  $[4+2]$  cycloadditions and photochemical  $[2+2]$  cycloadditions (and the reverse ring openings) are allowed, while photochemical  $[4+2]$  and thermal  $[2+2]$  ring closings (and openings) are forbidden. In general, cycloaddition reactions allowed thermally are those with  $4n + 2$  electrons, while those allowed photochemically have  $4n$  electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms: e.g., two  $\sigma$  bonds are formed (or broken) at about the same

<sup>2411</sup> Rzepa, H.S. *Chem. Commun.* **2005**, 5220.

time.<sup>2412</sup> The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the concerted, thermal Diels-Alder reaction is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given Diels-Alder reaction is also concerted. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal [2 + 2] cycloadditions in which the molecules assume a face to face geometry cannot<sup>2413</sup> take place by a cyclic mechanism because their activation energies would be too high. In **15-58** it will be seen that such reactions largely occur by two-step mechanisms. Similarly, [4 + 2] photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism.<sup>2414</sup>

In all of the above discussion it has been assumed that a given molecule forms both the new  $\sigma$  bonds from the same face of the  $\pi$  system. This manner of bond formation, called *suprafacial*, is certainly most reasonable and almost always takes place. The subscript *s* is used to designate this geometry, and a normal Diels-Alder reaction would be called a  $[\pi 2_s + \pi 4_s]$  cycloaddition (the subscript  $\pi$  indicates that  $\pi$  electrons are involved in the cycloaddition). However, there is another approach in which the newly forming bonds of the diene lie on *opposite* faces of the  $\pi$  system, that is, they point in opposite directions. This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a  $[\pi 2_s + \pi 4_a]$  cycloaddition (*a* stands for antarafacial).

The FMO shows that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a  $[\pi 2_s + \pi 4_a]$  reaction to proceed, overlap between the highest occupied  $\pi$  orbital of the alkene and the lowest unoccupied  $\pi$  orbital of the diene would have to occur, as shown in Figure 15.9, with a + lobe overlapping a - lobe. Since like signs are no longer overlapping, the thermal reaction is now forbidden.

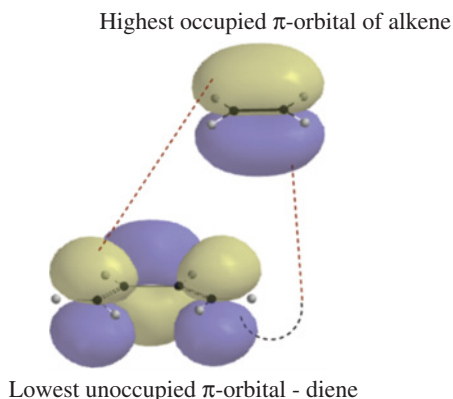

Similarly, thermal  $[\pi 4_s + \pi 2_a]$  and  $[\pi 2_s + \pi 4_a]$  cyclizations are forbidden, while thermal  $[\pi 4_a + \pi 2_a]$  and  $[\pi 2_s + \pi 2_a]$  cyclizations are allowed, and these considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a [4 + 2] cyclization,<sup>2415</sup> but larger ring closures could take place by such a pathway, and [2 + 2] thermal cyclizations, where the  $[\pi 2_s + \pi 2_s]$  pathway is forbidden, can also

<sup>2415</sup> A possible photochemical [4+2] cycloaddition has been reported: Hart, H.; Miyashi, T.; Buchanan, D.N.; Sasson, S. *J. Am. Chem. Soc.* **1974**, *96*, 4857.

**FIGURE 15.9.** Overlap of orbitals in an antarafacial thermal [4 + 2] cycloaddition.

do so in certain cases (see **15-59**). Whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules.

Symmetry considerations have also been advanced to explain predominant *endo* addition.<sup>2416</sup> In the case of [4 + 2] addition of butadiene to acrolein, the approach can be *exo* or *endo*. It can be seen (Figure 15.10) that whether the HOMO of the diene overlaps with the LUMO of acrolein or vice versa, the *endo* orientation is stabilized by additional secondary overlap of orbitals<sup>2417</sup> of like sign (dashed lines between heavy dots). Addition from the *exo* direction has no such stabilization since the sign of the orbitals do not match.

been reported.<sup>2433</sup> Note that the reaction of Danishefsky's diene with an imine,<sup>2434</sup> formed *in situ* by reaction of an aryl aldehyde and an aniline derivative, proceeds without a Lewis acid.<sup>2435</sup>

Ketones also react with suitably functionalized dienes.<sup>2436</sup> Hetero-Diels-Alder reactions involving carbonyls have been done in water.<sup>2437</sup> Polymer-supported dienes have been used.<sup>2438</sup>

Hetero-Diels-Alder reactions that proceed with good to excellent asymmetric induction are well known.<sup>2439</sup> Aldehydes react using a chiral Ti,<sup>2440</sup> Zr,<sup>2441</sup> Cu,<sup>2442</sup> Fe,<sup>2443</sup> or Mn<sup>2444</sup> catalysts to give the dihydropyran with good enantioselectivity, and organocatalysts have been used.<sup>2445</sup> Asymmetric chiral 1-aza dienes have been developed as substrates, for example.<sup>2446</sup> Azadienes also react with chiral dienophiles.<sup>2447</sup> Chiral catalysts have been developed.<sup>2448</sup>

Dienes related to **73** are known, and their reactivity has been examined. Amino-substituted dienes undergo what is known as hydrogen bonding-catalyzed reactions.<sup>2449</sup> Imines react with other substrates, such as allenes, to give tetrahydropyridine derivatives with good enantioselectivity in the presence of a chiral ligand.<sup>2450</sup> Azo compounds (–N=N–) react as dienophiles in the presence of an Ag catalyst.<sup>2451</sup> Iminium ions undergo Diels-Alder cycloaddition.<sup>2452</sup>

The Rh/phosphoramidite-catalyzed [4 + 2] cycloaddition of  $\alpha,\beta$ -unsaturated imines and isocyanates gave pyrimidinones.<sup>2453</sup> The chiral phosphoric acid-catalyzed nitroso-Diels-Alder reaction of nitrosoarenes with carbamate dienes gave *cis*-3,6-disubstituted dihydro-1,2-oxazines.<sup>2454</sup> The Cu-catalyzed nitroso Diels-Alder reaction gave

photosensitizer (Sec. 7.A.vi, category 5) such as eosin (a red xanthene dye). Among these is  $\alpha$ -terpinene, which is converted to ascaridole.<sup>2488</sup>

As in **14-6**, it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,<sup>2489</sup> so the reaction is actually a *Diels-Alder reaction* (see **15-56**) with singlet oxygen as dienophile:<sup>2490</sup> Like **15-56**, this reaction is reversible.

As previously discussed, the reaction of singlet oxygen with double bond compounds gave hydroperoxides (**14-6**). However, singlet oxygen can also react with double bonds in another way to give a 1,2-dioxetane intermediate<sup>2491</sup> which usually cleaves to aldehydes or ketones<sup>2492</sup> but has been isolated.<sup>2493</sup> Both the six-membered cyclic peroxides<sup>2494</sup> and the four-membered dioxetane<sup>2495</sup> have been formed from oxygenation reactions that do not involve singlet oxygen. If cyclic peroxides are desired, better reagents<sup>2496</sup> are triphenyl phosphite ozonide (PhO)<sub>3</sub>PO<sub>3</sub> and triethylsilyl hydrotrioxide (Et<sub>3</sub>SiOOH), but yields are not high.<sup>2497</sup>

### 15-59 [2 + 2] Cycloadditions<sup>2498</sup>

Two alkene molecules react under thermal conditions to give cyclobutane derivatives in what is known as a [2 + 2] cycloaddition. The cycloaddition occurs when the alkenes are the same or different, but the reaction is not general for all alkenes.<sup>2499</sup> Variations include

the reaction of ketenes with alkenes to give cyclobutanones or the reaction of ketenes with imines to give  $\beta$ -lactams. These reactions can be carried out at 100–225 °C, under pressure, although the reactions of alkene substrates shown in section 4 (see below) occur under milder conditions. Solvents are not necessary for [2 + 2] cycloadditions. However, the choice of solvent can control the distribution of products in photochemical [2 + 2] cycloaddition.<sup>2500</sup> Certain transition metal complexes can catalyze the cycloaddition.<sup>2501</sup>

Many variations of the basic reaction have been examined. The Ru-catalyzed [2 + 2] intramolecular cycloaddition of molecules that contain both an allene and an alkene moiety gave bicyclo[3.2.0]heptane skeletons that have a cyclobutane ring.<sup>2502</sup> Arene alkene cycloaddition reactions have been reviewed.<sup>2503</sup> Iron dinitrogen compounds catalyzed the intermolecular [2 + 2] cycloaddition of ethene and buta-1,3-diene to form vinylcyclobutane.<sup>2504</sup> Benzyne undergo cycloaddition to give biphenylene derivatives.<sup>2505</sup> Activated alkenes and certain methylenecyclopropanes also react.<sup>2506</sup> Alkenes react with alkynes<sup>2507</sup> or with activated alkynes, with a Ru<sup>2508</sup> or a Rh<sup>2509</sup> catalyst, to give cyclobutenes.<sup>2510</sup> Dimerization of allenes leads to bis(alkylidene) cyclobutenes.<sup>2511</sup>

Different alkenes combine as follows:

1.  $F_2C=CX_2$  ( $X = F$  or  $Cl$ ), especially  $F_2C=CF_2$ , form cyclobutenes with many alkenes. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal *Diels-Alder reactions*.<sup>2512</sup>
2. Allenes<sup>2513</sup> and ketenes<sup>2514</sup> react with activated alkenes and alkynes. Ketenes give 1,2-addition, even with conjugated dienes, to give cyclobutanone derivatives.<sup>2515</sup> Ketenes also add to unactivated alkenes if sufficiently long reaction times are

- used.<sup>2516</sup> Allenes and ketenes also add to each other,<sup>2517</sup> and substituted ketenes can dimerize to give cyclobutenone derivatives, although ketene itself dimerizes in a different manner, to give an unsaturated  $\beta$ -lactone (**16-89**).<sup>2518</sup> Lewis acid-catalyzed ketene alkene reactions are known,<sup>2519</sup> and intermolecular cycloadditions are well known.<sup>2520</sup> A typical reaction of dimethylketene and ethene gives 2,2-dimethylcyclobutanone.<sup>2521</sup> Ketimines<sup>2522</sup> and also imines<sup>2523</sup> reacted with allenates to give azetidines. A chiral NHC was used to catalyze the asymmetric [2 + 2] cycloaddition of alkylarylketenes with aldehydes to give stereodefined  $\beta$ -lactones.<sup>2524</sup>
- Enamines<sup>2525</sup> form four-membered rings with *Michael-type* alkenes<sup>2526</sup> and ketenes.<sup>2527</sup> In both cases, only enamines from aldehydes give stable four-membered rings. Generating the ketene *in situ* from an acyl halide and a tertiary amine is a convenient way to carry out the reaction of enamines with ketenes.
  - Alkenes with electron-withdrawing groups may form cyclobutanes with alkenes containing electron-donating groups.<sup>2528</sup> The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with alkenes of the form C=C–A, where A may be OR,<sup>2529</sup> SR (enol and thioenol ethers),<sup>2530</sup> cyclopropyl,<sup>2531</sup> or certain aryl groups.<sup>2532</sup>

Ketenes react with imines via a [2 + 2] cycloaddition to produce  $\beta$ -lactams, in what is commonly known as the *Staudinger reaction*, via a nonphotochemical [2 + 2] cycloaddition.<sup>2533</sup> See **19-70** for a discussion of reactions that give  $\beta$ -lactams. Ketenes have been generated using flow conditions (Sec. 7.D).<sup>2534</sup> Chiral *N*-heterocyclic carbenes catalyze

the Staudinger reaction of ketenes with imines to form  $\beta$ -lactam derivatives.<sup>2535</sup> The Rh-catalyzed cycloaddition of terminal alkynes and imines gave  $\beta$ -lactams.<sup>2536</sup> Cycloaddition of an imine with a conjugated ester in the presence of  $\text{Et}_3\text{MeSiH}$  and an Ir catalyst also gives a  $\beta$ -lactam.<sup>2537</sup> Ketene iminium salts reacted with alkenes<sup>2538</sup> to give azetidines and they reacted with alkynes to give dihydroacetidine.<sup>2539</sup> The *sulfa-Staudinger cycloaddition* (or *thio-Staudinger reaction*),<sup>2540</sup> based on the reaction of sulfonyl chlorides and imines with electron-donating N and C substituents, gave primarily *cis*- $\beta$ -sultams, whereas C electron-withdrawing substituents on the imine gave more of the *trans*- $\beta$ -sultam.<sup>2541</sup>

Enantioselective [2 + 2] cycloaddition reactions are known. Chiral organocatalysts lead to chiral cyclobutane derivatives.<sup>2542</sup> An enantiomeric photocycloaddition between an alkene with a (+)-camphor substituent and a conjugated ketone gave the polycyclic product.<sup>2543</sup>

Intramolecular [2 + 2] cycloadditions are common in which a diene is converted to a bicyclic compound with a four-membered ring fused to another ring. Heating *N*-vinyl imines, where the vinyl moiety is a silyl enol, gives  $\beta$ -lactams.<sup>2544</sup> Transition metal-catalyzed reactions have been reported, including the use of Fe complexes.<sup>2545</sup> Apart from photochemical initiation of such reactions (see below), intramolecular cycloaddition of two conjugated ketone units, in the presence of  $\text{PhMeSiH}_2$  and catalyzed by Co compounds, leads to the bicyclic compound with two ketone substituents.<sup>2546</sup>

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne bearing electron-withdrawing groups.<sup>2547</sup> These reactions are [ $\pi_2 + s_2$ ] cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems such as bicyclo[1.1.0]butanes<sup>2548</sup> and bicyclo[2.1.0]pentanes. For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbormane, as well as four other products.<sup>2549</sup> The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism.<sup>2550</sup>

It has been found that certain [2 + 2] cycloadditions that do not occur thermally can be made to take place without photochemical initiation using certain catalysts, usually transition metal compounds.<sup>2551</sup> Visible light mediates cycloaddition in the presence of a Rh catalyst.<sup>2552</sup> The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the  $\pi$  or  $\sigma$  bonds of the substrate.<sup>2553</sup> In such a case, the reaction would of course be a concerted [ $2_s + 2_s$ ] process.<sup>2554</sup> However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon  $\sigma$ -bonded intermediates, at least in most cases.<sup>2555</sup> For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by Ir complexes.<sup>2556</sup> Photochemical [ $\pi 2 + s 2$ ] cycloadditions<sup>2557</sup> have also been reported. The [2 + 2] photocycloaddition of cinnamates has been reported using flow conditions (Sec. 7.D).<sup>2558</sup> Some reverse cyclobutane ring openings can also be catalytically induced (18-38).

The photochemical cycloaddition of a carbonyl, generally from an aldehyde or ketone, and an alkene is called the *Paternò-Büchi reaction*.<sup>2559</sup> This [2 + 2] cycloaddition gives an oxetane (**74**) and the reaction is believed to proceed via a diradical intermediate. Silyl enol ethers react with aldehydes under nonphotochemical conditions using  $\text{ZnCl}_2$  at 25 °C or  $\text{SnCl}_4$  at –78 °C.<sup>2560</sup> A synthesis of stable oxetenes has been reported via the Pd-catalyzed [2 + 2] cycloaddition of alkynes with trifluoropyruvate.<sup>2561</sup> Quinones also react to give spirocyclic oxetanes.<sup>2562</sup>

In general, the mechanism consists of the addition of an excited state of the carbonyl compound to the ground state of the alkene. Both singlet ( $S_1$ )<sup>2563</sup> and  $n,\pi^*$  triplet<sup>2564</sup> states have been shown to add to alkenes to give oxetanes. A diradical intermediate<sup>2565</sup>  $\bullet\text{O}-\text{C}-\text{C}-\text{C}\bullet$  has been detected by spectroscopic methods.<sup>2566</sup> The reaction can be highly diastereoselective,<sup>2567</sup> and allylic alcohols were shown to react with aldehydes to give an oxetane with *syn* selectivity.<sup>2568</sup> There are several side reactions. When the reaction proceeds through a triplet state, it can in general be successful only when the alkene possesses a triplet energy comparable to, or higher than, the carbonyl compound; otherwise energy transfer from the excited carbonyl group to the ground-state alkene can take place (triplet–triplet photosensitization, Sec. 7.A.vi).<sup>2569</sup> Aldehydes and ketones also add photochemically to allenes to give the corresponding alkylidene oxetanes and dioxaspiro compounds.<sup>2570</sup> Aldehydes add to silyl enol ethers.<sup>2571</sup> An intramolecular reaction of ketones was reported to give a bicyclic oxetane via photolysis on the solid state.<sup>2572</sup>

A “transposed Paternò-Büchi” reaction used the  $\pi-\pi^*$  excited state of an alkene in an intramolecular reaction with an aldehyde chromophore to give the oxetane moiety.<sup>2573</sup>

Many, although by no means all, double bond compounds react *when photochemically excited* (either directly or by a photosensitizer, Sec. 7.A.vi, category 5), even if they are not in the above categories.<sup>2574</sup> Simple alkenes absorb in the far UV (Sec. 7.A.iii), which is difficult to reach experimentally, although this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to strained compounds such as cyclopropenes and cyclobutenes,<sup>2575</sup> but more often the double bond compounds involved are conjugated dienes,<sup>2576</sup>  $\alpha,\beta$ -unsaturated ketones,<sup>2577</sup> conjugated acids or acid derivatives, and quinones. Such conjugated compounds absorb at longer wavelengths (Sec. 7.A.iii).

Both dimerizations and mixed additions are common. Photochemical [2 + 2] cycloadditions can also take place intramolecularly if a molecule has two double bonds that are properly oriented.<sup>2578</sup> Two examples are the preparation of quadricyclane<sup>2579</sup> and of carvonecamphor from carvone.<sup>2580</sup>

However, attempted cyclizations of this kind are not always successful. In many cases, polymeric or other side products are obtained instead of the desired product.

It is possible that some of these photochemical cycloadditions take place by a  $[\pi 2_s + \pi 2_s]$  mechanism (which is of course allowed by orbital symmetry); when and if they do, one of the molecules must be in the excited singlet state ( $S_1$ ) and the other in the ground state. *Reactions between two excited molecules are extremely rare.* The nonphotosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,<sup>2581</sup> making it likely that the  $[\pi 2_s + \pi 2_s]$  mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place.<sup>2582</sup> In one intramolecular case, the intermediate diradical has been trapped.<sup>2583</sup> Photosensitized  $[2\pi + 2\pi]$  cycloadditions almost always involve the triplet state and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state (which is of course a singlet). Thus, in order to conserve spin,<sup>2584</sup> the initially formed diradical must be a triplet; that is, the two electrons must have the same spin. Consequently the second, or ring-closing, step of the mechanism cannot take place at once, because a new bond cannot form from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. The prediction is nonstereospecificity, and that is what is found.<sup>2585</sup> It has been believed that at least some [2 + 2] photocycloadditions take

<sup>2582</sup> Maradyn, D.J.; Weedon, A.C. *Tetrahedron Lett.* **1994**, *35*, 8107.

<sup>2583</sup> Becker, D.; Haddad, N.; Sahali, Y. *Tetrahedron Lett.* **1989**, *30*, 2661.

<sup>2584</sup> This is an example of the *Wigner spin conservation rule* (Sec. 7.A.vi, category 5). Note that spin conservation is something entirely different from symmetry conservation.

<sup>2585</sup> See, for example, Kramer, B.D.; Bartlett, P.D. *J. Am. Chem. Soc.* **1972**, *94*, 3934.

place by way of exciplex intermediates<sup>2586</sup> [an *exciplex*<sup>2587</sup> is an excited EDA complex (Sec. 7.A.vii) that is dissociated in the ground state; in this case one double bond is the donor and the other the acceptor], but there is evidence against this.<sup>2588</sup>

In **15-56**, the principle of conservation of orbital symmetry was used to explain why certain reactions take place readily and others do not. The orbital symmetry principle can also explain why certain molecules are stable although highly strained. Quadricyclane and hexamethylprismane<sup>2589</sup> are thermodynamically much less stable (because they are much more strained), for example, than their corresponding isomeric dienes, norbornadiene and hexamethylbicyclo[2.2.0]hexadiene (a Dewar benzene).<sup>2590</sup> Yet these two compounds can be kept indefinitely at room temperature, although in the absence of orbital symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a  $s_2 + s_2$  process) and, as seen previously, a thermal process of this sort is forbidden by the *Woodward-Hoffmann rules*. The process is allowed photochemically, so both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at room temperature or below.<sup>2591</sup> Although simple bond rearrangements can be imagined where hexamethylprismane is converted to hexamethylbenzene, which of course is far more stable, this rearrangement does not occur.

It has been calculated that hexamethylbenzene is at least  $90 \text{ kcal mol}^{-1}$  ( $380 \text{ kJ mol}^{-1}$ ) more stable than hexamethylprismane. A correlation diagram for this reaction<sup>2592</sup> discloses that it too is a symmetry forbidden process. Some “forbidden” reactions can take place when the compounds are heated, but the diradical mechanism is likely under these conditions.<sup>2592</sup>

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.<sup>2593</sup> These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the Dewar formula. Because of this, bicyclo[2.2.0]hexadiene is often called Dewar benzene. In the paragraph prior to Sec. 2.A, it was mentioned that Dewar formulas are canonical forms (although not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

Three mechanisms have been proposed for [2 + 2] cycloaddition.<sup>2594</sup>

The three mechanisms are a concerted pericyclic process, and two-step reactions involving, respectively, a diradical or a diion intermediate. As in **15-56**, a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, the diion mechanism is expected to be sensitive to changes in solvent polarity, while the concerted and the diradical mechanisms should be insensitive. The concerted mechanism is expected to be stereospecific, while the other two mechanisms probably would not be stereospecific. However, if the second step of these processes takes place very rapidly, before the diradical or the diion have a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations, such rapid ring closure might be more likely here than in a [4 + 2] cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal  $[\pi 2_s + \pi 2_s]$  mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a  $[\pi 2_s + \pi 2_a]$  mechanism is allowed (see above), and there is much evidence that ketenes and certain other linear molecules<sup>2595</sup> in which the steric hindrance to such an approach is minimal can and often do react by this mechanism. In a  $[\pi 2_s + \pi 2_a]$  cycloaddition the molecules must approach each other in such a way (Figure 15.11a) that the HOMO/LUMO overlap requires that the groups of one molecule project *into* the plane of the other. This does not happen with ordinary alkenes,<sup>2596</sup> but if one molecule is a ketene (Figure 15.11b), a group on carbon of the C=C unit is missing (relative to an alkene) and the  $[\pi 2_s + \pi 2_a]$  reaction can take place.

Among the evidence<sup>2597</sup> for this mechanism<sup>2598</sup> is the following:

1. The reactions are stereospecific.<sup>2599</sup>
2. The isomer that forms is the *more-hindered one*. Thus the reaction of methylketene plus cyclopentadiene gave only the *endo* product (**75**, A = H, R = CH<sub>3</sub>).<sup>2600</sup> Even

**FIGURE 15.11.** Steric interactions in  $[\pi 2_s + \pi 2_s]$  cycloaddition between (a) two alkene molecules and (b) a ketene and an alkene.

**FIGURE 15.12.** Orbital overlap in the reaction of a ketene with cyclopentadiene. Reproduced from Brook, P.R.; Harrison, J.M.; Duke, A.J. *J. Chem. Soc., D* **1970**, 589 with permission from the Royal Society of Chemistry.

more remarkably, when haloalkyl ketenes  $\text{RXC}=\text{C}=\text{O}$  were treated with cyclopentadiene, the *endo/exo* ratio of the product (**75/76**, A = halogen) actually *increased* substantially when R was changed from Me to *i*-Pr to *t*-Bu!<sup>2601</sup>

One would expect preferential formation of the *exo* products (**76**) from  $[\pi 2_s + \pi 2_s]$  cycloadditions where the molecules approach each other face to face. However, a  $[\pi 2_s + \pi 2_a]$  process leads to *endo* products because the ketene molecule (which for steric reasons would approach with its smaller group, methyl in the figure, directed toward the alkene) must twist as shown in Figure 15.12<sup>2602</sup> (*tert*-butyl = larger; methyl = smaller group) in order for the +lobes to interact. This process swings the larger group (*tert*-butyl) into the *endo* position.<sup>2602</sup> The experimental results in which the amount of *endo* isomer increases with the increasing size of the R group appears to be contrary to what would be expected from steric hindrance

considerations (called *masochistic steric effects*), but they are just what is predicted for a  $[\pi 2_s + \pi 2_a]$  reaction.

3. There is only moderate polar solvent acceleration.<sup>2603</sup>
4. The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.<sup>2604</sup> Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place by the  $[\pi 2_s + \pi 2_a]$  mechanism,<sup>2605</sup> but the evidence in these cases is more consistent with the diradical mechanism *b*.<sup>2606</sup>

The diradical mechanism is most prominent in the reactions involving fluorinated alkenes.<sup>2607</sup> These reactions are generally not stereospecific<sup>2608</sup> and are insensitive to solvent effects. Further evidence that a diion is not involved is that head to head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of  $F_2C=CFCl$  gives 1,2-dichloro-1,2,3,3,4,4-hexafluorocyclobutane, not 1,3-dichloro-1,2,2,3,4,4-hexafluorocyclobutane. If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.<sup>2609</sup>

The diion mechanism<sup>2610</sup> has been reported for at least some of the reactions<sup>2611</sup> in categories 3 and 4 (see above),<sup>2612</sup> as well as some ketene dimerizations.<sup>2613</sup>

The rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether, for example, was strongly influenced by changes in solvent polarity.<sup>2614</sup> Some of these reactions are nonstereospecific, but others are stereospecific.<sup>2615</sup> As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation

can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating groups and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given alkene reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the  $\alpha$  positions of diradical  $\bullet\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\bullet$  or diion  $^+\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2^-$  help to stabilize the diradical, while donors such as oxygen and nitrogen favor a diion (they stabilize the positively charged end).<sup>2616</sup> A table published elsewhere (Ref. 2616, p. 451) shows which mechanism is more likely for [2 + 2] cycloadditions of various pairs of alkenes.

Thermal cleavage of cyclobutanes<sup>2617</sup> to give two alkene molecules (*cycloreversion*,<sup>2618</sup> the reverse of [2 + 2] cycloaddition) operates by the diradical mechanism, and the  $[\sigma 2_s + \sigma 2_a]$  pathway has not been found<sup>2619</sup> (the subscripts  $\sigma$  indicate that  $\sigma$  bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds. The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see **15-61**)<sup>2620</sup> or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (Sec. 2.K.ii).<sup>2621</sup>

have been added to double bonds, but the reaction is often performed with  $\text{CH}_2$  itself, with halo and dihalocarbenes,<sup>2623</sup> and with carbalkoxycarbenes<sup>2624</sup> (generated from diazoacetic esters). Alkylcarbenes HCR have been added to alkenes,<sup>2625</sup> but more often these rearrange to give alkenes (Sec. 5.D.ii, category 4). The carbene can be generated in any of the ways normally used (Sec. 5.D.ii). However, most reactions in which a cyclopropane is formed by treatment of an alkene with a carbene “precursor” do not actually involve free carbene intermediates. In some cases it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (Sec. 5.D.ii) is actually involved.

Carbene itself ( $:\text{CH}_2$ ) is extremely reactive and gives many side reactions, especially insertion reactions (**12-21**), which greatly reduce yields. This competition is also true with Rh-catalyzed diazoalkane cyclopropanations<sup>2626</sup> (see below). When  $:\text{CH}_2$  must be added for preparative purposes, a free carbene is not used, but the Simmons-Smith procedure (see structure **79** later in this section) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.<sup>2627</sup> Vinyl diazotactone is a vinylcarbene precursor for a reaction with alkenes to give spirolactones.<sup>2628</sup>

Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the alkene increase the rate of the reaction, and electron-withdrawing groups decrease it,<sup>2629</sup> although the range of relative rates is not very great.<sup>2630</sup> The activation energies of carbene addition to alkenes has been estimated.<sup>2631</sup> As discussed in Sec. 5.D.i, carbenes in the singlet state (which is the most common state) react stereospecifically and *syn*,<sup>2632</sup> probably by a one-step mechanism.<sup>2633</sup> Infrared spectra of a carbene and the cyclopropane product have been observed in an argon matrix at 12–45 K.<sup>2634</sup>

Carbenes in the triplet state react nonstereospecifically,<sup>2635</sup> probably by a diradical mechanism.

For carbenes or carbenoids of the type  $R-C-R'$  with alkene systems  $ABC=CDM$ , where A and D are *trans* in the alkene and in the cyclopropane product, there is another aspect of stereochemistry.<sup>2636</sup> When these species are added to all but symmetrical alkenes, two isomers are possible, (R is *cis* to A or R is *trans* to A) even if the four groups originally on the double bond carbons maintain their configurations. Which isomer is predominantly formed depends on R, on R', and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species ( $R' = H$ ), and in these studies it is found that aryl groups generally prefer the more substituted side (*syn* addition) while carbethoxy groups usually show *anti* stereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for *syn* addition. Beyond this, it is difficult to make simple generalizations.

The absolute rate constant for addition of selected alkoxychlorocarbenes to butenes has been measured to range from 330 to  $1 \times 10^4 M^{-1} s^{-1}$ .<sup>2637</sup> Both entropy and enthalpy play a role in addition of some carbenes.<sup>2638</sup> A few of the many ways<sup>2639</sup> in which halocarbenes or carbenoids are generated are the reaction of organolithium reagents with dichloromethane, the photolysis of  $N_2CHBr$ , the reaction of chloroform with hydroxide,<sup>2640</sup> the thermolysis of  $PhHgCCl_2Br$ ,<sup>2641</sup> the reaction of  $NaI$  with  $Me_3SnCF_3$ ,<sup>2642</sup> and the electrolysis of 2,2-dibromopropane.<sup>2643</sup> An equilibration between halocarbene and halocarbanions has been observed.<sup>2644</sup> A trifluoromethylcarbene source has been developed.<sup>2645</sup> Difluorocarbene has been generated using continuous flow techniques (Sec. 7.D).<sup>2646</sup>

The reaction between  $CHCl_3$  and  $HO^-$  is often carried out under phase-transfer conditions.<sup>2647</sup> It has been shown that the reaction between  $PhCHCl_2$  and *t*-BuOK produces a carbenoid, but when the reaction is run in the presence of a crown ether, the carbene  $Ph(Cl)C:$

is formed instead.<sup>2648</sup> The reaction of iodoform and  $\text{CrCl}_2$  leads to iodocyclopropanes upon reaction with alkenes.<sup>2649</sup> Dihalocyclopropanes are very useful compounds<sup>2650</sup> that can be reduced to cyclopropanes, treated with Mg or Na to give allenes (**18-3**), or converted to a number of other products.

Alkenes of all types can be converted to cyclopropane derivatives by this reaction, but difficulty may be encountered with sterically hindered ones.<sup>2651</sup> Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.<sup>2652</sup> Conjugated dienes give 1,2-addition to give a vinylcyclopropane.<sup>2653</sup> Addition of a second molar equivalent gives bicyclic propyl derivatives.<sup>2654</sup> 1,4-Addition is rare but has been reported in certain cases.<sup>2655</sup> Carbene adds to ketene to give cyclopropanone.<sup>2656</sup> Allenes react with carbenes to give cyclopropanes with an exocyclic double bond.<sup>2657</sup> A second equivalent gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.<sup>2658</sup>

The *Büchner ring expansion* is a two-step C–C bond-forming reaction that gives seven-membered rings. The *retro-Büchner reaction* of 7-substituted 1,3,5-cycloheptatrienes, promoted by cationic gold, gave gold(I) carbenes and reaction with alkenes gave the cyclopropane.<sup>2659</sup>

Free carbenes can also be avoided by using transition metal/carbene complexes  $\text{L}_n\text{M}=\text{CRR}'$  (L = a ligand, M = a metal),<sup>2660</sup> which add the group CRR' to double bonds.<sup>2661</sup> An example is the reaction of an iron carbene ( $\text{Cp}(\text{CO})_2\text{Fe}=\text{CHMe}$ ) that reacted with styrene to give 3-methyl-1-phenylcyclopropane.<sup>2662</sup> These complexes can be isolated in some cases; in others they are generated *in situ* from appropriate precursors, of which diazo compounds are among the most important. Chromium complexes have been used for the cyclopropanation of alkenes.<sup>2663</sup>

reaction of enynols that have a propargyl alcohol moiety, which functions as  $\beta$ -oxocarbene precursors.<sup>2683</sup>

Asymmetric cyclopropanation reactions are a growing area of interest,<sup>2684</sup> and chiral complexes have been used for enantioselective cyclopropane synthesis.<sup>2685</sup> Decomposition of diazoalkanes in the presence of chiral Rh,<sup>2686</sup> Cu,<sup>2687</sup> Ir,<sup>2688</sup> Co,<sup>2689</sup> Au,<sup>2690</sup> or Ru<sup>2691</sup> complexes leads to optically active cyclopropanes. The Rh-catalyzed cycloaddition using chiral ligands leads to formation of cyclopropanes with good enantioselectivity.<sup>2692</sup> The use of chiral additives or auxiliaries with a metal complex also leads to cyclopropanes enantioselectively.<sup>2693</sup> An important chiral species is Rh<sub>2</sub>(S-DOSP)<sub>4</sub>,<sup>2694</sup> which leads to cyclopropanes with excellent enantioselectivity in carbene cyclopropanation reactions.<sup>2695</sup> Chiral organocatalysts have been used.<sup>2696</sup> Engineered myoglobin-based catalysts have been developed.<sup>2697</sup> Organocatalytic enantioselective cyclopropanation has been reported using continuous flow techniques (Sec. 7.D).<sup>2698</sup> Asymmetric, intramolecular cyclopropanation reactions have been reported.<sup>2699</sup> It is noted that the reaction of a diazo ester with a chiral dirhodium catalyst leads to  $\beta$ -lactones with modest enantioselectivity.<sup>2700</sup>

Triple bond compounds<sup>2701</sup> react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they

rearrange to allenes.<sup>2702</sup> Cyclopropenones (Sec. 2.K.i) are obtained by hydrolysis of dihalocyclopropenes.<sup>2703</sup> Transition metal-catalyzed reactions are well known.<sup>2704</sup>

Carbenes are so reactive that they add to the “double bonds” of aromatic rings.<sup>2705</sup> The products are usually unstable and rearrange to give ring expansion. Carbene reacts with benzene to give cyclohepta-1,3,5-triene.<sup>2706</sup>

The norcaradiene intermediate cannot be isolated in this case<sup>2707</sup> as it undergoes an electrocyclic rearrangement (18-27). However, certain substituted norcaradienes, for example, the product of addition of  $:\text{C}(\text{CN})_2$  to benzene,<sup>2708</sup> have been isolated.<sup>2709</sup> Not all carbenes are reactive enough to add to benzene. With  $:\text{CH}_2$ , insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding  $:\text{CH}_2$  to benzene rings without the use of free carbene is the catalytic decomposition of diazomethane ( $\text{CH}_2\text{N}_2$ ) in the aromatic compound as solvent with  $\text{CuCl}$  or  $\text{CuBr}$ .<sup>2710</sup> By this method better yields of cycloheptatrienes are obtained without insertion side products. *Picosecond optical grating calorimetry* has been used to investigate the photochemical decomposition of diazomethane in benzene, and it appears that a transient intermediate is formed that is consistent with a weak complex between singlet methylene and benzene.<sup>2711</sup> Chlorocarbene,  $:\text{CHCl}$ , is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. The activation parameters of arylchlorocarbenes for their electrophilicity with regard to additions to alkenes has been reported.<sup>2712</sup>

The Pd-catalyzed cyclopropanation of heterocycles is known.<sup>2713</sup> Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes<sup>2714</sup> via the initially formed adduct **77** in the case of the indole. In such cases, a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring expansion can occur even with nonaromatic compounds, especially when the driving force is supplied by relief of strain (see **78**).<sup>2715</sup>

As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons-Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion side products.<sup>2716</sup> This is known as a *carbenoid* reaction. Intramolecular variations are known.<sup>2717</sup> The Simmons-Smith procedure involves treatment of the double bond compound with  $\text{CH}_2\text{I}_2$  and a Zn/Cu couple and leads to cyclopropane derivatives in good yields.<sup>2718</sup> The Zn/Cu couple can be prepared in several ways,<sup>2719</sup> and heating Zn dust with CuCl in ether under nitrogen<sup>2720</sup> is particularly convenient. The reaction has also been done with unactivated Zn and ultrasound.<sup>2721</sup> When  $\text{TiCl}_4$  is used along with Zn and CuCl,  $\text{CH}_2\text{I}_2$  can be replaced by the cheaper  $\text{CH}_2\text{Br}_2$ .<sup>2722</sup> Borocyclopropanation of allylic ethers used boromethylzinc carbenoids.<sup>2723</sup> The effect of additives on certain zinc carbenoid reactions has been discussed.<sup>2724</sup>

The actual attacking species is an organozinc intermediate, probably  $(\text{ICH}_2)_2\text{Zn}\cdot\text{ZnI}_2$ , which is stable enough for isolable solutions.<sup>2725</sup> An X-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.<sup>2726</sup> The addition is stereospecifically *syn*, and a concerted mechanism is likely,<sup>2727</sup> perhaps involving **79**.<sup>2728</sup>

An iodomethylzinc phosphate has also been used for cyclopropanation reactions.<sup>2729</sup> Diiodomethane gives cyclopropanes in a reaction mediated by indium.<sup>2730</sup> Asymmetric induction is possible when chiral additives are used.<sup>2731</sup> Chiral complexes also lead to enantioselectivity in the cyclopropanation reaction.<sup>2732</sup> Organocatalysts have been used.<sup>2733</sup> With the Simmons-Smith procedure, as with free carbenes, conjugated dienes give 1,2-addition,<sup>2734</sup> and allenes give methylenecyclopropanes or spiropentanes.<sup>2735</sup>

An alternative way of carrying out the Simmons-Smith reaction is by treatment of the substrate with  $\text{CH}_2\text{I}_2$  or another dihalomethane and  $\text{Et}_2\text{Zn}$  in ether.<sup>2736</sup> The reaction of diethylzinc and diiodomethane gave ketones that were chain extended by one carbon.<sup>2737</sup> This method can be adapted to the introduction of  $\text{RCH}$  and  $\text{ArCH}$  by the use of  $\text{RCHI}_2$  or  $\text{ArCHI}_2$  instead of the dihalomethane.<sup>2738</sup> The reaction is compatible with other functionality in the carbenoid complex. The reaction of  $\text{RCO}_2\text{CH}_2\text{I}$  with diethyl zinc and an alkene under photolysis conditions give a cyclopropane.<sup>2739</sup> Samarium and  $\text{CH}_2\text{I}_2$  has been used for the cyclopropanation of conjugated amides.<sup>2740</sup> For the conversion of enolate anions to cyclopropanols,  $\text{CH}_2\text{I}_2$  has been used along with  $\text{SmI}_2$ .<sup>2741</sup> Diodomethane in the presence of isopropylmagnesium chloride has been used to cyclopropanate allyl alcohols.<sup>2742</sup>

The *Simmons-Smith reaction* is the basis of a method for the indirect  $\alpha$  methylation of a ketone.<sup>2743</sup> The ketone is first converted to an enol ether, an enamine (**16-12**), or a silyl enol ether<sup>2744</sup> (**12-17**), and cyclopropanation via the Simmons-Smith reaction is followed by hydrolysis to give the  $\alpha$ -methylated ketone. In another variation, phenols can be *ortho*-methylated in one laboratory step, by treatment with  $\text{Et}_2\text{Zn}$  and  $\text{CH}_2\text{I}_2$ .<sup>2745</sup>

Stable two-coordinate acyclic silylenes have been prepared.<sup>2746</sup>

## 15-61 Trimerization and Tetramerization of Alkynes

Aromatic compounds can be prepared by cyclotrimerization of alkynes<sup>2747</sup> or triynes. Cyclotrimerization is possible by heating to 450–600 °C with no catalyst.<sup>2748</sup> The *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF gave 1,2,3-tri-*tert*-butyl-4,5,6-trifluorobenzene (**81**), the first time three adjacent *tert*-butyl groups had been put onto a benzene ring.<sup>2749</sup> The fact that this is a head to head joining allows formation of **81** from two alkynes. The fact that **80** (a Dewar benzene) was also isolated lends support to this scheme.<sup>2750</sup>

When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.<sup>2751</sup> It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes,<sup>2752</sup> and this reaction has been used to prepare very crowded molecules. Dialkylalkynes were trimerized over CO<sub>2</sub>(CO)<sub>8</sub><sup>2753</sup> and over Hg[Co(CO)<sub>4</sub>]<sub>2</sub> to give hexaisopropylbenzene.<sup>2754</sup> The six isopropyl groups are not free to rotate but are lined up perpendicular to the plane of the benzene ring. Highly substituted benzene derivatives have also been prepared via cyclotrimerization using Rh,<sup>2755</sup> Ni,<sup>2756</sup> Ti,<sup>2757</sup> Mo,<sup>2758</sup> Ru,<sup>2759</sup> In,<sup>2760</sup> Fe,<sup>2761</sup>

Co,<sup>2762</sup> or Pd<sup>2763</sup> catalysts. Alkynes react with allenes and a Ni catalyst to give highly substituted benzene derivatives.<sup>2764</sup> Conjugated ketones react with internal alkynes with Me<sub>3</sub>Al and a Ni catalyst<sup>2765</sup> to give an aromatic ring fused to a cyclic ketone after reaction with DBU and air.<sup>2766</sup> *N*-Aryl chloroimines react with alkynes and a Rh catalyst to give quinolines,<sup>2767</sup> as do *N*-aryl alkynyl imines with a W complex.<sup>2768</sup>

Intramolecular cyclotrimerizations have been reported by condensation of a diyne<sup>2769</sup> with an alkyne in the presence of a Pd,<sup>2770</sup> Mo,<sup>2771</sup> Ni,<sup>2772</sup> Rh,<sup>2773</sup> Ir,<sup>2774</sup> Ag,<sup>2775</sup> Au/Ag,<sup>2776</sup> Co,<sup>2777</sup> or Ru catalyst.<sup>2778</sup> Triynes have been similarly condensed with a Rh<sup>2779</sup> or a Co<sup>2780</sup> catalyst. Note that this type of cyclization has been labeled as a [2+2+2] cycloaddition reaction, which is discussed in reaction 15-62. The internal cyclotrimerization of a triyne, utilizing a siloxy tether and a Co catalyst, has been reported.<sup>2781</sup> Fused-ring aromatic compounds are prepared by this method. Similar results were obtained from diynes and allenes with a Ni catalyst.<sup>2782</sup> A Ni-catalyzed cross cyclotrimerization and dimerization of allenes and alkynes has been reported.<sup>2783</sup> Solid-supported cyclotrimerizations have been reported.<sup>2784</sup> Benzene derivatives with *ortho* alkyne units can be converted to naphthalene derivatives in aqueous NaOH with hydrazine, Te, NaBH<sub>4</sub>, and sonication.<sup>2785</sup> Vinyl and alkyne substituents with a Ru catalyst lead to naphthalene derivatives.<sup>2786</sup> Cyclotrimerization occurs with alkynyl boronic esters.<sup>2787</sup>

There are many variations of this basic approach. Imino and iodo substituents with a silyl alkyne and a Pd catalyst lead to an isoquinoline.<sup>2788</sup> Benzene derivatives having *ortho*

imine and alkyne substituents give an isoquinoline when treated with iodine<sup>2789</sup> or with a Pd catalyst.<sup>2790</sup> Diynes with nitriles and a Ru catalyst lead to isoquinolines.<sup>2791</sup> Isocyanides and alkynes also react with a phosphine catalyst to give pyrroles.<sup>2792</sup>  $\alpha,\beta$ -Unsaturated oxime pivalates in the presence of cationic Rh complexes reacted with alkenes via irreversible migratory insertion to give 2,3-dihydropyridine products.<sup>2793</sup>

Nitriles react with 2 molar equivalents of acetylene, in the presence of a Co catalyst, to give 2-substituted pyridines.<sup>2794</sup> Propargyl amines react with cyclohexanone derivatives and a Au complex give tetrahydroquinolines.<sup>2795</sup> Treatment of alkynes with  $\text{Cp}_2\text{ZrEt}_2$  followed by reaction with acetonitrile and then a second alkyne, with a Ni catalyst, gives a highly substituted pyridine.<sup>2796</sup> This reaction can be done intramolecularly using a photochemically induced reaction with a Co catalyst and *p*-TolCN to give pyridines incorporated into macrocycles.<sup>2797</sup> Diynes react with *N*-heterocyclic carbenes in the presence of a Ni catalyst to give pyridines.<sup>2798</sup> Alkynyl esters react with enamino esters with a  $\text{ZnBr}_2$  catalyst to give substituted pyridines.<sup>2799</sup>

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene  $\text{RC}\equiv\text{CH}$ . The chief product is usually the 1,2,4 isomer,<sup>2800</sup> with lesser amounts of the 1,3,5 isomer also generally obtained, but little if any of the 1,2,3 isomer.

The mechanism of the catalyzed reaction to form benzenes<sup>2801</sup> is believed to go through a species **82**, in which two molecules of alkyne coordinate with the metal, and another species **83**, a five-membered heterocyclic intermediate.<sup>2802</sup> Such intermediates (where  $\text{M} = \text{Rh}$ ,  $\text{Ir}$ ,<sup>2803</sup> or  $\text{Ni}$ ) have been isolated and shown to give benzenes (**84**) when treated with

alkynes.<sup>2804</sup> Note that this pathway accounts for the predominant formation of the 1,2,4 isomer. Two possibilities for the last step are a *Diels-Alder reaction*, and a ring expansion, each followed by extrusion of the metal:<sup>2805</sup> In at least one case the mechanism is different, going through a cyclobutadiene/Ni complex (Sec. 2.K.ii), which has been isolated.<sup>2806</sup> Similar results were obtained with a Ti complex.<sup>2807</sup> Using a mixture of PdCl<sub>2</sub> and CuCl<sub>2</sub>, however, aliphatic alkynes are converted to the 1,3,5-trialkyl benzene derivative.<sup>2808</sup>

Alkoxy Cr carbenes (*Fischer carbene complexes*, see **15-54**) react with phenyl alkynes to give naphthalene derivatives.<sup>2809</sup> These Cr carbenes react with alkynyl boronates, cerium (IV) compounds, and then PhBr and a Pd catalyst to give a naphthoquinone.<sup>2810</sup> Diynes react to give cyclotrimerization.<sup>2811</sup> It is noted that vinyl Cr carbenes react directly with alkynes to give spirocyclic compounds (spiro[4.4]nona-1,3,6-trienes).<sup>2812</sup> Benzofurans can be prepared using methoxy carbenes.<sup>2813</sup> Imino-substituted Cr carbenes react with alkynes to give pyrrole derivatives.<sup>2814</sup> Fischer carbene complexes react with alkynes to give the *Dötz benzannulation*,<sup>2815</sup> giving *p*-alkoxyphenol derivatives. Modification of this basic technique can lead to eight-membered ring carbocycles (see **15-62**).<sup>2816</sup>

OS VII, 256; IX, 1; **80**, 93.

## 15-62 Other Cycloaddition Reactions

Cycloaddition reactions other than [4 + 2], [3 + 2], or [2 + 2] are possible, often providing synthetically useful routes to cyclic compounds. The Cu-catalyzed [3 + 1] cycloaddition of alkenyl diazoacetates and iminoiodinanes gave 2-azetines.<sup>2817</sup> A [3 + 3] annulation reaction was used to prepare 1-alkylquinolines.<sup>2818</sup> Tetrahydroquinolines have also been prepared.<sup>2819</sup> The enantioselective [3 + 3] cycloaddition of 2,3-disubstituted indoles and acrolein has been reported.<sup>2820</sup> Triazinines and azetidines have been prepared by [3 + 3]

cycloaddition reactions.<sup>2821</sup> Tetrahydropyridazines have been prepared by a [3 + 3] cycloaddition.<sup>2822</sup>

The reaction of a conjugated carbonyl compound with a diazo ester, in the presence of a Cu catalyst, leads to a dihydropyran in what is labeled a [4 + 1] cycloaddition.<sup>2823</sup> Dienes react with nitriles in a Ti-mediated [4 + 1] cycloaddition.<sup>2824</sup> Reaction with a chiral Rh catalyst converts dienes and diazo compounds to cycloheptadienes.<sup>2825</sup> The intramolecular [4 + 1] cycloaddition of a dialkoxycarbene and an electron-deficient diene gave 5–5, 6–5, and 7–5 fused *O*-heterocyclic compounds, where the stereoselectivity is dependent on the length of the tether.<sup>2826</sup> A spirophosphine-catalyzed [4 + 1] annulation of amines with allenes gave dihydropyrroles.<sup>2827</sup> The reaction of 3-bromooxindoles,  $\alpha,\beta$ -unsaturated *N*-tosylimines, and 2'-methyl  $\alpha$ -isocupreine led to  $\alpha$ -substituted ammonium ylids, which gave spirocyclic oxindoles.<sup>2828</sup> The Rh-catalyzed [4 + 1] annulation reaction of  $\alpha,\alpha$ -difluoromethylene alkyne, as a nontraditional one-carbon reaction partner, with *N*-methoxybenzamide derivatives gave isoindolin-1-one derivatives.<sup>2829</sup> Propargyl acetates of the type  $\text{RCH}(\text{OAc})\text{C}\equiv\text{C}(\text{CH}_3)=\text{CH}_2$  undergo [4 + 1] cycloaddition with CO, with a Rh catalyst, to give cyclopentenones.<sup>2830</sup> Methylenecyclopropanes reacted with enones via [4 + 1] cycloaddition using a Ni catalyst to give dihydrofurans.<sup>2831</sup> 2,5-Dihydrofurans were prepared by the gold-catalyzed [4 + 1] cycloaddition of  $\alpha$ -diazo esters and propargyl alcohols.<sup>2832</sup> The enantioselective [4 + 1] annulation of pyrazolones and 2-(acetoxymethyl)buta-2,3-dienoates, catalyzed by amino acid-derived phosphines, gave spiropyrazolones.<sup>2833</sup>

A Cu-catalyzed [5 + 1] annulation of 2-ethynylanilines with an *N,O*-acetal gave quinoline derivatives with 2-carboalkyl substituent.<sup>2834</sup> An Fe-mediated [5 + 1] cycloaddition of vinylcyclopropanes (VCPs) and CO gave  $\alpha,\beta$ -cyclohexenones.<sup>2835</sup> Dihydrofuro[3,2-*c*]pyridine was prepared by the reaction of ammonium acetate and 1-acyl-1-[(dimethylamino)alkenoyl]cyclopropanes via [5C + 1N] annulation.<sup>2836</sup>

The Rh-catalyzed intramolecular cycloaddition of a furan with a conjugated diazo ester gave a [4 + 3] cycloadduct.<sup>2837</sup> The suprafacial thermal addition of an allylic cation to a diene (a [4 + 3] cycloaddition) is allowed by the *Woodward-Hoffmann rules* (this reaction

would be expected to follow the same rules as the *Diels-Alder reaction*<sup>2838</sup>). Pyrroles react with allylic diazo compounds, in the presence of a Rh catalyst, to give bicyclic amines in a [4 + 3] cycloaddition.<sup>2839</sup> A different [4 + 3] cycloaddition involves the intramolecular reaction of a diene with an alkylidenecyclopropane unit, in the presence of a Pd catalyst, to give a seven-membered ring as part of a bicyclic system.<sup>2840</sup> Chiral cations have been used in [4 + 3] cycloadditions.<sup>2841</sup> An aza [4 + 3] cycloaddition of cyclic dienes and aza-oxyallyl cationic intermediates, generated *in situ* by the dehydrohalogenation of  $\alpha$ -haloamides, gave a bicyclic product.<sup>2842</sup> The [4 + 3] cycloaddition of aromatic conjugated aldehydes or ketones with epoxides, catalyzed by a Lewis acid, gave seven-membered ring oxacycles.<sup>2843</sup> Diaza [4 + 3] cycloadditions of cyclic dienes via diaza-oxyallyl cationic intermediates led to the 1,4-diamination of cyclic dienes.<sup>2844</sup> An aza [4 + 3] cycloaddition, Rh catalyzed, of vinyl aziridines and dienes gave azeprines.<sup>2845</sup> Indolizines have been prepared by an aza [4 + 3] annulation.<sup>2846</sup>

Conjugated dienes can be dimerized or trimerized at the 1,4-positions (formally [4 + 4] and [4 + 4 + 4] cycloadditions) by treatment with certain complexes or other transition metal compounds.<sup>2847</sup> Thus buta-1,3-diene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.<sup>2848</sup> The relative amount of each product can be controlled by use of the proper catalyst. Initial [4 + 4] photocycloaddition of an enyne with a pyridone yields a 1,2,5-cyclooctatriene; subsequent photooxidation gives a cyclopropanone and subsequent photoextrusion of carbon monoxide gave the observed 1,4-cycloheptadiene product.<sup>2849</sup>

A [5 + 2] cycloaddition<sup>2850</sup> of vinylcyclopropanes and alkenes, in the presence of a Rh catalyst, leads to seven-membered rings.<sup>2851</sup> A dual thiourea catalyst system was developed for an intramolecular oxidopyrylium [5 + 2] cycloaddition that gave tricyclic structures enantioselectively.<sup>2852</sup>

Cycloheptatriene reacts with terminal alkynes, using complex catalysts involving Co and Zn compounds, to give a bicyclic triene via a [6 + 2] cycloaddition.<sup>2853</sup> Eight-membered rings were formed by the Rh-catalyzed [6 + 2] cycloaddition of 4-allenals and alkynes.<sup>2854</sup> Tricyclopentanoids were prepared using organocatalysts via a [6 + 2] cycloaddition.<sup>2855</sup> The intramolecular Rh-catalyzed [6 + 2] cycloaddition of 4-allenals and alkynes or alkenes gave

6–8-fused bicyclic ketone derivatives.<sup>2856</sup> A Cu/ferrocene-catalyzed [6 + 3] cycloaddition of tropone and azomethine ylids gave piperidine-fused bicyclic heterocycles.<sup>2857</sup> Chromium catalysts are available for [6 + 4] cycloadditions.<sup>2858</sup>

As seen in **15-56**, the *Woodward-Hoffmann rules* allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is  $[4n + 2]$  and photochemically if the number is  $4n$ . Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight-membered or greater, concerted mechanisms, although allowed by orbital symmetry for the cases stated, become difficult to achieve. Due to the entropy factor, the two ends of one system must simultaneously encounter the two ends of the other, unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight-membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct [4 + 4] or [4 + 4 + 4] cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples are shown here:

Benzene rings can undergo photochemical cycloaddition with alkenes.<sup>2863</sup> The major product is usually the 1,3-addition product **85** (in which a three-membered ring has also been formed), although some of the 1,2-product **86** (**15-59**) is sometimes formed as well. (**86** is usually the main product where the alkene bears electron-withdrawing groups and the aromatic compound electron-donating groups, or vice versa.) The 1,4-product **87** is rarely formed. The reaction has also been run with benzenes substituted with alkyl, halo, OR, CN, and other groups, and with acyclic and cyclic alkenes bearing various groups.<sup>2864</sup>

Alkynes and isocyanates react with CO in the presence of a Ru catalyst to give imides,<sup>2865</sup> and other [2+2+1] cycloadditions are known.<sup>2866</sup> A [2+2+1] annulation of a terminal alkyne, a nitrile, and an oxygen atom from reaction of Au/carbene intermediates gave 2,5-disubstituted oxazoles,<sup>2867</sup> although PhIO with TfOH or Tf<sub>2</sub>NH has also been used to give an oxazole.<sup>2868</sup> The Ru-catalyzed [2+2+1] reaction of  $\alpha,\omega$ -diynes with DMSO gave bicyclic furans.<sup>2869</sup> A free radical-mediated [2+2+1] cycloaddition reaction of acetylenes, amidines, and CO gave five-membered  $\alpha,\beta$ -unsaturated lactams.<sup>2870</sup> The Ni-catalyzed [2+2+1] carbonylative cycloaddition reaction of imines and alkynes or norbornene used phenyl formate as a CO source to give *N*-benzenesulfonyl-, -tosyl, and -phosphoryl-substituted  $\gamma$ -lactams.<sup>2871</sup>

[2+2+2] cycloaddition reactions are known<sup>2872</sup> (also see **15-61**), usually with diynes, enynes, or intermolecular reactions of alkynes or alkenes<sup>2873</sup> with an alkyne, and facilitated

# Addition to Carbon–Heteroatom Multiple Bonds

## 16.A. MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds, and to the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15;<sup>1</sup> this is because C=O, C=N, and C≡N bonds are strongly polar, with the carbon always being the positive end (except for isocyanides, Sec. 16.B.iv). The carbonyl carbon is polarized δ+, so an attacking nucleophilic species always goes to the carbon.<sup>2</sup> Additions to C=S bonds are much less common,<sup>3</sup> but in a few cases the addition is in the other direction (reaction at sulfur is called *thiophilic addition* and addition to the carbon is called *carbophilic addition*).<sup>4</sup> For example, the reaction of phenyllithium with thiobenzophenone Ph<sub>2</sub>C=S gives, after hydrolysis, benzhydryl phenyl sulfide (Ph<sub>2</sub>CHSPh).<sup>5</sup>

The normal acyl addition of a nucleophile, represented by Y<sup>−</sup>, to a ketone forms a new C–Y bond and generates an alkoxide, and hydrolysis gives an alcohol.

Note that the product has a stereogenic carbon, but unless there is chirality in R or R' or the nucleophile is optically active, the product must be a racemic mixture because there is no facial bias for addition to the carbonyl. The same holds true for acyl-type addition to C=N and C=S bonds. The addition of a single nucleophile to the carbon–nitrogen triple

bond gives an imine, which can exist in (*E*) and (*Z*) forms (Sec. 4.K.i), but the imine is generally so reactive that further reactions ensue. Of course, if R or R' is chiral, a mixture of diastereomers will result, and the stereochemistry of addition can be studied in such cases. *Cram's rule* or the *Felkin-Anh model* (Sec. 4.H) allows the direction of nucleophilic attack to be predicted in many cases.<sup>6</sup> However, the relative orientation of the substrate molecule must be considered.

In Sec. 15.B.iii, electronic effects were shown to play a part in determining which face of a carbon–carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantan-2-ones (shown) electron-withdrawing (*-I*) groups W cause the attack to come from the *syn* face, while electron-donating groups cause it to come from the *anti* face.<sup>7</sup>

In 5,6-disubstituted norborn-2-en-7-one systems, the carbonyl appears to tilt away from the  $\pi$  bond, with reduction occurring from the more hindered face.<sup>8</sup> An *ab initio* study of nucleophilic addition to 4-*tert*-butylcyclohexanones attempted to predict  $\pi$ -facial selectivity.<sup>9</sup>

The mechanistic picture is further simplified by the fact that free-radical additions to carbon–heteroatom double bonds are not as prevalent (but see **16-31**).<sup>10</sup> In most cases, the nucleophile forms the first new bond to carbon, and these reactions are regarded as *nucleophilic additions*, which is usually followed by a protonation step to give the alcohol product. In almost all the reactions considered in this chapter the electrophilic atom is either hydrogen or carbon.<sup>11</sup> After the initial acyl addition, the alkoxide intermediate looks a little like the tetrahedral intermediate in Sec. 16.A.i, but carbon groups are poor leaving groups so subsequent substitution is not possible, allowing protonation to give the alcohol. When a conjugating C=C unit is present, it is noted that electrophilic attack at the double bond is often observed to be *anti* to the most electron-donating  $\sigma$  bond at the  $\alpha$  position (referred to as the *extended anomeric effect*).<sup>12</sup>

Both acids and bases can catalyze many of these reactions.<sup>13</sup> Bases catalyze the reaction by converting a reagent Y–H to the more powerful nucleophile Y<sup>-</sup> (Sec. 10.G.ii). Acids

catalyze reactions by converting the substrate to an heteroatom-stabilized cation (a resonance stabilized<sup>14</sup> *oxocarbenium ion*  ${}^+C-O-H \leftrightarrow C=O^+-H$ ; Sec. 5.A.ii), making it more attractive to nucleophilic attack and making the reverse reaction somewhat less favorable. Similar catalysis can also be achieved with metallic ions (e.g.,  $Ag^+$ ), which act as Lewis acids.<sup>15</sup> The oxocarbenium ion quickly reacts with the nucleophile to give the acyl addition product. The rate-determining step is usually the one involving nucleophilic attack. If one heteroatom such as oxygen stabilizes an adjacent carbocation, a second heteroatom (X) will stabilize an oxocarbenium ion ( $-X-C^+-X-$ ) to a greater extent.<sup>16</sup>

Reactivity factors for carbon-heteroatom multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution (Sec. 16.A.i).<sup>17</sup> If electron-donating groups such as alkyl groups are present, rates are decreased, and conversely the presence of electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule but is lost on going to the intermediate. Double bonds in conjugation with the carbon-heteroatom multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4-addition (Sec. 15.A.ii). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones such as hexamethylacetone and dioneopentyl ketone either do not undergo many of these reactions or require extreme conditions.

### 16.A.i. Nucleophilic Substitution at an Aliphatic Trigonal Carbon: The Tetrahedral Mechanism

All the mechanisms discussed in previous chapters for substitution take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double bonded to an oxygen, a sulfur, or a nitrogen. Substitution at a carbonyl group (or the corresponding nitrogen and sulfur analogs) most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*<sup>18</sup> *mechanism*.<sup>19</sup> The IUPAC designation is  $A_N + D_N$ . The  $S_N1$  mechanisms, involving carbocations, are sometimes found with these substrates, especially with essentially ionic substrates such as  $RCO^+ BF_4^-$ ; there is evidence that in certain cases simple  $S_N2$  mechanisms can take place, especially with a very good leaving group such as  $Cl^-$ ,<sup>20</sup> and an SET mechanism has also been reported.<sup>21</sup> However, the tetrahedral mechanism is by far the most prevalent. Although this mechanism displays second-order kinetics, it is not the same as the  $S_N2$

mechanism discussed in Sec. 10.A.i. In the tetrahedral mechanism, the nucleophile (Y) attacks to give an intermediate containing both X and Y (**1**). Since X is such reactions is a good leaving group, the electron pair on oxygen “kicks out” the X group, regenerating the carbonyl to give the new acyl derivative.

This sequence is impossible at a saturated carbon since there is no leaving group after the nucleophile reacts.

When reactions are carried out in acid solution the carbonyl reacts as a base with  $H^+$  to give an oxocarbenium ion. An electron pair on oxygen allows formation of a carbonyl as an oxocarbenium ion, with concomitant expulsion of the X leaving group to give the new acyl product.

The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.<sup>22</sup>

Evidence for the existence of the tetrahedral mechanism is as follows:<sup>23</sup>

1. The kinetics are first order in both the substrate and the nucleophile, as predicted by the mechanism.
2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate “constant” for the reaction between acetamide and hydroxylamine is not constant, but decreases with increasing hydroxylamine concentration.<sup>24</sup> This is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, *this result cannot happen if there is only one step: so, there must be two steps, and hence an intermediate.* Similar kinetic behavior has been found in other cases as well;<sup>25</sup> in particular, plots of rate against pH are often bell shaped.
3. Basic hydrolysis has been carried out on carboxylic esters labeled with  $^{18}O$  in the carbonyl group.<sup>26</sup> If this reaction proceeded by the normal  $S_N2$  mechanism, all the  $^{18}O$  would remain in the carbonyl group, even if, in an equilibrium process, some of

<sup>26</sup> Bender, M.L.; Thomas, R.J. *J. Am. Chem. Soc.* **1961**, 83, 4183, 4189.

the carboxylic acid formed went back to the starting material. On the other hand, if the tetrahedral mechanism operates then the tetrahedral intermediate would have the  $^{18}\text{O}^-$ , which will react with an acid such as water and be converted to the conjugate acid, symmetrical intermediate with the  $^{18}\text{OH}$  moiety. In such an intermediate the OH and the  $^{18}\text{OH}$  groups are equivalent with respect to reactivity, and (except for the small  $^{18}\text{O}/^{16}\text{O}$  isotope effect) either one can lose a proton with equal facility to generate an alkoxide, which can lose an alkoxide with  $^-\text{OH}$  or  $\text{H}^{18}\text{O}^-$  and regenerate the ester.

Reversion back to the ester from one intermediate will give the labeled ester whereas loss from the other intermediate will give the unlabeled ester. A test of the two possible mechanisms is to stop the reaction before completion and to analyze the recovered ester for  $^{18}\text{O}$ . Experiments by Bender and Thomas found that in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost  $^{18}\text{O}$ . A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that the ester also lost  $^{18}\text{O}$ . However, alkaline hydrolysis of substituted benzyl benzoates showed *no*  $^{18}\text{O}$  loss.<sup>27</sup> This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If either the labeled or unlabeled intermediate do not revert to ester, but go entirely to acid, no  $^{18}\text{O}$  loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates this situation may very well be happening, because formation of the acid relieves steric strain. Another possibility is that the labeled intermediate loses  $\text{OR}'$  before it can become protonated to give the unlabeled intermediate.<sup>28</sup> Even the experiments that *do* show  $^{18}\text{O}$  loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that  $^{18}\text{O}$  is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck<sup>29</sup> measured the rate of  $^{18}\text{O}$  loss in the hydrolysis of ethyl trifluorothioacetate- $^{18}\text{O}$ ,  $\text{F}_3\text{CC}^{18}\text{OSet}$ . This reaction had previously been shown<sup>30</sup> to involve an intermediate by the kinetic methods mentioned above. Bender and Heck showed that the rate of  $^{18}\text{O}$  loss and the value of the partitioning ratio  $k_2/k_3$  as determined by the oxygen exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original  $^{18}\text{O}$ -exchange measurements showed that there is a tetrahedral species present, but not necessarily on the reaction path, while the kinetic experiments showed that there is some intermediate present, but not necessarily tetrahedral. Bender and Heck's results demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

4. In some cases, tetrahedral intermediates have been isolated<sup>31</sup> or detected spectrally.<sup>32</sup>

Several studies have been made of the directionality of approach by the nucleophile.<sup>33</sup> Menger has proposed for reactions in general, and specifically for those that proceed by the tetrahedral mechanism, that there is no single definable preferred transition state, but rather a “cone” of trajectories. All approaches within this cone lead to reaction at comparable rates; it is only when the approach comes outside of the cone that the rate falls.

Directionality has also been studied for the second step. Once the tetrahedral intermediate (**1**) is formed, it loses Y (giving the product) or X (reverting to the starting compound). Deslongchamps<sup>34</sup> has proposed that one of the factors affecting this choice is the conformation of the intermediate; more specifically, the positions of the lone pairs. In this view, a leaving group X or Y can depart only if the other two atoms on the carbon both have an orbital antiperiplanar to the C–X or C–Y bond. For example, consider an intermediate **2** formed by attack of <sup>−</sup>OR on a substrate R'COX. Cleavage of the C–X bond with loss of X can take place from conformation **A**, because the two lone-pair orbitals marked \* are antiperiplanar to the C–X bond, but not from **B** because only the O<sup>−</sup> has such an orbital.

If the intermediate is in conformation **B**, the OR may leave (if X has a lone-pair orbital in the proper position) rather than X. This factor is called *stereoelectronic control*.<sup>35</sup> Free rotation in acyclic intermediates leads to many conformations, but some are preferred, and cleavage reactions may take place faster than rotation, so stereoelectronic control can be a factor in some situations. Much evidence has been presented for this concept.<sup>34</sup> More generally, the term *stereoelectronic effects* refers to any case in which orbital position requirements affect the course of a reaction. The back-side attack in the S<sub>N</sub>2 mechanism is an example of a stereoelectronic effect.

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.<sup>36</sup> There occur, in effect, two tetrahedral mechanisms. The first is:

and an example is shown in **16-57**. When this type of reaction occurs internally, it is a neighboring-group mechanism at a carbonyl carbon.<sup>37</sup> For example, the hydrolysis of phthalamic acid (**3**) takes place as follows via formation of phthalic anhydride, which is hydrolyzed to phthalic acid.

Evidence comes from comparative rate studies.<sup>38</sup> It was found that **3** was hydrolyzed  $\sim 10^5$  times faster than benzamide ( $\text{PhCONH}_2$ ) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of  $\text{COOH}$  (an electron-withdrawing group) was shown by the fact both *o*-nitrobenzamide and terephthalamic acid (the *para* isomer of **3**) were hydrolyzed more slowly than benzamide. Other examples of neighboring-group participation at a carbonyl carbon have been reported.<sup>39</sup> It is likely that nucleophilic catalysis is involved in enzyme-catalyzed ester hydrolysis.

The attack of a nucleophile on a carbonyl group can result in substitution or addition, depending on the substituents, but the first step of each mechanism is the same. The main factor that determines the product is the identity of the group X in  $\text{RCOX}$ . When X is alkyl or hydrogen, addition usually takes place and an alcohol is the product. When X is halogen,  $\text{OCOR}$ ,  $\text{NH}_2$ , and so on, the usual reaction is substitution and an acyl derivative is the product. When  $\text{X} = \text{OH}$ , protonation to generate  $^+\text{OH}_2$  is usually required before the group can be lost.

In both the  $\text{S}_{\text{N}}1$  and  $\text{S}_{\text{N}}2$  mechanisms the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways:

1. By altering the electron density at the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X, the greater the partial positive charge on C and the more rapid the attack by a nucleophile.
2. The nature of the leaving group affects the *position of equilibrium*. In the intermediate **1** above, there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y, then Y will preferentially leave and **4** will revert to the starting compounds. Thus there is a partitioning factor between **4** going on to product (loss of X) or back to starting compound (loss of Y).

The sum of these two factors causes the sequence of reactivity to be  $\text{RCOCl} > \text{RCOOCOR}' > \text{RCOOAr} > \text{RCOOR}' > \text{RCONH}_2 > \text{RCONR}'_2 > \text{RCOO}^-$ .<sup>40</sup> Note that this

<sup>37</sup> Kirby, A.J.; Fersht, A.R. *Prog. Bioorg. Chem.* **1971**, *1*, 1; Capon, B. *Essays Chem.* **1972**, *3*, 127.

<sup>39</sup> See Page, M.I.; Render, D.; Bernáth, G. *J. Chem. Soc., Perkin Trans. 2* **1986**, 867.

<sup>40</sup>  $\text{RCOOH}$  would belong in this sequence just after  $\text{RCOOAr}$ , but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the  $\text{C}=\text{O}$  group, are basic enough to take a proton from the acid, converting it to the unreactive  $\text{RCOO}^-$ .

TABLE 16.1 The more important synthetic reactions that take place by the tetrahedral mechanism<sup>a</sup>

Reaction No.	Reaction
16-56	$\text{RCOX} + \text{H}_2\text{O} \longrightarrow \text{RCOOH}$
16-57	$\text{RCOOCOR}' + \text{H}_2\text{O} \longrightarrow \text{RCOOH} + \text{R}'\text{COOH}$

<sup>a</sup> Catalysts are not shown.

order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

For a list of some of the more important reactions that operate by the tetrahedral mechanism, see Table 16.1.

## 16.B. REACTIONS

Many of the reactions in this chapter are simple additions to carbon–heteroatom multiple bonds, with the reaction ending when a new group has been added. But in many other cases subsequent reactions take place. There are generally two types, A and B:

In type A, the initially formed adduct loses water (or, in the case of addition to C=NH, ammonia, etc.), and the net result of the reaction is the substitution of C=Y for C=O (or C=NH, etc.). In type B there is a rapid substitution, and the OH (or NH<sub>2</sub>, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is nucleophilic in most cases: Y usually has an unshared electron pair and S<sub>N</sub>1 reactions occur very well on

this type of compound (Sec. 10.G.i, category 2), even when the leaving group is as poor as OH or NH<sub>2</sub>. In this chapter, reactions will be classified according to what is initially adding to the carbon–heteroatom multiple bond, even if subsequent reactions take place so rapidly that it is impossible to isolate the initial adduct.

Most of the reactions considered in this chapter can be reversed. In many cases, the reverse reactions will be considered with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another from this chapter (e.g., **16-2** and **16-12**). For reactions that are reversible, the principle of microscopic reversibility applies (see Sec. 6.H).

First, reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the heteroatom will be discussed. Secondly, reactions in which carbon adds to the heteroatom will be discussed. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, follow. Acyl substitution reactions that proceed by the tetrahedral mechanism, which mostly involve derivatives of carboxylic acids, are treated at the end.

## 16.B.i. Reactions in Which Hydrogen or a Metallic Ion Adds to the Heteroatom

### A. Attack by OH (Addition of H<sub>2</sub>O)

#### 16-1 The Addition of Water to Aldehydes and Ketones: Formation of Hydrates

The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.<sup>41</sup> These compounds are usually stable only in water solution and decompose on distillation; i.e., the equilibrium shifts back toward the carbonyl compound, usually via formation of an enol and tautomerization to the carbonyl. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20 °C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.<sup>42</sup> Aldehyde hydrates are highly unstable, transient intermediates but *N*-oxides are capable of stabilizing such compounds based on the formation of hydrogen bonds.<sup>43</sup>

It has been found, by exchange with <sup>18</sup>O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.<sup>44</sup> Since methyl, a +I group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral (trichloroacetaldehyde)<sup>45</sup> is a stable crystalline substance. In order

<sup>42</sup> Bell, R.P.; Clunie, J.C. *Trans. Faraday Soc.* **1952**, *48*, 439. See also, Bell, R.P.; McDougall, A.O. *Trans. Faraday Soc.* **1960**, *56*, 1281.

<sup>43</sup> Roth, A.J.K.; Tretbar, M.; Stark, C.B.W. *Chem. Commun.* **2015**, *51*, 14175.

<sup>44</sup> Cohn, M.; Urey, H.C. *J. Am. Chem. Soc.* **1938**, *60*, 679.

<sup>45</sup> For a review of chloral, see Luknitskii, F.I. *Chem. Rev.* **1975**, *75*, 259.

for it to revert to chloral,  ${}^{-}\text{OH}$  or  $\text{H}_2\text{O}$  must leave; this is made difficult by the electron-withdrawing character of the  $\text{Cl}_3\text{C}$  group and by the absence of a proton on the  $\alpha$  carbon, which is required for loss of water to form an enol. Some other<sup>46</sup> polychlorinated and polyfluorinated aldehydes and ketones<sup>47</sup> and  $\alpha$ -keto aldehydes also form stable hydrates, as do cyclopropanones.<sup>48</sup> In the last case,<sup>49</sup> formation of the hydrate relieves some of the *I* strain (Sec. 9.B) of the parent ketone.

The reaction is subject to both general-acid and general-base catalysis. The following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:<sup>50</sup>

As the hydroxide attacks in the base-catalyzed mechanism, the base pulls off a proton to give an alkoxide, which reacts with an endogenous acid (usually water,  $\text{H}-\text{O}-\text{H}$ ) to give the hydrate. In the acid-catalyzed mechanism, the carbonyl oxygen reacts with an acid to give an oxocarbenium ion which reacts with water to form an oxonium ion. Removal of the acidic hydrogen with an endogenous base, usually water, gives the hydrate.

Reactions in which the catalyst donates a proton to the electrophilic reagent in one direction and removes it in the other have been called *class e reactions*, and those reactions in which the catalyst does the same to the nucleophilic reagent are called *class n reactions*.<sup>51</sup> Thus the acid-catalyzed process here is a class e reaction, while the base-catalyzed process is a class n reaction.

For the reaction between ketones and  $\text{H}_2\text{O}_2$ , see **17-35**.

There are no OS references, but see OS **VIII**, 597, for the reverse reaction.

## 16-2 Hydrolysis of the Carbon–Nitrogen Double Bond<sup>52</sup>

Compounds containing C–N double bonds can be hydrolyzed to the corresponding aldehydes or ketones.<sup>53</sup> For imines ( $\text{W} = \text{R}$  or  $\text{H}$ ) the hydrolysis is easy and can be carried out with

<sup>53</sup> For proton affinities of imines, see Hammerum, S.; Sjølling, T.I. *J. Am. Chem. Soc.* **1999**, *121*, 6002.

water in some cases. When  $W = H$ , the imine is seldom stable enough for isolation, and in aqueous media hydrolysis usually occurs *in situ*, without isolation. The hydrolysis of *Schiff bases* ( $W = Ar$ ) is more difficult and requires acid or base catalysis. Oximes ( $W = OH$ ), arylhydrazones ( $W = NHAr$ ), and, most easily, semicarbazones ( $W = NHCONH_2$ ) can also be hydrolyzed. Often a reactive aldehyde (e.g., formaldehyde) is added to combine with the liberated amine. A number of reagents<sup>54</sup> have been used to cleave  $C=N$  bonds, especially those not easily hydrolyzable with acidic or basic catalysts or those that contain other functional groups that are attacked under these conditions.

Oximes have been converted to the corresponding aldehyde or ketone<sup>55</sup> by treatment with NBS in water,<sup>56</sup> Chloramine-T,<sup>57</sup>  $HCO_2H$  on  $SiO_2$  with microwave irradiation,<sup>58</sup>  $O_2/a$  nitrite-containing resin (FPA53- $NO_2$ )/Amberlyst-15,<sup>59</sup> anhydrous  $Ce(SO_4)_2$  in chloroform,<sup>60</sup> or in an ionic liquid on  $SiO_2$ .<sup>61</sup> Transition metal compounds have been used, including those of Sb,<sup>62</sup> Co,<sup>63</sup> Hg,<sup>64</sup> Bi,<sup>65</sup> Cu,<sup>66</sup> or Zn.<sup>67</sup> Oxidizing agents can be quite effective, including tetraalkylammonium permanganates,<sup>68</sup> and quinolinium dichromate<sup>69</sup> has also been used.

Phenylhydrazones can be converted to a ketone using Oxone<sup>®</sup> and  $KHCO_3$ ,<sup>70</sup> or polymer-bound iodonium salts.<sup>71</sup> Dimethylhydrazones have been converted to ketones with  $FeSO_4 \cdot 7 H_2O$  in chloroform,<sup>72</sup> or  $Me_3SiCl/NaI$  in acetonitrile with 1% water.<sup>73</sup> Hydrazones, such as RAMP or SAMP (**10-68**, category 4), can be hydrolyzed with aq.  $CuCl_2$ .<sup>74</sup> Tosylhydrazones can be hydrolyzed to the corresponding ketones with aqueous acetone and  $BF_3$ -etherate,<sup>75</sup> as well as with other reagents.<sup>76</sup> Semicarbazones have been cleaved with ammonium chlorochromates on alumina,<sup>77</sup>  $(Mg(HSO_4)_2$  on wet silica,<sup>78</sup> or by  $SbCl_3$  with microwave irradiation.<sup>79</sup>

The hydrolysis of C–N double bonds involves initial addition of water and elimination of a nitrogen moiety.<sup>80</sup> In specific cases there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.<sup>81</sup> Which step is rate determining also depends on the acidity and on the nature of W (see above) and of the groups connected to the carbonyl.<sup>82</sup>

Iminium ions (**4**)<sup>83</sup> would be expected to undergo hydrolysis quite readily (note that there is a resonance contributor with a positive charge on the carbon).

Indeed, iminium ions react with water at room temperature.<sup>84</sup> Acid-catalyzed hydrolysis of enamines to the corresponding carbonyl (the last step of the *Stork enamine reaction*, **10-69**), involves conversion to iminium ions that react with water. Loss of a proton gives the carbonyl.<sup>85</sup> The mechanism of enamine hydrolysis is similar to that of vinyl ether hydrolysis (**10-6**).

### 16-3 Hydrolysis of Aliphatic Nitro Compounds

Primary or secondary aliphatic nitro compounds can be hydrolyzed to aldehydes or ketones, respectively, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction*.<sup>86</sup> Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like **16-2**, this reaction involves hydrolysis of a C=N

<sup>80</sup> For reviews of the mechanism, see Bruylants, A.; Feytmants-de Medicis, E. in Patai, S. *The Chemistry of the Carbon-Nitrogen Double Bond*, Wiley, NY, **1970**, pp. 465–504; Salomaa, P. in Patai, S. *The Chemistry of the Carbonyl Group*, pt. 1, Wiley, NY, **1966**, pp. 199–205.

double bond. A possible mechanism involves initial formation of the *aci form* of the nitro compound (**5**).<sup>87</sup> Intermediates of type **6** have been isolated in some cases.<sup>88</sup>

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods.<sup>89</sup> Among these are treatment of the nitro compound with basic  $\text{H}_2\text{O}_2$  in an ionic liquid,<sup>90</sup> with DBU in MeCN,<sup>91</sup> or with ceric ammonium nitrate (CAN).<sup>92</sup>

When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for their preparation.<sup>93</sup> Both the Nef reaction and the hydroxamic acid process involve the *aci form*; the difference in products arises from higher acidity, for example, a difference in sulfuric acid concentration from 2 to 15.5 M changes the product from the aldehyde to the hydroxamic acid.<sup>94</sup> The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated *aci form* of the nitro compound is further protonated.

#### 16-4 Hydrolysis of Nitriles

Nitriles can be hydrolyzed to give either amides or carboxylic acids.<sup>95</sup> The amide is formed initially, but amides can be hydrolyzed using more vigorous acidic or basic conditions to give the carboxylic acid. When the acid is desired,<sup>96</sup> the reagent of choice is aqueous NaOH containing ~6 to 12%  $\text{H}_2\text{O}_2$ , but acid-catalyzed hydrolysis can also be used. The reaction of nitriles with TFA/acetic acid/sulfuric acid, followed by treatment with water, gives the corresponding amide.<sup>97</sup> A Rh-catalyzed hydrolysis with aqueous isopropyl alcohol leads

to the amide.<sup>98</sup> A “dry” hydrolysis of nitriles has been reported.<sup>99</sup> Enzymatic hydrolysis to give the amide was reported with nitrilase ZmNIT2.<sup>100</sup> Nitriles can be hydrolyzed to the carboxylic acids without disturbing carboxylic ester functions also present by the use of tetrachloro- or tetrafluorophthalic acid.<sup>101</sup>

Nitriles were hydrolyzed to the corresponding carboxylic acid using a recyclable ionic liquid, [bmim]HSO<sub>4</sub>.<sup>102</sup> The bioreduction of nitriles to carboxylic acids used *Rhodococcus erythropolis* SET1, a novel nitrile-hydrolyzing bacterial isolate, with a phosphate buffer.<sup>103</sup> Nitrilases converted nitriles to the corresponding carboxylic acid, and a chromogenic reagent has been developed to screen for nitrilase activity.<sup>104</sup> Cobalt-centered nitrile hydratases gave enantioselective hydrolysis.<sup>105</sup>

There are a number of procedures for stopping at the amide stage,<sup>106</sup> among them the use of concentrated H<sub>2</sub>SO<sub>4</sub> and of aqueous NaOH with PEG-400 and microwave irradiation.<sup>107</sup> The same result can also be obtained by use of water and certain metal ions or complexes<sup>108</sup> including In,<sup>109</sup> Au,<sup>110</sup> a Ru catalyst,<sup>111</sup> or MnO<sub>2</sub>/SiO<sub>2</sub> with microwave irradiation.<sup>112</sup> A bimetallic catalyst composed of Pd and a Lewis acid was used to convert nitriles to the amide.<sup>113</sup> Nitriles were hydrolyzed to amides using a Mo catalyst in water.<sup>114</sup> Hydrolysis of benzonitrile derivatives with 3 equivalents of KO-*t*-Bu in *t*-BuOH gave the benzamide derivative under anhydrous conditions.<sup>115</sup> A flow chemistry process (Sec. 7.D) for the hydration of nitriles gave the corresponding amide by passage of an aqueous solution of the nitrile through a column containing commercially available amorphous manganese dioxide.<sup>116</sup> The hydration of nitriles used amorphous manganese oxide with a reduced amount of water.<sup>117</sup> The mild hydration of nitriles to amides used a Cu catalyst.<sup>118</sup> The selective hydration of nitriles was catalyzed by a Pd catalyst in aqueous solution.<sup>119</sup>

## B. Attack by OR (Addition of ROH or RCO<sub>2</sub>H)

### 16-5 The Addition of Alcohols to Aldehydes and Ketones

Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.<sup>123</sup> Lewis acid derivatives of Ti,<sup>124</sup> Cu,<sup>125</sup> In,<sup>126</sup> Ru,<sup>127</sup> or Co<sup>128</sup> can be used in conjunction with alcohols. Organocatalysts have been used for this conversion under acid-free conditions.<sup>129</sup> This reaction is reversible, and acetals and ketals can be hydrolyzed by treatment with acid.<sup>130</sup> With small unbranched aldehydes the equilibrium lies to the right. If ketals or acetals of larger molecules are to be prepared the equilibrium must be shifted, usually by removal of water. Removal of water can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent such as  $\text{Al}_2\text{O}_3$  or a molecular sieve.<sup>131</sup> The reaction is not catalyzed in either direction by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This reaction is therefore a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope.

Most aldehydes are easily converted to acetals,<sup>132</sup> but the reaction with ketones is more difficult, presumably for steric reasons. The reaction of aldehydes with alcohols using a photochemical reaction under low-energy visible light irradiation in the presence of a catalytic amount of Eosin Y and green LEDs gave the corresponding acetal.<sup>133</sup> While the reaction with ketones often fails, many ketals, especially from cyclic ketones, have been made in this manner.<sup>134</sup> Many functional groups may be present without being affected. 1,2-Diols and 1,3-diols form cyclic acetals and ketals (1,3-dioxolanes<sup>135</sup> and 1,3-dioxanes,<sup>136</sup> respectively), and these are often used to protect aldehydes and ketones. Chiral dioxolanes have been prepared from chiral diols.<sup>137</sup> Dioxolanes have been prepared from ketones in ionic liquids.<sup>138</sup> Ketones are converted to dimethyl ketals by electrolysis with NaBr in methanol.<sup>139</sup> Intramolecular reactions are possible in which a keto diol or an aldehyde diol generates a bicyclic ketal or acetal. The Ru-catalyzed synthesis of mixed alkyl alkyl acetals occurred via addition of primary alcohols to allyl ethers.<sup>140</sup>

The mechanism for acid-catalyzed acetal/ketal formation involves initial formation of a *hemiacetal*,<sup>141</sup> and this reaction is the reverse of that given for acetal hydrolysis. In a study of the acid-catalyzed formation of hemiacetals, Grunwald showed<sup>142</sup> that the data best fit a mechanism in which the reaction is simultaneously catalyzed by acid and base, with water acting as the base.<sup>143</sup>

Hemiacetals themselves are no more stable than the corresponding hydrates (**16-1**). If the original aldehyde or ketone has an  $\alpha$  hydrogen, it is possible to lose water from the hemiacetal, and enol ethers can be prepared. Similarly, treatment with an anhydride and a catalyst can give an enol ester (see **16-5**).<sup>144</sup> As with hydrates, it is noted that hemiacetals of

cyclopropanones<sup>145</sup> and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

The conversion of acetals back to aldehydes or ketones is accomplished by many reagents, including aqueous acid. Heating with water under microwave irradiation converts acetals to the corresponding carbonyl compound.<sup>146</sup> Transition metal compounds of Bi<sup>147</sup> catalyze this conversion as well. When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, *transacetalation* is possible (see **10-13**). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,<sup>148</sup> in the presence of an acid catalyst. This is shown here for an ortho ester.

This method is useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. Alternatively, the substrate is treated with an alkoxy silane (ROSiMe<sub>3</sub>) in the presence of trimethylsilyl trifluoromethanesulfonate.<sup>149</sup> An In catalyst converted acyclic acetals and ketals in the presence of diols or triols under solvent-free conditions to give the corresponding new cyclic acetal or ketal.<sup>150</sup>

1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds.

Similarly, 1,5-diketones give pyrans.

1,4-Diphenylbut-2-en-1,4-dione, a conjugated 1,4-diketone, is converted to 2,5-diphenylfuran with formic acid, 5% Pd/C, PEG-200, and a sulfuric acid catalyst with microwave irradiation.<sup>151</sup>

Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of proton acids,<sup>152</sup>  $\text{BF}_3$ ,  $\text{LiBF}_4$ ,<sup>153</sup> and Lewis acid compounds of Fe,<sup>154</sup> In,<sup>155</sup> Cu,<sup>156</sup> Bi,<sup>157</sup> W,<sup>158</sup> or Zr.<sup>159</sup> *N*-Chlorosuccinimide (NCS) with thiourea is a highly efficient catalyst.<sup>160</sup> Silica-supported perchloric acid is useful for the preparation of acylals.<sup>161</sup>

Formic acid reacts with alcohols to give orthoformates. The Co-catalyzed intramolecular ketone hydroacylation reactions of 2-acylbenzaldehydes and 2-alkenylbenzaldehydes gave phthalide and indanone derivatives, respectively.<sup>162</sup>

OS IV, 489.

### 16-6 Reductive Alkylation of Alcohols

Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid<sup>163</sup> or by hydrogenation in alcoholic acid in the presence of a Pt catalyst.<sup>164</sup> The process can formally be regarded as addition of ROH to give a hemiacetal  $\text{RR}'\text{C}(\text{OH})\text{OR}^2$ , followed by reduction of the OH. In this respect, it is similar to **16-15**. Homoallylic ethers are formed by the Fe-catalyzed reaction of acetals and aldehydes,<sup>165</sup> and by reactions in ionic liquids.<sup>166</sup> The In-catalyzed reaction of aldehydes with allyltriethoxysilane leads to the corresponding ether.<sup>167</sup>

## 16-7 The Addition of Alcohols to Isocyanates

The reaction of an isocyanate with alcohols gives a carbamate (a substituted urethane),<sup>170</sup> is of wide scope, and gives good yields. Isocyanic acid  $\text{HNCO}$  gives unsubstituted carbamates. Addition of a second equivalent of  $\text{HNCO}$  gives an *allophanate*:  $\text{NH}(\text{CO}_2\text{R}')\text{CON}_2$ .

The isocyanate can be generated *in situ* by the reaction of an amine and oxalyl chloride, and subsequent reaction with  $\text{HCl}$  and then an alcohol gives the carbamate.<sup>171</sup> Combining compounds with two  $\text{NCO}$  groups with compounds containing two  $\text{OH}$  groups makes polyurethanes. Cyclic carbamates, such as 1,3-oxazine-2-ones, are generated by the reaction of an isocyanate with an oxetane, in the presence of a  $\text{Pd}$  catalyst.<sup>172</sup> Isothiocyanates similarly give thiocarbamates<sup>173</sup>  $\text{RNHCSOR}'$ , but they react slower than the corresponding isocyanates. Isocyanates react with  $\text{LiAlHSeH}$  and then iodomethane to give the corresponding selenocarbonate ( $\text{RNHCOSeMe}$ ).<sup>174</sup> The reaction of  $\text{CS}_2$ , amines, and boronic acids gave the corresponding dithiocarbamate using a  $\text{Cu}$  catalyst.<sup>175</sup>

The details of the mechanism are poorly understood,<sup>176</sup> but the oxygen of the alcohol certainly attacks the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.<sup>177</sup> Metallic compounds can also catalyze the addition of  $\text{ROH}$  to isocyanates,<sup>178</sup> as can light,<sup>179</sup> and, for tertiary  $\text{ROH}$ , so can lithium alkoxides<sup>180</sup> or *n*-butyllithium.<sup>181</sup>

## 16-8 Alcoholysis of Nitriles

The addition of dry HCl to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester. (Note that imino esters are also called imidates and imino ethers.) This reaction is called the *Pinner synthesis*.<sup>182</sup> The salt can be converted to the free imino ester by treatment with a weak base such as sodium bicarbonate, or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aqueous HCl can be used and the need for gaseous HCl is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.<sup>183</sup> Amides were prepared by the Ru-catalyzed reaction of alcohols and nitriles.<sup>184</sup>

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified and with no diester or diacid present.

OS I, 5, 270; II, 284, 310; IV, 645; VI, 507; VIII, 415.

## 16-9 The Formation of Carbonates and Xanthates

The reaction of phosgene with an alcohol generates a haloformic ester (XCO<sub>2</sub>R), and reaction with a second equivalent of alcohol gives a carbonate. This reaction is related to the acyl addition reactions of acyl chlorides in reaction 16-92. An important example is the preparation of carbobenzoxy chloride (PhCH<sub>2</sub>OCOCl; CbzCl) from phosgene and benzyl alcohol. When CbzCl reacts with an amine, the product is the benzyl carbamate, *N*-Cbz, which is widely used for the protection of amino groups during peptide synthesis. When an alcohol reacts with certain alkyl halides (e.g., benzyl chloride) and CO<sub>2</sub>, in the presence of Cs<sub>2</sub>CO<sub>3</sub> and tetrabutylammonium iodide, a mixed carbonate is formed.<sup>185</sup>

<sup>182</sup> See Compagnon, P.L.; Miocque, M. *Ann. Chim. (Paris)* **1970**, [14] 5, 23 (see pp. 24–26). Imino esters: see Neilson, D.G. in Patai, S. *The Chemistry of Amidines and Imidates*, Wiley, NY, **1975**, pp. 385–489.

<sup>185</sup> Kim, S.i.; Chu, F.; Dueno, E.E.; Jung, K.W. *J. Org. Chem.* **1999**, 64, 4578.

Epoxides reacted with CO<sub>2</sub> in the presence of an Al complex to give a carbonate.<sup>186</sup> An aluminum(salen) catalyst,<sup>187</sup> choline iodide,<sup>188</sup> cellulose/KI,<sup>189</sup> triethanolamine/KI,<sup>190</sup> 3-hydroxypridine/Bu<sub>4</sub>NI,<sup>191</sup> and phosphonium iodides in alcoholic solvents<sup>192</sup> have been used for this carbonate-forming reaction. Electrosynthesis has also been used.<sup>193</sup> A bromine-catalyzed reaction of CO<sub>2</sub> and epoxides to give cyclic carbonates has been reported using flow conditions (Sec. 7.D).<sup>194</sup> The *N*-heterocyclic carbene-catalyzed preparation of cyclic carbonates from diols and CO<sub>2</sub> has been reported.<sup>195</sup> Unsymmetrical carbonates were prepared from alcohols and dimethylcarbonate.<sup>196</sup>

The addition of alcohols to carbon disulfide (S=C=S) in the presence of a base produces xanthates.<sup>197</sup> The base is often HO<sup>-</sup>, but in some cases better results can be obtained by using methylsulfinyl carbanion MeSOCH<sub>2</sub><sup>-</sup>.<sup>198</sup> If an alkyl halide RX is present, the xanthate ester ROCSSR' can be produced directly. In a similar manner, alkoxide ions add to CO<sub>2</sub> to give carbonate ester salts (ROCO<sub>2</sub><sup>-</sup>).

OS V, 439; VI, 207, 418; VII, 139.

### C. Sulfur Nucleophiles

#### 16-10 The Addition of H<sub>2</sub>S and Thiols to Carbonyl Compounds

The addition of H<sub>2</sub>S to an aldehyde or ketone can result in a variety of products.  $\alpha$ -Hydroxy thiols (**7**) can be prepared from polychloro and polyfluoro aldehydes and ketones,<sup>199</sup> although hydroxy thiols appear to be stable only when prepared from these compounds. The most usual product is the trithiane **10**.<sup>200</sup> A much more useful application is the addition of thiols to aldehydes and ketones to give hemi-mercaptals (CH(OH)SR) and dithioacetals, CH(SR)<sub>2</sub> (**16-5**). The reaction of aldehydes or ketones with hydrogen sulfide is generally

not a good route to thioketones (**8**). *gem*-Dithiols (**9**) are much more stable than the corresponding hydrates or  $\alpha$ -hydroxy thiols.<sup>201</sup> *gem*-Dithiols have been prepared by the treatment of ketones with H<sub>2</sub>S under pressure<sup>202</sup> and under mild conditions with HCl as a catalyst.<sup>203</sup>

Thiols add to aldehydes and ketones to initially give hemi-mercaptals (RS–C–OH) and dithioacetals (RS–C–SR). Hemi-mercaptals are ordinarily unstable,<sup>204</sup> but they are usually more stable than the corresponding hemiacetals and can be isolated in certain cases.<sup>205</sup> The isolated product of this reaction is most often the dithioacetal, which, like the acetals obtained by reaction with an alcohol, are stable in the presence of base. The reaction of aldehydes or ketones with thiols most commonly uses a Lewis acid catalyst such as boron trifluoride etherate (BF<sub>3</sub>•OEt<sub>2</sub>).<sup>206</sup> to give the dithioacetal<sup>207</sup> or dithioacetal. Dithioacetals can also be prepared from aldehydes or ketones by treatment with thiols in the presence of a Lewis acid or of tosic acid on silica gel in dichloromethane,<sup>208</sup> while oxalic acid promotes the reaction.<sup>209</sup> Similarly, reactions that use 1,2-ethanedithiol or 1,3-propanedithiol lead to 1,3-dithiolanes (**11**)<sup>210</sup> or 1,3-dithianes (**12**).<sup>211</sup>

Dithioacetals and dithioketals are used as protecting groups for aldehydes and ketones, and after subsequent reactions involving the R or R' group, deprotection regenerates the carbonyl.<sup>212</sup> Simple hydrolysis is the most common method for converting thiocarbonyls to carbonyls, and there are a variety of reagents for this conversion.<sup>213</sup> Lewis acids such as aluminum chloride (AlCl<sub>3</sub>) and mercuric salts are common reagents (the *Corey-Seebach procedure*).<sup>214</sup> Other reagents, which include BF<sub>3</sub>•OEt<sub>2</sub> in aqueous THF containing mercuric oxide (HgO)<sup>215</sup> or ceric ammonium nitrate [Ce(NH<sub>4</sub>)<sub>2</sub>(NO<sub>3</sub>)<sub>6</sub>],<sup>216</sup> have been used.<sup>217</sup> When aldehydes and ketones react with mercapto alcohols, mixed acetals or ketals are formed. Aldehydes and ketones were converted to dithianes and dithiolanes via reaction with dithiolanylium and dithianylium derivatives on resin solid supports.<sup>218</sup>

Thioketones (**8**) can be prepared from certain ketones, such as diaryl ketones, by treatment with  $\text{H}_2\text{S}$  and an acid catalyst, usually  $\text{HCl}$ . They are often unstable and usually trimerize (to **10**) or react with air. Thioaldehydes<sup>219</sup> are even less stable and simple ones<sup>220</sup> apparently have never been isolated, although *tert*-BuCHS has been prepared in solution, where it exists for several hours at 20 °C.<sup>221</sup> A high-yield synthesis of thioketones involves treatment of acyclic<sup>222</sup> ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide<sup>223</sup> (**13**, known as *Lawesson's reagent*)<sup>224</sup>. Thioketones can also be prepared by treatment of ketones with  $\text{P}_4\text{S}_{10}$ ,<sup>225</sup> or  $\text{P}_4\text{S}_{10}$  on alumina.<sup>226</sup> Reagent **13** converts the  $\text{C}=\text{O}$  groups of amides and carboxylic esters<sup>227</sup> to  $\text{C}=\text{S}$  groups.<sup>228</sup> Lactones react with **13** in the presence of hexamethyldisiloxane under microwave irradiation to give the thiolactone.<sup>229</sup>

Other reagents that may be used for this transformation include  $\text{POCl}_3$  followed by  $\text{S}(\text{TMS})_2$ , which converts lactams to thiolactams.<sup>230</sup> Treatment with aqueous  $\text{S}(\text{NH}_4)_2$ <sup>231</sup> converts amides to thioamides, as does the microwave-assisted reaction with  $\text{PSCl}_2/\text{H}_2\text{O}/\text{Et}_3\text{N}$ , without solvent.<sup>232</sup>

If an aldehyde or ketone possesses an  $\alpha$  hydrogen, it can be converted to the corresponding enol thioether (**14**) by treatment with a thiol in the presence of  $\text{TiCl}_4$ .<sup>233</sup>

Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine/borane<sup>234</sup> in a reductive alkylation reaction, analogous to **16-6**.

OS **II**, 610; **IV**, 927; **VI**, 109; **VII**, 124, 372. Also see, OS **III**, 332; **IV**, 967; **V**, 780; **VI**, 556; **VIII**, 302.

The presence of a sulfur atom on a carbon enhances the acidity of a proton on that carbon, and in dithioacetals and dithioketals that proton ( $\text{RSCH}_2\text{SR}$ ) is even more acidic. The  $\text{p}K_{\text{a}}$  of such protons is typically 31–37,<sup>235</sup> so removal requires a strong base, and deprotonation<sup>236</sup> to form the corresponding carbanion is often quite slow. The reaction of 1,3-dithianes with a strong base such as butyllithium in THF<sup>237</sup> followed by reaction with an alkyl halide gave the 2-alkylated dithiane.<sup>238</sup>

Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS **VI**, 556) with 1,3-propanedithiol and can be hydrolyzed (**10-7**), this is a method for the conversion of an aldehyde to a ketone<sup>239</sup> (see also, **10-68** and **18-9**). A catalytic dithioacetalization process to give the corresponding 1,3-dithianes used aldehydes and 2-chloro-1,3-dithiane with an Fe catalyst.<sup>240</sup>

The alkylation reaction just described is another example of Umpolung (see **10-68**);<sup>241</sup> the normally electrophilic carbon of the aldehyde is made to behave as a nucleophile. The reaction can be applied to the unsubstituted dithiane ( $\text{R} = \text{H}$ ) and one or two alkyl groups can be introduced, so a wide variety of aldehydes and ketones can be made starting with formaldehyde.<sup>242</sup> The  $\text{R}'$  group may be primary alkyl, secondary alkyl, or benzylic. Carbanions generated from 1,3-dithianes also react with epoxides<sup>243</sup> to give the expected products. Reaction with epoxides leads to intermediates that undergo the *Brook rearrangement* (**18-44**), which is synthetically useful in what is known as *anion relay chemistry*.

A useful application of this reaction stems from the fact that dithianes can be desulfurated with *Raney nickel* (**14-22**). Aldehydes can therefore be converted first to the dithiane

and desulfurization gives the chain-extended hydrocarbons.<sup>244</sup> Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.<sup>245</sup>

Thioamides are converted to amides with *Caro's acid* ( $\text{H}_2\text{SO}_5$ ) on  $\text{SiO}_2$ .<sup>246</sup> The use of 2-mercaptoethanol ( $\text{HSCH}_2\text{CH}_2\text{OH}$ ), for example, leads to an oxathiolane<sup>247</sup> and 3-mercaptopropanol ( $\text{HSCH}_2\text{CH}_2\text{CH}_2\text{OH}$ ) leads to an oxathiane.

### 16-11 Formation of Bisulfite Addition Products

Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings),  $\alpha$ -keto esters, and isocyanates, upon treatment with sodium bisulfite ( $\text{NaHSO}_3$ ). Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base)<sup>248</sup> and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.<sup>249</sup> The effect of the counterion has been discussed.<sup>250</sup>

### D. Attack by $\text{NH}_2$ , $\text{NHR}$ , or $\text{NR}_2$ (Addition of $\text{NH}_3$ , $\text{RNH}_2$ , $\text{R}_2\text{NH}$ )

#### 16-12 The Addition of Amines to Aldehydes and Ketones

The addition of ammonia<sup>251</sup> to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be

<sup>249</sup> The reaction has also been used to protect an aldehyde group in the presence of a keto group: Chihara, T.; Wakabayashi, T.; Taya, K. *Chem. Lett.* **1981**, 1657.

<sup>250</sup> Kissane, M.G.; Frank, S.A.; Renner, G.A.; Ley, C.P.; Alt, C.A.; Stroud, P.A.; Vaid, R.K.; Boini, S.K.; McKee, L.A.; Vicenzi, J.T.; Stephenson, G.A. *Tetrahedron Lett.* **2013**, *54*, 6587.

<sup>251</sup> For a review of this reagent in organic synthesis, see Jeyaraman, R. in Pizey, J.S. *Synthetic Reagents*, Vol. 5, Wiley, NY, **1983**, pp. 9–83.

expected to be *hemi-aminals*,<sup>252</sup> but these compounds are generally unstable. In addition, many imines with a hydrogen on the nitrogen spontaneously polymerize.<sup>253</sup>

In contrast to ammonia, primary, secondary, and tertiary amines can add to aldehydes<sup>254</sup> and ketones to give different kinds of products. Primary amines give imines<sup>255</sup> and secondary amines give enamines (for reactions, see **10-69**).<sup>256</sup> Such imines are stable enough for isolation, but, in some cases, especially with simple R groups, they rapidly decompose or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable, they are usually called *Schiff bases*, and this reaction is the best way to prepare them.<sup>257</sup> Even sterically hindered imines can be prepared.<sup>258</sup> The initial *N*-substituted hemi-aminals<sup>259</sup> lose water to give the stable Schiff bases.

In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required.<sup>260</sup> In addition, the equilibrium must often be shifted, usually by removal of the water. This can be done either azeotropically by distillation or with a drying agent, such as a molecular sieve.<sup>261</sup> Imines have been formed from aldehydes and amines in an ionic liquid.<sup>262</sup>

Heating a primary alcohol and a primary amine with a Mn catalyst led to dehydrogenative coupling to form aldimines.<sup>263</sup> The Co-catalyzed<sup>264</sup> and an Fe-catalyzed<sup>265</sup> coupling of alcohols and amines to give imines has been reported. *N*-Acyl enamines<sup>266</sup> were prepared from ketones by reaction with *N,N,N',N'*-tetrakis(2-hydroxyethyl)ethylenediamine using a Ti catalyst, NEt<sub>3</sub>/Ac<sub>2</sub>O, and workup with ammonium hydroxide.<sup>267</sup>

<sup>252</sup> These compounds have been detected by <sup>13</sup>C NMR: Chudek, J.A.; Foster, R.; Young, D. *J. Chem. Soc., Perkin Trans. 2* **1985**, 1285.

<sup>253</sup> Methanimine CH<sub>2</sub>=NH is stable in solution for several hours at –95 °C, but rapidly decomposes at –80 °C: Braillon, B.; Lasne, M.C.; Ripoll, J.L.; Denis, J.M. *Nouv. J. Chim.* **1982**, *6*, 121. See also, Bock, H.; Dammel, R. *Chem. Ber.* **1987**, *120*, 1961.

The reaction of secondary amines with ketones leads to enamines (see **10-69** for the *Stork enamine reaction*).<sup>268</sup> When secondary amines are added to aldehydes or ketones, the initially formed *N,N*-disubstituted hemi-aminals cannot lose water since *the iminium ion intermediate does not have a proton on nitrogen*, and in some cases it is possible to isolate them.<sup>269</sup> However, they are generally highly reactive, and under the reaction conditions usually react further. If no  $\alpha$  hydrogen is present, a hemi-aminal is converted to the more stable *aminal*.<sup>270</sup> However, if an  $\alpha$  hydrogen is present, water or  $\text{RNH}_2$  can be lost in that direction to give an enamine.<sup>271</sup> This is the most common method for the preparation of enamines<sup>272</sup> and usually takes place when an aldehyde or ketone containing an  $\alpha$  hydrogen is treated with a secondary amine.<sup>273</sup> The water is usually removed azeotropically or with a drying agent,<sup>274</sup> and molecular sieves can also be used.<sup>275</sup> Stable primary enamines have also been prepared.<sup>276</sup> Enamino ketones have been prepared from diketones and secondary amines using low molecular weight amines in water,<sup>277</sup> or using microwave irradiation on silica gel.<sup>278</sup> Enamines have been prepared by the reaction of an aldehyde, using AgI in an ionic liquid,<sup>279</sup> CuI with microwave irradiation,<sup>280</sup> or a Au catalyst.<sup>281</sup> Tertiary amines can only give salts.

The reaction is often used to effect ring closure<sup>282</sup> and in the formation of heterocycles.<sup>283</sup> The *Friedländer quinoline synthesis*<sup>284</sup> is an example where *ortho* alkenyl aniline derivatives give the quinoline.<sup>285</sup> 3-Haloquinolines have been prepared from  $\alpha$ -halo ketones.<sup>286</sup> Pyrylium ions react with ammonia or primary amines to give pyridinium ions<sup>287</sup> (see **10-57**). Primary amines react with 1,4-diketones, with microwave

## 16-13 The Addition of Hydrazine Derivatives to Carbonyl Compounds

This section can be categorized as the preparation of functionalized imines,  $\text{R}_2\text{C}=\text{N}-\text{X}$ . When  $\text{X} = \text{OH}$ , the compound is an oxime, and when  $\text{X} = \text{NR}_2$ , the compound is a hydrazone. Oximes can be prepared by the addition of hydroxylamine ( $\text{NH}_2\text{OH}$ ) to aldehydes or ketones. Derivatives of hydroxylamine [e.g.,  $\text{H}_2\text{NOSO}_3\text{H}$  and  $\text{HON}(\text{SO}_3\text{Na})_2$ ] have also been used. For hindered ketones, such as 2,2,4,4-tetramethylpentan-3-one, high pressures (as high as 10 000 atm) may be necessary.<sup>305</sup> The reaction of hydroxylamine with unsymmetrical ketones or with aldehydes leads to a mixture of (*E*) and (*Z*) isomers. For aromatic aldehydes, heating with  $\text{K}_2\text{CO}_3$  led to the (*E*) isomer whereas heating with  $\text{CuSO}_4$  gave the (*Z*)-hydroxylamine.<sup>306</sup> Hydroxylamines react with ketones in ionic liquids.<sup>307</sup> Metal-mediated and metal-catalyzed synthesis of oximes are known.<sup>308</sup>

It has been shown<sup>309</sup> that the maximum rate of oxime formation is at a pH that depends on the substrate but is usually  $\sim 4$ . The rate decreases as the pH is either raised or lowered from this point (a bell-shaped curve). In Sec. 16.A.i, bell-shaped curves like this were shown to be caused by changes in the rate-determining step in many cases. In this case, at low pH values, loss of water to form the  $\text{C}=\text{N}$  moiety is rapid (because it is acid catalyzed), and the initial acyl addition of hydroxylamine to the carbonyl carbon is slow (and rate determining), because under these acidic conditions most of the  $\text{NH}_2\text{OH}$  molecules have been converted to the conjugate  $^+\text{NH}_3\text{OH}$  ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free  $\text{NH}_2\text{OH}$  molecules increases and, consequently, so does the reaction rate, until the maximum rate is reached at around pH 4. As the rising pH causes an increase in the rate of acyl addition, it also causes a *decrease* in the rate of the acid-catalyzed loss of water. This latter process has not yet affected the overall rate since loss of water is much faster than the acyl addition. However, when the pH goes above  $\sim 4$ , loss of water *does* become rate determining although the rate of acyl addition is still increasing, as it will until essentially all the  $\text{NH}_2\text{OH}$  is unprotonated. Since loss of water now determines the rate, and is slowed by the decrease in acid concentration, the overall rate decreases as the pH rises beyond  $\sim 4$ . It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.<sup>310</sup> It is noted that the intermediate,  $\text{HO}-\text{C}-\text{NHOH}$ ,<sup>311</sup> has been detected by NMR in the reaction between  $\text{NH}_2\text{OH}$  and acetaldehyde.<sup>312</sup> *O*-Methyl oximes were prepared from the reaction of ketones with *N,O*-bis-trimethylsilyl-*N*-methoxy carbamate, giving a mixture of *syn* and

*anti* isomers.<sup>313</sup> Aldehydes are reported to react with hydroxylamine using NaOH under solvent-free mechanochemical conditions.<sup>314</sup>

OS I, 318, 327; II, 70, 204, 313, 622; III, 690, IV, 229; V, 139, 1031; VII, 149. See also, OS VI, 670.

The product of condensation of a hydrazine and an aldehyde or ketone is called a *hydrazone*. Hydrazine itself gives hydrazones only with aryl ketones. With other aldehydes and ketones, either no useful product can be isolated, or the remaining NH<sub>2</sub> group condenses with a second equivalent of carbonyl compound to give an *azine*, ArCH=N–N=CHAr. This type of product is especially important for aromatic aldehydes. However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.<sup>315</sup> Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl,<sup>316</sup> are used much more often and give the corresponding hydrazones with most aldehydes and ketones.<sup>317</sup> Since these are usually solids, they make excellent derivatives to assist compound identification, and were commonly employed for this purpose in the past before the advent of modern spectroscopy methods. Cyclic hydrazones are known,<sup>318</sup> as are conjugated hydrazones.<sup>319</sup> Alkenes react with CO/H<sub>2</sub>, phenylhydrazine, and a diphosphine catalyst to give a regioisomeric mixture of phenylhydrazones that favored “anti-Markovnikov” addition.<sup>320</sup> Oximes are converted to hydrazones with water and hydrazine in refluxing ethanol.<sup>321</sup>

The preparation of Boc-, Bz-, Ts-, and Fmoc-protected hydrazones from carbonyl compounds and the corresponding hydrazine used a ball-mill.<sup>322</sup> Anthranilic acids and aminobenzoic acids act as superior catalysts for oxime or hydrazone formation by the reaction of aldehydes and oxime esters or hydrazine derivatives.<sup>323</sup> The reaction of pyrrolidine and aldehydes generated an iminium salt that reacted with hydroxylamine to give the oxime, and hydrazones were also prepared.<sup>324</sup>

$\alpha$ -Hydroxy aldehydes and ketones and  $\alpha$ -dicarbonyl compounds give *osazones*, in which two adjacent carbons have carbon–nitrogen double bonds: RNH–N=C–C=N–NHR. Osazones are particularly important in carbohydrate chemistry. The *osazone test*<sup>325</sup> with phenylhydrazine is used to test for the presence of sugars with an adjacent stereogenic carbon. In contrast to this behavior,  $\beta$ -diketones and  $\beta$ -keto esters give *pyrazoles* and *pyrazolones*, respectively. No azines are formed under these conditions. Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide

### 16-14 The Conversion of Aldehydes to Nitriles

Aldehydes can be converted to nitriles in one step by treatment with hydroxylamine hydrochloride and either formic acid,<sup>327</sup>  $\text{KF}\cdot\text{Al}_2\text{O}_3$ ,<sup>328</sup> or  $\text{NaHSO}_4\cdot\text{SiO}_2$  with microwave irradiation.<sup>329</sup> Heating in *N*-methylpyrrolidinone (NMP) is also effective with aryl aldehydes<sup>330</sup> and so is heating on dry alumina with an aliphatic aldehyde.<sup>331</sup> The reaction is a combination of **16-13** and **17-27**. Direct nitrile formation has also been accomplished with certain derivatives of  $\text{NH}_2\text{OH}$ , notably,  $\text{NH}_2\text{OSO}_2\text{OH}$ .<sup>332</sup> Treatment with hydroxylamine and  $\text{NaI}$ <sup>333</sup> or certain carbonates<sup>334</sup> also converts aldehydes to the nitrile. Another method involves treatment with hydrazoic acid, although the *Schmidt reaction* (**18-16**) may compete.<sup>335</sup> Microwave irradiation has been used with  $\text{NH}_2\text{OH}\cdot\text{HCl}$  and another reagent, which includes phthalic anhydride<sup>336</sup> or H-Y zeolite.<sup>337</sup> The reaction of an aldehyde with hydroxylamine followed by diethyl chlorophosphate ( $\text{EtOPOCl}_2$ ) gives the nitrile.<sup>338</sup> Heating with hydroxylamine in DMSO<sup>339</sup> and using hydroxylamine and oxalyl chloride<sup>340</sup> have been used. *tert*-Butanesulfinyl imines are also used for the conversion of aldehydes to nitriles.<sup>341</sup>

The reaction of a conjugated aldehyde with ammonia, CuCl, and 50% H<sub>2</sub>O<sub>2</sub> gave the conjugated nitrile.<sup>342</sup> Reaction of aldehydes with IBX (*o*-iodoxybenzoic acid) and liquid ammonia gives the nitrile.<sup>343</sup> Tetrabutylammonium tribromide in aqueous ammonia has also been used.<sup>344</sup>

Aldehydes were converted to nitriles by the reaction with *O*-(diphenylphosphinyl) hydroxylamine by heating in toluene.<sup>345</sup> Benzaldehydes reacted with ammonium acetate and a catalytic amount of 4-acetamido-2,2,6,6-tetramethylpiperidine-*N*-oxyl, NaNO<sub>2</sub>, and HNO<sub>3</sub>, and following aerobic oxidation under an O<sub>2</sub> balloon gave the nitrile.<sup>346</sup> Aldehydes were converted to the nitrile by reaction with *O*-(4-CF<sub>3</sub>-benzoyl)-hydroxylamine with the assistance of a Brønsted acid.<sup>347</sup> Hydroxylamine *O*-sulfonic acid in acidic water has also been used.<sup>348</sup> The conversion of aldehydes to nitriles in DMSO has been reported,<sup>349</sup> and so has heating in glycerol.<sup>350</sup> Aldehydes reacted with K<sub>4</sub>Fe(CN)<sub>6</sub> in water, with *Aloe vera*-mediated Ag nanoparticles as a catalyst, to give the nitrile.<sup>351</sup> Nitriles were prepared from aldehydes by reaction with an oxoammonium salt (4-acetylamino-2,2,6,6-tetramethylpiperidine-1-oxoammonium tetrafluoroborate) and hexamethyldisilazane (HMDS).<sup>352</sup>

OS V, 656.

### 16-15 Reductive Alkylation of Ammonia or Amines: Reductive Amination or Reductive Amidation

When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen gas and an appropriate catalyst such as Rh or Ir (heterogeneous or homogeneous),<sup>353</sup> *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.<sup>354</sup> The reaction can formally be regarded as occurring by addition of the amine to the carbonyl to give an iminium salt (**16-31**), followed by reduction of the C=N unit (**19-46**) in the intermediate to give the amine product.<sup>355</sup> The reagents

<sup>355</sup> Le Bris, A.; Lefebvre, G.; Coussemant, F. *Bull. Soc. Chim. Fr.* **1964**, 1366, 1374, 1584, 1594.

used to reduce the C=N intermediate include other reducing agents.<sup>356</sup> Rather than hydrogen and a catalyst, reducing agents include boranes,<sup>357</sup> triethylsilane with an Ir<sup>358</sup> or an In catalyst,<sup>359</sup> zinc and HCl, or Zn (with formaldehyde for reductive methylation).<sup>360</sup> Several hydride reducing agents can be used, including NaBH<sub>4</sub>,<sup>361</sup> NaBH<sub>4</sub>/H<sub>3</sub>BO<sub>4</sub>,<sup>362</sup> borohydride-exchange resin (BER),<sup>363</sup> LiBH<sub>4</sub>,<sup>364</sup> ZrBH<sub>4</sub>,<sup>365</sup> NaBH<sub>3</sub>CN,<sup>366</sup> or sodium triacetoxyborohydride.<sup>367</sup>

For ammonia and primary amines there are two possible pathways: (i) reduction of the imine intermediate or (ii) hydrogenolysis of a hydroxy amine intermediate. However, when secondary amines are involved, only the hydrogenolysis pathway (**19-59**) is possible; the OH unit is replaced by H to give the amine directly. The reaction is compatible with amino acids, giving the *N*-alkylated amino acid.<sup>368</sup> A *Hantzsch dihydropyridine* in conjunction with a Sc catalyst has been used,<sup>369</sup> and the use of a *Hantzsch ester* (**15**) in a reductive amination is sometimes called a hydrogen bond-catalyzed reaction.<sup>370</sup>

The reaction of an aldehyde and an amine in propan-2-ol, in the presence of Ni nanoparticles, involves reductive amination via hydrogen transfer.<sup>371</sup> Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent. Smaller aldehydes are usually too reactive to permit isolation of the primary amine.

Aldehydes and primary amines react with allylic halides, in the presence of Zn dust, to give a homoallylic secondary amine.<sup>372</sup> Reductive monoalkylation of nitroarenes used aldehydes as alkylating agents, H<sub>2</sub> as a reducing agent, and PtO<sub>2</sub> as a catalyst in methanol.<sup>373</sup> The reductive amination of carbonyl compounds with aromatic amines using stannous chloride gave tertiary amines while using inexpensive polymethylhydrosiloxane as reducing agent in methanol.<sup>374</sup> The reaction of ketones and amines led to reductive amination when treated with CO and a Ru catalyst, to give the amine.<sup>375</sup> The reaction of an alkyl cyclopropyl ketone with an amine and CO with a Rh catalyst gave the reductive amination product, whereas a Ru catalyst gave a pyrrolidine via ring expansion.<sup>376</sup> The reductive amination of aldehydes used NaBH<sub>4</sub> in the presence of an Fe catalyst.<sup>377</sup> Reductive amination of ketones or aldehydes with amines using triethylsilane and a Bi catalyst gave the amine.<sup>378</sup>

Reductive amination of ketones has been reported using flow conditions (Sec. 7.D).<sup>379</sup> Propargylamines were prepared by the coupling reaction of alkynyl carboxylic acids with amines and paraformaldehyde in water at 140 °C, using a continuous flow reaction system (Sec. 7.D).<sup>380</sup> Amines were prepared from cyclic ketones by use of ω-transaminases.<sup>381</sup> Amines reacted with aldehydes or ketones using a Ru catalyst and CO to give the amine.<sup>382</sup> The Ru-catalyzed reductive amination reaction has been extensively studied.<sup>383</sup> The reductive amination of ketones with electron-deficient anilines gave the amine derivative, using BH<sub>3</sub>·THF/AcOH/CH<sub>2</sub>Cl<sub>2</sub>, which required longer reaction times, or BH<sub>2</sub>·THF/TMSCl/DMF or NaBH<sub>4</sub>/TMSCl/DMF, when the reaction was complete in less than an hour.<sup>384</sup>

Reductive amination of amine with dimethyl carbonate using PhSiH<sub>3</sub> and a Pt catalyst gave the tertiary amine.<sup>385</sup> With a hydrogen source, reductive amination of carbonyl compounds used a Ni/Al alloy in water.<sup>386</sup> Tertiary amines were formed by the Ru-catalyzed reductive *N*-benzylation of imines by reaction with benzyl bromide derivatives using PhSiH<sub>3</sub>.<sup>387</sup> The reaction of ketones with a new amine dehydrogenase gave chiral (*R*)-1,3-dimethylbutylamines.<sup>388</sup>

The reductive amination of aldehydes or ketones in the presence of ammonia catalyzed by unsupported ultra-thin Pt nanowires gave the secondary amine.<sup>389</sup> Two equivalents of

ketone and an amine gave the hindered tertiary amine when treated with 50 atm of CO, MS 4 Å, and a Rh catalyst.<sup>390</sup> Aldehydes reacted with primary amines using a Pd/NiO (nickel oxide) catalyst and H<sub>2</sub> to give the primary amine. The Ir-catalyzed reductive alkylation reaction of primary or secondary amines with carboxylic acids gave the amine product in the presence of a silane reductant.<sup>391</sup>

Formic acid is an effective reagent for reductive amination<sup>392</sup> in what is called the *Wallach reaction*. Secondary amines react with formaldehyde and NaH<sub>2</sub>PO<sub>3</sub> to give the *N*-methylated tertiary amine<sup>393</sup> and microwave irradiation has also been used.<sup>394</sup> In the particular case where primary or secondary amines are reductively methylated with formaldehyde and formic acid, the method is called the *Eschweiler-Clarke procedure*. Heating with paraformaldehyde and oxalyl chloride has been used to give the same result.<sup>395</sup> It is possible to use ammonium (or amine) salts of formic acid,<sup>396</sup> or formamides, as a substitute for the *Wallach conditions*. This method is called the *Leuckart reaction*,<sup>397</sup> and in this case the products obtained are often the *N*-formyl derivatives of the amines instead of the free amines. A Rh-catalyzed variation has been reported.<sup>398</sup> Heating aldehydes and ketones with secondary amines and ammonium carbonate in a modified Leuckart reaction gave the tertiary amine.<sup>399</sup> The reductive amination of allylic alcohols via reaction with amines and formic acid, with a Ru catalyst, gave the saturated amine.<sup>400</sup> The Cu-catalyzed reductive methylation gave the methylamine product in the reaction of a secondary amine with formic acid; PhSiH<sub>3</sub> was the reductant.<sup>401</sup> Amines were prepared by the reaction of benzaldehyde and amines, catalyzed by Pd nanoparticles stabilized by a zwitterionic surfactant and using formate salts as hydrogen donors in aqueous isopropyl alcohol.<sup>402</sup>

Enantioselective reductive amination reactions are known, generating chiral amines. Ketones and anilines react in the presence of an organocatalyst and a catalytic amount of a chiral phosphoric acid to give the chiral amine.<sup>403</sup> The reaction of an aldehyde with a chiral amine initiated a reaction that gave a chiral primary amine.<sup>404</sup> An Yb-catalyzed reaction with a ketone gave a chiral secondary amine.<sup>405</sup> Aldehydes react with *N*-diphenylphosphinoylimines and Et<sub>2</sub>Zn, in the presence of a chiral Cu precatalyst, to give

## 16-16 The Addition of Amides to Aldehydes

Amides can add to aldehydes in the presence of bases (so the nucleophile is actually  $\text{RCONH}^-$ ) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides.<sup>411</sup> If the  $\text{R}^1$  group contains an  $\alpha$  hydrogen, water may split out.

Sulfonamides add to aldehydes to give the *N*-sulfonyl imine. Benzaldehyde reacts with  $\text{TsNH}_2$ , for example, with trifluoroacetic anhydride (TFAA) in  $\text{CH}_2\text{Cl}_2$  at reflux,<sup>412</sup> or with  $\text{TiCl}_4$  in dichloroethane at reflux,<sup>413</sup> to give the *N*-tosylimine,  $\text{Ts-N}=\text{CHPh}$ . In a similar manner, the reaction of  $\text{ToSO}_2\text{Na}$  and  $\text{PhSO}_2\text{Na}$  with an aldehyde in aqueous formic acid gives the *N*-phenylsulfonyl imine.<sup>414</sup> The reaction of an aldehyde with  $\text{Ph}_3\text{P}=\text{NTs}$  and a Ru catalyst gives the *N*-tosyl imine.<sup>415</sup>

Primary and secondary amines add to ketenes to give, respectively, *N*-substituted and *N,N*-disubstituted amides<sup>416</sup> and add to ketenimines to give amidines,  $\text{R}_2\text{N}-\text{C}(\text{R})=\text{N}-\text{R}$ .<sup>417</sup>

## 16-17 The Mannich Reaction

In the *Mannich reaction*, formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.<sup>418</sup> This can formally be considered as an addition of ammonia to give  $\text{H}_2\text{NCH}_2\text{OH}$ , followed by a nucleophilic substitution. The reaction can be carried out with salts of primary or secondary amines<sup>419</sup> or with amides,<sup>420</sup> rather than ammonia, in which cases the product is substituted on the nitrogen. The product is referred to as a *Mannich base*. The imine can be generated *in situ*. The reaction of a ketone, formaldehyde, and diethylamine with microwave irradiation gave the Mannich product, a  $\beta$ -amino ketone.<sup>421</sup> Arylamines do not normally give the reaction, but hydrazines can be used.<sup>422</sup> Vinylogous Mannich reactions are known<sup>423</sup> (see Sec. 6.B for vinylogy).

The Mannich base product can react further in three ways. If it is a primary or secondary amine, it may condense with one or two additional molecules of aldehyde and an active compound, to give  $\text{HN}(\text{CH}_2\text{CH}_2\text{COR})_2$  or  $\text{N}(\text{CH}_2\text{CH}_2\text{COR})_3$ . If the active hydrogen compound has two or three active hydrogen atoms, the Mannich base may condense with one or two additional molecules of aldehyde and ammonia or amine. Another reaction consists of condensation of the Mannich base with excess formaldehyde to give an imine. Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times they are side products. When the Mannich base contains an amino group  $\beta$  to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to  $\alpha,\beta$ -unsaturated aldehydes, ketones, esters, and so on.

Studies of the reaction kinetics have led to several proposals for the mechanism of the Mannich reaction.<sup>424</sup> The base-catalyzed reaction involves reaction with an enolate anion, whereas the acid-catalyzed reaction involves formation of an iminium ion, which reacts with an enol. There is kinetic evidence for the intermediacy of the iminium ion.<sup>425</sup>

When an unsymmetrical ketone is used as the active-hydrogen component, two products are possible. Regioselectivity has been obtained by treatment of the ketone with preformed iminium ions:<sup>426</sup> the use of  $\text{Me}_2\text{N}^+=\text{CH}_2 \text{CF}_3\text{COO}^-$  in  $\text{CF}_3\text{COOH}$  gives substitution at the more highly substituted position, while with  $(i\text{-Pr})_2\text{N}^+=\text{CH}_2 \text{ClO}_4^-$  the reaction takes place at the less highly substituted position.<sup>427</sup> The preformed iminium compound

dimethyl(methylene)ammonium iodide  $\text{CH}_2=\text{N}^+\text{Me}_2 \text{I}^-$ , called *Eschenmoser's salt*,<sup>428</sup> has also been used in Mannich reactions.<sup>429</sup> The analogous chloride salt has been condensed with an imine to give a  $\beta,\beta'$ -dimethylamino ketone after acid hydrolysis.<sup>430</sup>

Another type of preformed reagent (**17**) has been used to carry out diastereoselective Mannich reactions. The lithium salts **16** are treated with  $\text{TiCl}_4$  to give **17**, which is then treated with the enolate anion of a ketone.<sup>431</sup> The Pd-catalyzed Mannich reaction of enol ethers to imines is also known.<sup>432</sup> The reaction of silyl enol ethers and imines<sup>433</sup> is catalyzed by  $\text{HBF}_4$  in aqueous methanol.<sup>434</sup> Similarly, silyl enol ethers react with aldehydes and aniline in the presence of  $\text{InCl}_3$  to give the  $\beta$ -amino ketone.<sup>435</sup>

Enantioselective Mannich reactions are known.<sup>436</sup> Chiral catalysts are commonly used,<sup>437</sup> including proline,<sup>438</sup> proline derivatives or proline analogs,<sup>439</sup> other chiral amines,<sup>440</sup> a Pybox-La catalyst,<sup>441</sup> chiral aminosulfonamides,<sup>442</sup> or *Cinchona* alkaloids.<sup>443</sup> Other organocatalysts have been used.<sup>444</sup> Chiral Brønsted acids are also used as catalysts,<sup>445</sup> and also chiral ammonium salts.<sup>446</sup> Chiral diamine<sup>447</sup> or phosphine imine<sup>448</sup> ligands have

### 16-19 The Addition of Ammonia or Amines to Nitriles

Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.<sup>468</sup> Many amidines have been made in this way. Dinitriles of suitable chain length can give imidines such as **18**.<sup>469</sup>

Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; for example,  $\text{Cl}_3\text{CCN}$  gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.<sup>470</sup> The addition of ammonia to cyanamide ( $\text{NH}_2\text{CN}$ ) gives guanidine,  $(\text{NH}_2)_2\text{C}=\text{NH}$ . Guanidines can also be formed from amines.<sup>471</sup> The Cu-catalyzed cross-coupling reaction of amidine salts and aryl iodides gave monoarylated amidines.<sup>472</sup> The *N*-arylation of amidines and *N,N*-disubstituted amidines was accomplished by reaction of *o*-silylaryl triflate with  $\text{CsF}$ .<sup>473</sup> If water is present, in the presence of a  $\text{Ru}$ <sup>474</sup> or a  $\text{Pt}$  catalyst,<sup>475</sup> the addition of a primary or secondary amine to a nitrile gives an amide.

**16-20** The Addition of Amines to Carbon Disulfide and Carbon Dioxide

Salts of dithiocarbamic acid can be prepared by the addition of primary or secondary amines to carbon disulfide.<sup>476</sup> This reaction is similar to **16-9**. Hydrogen sulfide can be eliminated from the product, directly or indirectly, to give isothiocyanates (RNCS). Isothiocyanates can be obtained directly by the reaction of primary amines and CS<sub>2</sub> in pyridine in the presence of dicyclohexylcarbodiimide.<sup>477</sup> A tosyl chloride-mediated preparation of isothiocyanates is also known.<sup>478</sup> Aniline derivatives react with CS<sub>2</sub> and NaOH, and then ethyl chloroformate, to give the aryl isothiocyanate.<sup>479</sup> In the presence of diphenyl phosphite and pyridine, primary amines add to CO<sub>2</sub> and to CS<sub>2</sub> to give, respectively, symmetrically substituted ureas and thioureas.<sup>480</sup> Isoselenoureas, R<sub>2</sub>NC(=NR<sup>1</sup>)SeR<sup>2</sup>, can also be formed.<sup>481</sup>

The mechanism of *gem*-dichloride formation involves initial attack on  $\text{PCl}_4^+$  (which is present in solid  $\text{PCl}_5$ ) by the carbonyl oxygen, followed by addition of  $\text{Cl}^-$  to the carbon.<sup>489</sup> This chloride ion may come from  $\text{PCl}_6^-$  (which is also present in solid  $\text{PCl}_5$ ). There follows a two-step  $\text{S}_{\text{N}}1$  process. Alternatively, **19** can be converted to the product without going through the chlorocarbenium ion, by an  $\text{S}_{\text{N}}\text{i}$  process.

Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride  $\text{SF}_4$ .<sup>490</sup> Quinones give 1,1,4,4-tetrafluorocyclohexadiene derivatives. With ketones, yields can be raised and the reaction temperature lowered, by the addition of anhydrous  $\text{HF}$ .<sup>491</sup> Carboxylic acids, acyl chlorides, and amides react with  $\text{SF}_2$  to give 1,1,1-trifluorides. In these cases the first product is the acyl fluoride, and *gem*-difluorination gave  $\text{RCF}_3$ . The acyl fluoride can be isolated. Carboxylic esters also give trifluorides, but more vigorous conditions are required. In this case the carbonyl group of the ester is attacked first, and  $\text{RCF}_2\text{OR}'$  can be isolated from  $\text{RCO}_2\text{R}'$ <sup>492</sup> and then converted to the trifluoride. Anhydrides can react in either manner. Both types of intermediate are isolable under the right conditions, and  $\text{SF}_4$  even converts carbon dioxide to  $\text{CF}_4$ . A disadvantage of reactions with  $\text{SF}_4$  is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride  $\text{SeF}_4$  gives similar reactions, but atmospheric pressure and ordinary glassware can be used.<sup>493</sup> Another reagent that is often used to convert aldehydes and ketones to *gem*-difluorides is the commercially available diethylaminosulfur trifluoride (DAST,  $\text{Et}_2\text{NSF}_3$ ), and  $\text{CF}_2\text{Br}_2$  in the presence of zinc.<sup>494</sup> The mechanism with  $\text{SF}_4$  is probably similar in general nature, if not in specific detail, to that with  $\text{PCl}_5$ . The  $\alpha,\alpha$ -difluorination of acid chlorides was reported.<sup>495</sup> The synthesis of  $\alpha,\alpha$ -difluorohalo esters has been reported via ynol ethers.<sup>496</sup>

In a related process,  $\alpha$ -halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and  $\text{HX}$ . The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. The addition of  $\text{HX}$  to an aldehyde or ketone gives  $\alpha$ -halo alcohols, which are usually unstable, although exceptions are known, especially with perfluoro and perchloro species.<sup>497</sup>

## F. Attack at Carbon by Organometallic Compounds<sup>498</sup>

### 16-22 The Addition of Grignard or Organolithium Reagents to Aldehydes and Ketones

Halo organomagnesium compounds, commonly known as *Grignard reagents* (RMgX), are formed by the reaction of alkyl, vinyl, or aryl halides with magnesium metal, usually in ether solvents such as diethyl ether or THF (**12-37**). Halogen/Mg exchange can generate a Grignard reagent by reaction of aryl halides with reactive aliphatic Grignard reagents.<sup>499</sup> Microwave irradiation has been used to facilitate the formation of Grignard reagents from aryl chlorides that are slow to react otherwise.<sup>500</sup> Grignard reactions have been done using ionic liquids.<sup>501</sup> When a Grignard reagent was formed in the “phase vanishing” solvent system of diethyl ether, magnesium, perfluoro polyether, and iodoalkane, subsequent addition to carbonyl compounds in the ether layer gave the alkylated alcohol.<sup>502</sup>

The addition of Grignard reagents to aldehydes and ketones<sup>503</sup> is known as the *Grignard reaction*.<sup>504</sup> The initial product of reaction with a carbonyl is a magnesium alkoxide, requiring a hydrolysis step to generate the final alcohol product. Formaldehyde gives primary alcohols, other aldehydes give secondary alcohols, and ketones give tertiary alcohols. The reaction is of very broad scope. In many cases, the hydrolysis step is carried out with dilute HCl or H<sub>2</sub>SO<sub>4</sub>, but such strong acids cannot be used for the preparation of tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (**17-1**). In such cases (and often for other alcohols as well), an aqueous solution of ammonium chloride is used instead of a strong acid. Grignard reagents have been used in solid-phase synthesis.<sup>505</sup> Ionic liquids have been used for the Grignard reaction.<sup>506</sup>

Homoallylic alcohols were prepared by the reaction of allylic halides with carbonyl compounds, using magnesium powder as mediator under solvent-free conditions.<sup>507</sup> Cyclopropyl Grignard reagents reacted with aldehydes or ketones in the presence of diethyl phosphite to give homoallylic bromides.<sup>508</sup> The reactions and mechanism of reaction of allylmagnesium halides has been discussed.<sup>509</sup> Two different Grignard adducts were mixed and

heated to 65 °C; allyl crossover was observed, indicating that the addition is reversible.<sup>510</sup> A retro-Grignard reaction is known.<sup>511</sup> Aryl iodides undergo halogen/magnesium exchange when pretreated with PhMgCl, and subsequent reaction with an aldehyde gives the alcohol.<sup>512</sup>

A deep eutectic solvent (1 equivalent of choline chloride in combination with 2 equivalents of glycerol) was used for the addition of organolithium reagents and Grignard reagents to ketones, in air.<sup>513</sup> Note that a deep eutectic solvent is formed from a eutectic mixture of Lewis or Brønsted acids and bases that usually contain a variety of anionic and/or cationic species,<sup>514</sup> where the eutectic has a melting point much lower than either of the individual components.

The reaction of aldehydes or ketones with alkyl and aryl Grignard reagents was done in the earliest work without preliminary formation of RMgX, by mixing RX, the carbonyl compound, and magnesium metal in an ether solvent. This approach preceded Grignard's work, and is now known as the *Barbier reaction*.<sup>515</sup> Yields were generally satisfactory. Carboxylic ester, nitrile, and imide groups in the R are not affected by the reaction conditions.<sup>516</sup> Modern versions of the Barbier reaction employ other metals and/or reaction conditions, and will be discussed in **16-23**. Magnesium Barbier reactions are catalyzed by metal complexes other than Mg, such as Cu compounds.<sup>517</sup> Some transition metal compounds are stable in water, so some Grignard-Barbier reactions can be done in water.<sup>518</sup> A retro-Barbier reaction has been reported in which a cyclic tertiary alcohol was treated to an excess of bromine and potassium carbonate to give 6-bromohexan-2-one from 1-methylcyclopentanol.<sup>519</sup>

Transition metal catalysts can promote 1,2-addition of Grignard reagents to ketones. The Zn-mediated Grignard reaction with ketones has been studied.<sup>520</sup> In the presence of a catalytic amount of InCl<sub>3</sub>, Grignard reagents react to give a mixture of 1,2- and 1,4-addition products, with the 1,4-product predominating. However, there was an increase in 1,2-addition relative to the uncatalyzed reaction.<sup>521</sup> The Cu-catalyzed addition of Grignard reagents to aryl alkyl ketones gave the alcohol.<sup>522</sup> The Cu-catalyzed addition of arylmagnesium compounds to aryl heteroaryl ketones is also known.<sup>523</sup>

In a compound containing both an aldehyde and a ketone it is possible to add RMgX chemoselectively to the aldehyde without significantly disturbing the carbonyl of the ketone

group.<sup>524</sup> Diastereoselective addition<sup>525</sup> has been carried out with achiral reagents and chiral substrates.<sup>526</sup> The attacking atom in this reaction is carbon, so diastereoselective addition is possible with an achiral substrate and an optically active reagent.<sup>527</sup> Even if the organometallic compound is racemic, it still may be possible to get a diastereoselective reaction; that is, one pair of enantiomers is formed in greater amount than the other.<sup>528</sup>

Asymmetric Grignard reactions are possible under certain circumstances.<sup>529</sup> Chiral ligands with a chiral Cu<sup>530</sup> or a chiral Ti complex<sup>531</sup> gave alcohols with good enantioselectivity. Other chiral ligands have been developed.<sup>532</sup> An interesting method used an alkylmagnesium halide, dibutylmagnesium (Bu<sub>2</sub>Mg), and a chiral diamine, and subsequent reaction with an aldehyde led to the alcohol derived from acyl addition of a butyl group with good enantioselectivity.<sup>533</sup> *N*-Heterocyclic carbenes have been used as organocatalysts for asymmetric Grignard reactions.<sup>534</sup>

The reaction of RMgX or RLi with  $\alpha,\beta$ -unsaturated aldehydes or ketones can proceed via 1,4-addition (see organometallic conjugate addition in **15-21**) as well as normal 1,2-addition.<sup>535</sup> In general, alkyllithium reagents give less 1,4-addition than the corresponding Grignard reagents. Grignard reagents have been shown to add to some conjugated cyclic ketones with an  $\alpha,\beta$ -OTf group via 1,2-addition, followed by cleavage to give an alkynyl ketone.<sup>536</sup>

In some cases a Grignard reaction can be performed intramolecularly.<sup>537</sup> For example, treatment of 5-bromopentan-2-one with Mg and a small amount of mercuric chloride in THF produced 1-methyl-1-cyclobutanol in 60% yield.<sup>538</sup> Other four- and five-membered ring compounds were also prepared by this procedure. Similar closure of five- and

six-membered rings was achieved by treatment of a  $\delta$ - or  $\epsilon$ -halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenylporphine<sup>539</sup> (see **16-23**).

The *gem*-disubstituted Mg compounds formed from  $\text{CH}_2\text{Br}_2$  or  $\text{CH}_2\text{I}_2$  ( $\text{XMgCH}_2\text{MgX}$ ) react with aldehydes or ketones to give alkenes in moderate to good yields.<sup>540</sup> *Wittig-type reactions* also produce alkenes and are discussed in **16-44**. The reaction could not be extended to other *gem*-dihalides.

Most aldehydes and ketones react smoothly with most Grignard reagents via acyl addition, but there are several potential side reactions that occur,<sup>541</sup> mostly with sterically hindered ketones and with bulky Grignard reagents. The two most important of these are *enolization* and *reduction*.

While enolization requires that the aldehyde or ketone have an  $\alpha$  hydrogen, reduction requires that the Grignard reagent have a  $\beta$  hydrogen. There is general agreement that the mechanism leading to reduction<sup>542</sup> is usually a cyclic transition state with transfer to the  $\beta$  hydrogen from the Grignard reagent to the acyl carbon, and formation of the O–Mg bond and the Grignard substrate is converted to an alkene. There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium.<sup>543</sup>

Enolization is an acid–base reaction (**12-24**) in which a proton is removed from the  $\alpha$  carbon by the Grignard reagent, which is a strong base. The carbonyl compound is converted to its enolate anion,<sup>544</sup> which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol (e.g.,  $\beta$ -keto esters). It is noted that the addition of  $\text{NBu}_4\text{Cl}$  as a catalyst and diglyme assisted the nucleophilic addition reactions of Grignard reagents to ketones to give the tertiary alcohol, and suppressed enolization and reduction.<sup>545</sup>

The carbonyl compound can be reduced to an alcohol (**19-40**) by the Grignard reagent, which itself undergoes elimination to give an alkene. The Grignard reagent must have a  $\beta$  carbon that bears a hydrogen atom. Highly hindered Grignard reagents show this reaction.

Two other side reactions are condensation (between enolate ion and excess ketone) and *Wurtz-type coupling* (**10-64**). Addition of Grignard reagents to ketones cannot be used to prepare highly hindered tertiary alcohols such as triisopropylcarbinol, tri-*tert*-butylcarbinol, and diisopropylneopentylcarbinol (or they can be prepared only in extremely low yields) because reduction and/or enolization become prominent.<sup>546</sup> However, these alcohols can

<sup>539</sup> Corey, E.J.; Kuwajima, I. *J. Am. Chem. Soc.* **1970**, *92*, 395. For another method, see Molander, G.A.; McKie, J.A. *J. Org. Chem.* **1991**, *56*, 4112, and references cited therein.

be prepared by the use of alkyllithium reagents at  $-80\text{ }^{\circ}\text{C}$ <sup>547</sup> because enolization and reduction are much less important.<sup>548</sup> Other methods of increasing the degree of addition at the expense of reduction include complexing the Grignard reagent with  $\text{LiClO}_4$  or  $\text{Bu}_4\text{N}^+ \text{Br}^-$ ,<sup>549</sup> or using benzene or toluene instead of ether as solvent.<sup>550</sup> Both reduction and enolization can be avoided by adding  $\text{CeCl}_3$  to the Grignard reagent.<sup>551</sup>

There has been controversy regarding the mechanism of addition of Grignard reagents to aldehydes and ketones.<sup>552</sup> The reaction is difficult to study because of the variable nature of the species present in the Grignard solution (the *Schlenk equilibrium*; Sec. 5.B.ii) and because the presence of small amounts of impurities in the Mg seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.<sup>553</sup> There seem to be two basic mechanisms, depending on the reactants and the reaction conditions. In one of these, the R group is transferred to the carbonyl carbon with its electron pair,<sup>554</sup> based on the discovery that this reaction proceeds by two paths: one first order in  $\text{MeMgBr}$  and the other first order in  $\text{Me}_2\text{Mg}$ .<sup>555</sup> According to this proposal, both  $\text{MeMgBr}$  and  $\text{Me}_2\text{Mg}$  add to the carbonyl carbon, though the exact nature of the step by which  $\text{MeMgBr}$  or  $\text{Me}_2\text{Mg}$  reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:<sup>556</sup>

The other type of mechanism is a single-electron transfer (SET) process<sup>557</sup> with a ketyl intermediate.<sup>558</sup> This mechanism, which has been mostly studied with diaryl ketones, is more likely for aromatic and other conjugated aldehydes and ketones than it is for strictly aliphatic aldehydes and ketones.

Among the evidence<sup>559</sup> for the SET mechanism are ESR spectra<sup>560</sup> and the fact that  $\text{Ar}_2\text{C}(\text{OH}) \rightarrow \text{C}(\text{OH})\text{Ar}_2$  side products are obtained (from dimerization of the ketyl; see *pinacol coupling* in **19-80**).<sup>561</sup> In the case of addition of  $\text{RMgX}$  to benzil  $\text{PhCOCOPh}$ , ESR spectra of two different ketyl radicals were observed, both reported to be quite stable at room temperature.<sup>562</sup> Note that a separate study failed to observe freely diffusing radicals in the formation of Grignard reagents.<sup>563</sup> Carbon isotope effect studies with  $\text{Ph}^{14}\text{COPh}$  showed that the rate-determining step with most Grignard reagents is the carbon–carbon bond-forming step, although the rate-determining step is the initial electron-transfer step with allylmagnesium bromide.<sup>564</sup> In the formation of Grignard reagents from bromocyclopropane, diffusing cyclopropyl radical intermediates were found.<sup>565</sup> The concerted versus stepwise mechanism has been probed with chiral Grignard reagents.<sup>566</sup> It has been noted that there are similarities in reactivity for the  $\text{S}_{\text{RN}}1$  (Sec. 13.A.iv) and Grignard mechanisms.<sup>567</sup> Experimental evidence from this work suggests a linear rather than a chain mechanism.

Organolithium reagents ( $\text{RLi}$ ),<sup>568</sup> prepared from alkyl halides and Li metal or by exchange of an alkyl halide with a reactive organolithium (**12-37**), react with aldehydes and ketones by acyl addition to give the alcohol<sup>569</sup> after hydrolysis. Organolithium reagents are more basic than the corresponding *Grignard reagent*, which leads to problems of deprotonation in some cases. Organolithium reagents are generally more nucleophilic, however, and can add to hindered ketones with relative ease when compared to the analogous Grignard reagent.<sup>570</sup> Organolithium reagents tend to form aggregates, which influences the reactivity and selectivity of the addition reaction.<sup>571</sup> The addition of lithium amide/butyllithium mixed aggregates has been studied.<sup>572</sup> The organolithium analog of the Barbier reaction is known.<sup>573</sup>

Alkyl, vinyl,<sup>574</sup> and aryl organolithium reagents can be prepared and undergo acyl addition. Structural variations are also possible, including enantioselective 1,2-addition.<sup>575</sup> 1-Bromo-1-lithioethene has been prepared, and it reacts with an aldehyde to give an allylic

alcohol bearing a vinyl bromide unit.<sup>576</sup> The addition reaction of organolithium reagents is known to be reversible.<sup>577</sup>

The addition reactions of organolithium compounds can be carried out enantioselectively and diastereoselectively.<sup>578</sup> Chiral secondary alcohols have been obtained with high enantioselectivity by addition of Grignard and organolithium compounds to aromatic aldehydes in the presence of optically active amino alcohols as ligands.<sup>579</sup> The Ti-catalyzed addition of organolithium reagents to aldehydes proceeded with good enantioselectivity.<sup>580</sup> Chiral diol ligands have been developed for the asymmetric addition to aldehydes using organolithium reagents.<sup>581</sup>

Mechanisms for the addition of organolithium reagents have been investigated much less than the mechanism of acyl addition reactions of Grignard reagents.<sup>582</sup> Addition of a cryptand that binds Li<sup>+</sup> inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.<sup>583</sup>

A lithio epoxide was formed by treating an epoxide with *sec*-butyllithium in the presence of sparteine,<sup>584</sup> or with *n*-butyllithium/TMEDA,<sup>585</sup> and subsequent reaction with an aldehyde led to an epoxy alcohol. Alkylidene oxetanes react with lithium and then with an aldehyde to give a conjugated ketone.<sup>586</sup> The reaction of *gem*-dihalides with a carbonyl compound and Li or BuLi give epoxides<sup>587</sup> (see also, **16-46**).

for the addition of allylic groups,<sup>588</sup> and there are enantioselective reactions.<sup>589</sup> One of the most common methods is the *Barbier reaction* noted in **16-22**, which uses metals and metal compounds other than Mg or Li. With other metals, good yields are obtained with systems other than allylic compounds. Enantioselective In-mediated Barbier reactions are known.<sup>590</sup> Indium reacts with allylic bromides and ketones in aqueous media.<sup>591</sup> When allyl iodide is mixed with indium and TMSCl, reaction with a conjugated ketone proceed by 1,4-addition, but in the presence of 10% CuI, the major product is that of 1,2-addition.<sup>592</sup> Allyl bromide reacts with Mn/TMSCl and an In catalyst in water to give homoallylic alcohols from aldehydes.<sup>593</sup> Elimination of the homoallylic alcohol to form a conjugated diene can accompany the addition in some cases.<sup>594</sup>

Allyl bromide reacts with a ketone and Sm<sup>595</sup> or SmI<sub>2</sub><sup>596</sup> to give the homoallylic alcohol. Other metals can be used with allylic halides to give homoallylic alcohols from aldehydes or ketones,<sup>597</sup> including Zn,<sup>598</sup> La,<sup>599</sup> Mg/Cd,<sup>600</sup> or Rh,<sup>601</sup> and compounds of Ti,<sup>602</sup> Mn,<sup>603</sup> Fe,<sup>604</sup> Ga,<sup>605</sup> Ge,<sup>606</sup> Zr,<sup>607</sup> Nb,<sup>608</sup> Cd,<sup>609</sup> Ir,<sup>610</sup> Sb,<sup>611</sup> Te,<sup>612</sup> Ba,<sup>613</sup> Ce,<sup>614</sup> Nd,<sup>615</sup>

Hg,<sup>616</sup> Pr,<sup>617</sup> Bi,<sup>618</sup> In,<sup>619</sup> and Pb.<sup>620</sup> In addition, BiCl<sub>3</sub>/NaBH<sub>4</sub>,<sup>621</sup> Mg/BiCl<sub>3</sub>,<sup>622</sup> and CrCl<sub>2</sub>/NiCl<sub>2</sub><sup>623</sup> have been used. Allylic alcohols have been converted to organometallic reagents with diethylzinc and a Pd<sup>624</sup> or Ru catalyst,<sup>625</sup> leading to the homoallylic alcohol upon reaction with an aldehyde. Allylic acetates add to aldehydes in the presence of a Ru catalyst.<sup>626</sup> Organocerium reagents, generated from cerium chloride (CeCl<sub>3</sub> and a Grignard reagent or an organolithium reagent) give an organometallic reagent that adds chemoselectively.<sup>627</sup> Furthermore, organotitanium<sup>628</sup> reagents can be made to add chemoselectively to aldehydes in the presence of ketones.<sup>629</sup>

Enantioselective reactions are known.<sup>630</sup> A Cu-catalyzed reaction is known that proceeds with good enantioselectivity.<sup>631</sup> Allylzinc bromide adds to aldehydes under solvent-free conditions.<sup>632</sup> A chiral Cr/Mn complex has been used with allylic bromides in conjunction with trimethylsilyl chloride.<sup>633</sup> The enantioselective addition of methyltriisopropoxytitanium to aldehydes has been reported, for example.<sup>634</sup> Aryl halides that have a pendant ketone unit react with a Pd catalyst to give cyclization via acyl addition.<sup>635</sup> An enantioselective  $\alpha$ -vinylation of aldehydes occurred by reaction of vinyl iodonium triflate salts with aldehydes using a synergistic combination of Cu and chiral amine catalysts to give the  $\beta,\gamma$ -unsaturated aldehydes.<sup>636</sup>

As noted in **16-22**, enolate formation and reduction complicate some Grignard reactions. One way to avoid complications is to add Ti (or Zr) compounds to the Grignard or organolithium reagent.<sup>637</sup> The resulting organotitanium (or organozirconium) compounds are much more selective than Grignard or organolithium reagents.<sup>638</sup> Premixing an allylic Grignard reagent with ScCl<sub>3</sub> prior to reaction with the aldehyde gives direct

adds to ketones or aldehydes to give homoallylic alcohols with good enantioselectivity in the presence of a chiral Ti complex<sup>667</sup> or a chiral In complex.<sup>668</sup> Asymmetric induction has been reported.<sup>669</sup> The use of chiral Rh<sup>670</sup> or Ti<sup>671</sup> catalysts leads to enantioselective addition of allyltributyltin to aldehydes. Allyltributyltin reacts with aldehydes in the presence of SiCl<sub>4</sub> and a chiral phosphoramidate to give the homoallylic alcohol with moderate enantioselectivity.<sup>672</sup> Tetravinyltin adds to ketones in the presence of an In catalyst.<sup>673</sup> Tri-fluoromethylation of aldehydes and ketone used Bu<sub>3</sub>SnCF<sub>3</sub>.<sup>674</sup>

Aluminum catalysts such as methylaluminum bis(4-bromo-2,6-di-*tert*-butylphenoxide), MABR, facilitate addition of allyltributyltin to aldehydes.<sup>675</sup> Triphenylaluminum reacts with aryl aldehydes in the presence of a Ti catalyst.<sup>676</sup> Trimethylaluminum<sup>677</sup> and dimethyltitanium dichloride<sup>678</sup> exhaustively methylate ketones to give *gem*-dimethyl compounds<sup>679</sup> (see also, **10-63**). The alkyl group of trialkylaluminum compounds, such as AlEt<sub>3</sub>, adds to aldehydes enantioselectively in the presence of chiral transition metal complexes.<sup>680</sup> Vinylaluminum reagents have been used in reactions with aldehydes.<sup>681</sup> The Ti-catalyzed reaction of pyridyl aluminum reagents with aldehydes gave optically active diarylmethanols that contain various pyridyl groups.<sup>682</sup>

A complex of Me<sub>3</sub>Ti•MeLi has been shown to be selective for 1,2-addition with conjugated ketones in the presence of nonconjugated ketones.<sup>683</sup> Chiral amides react with aldehydes in the presence of TiCl<sub>4</sub> to give *syn*-selective addition products,<sup>684</sup> and Ti-catalyzed enantioselective additions are known.<sup>685</sup> Chiral dendritic Ti catalysts have been used to give moderate enantioselectivity.<sup>686</sup> Allyltitanocenes, cinnamyltitanocenes, and crotyltitanocenes reacted with five- to seven-membered cyclic enones to give the corresponding alcohol.<sup>687</sup> Allyltitanocenes also reacted with  $\alpha$ -chiral ketones to give the homoallylic

alcohol.<sup>688</sup> The titanocene-promoted Mn-mediated Barbier reaction of crotyl halides to carbonyls gave the alcohol.<sup>689</sup>

Organozinc compounds add to aldehydes and ketones,<sup>690</sup> dimethylzinc and diethylzinc are probably the most common reagents. An intramolecular version is possible by reaction of an allene aldehyde with dimethylzinc. Aryl halides react with Zn/Ni complexes to give acyl addition of the aryl group to an aldehyde.<sup>691</sup> The reaction of an allylic halide and Zn<sup>692</sup> or Zn/TMSCl<sup>693</sup> leads to acyl addition of aldehydes.

An enantioselective reaction of a carbonyl with a dialkylzinc or an organozinc halide<sup>694</sup> is possible when chiral catalysts are employed,<sup>695</sup> or when chiral ligands<sup>696</sup> are employed.<sup>697</sup> A comparison of the stereoselectivity for reactions of diphenylzinc and diethylzinc<sup>698</sup> has been reported.<sup>699</sup> A chiral ionic liquid has been developed for the addition of diethylzinc to aldehydes.<sup>700</sup> Dialkylzinc reagents, in the presence of a chiral Ti complex,<sup>701</sup> a Zn<sup>702</sup> or Al complex,<sup>703</sup> a chiral Cr complex,<sup>704</sup> a chiral Schiff base,<sup>705</sup> and other chiral complexes,<sup>706</sup> reacted with aldehydes or ketones to give the corresponding

alcohol with good enantioselectivity.<sup>707</sup> High enantioselectivity was obtained from R<sub>2</sub>Zn reagents (R = alkyl)<sup>708</sup> and aromatic aldehydes<sup>709</sup> by the use of a small amount of various catalysts.<sup>710</sup> The enantioselectivity is influenced by additives, such as LiCl.<sup>711</sup> Silica-immobilized chiral ligands<sup>712</sup> can be used in conjunction with dialkylzinc reagents, and polymer-supported ligands have been used.<sup>713</sup> The 1,2-addition of (*E*)-di- and (*E*)-trisubstituted vinylzinc reagents to β-silyloxy aldehydes, with alkyl zinc triflate and with nonaflate Lewis acids, gave the *anti*-allylic alcohol.<sup>714</sup> The reaction of benzaldehyde with RZnOAcMg(OAc)Br in the presence of Mg/TADDOLate gave the alcohol with good enantioselectivity.<sup>715</sup> Vinylzinc reagents were prepared by the reaction of vinyl iodides with ZnEt<sub>2</sub> and added to aldehydes in the presence of chiral additives to give the allylic alcohols.<sup>716</sup>

Organochromium compounds add to aldehydes or ketones.<sup>717</sup> The reaction of an organochromium reagent with an aldehyde or ketone is known as the *Nozaki-Hiyama reaction*. In the original version, a Cr(II) solution was prepared by reduction of chromic chloride by LiAlH<sub>4</sub>, and this was subsequently treated with an aldehyde and an allylic halide.<sup>718</sup> The coupling of allylic halides and aldehydes or ketones in the presence of a Cr catalyst and a chiral ligand gives products with good enantioselectivity.<sup>719</sup> Enantioselective coupling reactions catalyzed by Cr compounds are of increasing interest.<sup>720</sup> The organochromium reagent may be derived from vinyl halides, triflates, or aryl derivatives.<sup>721</sup> The Cr-catalyzed reaction of allylic chlorides with aldehydes, mediated by Mn, gave the homoallylic alcohol.<sup>722</sup>

Other metals facilitate addition of groups to an aldehyde, including the coupling of an alkene to an aldehyde using a Ni catalyst.<sup>723</sup> Vinyl bromides react with NiBr<sub>2</sub>/CrCl<sub>3</sub>/TMSCl to give a reagent that adds to aldehydes to give the allylic alcohol.<sup>724</sup> Vinyl complexes generated from alkynes and SmI<sub>2</sub> add intramolecularly, and eight-membered rings have been

formed in this way.<sup>725</sup> Vinyl reagents are formed *in situ* via organozirconium compounds with Me<sub>2</sub>Zn, Ti compounds, and terminal alkynes.<sup>726</sup>

Lithium dimethylcopper (Me<sub>2</sub>CuLi) reacts with aldehydes<sup>727</sup> and with certain ketones<sup>728</sup> to give the expected alcohols. Vinyltellurium compounds react with BF<sub>3</sub>•OEt<sub>2</sub> and cyanocuprates [R(2-thienyl)CuCNLi<sub>2</sub>] to give a reagent that adds 1,2- to the carbonyl of a conjugated ketone.<sup>729</sup> Vinyltellurium compounds also react with *n*-butyllithium to give a reagent that adds to nonconjugated ketones.<sup>730</sup> In conjunction with BeCl<sub>2</sub>, organolithium reagents add to conjugated ketones. In THF, 1,4-addition is observed, but in diethyl ether the 1,2-addition product is formed.<sup>731</sup> The lithium cation has been shown to play a key role in the transition state of the addition of allenyl cuprates to aldehydes.<sup>732</sup>

Alkynes add to aldehydes elsewhere in the same molecule in the presence of BEt<sub>3</sub> and a Ni catalyst to give a cyclic allylic alcohol.<sup>733</sup> Alkene aldehydes react similarly using Me<sub>3</sub>SiOTf.<sup>734</sup> In a similar manner, dienes<sup>735</sup> or alkynes<sup>736</sup> add to aldehydes in the presence of a Ni catalyst. Allenes add to aldehydes in the presence of a Ni catalyst, using a chiral imidazolynyl carbene ligand, and the product is trapped as the triethylsilyl ether by addition of Et<sub>3</sub>SiI.<sup>737</sup> Terminal alkynes react with Zr complexes and Me<sub>2</sub>Zn to give an allylic tertiary alcohol.<sup>738</sup> Internal alkynes also give allylic alcohols in the presence of BEt<sub>3</sub> and a Ni catalyst.<sup>739</sup> Reaction of an aldehyde containing a conjugated diene unit with diethylzinc and a Ni catalyst leads to cyclic alcohols having a pendant allylic unit.<sup>740</sup> A similar reaction was reported using a Cu catalyst.<sup>741</sup> The intramolecular addition of an alkene to an aldehyde leads to a saturated cyclic alcohol using PhSiH<sub>3</sub> and a Co catalyst.<sup>742</sup>

Aryl halides react with a Ni complex under electrolytic conditions to add the aryl group to aldehydes.<sup>743</sup>  $\alpha$ -Iodo phosphonate esters react with aldehydes and SmI<sub>2</sub> to give a  $\beta$ -hydroxy phosphonate ester.<sup>744</sup> Addition to the allene in the presence of a Ni catalyst<sup>745</sup> or a CeCl<sub>3</sub> catalyst<sup>746</sup> is followed by addition of the intermediate organometallic to the aldehyde to give the cyclic product.

Intramolecular addition of a conjugated ester (via the  $\beta$  carbon) to an aldehyde generates a cyclic ketone.<sup>747</sup> This type of coupling has been called the *Stetter reaction*,<sup>748</sup> which actually involves the addition of aldehydes to activated double bonds (**15-30**), mediated by a catalytic amount of thiazolium salt in the presence of a weak base. The intramolecular addition of the allene moiety to an aldehyde is catalyzed by a Pd complex in the presence of  $\text{Me}_3\text{SiSnBu}_3$ .<sup>749</sup> A highly enantio- and diastereoselective intramolecular Stetter reaction has been developed.<sup>750</sup> Alkynyl aldehydes react with silanes such as  $\text{Et}_3\text{SiH}$  and a Ni catalyst to give a cyclic compound having a silyl ether and an exocyclic vinylidene unit.<sup>751</sup> Alkene aldehydes give cyclic alcohols via intramolecular addition of the  $\text{C}=\text{C}$  unit to the carbonyl under electrolytic conditions using a phase-transfer catalyst.<sup>752</sup> A similar cyclization was reported using  $\text{SnCl}_4$ .<sup>753</sup> Vinylidene cycloalkanes react with aldehydes in the presence of a Pd catalyst to give a homoallylic alcohol where addition occurs at the carbon exocyclic to the ring.<sup>754</sup> Allenes react with benzaldehyde using  $\text{HCl}/\text{SnCl}_2$  with a Pd catalyst.<sup>755</sup> Silyl allenenes react with aldehydes in the presence of a chiral Sc catalyst to give homopropargylic alcohols with good enantioselectivity.<sup>756</sup> Intramolecular cyclization of allenyl aldehydes via reaction with PhI and a Pd catalyst gave cyclic alcohols with a pendant phenyl alkene unit.<sup>757</sup> Allenes add to ketones to give homoallylic alcohols in the presence of  $\text{SmI}_2$  and HMPA.<sup>758</sup> Conjugated dienes react with aldehydes via acyl addition of a terminal carbon of the diene in the presence of  $\text{Ni}(\text{acac})_2$  and  $\text{Et}_2\text{Zn}$ .<sup>759</sup>

The reaction of Na or K alkyne anions (e.g.,  $\text{RC}\equiv\text{C}-\text{M}$ , **16-38**) with ketones or aldehydes gives the propargylic alcohol via acyl addition.<sup>760</sup> The problems associated with propargyl allenyl systems in their addition reactions with carbonyl compounds has been reviewed.<sup>761</sup> In the reaction with terminal acetylenes,<sup>762</sup> sodium acetylides are the most common reagents, but lithium acetylides are commonly used.<sup>763</sup> While Na is the metal of choice for the addition of acetylenic groups, vinylic alanes (prepared as in **15-12**) are the reagents of choice for the addition of vinylic groups.<sup>764</sup> A chiral phosphoric acid was used with an Ir catalyst for the addition of terminal alkynes to aldehydes to give the homoallylic

alcohol.<sup>765</sup> The Cu-catalyzed reaction of enynes gave an organocopper intermediate that reacted with a carbonyl compound to give the homoallylic yne enol.<sup>766</sup>

A solvent-free reaction was reported that mixed a ketone, a terminal alkyne, and potassium *tert*-butoxide.<sup>767</sup> The reaction is sometimes called the *Nef reaction*. Li,<sup>768</sup> Mg, and other metallic acetylides have also been used. A particularly convenient reagent is lithium acetylide/ethylenediamine complex,<sup>769</sup> a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of a base, so that the acetylide is generated *in situ*. This procedure is called the *Favorskii reaction* – not to be confused with the Favorskii rearrangement (18-7).<sup>770</sup>

Zinc(II) chloride facilitates the addition of a terminal alkyne to an aldehyde to give a propargylic alcohol.<sup>771</sup> Zinc(II) triflate can also be used for alkyne addition to aldehydes,<sup>772</sup> and in the presence of a chiral ligand leads to good enantioselectivity in the propargyl alcohol product.<sup>773</sup> The reagents Et<sub>3</sub>Al, Et<sub>2</sub>Zn, and a terminal alkyne react with ketones, and in the presence of a *Cinchona* alkaloid gives the alkynyl alcohol in moderate enantiomeric excess.<sup>774</sup> Other enantioselective alkynylation reactions are known using various catalysts.<sup>775</sup> Terminal alkynes add to aryl aldehydes in the presence of InBr<sub>3</sub> and NEt<sub>3</sub>,<sup>776</sup> SmI<sub>2</sub>,<sup>777</sup> or Me<sub>2</sub>Zn.<sup>778</sup> A Zn-mediated reaction using iodoalkynes is known,<sup>779</sup> and catalytically generated zinc acetylides add to aldehydes.<sup>780</sup> An In-catalyzed addition of alkynes to aldehydes used a catalytic amount of BINOL and gave the alkynyl alcohol with high enantioselectivity.<sup>781</sup> Other enantioselective addition reactions of terminal alkynes are known.<sup>782</sup>

Propargylic acetate adds to aldehydes with good *anti* selectivity in the presence of Et<sub>2</sub>Zn and a Pd catalyst.<sup>783</sup> Aldehydes reacted with propargyl bromide using FeCl<sub>3</sub>/Zn or

$\text{CuCl}_2 \cdot \text{H}_2\text{O}/\text{Zn}$  to give the homopropargyl alcohol.<sup>784</sup> The Pd-catalyzed reaction of aldehydes and allylic bromides was mediated by  $\text{SnCl}_4 \cdot 2 \text{H}_2\text{O}$  and gave the homoallylic alcohol.<sup>785</sup> The Ag-catalyzed addition of terminal alkynes to cyclic ketones was reported using aqueous media.<sup>786</sup> The Ni-catalyzed, indium-mediated reaction of propargyl mesylates or carbonates with aldehydes has been reported.<sup>787</sup> The In-mediated reaction of aldehydes and ketones with propargyl bromides gave the 1,2-addition product, the homoallylic alcohol.<sup>788</sup> The Cr-catalyzed reaction of propargyl chlorides with ketones, mediated by Mn, gave the homopropargylic alcohol.<sup>789</sup>

## 16-24 The Addition of Organoboranes to Aldehydes and Ketones

Although organoboranes do not generally add to aldehydes and ketones,<sup>790</sup> allylic boranes are exceptions.<sup>791</sup> When they add, an allylic rearrangement always takes place. The use of a chiral catalyst leads to asymmetric induction<sup>792</sup> and chiral allylic boranes have been prepared.<sup>793</sup> It is noted that chloroboranes ( $\text{R}_2\text{BCl}$ ) react with aldehydes via acyl addition of the alkyl group, giving the corresponding alcohol after treatment with water.<sup>794</sup> Treatment with catecholborane gives addition to the conjugated ketone, and subsequent cyclization of the resulting organometallic at the nonconjugated ketone gives a cyclic alcohol with a pendant ketone unit, after treatment with methanol.<sup>795</sup> Addition of trialkylboranes to aldehydes is catalyzed by a Ni complex.<sup>796</sup>

A number of optically active allylic boron compounds have been used, including<sup>797</sup> *B*-allylbis(2-isocaranyl)borane (**20**),<sup>798</sup> (*E*)- and (*Z*)-crotyl-(*R,R*)-2,5-dimethylborolanes

(**21**),<sup>799</sup> and the borneol derivative **22**,<sup>800</sup> all of which add an allyl group to aldehydes, with good enantioselectivity. A recyclable 10-TMS-9-borabicyclo[3.3.2]decane has been used for asymmetric allyl and crotyl addition to aldehydes.<sup>801</sup> Where the substrate possesses an aryl group or a triple bond, using a metal carbonyl complex of the substrate enhances enantioselectivity.<sup>802</sup> Chiral biphenols catalyze the enantioselective reaction of allenyldioxoborolane with ketones, in the absence of solvent and under microwave irradiation, to give the homopropargylic alcohol.<sup>803</sup>

In the presence of Ru,<sup>804</sup> Cu,<sup>805</sup> Ni,<sup>806</sup> or Pd<sup>807</sup> compounds, RB(OH)<sub>2</sub> and arylboronic acids (ArB(OH)<sub>2</sub>, see **12-27**) add to aldehydes to give the corresponding alcohol, as in the Pd-catalyzed reaction that gave **23**.<sup>807</sup>

The Pd-catalyzed addition of arylboronic acids to aryl aldehydes gave the diaryl alcohol and it was observed that the solvent played a role in the course of the reaction.<sup>808</sup> Aldehydes reacted with arylboronic acids in the presence of a Rh catalyst.<sup>809</sup> The Rh-catalyzed 1,2-addition of arylboronic acids to  $\alpha$ -diketones gave  $\alpha$ -hydroxy ketones.<sup>810</sup> The sealed-vessel microwave heating of aromatic and aliphatic aldehydes with arylboronic acids at 180 °C in toluene, with a Ni catalyst, gave the alcohol.<sup>811</sup> The Co-catalyzed reaction of a vinylboronic acid and carbonyl compounds gave the corresponding allylic alcohols.<sup>812</sup>

Arylboronic acids add to aldehydes in the presence of a chiral ligand to give an alcohol with good enantioselectivity.<sup>813</sup> An enantioselective intramolecular reaction of an arylboronic acid to a pendant ketone moiety used a Pd catalyst.<sup>814</sup> The Ru-catalyzed reaction

of arylboronic acids with aryl aldehydes gave chiral diarylmethanols with excellent enantioselectivity.<sup>815</sup> An intramolecular version of the phenylboronic acid-induced reaction is known, where a molecule with ketone and conjugated ketone units is converted to a cyclic alcohol using a chiral Rh catalyst.<sup>816</sup>

Boronic esters (boronates) can also be used in this acyl addition reaction. Allylic boronates add to aldehydes,<sup>817</sup> and there are enantioselective reactions.<sup>818</sup> The Cu-catalyzed reaction of aryl aldehydes with [(Pin)B]<sub>2</sub>CH(Me) gave the *syn*-1,2-hydroxyboronate.<sup>819</sup> The Cu-catalyzed propargylation of aldehydes with trimethylsilyl propargyl boronates gave 1-TMS homopropargyl alcohols.<sup>820</sup> Cyclopropylmethyl boronates reacted with aldehydes in the presence of PhBCl<sub>2</sub> to give bis(homoallyl) alcohols.<sup>821</sup> Allenyl boronates reacted with aldehydes to give the homopropargyl alcohols, catalyzed by (BINOL)-derived phosphoric acids.<sup>822</sup> 1-Alkenyl boronates generated a transient allylic boronate intermediate that reacted with aldehydes to give the *anti*-homoallylic alcohol.<sup>823</sup> The ZnEt<sub>2</sub>-catalyzed reaction of allenyl boronate and aldehydes or ketones gave the allenyl alcohol.<sup>824</sup> Polymer-bound aryl borates add an aryl group to aldehydes in the presence of a Rh catalyst.<sup>825</sup> The CuCl/bipyridine-catalyzed addition reaction of arylboroxines with aldehydes gave the corresponding alcohol.<sup>826</sup> A Rh/diene-catalyzed reaction of arylboroxines/arylboronic acids with ketones gave the tertiary alcohol.<sup>827</sup>

The Pd-catalyzed reaction of aryl aldehydes with PhBF<sub>3</sub>K gave a diaryl alcohol.<sup>828</sup> A Ru-catalyzed reaction of aryltrifluoroborates led to sterically hindered diaryl ketones.<sup>829</sup> Aliphatic aldehydes react with trifluoroborates, in the presence of BF<sub>3</sub>•OEt<sub>2</sub>, to give the homoallylic alcohol with allylic rearrangement and a preference for the *syn* diastereomer,<sup>830</sup> and aryl aldehydes react as well.<sup>831</sup> Allylic trifluoroborates (**12-27**) reacted with aldehydes to give the homoallylic alcohol. Aldehydes reacted with potassium allyltrifluoroborate to give the allylated product using a lanthanide catalyst.<sup>832</sup> The propargylation of aldehydes

using potassium allenyltrifluoroborate was promoted by tonsil clay.<sup>833</sup> Potassium alkynyltrifluoroborates (**12-27**) reacted with aldehydes and a secondary amine, in an ionic liquid, to give a propargylic amine.<sup>834</sup>

### 16-25 The Addition of Trialkylallylsilanes to Aldehydes and Ketones

Allylic alcohols can be treated with TMS-Cl and NaI, and then Bi, to give an organometallic reagent that adds to aldehydes.<sup>835</sup> Allyltrichlorosilanes have also been used in addition reactions with aldehydes.<sup>836</sup> Hünig's base (*i*-Pr<sub>2</sub>NEt) and a sulfoxide have also been used to facilitate the addition of an allyl group to an aldehyde from allyltrichlorosilane.<sup>837</sup> The mechanism of this reaction has been examined.<sup>838</sup> The *Sakurai reaction*, also called the *Hosomi-Sakurai reaction*,<sup>839</sup> is the reaction of allyltrimethylsilanes with aldehydes or ketones in the presence of Lewis or Brønsted acid to give homoallylic alcohols such as **24**.<sup>839</sup> Alternative catalysts include HClO<sub>4</sub> supported on silica gel,<sup>840</sup> and organocatalysts.<sup>841</sup> The zinc-catalyzed hydrosilylation of ketones is known.<sup>842</sup> The transition state for the bipyridine *N*-oxide-catalyzed, enantioselective propargylation of aromatic aldehydes with allenyltrichlorosilanes was examined using density functional theory.<sup>843</sup>

Allylic trialkyl, trialkoxy, and trihalosilanes add to aldehydes to give the homoallylic alcohols in the presence of a Lewis acid<sup>844</sup> (including TaCl<sub>5</sub><sup>845</sup> and YbCl<sub>3</sub><sup>846</sup>), fluoride ion,<sup>847</sup> proazaphosphatranes,<sup>848</sup> or a catalytic amount of iodine.<sup>849</sup> A Ru catalyst has been

and Ba(OH)<sub>2</sub> in aqueous methanol.<sup>889</sup> An intramolecular version of the Baylis-Hillman reaction generated cyclopentenone derivatives from alkyne aldehydes and a Rh catalyst.<sup>890</sup> Other intramolecular cyclization reactions are known.<sup>891</sup> Less reactive ketones and acrylamides gave an intramolecular Baylis-Hillman reaction with DABCO to give functionalized  $\alpha$ -methylene- $\gamma$ -lactams.<sup>892</sup>

Enantioselective Baylis-Hillman reactions<sup>893</sup> are possible using a chiral auxiliary via an amide<sup>894</sup> or ester.<sup>895</sup> Organocatalysts can be used to give products with good enantioselectivity.<sup>896</sup> Sugars have been used as ester auxiliaries, and in reaction with aryl aldehydes and 20% DABCO gave the allylic alcohol with modest enantioselectivity.<sup>897</sup>

Another variation is the *Rauhut-Currier cyclization* reaction,<sup>898</sup> which involves the reaction of a conjugated carbonyl with the allylic site of a second conjugated system. Intramolecular variations of this latter method are known.<sup>899</sup> The coupling of aldehydes with conjugated ketones used TiCl<sub>4</sub>,<sup>900</sup> dialkylaluminum halides,<sup>901</sup> or with (polymethyl)hydrosiloxane and a Cu catalyst.<sup>902</sup> Conjugated esters were coupled to aldehydes with DABCO and a La catalyst.<sup>903</sup>

Alkyl halides are coupled with conjugated carbonyls to give the alkylated derivative in what is known as *Morita-Baylis-Hillman alkylation*.<sup>904</sup>  $\alpha$ -Bromomethyl esters react with the  $\alpha$  carbon of the C=C unit of conjugated ketones in the presence of DABCO to give the alkylated alkene coupling product, which is a nonconjugated diene.<sup>905</sup> The asymmetric organocatalytic allylic substitution of Baylis-Hillman carbonates with allylamines has been used for the preparation of 2,5-dihydropyrroles.<sup>906</sup> The allylic alkylation of Baylis-Hillman carbonates with allyl ketones has been reported.<sup>907</sup> The preparation of  $\gamma$ -alkylidenebutenolides was achieved via sequential indium-mediated Barbier-type reaction

of Morita-Baylis-Hillman bromides with an aldehyde, followed by lactonization, and finally double bond isomerization.<sup>908</sup> The reaction can be modified to give additional products, as with the reaction of *o*-hydroxybenzaldehyde and methyl vinyl ketone with DABCO, where the initial Baylis-Hillman product cyclized via conjugate addition of the phenolic oxygen to the conjugated ketone (**15-27**).<sup>909</sup>

See OS **2010**, 87, 201.

## 16-27 The Reformatsky Reaction

The *Reformatsky reaction*<sup>910</sup> is very similar to **16-24**. An aldehyde or ketone is treated with Zn and a halide; the halide is usually an  $\alpha$ -halo ester or a vinylog (Sec. 6.B) of an  $\alpha$ -halo ester (e.g.,  $\text{RCHBrCH}=\text{CHCOOEt}$ ), although  $\alpha$ -halo nitriles,<sup>911</sup>  $\alpha$ -halo ketones,<sup>912</sup> and  $\alpha$ -halo *N,N*-disubstituted amides have also been used. Especially high reactivity can be achieved with activated Zn<sup>913</sup> and with Zn and ultrasound.<sup>914</sup> The reaction is catalytic in Zn in the presence of iodine and ultrasound.<sup>915</sup> Metals other than Zn can be used, including In,<sup>916</sup> Mn,<sup>917</sup> low valent Ti,<sup>918</sup> metal compounds of Ti,<sup>919</sup> Sn,<sup>920</sup> Sm,<sup>921</sup> Ce,<sup>922</sup> or Sc.<sup>923</sup> The use of additives, such as Ge<sup>924</sup> or  $\text{Me}_2\text{Zn}$ ,<sup>925</sup> can lead to highly selective reactions.<sup>926</sup> The aldehyde or ketone can be aliphatic, aromatic, or heterocyclic or contain various functional groups. Solvents used are generally ethers, including  $\text{Et}_2\text{O}$ , THF, and 1,4-dioxane, although the reaction can be done in water<sup>927</sup> using dibenzoyl peroxide and  $\text{MgClO}_4$ . Dialkylzinc compounds are an alternative source of Zn in the Reformatsky reaction. The reaction of an  $\alpha$ -bromo ester, an aldehyde, and diethylzinc in THF, with a Rh catalyst, gave a  $\beta$ -hydroxy ester.<sup>928</sup>

Using chiral auxiliaries<sup>929</sup> or chiral catalysts,<sup>930</sup> and organocatalysts,<sup>931</sup> good enantioselectivity<sup>932</sup> can be achieved. Formally, the reaction is somewhat analogous to the *Grignard reaction* (16-22), with  $\text{EtO}_2\text{C}-\text{C}-\text{ZnBr}$  as an intermediate analogous to  $\text{RMgX}$ .<sup>933</sup> There is a cyclic intermediate, which is a coordination complex of the ester carbonyl oxygen and Zn, and the structure has been characterized by X-ray crystallography of the solid intermediate prepared from  $t\text{-BuOCOCH}_2\text{Br}$  and Zn.<sup>934</sup>

After hydrolysis, the alcohol is the usual product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an alkene. By the use of  $\text{Bu}_3\text{P}$  along with Zn, the alkene can be made the main product,<sup>935</sup> making this an alternative to the *Wittig reaction* (16-44). Since *Grignard reagents* cannot be formed from  $\alpha$ -halo esters, the method is quite useful, but competing reactions sometimes lead to low yields. A similar reaction (called the *Blaise reaction*) has been carried out on nitriles:<sup>936</sup>

Carboxylic esters have also been used as substrates, but then, as might be expected (Sec. 16.A), the result is substitution to give a  $\beta$ -keto ester, and not addition. The product in this case is the same as with the corresponding nitrile, although the pathways are different.

Aza-Reformatsky reactions have been reported.<sup>937</sup>

by reaction of the carboxylic acid with a large excess of  $R^1Li$ . The  $R'$  group may be aryl or primary, secondary, or tertiary alkyl and  $R$  may be alkyl or aryl. Tertiary alcohols are side products. Using  $R(PrNH)Mg$ , carboxylic acid salts react to form ketones.<sup>940</sup> A related reaction treats the lithium carboxylate with lithium metal and the alkyl halide, with sonication, to give the ketone.<sup>941</sup> Phenylboronic acid (**12-27**) reacts with aryl carboxylic acids in the presence of a Pd catalyst and disuccinoyl carbonate to give a diaryl ketone.<sup>942</sup> Carboxylic acids were converted directly into methyl, *n*-butyl, and isopropyl ketones by reaction with an excess of cyanocuprates  $R_2CuLi \cdot LiCN$ .<sup>943</sup> Trimethylaluminum, which exhaustively methylates ketones (**16-22**), also exhaustively methylates carboxylic acids to give *tert*-butyl compounds<sup>944</sup> (see also **10-63**).

OS V, 775.

Acyl halides react cleanly and under mild conditions with lithium dialkylcopper reagents (see **10-58**)<sup>945</sup> to give high yields of ketones.<sup>946</sup> The  $R'$  group may be primary, secondary, or tertiary alkyl or aryl and may contain iodo, keto, ester, nitro, or cyano groups. The  $R$  groups that have been used successfully are methyl, primary alkyl, and vinylic. Secondary and tertiary alkyl groups can be introduced by the use of  $PhS(R)CuLi$  (**10-58**) instead of  $R_2CuLi$ ,<sup>947</sup> or by the use of either the mixed homocuprate  $(R'SO_2CH_2CuR)^-Li^+$ ,<sup>948</sup> or a magnesium dialkylcopper reagent " $RMeCuMgX$ ."<sup>949</sup> Secondary alkyl groups can also be introduced with the copper/zinc reagents  $RCu(CN)ZnI$ .<sup>950</sup> Organocopper reagents generated *in situ* from highly reactive copper, and containing such functional groups as cyano, chloro, and ester, react with acyl halides to give ketones.<sup>951</sup>

When the organometallic compound is a *Grignard reagent*,<sup>952</sup> ketones are generally not obtained because the initially formed ketone reacts with a second molecule of  $RMgX$  to give the salt of a tertiary alcohol (**16-29**). Ketones *have* been prepared in this manner by the use of low temperatures, inverse addition (i.e., addition of the Grignard reagent to the acyl halide rather than the other way), excess acyl halide, and so on, but the yields are usually

low, although high yields have been reported in THF at  $-78\text{ }^{\circ}\text{C}$ .<sup>953</sup> Pretreatment with a trialkylphosphine followed by the Grignard reagent gave the ketone.<sup>954</sup> Using  $\text{CuBr}$ <sup>955</sup> or a Ni catalyst<sup>956</sup> with the Grignard reagent can lead to the ketone. Some ketones are unreactive toward Grignard reagents for steric or other reasons; these can be prepared in this way.<sup>957</sup> Certain metallic halides, notably ferric and cuprous halides, are catalysts that improve the yields of ketone at the expense of tertiary alcohol.<sup>958</sup> Both free-radical and ionic mechanisms have been proposed for this catalysis.<sup>959</sup>

Other organometallic reagents<sup>960</sup> give good yields of ketones when treated with acyl halides. A particularly useful class of organometallic reagent is the organocadmium reagents  $\text{R}_2\text{Cd}$ , prepared from Grignard reagents (**12-22**). In this case, R may be aryl or primary alkyl. In general, secondary and tertiary alkylcadmium reagents are not stable enough to be useful in this reaction.<sup>961</sup> Direct treatment of the acid chloride with an alkyl halide and Cd metal leads to the ketone in some cases.<sup>962</sup> Organozinc compounds behave similarly to dialkylcadmium reagents, but are used less often.<sup>963</sup> Allylic halides and In metal react with acyl chlorides to give the ketone.<sup>964</sup> Other reagents include organomanganese,<sup>965</sup> organobismuth,<sup>966</sup> and organothallium compounds.<sup>967</sup>

Acid chlorides are generally so reactive that the initially formed ketone reacts further, giving the alcohol as the product. However, it is possible for the ketone to be isolated, and the use of lithium dialkylcuprates (or dialkylcadmium reagents) are common. Grignard reagents react with acid chlorides to give the ketones, mediated by simple amides such as NMP or DMF.<sup>968</sup> Aryl heteroaryl ketones were prepared by reaction of an aryl carboxylic acid with *i*-PrMgBr, followed by reaction with 2-iodopyridine, and, finally, treatment with EtMgBr.<sup>969</sup> The Ni-catalyzed coupling of carboxylic acid chlorides and alkyl iodides or benzylic chlorides gave unsymmetrical dialkyl ketones.<sup>970</sup> Aryl acid chlorides were

coupled with secondary alkyl halides using a Ni catalyst, 3 equivalents of Zn, and 15 equivalents of  $MgCl_2$  to give the ketone.<sup>971</sup> The reaction of acid chlorides with alkynylzinc reagents gave the ynone using a Pd catalyst.<sup>972</sup> The Pd-catalyzed reaction of aryl- or alkenylboronic acids with acid chlorides in the presence of copper(I) thiophene-2-carboxylate as an activator gave diaryl ketones.<sup>973</sup> Arylboronic acids were heated with  $Bu_3SnOMe$  and then the Pd-catalyzed reaction with aryl acid chlorides gave the diaryl ketone.<sup>974</sup> The Pd-catalyzed reaction of an acyl chloride and an arylboronic acid<sup>975</sup> or an alkenylboronic acid<sup>976</sup> gives a ketone. Surfactants are known to promote arylboronic acid coupling reactions.<sup>977</sup> Arylboronic esters add to carbamoyl halides, in the presence of a Pd catalyst, to give the corresponding benzamide.<sup>978</sup> Arylboronic acids also react with anhydrides to give a ketone in the presence of a Pd catalyst.<sup>979</sup>

In the presence of  $BCl_3$ , ynones were prepared by the reaction of acyl chlorides and potassium alkynyltrifluoroborate salts.<sup>980</sup> Silica-supported zinc bromide ( $ZnBr_2/SiO_2$ ) catalyzed the reaction of acid chlorides with terminal alkynes to give the ynone.<sup>981</sup>

Conjugated alkynyl ketones can be prepared from an acyl halide, a terminal alkyne, catalyzed by  $CuI$ ,<sup>982</sup>  $Pd$ ,<sup>983</sup>  $Fe$ ,<sup>984</sup> or an  $In$  metal.<sup>985</sup> Terminal alkynes react with chloroformates and a Pd catalyst to give the corresponding propargyl ester.<sup>986</sup> Similar reaction of an alkyne with an acid chloride and a  $Pd/Cu$ <sup>987</sup> or  $CuI$  catalyst,<sup>988</sup> both with microwave irradiation, gave alkynyl ketones.

It is noted that arylboronic acids also react with dialkyl anhydrides, with a  $Rh$  catalyst<sup>989</sup> or a Pd catalyst,<sup>990</sup> to give the ketone. Aryl iodides react with acetic anhydride, with a Pd catalyst, to give the aryl methyl ketone.<sup>991</sup>

### 16-29 The Reaction of Organometallic Compounds With Carboxylic Acid Derivatives

As is the case with acyl halides (**16-28**), anhydrides and carboxylic esters give tertiary alcohols (**16-29**) when treated with Grignard reagents.<sup>992</sup> Low temperatures,<sup>993</sup> the solvent HMPA,<sup>994</sup> and inverse addition have been used to increase the yields of ketone.<sup>995</sup> Esters or amides can be used in reactions with organometallic compounds to give ketones.<sup>996</sup>

When carboxylic esters are treated with Grignard reagents, addition to the carbonyl initially generates a ketone (**16-22**). Under the reaction conditions, the initially formed ketone is more reactive than the ester and usually undergoes further reaction to give a tertiary alcohol in which two R groups are the same. Possible side reactions include enolization, condensations, and cleavages. Organolithium compounds have been used to give ketones from carboxylic esters, but a high-boiling solvent such as toluene is required, since reaction at lower temperatures gives tertiary alcohols.<sup>997</sup> Isolation of the ketone as the major product is possible in some cases, particularly when the reaction is done at low temperature<sup>998</sup> and when there is steric hindrance to the carbonyl in the first-formed ketone. Esters of formic acid, dialkyl formamides, and lithium or sodium formate<sup>999</sup> give good yields of aldehydes when treated with Grignard reagents. Formates react to give secondary alcohols and carbonates give tertiary alcohols in which all three R groups are the same:

Symmetrical aromatic 1,3-diols were prepared by the reaction of substituted aryl Grignard reagents with isopropenyl acetate in a one-step reaction.<sup>1000</sup> Tertiary alcohols were prepared by the CuO-catalyzed reaction of Mg and unactivated alkyl or aryl bromides with an ester.<sup>1001</sup> When 1,4-dimagnesium compounds are used, carboxylic esters are converted to cyclopentanols.<sup>1002</sup> 1,5-Dimagnesium compounds give cyclohexanols, but in lower yields.<sup>1003</sup>

Sodium naphthalenide reacts with esters to give naphthyl ketones.<sup>1004</sup> Trimethylaluminum reacts with esters to form ketones in the presence of *N,N'*-dimethylethylenediamine.<sup>1005</sup> Trialkylboranes have been used to convert thioesters to ketones.<sup>1006</sup> Thioesters (RCOSR') react with arylboronic acids, in the presence of a Pd catalyst, to give the corresponding ketone,<sup>1007</sup> and esters react similarly with arylboronic acids (Pd catalyst)<sup>1008</sup> or arylboronates (Ru catalyst).<sup>1009</sup> Thioesters are converted to ketones with organoindium compounds.<sup>1010</sup> Thioesters give good yields of ketones when treated with lithium dialkylcopper reagents R<sup>2</sup><sub>2</sub>CuLi (R<sup>2</sup> = primary or secondary alkyl or aryl).<sup>1011</sup> Organozinc reagents convert thioesters to ketones.<sup>1012</sup> Diaryl- or dialkylzinc reagents react with anhydrides and a Pd<sup>1013</sup> or Ni catalyst<sup>1014</sup> to give the ketone. The reaction of alkylzinc halides and thioesters leads to ketones in the presence of 1.5% Pd/C,<sup>1015</sup> in what has been called *Fukuyama coupling*.<sup>1016</sup> The Fukuyama reaction couples a thioester with an organozinc compound, using a Pd catalyst, to give the corresponding ketone.<sup>1017</sup> The Pd-catalyzed Fukuyama cross coupling of secondary organozinc reagents with thioesters or acid chlorides using a ZnCl<sub>2</sub> mediator gave the ketone.<sup>1018</sup>

Amides give better yields of the ketone at room temperature, but yields are still not very high.<sup>1019</sup> Anhydrides can react with arylmagnesium halides at low temperature, and in the presence of (–)-sparteine, to give a keto acid with good enantioselectivity.<sup>1020</sup> Organocadmium reagents are less successful with these substrates than with acyl halides (16-28). Tertiary amides reacted with Grignard reagents to give the ketone and an amine.<sup>1021</sup> The reaction of Grignard reagents with thioamides and thioformamides has been reviewed.<sup>1022</sup>

Organolithium reagents also give good yields of carbonyl compounds with *N,N*-disubstituted amides.<sup>1023</sup> Dialkylformamides react to give aldehydes, other disubstituted

amides give ketones, and other acid derivatives have been used.<sup>1024</sup> Disubstituted formamides can react with 2 molar equivalents of Grignard reagent. The products of this reaction when R = H (called *Bouveault reaction*) are an aldehyde and a tertiary amine.<sup>1025</sup>

The use of an amide other than a formamide can give a ketone instead of an aldehyde, but yields are generally low. However, the addition of 2 molar equivalents of phenyllithium to a carbamate gave good yields of the ketone.<sup>1026</sup>

Ketones can be prepared by treatment of thioamides with organolithium compounds (alkyl or aryl).<sup>1027</sup> Cerium reagents, such as MeCeCl<sub>2</sub>, also add two R groups to an amide.<sup>1028</sup> More commonly, an organolithium reagent is treated with CeCl<sub>3</sub> to generate the organocerium reagent *in situ*.<sup>1029</sup> It has proven possible to add two different R groups by sequential addition of two Grignard reagents.<sup>1030</sup> When an amide having a *gem*-dibromocyclopropyl unit elsewhere in the molecule was treated with methylithium, Li-Br exchange was accompanied by intramolecular acyl addition to the amide carbonyl, giving a bicyclic amino alcohol.<sup>1031</sup>

*N*-Methoxy *N*-methyl amides, such as **25**, are referred to as a *Weinreb amide*.<sup>1032</sup> When a *Weinreb amide* reacts with a *Grignard reagent* or an organolithium reagent,<sup>1033</sup> the product is the ketone. The reaction of **25** (Bn = benzyl) with ethylmagnesium bromide to give ketone **26** is a typical example, taken from the Goswami and Kuilya synthesis of carolacton.<sup>1034</sup> Intramolecular displacement of a *Weinreb amide* by an organolithium reagent generated *in situ* from an iodide precursor leads to cyclic ketones.<sup>1035</sup> Reaction with vinylmagnesium bromide led to a  $\beta$ -*N*-methoxy-*N*-methylamino ketone, presumably by initial formation of the conjugated ketone followed by *Michael addition (15-20)* of the liberated amine.<sup>1036</sup> By the use of the compound *N*-methoxy-*N,N',N'*-trimethylurea, it is possible to add two R

### 16-30 The Addition of Organometallic Compounds to $\text{CO}_2$ and $\text{CS}_2$

Grignard reagents add to one C=O bond of  $\text{CO}_2$  ( $\text{O}=\text{C}=\text{O}$ ) as they do with an aldehyde or a ketone,<sup>1046</sup> but the product is the salt of a carboxylic acid. The reaction is usually performed by adding the Grignard reagent to dry ice. Many carboxylic acids have been prepared in this manner, and this constitutes an important way of increasing a carbon chain by one unit. Since labeled  $\text{CO}_2$  is commercially available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also

been used (RLi,<sup>1047</sup> RNa, RCaX, RBa,<sup>1048</sup> etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO<sub>2</sub> to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also 16-42).

Aryl organoboronates react with CO<sub>2</sub>, in the presence of a Ru catalyst, to give the corresponding aryl carboxylic acid.<sup>1049</sup> Aryl and alkenyl boronic esters are carboxylated in the presence of a Cu catalyst.<sup>1050</sup> Vinyl halides react with CO and water, with a Pd catalyst in an ionic liquid, to give the conjugated carboxylic acid.<sup>1051</sup> Organozinc compounds are carboxylated with CO<sub>2</sub> and a Ni catalyst.<sup>1052</sup> Metal-free carboxylation of organozinc reagents is also known.<sup>1053</sup> In the presence of CO<sub>2</sub> and an organocatalyst, aromatic aldehydes are converted to the corresponding carboxylic acid.<sup>1054</sup> Direct carboxylation of aryl bromides is possible using CO<sub>2</sub> and a Pd catalyst.<sup>1055</sup> Allenes are converted to β,γ-unsaturated acids with CO<sub>2</sub> in the presence of Et<sub>2</sub>Zn.<sup>1056</sup>

When chiral additives such as (–)-sparteine have been added to the initial reaction with the organolithium reagent, quenching with CO<sub>2</sub> produces carboxylic acids with good asymmetric induction.<sup>1057</sup>

Heating *N*-tosylhydrazones and CO<sub>2</sub> with 3 equivalents of Cs<sub>2</sub>CO<sub>3</sub> in DMSO gave the corresponding α-arylacrylic acid.<sup>1058</sup> Benzoic acid (de)carboxylases reacted with styrene derivatives to selectively give *o*-hydroxybenzoic acid derivatives, whereas phenolic acid (de)carboxylases reacted at the β carbon atom of styrenes to give (*E*)-cinnamic acids.<sup>1059</sup> The Cu(I)/NHC-catalyzed reaction of allylboronic pinacol esters with CO<sub>2</sub> gave the more substituted β,γ-unsaturated carboxylic acid.<sup>1060</sup> The reaction of alkenylzirconocenes with CO<sub>2</sub> using (IMes)CuCl as a catalyst gave the α,β-unsaturated carboxylic acids.<sup>1061</sup> A Cu-containing ionic liquid was used to catalyze the reaction of terminal alkynes with ambient CO<sub>2</sub> in the presence of iodobutane to give a butyl propiolate derivative.<sup>1062</sup> The Ni-catalyzed carboxylation of benzyl halides with CO<sub>2</sub> gave phenylacetic acids.<sup>1063</sup> The Ni-catalyzed carboxylation of primary alkyl bromides and sulfonates with CO<sub>2</sub> gave the aliphatic carboxylic acid.<sup>1064</sup> Allylic carboxylic acids were generated by the Ni-catalyzed reaction of allylic acetates with CO<sub>2</sub>.<sup>1065</sup> In a closely related reaction, Grignard reagents add to CS<sub>2</sub>

### 16-31 The Addition of Organometallic Compounds to C=N Compounds

Aldimines can be converted to secondary amines by treatment with *Grignard reagents*.<sup>1069</sup> Ketimines generally react with Grignard reagents to give reduction instead of addition. However, organolithium compounds react to give the normal addition product with both aldimines and ketimines.<sup>1070</sup> The solvent and the aggregation state of the organolithium play a role in the addition, however.<sup>1071</sup> Addition of R<sup>2</sup>MgX or R<sup>2</sup>Li to aldimines gives ArCHR<sup>2</sup>NH<sub>2</sub> after hydrolysis.<sup>1072</sup> An intramolecular version of the addition of organolithium reagents gave 2-phenylpyrrolidine.<sup>1073</sup> Grignard reagents add to imines in the presence of various transition metal catalysts, including Sc(OTf)<sub>3</sub><sup>1074</sup> or Cp<sub>2</sub>ZrCl<sub>2</sub>.<sup>1075</sup> Alkynes add to imines to give propargylic amines.<sup>1076</sup> Allylic alcohols add to imines in the presence of a Pd catalyst to give the homoallylic amine.<sup>1077</sup> Alkyl and aryl halides reacted with imines under electrochemical conditions using zinc electrodes to give the amine.<sup>1078</sup>

When chiral additives are used in conjunction with the organolithium reagent, chiral amines are produced<sup>1079</sup> with good asymmetric induction.<sup>1080</sup> Chiral auxiliaries have been used in addition reactions of organometallic compounds to imines<sup>1081</sup> and to oxime derivatives.<sup>1082</sup> The Cu-mediated and catalyzed asymmetric alkylation of imines has been reviewed.<sup>1083</sup> Chiral catalysts lead to enantioselective addition of alkynes to imines to

Iminium salts<sup>1130</sup> give tertiary amines directly, via 1,2-addition to the C=N unit. Chloroiminium salts  $\text{ClCH}=\text{NR}_2'\text{Cl}^-$  (generated *in situ* from an amide,  $\text{HCONR}_2'$ , and phosphene,  $\text{COCl}_2$ ) react with 2 molar equivalents of a Grignard reagent  $\text{RMgX}$ , one adding to the C=N and the other replacing the Cl, to give tertiary amines  $\text{R}_2\text{CHNR}_2'$ .<sup>1131</sup> Alkoxy carbonyl iminium salts were prepared by the oxidation of tetrasubstituted amino ketene silyl acetals, and subsequent nucleophilic addition of Grignard reagents gave  $\alpha,\alpha$ -disubstituted  $\alpha$ -amino ester derivatives.<sup>1132</sup> The reaction of aldehydes, secondary amines, proton sponge, and silyl triflate generated an iminium salt *in situ*. This salt reacted with difluorocarbene, generated in HMPA from  $\text{Me}_3\text{SiCF}_2\text{Br}$ , to give the  $\alpha$ -bromodifluoromethyl amine.<sup>1133</sup>

Arylboronic acids (**12-27**) add the aryl group to *N*-tosyl imines using a Rh<sup>1134</sup> or Pd<sup>1135</sup> catalyst. Arylboronic acids react similarly and, in the presence of a chiral Rh<sup>1136</sup> or Ir<sup>1137</sup> catalyst, give a chiral sulfinamide or sulfonamide. The Rh-catalyzed arylation of aliphatic *N*-tosylaldimines with arylboronic acids gave the corresponding tosylamine with good enantioselectivity.<sup>1138</sup> The Pd-catalyzed addition of arylboronic acids to cyclic ketimines gave the amine with good enantioselectivity.<sup>1139</sup> The allylation reaction of organoboron reagents with imines has been reviewed.<sup>1140</sup>

Arylboronates (**12-27**) add to *N*-sulfonyl imines in the presence of a Rh catalyst to give the corresponding sulfonamide.<sup>1141</sup> Chiral Cu complexes have also been used for effective allylation of ketimines.<sup>1142</sup> Allylic boronates also add to aldehydes, and subsequent treatment with ammonia gives the homoallylic amine.<sup>1143</sup> Vinyl boronates add to nitrones in the presence of  $\text{Me}_2\text{Zn}$ , transferring the vinyl group to the C=N unit.<sup>1144</sup> The organocatalyst-mediated reaction of allenyl boronates and *N*-Boc imines gave the  $\alpha$ -allenyl *N*-Boc amine.<sup>1145</sup> The enantioselective Cu-catalyzed reactions of (pinacolato)allylborons with aryl-, heteroaryl-, alkyl-, or alkenyl-substituted *N*-phosphinoylimines gave homoallylamides.<sup>1146</sup> Triethylborane was used to initiate a radical coupling reaction of *N*-Boc- and *N*-Cbz-imines and  $\text{PivOCH}_2\text{I}$  to give the corresponding amine product.<sup>1147</sup>

Potassium allyltrifluoroborates react with *N*-tosylimines in the presence of a Pd catalyst.<sup>1148</sup> Potassium alkenyltrifluoroborates added to *N*-tosylimines using a rhodium catalyst to give the *N*-tosylallylic amine with good enantioselectivity.<sup>1149</sup>

Allylic silanes, such as allyltrimethylsilane, add to *N*-substituted imines in the presence of a Pd catalyst to give the homoallylic amine.<sup>1150</sup> Similar results are obtained when the allylic silane and imine are treated with a catalytic amount of tetrabutylammonium fluoride.<sup>1151</sup> Allylic trichlorosilanes add to hydrazones to give homoallylic hydrazine derivatives with excellent *anti* selectivity<sup>1152</sup> and with good enantioselectivity using a chiral ligand.<sup>1153</sup> Chiral allylic silane derivatives have been developed, and add to hydrazones with good enantioselectivity.<sup>1154</sup> The chiral Mg-BINOL phosphate-catalyzed phosphination of imines gave  $\alpha$ -amino phosphine oxides.<sup>1155</sup>

There is an *aza-Baylis-Hillman reaction* that converts imines and conjugated carbonyl derivatives to the  $\alpha$ -amino-conjugated derivative.<sup>1156</sup> *N*-Tosylimines can be used in place of aldehydes, and the reaction of the imine, a conjugated ester, and DABCO gave the allylic *N*-tosylimine.<sup>1157</sup> A “double Baylis-Hillman” reaction has also been reported using *N*-tosylimines and conjugated ketones.<sup>1158</sup> The use of chiral catalysts leads to enantioselective product formation.<sup>1159</sup> Enantioselective *aza*-Baylis-Hillman reactions<sup>1160</sup> were reported, including using a chiral reaction medium.<sup>1161</sup> Aldehydes add via the  $\alpha$  carbon using proline, to give  $\beta$ -amino aldehydes with good selectivity.<sup>1162</sup>

Nitro compounds add to *N*-carbamoyl imines with a chiral diamine catalyst with some enantioselectivity.<sup>1163</sup> Nitro compounds add via carbon using a Cu catalyst, and with good enantioselectivity, when a chiral ligand is used.<sup>1164</sup> The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of  $\text{ClCH=NMe}_2^+ \text{Cl}^-$  to give oximes.<sup>1165</sup>

Many other C=N systems such as hydrazones and oximes give 1,2-addition when treated with *Grignard reagents*; others give reductions; others give miscellaneous reactions.

### 16-32 The Addition of Carbenes and Diazoalkanes to $\text{C}=\text{N}$ Compounds

In the presence of metal catalysts such as  $\text{Yb}(\text{OTf})_3$ , diazoalkanes add to imines to generate aziridines.<sup>1179</sup> The reaction is somewhat selective for the *cis* diastereomer. The use of chiral additives in this reaction leads to aziridines enantioselectively.<sup>1180</sup> Imines are formed by the reaction of amines with an aldehyde or ketone (**16-12**). *N*-Tosyl imines react with diazoalkenes to form *N*-tosyl aziridines, with good *cis* selectivity<sup>1181</sup> and modest enantioselectivity in the presence of a chiral Cu catalyst<sup>1182</sup> but with excellent enantioselectivity

with a chiral Rh catalyst<sup>1183</sup> or with the use of an organocatalyst.<sup>1184</sup> It is noted that *N*-tosyl aziridines are formed by the reaction of an alkene with PhI=NTs and a Cu catalyst.<sup>1185</sup> *N*-Acylimines react with diazoesters via C–H insertion using a Pt catalyst.<sup>1186</sup> The Pd-catalyzed intramolecular insertion of alkenes into the C–N bond of  $\beta$ -lactams has been reported.<sup>1187</sup>

### 16-33 The Addition of Grignard Reagents to Nitriles and Isocyanates

The addition of *Grignard reagents* to nitriles, followed by hydrolysis of the initially formed imine anion, gives ketones. When both R groups are alkyl, yields are not high.<sup>1188</sup> Yields can be improved by the use of Cu(I) salts<sup>1189</sup> or by using benzene containing 1 equivalent of ether as the solvent, rather than ether alone.<sup>1190</sup> In general, the ketimine salt does not react with Grignard reagents: hence tertiary alcohols or tertiary alkyl amines are not often side products.<sup>1191</sup> By careful hydrolysis of the salt it is sometimes possible to isolate ketimines ( $\text{RR}'\text{C}=\text{NH}$ ),<sup>1192</sup> especially when R and R' = aryl. The addition of Grignard reagents to the  $\text{C}\equiv\text{N}$  group is normally slower than to the  $\text{C}=\text{O}$  group, and cyano groups containing aldehydes add the Grignard reagent without disturbing the CN group.<sup>1193</sup> The addition of Grignard reagents to nitriles has been reported using flow conditions (Sec. 7.D).<sup>1194</sup> The mechanism probably involves addition of the carbon group to the nitrile carbon to form an  $\text{N}-\text{MgBr}$  imine, although dialkylmagnesium addition to the nitrile may be involved.<sup>1195</sup>

Organolithium reagents add to nitriles, mediated by LiBr, to form *N*-acetyl enamines.<sup>1196</sup> Secondary thioamides were prepared by the reaction of functionalized organolithium reagents with isothiocyanates followed by aqueous acid hydrolysis.<sup>1197</sup> Other metal compounds have been used, including Sm with allylic halides<sup>1198</sup> and organocerium

compounds.<sup>1199</sup> Allylic halides react with an excess of Zn metal in the presence of 40% AlCl<sub>3</sub>, and in the presence of a nitrile, to give homoallylic ketones after hydrolysis.<sup>1200</sup> The *Blaise reaction* is the reaction of the organozinc reagent derived from an  $\alpha$ -bromo ester with Zn metal and a nitrile to give the corresponding  $\beta$ -keto ester.<sup>1201</sup> Arenes add to nitriles in the presence of a Pd catalyst in DMSO/trifluoroacetic acid to give a diaryl ketone.<sup>1202</sup> *N*-Aryl amides were prepared by the Cu-catalyzed reaction of aryl halides and nitriles.<sup>1203</sup>

Arylboronic acids add to nitriles in the presence of a Pd catalyst.<sup>1204</sup> Aryl and alkenylboronic acids add to isocyanates in the presence of a Pd<sup>1205</sup> or Rh<sup>1206</sup> catalyst. Arylboronic acids added to aliphatic nitriles using a Pd catalyst to give alkyl aryl ketones.<sup>1207</sup> The boron trifluoride-mediated double allylboration of nitriles to give bis(allyl) amines by reaction with potassium allyltrifluoroborate proceeded at room temperature.<sup>1208</sup>

The Ag-catalyzed reactions of isocyanides have been reviewed.<sup>1209</sup> It is noted that terminal alkynes add to the carbon of an isonitrile in the presence of a uranium complex, giving a propargylic imine.<sup>1210</sup> The addition of Grignard reagents to isocyanates gives, after hydrolysis, *N*-substituted amides.<sup>1211</sup> This is a very good reaction and can be used to prepare derivatives of alkyl and aryl halides. The reaction has also been performed with alkyllithium compounds.<sup>1212</sup> Isothiocyanates give *N*-substituted thioamides. Nitroso compounds react with activated nitriles in the presence of LiBr and microwave irradiation to give a cyano imine, ArN=C(CN)Ar.<sup>1213</sup> This transformation has been called the *Ehrlich-Sachs reaction*.<sup>1214</sup>

OSCV III, 26, 562; V, 120, 520.

## G. Carbon Attack by Active Hydrogen Compounds

Reactions 16-34 to 16-49 are base-catalyzed condensations (although some of them are also catalyzed by acids).<sup>1215</sup> In 16-34 to 16-44, a base removes a C–H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an  $\alpha$  hydrogen is present and on whether

the new double bond would be in conjugation with double bonds already present. The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 16.2 illustrates the differences. Reaction 16-49 is an analogous reaction involving addition to  $C\equiv N$ .

16-34 The Aldol Condensation<sup>1216</sup>

In the *aldol reaction* or *aldol condensation* the  $\alpha$  carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.<sup>1217</sup> Although acid-catalyzed aldol reactions are known,<sup>1218</sup> the most common form of the reaction uses a base. There is evidence that an SET mechanism can intervene when the substrate is an aromatic ketone.<sup>1219</sup> Although hydroxide was commonly used in early versions of this reaction, stronger bases, such as alkoxides ( $\text{RO}^-$ ) or amides ( $\text{R}_2\text{N}^-$ ), are also common. Amine bases have been used to catalyze the aldol condensation.<sup>1220</sup> With weaker bases, not all of an aldehyde or ketone is converted to the corresponding enolate ion, so the equilibrium lies well to the left, for both aldehydes and ketones. Nevertheless, enough enolate ion is present for reaction with the carbonyl carbon to give the  $\beta$ -alkoxide product. Hydrolysis gives the aldol product. Homoaldol condensation products are known<sup>1221</sup> as well as vinylogous aldol reactions.<sup>1222</sup> Aza-aldol reactions have been reported.<sup>1223</sup>

The reaction with hydroxide generates water ( $\text{p}K_{\text{a}}$  15.7) as the conjugate acid, which is a stronger acid than the carbonyl ( $\text{p}K_{\text{a}}$  about 20–22), so the water reacts with the enolate anion to shift the equilibrium back to the left. With amide bases, the conjugate acid is the amine ( $\text{p}K_{\text{a}}$  about 36), which is a much weaker acid than the carbonyl. So, particularly with aprotic solvents, the equilibrium usually lies to the right when compared with alkoxides or hydroxide. Protic solvents have an acidic hydrogen (e.g., water or alcohol), and the solvent is acidic enough to react with the enolate anion and shift the equilibrium to the left. An aprotic solvent, such as ether or THF, does not have an acidic hydrogen atom and cannot react with the enolate anion. A strong amide base, such as lithium diisopropylamide (LDA, Sec. 8.F, category 7), generates an amine conjugate acid that reacts very slowly with the

enolate and the equilibrium lies more to the right.<sup>1224</sup> A variety of amide bases can be used to deprotonate the ketone or aldehyde. In the case of an unsymmetrical ketone, removal of the more acidic proton leads to the kinetic enolate anion.<sup>1225</sup> Note that a polymer-bound amide base has been used<sup>1226</sup> and solid-phase chiral lithium amides are known.<sup>1227</sup> The aldol reaction has been done in ionic liquids.<sup>1228</sup>

The product of an aldol condensation is a  $\beta$ -hydroxy aldehyde (called an *aldol*) or a  $\beta$ -hydroxy ketone, which is often dehydrated during the course of the reaction if the resulting C=C unit is conjugated. Indeed, *the aldol product is relatively easy to isolate* when the reaction is done in aprotic solvents with a mild workup procedure, *unless the substrate is an aromatic aldehyde or ketone*.<sup>1229</sup> A retro-aldol condensation has been exploited for crossed-aldol reactions.<sup>1230</sup> Enzyme-mediated aldol reactions have been reported using two aldehydes, including formaldehyde.<sup>1231</sup> A vinylogous (Sec. 6.B) aldol reaction is known,<sup>1232</sup> as is a “double” aldol.<sup>1233</sup> Under the principle of vinylogy (Sec. 6.B), the active hydrogen can be one in the  $\gamma$  position of an  $\alpha,\beta$ -unsaturated carbonyl compound.

The scope of the aldol reaction may be discussed under five headings.

1. *Reaction between two molecules of the same aldehyde*, which is called *homocoupling*. Hydroxide or alkoxide bases are typically used in protic solvents,<sup>1234</sup> and the reaction is quite feasible. Nowadays, the use of dialkylamide bases in aprotic solvents such as ether or THF is more common. Many aldehydes have been converted to aldols and/or their dehydration products in this manner. The most effective

catalysts are basic ion-exchange resins. Of course, the aldehyde must possess an  $\alpha$  hydrogen.

2. *Reaction between two molecules of the same ketone. homo-coupling.* With hydroxide or alkoxide bases in protic solvents the equilibrium lies well to the left,<sup>1235</sup> and the reaction is most feasible if the equilibrium can be shifted. Such an equilibrium shift can often be done by allowing the reaction to proceed in a Soxhlet extractor (e.g., see *OS I*, 199). As with aldehydes, the use of dialkylamide bases such as LDA or lithium hexamethyldisilazide (Sec. 8.F, category 7) in aprotic solvents such as ether or THF are more common. Unsymmetrical ketones condense on the least substituted side (more acidic H) with dialkylamide bases in aprotic solvents, but on the more substituted side (less acidic H) with alkoxide bases in alcohol solvents.
3. *Reaction between two different aldehydes: cross-coupling.* In protic solvents with an alkoxide base this will produce a mixture of four products (eight, if the alkenes are counted). However, if one aldehyde does not have an  $\alpha$  hydrogen, only two aldols are possible, and in many cases the crossed product is the main one. The crossed aldol reaction is often called the *Claisen-Schmidt reaction*.<sup>1236</sup> Nowadays, the crossed aldol reaction is readily accomplished using amide bases in an aprotic solvent. For example, the first aldehyde is treated with LDA in THF at  $-78^\circ\text{C}$  to form the enolate anion and since the solvent is not acidic the equilibrium lies to the right, and there is a reasonable concentration of the enolate anion. Subsequent treatment with a second aldehyde allows the initially formed enolate anion to react via acyl addition to give the mixed aldol product. Note that the crossed aldol of two aldehydes has been done using potassium *tert*-butoxide and  $\text{Ti}(\text{OBu})_4$ .<sup>1237</sup>
4. *Reaction between two different ketones: cross-coupling.* When hydroxide or alkoxide bases are used, the more acidic hydrogen is removed from the less-substituted  $\alpha$  carbon and the conjugate acid is an alcohol. As this is more acidic than the ketone the equilibrium lies to the right. This situation allows the  $\alpha$  hydrogen from the more-substituted carbon to be removed (it is only 1–2  $\text{p}K_{\text{a}}$  units less acidic after all) to form the more-substituted enolate anion. Since the alcohol conjugate acid also reacts with this enolate anion, this is also a reversible reaction and a dynamic equilibrium is established with both enolate anions and the initial carbonyl. The equilibrium shifts toward the thermodynamically more stable enolate anion, which is the more-substituted enolate anion, and this then reacts with the second added ketone to give the major product. Note that the less-substituted enolate anion (the kinetic enolate) also reacts, so there is a mixture of products that favors the product of the reaction with the more substituted (thermodynamic) enolate anion. If this reaction is done with amide bases in aprotic solvents, the kinetic enolate anion is formed first and the equilibrium is to the right, so the major contributor to the acid–base equilibrium is the kinetic enolate anion. It is this enolate anion that reacts with the second ketone to give the alkoxide product.
5. *Reaction between an aldehyde and a ketone.* This coupling is usually feasible with hydroxide or alkoxides bases in protic solvents when the aldehyde has no  $\alpha$

<sup>1235</sup> The equilibrium concentration of the product from acetone in pure acetone was determined to be 0.01%: Maple, S.R.; Allerhand, A. *J. Am. Chem. Soc.* **1987**, *109*, 6609.

<sup>1236</sup> In aqueous media: see Buonora, P.T.; Rosauer, K.G.; Dai, L. *Tetrahedron Lett.* **1995**, *36*, 4009.

<sup>1237</sup> Han, Z.; Yorimitsu, H.; Shinokubo, H.; Oshima, K. *Tetrahedron Lett.* **2000**, *41*, 4415.

hydrogen, since there is no competition from ketone condensing with itself.<sup>1238</sup> This is also called the *Claisen-Schmidt reaction*. Even when the aldehyde has an  $\alpha$  hydrogen, it is generally the  $\alpha$  carbon of the ketone that adds to the carbonyl of the aldehyde, not the other way around. Mixtures are usually produced, however. The kinetic–thermodynamic enolate anion conditions in point 4 (above) also apply to this reaction. If the ketone or the aldehyde is treated with an amide base in aprotic solvents, a second aldehyde or ketone can be added to give the aldolate with high regioselectivity.

A computational study gave the gas-phase activation energies for lithium enolate anions in an aldol-type reaction.<sup>1239</sup> There is a computational study of the mechanism for an aldol reaction in pure water.<sup>1240</sup> A computational study of the aldol reaction between benzaldehyde and acetone to determine the origin of the enhanced rates and enantioselectivities derived from an enamine-based catalytic antibody 33F12 and a chiral organocatalyst.<sup>1241</sup>

Base-induced formation of the enolate anion generally leads to a mixture of (*E*)- and (*Z*)-isomers, and dialkyl amide bases are used in most cases. The (*E/Z*) stereoselectivity depends on the structure of the lithium dialkylamide base, with the highest (*E/Z*) ratios obtained with LiTMP/butyllithium mixed aggregates in THF.<sup>1242</sup> The use of LiHMDS resulted in a reversal of the (*E/Z*) selectivity. In general, metallic (*Z*)-enolates give the *syn* (or *erythro*) pair, and this reaction is highly useful for the diastereoselective synthesis of these products.<sup>1243</sup> The (*E*)-isomers generally react nonstereoselectively. However, *anti* stereoselectivity has been achieved in a number of cases, with Ti enolates,<sup>1244</sup> with Mg enolates,<sup>1245</sup> and with certain enol borinates.<sup>1246</sup> Enolization and reprotonation accounts for *syn-anti* isomerization of aldols.<sup>1247</sup> In another variation, a  $\beta$ -keto *Weinreb amide* (see **16-29**) reacted with  $\text{TiCl}_4$  and *Hünig's base* (*i*-Pr<sub>2</sub>NEt) and then an aldehyde to give the  $\beta$ -hydroxy ketone.<sup>1248</sup>

The aldol reaction can be made regioselective by preparing an enol derivative of the ketone separately<sup>1249</sup> under kinetic conditions and then adding this to the aldehyde (or ketone). Other types of preformed derivatives that react with aldehydes and ketones are enamines (with a Lewis acid catalyst),<sup>1250</sup> and enol borinates  $\text{R}'\text{CH}=\text{CR}^2\text{—OBR}_2$ <sup>1251</sup>

(which can be synthesized by reaction **15-23** or directly from an aldehyde or ketone).<sup>1252</sup> Metallic enolates can be used for aldol reactions, either preformed or generated *in situ*, with a catalytic amount of a metal compound: Mg,<sup>1253</sup> Ti,<sup>1254</sup> Zn,<sup>1255</sup> Zr,<sup>1256</sup> Pd,<sup>1257</sup> In,<sup>1258</sup> Sn,<sup>1259</sup> La,<sup>1260</sup> and Sm.<sup>1261</sup> Such reactions give products with moderate to excellent diastereoselectivity<sup>1262</sup> and regioselectivity.

The reactions with preformed enol derivatives provide a way to control the stereoselectivity of the aldol reaction.<sup>1263</sup> As with the Michael reaction (**15-20**), the aldol reaction creates two new stereogenic centers, and, in the most general case, there are four stereoisomers of the aldol product (two racemic diastereomers), which can be represented as the *syn* and *anti* diastereomers shown.

The reaction may be diastereoselective, however, if one is preferred over the other. The Zimmerman-Traxler model has been used to predict the major diastereomer.<sup>1264</sup>

Among the preformed enol derivatives used for diastereoselective aldol condensations have been enolates of Li,<sup>1265</sup> Mg, Ti,<sup>1266</sup> and Sn,<sup>1267</sup> silyl enol ethers,<sup>1268</sup> enol borinates,<sup>1269</sup>

and enol borates  $R'CH=CR^2-OB(OR)_2$ .<sup>1270</sup> The nucleophilicity of silyl enol ethers has been examined.<sup>1271</sup>

There are discussions that relate to the transition state of the aldol condensation.<sup>1272</sup> There is experimental evidence for chair-like transition states in the aldol reactions of methyl ketone lithium enolate anions.<sup>1273</sup> The most popular transition state is the closed or chelated transition state, similar to that proposed by Zimmerman and Traxler<sup>1274</sup> for the *Ivanov condensation*<sup>1275</sup> of phenylacetic acid and benzaldehyde. Subsequent reaction with a carbonyl compound (benzaldehyde) led to an aldol-like product (3-hydroxy-2,3-diphenylpropanoic acid).<sup>1274</sup> When applied to the aldol condensation, with a lithium counterion, cyclic models **27** or **27'** give the stereoisomeric products. These models are used to predict stereochemistry in the aldol condensation, and are referred to as the *Zimmerman-Traxler model*.<sup>1274</sup>

Aldol reactions are enantioselective under the proper conditions<sup>1276</sup> (in which case only one of the four isomers predominates)<sup>1277</sup> by using chiral enol derivatives,<sup>1278</sup> chiral aldehydes or ketones,<sup>1279</sup> or both.<sup>1280</sup> Chiral amine bases,<sup>1281</sup> such as

solvents,<sup>1292</sup> and under solvent-free conditions.<sup>1293</sup> Chiral auxiliaries<sup>1294</sup> have been developed that can be used in conjunction with the aldol condensation, and chiral ligands<sup>1295</sup> that can be used in catalytic reactions. An  $\alpha$ -hydroxy ketone was condensed with an aldehyde using a chiral Zn catalyst to give the aldol (an  $\alpha,\beta$ -dihydroxy ketone) with good *syn* selectivity and good enantioselectivity.<sup>1296</sup> Chiral vinylogous (Sec. 6.B) aldol reactions have been reported.<sup>1297</sup> The magnesium enolate anion formed from a chiral amide adds to aldehydes to give the alcohol enantioselectively.<sup>1298</sup> Diamine protonic acids have been used for catalytic asymmetric aldol reactions.<sup>1299</sup>

It is possible to make the  $\alpha$  carbon of the aldehyde add to the carbonyl carbon of the ketone by using an imine instead of an aldehyde and by using  $\text{LiN}(i\text{-Pr})_2$  as the base to form an  $\alpha$ -lithio imine.<sup>1300</sup> This is known as a *directed aldol reaction*. Similar reactions have been performed with  $\alpha$ -lithiated dimethylhydrazones of aldehydes or ketones<sup>1301</sup> and with  $\alpha$ -lithiated aldoximes.<sup>1302</sup>

The aldol reaction can also be performed with acid catalysts, as mentioned above, in which case dehydration usually follows. Here there is initial protonation of the carbonyl group to form an oxocarbenium ion, and this is attacked by the  $\alpha$  carbon of the *enol* form of the other molecule.<sup>1303</sup> Loss of a proton generates the aldol product. Loss of water under the acidic conditions leads to the conjugated product. With respect to the enol, this mechanism is similar to that of halogenation (12-4). A side reaction that is sometimes troublesome is further condensation, since the product of an aldol reaction is still an aldehyde or ketone.

The intramolecular aldol condensation is well known, and aldol reactions are often used to close five- and six-membered rings. Because of the favorable entropy (Sec. 6.D), such ring closures generally take place with ease<sup>1304</sup> when using hydroxide or alkoxide bases in protic solvents. In aprotic solvents with amide bases, formation of the enolate anion occurs by deprotonation of the more acidic site, followed by cyclization to the second carbonyl. The acid-catalyzed intramolecular aldol condensation is known, and the mechanism has been studied.<sup>1305</sup> An asymmetric intramolecular aldol reaction was catalyzed by a

chiral amine.<sup>1306</sup> Chiral ligands, in conjugation with Cu compounds,<sup>1307</sup> led to asymmetric intramolecular aldol condensation reactions. The regioselectivity of an intramolecular aldol condensation of unsaturated 1,5-diketones is strongly influenced by the presence or absence of a trialkylphosphine.<sup>1308</sup> The Tf<sub>2</sub>NH-mediated intermolecular/intramolecular sequential aldol reaction of disilyl enol ethers gave five-, six-, and seven-membered ring products.<sup>1309</sup>

An important extension of the intramolecular aldol condensation is the *Robinson annulation* reaction,<sup>1310</sup> which has often been used in the synthesis of steroids and terpenes. In original versions of this reaction a cyclic ketone is converted to another cyclic ketone under equilibrium conditions using hydroxide or alkoxide bases in a protic solvent (thermodynamic or equilibrium conditions), forming one additional six-membered ring containing a double bond. The reaction can be done in a stepwise manner using amide bases in aprotic solvents. In the reaction with hydroxide or alkoxide bases in alcohol or water solvents, the substrate is treated with methyl vinyl ketone (or a simple derivative of methyl vinyl ketone) and a base.<sup>1311</sup> The enolate ion of the substrate adds to the methyl vinyl ketone in a *Michael reaction* (**15-20**) to give a diketone (**28**) that undergoes or is made to undergo an internal aldol reaction. Subsequent dehydration gave the bicyclic product.<sup>1312</sup>

The Robinson annulation can be combined with alkylation.<sup>1313</sup> An organocatalyst-mediated aldol-Robinson cascade reaction has been reported.<sup>1314</sup> Enantioselective Robinson annulation techniques have been developed, including a proline-catalyzed reaction.<sup>1315</sup> The Robinson annulation has been done in ionic liquids<sup>1316</sup> and a solvent-free version of the reaction is known.<sup>1317</sup>

Because methyl vinyl ketone has a tendency to polymerize, surrogates are often used instead. Such surrogates are compounds that will give methyl vinyl ketone when treated with a base. One common example, MeCOCH<sub>2</sub>CH<sub>2</sub>NEt<sub>2</sub>Me<sup>+</sup> I<sup>-</sup> (see **17-7**), is easily prepared by quaternization of MeCOCH<sub>2</sub>CH<sub>2</sub>NEt<sub>2</sub>, which itself is prepared by a *Mannich reaction* (**16-17**) involving acetone, formaldehyde, and diethylamine.  $\alpha$ -Silylated vinyl

ketones,  $\text{RCOC}(\text{SiMe}_3)=\text{CH}_2$ , have also been used successfully in annulation reactions<sup>1318</sup> because the  $\text{SiMe}_3$  group is easily removed.

When the ring closure of a 1,5-diketone is catalyzed by the amino acid (*S*)-proline, the product is optically active with high enantiomeric excess.<sup>1319</sup>

Examples of nitroso aldol reactions have been reported.<sup>1320</sup>

### 16-35 Mukaiyama Aldol and Related Reactions<sup>1321</sup>

An important variation of the aldol condensation involves treatment of an aldehyde or ketone with a ketene silyl acetal  $\text{R}_2\text{C}=\text{C}(\text{OSiMe}_3)\text{OR}'$ <sup>1322</sup> or a silyl enol ether, in the presence of  $\text{TiCl}_4$ <sup>1323</sup>, to give the  $\beta$ -hydroxyl carbonyl. This variation is known as the *Mukaiyama aldol reaction* or, simply, the *Mukaiyama reaction*.<sup>1324</sup> Note that esters have been used rather than aldehydes in this reaction.<sup>1325</sup> The ketene silyl acetal can be considered a preformed enolate that gives aldol product with  $\text{TiCl}_4$  in aqueous solution, or with no catalyst at all.<sup>1326</sup> Reaction at the carbonyl of saturated carbonyl compounds is significantly faster than 1,2-addition to unsaturated carbonyl compounds.<sup>1327</sup> The mechanism of this reaction has been explored.<sup>1328</sup> An *ab initio* study of the uncatalyzed Mukaiyama aldol reaction showed that the nucleophilicity of the silyl enol ether and the electrophilicity of the aldehyde are important in promoting the reactivity.<sup>1329</sup> Other

### 16-36 Condensation Reactions between Carboxylic Acid Derivatives and Aldehydes or Ketones

In the presence of a strong base, removal of a proton from the  $\alpha$  carbon of a carboxylic ester or other acid derivative generates an enolate anion that can condense with the carbonyl carbon of an aldehyde or ketone to give a  $\beta$ -hydroxy ester,<sup>1379</sup> amide, and so on. Dehydration of such products will give the  $\alpha,\beta$ -unsaturated derivative. This enolate reaction is called the *Claisen condensation*.<sup>1380</sup> This reaction has been called the *Claisen reaction*, which is unfortunate since that name is more firmly connected to **16-81**. Early reactions used hydroxide or an alkoxide base in water or alcohol solvents, where self-condensation was the major process. Under such conditions, the aldehyde or ketone was usually chosen for its lack of an  $\alpha$  proton. Much better control of the reaction was achieved when dialkylamide bases<sup>1381</sup> in aprotic solvents, such as ether or THF, were used to give the enolate anion.<sup>1382</sup> Additives play an important role in the LDA-mediated enolization of esters.<sup>1383</sup>

Transition metal-mediated condensation of esters with aldehydes is known. The enolate anion reaction of acetate derivatives using metal enolates has been reviewed.<sup>1384</sup> The reaction of a thioester and an aryl aldehyde with  $\text{TiCl}_4/\text{NBu}_3$ , for example, gave a  $\beta$ -hydroxy thioester with good *syn* selectivity.<sup>1385</sup> The reaction of an  $\alpha,\beta$ -unsaturated ester and benzaldehyde with a chiral Rh catalyst gave a  $\beta$ -hydroxy ester with good diastereoselectivity and good enantioselectivity.<sup>1386</sup> Besides ordinary esters (containing an  $\alpha$  hydrogen), the reaction can also be carried out with lactones and, as in **16-34**, with the  $\gamma$  position of  $\alpha,\beta$ -unsaturated esters (vinylogy; Sec. 6.B). The enolate anion of an amide can be condensed with an aldehyde.<sup>1387</sup> Thioesters undergo aldol-type condensations.<sup>1388</sup>

For most esters, a much stronger base is needed than for aldol reactions;  $(i\text{-Pr})_2\text{NLi}$  (LDA, Sec. 8.F, category 7),  $\text{Ph}_3\text{CNa}$ , and  $\text{LiNH}_2$  are among those employed. However, esters of malonic acid and succinic acid react more easily and such strong bases are not needed. For example, diethyl succinate and its derivatives condense with aldehydes and ketones in the presence of bases such as  $\text{NaOEt}$ ,  $\text{NaH}$ , or  $\text{KOCMe}_3$ . This reaction is called the *Stobbe condensation*.<sup>1389</sup> One of the ester groups (sometimes both) is hydrolyzed in the

course of the reaction. The Stobbe condensation has been extended to di-*tert*-butyl esters of glutaric acid.<sup>1390</sup> The boron-mediated reaction is known.<sup>1391</sup>

The intramolecular reaction of an aldehyde/carboxylic acid in the presence of triethylamine and a pyridinium salt led to the ring-forming condensation reaction, followed by formation of a  $\beta$ -lactone.<sup>1392</sup>

Chiral additives such as diazaborolidines can be added to an ester, and subsequent treatment with a base and then an aldehyde leads to a chiral  $\beta$ -hydroxy ester.<sup>1393</sup> A variety of chiral amide or oxazolidinone derivatives have been used to form amide linkages to carboxylic acid derivatives. These chiral auxiliaries lead to chirality transfer from the enolate anion of such derivatives, in both alkylation reactions and acyl substitution reactions with aldehydes and ketones. The so-called *Evans auxiliaries* (see **29**) are commonly used and give good enantioselectivity.<sup>1394</sup>

A variation is the magnesium halide-catalyzed anti-aldol reaction of chiral *N*-acylthiazolidinethiones.<sup>1395</sup> The use of chiral *N*-acyloxazolidinethiones with  $\text{TiCl}_4$  and sparteine also gave good selectivity in the acyl addition.<sup>1396</sup> Chiral diazaboron derivatives have also been used to facilitate the condensation of a  $\alpha$ -phenylthio ester with an aldehyde.<sup>1397</sup>

Amides participate in this condensation reaction, reacting with aldehydes in the presence of a Ba catalyst to give a  $\beta$ -hydroxy amide derivative.<sup>1398</sup> The reaction of an amide with LDA in the presence of an acyl silane, followed by reaction with an alkyl halide, leads to the  $\beta$ -hydroxy amide with the additional alkyl group at the  $\beta$  carbon.<sup>1399</sup> The enolate condensation of amides was reported using phosphazene-based catalysts.<sup>1400</sup> Thioamides reacted with copper complexes and  $\text{LiOAr}$  to form the enolate anion, which reacted with aldehydes to give the  $\beta$ -hydroxythioamide with good enantioselectivity.<sup>1401</sup>

The condensation of an ester enolate and a ketone<sup>1402</sup> can be used as part of a *Robinson annulation*-like sequence (see **16-34**). The aldol-like reaction of enol borates and methyl

### 16-37 Condensation of Nitro Compounds: the Henry Reaction<sup>1404</sup>

The condensation of an aliphatic nitro compound with an aldehyde or ketone is usually called the *Henry reaction*<sup>1405</sup> or the *Kamlet reaction*, and is essentially a nitro aldol reaction. An investigation of solvent effects and how they influence the rate and the stereoselectivity of the Henry reaction has been reported.<sup>1406</sup>

A variety of conditions have been reported, including the use of a recoverable polymer catalyst,<sup>1407</sup> a silica catalyst,<sup>1408</sup> a tetraalkylammonium hydroxide,<sup>1409</sup> proazaphosphatranes,<sup>1410</sup> a mesoporous nickel hydroxyapatite nanocomposite,<sup>1411</sup> and In,<sup>1412</sup> and it has been done in aqueous media<sup>1413</sup> or an ionic liquid.<sup>1414</sup> A solvent-free Henry reaction was reported in which a nitroalkane and an aldehyde were reacted on KOH powder,<sup>1415</sup> and a solvent-free microwave-assisted reaction was reported.<sup>1416</sup> Potassium phosphate has been used with nitromethane and aryl aldehydes. A gel-entrapped base has been used to catalyze this reaction.<sup>1417</sup>

Catalytic enantioselective Henry reactions are known,<sup>1418</sup> and include the use of Cu,<sup>1419</sup> Zn,<sup>1420</sup> Nd,<sup>1421</sup> Ni,<sup>1422</sup> Cr,<sup>1423</sup> or Ti catalysts.<sup>1424</sup> A heterobimetallic Cu/Sm catalyst has been used.<sup>1425</sup> The Henry reaction of nitromethane and a chiral aldehyde under high pressure gives the  $\beta$ -nitro alcohol with excellent enantioselectivity.<sup>1426</sup> Enantioselective nitro-aldol reactions are catalyzed by organocatalysts such as *Cinchona* alkaloids<sup>1427</sup> or other organocatalysts<sup>1428</sup> and biocatalysts.<sup>1429</sup> Biocatalysts have been used.<sup>1430</sup> An *anti*-selective Henry reaction used an urea/transition metal cooperative catalyst.<sup>1431</sup> The development of new chiral ligands is of ongoing importance.<sup>1432</sup> An asymmetric Henry reaction has been reported using flow conditions (Sec. 7.D).<sup>1433</sup>

*Aza-Henry reactions*<sup>1434</sup> condense nitroalkanes with imine derivatives, and the resulting amino nitro compounds are formed with good enantioselectivity in the presence of organocatalysts<sup>1435</sup> or Brønsted acid catalysts.<sup>1436</sup> Samarium or sodium iodide salts have been used with the aza-Henry reaction.<sup>1437</sup> Aza-Henry products are also formed by the reaction of amines with activated unsaturated compounds.<sup>1438</sup>

## 16-38 The Knoevenagel Reaction

The condensation of aldehydes or ketones, traditionally not containing an  $\alpha$  hydrogen, with compounds of the form  $\text{Z}-\text{CH}_2-\text{Z}'$  or  $\text{Z}-\text{CHR}-\text{Z}'$  is called the *Knoevenagel reaction*.<sup>1439</sup> Both Z and Z' may be CHO, COR, CO<sub>2</sub>H, CO<sub>2</sub>R, CN, NO<sub>2</sub>, SO<sub>2</sub>R, SO<sub>2</sub>OR, or similar electron-withdrawing groups. The presence of two electron-withdrawing groups makes this  $\alpha$  proton much more acidic (Table 8.1 in Sec. 8.A.i), and such compounds have a significantly higher enol content.<sup>1440</sup> When Z = CO<sub>2</sub>H, decarboxylation of the product often takes place *in situ*.<sup>1441</sup> Nitroalkanes<sup>1404</sup> as well as  $\beta$ -keto sulfoxides<sup>1442</sup> undergo the reaction.

As with **16-34**, these reactions have sometimes been mediated by an acid catalyst.<sup>1443</sup> Ionic liquid solvents have been used,<sup>1444</sup> and heating on quaternary ammonium salts without solvent has been used for a Knoevenagel reaction.<sup>1445</sup> Other solvent-free reactions are known.<sup>1446</sup> Ultrasound has been used to promote the reaction,<sup>1447</sup> and it has also been done using microwave irradiation.<sup>1448</sup> High pressure conditions have been used.<sup>1449</sup> Transition metal compounds of Pd,<sup>1450</sup> Sm,<sup>1451</sup> Ce,<sup>1452</sup> In,<sup>1453</sup> Cu,<sup>1454</sup> Ti,<sup>1455</sup> or Bi<sup>1456</sup> have been used to promote the Knoevenagel reaction.<sup>1457</sup> Organocatalysts have been developed.<sup>1458</sup> Domino reactions based on Knoevenagel condensation for the synthesis of heterocyclic compounds have been reviewed.<sup>1459</sup>

With most of these reagents, dehydration to the conjugated system can occur,<sup>1460</sup> but with a careful workup the alcohol is the major product. With suitable reactants, the Knoevenagel reaction, like the aldol condensation (**16-34**), has been carried out diastereoselectively<sup>1461</sup> and enantioselectively.<sup>1462</sup> When the reactant is of the form  $ZCH_2Z'$ , aldehydes react much better than ketones. In reactions with  $ZCH_2Z'$ , the catalyst is most often a secondary amine (piperidine is common), but many other catalysts have been used, including alkoxides. When the catalyst is pyridine (to which piperidine may or may not be added) the reaction is known as the *Doebner modification* of the Knoevenagel reaction and dehydration and decarboxylation occur after condensation with the aldehyde to give a conjugated acid. Microwave-induced Doebner condensation reactions are known.<sup>1463</sup>

A number of special applications of the Knoevenagel reaction follow.

1. The dilithio derivative of *N*-methanesulfinyl-*p*-toluidine<sup>1464</sup> (**30**) adds to aldehydes and ketones to give, after hydrolysis, the hydroxysulfinamides **31**. Subsequent heating leads to a stereospecific *syn* elimination to give an alkene.<sup>1465</sup> The reaction is thus a method for achieving the conversion  $RR'CO \rightarrow RR'C=CH_2$  and represents an alternative to the *Wittig reaction*.<sup>1466</sup>

2. The reaction of ketones with tosylmethylisocyanide ( $\text{TsCH}_2^+\text{N}\equiv\text{C}^-$ ) gives different products,<sup>1467</sup> depending on the reaction conditions. When potassium *tert*-butoxide in THF is used at  $-5^\circ\text{C}$ , one obtains (after hydrolysis) the normal Knoevenagel product [ $\text{R}_2\text{C}=\text{C}(\text{Ts})\text{NHCHO}$ ], except that the isocyano group has been hydrated (**16-91**).<sup>1468</sup> With the same base but with 1,2-dimethoxyethane (DME) as solvent the product is the nitrile ( $\text{R}_2\text{CHC}\equiv\text{N}$ ).<sup>1469</sup> The conversions to  $\text{RCHR}'\text{COOH}$  and to  $\text{RCHR}'\text{CN}$ <sup>1470</sup> have also been carried out with certain aldehydes ( $\text{R}' = \text{H}$ ).

- Aldehydes and ketones,  $\text{RCOR}'$ , react with  $\alpha$ -methoxyvinyl lithium,  $\text{CH}_2=\text{C}(\text{Li})\text{OMe}$ , to give hydroxy enol ethers,  $\text{RR}'\text{C}(\text{OH})\text{C}(\text{OMe})=\text{CH}_2$ , which are easily hydrolyzed to acylins,  $\text{RR}'\text{C}(\text{OH})\text{COMe}$ .<sup>1471</sup> In this reaction, the  $\text{CH}_2=\text{C}(\text{Li})\text{OMe}$  is a synthon for the unavailable  $\text{H}_3\text{C}-\text{C}=\text{O}$ ,<sup>1472</sup> and is termed an *acyl anion equivalent*. The reagent also reacts with esters,  $\text{RCOOR}'$ , to give  $\text{RC}(\text{OH})\text{C}(\text{OMe})=\text{CH}_2$ . A synthon for the  $\text{Ph}-\text{C}=\text{O}$  ion is  $\text{PhC}(\text{CN})\text{OSiMe}_3$ , which adds to aldehydes and ketones,  $\text{RCOR}'$ , to give, after hydrolysis, the  $\alpha$ -hydroxy ketones,  $\text{RR}'\text{C}(\text{OH})\text{COPh}$ .<sup>1473</sup>
- Lithiated allylic carbamates react with aldehydes or ketones ( $\text{RCOR}$ ) in a reaction accompanied by an allylic rearrangement to give (after hydrolysis)  $\gamma$ -hydroxy aldehydes or ketones.<sup>1474</sup> The reaction is called *the homoaldol reaction*, since the product is a homologue of the product of **16-34**. The reaction has been performed enantioselectively.<sup>1475</sup>
- The lithium salt of an active hydrogen compound adds to the lithium salt of the tosylhydrazone of an aldehyde to give product **32**.

If  $\text{X} = \text{CN}$ ,  $\text{SPh}$ , or  $\text{SO}_2\text{R}$ , **32** spontaneously loses  $\text{N}_2$  and  $\text{LiX}$  to give the alkene. The entire process is done in one reaction vessel. The active hydrogen compound is mixed with the tosylhydrazone and the mixture is treated with  $(i\text{-Pr})_2\text{NLi}$  to form both salts at once.<sup>1476</sup> This process is another alternative to the *Wittig reaction* for forming double bonds.

occurs; the  $\beta$ -hydroxy acid salt is rarely isolated. In some cases, anhydrides of the form  $(R_2CHCO)_2O$  have been used, and then the hydroxy compound is the product since dehydration cannot take place. The base in the Perkin reaction is nearly always the salt of the acid corresponding to the anhydride. Although the Na and K salts have been most frequently used, higher yields and shorter reaction times have been reported for the Cs salt.<sup>1478</sup> Besides aromatic aldehydes, their vinylogs  $ArCH=CHCHO$  also give the reaction (Sec. 6.B). Otherwise, the reaction does not work for aliphatic aldehydes.<sup>1479</sup>

### 16-40 Darzens Glycidic Ester Condensation

Aldehydes and ketones condense with  $\alpha$ -halo esters in the presence of bases to give  $\alpha,\beta$ -epoxy esters, called *glycidic esters*. This is called *the Darzens condensation*.<sup>1480</sup> The reaction consists of an initial Knoevenagel-type reaction (**16-38**), followed by an internal  $S_N^2$  reaction (**10-9**).<sup>1481</sup> Although the intermediate halo alkoxide is generally not isolated,<sup>1482</sup> it has been with  $\alpha$ -chloro esters and also with  $\alpha$ -fluoro esters (fluorine is generally a poor leaving group in nucleophilic substitutions).<sup>1483</sup> This is only one of several types of evidence that rule out a carbene intermediate.<sup>1484</sup> Sodium ethoxide is often used as the base but other bases, including sodium amide, are sometimes used. Aromatic aldehydes and ketones give good yields. Simple aliphatic aldehydes as well as aromatic aldehydes and ketones also give good yields by treatment of the  $\alpha$ -halo ester with the base lithium bis(trimethylsilyl)amide,  $LiN(SiMe_3)_2$ , in THF at  $-78^\circ C$  (to form the conjugate base of the ester) and addition of the aldehyde or ketone to this solution.<sup>1485</sup> If a preformed dianion of an  $\alpha$ -halo carboxylic acid  $^-CR(Cl)CO_2^-$  is used instead,  $\alpha,\beta$ -epoxy acids are produced directly.<sup>1486</sup> The Darzens reaction has also been carried out on  $\alpha$ -halo ketones,  $\alpha$ -halo nitriles,<sup>1487</sup>  $\alpha$ -halo sulfoxides<sup>1488</sup> and sulfones,<sup>1489</sup>  $\alpha$ -halo *N,N*-disubstituted amides,<sup>1490</sup>  $\alpha$ -halo ketimines,<sup>1491</sup> and even on

allylic<sup>1492</sup> and benzylic halides. Phase-transfer catalysis has been used.<sup>1493</sup> Note that the reaction of a  $\beta$ -bromo- $\alpha$ -oxo ester and a Grignard reagent leads to the glycidic ester.<sup>1494</sup> Acid-catalyzed Darzens reactions have also been reported.<sup>1495</sup> (see also **16-46**).

Diastereoselective Darzens condensations are possible.<sup>1496</sup> The Darzens reaction has been performed with good enantioselectivity,<sup>1497</sup> and chiral additives have proven to be effective.<sup>1498</sup> Chiral phase-transfer agents have been used to give epoxy ketones with modest enantioselectivity.<sup>1499</sup>

The reaction has been extended to the formation of analogous aziridines by treatment of an imine with an  $\alpha$ -halo ester or an  $\alpha$ -halo *N,N*-disubstituted amide and *t*-BuOK in the solvent 1,2-dimethoxyethane.<sup>1500</sup> However, yields were not high. Aza-Darzens aziridine synthesis has been reported via diazoalkane azomethine reactions.<sup>1501</sup> Catalytic aza-Darzens reactions have been reported.<sup>1502</sup>

OS **III**, 727; **IV**, 459, 649.

### 16-41 The Peterson Alkenylation Reaction

In the *Peterson alkenylation reaction*<sup>1503</sup>, the lithio (or sometimes magnesio) derivative of a trialkylsilane adds to an aldehyde or ketone to give a  $\beta$ -hydroxysilane, which spontaneously eliminates water, or can be made to do so by treatment with acid or base, to produce an alkene. This reaction is still another alternative to the *Wittig reaction* (**16-44**), and is sometimes called the *silyl-Wittig reaction*.<sup>1504</sup> The R group can also be a COOR group, in which

case the product is an  $\alpha,\beta$ -unsaturated ester,<sup>1505</sup> or the R group can be an SO<sub>2</sub>Ph group, in which case the product is a vinylic sulfone.<sup>1506</sup> The stereochemistry of the product can often be controlled by whether an acid or a base is used to achieve elimination. The role of Si–O interactions has also been examined.<sup>1507</sup> Use of a base generally gives *syn* elimination (E<sup>i</sup> mechanism, Sec. 17.C.i), while an acid usually results in *anti* elimination (E2 mechanism, Sec. 17.A.i).<sup>1508</sup> Samarium(II) iodide in HMPA has also been used for elimination of the hydroxy sulfone.<sup>1509</sup>

When aldehydes or ketones are treated with reagents such as Me<sub>3</sub>SiCMe(Cl)Li, the product is an epoxy silane (**16-46**) that can be hydrolyzed to a methyl ketone.<sup>1510</sup> For aldehydes, this is a method for converting RCHO to a methyl ketone RCH<sub>2</sub>COMe. The reagents Me<sub>3</sub>SiCHRM (M = Li or Mg) are often prepared from Me<sub>3</sub>SiCHRCI<sup>1511</sup> (by **12-37** or **12-38**), but they have also been made by **12-22** and by other procedures.<sup>1512</sup> Lithio alkenylsilanes have been used for this reaction.<sup>1513</sup>

An aza-Peterson reaction has been reported, using bis(trimethylsilane) reagents and sulfonyl imines.<sup>1514</sup> A Peterson-like synthesis of alkenyl nitriles has been reported using catalytic conditions.<sup>1515</sup> A new version of the reaction has been developed, reacting Me<sub>3</sub>SiCH<sub>2</sub>CO<sub>2</sub>Et with an aldehyde and a catalytic amount of CsF in DMSO.<sup>1516</sup> A selenoamide derivative has been used in a similar manner.<sup>1517</sup>

See OS VIII, 602, for a related reaction.

## 16-42 The Reaction of Active Hydrogen Compounds With Metal Carbonates, CO<sub>2</sub>, or CS<sub>2</sub>

Ketones of the form RCOCH<sub>3</sub> and RCOCH<sub>2</sub>R' can be carboxylated indirectly by treatment with magnesium methyl carbonate.<sup>1518</sup> Because formation of the chelate **33** provides the driving force of the reaction, carboxylation cannot be achieved at a disubstituted  $\alpha$  position.

### 16-43 Tollens' Reaction

In the *Tollens' reaction* an aldehyde or ketone containing an  $\alpha$  hydrogen is treated with formaldehyde in the presence of  $\text{Ca(OH)}_2$  or a similar base. The first step is formation of an enolate anion and a mixed aldol reaction (**16-34**). The reaction can be stopped at this point, but more often a second equivalent of formaldehyde is permitted to reduce the newly formed aldol to a 1,3-diol, in a *crossed Cannizzaro reaction* (**19-85**). If the aldehyde or ketone has several  $\alpha$  hydrogen atoms, they can all be replaced. An important use of the reaction is to prepare pentaerythritol [ $\text{C}(\text{CH}_2\text{OH})_4$ ] by reaction of acetaldehyde with 4 or more equivalents of formaldehyde.

OS I, 425; IV, 907; V, 833.

### 16-44 The Wittig Reaction<sup>1524</sup>

In the *Wittig reaction* an aldehyde or ketone is treated with a *phosphorus ylid* (a *phosphorane*; also spelled *ylide*) to give an alkene.<sup>1525</sup> The conversion of a carbonyl compound to

Chem.* **1983**, *109*, 165; Maercker, A. *Org. React.* **1965**, *14*, 270. For related reviews, see Zbiral, E. *Synthesis* **1974**,

an alkene with a phosphorus ylid is called the *Wittig reaction*. Phosphorus ylids are usually prepared by treatment of a phosphonium salt with a base,<sup>1526</sup> and phosphonium salts (**34**) are usually prepared from a triarylphosphine, or a phosphine that does not have an  $\alpha$  hydrogen, and an alkyl halide (**10-30**).

The reaction of triphenylphosphine and an alkyl halide is facilitated by the use of microwave irradiation.<sup>1527</sup> Indeed, the Wittig reaction itself is assisted by microwave irradiation.<sup>1528</sup> Phosphonium salts are also prepared by addition of phosphines to *Michael alkenes* (like **15-8**) and in other ways.<sup>1529</sup>

If an alkyl halide is viewed as the starting material in the reaction

then the halogen-bearing carbon of an alkyl halide must contain at least one hydrogen, for deprotonation at the phosphonium salt stage.

The phosphonium salts are most often converted to the ylids by treatment with a strong base such as butyllithium, sodium amide,<sup>1530</sup> sodium hydride, or a sodium alkoxide, though weaker bases can be used if the salt is acidic enough. In some cases an excess of fluoride ion is sufficient.<sup>1531</sup> For  $(\text{Ph}_3\text{P}^+)_2\text{CH}_2$ , sodium carbonate is a strong-enough base.<sup>1532</sup> When the base used does not contain lithium, the ylid is said to be prepared under “salt-free” conditions<sup>1533</sup> because the lithium halide (where the halide counterion comes from the phosphonium salt) is absent. Wittig reactions can be done in aqueous media in the presence of surfactants.<sup>1534</sup>

When the phosphorus ylid reacts with the aldehyde or ketone to form an alkene, a phosphine oxide is also formed. When triphenylphosphine is used to give  $\text{Ph}_3\text{P}=\text{CRR}'$ , for example, the by-product is triphenylphosphine oxide,  $\text{Ph}_3\text{PO}$ , which is sometimes difficult

to separate from the other reaction products. Other triarylphosphines<sup>1535</sup> and trialkylphosphines<sup>1536</sup> have been used, but phosphines that have an  $\alpha$  hydrogen should be avoided, so that reaction with the chosen alkyl halide will lead to a phosphonium salt (**34**) with the  $\alpha$  proton at the desired position. This limitation is essential if a specific ylid is to be formed from the alkyl halide precursor. The Wittig reaction has been carried out with polymer-supported ylids.<sup>1537</sup> It has also been done on silica gel.<sup>1538</sup> Polymer-bound aryldiphenylphosphino compounds<sup>1539</sup> have been used in reactions with alkyl halides to complete a Wittig reaction.

The reaction is very general.<sup>1540</sup> The aldehyde or ketone may be aliphatic, alicyclic, or aromatic (including diaryl ketones). Wittig reactions are known in which the ylid and/or the carbonyl substrate contain double or triple bonds. Various functional groups may be present, such as OH, OR, NR<sub>2</sub>, aromatic nitro or halo, acetal, amide,<sup>1541</sup> or even ester groups.<sup>1542</sup> An important advantage of the Wittig reaction is that the *position* of the new double bond is always certain, in contrast to the result in most of the base-catalyzed condensations (**16-34** to **16-43**).

$\beta$ -Lactams have been converted to alkenyl azetidine derivatives using phosphorus ylids.<sup>1543</sup> Double or triple bonds *conjugated* with the carbonyl also do not interfere, the attack being at the C=O carbon.

As noted above, the phosphorus ylid may also contain double or triple bonds and certain functional groups. Simple ylids (R, R' = hydrogen or alkyl) are highly reactive, reacting with oxygen, water, hydrohalic acids, and alcohols, as well as carbonyl compounds and carboxylic esters, so the reaction must be run under conditions where these materials are absent. When an electron-withdrawing group, for example, COR, CN, CO<sub>2</sub>R, CHO, is present in the  $\alpha$  position, the ylids are much more stable, because the charge on the carbon is delocalized by resonance. Such ylids react readily with aldehydes, but slowly or not at all with ketones.<sup>1544</sup> In extreme cases (e.g., where the carbanion unit is part of the aromatic cyclopentadienyl anion), the ylid does not react with ketones *or* aldehydes. Besides these groups, the ylid may contain one or two  $\alpha$  halogens<sup>1545</sup> or an  $\alpha$  OR or OAr group. In the latter case, the product of the reaction with an aldehyde or ketone is an enol ether, which can be hydrolyzed (**10-6**) to an aldehyde,<sup>1546</sup> so that this reaction is a means of achieving the conversion RCOR'  $\rightarrow$  RR'CHCHO.<sup>1547</sup> However, the ylid may not contain an  $\alpha$  nitro group. If the phosphonium salt contains a potential leaving group, such as Br or OMe, in

the  $\beta$  position, treatment with a base gives elimination and the product is the vinyl phosphonium salt rather than the ylid. However, a  $\beta$   $\text{COO}^-$  group may be present, and the product is a  $\beta,\gamma$ -unsaturated acid.<sup>1548</sup> This approach is the only convenient way to make these compounds, since elimination by any other route gives the thermodynamically more stable  $\alpha,\beta$ -unsaturated isomers, which is an illustration of the utility of the Wittig method for the specific location of a double bond. Another illustration is the conversion of cyclohexanones to alkenes containing exocyclic double bonds (e.g., cyclohexanone to methylenecyclohexane).<sup>1549</sup> Still another example is the formation of *anti-Bredt* bicycloalkenones<sup>1550</sup> (Sec. 4.Q.iii).

As indicated above,  $\alpha,\alpha'$ -dihalophosphoranes can be used to prepare 1,1-dihaloalkenes. Another way to prepare haloalkenes<sup>1551</sup> is to treat the carbonyl compound with a mixture of  $\text{CX}_4$  ( $\text{X} = \text{Cl}, \text{Br}, \text{or I}$ ) and triphenylphosphine, either with or without the addition of zinc dust (which allows less  $\text{Ph}_3\text{P}$  to be used).<sup>1552</sup> Aryl aldehydes react with these dihalophosphoranes to give aryl alkynes after treatment of the initially formed vinyl halide with potassium *tert*-butoxide.<sup>1553</sup> Functionalized styrenes including terminal 1,3-dienes have been prepared from benzylic and allylic alcohols by initial reaction with  $\text{Et}_3\text{P}\cdot\text{HBr}$  under microwave conditions, followed by reaction with aqueous formalin and  $\text{K}_2\text{CO}_3$  under microwave conditions.<sup>1554</sup> A photochemical Wittig reaction has been reported.<sup>1555</sup>

The generally accepted mechanism<sup>1556</sup> of the key step of the Wittig reaction is as shown.<sup>1557</sup>

The energetics of ylid formation and their reaction in solution has been studied.<sup>1558</sup> For many years it was assumed that a diionic compound, called a *betaine*,<sup>1559</sup> is an intermediate on the pathway from the starting compounds to the oxaphosphetane, but it has been

<sup>1557</sup> For a discussion of the second step, see López, J.G.; Ramallal, A.-M.; González, J.; Rocas, L.; García-Granda, S.; Iglesias, M.J.; Oña-Burgos, P.; Ortiz, F.L. *J. Am. Chem. Soc.* **2012**, *134*, 19504. It has been contended that another mechanism, involving single electron transfer, may be taking place in some cases: Olah, G.A.; Krishnamurthy, V.V. *J. Am. Chem. Soc.* **1982**, *104*, 3987; Yamataka, H.; Nagareda, K.; Hanafusa, T.; Nagase, S. *Tetrahedron Lett.* **1989**, *30*, 7187. A diradical mechanism has also been proposed for certain cases: Ward Jr., W.J.; McEwen, W.E. *J. Org. Chem.* **1990**, *55*, 493.

<sup>1558</sup> Arnett, E.M.; Wernett, P.C. *J. Org. Chem.* **1993**, *58*, 301.

<sup>1559</sup> See Schmidt, A.; Guan, Z. *Synthesis* **2012**, *44*, 3251.

argued that there is little evidence for it.<sup>1560</sup> However, "betaine" precipitates have been isolated in certain Wittig reactions,<sup>1561</sup> although these are betaine/lithium halide adducts, and might just as well have been formed from the oxaphosphetane as from a true betaine.<sup>1562</sup> There is one report of a betaine lithium salt that was formed during the course of a Wittig reaction.<sup>1563</sup>

An X-ray structure was determined for a *gauche* betaine from a thio-Wittig reaction.<sup>1564</sup> In contrast, there is much evidence for the presence of the oxaphosphetane intermediates, at least with unstable ylids. For example, <sup>31</sup>P NMR spectra taken of the reaction mixtures at low temperatures<sup>1565</sup> are compatible with an oxaphosphetane structure that persists for some time but not with a tetra-coordinated phosphorus species. Since a betaine, an ylid, and a phosphine oxide all have tetracoordinated phosphorus, these species could not be causing the spectra, leading to the conclusion that an oxaphosphetane intermediate is present in the solution. In certain cases oxaphosphetanes have been isolated.<sup>1566</sup> It has been possible to detect *cis* and *trans* isomers of the intermediate oxaphosphetanes by NMR spectroscopy.<sup>1567</sup> According to this mechanism, an optically active phosphonium salt  $RR^1R^2P^+CHR^2$  should retain its configuration all the way through the reaction, and it should be preserved in the phosphine oxide  $RR^1R^2PO$ . Such retention has been shown to be the case.<sup>1568</sup>

It is noted that the proposed betaine intermediates can be formed, in a completely different manner, by nucleophilic substitution by a phosphine on an epoxide (**10-34**). Betaines formed in this way can then be converted to the alkene, and this is one reason why betaine intermediates were long accepted in the Wittig reaction. It is also noteworthy that stable phosphonium enolate zwitterions have been formed by the reaction of an aryl aldehyde, a phosphine, and a propargylic ester.<sup>1569</sup>

Vinylogous Wittig reaction have been reported, using  $PBu_3$  to mediate the reaction.<sup>1570</sup> Vinyl ethers were formed followed by hydrogenation using continuous flow techniques (Sec. 7.D).<sup>1571</sup> Phosphorus is not the only key element used to produce useful ylids. Triphenylarsine<sup>1572</sup> has been used. Tellurium ylids have been prepared *in situ* from  $\alpha$ -halo esters and  $BrTeBu_2OTeBu_2Br$  and react with aldehydes to give conjugated esters.<sup>1573</sup>

The Wittig reaction has been carried out with phosphorus ylids other than phosphoranes, the most important being prepared from phosphonate esters such as **35**.<sup>1574</sup>

This method, called the *Horner-Emmons*, *Wadsworth-Emmons*, *Wittig-Horner*, or *Horner-Wadsworth-Emmons reaction*,<sup>1575</sup> has several advantages over the use of phosphoranes, including selectivity.<sup>1576</sup> Once formed, these ylids are more reactive than the corresponding phosphoranes, and when R<sup>1</sup> or R<sup>2</sup> is an electron-withdrawing group, these compounds often react with ketones that are inert to phosphoranes. High pressure has been used to facilitate this reaction.<sup>1577</sup> In addition, the phosphorus product is a phosphate ester and hence is soluble in water, unlike Ph<sub>3</sub>PO, which makes it easy to separate it from the alkene product. Phosphonates are also cheaper than phosphonium salts and can easily be prepared by the *Arbuzov reaction*, which is the reaction of trialkoxyphosphines (trialkyl phosphite) with alkyl halides:<sup>1578</sup>

Phosphonates have also been prepared from alcohols and (ArO)<sub>2</sub>P(=O)Cl, NEt<sub>3</sub>, and a TiCl<sub>4</sub> catalyst.<sup>1579</sup> α-Aryl phosphonoacetates have been prepared and are useful synthetic precursors.<sup>1580</sup> The reaction of (RO)<sub>2</sub>P(=O)H and aryl iodides with a CuI catalyst leads to aryl phosphonates.<sup>1581</sup> Polymer-bound phosphonate esters have been used for olefination.<sup>1582</sup> Dienes are produced when allylic phosphonate esters react with aldehydes.<sup>1583</sup> Nucleophilicity parameters have been determined for phosphoryl-stabilized carbanions.<sup>1584</sup>

A Zn-promoted reaction is known using diprotic phosphonates.<sup>1585</sup> Wittig reactions of stabilized phosphorus ylids have also been done in water.<sup>1586</sup> The reaction of diethyl 3-diazo-2-oxopropylphosphonate and aldehydes in the presence of a base gave  $\alpha,\beta$ -unsaturated diazo ketones via a Horner-Wadsworth-Emmons reaction.<sup>1587</sup>

Stereoselective alkenylation reactions have been achieved using chiral additives<sup>1588</sup> or auxiliaries.<sup>1589</sup> The stereoselectivity of the reaction has been linked to steric effects.<sup>1590</sup> (*Z*)-selective reagents are known.<sup>1591</sup> The reaction of a functionalized aldehyde ( $R-CHO$ ) with  $(MeO)_2POCHN_2$  leads to an alkyne ( $R-C\equiv CH$ ).<sup>1592</sup> Organocatalytic asymmetric Wittig reactions have been reported,<sup>1593</sup> and microwave-assisted catalytic Wittig reactions are known.<sup>1594</sup> The phospholane-catalyzed Wittig reaction is known.<sup>1595</sup> Catalytic intramolecular Wittig reactions have been reported.<sup>1596</sup> An interesting intramolecular version of the Horner-Emmons reaction leads to alkynes.<sup>1597</sup>

Some Wittig reactions give the (*Z*)-alkene; some the (*E*)-alkene, and others give mixtures, and the question of which factors determine the stereoselectivity has been much studied.<sup>1598</sup> It is generally found that ylids containing stabilizing groups or formed from trialkylphosphines give (*E*)-alkenes. Keto-stabilized ylids reacted with *ortho*-heteroatom-substituted benzaldehydes to give higher than expected amounts of (*Z*)-alkenes.<sup>1599</sup> The origin of the (*E*)-selectivity in salt-free stabilized ylids may be related to dipole-dipole interactions.<sup>1600</sup> The energy of the elimination transition state must also be taken into account.<sup>1601</sup> It has been shown that ylids formed from triarylphosphines and not containing stabilizing groups often give (*Z*)-alkenes or a mixture of (*Z*)- and (*E*)-alkenes.<sup>1602</sup> One explanation for this<sup>1568</sup> is that the reaction of the ylid with the carbonyl compound is a [2 + 2] cycloaddition,

which in order to be concerted must adopt the  $[\pi 2_s + \pi 2_a]$  pathway. As discussed in **15-59**, this pathway leads to the formation of the more sterically crowded product, in this case the (*Z*)-alkene. If this explanation is correct, it is not easy to explain the predominant formation of (*E*)-products from stable ylids, but (*E*)-compounds are of course generally thermodynamically more stable than the (*Z*)-isomers, and the stereochemistry seems to depend on many factors.

The (*E/Z*) ratio of the product can often be changed by a change in solvent or by the addition of salts.<sup>1603</sup> Another way of controlling the stereochemistry of the product is by use of the aforementioned phosphonic acid bisamides. In this case, the betaine does form and, when treated with water, gives the  $\beta$ -hydroxyphosphonic acid bisamides, which can be crystallized and then cleaved to  $R^1R^2C=CR^3R^4$  by refluxing in benzene or toluene in the presence of silica gel.<sup>1604</sup>  $\beta$ -Hydroxy products are generally formed as mixtures of diastereomers, and these mixtures can be separated by recrystallization. Each diastereomer will give one of the two isomeric alkenes. Optically active phosphonic acid bis(amides) have been used to give optically active alkenes.<sup>1605</sup> Another method of controlling the stereochemistry of the alkene [to obtain either the (*Z*)- or (*E*)-isomer] starting with a phosphine oxide ( $Ph_2POCH_2R$ ), has been reported.<sup>1606</sup>

In reactions where the betaine/lithium halide intermediate is present, it is possible to extend the chain further if a hydrogen is present  $\alpha$  to the phosphorus. For example, reaction of ethylidetriphenylphosphorane with heptanal at  $-78^\circ C$  gave **36**, and subsequent treatment with butyllithium gave the ylid, **37**. Treatment of **37** with an aldehyde  $R'CHO$  gave the intermediate **38** that gave, after workup, **39**<sup>1607</sup> stereoselectively.

Alkoxide **37** also reacts with other electrophiles. For example, treatment of **37** with NCS or  $PhICl_2$  gave the vinylic chloride  $RCH=CMeCl$  stereoselectively: NCS gave the *cis* and  $PhICl_2$  the *trans* isomer.<sup>1608</sup> The use of  $Br_2$  and  $FCIO_3$  (note that several explosions have been observed with this reagent<sup>1609</sup>) gives the corresponding bromide or fluoride, respectively.<sup>1610</sup> Reactions of **37** with electrophiles have been called *scoopy reactions* ( $\alpha$  substitution plus carbonyl alkenylation via  $\beta$ -oxido phosphorus ylids).<sup>1611</sup>

The reaction of a phosphonate ester, DBU, NaI, and HMPA with an aldehyde leads to a conjugated ester with excellent (*Z*)-selectivity.<sup>1612</sup> A (*Z*)-selective reaction was reported using a trifluoroethyl phosphonate in a reaction with an aldehyde and potassium *tert*-butoxide.<sup>1613</sup>

<sup>1613</sup> Touchard, F.P. *Tetrahedron Lett.* **2004**, *45*, 5519.

The Wittig reaction has been carried out intramolecularly, to prepare rings containing from 5 to 16 carbons,<sup>1614</sup> both by single ring closure to give cyclic alkenes, or by double ring closure, as in the conversion of 1,2-bis(triphenylphosphinomethyl)benzene to (5*Z*,11*Z*)-dibenzo[*a,e*][8]annulene).<sup>1615</sup>

The Wittig reaction has proved very useful in the synthesis of natural products, some of which are quite difficult to prepare in other ways.<sup>1616</sup>

Phosphorus ylids also react in a similar manner with the C=O bonds of ketenes,<sup>1617</sup> isocyanates,<sup>1618</sup> certain anhydrides,<sup>1619</sup> lactones,<sup>1620</sup> and imides,<sup>1621</sup> with the N=O of nitroso groups, and with the C=N of imines.<sup>1622</sup> Phosphorus ylids react with carbon dioxide to give isolable salts such as **40**,<sup>1623</sup> which can be hydrolyzed to the carboxylic acids **41** (thus achieving the conversion RR'CHX → RR'CHCOOH) or (if neither R nor R' is hydrogen) dimerized to allenes (**42**).

Although phosphorus ylids are most commonly used for alkenylation reactions, nitrogen ylids can occasionally be used.<sup>1624</sup> However, nitrogen ylids are often difficult to form, unstable, and highly reactive. The reaction of *N*-benzyl-*N*-phenylpiperidinium bromide with base to give a *N*-ylid is one example, and it reacted with benzaldehyde to form styrene.<sup>1625</sup> The structure has been determined for an intermediate in an *aza*-Wittig reaction.<sup>1626</sup> An *aza*-Wittig reaction<sup>1627</sup> has been used to prepare pyrrolines and tetrahydropyridines.<sup>1628</sup> A boron-Wittig reaction with aldehydes gave vinyl boronates.<sup>1629</sup>

16-45 Tebbe, Petasis, And Alternative Alkenylations<sup>1630</sup>

A useful alternative to phosphorus ylids are Ti reagents such as **43** prepared from dicyclopentadienyltitanium dichloride and trimethylaluminum.<sup>1631</sup> Treatment of a carbonyl compound with **43** (the *Tebbe reagent*) in toluene/THF containing a small amount of pyridine<sup>1632</sup> leads to the alkene. Dimethyltitanocene ( $\text{Me}_2\text{TiCp}_2$ , the *Petasis reagent*) is a convenient, more stable, easier to prepare, and highly useful alternative to **43**.<sup>1633</sup> The mechanism of Petasis olefination has been examined.<sup>1634</sup> Both the Tebbe reagent and the Petasis reagent give good results with ketones.<sup>1635</sup> An important feature of these new reagents is their reaction with the C=O group of carboxylic esters and lactones<sup>1636</sup> which gave the corresponding enol ethers in good yields. The enol ether can be hydrolyzed to a ketone (**10-6**), so this is also an indirect method for making the conversion  $\text{RCO}_2\text{R}' \rightarrow \text{RCOCH}_3$  (see also, **16-29**). Conjugated esters are converted to alkoxy dienes with this reagent.<sup>1637</sup> Lactams, including  $\beta$ -lactams, are converted to alkylidene cycloamines (alkylidene azetidines from  $\beta$ -lactams, which are easily hydrolyzed to  $\beta$ -amino ketones).<sup>1638</sup> Formation of alkenes using Petasis reagent has been done using flow conditions (Sec. 7.D).<sup>1639</sup>

Besides stability and ease of preparation, another advantage of the Petasis reagent is that structural analogs can be prepared, including  $\text{Cp}_2\text{Ti}(\text{C}_3\text{H}_5)_2$ <sup>1640</sup> ( $\text{C}_3\text{H}_5$  = cyclopropyl),  $\text{CpTi}(\text{CH}_2\text{SiMe}_3)_3$ ,<sup>1641</sup>  $\text{Me}(i\text{-PrO})_3\text{Ti}$ ,<sup>1642</sup> and  $\text{Cp}_2\text{TiMe}(\text{CH}=\text{CH}_2)$ .<sup>1643</sup> Accelerated Petasis reactions have been reported.<sup>1644</sup> An alternative Ti reagent was prepared using  $\text{TiCl}_4$ , Mg metal, and dichloromethane, reacting with both ketones<sup>1645</sup> and esters<sup>1646</sup> to give alkenes or vinyl ethers, respectively. Other catalysts have been used,<sup>1647</sup> including

copper.<sup>1648</sup> Alkenes are generated from ketones and alkyl iodides in the presence of a catalytic amount of  $\text{Cp}_2\text{Ti}[\text{P}(\text{OEt})_3]_2$ .<sup>1649</sup> 1-Alkenyl bromides have been prepared using a  $\text{CHBr}_3/\text{TiCl}_4/\text{Mg}$  system.<sup>1650</sup>

Enantioselective Petasis reactions using BINOL have been reported.<sup>1651</sup> The enantioselective preparation of allenes was reported using a “catalyst-traceless” Petasis reaction.<sup>1652</sup> The catalytic asymmetric Petasis reaction of vinylboranes has been reported.<sup>1653</sup>

Carboxylic esters undergo the conversion  $\text{C}=\text{O} \rightarrow \text{C}=\text{CHR}$  (R = primary or secondary alkyl) when treated with  $\text{RCHBr}_2$ , Zn,<sup>1654</sup> and  $\text{TiCl}_4$  in the presence of *N,N,N',N'*-tetramethylethylenediamine.<sup>1655</sup> Metal carbene complexes<sup>1656</sup>  $\text{R}_2\text{C}=\text{ML}_n$  (L = ligand), where M is a transition metal such as Zr, W, or Ta, have also been used to convert the  $\text{C}=\text{O}$  of carboxylic esters and lactones to  $\text{CR}_2$ .<sup>1657</sup> It is likely that the complex  $\text{Cp}_2\text{Ti}=\text{CH}_2$  is an intermediate in the reaction with the Tebbe reagent. Indeed, Ti carbenoids have been used to convert carbonyl groups to the corresponding alkene.<sup>1658</sup>

Alternative alkene-forming reactions have been developed. The *Nysted reagent* (cyclo-dibromodi- $\mu$ -methylene[ $\mu$ -(tetrahydrofuran)]trizinc)<sup>1659</sup> is commercially available, and it reacts with aldehydes or ketones in the presence of  $\text{BF}_3 \cdot \text{etherate}$  to give an alkene.<sup>1660</sup> Reaction with (*S*)-2-phenylpropanal, for example, gave an 82% yield of (*R*)-but-3-en-2-ylbenzene.<sup>1661</sup> Other metal-ylid type reagents have been developed, including a Cr-based reagent. The *Takai reaction*<sup>1662</sup> used an alkyl di- or triiodide in the presence of  $\text{CrCl}_2$  to react with an aldehyde or ketone to generate an alkene moiety. A methylenation reaction for aldehydes and ketones used a Julia-type<sup>1663</sup> reagent, 1-methyl-2-(methylsulfonyl)benzimidazole.<sup>1664</sup> The Julia-Kocienski reaction<sup>1665</sup> prepared alkenes via reaction of aldehydes with benzothiazol-2-yl sulfones.<sup>1666</sup>

There are a few other methods for converting ketones or aldehydes to alkenes.<sup>1667</sup> Carbonyl compounds react with bis(iodozincio)methane to give alkenes.<sup>1668</sup> When a ketone is treated with  $\text{CH}_3\text{CHBr}_2/\text{Sm}/\text{SmI}_2$ , with a catalytic amount of  $\text{CrCl}_3$ , the alkene is formed.<sup>1669</sup>  $\alpha$ -Halo esters also react with  $\text{CrCl}_2$  in the presence of a ketone to give vinyl halides.<sup>1670</sup> Organozinc reagents have been used to convert carbonyl compounds to alkenes in the presence of Lewis acids.<sup>1671</sup>  $\alpha$ -Diazo esters react with ketones in the presence of an Fe catalyst to give the corresponding alkene.<sup>1672</sup>  $\alpha$ -Diazo silylalkanes react similarly in the presence of a Rh catalyst.<sup>1673</sup> Ketone olefination has been accomplished using methyltrioxorhenium.<sup>1674</sup>  $\alpha$ -Halosulfones react with aldehydes in the presence of  $\text{LiHMDS}$  and  $\text{MgBr}_2 \cdot \text{OEt}_2$  to give a vinyl chloride.<sup>1675</sup> It is noted that an engineered myoglobin variant catalyzed the reaction of aldehydes and  $\alpha$ -diazo esters to give the alkene with excellent (*E*) diastereoselectivity.<sup>1676</sup>

For a monograph on sulfur ylids, see Trost, B.M.; Melvin Jr., L.S. *Sulfur Ylids*, Academic Press, NY, **1975**.

sulfur ylids with enones has been examined.<sup>1681</sup> Ylid **45** is rather unstable and ordinarily must be used as soon as it is formed, while **44** can be stored for several days at room temperature. When diastereomeric epoxides can be formed, **45** usually attacks from the more-hindered side and **44** from the less-hindered side.

Thus, if 4-*tert*-butylcyclohexanone is treated with **44** it gives exclusively **46** with an axial O, while **45** gives mostly **47** with an equatorial O.<sup>1682</sup>

Another difference in behavior between the two reagents is that with  $\alpha,\beta$ -unsaturated ketones, **44** gives only cyclopropanes (reaction **15-60**), while **45** gives oxirane formation. Other sulfur ylids have been used in an analogous manner, to transfer CHR or CR<sub>2</sub>.<sup>1683</sup> A solvent-free version of this reaction has been developed using powdered potassium *tert*-butoxide and Me<sub>3</sub>S<sup>+</sup>I<sup>-</sup>.<sup>1684</sup> Note that treatment of epoxides with 2 equivalents of Me<sub>2</sub>S=CH<sub>2</sub> leads to allylic alcohols.<sup>1685</sup> Note too that phosphorus ylids do not give this epoxidation reaction, but give **16-44** instead.

Chiral sulfur ylids<sup>1686</sup> have been prepared, giving the epoxide with good asymmetric induction,<sup>1687</sup> and chiral additives have also been used.<sup>1688</sup> Chiral Se ylids have been used in a similar manner.<sup>1689</sup> Cyclic sulfur ylids have been used to prepare epoxy amides.<sup>1690</sup>

The generally accepted mechanism for the reaction between sulfur ylids and aldehydes or ketone is formation of **48**, with displacement of the Me<sub>2</sub>S leaving group by the alkoxide.<sup>1691</sup>

This mechanism is similar to that of the reaction of sulfur ylids with C=C double bonds (**15-60**).<sup>1692</sup> The stereochemical difference in the behavior of **44** and **45** has been attributed to formation of the betaine **48** being reversible for **44** but not for the less stable **45**. The result is that the more-hindered product is the result of kinetic control and the less-hindered product is the result of thermodynamic control.<sup>1693</sup>

The *Juliá-Colonna epoxidation* is an asymmetric poly(leucine)-catalyzed epoxidation of electron-deficient alkenes.<sup>1694</sup> Supramolecular catalysis of this reaction has been reported.<sup>1695</sup> The stereoselectivity of this reaction has been inverted.<sup>1696</sup>

Aldehydes and ketones can also be converted to epoxides by treatment with a diazoalkane,<sup>1697</sup> most commonly diazomethane, but an important side reaction is the formation of an aldehyde or ketone with one more carbon than the starting compound (reaction **18-9**). The reaction can be carried out with many aldehydes, ketones, and quinones, usually with a Rh catalyst.<sup>1698</sup>

An alternative route to epoxides from ketones uses  $\alpha$ -chloro sulfones and potassium *tert*-butoxide to give  $\alpha,\beta$ -epoxy sulfones.<sup>1699</sup> A similar reaction was reported using KOH and 10% of a chiral phase-transfer agent, giving moderate enantioselectivity in the epoxy sulfone product.<sup>1700</sup>

Dihalocarbenes and carbenoids, which readily add to C=C bonds (**15-60**), do not generally add to the C=O bonds of ordinary aldehydes and ketones.<sup>1701</sup> (See also **16-85**.) Carbonyl-stabilized ammonium ylids reacted with aldehydes to give epoxy amides.<sup>1702</sup> Terminal epoxides were prepared with high enantioselectivity using ylid reactions.<sup>1703</sup> There is a report of a strained azetidinium ylid that has been used for epoxidation.<sup>1704</sup>

OS V, 358, 755.

Double-bond compounds that undergo the *Michael reaction* (**15-20**) can be converted to cyclopropane derivatives with sulfur ylids.<sup>1705</sup> Among the most common of these is

dimethyloxosulfonium methylid **44**,<sup>1706</sup> which reacts with conjugated C=C units to give anion **49**; intramolecular displacement of the DMSO leaving group gave the cyclopropane.

Other sulfur ylids have also been used. A combination of DMSO and KOH in an ionic liquid converts conjugated ketones to  $\alpha,\beta$ -cyclopropyl ketones.<sup>1707</sup> Both CHR and  $\text{CR}_2$  can be added in a similar manner with certain nitrogen-containing compounds. Functionalized ylids,<sup>1708</sup> such as  $\text{Ph}(\text{Me}_2\text{N})\text{SO}-\text{CH}_2$ , add various groups to activated double bonds.<sup>1709</sup> Sulfur ylids react with allylic alcohols in the presence of  $\text{MnO}_2$  and molecular sieve 4 Å to give the cyclopropyl aldehyde.<sup>1710</sup> Similar reactions have been performed with phosphorus ylids<sup>1711</sup> or with pyridinium ylids.<sup>1712</sup> The reactions with ylids such as these of course involve nucleophilic acyl addition. Enantioselective cyclopropanation occurs in the presence of certain organocatalysts<sup>1713</sup> or chiral metal catalysts.<sup>1714</sup> The organocatalytic reaction of  $\beta,\gamma$ -unsaturated  $\alpha$ -keto esters with stabilized sulfur ylids gave 1,2,3-trisubstituted cyclopropane derivatives.<sup>1715</sup>

#### 16-47 The Formation of Aziridines from Imines

Just as sulfur ylids such as **44** react with the carbonyl of an aldehyde or ketone to give an epoxide, *Te ylids react with imines to give an aziridine*. The reaction of an allylic Te salt,  $\text{RCH}=\text{CHCH}_2\text{Te}^+\text{Bu}_2\text{Br}^-$ , with lithium hexamethyldisilazide in HMPA/toluene leads to the Te ylid via deprotonation. In the presence of an imine, the ylid adds to the imine; subsequent displacement of  $\text{Bu}_2\text{Te}$  generates an aziridine with a pendant vinyl group.<sup>1716</sup> Catalytic aziridination of tosylimines was reported, mediated by arsonium ylids.<sup>1717</sup>

The enantioselective synthesis of aryl aziridines has been reported.<sup>1718</sup> The asymmetric aziridine-forming reaction of aldehydes with protected amines and  $\alpha$ -diazo esters in the presence of a boroxinate catalyst was reported.<sup>1719</sup> The organocatalyzed aziridination of  $\beta$ -dicarbonyl compounds using TMS azide was reported.<sup>1720</sup> Terminal aziridines were prepared by methylene transfer from sulfonium ylids to imines.<sup>1721</sup> Imines reacted with  $\alpha$ -keto esters to give aziridine 2-carboxylates using  $P(NMe_2)_3$  as a mediator.<sup>1722</sup>

The reaction of tosylaldimines with  $BnHN-OBz$  and an optically active phase-transfer catalyst gave optically active diaziridines.<sup>1723</sup> A chiral thiourea organocatalyst was used for a catalytic asymmetric oxaziridination reaction.<sup>1724</sup>

### 16-48 The Formation of Episulfides and Episulfones<sup>1725</sup>

Epoxides can be converted directly to episulfides by treatment with  $NH_4SCN$  and ceric ammonium nitrate.<sup>1726</sup> Diazoalkanes, treated with sulfur, give episulfides.<sup>1727</sup> It is likely that  $R_2C=S$  is an intermediate, which is attacked by another molecule of diazoalkane, in a process similar to that is shown in **16-46**. Thioketones *do* react with diazoalkanes to give episulfides,<sup>1728</sup> and have also been converted to episulfides with sulfur ylids.<sup>1682</sup>

Alkanesulfonyl chlorides give episulfones when treated with diazomethane in the presence of a base (usually a tertiary amine).<sup>1729</sup> The base removes  $HCl$  from the sulfonyl halide to produce the highly reactive sulfene ( $RCH=SO_2$ ) (see **17-12**), which then adds  $CH_2$ . The episulfone can subsequently be heated to give off  $SO_2$  (see **17-18**), making the entire process a method for achieving the conversion  $RCH_2SO_2Cl \rightarrow RCH=CH_2$ .<sup>1730</sup>

## 16-49 The Thorpe Reaction

In the *Thorpe reaction*, the  $\alpha$  carbon of one nitrile molecule is added to the CN carbon of another, so this reaction has analogies with the aldol reaction (16-34). The imine unit is, of course, subject to hydrolysis (16-2), so  $\beta$ -keto nitriles can be prepared in this manner. The Thorpe reaction can be done intramolecularly, in which case it is called the *Thorpe-Ziegler reaction*.<sup>1731</sup> As with other cyclization methods, yields are high for five- to eight-membered rings, fall off to about zero for rings of nine to thirteen members, but are high again for fourteen-membered and larger rings, if high-dilution techniques are employed. The product in the Thorpe-Ziegler reaction is not the imine, but the tautomeric enamine, which can be hydrolyzed to an  $\alpha$ -cyano ketone (16-2) if desired. In turn this product can be hydrolyzed and decarboxylated (16-4, 12-39). Other active-hydrogen compounds can also be added to nitriles.<sup>1732</sup>

OS VI, 932.

## 16-50 The Addition of Silanes

Allylic silanes react with aldehydes, in the presence of Lewis acids, to give a homoallylic alcohol.<sup>1733</sup> In the case of benzylic silanes, this addition reaction has been induced with  $\text{Mg}(\text{ClO}_4)_2$  under photochemical conditions.<sup>1734</sup> Cyclopropylcarbinyl silanes add to acetals in the presence of TMSOTf to give a homoallylic alcohol.<sup>1735</sup> Allyltrichlorosilane adds an allyl group to an aldehyde in the presence of a cyclic urea and  $\text{AgOTf}$ .<sup>1736</sup> The use of chiral additives leads to the alcohol with good asymmetric induction.<sup>1737</sup>

## 16-51 The Formation of Cyanohydrins

The addition of HCN to aldehydes or ketones produces cyanohydrins.<sup>1738</sup> This is an equilibrium reaction, and for aldehydes and aliphatic ketones the equilibrium lies to the right so the reaction is quite feasible, except with sterically hindered ketones such as diisopropyl ketone. However, aryl ketones (ArCOR) give poor yields, and the reaction cannot be carried out with diaryl ketones (ArCOAr) since the equilibrium lies too far to the left. With aromatic aldehydes the *benzoin condensation* (16-54) competes. With  $\alpha,\beta$ -unsaturated aldehydes and ketones, 1,4-addition competes (15-34).

Ketones of low reactivity, such as ArCOR, can be converted to cyanohydrins by treatment with diethylaluminum cyanide ( $\text{Et}_2\text{AlCN}$ ) (see OS VI, 307) or, indirectly, with cyanotrimethylsilane ( $\text{Me}_3\text{SiCN}$ )<sup>1739</sup> in the presence of a Lewis acid or base,<sup>1740</sup> followed by hydrolysis of the resulting *O*-trimethylsilyl cyanohydrin. Both direct formation of the cyanohydrin (hydrocyanation) and formation of the cyano-*O*-silyl ether have been carried out enantioselectively using chiral catalysts,<sup>1741</sup> including chiral organocatalysts,<sup>1742</sup> or chiral additives.<sup>1743</sup> Biocatalysts have been used.<sup>1744</sup> Hydrogen cyanide adds to aldehydes in the presence of a lyase to give the cyanohydrin with good enantioselectivity.<sup>1745</sup> Cyanohydrins have been formed using a lyase in an ionic liquid.<sup>1746</sup>

Solvent-free conditions have been reported using TMSCN, an aldehyde, and potassium carbonate.<sup>1747</sup> Amine *N*-oxides catalyze the reaction,<sup>1748</sup> as does tetrabutylammonium cyanide.<sup>1749</sup> Lithium perchlorate in ether facilitates this reaction,<sup>1750</sup> and lithium chloride catalyzes the reaction with  $\text{Me}_3\text{SiCN}$ .<sup>1751</sup> *N*-Heterocyclic carbenes catalyze the

reaction,<sup>1752</sup> as do certain ionic liquids.<sup>1753</sup> With MgBr<sub>2</sub> as a catalyst, the reaction proceeds with good *syn* selectivity.<sup>1754</sup> Other useful catalysts include Pt,<sup>1755</sup> Au,<sup>1756</sup> Ru/Li,<sup>1757</sup> or Ti<sup>1758</sup> compounds, and InBr<sub>3</sub>.<sup>1759</sup> The reaction of aldehydes and 2 equivalents of TMSCN used a V catalyst to give the cyanohydrin.<sup>1760</sup> Chiral transition metal catalysts have been used to give *O*-trialkylsilyl cyanohydrins with good enantioselectivity.<sup>1761</sup> Titanium catalysts, a Si(IV),<sup>1762</sup> Al,<sup>1763</sup> or Lewis base<sup>1764</sup> were used to give the OTMS cyanohydrin.<sup>1765</sup> The use of chiral additives leads to cyanohydrins with good asymmetric induction.<sup>1766</sup> A V catalyst has been used in an ionic liquid.<sup>1767</sup> Note that the reaction of an aldehyde and TMSCN in the presence of aniline and a BiCl<sub>3</sub> catalyst leads to an  $\alpha$ -cyano amine.<sup>1768</sup> Enzymatic catalysis has been used for the formation of cyanohydrins.<sup>1769</sup>

Rather than direct reaction with an aldehyde or ketone, the bisulfite addition product is often treated with cyanide. The reaction rate is increased by the addition of base, as demonstrated by Lapworth in 1903; this was one of the first organic mechanisms to be known.<sup>1770</sup> This method is especially useful for aromatic aldehydes, since it avoids competition from the benzoin condensation. If desired, it is possible to hydrolyze the cyanohydrin *in situ* to the corresponding  $\alpha$ -hydroxy acid. This reaction is important in the *Kiliani-Fischer* method of extending the carbon chain of a sugar.

A particularly useful variation of this reaction uses a cyanide source rather than HCN.  $\alpha$ -Amino nitriles<sup>1771</sup> can be prepared in one step by the treatment of an aldehyde or ketone with NaCN and NH<sub>4</sub>Cl. This reaction is called the *Strecker synthesis*;<sup>1772</sup> and it is a special case of the *Mannich reaction* (16-17). Since the CN group is easily hydrolyzed to the acid,

imines in the presence of  $\text{BF}_3 \cdot \text{OEt}_2$  to give the  $\alpha$ -cyano *N*-tosyl amine.<sup>1788</sup> In the presence of a chiral  $\text{Zr}$ <sup>1789</sup> or  $\text{Al}$ <sup>1790</sup> catalyst,  $\text{Bu}_3\text{SnCN}$  reacts with imines to give  $\alpha$ -cyano amines enantioselectively. The reaction of an imine and  $\text{TMSCN}$  gives the cyano amine with good enantioselectivity using a chiral  $\text{Sc}$  catalyst.<sup>1791</sup> Titanium catalysts have been used in the presence of a chiral Schiff base.<sup>1792</sup>

The addition of  $\text{KCN}$  to triisopropylbenzenesulfonyl hydrazones provides an indirect method for achieving the conversion  $\text{RR}'\text{CO} \rightarrow \text{RR}'\text{CHCN}$ .<sup>1793</sup> The reaction is successful for hydrazones of aliphatic aldehydes and ketones.  $\text{HCN}$  can also be added to the  $\text{C}\equiv\text{N}$  bond to give iminonitriles or  $\alpha$ -aminomalononitriles  $[\text{R}(\text{H}_2\text{N})\text{C}(\text{CN})_2]$ .<sup>1794</sup> The acylation of imines is known, and enantioselectivity is achieved with a suitable catalyst.<sup>1795</sup>

OS V, 344. See also, OS V, 269.

### 16-53 The Prins Reaction

The addition of an alkene to formaldehyde in the presence of an acid catalyst<sup>1796</sup> is called the *Prins reaction*.<sup>1797</sup> Three main products are possible; which one predominates depends on the alkene and the conditions.

When the product is the 1,3-diol or the dioxane,<sup>1798</sup> the reaction involves addition to the  $\text{C}=\text{C}$  as well as to the  $\text{C}=\text{O}$ . The mechanism is one of electrophilic attack on both double bonds. The acid first protonates the  $\text{C}=\text{O}$ , and the resulting oxocarbenium ion is attacked by the  $\text{C}=\text{C}$  unit of the alkene to give  $\text{HO}-\text{C}-\text{C}-\text{C}^+$ , which can undergo loss of a proton to give the alkene or add water to give the diol.<sup>1799</sup> It has been proposed that the intermediate carbocation is stabilized by neighboring-group attraction with either the oxygen (to give a protonated oxetane)<sup>1800</sup> or a carbon (to give a cyclic oxocarbenium ion)<sup>1801</sup> stabilizing the

charge. This stabilization is postulated to explain the fact that with but-2-enes<sup>1802</sup> and with cyclohexenes the addition is *anti*. A back-side attack of H<sub>2</sub>O on the three- or four-membered ring would account for it. Additional evidence for the intermediacy of a protonated oxetane is the finding that oxetanes that are subjected to the reaction conditions give essentially the same product ratios as the corresponding alkenes.<sup>1803</sup> An argument against the intermediacy of the protonated oxetane or a cyclic oxocarbenium ion is that not all alkenes show the *anti* stereoselectivity mentioned above. Indeed, the stereochemical results are often quite complex, with *syn*, *anti*, and nonstereoselective addition reported, depending on the nature of the reactants and the reaction conditions.<sup>1804</sup> Since addition to the C=C bond is electrophilic, the reactivity of the alkene increases with alkyl substitution and *Markovnikov's rule* is followed. The dioxane product may arise from a reaction between the 1,3-diol and formaldehyde<sup>1805</sup> (**16-5**) or between a protonated oxetane and formaldehyde. Racemization may occur in the Prins cyclization reaction by 2-oxonia-Cope rearrangements (see **18-32**) by way of a (*Z*)-oxocarbenium ion intermediate.<sup>1806</sup> A catalytic asymmetric Prins cyclization has been reported.<sup>1807</sup> A catalytic asymmetric vinylogous Prins cyclization has been reported.<sup>1808</sup> The Prins reaction with ketones has been reported.<sup>1809</sup> A solvent-free and metal-free Prins cyclization has been reported as a green chemistry contribution.<sup>1810</sup>

Iodine can promote the Prins reaction.<sup>1811</sup> Lewis acids such as SnCl<sub>4</sub> also catalyze the reaction, in which case the species that adds to the alkenes is H<sub>2</sub>C<sup>+</sup>-O-SnCl<sub>4</sub>.<sup>1812</sup> The reaction can also be catalyzed by peroxides, in which case the mechanism is probably a free-radical one. Other transition metal complexes can be used to form homoallylic alcohols. Samarium iodide promotes this addition reaction.<sup>1813</sup> Dienes react with alcohols in the presence of a transition metal compound to give alkenyl alcohols.<sup>1814</sup> Allenes also add to aldehydes<sup>1815</sup> and enynes undergo Prins cyclization with Au catalysts.<sup>1816</sup>

A closely related reaction has been performed with activated aldehydes or ketones; without a catalyst such as chloral and acetoacetic ester, but with heat.<sup>1817</sup> The product in these cases is a β-hydroxy alkene, a homoallylic alcohol, and the mechanism is pericyclic.<sup>1818</sup> This reaction is reversible and suitable β-hydroxy alkenes can be cleaved by heat (**17-30**). There is evidence that the cleavage reaction occurs by a cyclic mechanism (see **17-30**),

<sup>1818</sup> See Ben Salem, R.; Jenner, G. *Tetrahedron Lett.* **1986**, 27, 1575. There is evidence that the mechanism is somewhat more complicated: Kwart, H.; Brechbiel, M. *J. Org. Chem.* **1982**, 47, 3353.

and, by the principle of microscopic reversibility, the addition mechanism should be cyclic too.<sup>1818,1819</sup> Note that this reaction is an oxygen analog of the ene synthesis (15-19). This reaction can also be carried out with unactivated aldehydes<sup>1820</sup> and ketones<sup>1821</sup> if Lewis acid catalysts such as dimethylaluminum chloride (Me<sub>2</sub>AlCl) or ethylaluminum dichloride (EtAlCl<sub>2</sub>) are used.<sup>1822</sup> Lewis acid catalysts also increase rates with activated aldehydes.<sup>1823</sup> The use of optically active catalysts has given optically active products with high % ee.<sup>1824</sup>

In a related reaction, alkenes can be added to aldehydes and ketones to give  $\gamma$ -alkylated alcohols, which has been accomplished by several methods,<sup>1825</sup> including treatment with SmI<sub>2</sub><sup>1826</sup> or Zn and Me<sub>3</sub>SiCl,<sup>1827</sup> and by electrochemical<sup>1828</sup> and photochemical<sup>1829</sup> methods. Most of these methods have been used for intramolecular addition and most or all involve free radical intermediates. The Prins reaction of enol ethers led to tetrahydrofuran derivatives.<sup>1830</sup> Silyl enol ethers were used to prepare tetrahydropyran-4-one derivatives.<sup>1831</sup> A thia-Prins bicyclization was used to prepare dithia-bicycles.<sup>1832</sup> The reaction of allenylsilanes led to heterocyclic compounds.<sup>1833</sup>

There is an *aza-Prins reaction*, promoted by TiI<sub>4</sub> and I<sub>2</sub>.<sup>1834</sup> Piperidine derivatives have been prepared via a supramolecular assembly-catalyzed bimolecular aza-Prins cyclization of formaldehyde with amines that have a distal alkene unit, and a transannular 1,5-hydride transfer as observed.<sup>1835</sup> Azabicycles have been prepared via cascade aza-Prins reactions.<sup>1836</sup>

The benzoin product results from self-condensation of the aryl aldehyde. The reaction only occurs with aromatic aldehydes, but not all of them,<sup>1837</sup> and for glyoxals RCOCHO. An aldehyde such as *p*-dimethylaminobenzaldehyde cannot condense with itself, but it can condense with benzaldehyde to give a benzoin. *N*-Alkyl-3-methylimidazolium salts catalyze the reaction,<sup>1838</sup> as does an imidazole-based solid-supported catalyst.<sup>1839</sup> The benzaldehyde lyase from *Pseudomonas fluorescens* has been reported to catalyze the stereoselective aliphatic aromatic cross benzoin reaction.<sup>1840</sup>

The accepted mechanism<sup>1841</sup> for this reversible reaction is shown, as originally proposed by Lapworth in 1903:<sup>1842</sup>

The key step, the loss of the aldehyde proton, can take place because the acidity of this C–H bond is increased by the electron-withdrawing power of the CN group. Thus, cyanide is a highly specific catalyst for this reaction, because, almost uniquely, it can perform three functions: (i) it acts as a nucleophile; (ii) its electron-withdrawing ability permits loss of the aldehyde proton; and (iii) having done this, it then acts as a leaving group.

Certain thiazolium salts can also catalyze the reaction.<sup>1843</sup> In this case, aliphatic aldehydes can also be used<sup>1844</sup> (the products are *acyloins*), and mixtures of aliphatic and aromatic aldehydes give mixed  $\alpha$ -hydroxy ketones.<sup>1845</sup> The reaction has also been carried out without cyanide, by using the benzoylated cyanohydrin as one of the components in a phase-transfer catalyzed process. By this means, products can be obtained from aldehydes that normally fail to self-condense.<sup>1846</sup>

The condensation has also been done with excellent enantioselectivity.<sup>1847</sup> Enantiopure triazolium salts have been evaluated as catalysts in the enantioselective benzoin condensation.<sup>1848</sup> *N*-Heterocyclic carbene catalysts have been used for asymmetric

## 16-55 Addition of Radicals to C=O, C=S, and C=N Compounds

Radical cyclization is not limited to reaction with a C=C unit (see **15-25** and **15-26**), and reactions with both C=N and C=O moieties are known. Reaction of  $\text{MeON=CH(CH}_2)_3\text{CHO}$  with  $\text{Bu}_3\text{SnH}$  and AIBN, for example, led to *trans*-2-(methoxyamino)cyclopentanol in good yield.<sup>1853</sup> Conjugated ketones add to aldehydes via the  $\beta$  carbon under radical conditions (2 molar equivalents of  $\text{Bu}_3\text{SnH}$  and 0.1 equivalent of  $\text{CuCl}$ ) to give a  $\beta$ -hydroxy ketone.<sup>1854</sup>

Radical addition to simple imines leads to aminocycloalkenes.<sup>1855</sup> Radicals also add to the carbonyl unit of phenylthio esters to give cyclic ketones.<sup>1856</sup> The reaction of  $\alpha$ -bromo ketones with a Cu catalyst in the presence of an aryl hydroxylamine generated an  $\alpha$ -keto radical that added to a nitron, generated *in situ*, to give an  $\alpha$ -amino ketone.<sup>1857</sup>

Secondary alkyl iodides add to *O*-alkyl oximes in the presence of  $\text{BEt}_3$  and AIBN, and this methodology was used to convert  $\text{MeO}_2\text{C-CH=NOBn}$  to  $\text{MeO}_2\text{C-CH(R)NOBn}$ .<sup>1858</sup> Benzylic halides add to imines under photochemical conditions and in the presence of 1-benzyl-1,4-dihydronicotinamide<sup>1859</sup> or with  $\text{BEt}_3$  in aqueous methanol.<sup>1860</sup> *O*-Trityl oximes of 5- and 6-iodoaldehydes undergo radical cyclization to give oximes<sup>1861</sup> (also see **15-26**). Enantioselective radical addition reactions to *N*-benzoyl hydrazones used chiral ammonium salts.<sup>1862</sup> The Mn-mediated reaction of allyl iodides with chiral *N*-acyl hydrazones leads to chiral hydrazine derivatives.<sup>1863</sup> *N,N*-Dimethylaniline reacts with aldehydes under photochemical conditions to give acyl addition via the carbon atom of one

of the methyl groups.<sup>1864</sup> The reaction of PhNMe<sub>2</sub> and benzaldehyde, for example, gave PhN(Me)CH<sub>2</sub>CH(OH)Ph upon photolysis.

## 16.B.ii. Acyl Substitution Reactions

### A. O, N, and S Nucleophiles

#### 16-56 Hydrolysis of Acyl Halides

Acyl halides are so reactive that hydrolysis is easily carried out.<sup>1865</sup> In fact, most simple acyl halides must be stored under anhydrous conditions or they may react with water in the air. Consequently, water is usually a strong enough nucleophile for the reaction, but in unreactive systems hydroxide ion may be required. The reactivity order is F < Cl < Br < I.<sup>1866</sup> If a carboxylic acid is used as the nucleophile, an exchange may take place (see 16-78). The mechanism<sup>1866</sup> of hydrolysis can be either S<sub>N</sub>1 or tetrahedral, the former occurring in highly polar solvents and in the absence of strong nucleophiles.<sup>1867</sup> There is also evidence for the S<sub>N</sub>2 mechanism in some cases.<sup>1868</sup>

Hydrolysis of acyl halides is not usually catalyzed by acids, except for acyl fluorides, where hydrogen bonding can assist in the removal of a fluorine atom.<sup>1869</sup> There are several methods available for the hydrolysis of acyl fluorides.<sup>1870</sup>

OS II, 74.

#### 16-57 Hydrolysis of Anhydrides

Anhydrides are somewhat more difficult to hydrolyze than acyl halides, but here too water is usually a strong enough nucleophile. The mechanism is usually tetrahedral.<sup>1871</sup> The S<sub>N</sub>1 mechanism only occurs with acid catalysis and seldom even then.<sup>1872</sup> Anhydride hydrolysis can also be catalyzed by bases. Of course, hydroxide ion attacks more readily than water, but other bases can also catalyze the reaction. This phenomenon, called *nucleophilic catalysis* (Sec. 16.A.i, category 4), is actually the result of two successive tetrahedral mechanisms.

For example, pyridine catalyzes the hydrolysis of acetic anhydride in this manner.<sup>1873</sup> Many other nucleophiles similarly catalyze the reaction.

OS I, 408; II, 140, 368, 382; IV, 766; V, 8, 813.

## 16-58 Hydrolysis of Carboxylic Esters

Ester hydrolysis is usually catalyzed by acids or bases. Since OR is a much poorer leaving group than halide or OCOR, water alone does not hydrolyze most esters. When bases catalyze the reaction, the attacking species is the more powerful nucleophile  $^-\text{OH}$  and the product is the carboxylate anion, requiring treatment with aqueous acid to generate the carboxylic acid. This reaction is called *saponification* since treatment with base used to convert glycerols to the salts of long-chain fatty acids, which are soaps.<sup>1874</sup> Acids catalyze the reaction by making the carbonyl carbon more positive and therefore more susceptible to attack by the nucleophile. Both reactions are equilibrium reactions, so there must be a way to shift the equilibrium to the right for this to be useful. Since formation of the salt does just this, ester hydrolysis is almost always done for preparative purposes in basic solution, unless the compound is base sensitive.

Ester hydrolysis can also be catalyzed<sup>1875</sup> by metal ions, by cyclodextrins,<sup>1876</sup> by enzymes,<sup>1877</sup> and by nucleophiles.<sup>1878</sup> Other reagents used to cleave carboxylic esters include Dowex-50,<sup>1879</sup>  $\text{Me}_3\text{SiI}$ ,<sup>1880</sup> and  $\text{InCl}_3$  on moist silica gel using microwave irradiation.<sup>1881</sup> Cleavage of phenolic esters is usually faster than carboxylic esters derived from aliphatic acids. The Lewis acid-mediated selective mono-hydrolysis of geminal diesters has been reported.<sup>1882</sup> The reagent  $\text{Sm}/\text{I}_2$  at  $-78^\circ\text{C}$  has been used,<sup>1883</sup> as have ammonium acetate in aqueous methanol,<sup>1884</sup> and Amberlyst 15 in methanol.<sup>1885</sup> Phenolic esters have been selectively hydrolyzed in the presence of alkyl esters on alumina with microwave

( $\Delta H^\ddagger = 20.0 \text{ kcal mol}^{-1}$ ;  $T\Delta S^\ddagger = -6.1 \text{ kcal mol}^{-1}$ ). These data showed that acetylcholine is more susceptible to neutral and base-catalyzed hydrolysis than ethyl acetate but less susceptible to acid-catalyzed hydrolysis.<sup>1908</sup>

Ingold<sup>1909</sup> has classified the acid- and base-catalyzed hydrolyses of esters (and the formation of esters, since these are reversible reactions and thus have the same mechanisms) into eight possible mechanisms,<sup>1910</sup> depending on the following criteria: (i) acid or base catalyzed, (ii) unimolecular or bimolecular, and (iii) acyl cleavage or alkyl cleavage.<sup>1911</sup> All eight of these are  $S_N1$ ,  $S_N2$ , or tetrahedral mechanisms. The acid-catalyzed mechanisms are shown with reversible arrows. They are not only reversible, but also symmetrical; that is, the mechanisms for ester formation are exactly the same as for hydrolysis, except that H replaces R. Internal proton transfers may not actually be direct but may take place through the solvent. There is much physical evidence to show that esters are initially protonated on the carbonyl and not on the alkyl oxygen.<sup>1912</sup> Nevertheless the  $A_{AC}1$  mechanism is shown as proceeding through the ether-protonated intermediate **A**, since it is difficult to envision  $OR'$  as a leaving group here. It is of course possible for a reaction to proceed through an intermediate even if only a tiny concentration is present. The designations  $A_{AC}1$ , and so on, are those of Ingold. The  $A_{AC}2$  and  $A_{AC}1$  mechanisms are also called A2 and A1, respectively. Note that the  $A_{AC}1$  mechanism is actually the same as the  $S_N1cA$  mechanism for this type of substrate and that  $A_{AL}2$  is analogous to  $S_N2cA$ . Some authors use A1 and A2 to refer to all types of nucleophilic substitution in which the leaving group first acquires a proton. The base-catalyzed reactions are not shown with reversible arrows, since they are reversible only in theory and not in practice. Hydrolyses taking place under neutral conditions are classified as B mechanisms. Molecular dynamics has shown that "the rate of hydrolysis of methyl formate in pure water is consistent with mechanisms involving cooperative catalysis by autoionization-generated hydroxide and hydronium, a process known to have an activation free energy of  $23.8 \text{ kcal mol}^{-1}$  ( $99.6 \text{ kJ mol}^{-1}$ )."<sup>1913</sup>

Of the eight mechanisms, seven have actually been observed in the hydrolysis of carboxylic esters. The one that has not been observed is the  $B_{AC}1$  mechanism.<sup>1914</sup> The most common mechanisms are the  $B_{AC}2$  for basic catalysis and the  $A_{AC}2$ <sup>1915</sup> for acid catalysis, that is, the two tetrahedral mechanisms. Both involve acyl-oxygen cleavage. The evidence is: (i) hydrolysis with  $H_2^{18}O$  results in the  $^{18}O$  appearing in the acid and not in the alcohol;<sup>1916</sup> (ii) esters with chiral  $R'$  groups give alcohols with *retention* of configuration;<sup>1917</sup> (iii) allylic  $R'$  gives no allylic rearrangement;<sup>1918</sup> (iv) neopentyl  $R'$  gives no

rearrangement.<sup>1919</sup> All these facts indicate that the O—R' bond is not broken. It has been concluded that two molecules of water are required in the A<sub>AC</sub>2 mechanism. This conclusion stems from a value of *w* (Sec. 8.C) of ~5, indicating that water acts as a proton donor here as well as a nucleophile.<sup>1920</sup> Termolecular processes are rare, but in this case the two water molecules are already connected by a hydrogen bond. (A similar mechanism, called B<sub>AC</sub>3, also involving two molecules of water, has been found for esters that hydrolyze without a catalyst.<sup>1921</sup> Primarily, such esters are those containing halogen atoms in the R group.)

The other mechanism involving acyl cleavage is the A<sub>AC</sub>1 mechanism, which is rare, being found only where R is very bulky, so that bimolecular attack is sterically hindered, and only in ionizing solvents. The mechanism has been demonstrated for esters of 2,4,6-trimethylbenzoic acid (mesitoic acid). This acid depresses the freezing point of sulfuric acid four times as much as would be predicted from its molecular weight, which is evidence for the equilibrium involving the acylium ion. In a comparable solution of benzoic acid the freezing point is depressed only twice the predicted amount, indicating only a normal acid-base reaction. Further, a sulfuric acid solution of methyl mesitoate when poured into water gave mesitoic acid, while a similar solution of methyl benzoate similarly treated did not.<sup>1922</sup> The A<sub>AC</sub>1 mechanism is also found when acetates of phenols or of primary alcohols are hydrolyzed in concentrated (>90%) H<sub>2</sub>SO<sub>4</sub> (the mechanism under the more usual dilute acid conditions is the normal A<sub>AC</sub>2).<sup>1923</sup>

The mechanisms involving alkyl-oxygen cleavage are ordinary S<sub>N</sub>1 and S<sub>N</sub>2 mechanisms in which OCOR (an acyloxy group) or its conjugate acid is the leaving group. Two of the three mechanisms, the B<sub>AL</sub>1 and A<sub>AL</sub>1 mechanisms, occur most readily when R' comes off as a stable carbocation, that is, when R' is tertiary alkyl, allylic, benzylic, and so on. For acid catalysis, most esters with this type of alkyl group (especially tertiary alkyl) cleave by this mechanism, but even for these substrates, the B<sub>AL</sub>1 mechanism occurs only in neutral or weakly basic solution, where the rate of attack by hydroxide is so slowed that the normally slow (by comparison) unimolecular cleavage takes over. These two mechanisms have been established by kinetic studies, <sup>18</sup>O labeling, and isomerization of R'.<sup>1924</sup> Secondary and benzylic acetates hydrolyze by the A<sub>AC</sub>2 mechanism in dilute H<sub>2</sub>SO<sub>4</sub>, but in concentrated acid the mechanism changes to A<sub>AL</sub>1.<sup>1665</sup> Despite its designation, the B<sub>AL</sub>1 mechanism is actually uncatalyzed (as is the unknown B<sub>AC</sub>1 mechanism).

The two remaining mechanisms, B<sub>AL</sub>2 and A<sub>AL</sub>2, are very rare, the B<sub>AL</sub>2 because it requires hydroxide ion to attack an alkyl carbon when an acyl carbon is also available,<sup>1925</sup> and the A<sub>AL</sub>2 because it requires water to be a nucleophile in an S<sub>N</sub>2 process. Both have been observed, however. The B<sub>AL</sub>2 has been seen in (i) the hydrolysis of β-lactones under

neutral conditions<sup>1926</sup> (because cleavage of the C—O bond in the transition state opens the four-membered ring and relieves strain) and (ii) the alkaline hydrolysis of methyl 2,4,6-tri-*tert*-butyl benzoate.<sup>1927</sup> When it does occur, the B<sub>AL</sub>2 mechanism is easy to detect, since it is the only one of the base-catalyzed mechanisms that requires inversion at R'. However, in the second example given, the mechanism is evident from the nature of the product, since the ether could have been formed in no other way. The A<sub>AL</sub>2 mechanism has been reported in the acid cleavage of  $\gamma$ -lactones.<sup>1928</sup>

To sum up the acid-catalysis mechanisms:

- A<sub>AC</sub>2 and A<sub>AL</sub>1 are the common mechanisms, the latter for R' that give stable carbocations, the former for practically all the rest.
- The A<sub>AC</sub>1 mechanism is rare, being found mostly with strong acids and sterically hindered R.
- The A<sub>AL</sub>2 mechanism is even rarer.
- For basic catalysis, B<sub>AC</sub>2 is almost universal.
- B<sub>AL</sub>1 occurs only with R' that give stable carbocations and then only in weakly basic or neutral solutions.
- B<sub>AL</sub>2 is very rare.
- B<sub>AC</sub>1 has never been observed.

The above results pertain to reactions in solution. In the gas phase<sup>1929</sup> reactions can take a different course, as illustrated by the reaction of carboxylic esters with MeO<sup>-</sup>, which in the gas phase was shown to take place only by the B<sub>AL</sub>2 mechanism,<sup>1930</sup> even with aryl esters,<sup>1931</sup> where this means that an S<sub>N</sub>2 mechanism takes place at an aryl substrate.

In the special case of alkaline hydrolysis of *N*-substituted aryl carbamates, there is another mechanism,<sup>1932</sup> involving elimination addition.<sup>1933</sup> This mechanism does not apply to unsubstituted or *N,N*-disubstituted aryl carbamates, which hydrolyze by the normal mechanisms. Carboxylic esters substituted in the  $\alpha$  position by an electron-withdrawing group (e.g., CN or CO<sub>2</sub>Et) can also hydrolyze by a similar mechanism involving a ketene intermediate.<sup>1934</sup> These elimination–addition mechanisms usually are referred to as E1cB mechanisms, because that is the name given to the elimination portion of the mechanism (Sec. 17.A.iii).

The acid-catalyzed hydrolysis of enol esters RCOOC(R')=CR can take place either by the normal A<sub>AC</sub>2 mechanism or by a mechanism involving initial protonation on the double-bond carbon, similar to the mechanism for the hydrolysis of enol ethers given in **10-6**,<sup>1935</sup> depending on reaction conditions.<sup>1936</sup> In either case, the products are the carboxylic acid RCO<sub>2</sub>H and the aldehyde or ketone RCHCOR'.

### 16-59 Hydrolysis of Amides

Amides are quite useful in synthesis.<sup>1937</sup> Unsubstituted amides (RCONH<sub>2</sub>) can be hydrolyzed with either acidic or basic catalysis, and the products are, respectively, the free acid and the ammonium ion or the salt of the acid and ammonia. *N*-Substituted (RCONHR') and *N,N*-disubstituted (RCONR<sub>2</sub>') amides can be hydrolyzed analogously, and the product is the primary or secondary amine, respectively (or their salts), rather than ammonia. Twisting of the amide bond leads to an acceleration of water-promoted hydrolysis reactions.<sup>1938</sup> Lactams, imides, cyclic imides, hydrazides, and so on, also undergo the reaction.

Water alone is not sufficient to hydrolyze most amides<sup>1939</sup> since NH<sub>2</sub> is an even poorer leaving group than OR.<sup>1940</sup> Prolonged heating is often required, often with acidic or basic catalysts.<sup>1941</sup> Treatment of primary amides with phthalic anhydride at 250 °C and 4 atm gives the carboxylic acid and phthalimide.<sup>1942</sup> Hydrolysis of carbamates (RNHCO<sub>2</sub>R) to the corresponding amine can be categorized in this section. Although the product is an amine and the carboxyl unit fragments, this reaction is simply a variation of amide hydrolysis. Strong acids, such as trifluoroacetic acid (in dichloromethane), are typically employed.<sup>1943</sup> Treatment of *N*-Boc derivatives (RNHCO<sub>2</sub>*t*-Bu) with AlCl<sub>3</sub><sup>1944</sup> or with aqueous sodium *tert*-butoxide<sup>1945</sup> gave the amine. High temperature Boc deprotection has been reported using flow conditions (Sec. 7.D).<sup>1946</sup> The by-products of this reaction are typically carbon dioxide and isobutylene.

In difficult cases, nitrous acid, NOCl, N<sub>2</sub>O<sub>4</sub>,<sup>1947</sup> or a similar compound can be used (unsubstituted amides only) to give the carboxylic acid and nitrogen gas.<sup>1948</sup> These reactions involve a diazonium ion (see 13-19) and are much faster than ordinary hydrolysis.

<sup>1948</sup> See Flynn, D.L.; Zelle, R.E.; Grieco, P.A. *J. Org. Chem.* **1983**, *48*, 2424.

*N*-*tert*-Butylamides were converted to the corresponding carboxylic acids by simple nitrosation.<sup>1949</sup> The benzamide/nitrous acid reaction took place  $2.5 \times 10^7$  times faster than ordinary hydrolysis, for example.<sup>1950</sup> In another method, the amide is treated with water and *t*-BuOK at room temperature.<sup>1951</sup> A kinetic study has been done on the alkaline hydrolyses of *N*-trifluoroacetyl aniline derivatives.<sup>1952</sup> Aromatic carboxamides reacted with 3 equivalents of amyl nitrite in acetic acid at 80 °C to give the corresponding aromatic carboxylic acid.<sup>1953</sup>

The same framework of eight possible mechanisms discussed for ester hydrolysis in **16-58** can also be applied to amide hydrolysis.<sup>1954</sup> Both the acid- and base-catalyzed hydrolyses are essentially irreversible, since alkoxide salts are formed in both cases as the tetrahedral intermediate. The mechanism is B<sub>AC</sub>2 for basic catalysis.<sup>1955</sup> There is much evidence for this mechanism, similar to that discussed for ester hydrolysis. Molecular orbital studies on the mechanism of amide hydrolysis suggest a highly tetrahedral transition state.<sup>1956</sup> In certain cases, kinetic studies have shown that the reaction is second order in OH<sup>-</sup>, indicating that the tetrahedral intermediate can lose a proton to give a dianion.<sup>1957</sup> Depending on the nature of R', such a dianion can cleave directly to give the two negative ions or become *N*-protonated prior to or during the act of cleavage, in which case the products are obtained directly and a final proton transfer is not necessary.<sup>1958</sup> Studies of the effect on the rate of hydrolysis and on the ratio  $k_{-1}/k_2$  of substituents on the aromatic rings in a series of amides CH<sub>3</sub>CONHAr led to the conclusion that path *a* is taken when Ar contains electron-withdrawing substituents and path *b* when electron-donating groups are present.<sup>1959</sup>

The presence of electron-withdrawing groups helps stabilize the negative charge on the nitrogen, so that <sup>-</sup>NR<sub>2</sub>' can be a leaving group. Otherwise, the C–N bond does not cleave until the nitrogen is protonated (either prior to or in the act of cleavage), so that the leaving group, *even in the base-catalyzed reaction*, is not <sup>-</sup>NR<sub>2</sub>' but the conjugate acid NHR<sub>2</sub>'. It is known that formation of the tetrahedral intermediate is the rate-determining step in the B<sub>AC</sub>2 mechanism, but only at high base concentrations. At lower concentrations of base, cleavage of the tetrahedral intermediate becomes rate determining.<sup>1960</sup>

For acid catalysis, matters are less clear. The reaction is generally second order, and it is known that amides are primarily protonated on the oxygen. Because of these facts it has been generally agreed that most acid-catalyzed amide hydrolysis takes place by the  $A_{AC}2$  mechanism. Further evidence for this mechanism is that a small but detectable amount of  $^{18}O$  exchange (see Sec. 16.A.i, category 3) has been found in the acid-catalyzed hydrolysis of benzamide<sup>1961</sup> ( $^{18}O$  exchange has also been detected for the base-catalyzed process,<sup>1962</sup> in accord with the  $B_{AC}2$  mechanism). Kinetic data have shown that three molecules of water are involved in the rate-determining step,<sup>1963</sup> suggesting that, as in the  $A_{AL}2$  mechanism for ester hydrolysis (16-58), additional water molecules take part in a process.

The four mechanisms involving alkyl–N cleavage (the AL mechanisms) do not apply to this reaction. They are not possible for unsubstituted amides, since the only N–C bond is the acyl bond. They are possible for *N*-substituted and *N,N*-disubstituted amides, but in these cases they give entirely different products and are not amide hydrolyses at all.

Attack of hydroxide can rarely occur on an *N*-alkyl group to give the amide and an alcohol. While rare, it has been observed for various *N-tert*-butylamides in 98% sulfuric acid, where the mechanism was the  $A_{AL}1$  mechanism,<sup>1964</sup> and for certain amides containing an azo group, where a  $B_{AL}1$  mechanism was postulated.<sup>1965</sup> Of the two first-order acyl cleavage mechanisms, only the  $A_{AC}1$  has been observed, in concentrated sulfuric acid solutions.<sup>1966</sup> Of course, the diazotization of unsubstituted amides might be expected to follow this mechanism, and there is evidence that this is true.<sup>1950</sup>

The hydrolysis of amides has been catalyzed by DNA.<sup>1967</sup>

## B. Attack by OR at an Acyl Carbon

### 16-60 Alcoholysis of Acyl Halides

The reaction between acyl halides and alcohols or phenols is the best general method for the preparation of carboxylic esters. It is believed to proceed by a  $S_N2$  mechanism.<sup>1968</sup> As with 16-56, however, the mechanism can be  $S_N1$  or tetrahedral.<sup>1866</sup> Lewis acids such as lithium perchlorate can be used.<sup>1969</sup> The reaction is of wide scope, and many functional groups do not interfere. A base is frequently added to combine with the HX formed. When aqueous

alkali is used, this is called the *Schotten-Baumann procedure*, but pyridine is also frequently used. Indeed, pyridine catalyzes the reaction by the nucleophilic catalysis route (see **16-57**). Both R and R' may be primary, secondary, or tertiary alkyl or aryl. Enol esters can also be prepared by this method, although C-acylation competes in these cases. In difficult cases, especially with hindered acids or tertiary R', the alkoxide can be used instead of the alcohol.<sup>1970</sup>

Activated alumina has also been used as a catalyst, for tertiary R'.<sup>1971</sup> Thallium salts of phenols give very high yields of phenolic esters,<sup>1972</sup> and BiOCl is very effective for the preparation of phenolic acetates.<sup>1973</sup> Phase-transfer catalysis has been used for hindered phenols.<sup>1974</sup> Zinc has been used to couple alcohols and acyl chlorides,<sup>1975</sup> as have Zr compounds.<sup>1976</sup> Selective acylation is possible in some cases.<sup>1977</sup> The Cu-mediated trifluoromethylthiolation reaction of acid chlorides and (bpy)CuSCF<sub>3</sub> gave S-trifluoromethyl esters.<sup>1978</sup> Acid chlorides reacted with thiols in 1,1,1,3,3,3-hexafluoropropan-2-ol to give the thioester.<sup>1979</sup> The reaction of benzoyl chloride and a cyclic diol gave the monobenzoyl derivative in water using Me<sub>2</sub>SnCl<sub>2</sub> as a catalyst.<sup>1980</sup> Diols were resolved using catalytic acetylation using a chiral confined imidodiphosphoric acid catalyst.<sup>1981</sup>

Acyl halides react with thiols, in the presence of zinc, to give the corresponding thioester.<sup>1982</sup> The reaction of acid chlorides or anhydrides (see **16-61**) with diphenyldiselenide, in the presence of Sm/CoCl<sub>2</sub><sup>1983</sup> or Sm/CrCl<sub>3</sub>,<sup>1984</sup> gave the corresponding selenoester (PhSeCOMe). The reaction of acyl iodides and thiols gave the thioester.<sup>1985</sup>

right.<sup>2004</sup> There are many ways of doing this, among which are (i) addition of an excess of one of the reactants, usually the alcohol; (ii) removal of the ester or the water by distillation; (iii) removal of water by azeotropic distillation; and (iv) removal of water by use of a dehydrating agent, silica gel,<sup>2005</sup> or a molecular sieve.

When R' is methyl, the most common way of driving the equilibrium is by adding excess MeOH; when R' is ethyl or larger, it is preferable to remove water by azeotropic distillation.<sup>2006</sup>

The most common catalysts are H<sub>2</sub>SO<sub>4</sub> and TsOH, but some reactive carboxylic acids (e.g., formic,<sup>2007</sup> trifluoroacetic<sup>2008</sup>) do not require a catalyst. Ammonium salts have been used to initiate esterification.<sup>2009</sup>

The R' group may be primary or secondary alkyl groups other than methyl or ethyl, but tertiary alcohols usually give carbocations and elimination. Phenols can sometimes be used to prepare phenolic esters, but yields are generally very low. Selective esterification of an aliphatic carboxylic acid in the presence of an aromatic acid was accomplished with NaHSO<sub>4</sub>•SiO<sub>2</sub> and methanol.<sup>2010</sup> Photoirradiation of carboxylic acid with CBr<sub>4</sub><sup>2011</sup> or CCl<sub>4</sub><sup>2012</sup> in methanol was shown to give the methyl ester, with high selectivity for nonconjugated acids in the case of CBr<sub>4</sub>. Esterification has been accomplished in ionic liquids.<sup>2013</sup> A solid-state esterification was reported on P<sub>2</sub>O<sub>5</sub>/SiO<sub>2</sub>.<sup>2014</sup> Vinyl acetate and iodine has been used for the acetylation of alcohols.<sup>2015</sup> The phase-transfer esterification of carboxylic acids has been reported using diethoxymethane as a solvent.<sup>2016</sup> Esters have been formed from carboxylic acids and alcohols in deep eutectic solvents.<sup>2017</sup> Graphene oxide was used as a catalyst for the reaction of carboxylic acids and alcohols to give esters.<sup>2018</sup> The Yamaguchi reagent (2,4,6-trichlorobenzoyl chloride) was used for the coupling of carboxylic acids and alcohols to give the ester.<sup>2019</sup> Methyl esters were formed from carboxylic acids via continuous flow (Sec. 7.D) diazotization of methylamine with 1,3-propanedinitrite in THF.<sup>2020</sup>

The Ir-catalyzed allylic esterification of carboxylates with allylic phosphates gave branched allylic esters.<sup>2021</sup> The O-alkylation of carboxylic acids with alkylboronic acids gave the ester using a Cu catalyst.<sup>2022</sup> The MnO<sub>2</sub> reaction of hydrazones of

benzaldehydes and aryl ketones gave the diazoalkane that reacted with carboxylic acids to form the ester.<sup>2023</sup> Carboxylic acids reacted with alcohols to give the ester using a macroporous polymeric acid catalyst.<sup>2024</sup> Carboxylic esters reacted with perfluorinated alcohols, mediated by XtalFluor-E [(diethylamino)difluorosulfonium tetrafluoroborate], to give the ester.<sup>2025</sup> Sulfonated polypyrene (S-PPR) was used as a catalyst for the reaction of carboxylic acids and alcohols to give the corresponding esters.<sup>2026</sup> Transition metal compounds of Ti,<sup>2027</sup> Fe,<sup>2028</sup> or Co<sup>2029</sup> catalyze esterification. Allylic sulfonium salts react with carboxylic acids to give allylic esters in the presence of CuBr.<sup>2030</sup> Triphenylphosphine dibromide is a useful esterification reagent.<sup>2031</sup> Phenols can be esterified using amide acetals.<sup>2032</sup> The reaction of a carboxylic acid with an alcohol, in the presence of triphenylphosphine and diethyl azodicarboxylate (DEAD), gives the corresponding ester. This reaction is known as the *Mitsunobu reaction* (see **10-17**). A variation of this esterification reaction used azopyridines to mediate formation of the ester.<sup>2033</sup>

Both  $\gamma$ - and  $\delta$ -hydroxy acids are easily converted to a lactone by treatment with acids, or often simply on standing, but larger and smaller lactone rings cannot be made in this manner.<sup>2034</sup> Often the conversion of a group to a hydroxyl group gives the lactone directly when the hydroxy acid cyclizes too rapidly for isolation. Such groups include keto or halogen that are  $\gamma$  or  $\delta$  to a carboxyl group.  $\beta$ -Substituted  $\beta$ -hydroxy acids can be converted to  $\beta$ -lactones by treatment with benzenesulfonyl chloride in pyridine at 0–5 °C.<sup>2035</sup>  $\epsilon$ -Lactones (seven-membered rings) have been made by cyclization of  $\epsilon$ -hydroxy acids at high dilution.<sup>2036</sup> Macrocyclic lactones<sup>2037</sup> can be prepared indirectly in very good yields by conversion of the hydroxy acids to 2-pyridinethiol esters and adding these to xylene at reflux.<sup>2038</sup>

A closely related method, which often gives higher yields of a macrocyclic lactone, involves treatment of the hydroxy acids with 1-methyl- or 1-phenyl-2-halopyridinium salts, especially 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).<sup>2039</sup> A macrocyclization technique has been developed based on formation of a mixed anhydride. *Yamaguchi protocol*<sup>2040</sup> reacts a seco acid (the hydroxy acid precursor of a macrocyclic lactone) with 2,4,6-trichlorobenzoyl chloride, and the resulting mixed anhydride is heated with DMAP (4-*N,N*-dimethylaminopyridine) in toluene.

Esterification is catalyzed by acids (not bases), as discussed in **16-58**.<sup>1911</sup> The mechanisms are usually  $A_{AC}2$ , but  $A_{AC}1$  and  $A_{AL}1$  have also been observed.<sup>2041</sup> Certain acids, such as 2,6-di-ortho-substituted benzoic acids, cannot be esterified by the  $A_{AC}2$  mechanism because of steric hindrance (Sec. 10.G.i, category 1). In such cases, esterification can be accomplished by dissolving the acid in 100%  $H_2SO_4$  (forming the ion  $RCO^+$ ) and pouring the solution into the alcohol ( $A_{AC}1$  mechanism). The reluctance of hindered acids to undergo the normal  $A_{AC}2$  mechanism can sometimes be put to advantage when, in a molecule containing two  $CO_2H$  groups, only the less hindered one is esterified. The  $A_{AC}1$  pathway cannot be applied to unhindered carboxylic acids.

Another way to esterify a carboxylic acid is to treat it with an alcohol in the presence of a dehydrating agent.<sup>2005</sup> One such dehydrating agent is dicyclohexylcarbodiimide (DCC), which is converted in the process to dicyclohexylurea (DHU).

The mechanism<sup>2042</sup> has much in common with the nucleophilic catalysis mechanism; the acid is converted to a compound with a better leaving group, but the conversion is not by a tetrahedral mechanism (as it is in nucleophilic catalysis), since the C–O bond remains intact. The carboxylic acid adds to the electrophilic carbon of the diimide to give acyloxyurea. In effect, the H–CO–N unit (a putative urea) becomes a good leaving group, allowing reaction of the acyl group with the alcohol, and loss of dicyclohexylurea gives the ester. Evidence for this mechanism was the preparation of *O*-acylureas and the finding that when catalyzed by acids they react with alcohols to give esters.<sup>2043</sup> Hindered tertiary alcohols can be coupled via DCC to give the hindered ester.<sup>2044</sup>

There are limitations to the use of DCC for esterification. The yields are variable and *N*-acylureas are side products, which are sometimes very difficult to remove even by chromatography. Many other dehydrating agents<sup>2045</sup> have been used, including DCC and an aminopyridine,<sup>2046</sup> chlorosilanes,<sup>2047</sup> and *N,N'*-carbonyldiimidazole.<sup>2048</sup> In the latter case acyl imidazolides are intermediates that react with alcohols.

Carboxylic acids were coupled with primary alcohols to give the esters using the water-soluble carbodiimide 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDCI) and (2,2-dimethyl-1,3-dioxolan-4-yl)methyl 2-cyano-2-(hydroxyimino)acetate.<sup>2049</sup> Methyl esters were formed by the reaction of carboxylic acids and methanol, catalyzed by polymer-supported triphenylphosphine/2,4,6-trichloro-1,3,5-triazine/Na<sub>2</sub>CO<sub>3</sub>.<sup>2050</sup>

It is known that the Lewis acid BF<sub>3</sub> promotes esterification by converting an acid to an acylium ion so the reaction can proceed by an A<sub>AC</sub>1 type of mechanism. The use of BF<sub>3</sub>-etherate is simple and gives high yields.<sup>2051</sup> Other Lewis acids can be used.<sup>2052</sup>

Carboxylic esters can also be prepared by treating carboxylic acids with *tert*-butyl ethers and acid catalysts.<sup>2053</sup> Carboxylic esters can be formed from the carboxylate anion and a suitable alkylating agent (**10-26**). Aryl esters were formed by the reaction of carboxylic acids and diaryliodonium salts.<sup>2054</sup>

Thioesters of the type RSC(=S)R' (a dithiocarboxylic ester) and RSC(C=O)R' (a thio-carboxylic ester) can be generated by reaction of carboxylic acids with thiols. In one example, phosphorus pentasulfide was used in conjunction with a thiol to make dithiocarboxylic esters<sup>2055</sup> or thiocarboxylic esters.<sup>2056</sup> Thiocarboxylic esters were prepared from thiols and triflic acid.<sup>2057</sup>

many cases low-boiling esters can be converted to higher-boiling ones by the distillation of the lower-boiling alcohol as fast as it is formed. Reagents used to catalyze<sup>2064</sup> transesterification include various Lewis acids.<sup>2065</sup> Transition metal catalysts have been used, including Fe,<sup>2066</sup> Zn,<sup>2067</sup> Pd,<sup>2068</sup> La,<sup>2069</sup> or Y compounds.<sup>2070</sup> Organocatalysts have also been used.<sup>2071</sup> Tetraethylammonium hydrogencarbonate has been used as a catalyst.<sup>2072</sup> Transesterification has been catalyzed by dilithium tetra-*tert*-butylzincate.<sup>2073</sup> A polymer-bound siloxane has been used to induce transesterification.<sup>2074</sup> A solvent-free transesterification has been reported using a ball-mill over an alumina surface.<sup>2075</sup> The high-pressure transesterification of sterically hindered esters has been reported.<sup>2076</sup> Enzymatic transesterification reactions are known.<sup>2077</sup>

Vinyl acetate has been used for transesterification, usually with a co-reagent or metal mediator,<sup>2078</sup> and is a method for the acylation of a primary OH in the presence of a secondary OH.<sup>2079</sup> Regioselectivity has also been accomplished by using enzymes (lipases) as catalysts.<sup>2080</sup> Lactones are easily opened by treatment with alcohols<sup>2081</sup> to give open-chain hydroxy esters. Transesterification has been carried out with phase-transfer catalysts, without an added solvent.<sup>2082</sup> Nonionic superbases (Sec. 8.A.i) of the type P(RNCH<sub>2</sub>CH<sub>2</sub>)<sub>3</sub>N catalyze the transesterification of carboxylic acid esters at 25 °C.<sup>2083</sup> Thioesters are converted to phenolic esters by treatment with triphosgene/pyridine and then phenol.<sup>2084</sup> The In/I<sub>2</sub> mediated conversion of dithioesters to esters has been reported.<sup>2085</sup>

Transesterification occurs by mechanisms<sup>2086</sup> that are identical with those of ester hydrolysis and transesterification reactions frequently fail when R' is tertiary, since this

type of substrate most often reacts by alkyl-oxygen cleavage. In such cases, the reaction is of the Williamson type with OCOR as the leaving group (see **10-10**).

With enol esters, reaction with an alcohol gives an ester and the enol of a ketone, which readily tautomerizes to the ketone. Hence, enol esters are good acylating agents for alcohols.<sup>2087</sup> This transformation has been accomplished in ionic liquid media,<sup>2088</sup> and there is a PdCl<sub>2</sub>/CuCl<sub>2</sub>-mediated version.<sup>2089</sup> Isopropenyl acetate can also be used to convert other ketones to the corresponding enol acetates in an exchange reaction.<sup>2090</sup> Enol esters can also be prepared in the opposite type of exchange reaction, where a carboxylic acid reacts with an enol ester, catalyzed by mercuric acetate<sup>2091</sup> or Pd(II) chloride<sup>2092</sup> to give a new enol ester and another carboxylic acid.

## 16-64 Esters From Amides

Alcoholysis of amides is possible,<sup>2093</sup> although it is usually difficult. It is most common with the imidazole type of amides, acylimidazoles. For other amides, an activating agent is usually necessary before the alcohol will replace the NR<sub>2</sub> unit. A scandium triflate (ScOTf)<sub>3</sub>-catalyzed reaction of primary amides and esters gave the primary amide.<sup>2094</sup> The esterification of *N*-β-hydroxyethyl amides was catalyzed by manganese compounds.<sup>2095</sup>

Dimethylformamide reacted with primary alcohols in the presence of 2,4,6-trichloro-1,3,5-pyrazine (cyanuric acid) to give the corresponding formate ester.<sup>2096</sup> Treatment of an amide with triflic anhydride (CF<sub>3</sub>SO<sub>2</sub>OSO<sub>2</sub>CF<sub>3</sub>) in the presence of pyridine and then with an excess of alcohol leads to the ester,<sup>2097</sup> as does treatment with Me<sub>2</sub>NCH(OMe)<sub>2</sub> followed by the alcohol.<sup>2098</sup> Trimethyloxonium tetrafluoroborate converted primary amides to methyl esters.<sup>2099</sup> Acyl hydrazides (RCONHNH<sub>2</sub>) were converted to esters by reaction with alcohols and various reagents,<sup>2100</sup> and methoxyamides (RCONHOMe) were converted

to esters with  $\text{TiCl}_4/\text{ROH}$ .<sup>2101</sup> The reaction of an oxazolidinone amide **50** with methanol and 10%  $\text{MgBr}_2$  gave the corresponding methyl ester.<sup>2102</sup>

Thioesters were prepared via the solvent-free reaction of thioamide derivatives with alkyl halides, with DABCO and with small quantities of water.<sup>2103</sup> *N*-Alkoxy amides were converted to esters using an electrochemical method using *n*- $\text{Bu}_4\text{NI}$  as the redox catalyst as well as the supporting electrolyte.<sup>2104</sup>

### C. Attack by OCOR at an Acyl Carbon

#### 16-65 Acylation of Carboxylic Acids With Acyl Halides

Unsymmetrical, as well as symmetrical, anhydrides are often prepared by the treatment of an acyl halide with a carboxylic acid salt. If a metallic salt is used,  $\text{Na}^+$ ,  $\text{K}^+$ , or  $\text{Ag}^+$  are the most common cations, but more often pyridine or another tertiary amine is added to the free acid and the resulting salt is subsequently treated with the acyl halide. Zinc/DMF has been used to mediate the synthesis of symmetrical anhydrides from acid chlorides.<sup>2105</sup> Cobalt(II) chloride ( $\text{CoCl}_2$ ) has been used as a catalyst.<sup>2106</sup> Mixed formic anhydrides are prepared from sodium formate and an aryl halide, by use of a solid-phase copolymer of pyridine-1-oxide.<sup>2107</sup> Symmetrical anhydrides can be prepared by reaction of the acyl halide with aqueous  $\text{NaOH}$  or  $\text{NaHCO}_3$  under phase-transfer conditions,<sup>2108</sup> or with sodium bicarbonate with ultrasound.<sup>2109</sup> Using a Sc catalyst, anhydrides were formed from twisted amides.<sup>2110</sup>

OS **III**, 28, 422, 488; **IV**, 285; **VI**, 8, 910; **VIII**, 132. See also, OS **VI**, 418.

#### 16-66 Acylation of Carboxylic Acids With Carboxylic Acids

Anhydrides can be formed from two molecules of an ordinary carboxylic acid only if a dehydrating agent is present so that the equilibrium can be driven to the right.

<sup>2110</sup> Liu, Y.; Liu, R.; Szostak, M. *Org. Biomol. Chem.* **2017**, *15*, 1780.

Common dehydrating agents<sup>2111</sup> are acetic anhydride, trifluoroacetic anhydride, dicyclohexylcarbodiimide,<sup>2112</sup> and P<sub>2</sub>O<sub>5</sub>. Triphenylphosphine/CCl<sub>3</sub>CN with triethylamine has also been used with benzoic acid derivatives.<sup>2113</sup> The method is very poor for the formation of mixed anhydrides, which in any case generally undergo disproportionation to the two simple anhydrides when they are heated. However, simple heating of dicarboxylic acids does give cyclic anhydrides, provided that the ring formed contains five, six, or seven members. Malonic acid and its derivatives, which would give four-membered cyclic anhydrides, do not give this reaction when heated, but undergo decarboxylation (**12-39**) instead.

Carboxylic acids exchange with amides and esters; these methods are sometimes used to prepare anhydrides if the equilibrium can be shifted. Enolic esters are especially good for this purpose, because the equilibrium is shifted by formation of the ketone. The combination of KF with 2-acetoxypiprene under microwave conditions was effective.<sup>2114</sup> Carboxylic acids also exchange with anhydrides; indeed, this is how acetic anhydride acts as a dehydrating agent in this reaction.

Anhydrides can be formed from certain carboxylic acid salts, as exemplified by the treatment of trimethylammonium carboxylates with phosgene<sup>2115</sup> or of thallium(I) carboxylates with thionyl chloride,<sup>1973</sup> or of sodium carboxylates with CCl<sub>4</sub> and a catalyst such as CuCl or FeCl<sub>2</sub>.<sup>2116</sup>

### 16-67 Preparation of Mixed Organic-Inorganic Anhydrides

Mixed organic-inorganic anhydrides are seldom isolated, although they are often intermediates when acylation is carried out with acid derivatives catalyzed by inorganic acids. Sulfuric, perchloric, phosphoric, and other acids form similar anhydrides, most of which are unstable or not easily obtained because the equilibrium lies in the wrong direction. These intermediates are formed from amides, carboxylic acids, and esters, as well as anhydrides. Organic anhydrides of phosphoric acid are more stable than most others; for example, RCOOPO(OH)<sub>2</sub> can be prepared in the form of its salts.<sup>2117</sup> Mixed anhydrides of carboxylic and sulfonic acids (RCOOSO<sub>2</sub>R') are obtained in high yields by treatment of sulfonic acids with acyl halides or (less preferred) with anhydrides.<sup>2118</sup>

16-68 Attack by SH or SR at an Acyl Carbon<sup>2119</sup>

Thiol acids and thiol esters<sup>2120</sup> can be prepared from acid chlorides, which is analogous to **16-56** and **16-63**. Anhydrides<sup>2121</sup> and aryl esters (RCOAr)<sup>2122</sup> are also used as substrates, but the reagents in these cases are usually HS<sup>-</sup> and RS<sup>-</sup>. Thiol esters can also be prepared by treatment of carboxylic acids with P<sub>4</sub>S<sub>10</sub>/Ph<sub>3</sub>SbO,<sup>2123</sup> or with a thiol (RSH) and either polyphosphate ester or phenyl dichlorophosphate (PhOPOCl<sub>2</sub>).<sup>2124</sup> Carboxylic acids are converted to thioacids with *Lawesson's reagent* (structure **13** in **16-10**).<sup>2125</sup> Esters (RCOOR') can be converted to thioesters (RCOSR<sup>2</sup>) by treatment with trimethylsilyl sulfides (Me<sub>3</sub>SiSR<sup>2</sup>) and AlCl<sub>3</sub>.<sup>2126</sup>

## 16-69 Transamidation

It is sometimes necessary to replace one amide group with another, particularly when the group attached to nitrogen functions as a protecting group.<sup>2127</sup> Transamidation has been catalyzed by transition metals, as in the reaction of carboxamides with a Sb<sup>2128</sup> or Zr<sup>2129</sup> catalyst, with an Fe catalyst and water,<sup>2130</sup> or under solvent-free conditions.<sup>2131</sup> Boric acid,<sup>2132</sup> L-proline,<sup>2133</sup> and hydroxylamine hydrochloride<sup>2134</sup> have been used as catalysts. *N*-Benzyl amides can be converted to the corresponding *N*-allyl amide with allylamine and Ti catalysts.<sup>2135</sup> Reaction of *N*-Boc 2-phenylethylamine with Ti(Oi-Pr)<sub>4</sub> and benzyl alcohol,

for example, gives the *N*-Cbz derivative (Cbz = carbobenzyloxycarbonyl).<sup>2136</sup> *N*-Carbamoyl amines were converted to *N*-acetyl amines with acetic anhydride, Bu<sub>3</sub>SnH, and a Pd catalyst.<sup>2137</sup>

Aryl amides with a N(Ph)Boc unit reacted with secondary amines and triethylamine to give the transamidation product, ArCONR<sub>2</sub>.<sup>2138</sup> Microwave irradiation of primary amides with primary amines in 1,4-dioxane gave the secondary amide.<sup>2139</sup> Microwave irradiation of nonactivated carboxamides with amines in an ionic liquid led to transamidation.<sup>2140</sup> The reaction of amines with formamide and NaOMe gave the new formamide.<sup>2141</sup> A related process reacts acetamide with amines and aluminum chloride to give the *N*-acetyl amine.<sup>2142</sup>

Thioamides can be prepared from amides by reaction with an appropriate sulfur reagent. Lawesson's reagent has been used to convert amides to thioamides.<sup>2143</sup> The reaction of *N,N*-dimethylacetamide, under microwave irradiation, with a polymer-bound reagent gave a thioamide.<sup>2144</sup> Ammonium phosphorodithioate has been used to convert amides to thioamides.<sup>2145</sup> Thioamides were converted to the amide with visible light-mediated, eosin Y-catalyzed aerobic desulfurization.<sup>2146</sup> Reaction of the thioamide with Bi(NO<sub>3</sub>)<sub>3</sub>·5H<sub>2</sub>O regenerates the amide.<sup>2147</sup> Other methods are known to convert a thioamide to an amide.<sup>2148</sup> Selenoamides (RC(=Se)NR'<sub>2</sub>) have also been prepared from amides.<sup>2149</sup>

## D. Attack by Halogen

### 16-70 The Conversion of Carboxylic Acids to Alkyl Halides

In certain cases, carboxyl groups can be replaced by halides. Acrylic acid derivatives ArCH=CHCOOH, for example, react with 3 molar equivalents of Oxone in the presence of NaBr to give a vinyl bromide ArCH=CHBr.<sup>2150</sup> Diphosphorus tetraoxide/tetraethylammonium bromide (TEAB) readily converts conjugated acids to vinyl bromides.<sup>2151</sup> In other cases, conjugated acids have been converted to the vinyl bromide by reaction with *N*-bromosuccinimide (NBS, reaction **14-3**) and LiOAc.<sup>2152</sup>

Alkyl chlorides were prepared from carboxylic acids by treatment with  $\text{CuCl}_2$  with a  $\text{GaCl}_3$  catalyst and a hydrosiloxane.<sup>2153</sup> The Ir-catalyzed conversion of carboxylic acids to alkyl bromides was reported.<sup>2154</sup>

## E. Attack by Nitrogen at an Acyl Carbon<sup>2155</sup>

### 16-71 Acylation of Amines by Acyl Halides

The treatment of acyl halides with ammonia or amines is a very general reaction for the preparation of amides.<sup>2156</sup> The reaction is exothermic and must be carefully controlled, usually by cooling or dilution. Ammonia gives unsubstituted amides, primary amines give *N*-substituted amides,<sup>2157</sup> and secondary amines give *N,N*-disubstituted amides. Arylamines can be similarly acylated. Hydroxamic acids have been prepared by this route.<sup>2158</sup> In some cases, aqueous alkali is added to combine with the liberated HCl. This is called the *Schotten-Baumann procedure*, as in **16-60**. Activated Zn can be used to increase the rate of amide formation when hindered amines and/or acid chlorides are used.<sup>2159</sup> A solvent-free reaction was reported using DABCO and methanol.<sup>2160</sup> Metal-mediated reactions using In,<sup>2161</sup> Sm,<sup>2162</sup> or a BiOCl-mediated reaction<sup>2163</sup> have been reported. Formic acid and iodine react with amines to give the formamide.<sup>2164</sup> The Ag-catalyzed reaction of amines and acyl chlorides gave the amide.<sup>2165</sup>

Hydrazine and hydroxylamine also react with acyl halides to give, respectively, hydrazides ( $\text{RCONHNH}_2$ )<sup>2166</sup> and hydroxamic acids ( $\text{RCONHOH}$ ).<sup>2167</sup> When phosgene is the acyl halide, both aliphatic and aromatic primary amines give chloroformamides ( $\text{CICONHR}$ ) that lose HCl to give isocyanates ( $\text{RNCO}$ ).<sup>2168</sup> This is one of the most common methods for the preparation of isocyanates.<sup>2169</sup> Similar treatment with thiophosgene<sup>2170</sup>

gives isothiocyanates. A safer substitute for phosgene in this reaction is trichloromethyl chloroformate (CCl<sub>3</sub>OCOC<sub>l</sub>).<sup>2171</sup> When chloroformates (ROCOCl) are treated with primary amines, carbamates (ROCONHR') are obtained.<sup>2172</sup> An example of this reaction is the use of benzyl chloroformate to protect the amino group of amino acids and peptides.

The PhCH<sub>2</sub>OCO group is the carbobenzoxy group,<sup>2173</sup> and is often abbreviated Cbz or Z, but it is really a benzyl carbamate when the Cbz group is attached to nitrogen. Another important group similarly used is Boc, which is a *tert*-butyl carbamate when the Boc group is attached to nitrogen. In this case, the chloride (Me<sub>3</sub>COCOCl) is unstable, so the anhydride, (Me<sub>3</sub>COCO)<sub>2</sub>O is used instead, in an example of **16-72**. Amino groups in general are often protected by conversion to amides.<sup>2174</sup> The reactions proceed by the tetrahedral mechanism.<sup>2175</sup> Weinreb amides were prepared by the reaction of carboxylic acids and MeNHOMe in the presence of PCl<sub>3</sub>.<sup>2176</sup>

### 16-72 Acylation of Amines by Anhydrides

This reaction, similar in scope and mechanism<sup>2177</sup> to **16-71**, can be carried out with ammonia or primary or secondary amines.<sup>2178</sup> Note that there is a report where a tertiary amine (an *N*-alkylpyrrolidine) reacted with acetic anhydride at 120 °C, in the presence of a BF<sub>3</sub>•etherate catalyst, to give *N*-acetylpyrrolidine (an acylative dealkylation).<sup>2179</sup> Amino acids can be *N*-acylated using acetic anhydride and ultrasound.<sup>2180</sup> However, ammonia and primary amines can also give imides, in which two acyl groups are attached to the nitrogen. The conversion of cyclic anhydrides to cyclic imides is generally facile,<sup>2181</sup> although elevated temperatures are occasionally required to generate the imide.<sup>2182</sup> Microwave

<sup>2182</sup> Tsubouchi, H.; Tsuji, K.; Ishikawa, H. *Synlett* **1994**, 63.

irradiation of formamide and a cyclic anhydride generates the cyclic imide.<sup>2183</sup> Cyclic imides have been formed in ionic liquids.<sup>2184</sup> Cyclic imides were also formed by microwave irradiation of a polymer-bound phthalate after initial reaction with an amine.<sup>2185</sup> The second step for imide formation, which is much slower than the first, is the attack of the amide nitrogen on the carboxylic carbon. Unsubstituted and *N*-substituted amides have been used instead of ammonia. Since the other product of this reaction is RCOOH, this is a way of “hydrolyzing” such amides in the absence of water.<sup>2186</sup> The reaction of *meso*-diamines with benzoic anhydride in the presence of 4-(dimethylamino)pyridine, and a chiral amide–thiourea co-catalyst gave desymmetrization and formation of the monobenzamide.<sup>2187</sup> The Fe-catalyzed amide-forming reaction is known.<sup>2188</sup>

Even though formic anhydride is not a stable compound (see **11-17**), amines can be formylated with the mixed anhydride of acetic and formic acids HCOOCOMe<sup>2189</sup> or with a mixture of formic acid and acetic anhydride. Acetamides are not formed with these reagents. Secondary amines can be acylated in the presence of a primary amine by conversion to their salts and addition of 18-crown-6.<sup>2190</sup> The crown ether complexes the primary ammonium salt, preventing its acylation, while the secondary ammonium salts, which do not fit easily into the cavity, are free to be acylated. Dimethyl carbonate can be used to prepare methyl carbamates in a related procedure.<sup>2191</sup> *N*-Acetylsulfonamides were prepared from acetic anhydride and a primary sulfonamide, catalyzed by Montmorillonite K10/FeO<sup>2192</sup> or sulfuric acid.<sup>2193</sup>

### 16-73 Acylation of Amines by Carboxylic Acids

When carboxylic acids are treated with ammonia or amines, salts are obtained.<sup>2194</sup> The salts of ammonia or primary or secondary amines can be pyrolyzed to give amides,<sup>2195</sup> but the method is less convenient than **16-71**, **16-72**, and **16-74** and is of less preparative value.<sup>2196</sup> Heating in the presence of a base such as hexamethyldisilazide makes the amide-forming process more efficient.<sup>2197</sup> Boronic acids catalyze the direct conversion

of carboxylic acids and amines to amides.<sup>2198</sup> Polymer-bound reagents have also been used.<sup>2199</sup> Triphenylphosphine/trichloroisocyanuric acid converts acids and amides to the amide.<sup>2200</sup> The *Burgess reagent* ( $\text{Et}_3\text{N}^+ \text{SO}_2\text{NCO}_2\text{Me}$ ; see **17-27**) activates carboxylic acids for amide formation.<sup>2201</sup> The reaction of a carboxylic acid and imidazole under microwave irradiation gives the amide.<sup>2202</sup> Microwave irradiation of a secondary amine, formic acid, 2-chloro-4,6-dimethoxy[1,3,5]triazine, and a catalytic amount of DMAP (4-dimethylaminopyridine) leads to the formamide.<sup>2203</sup> Ammonium bicarbonate and formamide converts acids to amides with microwave irradiation.<sup>2204</sup> The coupling reaction of lithium, sodium, or potassium carboxylates with amines in the presence of *i*-Pr<sub>2</sub>NEt and lithium 5-bromo-1*H*-pyrrole-2-carboxylate gave the amide.<sup>2205</sup> The PPh<sub>3</sub>-catalyzed reaction of carboxylic acids and amines gave the amide.<sup>2206</sup> The activation of carboxylic acids, catalyzed by polymer-bound PPh<sub>3</sub>, with 2,4,6-trichloro-1,3,5-triazine was followed by reaction with an amine to give the amide.<sup>2207</sup> Similarly, ion-supported PPh<sub>3</sub> has been used to prepare amides.<sup>2208</sup> Metal catalysts such as Zr,<sup>2209</sup> W,<sup>2210</sup> Ti,<sup>2211</sup> Cu,<sup>2212</sup> Au,<sup>2213</sup> or Al<sup>2214</sup> have been used for the coupling of carboxylic acids and amines.

Although treatment of carboxylic acids with amines does not directly give amides, the reaction can be made to proceed in good yield at room temperature or slightly above by the use of coupling agents,<sup>2215</sup> the most important of which is dicyclohexylcarbodiimide (DCC, see **16-62**). This reagent is very convenient and is used<sup>2216</sup> a great deal in peptide synthesis.<sup>2217</sup> A polymer-supported carbodiimide has been used.<sup>2218</sup> An anhydride

intermediate has been isolated from a DCC reaction mixture and then used to acylate an amine.<sup>2219</sup>

The synthetically important *Weinreb amides* [RCON(Me)OMe, see **16-29**] can be prepared from the carboxylic acid and MeO(Me)NH•HCl in the presence of tributylphosphine and 2-pyridine-*N*-oxide disulfide.<sup>2220</sup> Di(2-pyridyl)carbonate has been used in a related reaction that generates amides directly.<sup>2221</sup> Other promoting agents<sup>2222</sup> are ArB(OH)<sub>2</sub> reagents,<sup>2223</sup> *N,N'*-carbonyldiimidazole,<sup>2224</sup> POCl<sub>3</sub>,<sup>2225</sup> TiCl<sub>4</sub>,<sup>2226</sup> molecular sieves,<sup>2227</sup> *Lawesson's reagent* (**16-10**),<sup>2228</sup> and (MeO)<sub>2</sub>POCl.<sup>2229</sup> Certain dicarboxylic acids form amides simply on treatment with primary aromatic amines. In these cases, the cyclic anhydride is an intermediate and is the species actually attacked by the amine.<sup>2230</sup> Carboxylic acids can also be converted to amides with sulfonic acids, or phosphoric acids,<sup>2231</sup> or by treatment with trisalkylaminoboranes [B(NHR')<sub>3</sub>].

Lactams are readily produced from  $\gamma$ - or  $\delta$ -amino acids.<sup>2232</sup> This lactonization process can be promoted by enzymes, such as pancreatic porcine lipase.<sup>2233</sup> Reduction of  $\omega$ -azide carboxylic acids leads to macrocyclic lactams.<sup>2234</sup>

Many other methods have been developed. The activation of carboxylic acids by the reagent combination of trimethyl phosphite and iodine allowed the reaction with aromatic amines to give the amide.<sup>2235</sup> The coupling of carboxylic acids and amines, catalyzed by *ortho*-iodophenylboronic acids with molecular sieve 4 Å gave the corresponding amide.<sup>2236</sup> Amides have been prepared using B(OCH<sub>2</sub>CF<sub>3</sub>)<sub>3</sub><sup>2237</sup> or (2-(thiophen-2-ylmethyl)phenyl)boronic acid<sup>2238</sup> as the catalyst. Primary alkylboronic acids have been used to couple  $\alpha$ -hydroxycarboxylic acids and amines.<sup>2239</sup> A solid-supported

*ortho*-iodoarylboronic acid has been used to catalyze the reaction.<sup>2240</sup> 2-Furanylboronic acid was used as a catalyst.<sup>2241</sup> Mesoporous silica SBA-15 has been used as a catalyst.<sup>2242</sup>

Mechanosynthesis has been used with the carbonylimidazole approach under solvent-free conditions.<sup>2243</sup> The fluorine-containing catalyst XtalFluor-E has been used to couple carboxylic acids and amines.<sup>2244</sup> The reaction of amines with prop-2-ene-1-sulfinyl chloride gave the sulfinylamide that reacted with carboxylic acids to give the amide.<sup>2245</sup> Carboxylic acids reacted with imidazole under solvent-free conditions to form the carbonylimidazole, which reacted with secondary amines to give the amide.<sup>2246</sup> Amines and carboxylic acids were coupled using the uronium salt (1-cyano-2-ethoxy-2-oxoethylidenaminoxy)dimethylaminomorpholinocarbenium hexafluorophosphate) as a coupling reagent, with 2,6-lutidine, and TPGS-750-M [DL- $\alpha$ -tocopherol methoxypolyethylene glycol succinate solution] to give the amide.<sup>2247</sup> The Pd-catalyzed coupling of organoboronic acids and amines gave tertiary amides in the presence of CO and O<sub>2</sub>.<sup>2248</sup> The photogeneration of Vilsmeier-Haack reagents (**12-16**) from DMF and CBr<sub>4</sub> mediated the coupling of carboxylic acids and amines to give the amide.<sup>2249</sup>

The reaction of thiocarboxylic acids and azides, in the presence of triphenylphosphine, gives the corresponding amide.<sup>2250</sup> Heating secondary amines and carboxylic acids with sulfur gave the thioamide.<sup>2251</sup>

Before leaving this section, it is important to mention the peptide synthesis protocol discovered by R.B. Merrifield<sup>2252</sup> and used for the synthesis of many peptides.<sup>2253</sup> This methodology is called *solid-phase synthesis* or *polymer-supported synthesis*.<sup>2254</sup> The reactions used are the same as in ordinary synthesis, but one of the reactants is anchored onto a solid polymer. For example, if it is desired to couple two amino acids (to form a dipeptide), the polymer selected might be polystyrene with CH<sub>2</sub>Cl side chains. One of the amino

acids, protected by a Boc,<sup>2255</sup> would then be coupled to the side chains. It is not necessary that all the side chains be converted, but a random selection will be. The Boc group is then removed by hydrolysis with trifluoroacetic acid in CH<sub>2</sub>Cl<sub>2</sub> and the second amino acid is coupled to the first, using DCC or some other coupling agent. The second Boc group is removed, resulting in a dipeptide that is still anchored to the polymer. If this dipeptide is the desired product, it can be cleaved from the polymer by various methods,<sup>2256</sup> one of which is treatment with HF. If a longer peptide is wanted, additional amino acids can be added by repeating the requisite steps.

The basic advantage of the polymer-support techniques is that the polymer (including all chains attached to it) is easily separated from all other reagents, because it is insoluble in the solvents used. Excess reagents, other reaction products (e.g., dicyclohexylurea), side products, and the solvents themselves are quickly washed away. Purification of the polymeric species is rapid and complete. The process can even be automated,<sup>2257</sup> and commercial automated peptide synthesizers are now available.<sup>2258</sup>

Although the solid-phase technique was first developed for the synthesis of peptide chains and has seen considerable use for this purpose, it has also been used to synthesize chains of polysaccharides and polynucleotides; in the latter case, solid-phase synthesis has almost completely replaced synthesis in solution.<sup>2259</sup> The technique has been applied less often to reactions in which only two molecules are brought together (nonrepetitive syntheses), but many examples have been reported.<sup>2260</sup> Combinatorial chemistry in some ways can be viewed as an extension of the Merrifield synthesis, particularly when applied to peptide synthesis, and continues as an important part of modern organic chemistry.<sup>2261</sup>

amine<sup>2262</sup> or ammonia.<sup>2263</sup> Both R and R' can be alkyl or aryl, but *an especially good leaving group is p-nitrophenyl*. Ethyl trifluoroacetate was found to react selectively with primary amines to form the corresponding trifluoroacetyl amide.<sup>2264</sup> Many simple esters (R = Me, Et, etc.) are not very reactive, and strongly basic catalysis has been used in such cases,<sup>2265</sup> but catalysis by cyanide ion<sup>2266</sup> and acceleration by high pressure<sup>2267</sup> have been reported. Methyl esters<sup>2268</sup> and ethyl esters<sup>2269</sup> have been converted to the corresponding amide under microwave irradiation. The metal-catalyzed reaction of esters and amines gave the amide, using Mg,<sup>2270</sup> In,<sup>2271</sup> Ru,<sup>2272</sup> Au,<sup>2273</sup> Al,<sup>2274</sup> Sm,<sup>2275</sup> La,<sup>2276</sup> Zr,<sup>2277</sup> or Ta<sup>2278</sup> catalysts. Lithium amides have been used to convert esters to amides as well.<sup>2279</sup>  $\beta$ -Keto esters undergo the reaction especially easily.<sup>2280</sup> Aniline was treated with *n*-butyllithium to form the lithium amide, which reacted with an ester to give the amide.<sup>2281</sup> An enzyme-mediated amidation is known using amino cyclase I.<sup>2282</sup> The reaction of dimethyl carbonate and an amine is an effective way to prepare methyl carbamates.<sup>2283</sup> Amides have been prepared from nonnucleophilic amines using flow conditions (Sec. 7.D).<sup>2284</sup> Acetic acid has been used as a catalyst.<sup>2285</sup> The biocatalytic *N*-formylation of amines used ethyl formate as the formylating reagent.<sup>2286</sup>

Amines reacted with the solid-phase reagents macroporous polystyrene-bound 1-hydroxybenzotriazole (P-HOBT) and silica-bound 1-hydroxybenzotriazole (Si-HOBT) to prepare small combinatorial libraries of acetamides and benzamides.<sup>2287</sup> The solvent-free

formylation of amines in protic ionic liquids has been reported.<sup>2288</sup> The solvent-free amidation of esters used ammonium nitrate as a catalyst.<sup>2289</sup>

Lactones give lactams when treated with ammonia or primary amines.<sup>2290</sup> Lactams are also produced from  $\gamma$ - and  $\delta$ -amino esters in an internal example of this reaction. Lactonization has been accomplished in ionic liquids.<sup>2291</sup>

The mechanism of the acylation of amines with carboxylic esters has been extensively studied.<sup>2292</sup> The mechanistic details of the amidation of esters mediated by sodium formate has been studied.<sup>2293</sup> In its broad outlines, the mechanism appears to be essentially  $B_{AC}2$ .<sup>2294</sup> Under the normal basic conditions, the reaction is general base catalyzed,<sup>2295</sup> indicating that a proton is being transferred in the rate-determining step and that two molecules of amine are involved.<sup>2296</sup> Alternatively, another base, such as  $H_2O$  or  $^-OH$ , can substitute for the second molecule of amine. With some substrates and under some conditions, especially at low pH, the breakdown of the tetrahedral intermediate can become rate determining.<sup>2297</sup> The reaction also takes place under acidic conditions and is general acid catalyzed, so that reaction of the tetrahedral intermediate is rate determining.<sup>2298</sup> The reagent used to protonate the alkoxide moiety of the tetrahedral intermediate may be  $R^2NH_3^+$  or another acid. Even under basic conditions, a proton donor may be necessary to assist leaving-group removal. Evidence for this is that the rate is lower with  $^-NR_2$  in liquid ammonia than with  $NHR_2$  in water, apparently owing to the lack of acids to protonate the leaving oxygen.<sup>2299</sup>

In the special case of  $\beta$ -lactones, where small-angle strain is an important factor, alkyl-oxygen cleavage is observed ( $B_{AL}2$  mechanism, as in the similar case of hydrolysis of  $\beta$ -lactones, **16-58**), and the product is not an amide but a  $\beta$ -amino acid ( $\beta$ -alanine). A similar result has been found for certain sterically hindered esters.<sup>2300</sup> This reaction is similar to **10-30**, with  $OCOR$  as the leaving group. Other lactones have been opened to  $\omega$ -hydroxy amides with  $Dibal:BnNH_2$ .<sup>2301</sup>

As in **16-71**, hydrazides and hydroxamic acids can be prepared from carboxylic esters, with hydrazine and hydroxylamine,<sup>2302</sup> respectively. Both hydrazine and hydroxylamine

### 16-75 Acylation of Amines by Amides

This is an exchange reaction and is usually carried out with the salt of the amine.<sup>2305</sup> The leaving group is usually  $\text{NH}_2$  rather than  $\text{NHR}$  or  $\text{NR}_2$  and primary amines (in the form of their salts) are the most common reagents. Boron trifluoride can be added to complex with the leaving ammonia. Neutral amines also react in some cases to give the new amide.<sup>2306</sup> The reaction is catalyzed by  $\text{Al(III)}$ .<sup>2307</sup> The reaction is often used to convert urea to substituted ureas.<sup>2308</sup>

*N*-Alkyl substituted amides (alkyl = R) are converted to *N*-substituted amides (alkyl = R') by treatment with  $\text{N}_2\text{O}_4$  to give an *N*-nitroso compound, followed by treatment of this with a primary amine  $\text{R}'\text{NH}_2$ .<sup>2309</sup> Lactams can be converted to ring-expanded lactams if a side chain containing an amino group is present on the nitrogen. A strong base is used to convert the  $\text{NH}_2$  to  $\text{NH}^-$ , which then acts as a nucleophile, expanding the ring by means of a transamidation.<sup>2310</sup> The discoverers call it the *Zip reaction*.<sup>2311</sup> Lactams can be opened to  $\omega$ -amino amides by reaction with amines at 10 kbar.<sup>2312</sup> An *N*-aryl group of a urea can be converted to a *N,N*-dialkyl group by heating the urea with the amine in an autoclave.<sup>2313</sup>

## 16-76 Acylation of Amides by Miscellaneous Methods

Many acid derivatives, including amides, thiol acids  $\text{RCOSH}$ , thiol esters  $\text{RCOSR}$ ,<sup>2314</sup> acyloxyboranes  $\text{RCO}(\text{OR}')_2$ ,<sup>2315</sup>  $\alpha$ -keto nitriles, acyl azides, and nonenolizable ketones (see the *Haller-Bauer reaction*, **12-33**) can be converted to imide derivatives. *N*-Acylsulfonamides react with primary amines to form the amide ( $\text{AcNHR}$ ).<sup>2316</sup> Carbonylation reactions can be used to prepare amides and related compounds. The reaction of a primary amine and an alkyl halide with  $\text{CO}_2$ , in the presence of  $\text{Cs}_2\text{CO}_3/\text{Bu}_4\text{NI}$ , gave the corresponding carbamate.<sup>2317</sup>

OS **III**, 394; **IV**, 6, 569; **V**, 160, 166; **VI**, 1004.

Imides can be prepared by the attack of amides or their salts on acyl halides, anhydrides, and carboxylic acids or esters.<sup>2318</sup> A good synthetic method for the preparation of acyclic imides is the reaction between an amide and an anhydride at  $100^\circ\text{C}$ , catalyzed by  $\text{H}_2\text{SO}_4$ .<sup>2319</sup> When acyl chlorides are treated with amides in a 2:1 molar ratio at low temperatures in the presence of pyridine, the products are *N,N*-diacylamides,  $(\text{RCO})_3\text{N}$ .<sup>2320</sup> This reaction is often used to prepare urea derivatives, an important example being the preparation of barbituric acid, **51**.<sup>2321</sup>

Heating hydroxylamines with  $\text{PSCl}_3/\text{H}_2\text{O}/\text{NEt}_3$  gave the thioamide.<sup>2322</sup> The acylation of amines or amides with potassium acyltrifloroborates has been reported.<sup>2323</sup> Tertiary amines reacted with arylketenes to form zwitterions, which undergo amine-catalyzed dealkylation to form *N,N*-disubstituted amides.<sup>2324</sup> Isocyanates reacted with trimethyl ketene imines gave the amide.<sup>2325</sup> The ruthenium/*N*-heterocyclic carbene-catalyzed dehydrogenation of methanol allowed reaction with primary or secondary amines to give formamides.<sup>2326</sup> Isonitriles have been important precursors to complex amides.<sup>2327</sup> The boric

### 16-77 Acylation of Azides

The reaction of an aldehyde with sodium azide and  $\text{Et}_4^+ \text{I}^-(\text{OAc})_2$  or polymer-bound  $\text{PhI}(\text{OAc})_2$  leads to an acyl azide.<sup>2332</sup> Acyl azides are also prepared directly from aldehydes using *tert*-butyl hypochlorite.<sup>2333</sup> Acyl azides were prepared by the reaction of carboxylic acids with sodium azide using trichloroisocyanuric acid/triphenylphosphine.<sup>2334</sup>

## F. Attack by Halogen at an Acyl Carbon

### 16-78 Formation of Acyl Halides from Carboxylic Acids

The inorganic acid halides that convert alcohols to alkyl halides (**10-47**) for the most part also convert carboxylic acids to acyl halides.<sup>2335</sup> The reaction is the best and the most common method for the preparation of acyl chlorides. Bromides and iodides<sup>2336</sup> are also made in this manner, but much less often. Thionyl chloride<sup>2337</sup> is a good reagent, since the by-products are gases and the acyl halide is easily isolated, but  $\text{PX}_3$  and  $\text{PX}_5$  ( $\text{X} = \text{Cl}$  or  $\text{Br}$ ) are also commonly used.<sup>2338</sup> Acyl bromides can be prepared with  $\text{BBr}_3$  on alumina<sup>2339</sup> or with ethyl tribromoacetate/ $\text{PPh}_3$ .<sup>2340</sup>

Hydrogen halides do not give the reaction. A particularly mild procedure, similar to one mentioned in **10-47**, involves reaction of the acid with  $\text{Ph}_3\text{P}$  in  $\text{CCl}_4$ , whereupon acyl chlorides are produced without obtaining any acidic compounds as by-products.<sup>2341</sup> The reaction of aryl iodides with CO and a chloride ion source, with a Pd catalyst, gave the acid chloride.<sup>2342</sup> *tert*-Butyl esters reacted with thionyl chloride and water to give the corresponding acid chloride.<sup>2343</sup>

Oxalyl chloride and oxalyl bromide are mild and often superior reagents, since the oxalic acid by-product decomposes to CO and  $\text{CO}_2$ , and the equilibrium is thus driven to the side of the other acyl halide.<sup>2344</sup> These reagents are commonly the reagent of choice, particularly when sensitive functionality is present elsewhere in the molecule.

Acyl halides are also used as reagents in an exchange reaction, which probably involves an anhydride intermediate. This is an equilibrium reaction that must be driven to the desired side. When halide exchange is done, it is always acyl bromides and iodides that are made from chlorides, since chlorides are by far the most readily available.<sup>2345</sup>

OS **I**, 12, 147, 394; **II**, 74, 156, 169, 569; **III**, 169, 490, 547, 555, 613, 623, 712, 714; **IV**, 34, 88, 154, 263, 339, 348, 554, 608, 616, 620, 715, 739, 900; **V**, 171, 258, 887; **VI**, 95, 190, 549, 715; **VII**, 467; **VIII**, 441, 486, 498.

These reactions are most important for the preparation of acyl fluorides.<sup>2346</sup> Acyl fluorides can be prepared by treatment of carboxylic acids with cyanuric fluoride.<sup>2347</sup> *C,N*-Chelated di-*n*-butyltin(IV) fluoride has been used to prepare acyl fluorides.<sup>2348</sup> Acid salts are also sometimes used as substrates. Acyl chlorides and anhydrides can be converted to acyl fluorides by treatment with polyhydrogen fluoride/pyridine solution<sup>2349</sup> or with liquid HF at  $-10^\circ\text{C}$ .<sup>2350</sup> Formyl fluoride, which is a stable compound, was prepared by the latter procedure from the mixed anhydride of formic and acetic acids.<sup>2351</sup> Acyl fluorides can also be obtained by reaction of acyl chlorides with KF in acetic acid<sup>2352</sup> or with diethylaminosulfur trifluoride (DAST).<sup>2353</sup>

### G. Attack by Carbon at an Acyl Carbon<sup>2354</sup>

#### 16-79 The Coupling of Acyl Halides

Acyl halides can be coupled with pyrophoric lead to give symmetrical  $\alpha$ -diketones in a *Wurtz-type reaction*.<sup>2355</sup> The reaction has been performed with R = Me and Ph. Samarium iodide<sup>2356</sup> gives the same reaction. The photochemical coupling of acyl iodides gives  $\alpha$ -diketones.<sup>2357</sup> Benzoyl chloride was coupled to give benzil by subjecting it to ultrasound in the presence of Li wire:<sup>2358</sup>

Unsymmetrical  $\alpha$ -diketones RCOCOR' have been prepared by treatment of an acyl halide (RCOCl) with an acyltin reagent (R'COSnBu<sub>3</sub>), with a Pd complex catalyst.<sup>2359</sup>

#### 16-80 Acylation at a Carbon Bearing an Active Hydrogen

This reaction is similar to **10-67**, but there are fewer examples.<sup>2360</sup> Either Z or Z' may be any of the electron-withdrawing groups listed in **10-67** (such as CO<sub>2</sub>R, COR, CN, etc.).<sup>2361</sup> Anhydrides react similarly but are used less often. The product actually contains three Z groups, since RCO is also a Z group. One or two of these can be cleaved (**12-39**, **12-42**). In this way a compound ZCH<sub>2</sub>Z' can be converted to ZCH<sub>2</sub>Z<sup>2</sup> or an acyl halide (RCOCl) can be converted to a methyl ketone (RCOCH<sub>3</sub>). *O*-Acylation is sometimes a side reaction.<sup>2362</sup> When thallium(I) salts of ZCH<sub>2</sub>Z' are used, it is possible to achieve regioselective acylation at either the C or the O position. For example, treatment of the thallium(I) salt of MeCOCH<sub>2</sub>COMe with acetyl chloride at -78 °C gave >90% *O*-acylation, while acetyl

<sup>2360</sup> For examples of reactions in this section, with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, **1999**, pp. 1484–1485, 1522–1527.

<sup>2361</sup> For an improved procedure, see Rathke, M.W.; Cowan, P.J. *J. Org. Chem.* **1985**, 50, 2622.

<sup>2362</sup> When phase-transfer catalysts are used, *O*-acylation becomes the main reaction: Jones, R.A.; Nokkeo, S.; Singh, S. *Synth. Commun.* **1977**, 7, 195.

fluoride at room temperature gave >95% C-acylation.<sup>2363</sup> The use of an alkyl chloroformate gives triesters.<sup>2364</sup>

The application of this reaction to simple ketones<sup>2365</sup> (in parallel with **10-68**) requires a strong base, such as  $\text{NaNH}_2$  or  $\text{Ph}_3\text{CNa}$ , and is often complicated by O-acylation, which in many cases becomes the principal pathway because acylation at the oxygen is usually much faster. It is possible to increase the proportion of C-acylated product by employing an excess (2–3 molar equivalents) of enolate anion (and adding the substrate to this, rather than vice versa), by the use of a relatively nonpolar solvent and a metal ion (e.g.,  $\text{Mg}^{2+}$ ) which is tightly associated with the enolate oxygen atom, by the use of an acyl halide rather than an anhydride,<sup>2366</sup> and by working at low temperatures.<sup>2367</sup> Simple ketones can also be acylated by treatment of their silyl enol ethers with an acyl chloride in the presence of  $\text{ZnCl}_2$  or  $\text{SbCl}_3$ .<sup>2368</sup> Ketones can be acylated by anhydrides to give  $\beta$ -diketones, with  $\text{BF}_3$  as catalyst.<sup>2369</sup> Simple esters  $\text{RCH}_2\text{CO}_2\text{Et}$  can be acylated at the  $\alpha$  carbon (at  $-78^\circ\text{C}$ ) if a strong base such as lithium *N*-isopropylcyclohexylamide is used to remove the proton.<sup>2370</sup>

Silyl enol esters react with acetic anhydride, in the presence of a chiral Fe complex, to give a chiral  $\beta$ -keto ester.<sup>2371</sup>

### 16-81 Acylation of Carboxylic Esters by Carboxylic Esters: The *Claisen* and *Dieckmann Condensations*

When carboxylic esters containing an  $\alpha$  hydrogen are treated with a strong base, such as sodium ethoxide, a condensation occurs to give a  $\beta$ -keto ester via an ester enolate anion.<sup>2372</sup> This reaction is called the *Claisen condensation*. When it is carried out with a mixture of two different esters, each of which possesses an  $\alpha$  hydrogen (this reaction is called a *mixed Claisen* or a *crossed Claisen condensation*), a mixture of all four products is generally obtained and the reaction is seldom useful synthetically.<sup>2373</sup> However, if only one of the esters has an  $\alpha$  hydrogen, the mixed reaction is frequently satisfactory. Among esters lacking  $\alpha$  hydrogen atoms (hence acting as the substrate ester) that are commonly used in this way are esters of aromatic acids, ethyl carbonate, and ethyl oxalate. When the ester

<sup>2372</sup> See Rablen, P.R.; Bentrup, K.L.H. *J. Am. Chem. Soc.* **2003**, *125*, 2142.

<sup>2373</sup> See Tanabe, Y. *Bull. Chem. Soc. Jpn.* **1989**, *62*, 1917.

enolate reacts with ethyl carbonate, the product is a malonic ester, and reaction with ethyl formate introduces a formyl group. Claisen condensation of phenyl esters with  $ZrCl_4$  and diisopropylethylamine (*Hünigs base*) gave the corresponding keto ester.<sup>2374</sup> Titanium compounds catalyze a crossed-Claisen condensation.<sup>2375</sup> Boron(III) compounds also catalyzed ester condensation reactions.<sup>2376</sup>

As with ketone enolate anions (see **16-34**), the use of amide bases under kinetic control conditions (strong base with a weak conjugate acid, aprotic solvents, low temperatures), allows a mixed Claisen condensation to proceed. Self-condensation of the lithium enolate with the parent ester remains a problem even when LDA is used as a base,<sup>2377</sup> but self-condensation is minimized with LICA.<sup>2378</sup> Note that solvent-free Claisen condensation reactions have been reported.<sup>2379</sup> The In-catalyzed reaction of carboxylic acids and ketene silyl acetals in the presence of  $(MeO)_3SiH$  gave the  $\beta$ -keto ester product.<sup>2380</sup> Acetate derivatives reacted with formate esters in the presence of  $TiCl_4/NEt_3$  to give (*E*)- $\beta$ -alkoxy- and (*E*)- $\beta$ -aryloxyacrylate products.<sup>2381</sup> A phosphorus Claisen condensation is known.<sup>2382</sup>

Retro-Claisen reactions have been reported.<sup>2383</sup>

When the two ester groups are involved in an intramolecular condensation, the product is a cyclic  $\beta$ -keto ester (**52**) and the reaction is called the *Dieckmann condensation*:<sup>2384</sup>

The Dieckmann condensation is most successful for the formation of five-, six-, and seven-membered rings, and yields for rings of 9–12 members are very low or nonexistent. Reactions that form large rings are generally assisted by high dilution. A solvent-free Dieckmann condensation has been reported on solid potassium *tert*-butoxide.<sup>2385</sup> Dieckmann condensation of unsymmetrical substrates can be made regioselective by the use of solid-phase supports.<sup>2386</sup> The Dieckmann condensation has also been done using  $TiCl_3/NBu_3$  with a TMSOTf catalyst.<sup>2387</sup> A Dieckmann-like condensation was reported where an  $\alpha,\omega$ -dicarboxylic acid was heated to 450 °C on graphite, with microwave irradiation, to give

the cyclic ketone.<sup>2388</sup> Piperazine-2,5-diones were prepared by a Dieckmann cyclization route.<sup>2389</sup>

The mechanism of the Claisen and Dieckmann reactions is the ordinary *tetrahedral mechanism*,<sup>2390</sup> with one molecule of ester being converted to an enolate anion by the base and the other serving as the substrate. This reaction illustrates the fact that carboxylic esters react via acyl substitution whereas aldehydes and ketones react via acyl addition.

Ordinary esters react quite well, that is, two Z groups are not needed. A lower degree of acidity ( $pK_a$  about 24–25 for an ester versus  $pK_a$  19–20 for a ketone; Sec. 8.A.i) is sufficient that deprotonation occurs upon treatment with strong base. The initial acid–base deprotonation is an equilibrium but sufficient enolate anion is present to attack the ester substrate. The use of a stronger base, such as  $\text{NaNH}_2$ ,  $\text{NaH}$ , or  $\text{KH}$ ,<sup>2391</sup> often increases the yield.

OS I, 235; II, 116, 194, 272, 288; III, 231, 300, 379, 510; IV, 141; V, 288, 687, 989; VIII, 112.

### 16-82 Acylation of Ketones and Nitriles by Carboxylic Esters

Carboxylic esters can be treated with ketones to give  $\beta$ -diketones. The reaction is so similar to the Claisen condensation that it is sometimes also called the *Claisen reaction*, but this usage may be confusing. A strong base, such as sodium amide or sodium hydride, is required. Yields can be increased by the catalytic addition of crown ethers.<sup>2392</sup> Esters of formic acid ( $\text{R} = \text{H}$ ) give  $\beta$ -keto aldehydes and ethyl carbonate gives  $\beta$ -keto esters.  $\beta$ -Keto esters can also be obtained by treating the lithium enolates of ketones with methyl cyanofornate  $\text{MeOCOCN}$ <sup>2393</sup> (in this case  $\text{CN}$  is the leaving group) and by treating ketones with  $\text{KH}$  and diethyl dicarbonate,  $(\text{EtOCO})_2\text{O}$ .<sup>2394</sup> This reaction has been used to effect cyclization, especially to prepare five- and six-membered rings. Nitriles are frequently used instead of ketones, the products being  $\beta$ -keto nitriles.

Other nucleophilic carbon reagents, such as acetylide ions and ions derived from  $\alpha$ -methylpyridines, can be used. A particularly useful nucleophile is the methylsulfonyl carbanion  $\text{CH}_3\text{SOCH}_2^-$  (the conjugate base of DMSO),<sup>2395</sup> since the  $\beta$ -keto sulfoxide produced can easily be reduced to a methyl ketone (see 10-67). The methylsulfonyl carbanion  $\text{CH}_2\text{SO}_2\text{CH}_2^-$  (the conjugate base of dimethyl sulfone) behaves similarly,<sup>2396</sup> and the product can be similarly reduced. Certain carboxylic esters, acyl halides, and DMF will acylate

<sup>2388</sup> Marquié, J.; Laporterie, A.; Dubac, J.; Roques, N. *Synlett* **2001**, 493.

<sup>2389</sup> Aboussafy, C.L.; Clive, D.L.J. *J. Org. Chem.* **2012**, *77*, 5125.

<sup>2390</sup> An SET mechanism may be involved: Ashby, E.C.; Park, W. *Tetrahedron Lett.* **1983**, 1667. See Nishimura, T.; Sunagawa, M.; Okajima, T.; Fukazawa, Y. *Tetrahedron Lett.* **1997**, *38*, 7063.

<sup>2393</sup> Mander, L.N.; Sethi, P. *Tetrahedron Lett.* **1983**, *24*, 5425.

<sup>2394</sup> Hellou, J.; Kingston, J.F.; Fallis, A.G. *Synthesis* **1984**, 1014.

<sup>2395</sup> See Durst, T. *Adv. Org. Chem.* **1969**, *6*, 285 (pp. 296–301).

<sup>2396</sup> Schank, K.; Hasenfratz, H.; Weber, A. *Chem. Ber.* **1973**, *106*, 1107; House, H.O.; Larson, J.K. *J. Org. Chem.* **1968**, *33*, 61.

1,3-dithianes<sup>2397</sup> (see **10-71**) to give, after oxidative hydrolysis with NBS or NCS,  $\alpha$ -keto aldehydes or  $\alpha$ -diketones.<sup>2398</sup>

As in **10-67**, a ketone is deprotonated at the most acidic proton first and the second most acidic position after that if 2 equivalents of base are used, to give dianion **53**. Thus,  $\beta$ -diketones have been converted to 1,3,5-triketones.<sup>2399</sup> Side reactions are condensation of the ketone with itself (**16-34**), of the ester with itself, and of the ketone with the ester but with the ester supplying the  $\alpha$  position (**16-36**). The mechanism is the same as in **16-81**.<sup>2400</sup> These ions can also be acylated on treatment with a carboxylic ester<sup>2401</sup> to give salts of  $\beta$ -keto acids.

As seen previously (**10-70**), dianions of carboxylic acids can be alkylated in the  $\alpha$  position. The carboxylic acid can be of the form  $\text{RCH}_2\text{CO}_2\text{H}$  or  $\text{RR}^2\text{CHCO}_2\text{H}$ . If the ester is ethyl formate, an  $\alpha$ -formyl carboxylate salt ( $\text{R}' = \text{H}$ ) is formed, which on acidification spontaneously decarboxylates into an aldehyde.<sup>2402</sup> This method accomplishes the conversion  $\text{RCH}_2\text{CO}_2\text{H} \rightarrow \text{RCH}_2\text{CHO}$ , and is an alternative to the reduction methods discussed in **19-43**. When the carboxylic acid is of the form  $\text{RR}^2\text{CHCO}_2\text{H}$ , better yields are obtained by acylating with acyl halides rather than esters.<sup>2403</sup>

### 16-83 Preparation of Acyl Cyanides

Acyl cyanides<sup>2404</sup> can be prepared by treatment of acyl halides with copper cyanide. The mechanism could be free radical or nucleophilic substitution. The reaction has also been accomplished with thallium(I) cyanide,<sup>2405</sup> with  $\text{Me}_3\text{SiCN}$  and an  $\text{SnCl}_4$  catalyst,<sup>2406</sup> and with  $\text{Bu}_3\text{SnCN}$ ,<sup>2407</sup> but these reagents are successful only when  $\text{R} = \text{aryl}$  or tertiary alkyl.

### 16-84 Ketones via Decarboxylation of Carboxylic Acids<sup>2410</sup>

Carboxylic acids can be converted to symmetrical ketones by pyrolysis in the presence of thorium oxide. In a mixed reaction, formic acid and another acid were heated over thorium oxide and gave aldehydes. Mixed alkyl aryl ketones have been prepared by heating mixtures of ferrous salts.<sup>2411</sup> When the R group is large, the methyl ester rather than the acid can be decarbomethoxylated over thorium oxide to give the symmetrical ketone.

The reaction has been performed on dicarboxylic acids, whereupon cyclic ketones are obtained. This process, called *Ruzicka cyclization*, is good for the preparation of rings of six and seven members and, with lower yields, of C<sub>8</sub>–C<sub>10</sub> to C<sub>30</sub> cyclic ketones.<sup>2412</sup>

Not much work has been done on the mechanism of this reaction. However, a free-radical mechanism has been suggested on the basis of a thorough study of all the side products.<sup>2413</sup>

## 16.B.iii. Reactions in Which Carbon Adds to the Heteroatom

### A. Oxygen Adding to the Carbon

#### 16-85 The Ritter Reaction

Alcohols can be added to nitriles in an entirely different manner from that seen in reaction 16-8. In this reaction, the alcohol is converted by a strong acid to an oxonium ion, which loses water to give a carbocation, which is attacked by the nucleophilic nitrogen atom to give 54. Subsequent addition of water to the electrophilic carbon atom leads to the enol form of the amide, which tautomerizes (Sec. 2.N.i) to the *N*-alkyl amide.

<sup>2412</sup> See Ruzicka, L.; Stoll, M.; Schinz, H. *Helv. Chim. Acta* **1926**, *9*, 249; **1928**, *11*, 1174; Ruzicka, L.; Brugger, W.; Seidel, C.F.; Schinz, H. *Helv. Chim. Acta* **1928**, *11*, 496.

<sup>2413</sup> Hites, R.A.; Biemann, K. *J. Am. Chem. Soc.* **1972**, *94*, 5772. See also, Bouchoule, C.; Blanchard, M.; Thomassin, R. *Bull. Soc. Chim. Fr.* **1973**, 1773.

Only alcohols that give rise to fairly stable carbocations react (secondary, tertiary, benzylic, etc.); nonbenzylic primary alcohols do not give the reaction. The carbocation need not be generated from an alcohol but may come from protonation of an alkene or from other sources. In any case, the reaction is called the *Ritter reaction*.<sup>2414</sup> Lewis acids, such as  $\text{Mg}(\text{HSO}_4)_2$ , have been used to promote the reaction.<sup>2415</sup> Highly sterically hindered nitriles have been converted to *N*-methyl amides by heating with methanol and sulfuric acid.<sup>2416</sup> HCN also gives the reaction, the product being a formamide. Trimethylsilyl cyanide has also been used.<sup>2417</sup>

Since the amides (especially the formamides) are easily cleaved to amines under hydrolysis conditions, the Ritter reaction provides a method for achieving the conversions  $\text{R}'\text{OH} \rightarrow \text{R}'\text{NH}_2$  (see **10-31**) and alkene  $\rightarrow \text{R}'\text{NH}_2$  (see **15-8**) in those cases where  $\text{R}'$  can form a relatively stable carbocation. The reaction is especially useful for the preparation of tertiary alkyl amines because there are few alternate ways of preparing these compounds. The reaction can be extended to primary alcohols by treatment with triflic anhydride<sup>2418</sup> or  $\text{Ph}_2\text{CCl}^+ \text{SbCl}_6^-$  or a similar salt<sup>2419</sup> in the presence of the nitrile. A mixture of  $\text{P}_2\text{O}_5$  and silica gel has been used to mediate the Ritter reaction.<sup>2420</sup> There is a Nafion-catalyzed, microwave-assisted variation,<sup>2421</sup> as well as Fe-catalyzed<sup>2422</sup> and iodine-catalyzed<sup>2423</sup> reactions. Organocatalysts have been used.<sup>2424</sup> Amides have been prepared by the Ritter reaction in ionic liquids.<sup>2425</sup>

In a related reaction, cyclic alkanes reacted with a Cu catalyst,  $\text{Zn}(\text{OTf})_2$ , and F-TEDA- $\text{PF}_6$  [1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(hexafluorophosphate), a greener Selectfluor reagent] to give the *N*-alkylacetamide.<sup>2426</sup>

Alkenes of the form  $\text{RCH}=\text{CHR}'$  and  $\text{RR}'\text{C}=\text{CH}_2$  add to nitriles in the presence of mercuric nitrate to give, after treatment with  $\text{NaBH}_4$ , the same amides that would be obtained

by the Ritter reaction.<sup>2427</sup> This method has the advantage of avoiding strong acids. The Ritter reaction can be applied to cyanamides RNHCN to give ureas RNHCONHR'.<sup>2428</sup>

OS V, 73, 471.

### 16-86 The Addition of Aldehydes to Aldehydes

When catalyzed by acids, low molecular weight aldehydes add to each other to give cyclic acetals, the most common product being the trimer.<sup>2429</sup> The cyclic trimer of formaldehyde is called *trioxane*,<sup>2430</sup> and that of acetaldehyde is known as *paraldehyde*. Under certain conditions, it is possible to get tetramers<sup>2431</sup> or dimers. Aldehydes can also polymerize to linear polymers, but a small amount of water is required to form hemiacetal groups at the ends of the chains. The linear polymer formed from formaldehyde is called *paraformaldehyde*. Since trimers and polymers of aldehydes are acetals, they are stable to bases but can be hydrolyzed by acids. Because formaldehyde and acetaldehyde have low boiling points, it is often convenient to use them in the form of their trimers or polymers.

Unsymmetrical alkenes were formed by the reductive coupling of two different aldehydes by reaction of the first aldehyde with a phosphanyl phosphonate to give a phosphoalkene intermediate which, upon activation by hydroxide, reacts with the second aldehyde to give an unsymmetrical (*E*)-alkene.<sup>2432</sup>

## B. Nitrogen Adding to the Carbon

### 16-87 The Addition of Isocyanates to Isocyanates (Formation of Carbodiimides)

The treatment of isocyanates with 3-methyl-1-ethyl-3-phospholene-1-oxide (**55**) is a useful method for the synthesis of carbodiimides<sup>2433</sup> in good yields.<sup>2434</sup> The mechanism does not simply involve the addition of one molecule of isocyanate to another, since the kinetics

<sup>2427</sup> See Fry, A.J.; Simon, J.A. *J. Org. Chem.* **1982**, *47*, 5032.

<sup>2428</sup> Anatol, J.; Berecoechea, J. *Bull. Soc. Chim. Fr.* **1975**, 395; *Synthesis* **1975**, 111.

<sup>2429</sup> See Bevington, J.C. *Q. Rev. Chem. Soc.* **1952**, *6*, 141.

<sup>2430</sup> See Camarena, R.; Cano, A.C.; Delgado, F.; Zúñiga, N.; Alvarez, C. *Tetrahedron Lett.* **1993**, *34*, 6857.

<sup>2432</sup> Esfandiartard, K.; Mai, J.; Ott, S. *J. Am. Chem. Soc.* **2017**, *139*, 2940.

<sup>2433</sup> Williams, A.; Ibrahim, I.T. *Chem. Rev.* **1981**, *81*, 589; Mikolajczyk, M.; Kielbasinski, P. *Tetrahedron* **1981**, *37*, 233; Kurzer, F.; Douraghi-Zadeh, K. *Chem. Rev.* **1967**, *67*, 107.

<sup>2434</sup> Campbell, T.W.; Monagle, J.J.; Foldi, V.S. *J. Am. Chem. Soc.* **1962**, *84*, 3673.

are first order in isocyanate and first order in catalyst. The following mechanism has been proposed (the catalyst is here represented as  $R_3P^+-O^-$ ):<sup>2435</sup>

According to this mechanism, one molecule of isocyanate undergoes addition to  $C=O$ , and the other addition to  $C=N$ . Evidence is that  $^{18}O$  labeling experiments have shown that each molecule of  $CO_2$  produced contains one oxygen atom derived from the isocyanate and one from **55**,<sup>2436</sup> precisely what is predicted by this mechanism. Certain other catalysts are also effective.<sup>2437</sup> High load, soluble oligomeric carbodiimides have been prepared.<sup>2438</sup>

The conversion of 1,3-diphenylthiourea into diphenylcarbodiimide was reported by reaction with [hydroxy(tosyloxy)iodo]benzene and an amine.<sup>2439</sup>

OS V, 501.

## 16-88 The Conversion of Carboxylic Acid Derivatives to Nitriles

Salts of aliphatic or aromatic carboxylic acids can be converted to the corresponding nitriles by heating with  $BrCN$  or  $ClCN$ . Heating with acetonitrile in sulfuric acid also gave the nitrile.<sup>2440</sup> Despite appearances, this is not a substitution reaction. When  $R^{14}COO^-$  was used, the label appeared in the nitrile, not in the  $CO_2$ ,<sup>2441</sup> and optical activity in the  $R$  group was retained.<sup>2442</sup> The acyl isocyanate  $RCON=C=O$  could be isolated from the reaction mixture and a cycloaddition mechanism was proposed.<sup>2441</sup>

The reaction of *N,N*-dimethyl amides, *N*-methoxy-*N*-methyl amides, or isopropyl esters with  $dibalH$ , followed by treatment with  $I_2$  in aqueous ammonia, gave the corresponding nitriles.<sup>2443</sup> Triflic anhydride and 2-fluoropyridine dehydrate secondary amides to give nitriles.<sup>2444</sup> The Fe-catalyzed dehydration of amides to the corresponding nitriles used *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide.<sup>2445</sup>

### C. Carbon Adding to the Carbon

The reactions in this group are cycloadditions.

#### 16-89 The Formation of $\beta$ -Lactones and Oxetanes

Aldehydes, ketones, and quinones react with ketenes to give  $\beta$ -lactones,<sup>2446</sup> diphenylketene being used most often.<sup>2447</sup> The reaction is catalyzed by Lewis acids, and without them most ketenes do not give adducts because the adducts decompose at the high temperatures necessary when no catalyst is used. The phosphine-catalyzed reaction of disubstituted ketenes with aldehydes gave the  $\beta$ -lactone,<sup>2448</sup> and a chiral variation was reported using  $\alpha$ -oxyaldehydes.<sup>2449</sup> The Rh-catalyzed intramolecular C–H insertion into the ester group of aryl diazoacetates led to the asymmetric synthesis of  $\beta$ -lactones.<sup>2450</sup>

When ketene was added to chloral ( $\text{Cl}_3\text{CCHO}$ ) in the presence of the chiral catalyst (+)-quinidine, one enantiomer of the  $\beta$ -lactone was produced with excellent enantioselectivity.<sup>2451</sup> Enantioselective  $\beta$ -lactone formation was accomplished using chiral oxazaborolidines.<sup>2452</sup> The use of a chiral Al catalyst also led to  $\beta$ -lactones with good *syn* selectivity and good enantioselectivity.<sup>2453</sup> Other di- and trihalo aldehydes and ketones also give the reaction enantioselectively, with somewhat lower enantioselectivity.<sup>2454</sup> Dimerization of ketene leads to an alkylidene  $\beta$ -lactone, along with the isomeric conjugated  $\beta$ -lactone. This dimerization is so rapid that ketene does not form  $\beta$ -lactones with aldehydes or ketones, except at low temperatures. Other ketenes dimerize more slowly. In these cases the major dimerization product is not the  $\beta$ -lactone, but a cyclobutanedione (see **15-59**). However, the proportion of ketene that dimerizes to  $\beta$ -lactone can be increased by the addition of catalysts such as triethylamine or triethyl phosphite.<sup>2455</sup> Ketene acetals  $\text{R}_2\text{C}=\text{C}(\text{OR}')_2$  add to aldehydes and ketones in the presence of  $\text{ZnCl}_2$  to give the corresponding oxetanes.<sup>2456</sup>

The chemistry of  $\beta$ -thiolactones has been compared to that of  $\beta$ -lactones.<sup>2457</sup>

16-90 The Formation of  $\beta$ -Lactams

Ketenes add to imines to give  $\beta$ -lactams<sup>2458</sup> in a [2 + 2] cycloaddition product (see **15.54**, **15.55**). This reaction probably occurs by a different mechanism. This alternative mechanism probably involves a radical or dipolar intermediate or it occurs via by HOMO–HOMO or LUMO–LUMO interactions.<sup>2459</sup> The reaction is generally carried out with ketenes of the form  $R_2C=C=O$ . It has not been successfully applied to  $RCH=C=O$ , except when these are generated *in situ* by decomposition of a diazo ketone (the *Wolff rearrangement*, **18-8**) in the presence of the imine. Thioketenes<sup>2460</sup> ( $R_2C=C=S$ ) give  $\beta$ -thiolactams.<sup>2461</sup> Imines also form  $\beta$ -lactams when treated with zinc (or another metal<sup>2462</sup>) and an  $\alpha$ -bromo ester (*Reformatsky* conditions, **16-27**),<sup>2463</sup> or the chromium carbene complexes  $(CO)_5Cr=C(Me)OMe$ .<sup>2464</sup> Ketenes have also been added to certain hydrazones (e.g.,  $PhCH=NNMe_2$ ) to give *N*-amino  $\beta$ -lactams.<sup>2465</sup> A polymer-bound pyridinium salt facilitates  $\beta$ -lactam formation from carboxylic acids and imines.<sup>2466</sup>  $\alpha$ -Chloroimines have been used as chiral inductors in this reaction.<sup>2467</sup> The synthesis of  $\beta$ -lactams with  $\pi$ -electron substituents has been reported.<sup>2468</sup> The cycloreversion of  $\beta$ -lactams is known via photoinduced electron transfer.<sup>2469</sup> The Pd-catalyzed intramolecular amination of aminoquinoline carboxamides using  $C_6F_5I$  generated the  $\beta$ -lactam.<sup>2470</sup> Organocatalysts have been used.<sup>2471</sup> An intramolecular version of this ketene imine reaction is known.<sup>2472</sup> Most of these reactions probably take place by a diionic mechanism (see **15-59**).<sup>2473</sup>

Enantioselective versions of this reaction have been reported.<sup>2474</sup> *N*-Tosyl imines react with ketenes (see **15-59**), Proton Sponge (Sec. 8.A.i), and a chiral amine to give the *N*-tosyl

$\beta$ -lactam with good enantioselectivity.<sup>2475</sup> Catalyzed by a chiral bis(phosphine), ketenes reacted with tosylimines to give the corresponding chiral *N*-tosyl  $\beta$ -lactam.<sup>2476</sup> A chiral ferrocenyl catalyst also gives good enantioselectivity,<sup>2477</sup> and chiral ammonium salts<sup>2478</sup> or chiral *Cinchona* alkaloids<sup>2479</sup> have been used as catalysts. A catalytic amount of benzoyl quinine gives  $\beta$ -lactams with good enantioselectivity.<sup>2480</sup> In a synthesis of  $\beta$ -lactams, LiH-MDS and TMEDA reacted with a chiral 2-imidazolidinone auxiliary followed by addition of an aldimine to give the  $\beta$ -lactam.<sup>2481</sup>

The synthesis of spiro-fused  $\beta$ -lactams has been reviewed.<sup>2482</sup> A theoretical study<sup>2483</sup> of the Cu-catalyzed [2 + 2] cycloaddition of nitrones and alkynes to give  $\beta$ -lactams, called the *Kinusaga reaction*,<sup>2484</sup> has been reported. This reaction has been used for the synthesis of natural products.<sup>2485</sup>

The mechanical activation of a  $\beta$ -lactam mechanophore used ultrasound to induce a formal [2 + 2] cycloelimination reaction that gave a ketene and an imine,<sup>2486</sup> which is formally the reverse reaction of the *Staudinger cycloaddition* (15-59).

The reactive compound chlorosulfonyl isocyanate<sup>2487</sup> (ClSO<sub>2</sub>NCO) forms  $\beta$ -lactams even with unactivated alkenes,<sup>2488</sup> as well as with imines,<sup>2489</sup> allenes,<sup>2490</sup> conjugated dienes,<sup>2491</sup> and cyclopropenes.<sup>2492</sup> With microwave irradiation, alkyl isocyanates also react.<sup>2493</sup> The preparation of *trans*- $\beta$ -lactams by the reaction of imines and aryl-substituted acetic acids used T3P (2,4,6-tripropyl-1,3,5,2,4,6-trioxatriphosphorinane-2,4,6-trioxide solution) as an activating agent.<sup>2494</sup>

$\beta$ -Lactams have also been prepared in the opposite manner by the addition of enamines to isocyanates.<sup>2495</sup>  $\alpha$ -Diazo ketones react with imines and microwave irradiation to give  $\beta$ -lactams.<sup>2496</sup> A different approach to  $\beta$ -lactams involved heating aziridines with CO and

#### 16.B.iv. Addition to Isocyanides<sup>2501</sup>

Addition to  $R-N^+ \equiv C^-$  is not a matter of a species with an electron pair adding to one atom and a species without a pair adding to the other, as is addition to the other types of double and triple bonds in this chapter and Chapter 15. The electrophile and the nucleophile *both add to the carbon*.

#### 16-91 The Addition of Water to Isocyanides

Formamides can be prepared by the acid-catalyzed addition of water to isocyanides. The mechanism probably involves protonation of the isocyanide followed by addition of water.<sup>2502</sup> The reaction has also been carried out under alkaline conditions, with hydroxide in aqueous dioxane.<sup>2503</sup> The mechanism here involves nucleophilic attack by hydroxide at the carbon atom. An intramolecular addition of an alkyne (in an *ortho* alkynyl phenyl isonitrile) to the carbon of an isonitrile occurred with heating in methanol to give quinoline derivatives.<sup>2504</sup>

#### 16-92 The Passerini and Ugi Reactions<sup>2505</sup>

When an isocyanide is treated with a carboxylic acid and an aldehyde or ketone, an  $\alpha$ -acyloxy amide is the product in what is called the *Passerini reaction*.<sup>2506</sup> A  $SiCl_4$ -mediated

<sup>2506</sup> Ramozzi, R.; Morokuma, K. *J. Org. Chem.* **2015**, *80*, 5652. See Chandgude, A.L.; Dömling, A. *Org. Lett.* **2016**, *18*, 6396.

reaction in the presence of a chiral bis-phosphoramidate gives an  $\alpha$ -hydroxy amide with good enantioselectivity.<sup>2507</sup> There is a solvent-free Passerini reaction<sup>2508</sup> and ionic liquids<sup>2509</sup> can be used. The mechanism involves a cyclic transition state and addition of the acid carbonyl oxygen to the isonitrile followed by an acyl rearrangement to give the  $\alpha$ -acyloxy amide. The phosphoric acid-catalyzed Passerini reaction proceeds with good enantioselectivity.<sup>2510</sup>

If ammonia or an amine is also added to the mixture (in which case the reaction is known as the *Ugi reaction*<sup>2511</sup> or the *Ugi four-component condensation*),<sup>2512</sup> the product is  $R'(C=C)NH-C-(C=O)NHR$  (the corresponding bis(amide) from  $NH_3$ ) or  $R'(C=C)NR'-C-(C=O)NHR$  (from a primary amine  $RNH_2$ ).

There is a catalytic *three-component Ugi reaction*.<sup>2513</sup> Repetitive Ugi reactions are known.<sup>2514</sup> This product probably arises from a reaction between the carboxylic acid, the isocyanide, and the *imine* formed from the aldehyde or ketone and ammonia or the primary amine. "Isocyanide-free" Ugi reactions use alkyl halides/silver cyanide and KCN to generate the isocyanide *in situ*.<sup>2515</sup> The use of an *N*-protected amino acid<sup>2516</sup> or peptide as the carboxylic acid component and/or the use of an isocyanide containing a *C*-protected carboxyl group allows the reaction to be used for peptide synthesis.<sup>2517</sup> Rare earth metal triflates catalyze this reaction.<sup>2518</sup>

## 16-93 The Formation of Metalated Aldimines

Isoyanides that do not contain an  $\alpha$  hydrogen react with alkyllithium compounds,<sup>2519</sup> as well as with Grignard reagents, to give lithium (or magnesium) aldimines.<sup>2520</sup> These metalated aldimines are versatile nucleophiles and react with various substrates. The reaction therefore constitutes a method for converting an organometallic compound  $R'M$  to an

aldehyde R'CHO (**12-32**), an  $\alpha$ -keto acid,<sup>2521</sup> a ketone R'COR (**12-32**), an  $\alpha$ -hydroxy ketone, or a  $\beta$ -hydroxy ketone. In each case the C=N bond is hydrolyzed to a C=O bond (**16-2**).

OS VI, 751.

### 16.B.v. Nucleophilic Substitution at a Sulfonyl Sulfur Atom<sup>2522</sup>

Nucleophilic substitution at RSO<sub>2</sub>X is similar to attack at RCOX. Many of the reactions are essentially the same, though sulfonyl halides are less reactive than halides of carboxylic acids.<sup>2523</sup> The mechanisms<sup>2524</sup> are not identical, because a "tetrahedral" intermediate in this case (**56**) would have five groups on the central atom. This is possible since sulfur can accommodate up to 12 electrons in its valence shell, but it seems more likely that these mechanisms more closely resemble the S<sub>N</sub>2 mechanism, with a trigonal-bipyramidal transition state (**57**).

There are two major experimental results leading to this conclusion.

1. The stereospecificity of this reaction is more difficult to determine than that of nucleophilic substitution at a saturated carbon, where chiral compounds are relatively easy to prepare. Recall (see Sec. 4.C, category 2) that optical activity is possible in a compound of the form RSO<sub>2</sub>X if one oxygen is <sup>16</sup>O and the other <sup>18</sup>O. When a sulfonate ester possessing this type of chirality was converted to a sulfone by reaction with a *Grignard reagent* (**16-98**), inversion of configuration was found.<sup>2525</sup> This is not incompatible with an intermediate such as **56** but it is in good accord with an S<sub>N</sub>2-like mechanism with back-side attack.
2. More direct evidence against **56** (though still not conclusive) was found in an experiment involving acidic and basic hydrolysis of aryl arenesulfonates, where it has been shown by the use of <sup>18</sup>O that an intermediate like **56** is not reversibly formed, since ester recovered when the reaction was stopped before completion contained no <sup>18</sup>O when the hydrolysis was carried out in the presence of labeled water.<sup>2526</sup>

Other evidence favoring the S<sub>N</sub>2-like mechanism comes from kinetics and substituent effects.<sup>2527</sup> However, evidence for the mechanism involving **56** is that the rates did not

<sup>2521</sup> See Cooper, A.J.L.; Ginos, J.Z.; Meister, A. *Chem. Rev.* **1983**, 83, 321.

<sup>2526</sup> Kaiser, E.T.; Zaborsky, O.R. *J. Am. Chem. Soc.* **1968**, 90, 4626.

<sup>2527</sup> Arcoria, A.; Ballistreri, F.P.; Spina, E.; Tomaselli, G.A.; Maccarone, E. *J. Chem. Soc., Perkin Trans. 2* **1988**, 1793; Gnedin, B.G.; Ivanov, S.N.; Shchukina, M.V. *J. Org. Chem. USSR* **1988**, 24, 731.

change much with changes in the leaving group<sup>2528</sup> and the  $\rho$  values were large, indicating that a negative charge builds up in the transition state.<sup>2529</sup>

In certain cases in which the substrate carries an  $\alpha$  hydrogen, there is strong evidence<sup>2530</sup> that at least some of the reaction takes place by an elimination–addition mechanism (E1cB, similar to the one shown in **16-68**) going through a *sulfene* intermediate ( $\text{CH}_2=\text{SO}_2$ ),<sup>2531</sup> as in the reaction between methanesulfonyl chloride and aniline to give the sulfonamide.

In the special case of nucleophilic substitution at a sulfonic ester  $\text{RSO}_2\text{OR}'$ , where  $\text{R}'$  is alkyl,  $\text{R}'\text{—O}$  cleavage is much more likely than  $\text{S—O}$  cleavage because the  $\text{OSO}_2\text{R}$  group is such a good leaving group (Sec. 10.G.iii).<sup>2532</sup> Many of these reactions have been considered previously (e.g., **10-4**, **10-10**) as nucleophilic substitutions at an alkyl carbon atom and not at a sulfur atom. However, when  $\text{R}'$  is aryl, then the  $\text{S—O}$  bond is much more likely to cleave because of the low tendency of aryl substrates to undergo nucleophilic substitution.<sup>2533</sup>

The order of nucleophilicity toward a sulfonyl sulfur has been reported as  $\text{OH}^- > \text{RNH}_2 > \text{N}_3^- > \text{F}^- > \text{AcO}^- > \text{Cl}^- > \text{H}_2\text{O} > \text{I}^-$ .<sup>2534</sup> This order is similar to that at a carbonyl carbon (Sec. 10.G.ii). Both of these substrates can be regarded as relatively hard acids, compared to a saturated carbon which is considerably softer and which has a different order of nucleophilicity (Sec. 10.G.ii).

### 16-94 Attack by OH: Hydrolysis of Sulfonic Acid Derivatives and Phosphoric Acid Derivatives

Sulfonyl chlorides as well as esters and amides of sulfonic acids can be hydrolyzed to the corresponding acids. Sulfonyl chlorides can be hydrolyzed with water or with an alcohol in the absence of acid or base. Basic catalysis is also used, though of course the salt is the product obtained. Esters are readily hydrolyzed, many with water or dilute alkali. This is the same reaction as **10-4**, and usually involves  $\text{R}'\text{—O}$  cleavage, except when  $\text{R}'$  is aryl. In some cases, retention of configuration has been shown at alkyl  $\text{R}'$ , indicating  $\text{S—O}$  cleavage.<sup>2535</sup> Sulfonamides are generally *not* hydrolyzed by alkaline treatment, not even with hot concentrated alkali. However, the alkaline hydrolysis of sulfonate esters has been discussed.<sup>2536</sup> Acids, however, do hydrolyze sulfonamides, but less readily than they do sulfonyl halides or sulfonic esters. Of course, ammonia or the amine appears as the salt. However, sulfonamides can be hydrolyzed with base if the solvent is HMPA.<sup>2537</sup>

## 16-95 Attack by OR: Formation of Sulfonic Esters and Phosphoric Esters

Sulfonic esters (sulfonates) are most frequently prepared by treatment of the corresponding sulfonyl halides with alcohols in the presence of a base.<sup>2538</sup> This procedure is the most common method for the conversion of alcohols to tosylates, brosylates, and similar sulfonic esters. Both R and R' may be alkyl or aryl. The base is often pyridine or another amine, which functions as a nucleophilic catalyst.<sup>2539</sup> Primary alcohols react the most rapidly, and it is often possible to sulfonate a primary OH group selectively in a molecule that also contains secondary or tertiary OH groups. The reaction with sulfonamides has been much less frequently used and is limited to *N,N*-disubstituted sulfonamides. The nucleophile in this case is actually RO<sup>-</sup>. Acidic catalysts are used in this case.<sup>2540</sup> Sulfonic acids have been converted directly to sulfonates by treatment with triethyl or trimethyl orthoformate HC(OR)<sub>3</sub>, without catalyst or solvent,<sup>2541</sup> and with a trialkyl phosphite, P(OR)<sub>3</sub>.<sup>2542</sup>

Thiols were oxidized by reaction with ZnCr<sub>2</sub>O<sub>7</sub>·3H<sub>2</sub>O to give thiosulfonates.<sup>2543</sup> Asymmetric thiosulfonates were prepared by the Fe-catalyzed reaction of thiols and sodium sulfonates.<sup>2544</sup>

The Cu-catalyzed reaction of dialkyl phosphonates with diaryliodonium salts gave monoarylated alkyl aryl phosphonates.<sup>2545</sup> Benzyl phosphonate esters were prepared by the reaction of benzylic alcohols with P(OEt)<sub>3</sub> and ZnI<sub>2</sub>.<sup>2546</sup> The Zn-mediated reaction gave dialkyl and diaryl benzylphosphonates. The phosphorylation of alcohols to give the corresponding phosphate monoesters via reaction with trichloroacetonitrile gave the organophosphate as the ammonium salt.<sup>2547</sup> The phosphorylation of alcohols was reported by the reaction with triallyl phosphite and molecular iodine.<sup>2548</sup> The esterification of alkylphosphonic acids to give the phosphonate involved the reaction of primary alcohols, iodine, imidazole and polymer-bound triphenylphosphine.<sup>2549</sup>

The preparation of thiophosphates used diphenylphosphine oxide and sulfonyl chlorides.<sup>2550</sup>

Amines, alcohols, and sulfoximines reacted with phosphites with a molecular iodine catalyst and H<sub>2</sub>O<sub>2</sub> as oxidant to give phosphoramidates, phosphorus triesters, and sulfoximine-derived phosphoramidites, respectively.<sup>2551</sup>

## 16-96 Attack by Nitrogen: Formation of Sulfonamides and Phosphoramides

The reaction of amines with a sulfonation reagent leads to the sulfonamide,<sup>2552</sup> and the functionalization of sulfonamides has been reviewed.<sup>2553</sup> The treatment of sulfonyl chlorides with ammonia or amines is the usual way of preparing sulfonamides.<sup>2554</sup> Nonracemic sulfonamides have been prepared.<sup>2555</sup> Primary amines give *N*-alkyl sulfonamides, and secondary amines give *N,N*-dialkyl sulfonamides. The reaction is the basis of the *Hinsberg test* for distinguishing between primary, secondary, and tertiary amines. *N*-Alkyl sulfonamides, having an acidic hydrogen, are soluble in alkali, while *N,N*-dialkyl sulfonamides are not. Since tertiary amines are usually recovered unchanged, primary, secondary, and tertiary amines can be told apart. However, the test is limited for at least two reasons:<sup>2556</sup> (i) many *N*-alkyl sulfonamides in which the alkyl group has six or more carbons are insoluble in alkali, despite their acidic hydrogen,<sup>2557</sup> so that a primary amine may appear to be a secondary amine, and (ii) if the reaction conditions are not carefully controlled, tertiary amines may not be recovered unchanged.<sup>2542</sup> A primary or a secondary amine can be protected by reaction with phenacylsulfonyl chloride ( $\text{PhCOCH}_2\text{SO}_2\text{Cl}$ ) to give a sulfonamide ( $\text{RNHSO}_2\text{CH}_2\text{COPh}$  or  $\text{R}_2\text{NSO}_2\text{CH}_2\text{COPh}$ ).<sup>2558</sup> The protecting group can be removed when desired with zinc and acetic acid.

The iodine-catalyzed reaction of amines with arylsulfonyl hydrazides in the presence of TBHP gave sulfonamides.<sup>2559</sup> Sulfonamides were prepared by the electrochemical oxidative amination of sodium sulfinates with amines using a substoichiometric amount of  $\text{NH}_4\text{I}$ .<sup>2560</sup> The reaction between *N*-tosylhydrazone, amines, and DABSO [DABCO-bis(sulfur dioxide)] as a  $\text{SO}_2$  source gave alkyl sulfonamides.<sup>2561</sup> Arylboronic acids reacted with  $\text{F}_3\text{SNEt}_2$  to give the sulfonamide, which was oxidized.<sup>2562</sup> The reaction of aryl sulfonyl chlorides and  $\text{Ph}_3\text{SiNH}_2$  gave the primary sulfonamide, and reaction with  $\text{PhNHSiMe}_3$  gave the *N*-aryl sulfonamide.<sup>2563</sup> The ultrasonic irradiation of methyl sulfinates and primary or secondary amines (neat) gave sulfonamides, and subsequent mcpba oxidation gave the corresponding sulfonamide.<sup>2564</sup> The reaction of  $\text{PhSO}_2\text{Na}$ , benzylamine,  $\text{Bu}_4\text{NBr}$ , and mcpba gave *N*-benzyl benzenesulfonamide.<sup>2565</sup>

An alternative synthesis of sulfonamides involved the reaction of allyltrityltin with  $\text{PhI}=\text{NTs}$  in the presence of copper (II) triflate.<sup>2566</sup> The Rh- and Ag-catalyzed reaction

### 16-97 Attack by Halogen: Formation of Sulfonyl Halides and Phosphoryl Halides

This reaction, parallel with 16-78, is the standard method for the preparation of sulfonyl halides. Both  $\text{PCl}_3$  and  $\text{SOCl}_2$  have been used, and sulfonic acid salts can also serve as substrates. Cyanuric acid (2,4,6-trichloro[1,3,5]triazene) serves as a chlorinating agent.<sup>2571</sup> Sulfonyl bromides and iodides have been prepared from sulfonyl hydrazides ( $\text{ArSO}_2\text{NHNH}_2$ , themselves prepared by 16-96) by treatment with bromine or iodine.<sup>2572</sup> Sulfonyl fluorides are generally prepared from the chlorides, by halogen exchange.<sup>2573</sup> Alkanesulfonyl chlorides were prepared by the reaction of *S*-alkyl isothioureia salts with aqueous bleach and 2 M HCl.<sup>2574</sup>

OS I, 84; IV, 571, 693, 846, 937; V, 196. See also, OS VII, 495.

### 16-98 Attack by Carbon: Preparation of Sulfones

There are many methods for the synthesis of sulfones.<sup>2575</sup> Grignard reagents convert aromatic sulfonyl chlorides or aromatic sulfonates to sulfones. Organolithium reagents react with sulfonyl fluorides at  $-78^\circ\text{C}$  to give the corresponding sulfone.<sup>2576</sup> Aromatic sulfonates have been converted to sulfones with organolithium compounds,<sup>2577</sup> with aryltin compounds,<sup>2578</sup> with an Fe catalyst,<sup>2579</sup> and with alkyl halides and Zn metal.<sup>2580</sup> Vinylic and allylic sulfones have been prepared by treatment of sulfonyl chlorides with a vinylic

# Elimination Reactions

A general feature of elimination reactions is that the atom bearing a leaving group is the  $\alpha$  atom and the adjacent atom is the  $\beta$  atom. A so-called  $\beta$ -elimination reaction occurs when two groups are lost from adjacent atoms so that a new double<sup>1</sup> (or triple) bond is formed.<sup>2</sup> In an  $\alpha$ -elimination both groups are lost from the same atom to give a carbene (or a nitrene). In a  $\gamma$ -elimination, a three-membered ring is formed.

Some of these processes were discussed in Chapter 10. Another type of elimination involves the expulsion of a fragment from within a chain or ring ( $X-Y-Z \rightarrow X-Z+Y$ ). Such reactions are called *extrusion reactions*. This chapter discusses  $\beta$ -elimination and extrusion reactions (Sec. 2.F.vi), but  $\beta$ -elimination in which both X and Z are hydrogen atoms are oxidation reactions and are treated in Chapter 19.

## 17A. MECHANISMS AND ORIENTATION

There are two  $\beta$ -elimination reactions that are categorized here. One type takes place largely in solution, while the other (pyrolytic elimination) takes place mostly in the gas phase. In the reactions, one group leaves with its electrons and the other without (i.e., it is pulled off), with the latter most often being hydrogen. In these cases, the former group is the *leaving group* or *nucleofuge*. Substitution reactions can sometimes compete with elimination reactions.<sup>3</sup> For pyrolytic eliminations, there are two principal mechanisms, one pericyclic and the other a free-radical pathway. A few photochemical eliminations are also known (the most important is Norrish type II cleavage of ketones, Sec. 7.A.vii), but these are not generally of synthetic importance<sup>4</sup> and will not be discussed further. In most  $\beta$ -eliminations the new bonds are  $C=C$  or  $C\equiv C$ ; the discussion of mechanisms is largely confined to these cases.<sup>5</sup>

Mechanisms in solution (E2, E1)<sup>6</sup> and E1cB are discussed first. While standard methods are used to examine elimination reactions, new techniques such as the velocity map ion imaging technique have been used to study ultrafast elimination reactions.<sup>7</sup>

### 17.A.i. The E2 Mechanism

In the E2 mechanism (elimination, bimolecular), the proton on the  $\beta$  carbon is pulled off by a base, leading to near-simultaneous expulsion of the leaving group (known as a nucleofuge):

The mechanism takes place in one step and is kinetically second order: first order in substrate and first order in base. An *ab initio* study has produced a model for the E2 transition state geometry.<sup>8</sup> The IUPAC designation is  $A_{\text{xH}}D_{\text{H}}D_{\text{N}}$  or, more generally (to include cases where the electrofuge is not hydrogen),  $A_{\text{n}}D_{\text{E}}D_{\text{N}}$ . This type of elimination often competes with the  $S_{\text{N}}2$  mechanism (Sec. 10.A.i).<sup>9</sup> With respect to the substrate, the difference between the two pathways is whether the species with the unshared pair attacks the carbon (and thus acts as a nucleophile) or attacks the hydrogen (and thus acts as a base).

Evidence for the existence of the E2 mechanism includes: (i) the reaction displays the proper second-order kinetics; and (ii) when the hydrogen is replaced by deuterium in second-order eliminations, there is an isotope effect of from 3 to 8, consistent with breaking of this bond in the rate-determining step.<sup>10</sup> However, neither of these results alone could prove an E2 mechanism, since both are compatible with other mechanisms also (e.g., see E1cB, Sec. 17.A.iii). The most compelling evidence for the E2 mechanism is found in stereochemical studies.<sup>11</sup>

As will be illustrated in the examples, the E2 mechanism is stereospecific: the five atoms involved (including the base) in the transition state must be in one plane. There are two ways for this to happen. The H and X may be *trans* to one another (**A**) with a dihedral angle of  $180^\circ$ , or they may be *cis* (**B**) with a dihedral angle of  $0^\circ$ .<sup>12</sup>

<sup>12</sup> DePuy, C.H.; Morris, G.F.; Smith, J.S.; Smat, R.J. *J. Am. Chem. Soc.* **1965**, *87*, 2421.

Conformation **A** is called *anti-periplanar*, and this type of elimination, in which H and X depart in opposite directions, is called *anti elimination*. Conformation **B** is *syn-periplanar*, and this type of elimination, with H and X leaving in the same direction, is called *syn elimination*. Many examples of both kinds have been discovered. If the reaction with base to remove the  $\beta$ -hydrogen atom is intermolecular, *anti* elimination is greatly favored over *syn* elimination, largely because the *anti* transition state molecule requires less energy and the molecule is expected to have a greater percentage of this conformation. If the base is “tethered” to the molecule such that approach to the  $\beta$ -hydrogen atom must be intramolecular, the higher energy eclipsed transition state **B** is required for reaction and much less of this conformation is expected. Solvent effects play an important role in the conformational preference. Several experimental details confirm these hypotheses.

1. The elimination is stereospecific. Elimination of HBr from *meso*-1,2-dibromo-1,2-diphenylethane gave *cis*-2-bromostilbene, while the (+) or (–) isomer gave the *trans* isomer. This stereospecific result was obtained in 1904,<sup>13</sup> and demonstrated that in this case elimination is *anti*. Many similar examples have been discovered since. *Anti* elimination requires that an *erythro dl* pair (or either isomer) give the *cis* alkene, and the *threo dl* pair (or either isomer) give the *trans* isomer, which has been confirmed many times. *Anti* elimination has also been demonstrated in cases where the electrofuge is not hydrogen. In the reaction of 2,3-dibromobutane with iodide ion, the two bromines are removed (**17-20**).<sup>14</sup>
2. In open-chain compounds, rotation about C–C bonds usually leads to a conformation in which H and X are anti-periplanar. However, in cyclic systems this is not always the case. There are nine stereoisomers of 1,2,3,4,5,6-hexachlorocyclohexane: seven *meso* forms and a *dl* pair (Sec. 4.G). Four of the *meso* compounds and the *dl* pair were treated with base to initiate elimination. Only one of these (**1**) has no Cl that is *trans* to an H. Of the other isomers, the fastest elimination rate was about three times as fast as the slowest, but the rate for **1** was 7000 times slower than that of the slowest of the other isomers.<sup>15</sup> This result demonstrates that *anti* elimination is greatly favored over *syn* elimination, although the latter must be taking place on **1**, but very slowly, to be sure.

<sup>13</sup> Pfeiffer, P. *Z. Phys. Chem.* **1904**, *48*, 40.

<sup>14</sup> Winstein, S.; Pressman, D.; Young, W.G. *J. Am. Chem. Soc.* **1939**, *61*, 1645.

<sup>15</sup> Cristol, S.J.; Hause, N.L.; Meek, J.S. *J. Am. Chem. Soc.* **1951**, *73*, 674.

3. The preceding result shows that elimination of HCl in a six-membered ring proceeds best when the H and X are *trans* and diaxial to each other. Adjacent *trans* groups on a six-membered ring can be diaxial or diequatorial (Sec. 4.O.ii) and the molecule will exist in both conformations. Barring special circumstances, the conformation with the most groups in the axial position will have a higher energy, and that with the most equatorial groups will have the lower energy. For an E2-type reaction, the  $\beta$ -hydrogen that is removed by the base must be anti-periplanar to the leaving group, which requires that the leaving group and the  $\beta$ -hydrogen atom be *trans* and diaxial, if this is the conformation of higher energy.

The results with menthyl and neomenthyl chlorides are interpretable on the basis of a *trans* diaxial relationship of the  $\beta$ -hydrogen and the leaving group. Menthyl chloride has two chair conformations, **2** and **3**. Compound **3**, in which the three substituents are all equatorial, is the more stable and less reactive. The more stable chair conformation of neomenthyl chloride is **4**, in which the chlorine is axial, and there are axial hydrogen atoms on both C-2 and C-4. The results are: neomenthyl chloride gives rapid E2 elimination and the alkene produced is predominantly **6** (**6/5** ratio is  $\sim 3:1$ ) in accord with *Zaitsev's rule* (see **12-2**, Sec. 17.B). Since an axial hydrogen is available on both sides, this factor does not control the direction of elimination and *Zaitsev's rule* is free to operate. In other words, the more substituted, and more stable, alkene (**5**) is the product. For menthyl chloride, elimination is much slower and the product is entirely the anti-*Zaitsev* alkene **5**. It is slow because the unfavorable conformation **2** must be achieved before elimination can take place. There an axial hydrogen only on this side so the product is **5**.<sup>16</sup>

4. *Anti* elimination also occurs in the formation of triple bonds, as shown by elimination from *cis*- and *trans*-HO<sub>2</sub>C-CH=C(Cl)CO<sub>2</sub>H. In this case, the product in both

<sup>16</sup> Hughes, E.D.; Ingold, C.K.; Rose, J.B. *J. Chem. Soc.* **1953**, 3839.

cases is  $\text{HO}_2\text{C}\equiv\text{CCO}_2\text{H}$ , but the *trans* isomer reacts  $\sim 50$  times faster than the *cis* compound.<sup>17</sup>

Some examples of *syn* elimination have been found in molecules where H and X could not achieve an anti-periplanar conformation.

1. The deuterated norbornyl bromide (**7**, X = Br) gave 94% of the product containing no deuterium.<sup>18</sup> Similar results were obtained with other leaving groups and with bicyclo[2.2.2] compounds.<sup>19</sup>

In these cases the *exo* X group cannot achieve a dihedral angle of  $180^\circ$  with the *endo*  $\beta$  hydrogen because of the rigid structure of the molecule. The dihedral angle here is  $\sim 120^\circ$ . *Syn* elimination with a dihedral angle of  $\sim 0^\circ$  is clearly preferred to *anti* elimination where the angle is restricted to  $\sim 120^\circ$ .

2. Molecule **8** is a particularly graphic example of the need for a planar transition state. In **8**, each Cl has an adjacent hydrogen *trans* to it, and if planarity of leaving groups were not required, *anti* elimination could easily take place. However, the crowding of the rest of the molecule forces the dihedral angle to be  $\sim 120^\circ$ , and elimination of HCl from **8** is much slower than from corresponding nonbridged compounds.<sup>20</sup> Note that *syn* elimination from **8** is even less likely than *anti* elimination. *Syn* elimination can take place from the *trans* isomer of **8** (dihedral angle  $\sim 0^\circ$ ); this isomer reacted about eight times faster than **8**.<sup>20</sup>

The examples given so far illustrate two points. (i) *Anti* elimination requires a dihedral angle of  $180^\circ$ . When this angle cannot be achieved, *anti* elimination is greatly slowed or prevented entirely. (ii) For the simple systems so far discussed *syn* elimination is not found to any significant extent unless *anti* elimination is greatly diminished by failure to achieve the  $180^\circ$  angle.

The concept of vinylogy was introduced in Sec. 6.B and in **10-68**, category 4. Using this concept, a 1,2-elimination can be extended to give a 1,*x*-elimination when  $\pi$  bonds are incorporated between the carbon bearing the acidic proton and the leaving group: e.g.,  $\text{X}-\text{C}-\text{C}=\text{C}-\text{C}$ ,  $\text{X}-\text{C}-\text{C}=\text{C}-\text{C}=\text{C}-\text{C}$ , or  $\text{X}-\text{C}-\text{C}\equiv\text{C}-\text{C}$ .<sup>21</sup>

As noted in Sec. 4.Q.ii, six-membered rings are the only ones among rings of 4–13 members in which strain-free anti-periplanar conformations can be achieved. It is not surprising,

<sup>17</sup> Michael, A. *J. Prakt. Chem.* **1895**, 52, 308. See also, Marchese, G.; Naso, F.; Modena, G. *J. Chem. Soc. B* **1968**, 958.

<sup>18</sup> Kwart, H.; Takeshita, T.; Nyce, J.L. *J. Am. Chem. Soc.* **1964**, 86, 2606.

<sup>19</sup> See Bartsch, R.A.; Lee, J.G. *J. Org. Chem.* **1991**, 56, 212, 2579.

<sup>20</sup> Cristol, S.J.; Hause, N.L. *J. Am. Chem. Soc.* **1952**, 74, 2193.

<sup>21</sup> See Werner, C.; Hopf, H.; Dix, I.; Bubenitschek, P.; Jone, P.G. *Chem. Eur. J.* **2007**, 13, 9462.

therefore, that *syn* elimination is least common in six-membered rings. Cycloalkyltrimethylammonium hydroxides were subjected to elimination (**17-6**) and the following percentages of *syn* elimination were found with each ring size: four-membered, 90%; five-membered, 46%; six-membered, 4%; seven-membered, 31–37%.<sup>22</sup> Note that the  $\text{NMe}_3^+$  group has a greater tendency to *syn* elimination than do other common leaving groups, such as OTs, Cl, and Br.

Other examples of *syn* elimination have been found in medium-ring compounds, where both *cis* and *trans* alkenes are possible (Sec. 4.K.i). The elimination reaction of 1,1,4,4-tetramethyl-7-cyclodecyltrimethylammonium chloride,<sup>23</sup> for example, gave mostly *trans*- but also some *cis*-tetramethylcyclodecenes as products. Note that *trans*-cyclodecenes, although stable, are less stable than the *cis* isomers. In order to determine the stereochemistry of the reaction, the elimination was repeated, this time using deuterated substrates. When deuterated in the *trans* position, there was a substantial isotope effect in the formation of both *cis* and *trans* alkenes, but when deuterated in the *cis* position, there was no isotope effect in the formation of either alkene. Since an isotope effect is expected for an E2 mechanism,<sup>24</sup> these results indicated that *only* the *trans* hydrogen ( $\text{H}_t$ ) was lost, whether the product was the *cis* or the *trans* isomer.<sup>25</sup> In turn, this result means that *the cis isomer must have been formed by anti elimination and the trans isomer by syn elimination*. Anti elimination could take place from approximately the *anti* conformation, but for *syn* elimination the molecule must twist into a conformation in which the C–H and C– $\text{NMe}_3^+$  bonds are *syn*-periplanar. Other types of evidence have also demonstrated this remarkable result, called the *syn/anti* dichotomy.<sup>26</sup> The fact that *syn* elimination in this case predominates over *anti* (as indicated by the formation of *trans* isomer in greater amounts than *cis*) has been explained by conformational factors.<sup>27</sup> The *syn/anti* dichotomy has also been found in other medium-ring systems (8- to 12-membered rings),<sup>28</sup> although the effect is greatest for 10-membered rings. With leaving groups,<sup>29</sup> the extent of this behavior decreases in the order  $^+\text{NMe}_3 > \text{OTs} > \text{Br} > \text{Cl}$ , which parallels steric requirements. When the leaving group is unchanged, *syn* elimination is favored by strong bases and by weakly ionizing solvents.<sup>30</sup>

*Syn* elimination and the *syn/anti* dichotomy have also been found in open-chain systems, although to a lesser extent than in medium-ring compounds. For example, in the conversion of 3-hexyl-4-*d*-trimethylammonium ion to hex-3-ene with potassium *sec*-butoxide, ~67% of the reaction followed the *syn/anti* dichotomy.<sup>31</sup> In general *syn* elimination in open-chain systems is only important in cases where certain types of steric effect are present. One such type is compounds in which substituents are found on both the  $\beta'$  and the  $\gamma$  carbons

<sup>22</sup> Cooke Jr., M.P.; Coke, J.L. *J. Am. Chem. Soc.* **1968**, *90*, 5556. See also, Coke, J.L.; Smith, G.D.; Britton Jr., G.H. *J. Am. Chem. Soc.* **1975**, *97*, 4323.

<sup>23</sup> Závada, J.; Svoboda, M.; Sicher, J. *Collect. Czech. Chem. Commun.* **1968**, *33*, 4027.

<sup>24</sup> Other possible mechanisms, such as E1cB (Sec. 17.A.iii) or  $\alpha',\beta$  elimination (**17-8**), were ruled out in all these cases by other evidence.

<sup>25</sup> This conclusion has been challenged by Coke, J.L. *Sel. Org. Transform* **1972**, *2*, 269.

(the unprimed letter refers to the branch in which the elimination takes place). The factors that cause these results are not completely understood, but the following conformational effects have been proposed as a partial explanation.<sup>32</sup> The two anti-periplanar and two syn-periplanar conformations are, for a quaternary ammonium salt:

In order for an E2 mechanism to take place, a base must approach the proton marked\*, which is anti-periplanar to the ammonium leaving group (C). In C, removal of this proton by *anti* elimination leads to the *trans* product. In D, *anti* elimination would give more *cis* product than *trans*. When *syn* elimination begins to appear, it seems clear that E, which has fewer eclipsing interactions than F, should be favored and *syn* elimination should generally give the *trans* isomer. Predominant *syn* elimination has also been found in compounds of the form  $R^1R^2CHCHDNMe_3^+$ , where  $R^1$  and  $R^2$  are both bulky.<sup>33</sup> In this case, the conformation leading to *syn* elimination (H) is also less strained than G, which gives *anti* elimination. The G compound has three bulky groups (including  $NMe_3^+$ ) in the *gauche* position to each other.

It was mentioned above that weakly ionizing solvents promote *syn* elimination when the leaving group is uncharged. This is probably caused by ion pairing, which is greatest in non-polar solvents.<sup>34</sup> Ion pairing can cause *syn* elimination with an uncharged leaving group by means of the transition state shown in 9. This effect was graphically illustrated by elimination from 1,1,4,4-tetramethyl-7-cyclodecyl bromide.<sup>35</sup> The ratio of *syn* to *anti* elimination when this compound was treated with *t*-BuOK in the nonpolar benzene was 55.0. When the crown ether dicyclohexano-18-crown-6 was added (this compound selectively removes  $K^+$  from the  $t\text{-BuO}^- K^+$  ion pair and thus leaves  $t\text{-BuO}^-$  as a free ion), the *syn/anti* ratio decreased to 0.12. Large decreases in the *syn/anti* ratio on addition of the crown ether were

<sup>35</sup> Svoboda, M.; Hapala, J.; Závada, J. *Tetrahedron Lett.* **1972**, 265.

also found with the corresponding tosylate and with other nonpolar solvents.<sup>36</sup> However, with positively charged leaving groups the effect is reversed. Here, ion pairing *increases* the amount of *anti* elimination.<sup>37</sup> In this case, a relatively free base (e.g.,  $\text{PhO}^-$ ) can be attracted to the polar leaving group, putting it in a favorable position for attack on the *syn*  $\beta$  hydrogen, while ion pairing would reduce this attraction.

It can be concluded that *anti* elimination is generally favored in the E2 mechanism, but that steric (inability to form the anti-periplanar transition state), conformational, ion-pairing, and other factors cause *syn* elimination to intervene (and even predominate) in some cases.

### 17.A.ii. The E1 Mechanism

The E1 mechanism is a two-step process in which the rate-determining step is ionization of the substrate to give a carbocation that rapidly loses a  $\beta$  proton to a base, usually the solvent.

The IUPAC designation is  $\text{D}_\text{N} + \text{D}_\text{E}$  (or  $\text{D}_\text{N} + \text{D}_\text{H}$ ). This mechanism normally operates without an *added* base. Just as the E2 mechanism competes with the  $\text{S}_\text{N}2$ ,<sup>38</sup> so the E1 mechanism competes with the  $\text{S}_\text{N}1$ . In fact, the first step of the E1 is exactly the same as that of the  $\text{S}_\text{N}1$  mechanism. The second step differs in that the solvent pulls a proton from the  $\beta$  carbon of the carbocation rather than attacking it at the positively charged carbon, as in the  $\text{S}_\text{N}1$  process. In a pure E1 reaction (without ion pairs, etc.), the product should be completely nonstereospecific, since a carbocation should be planar with no facial differentiation, and bond rotation is possible before deprotonation.

Some of the evidence for the E1 mechanism is as follows:

1. The reaction exhibits first-order kinetics (in substrate) as expected, since ionization to the carbocation is the slow step. Of course, the solvent is not expected to appear in the rate equation, even if it were involved in the rate-determining step (Sec. 6.J.vi), but this point can be easily checked by adding a small amount of the conjugate base of the solvent. It is generally found that such an addition does not increase the rate of the reaction. If this more powerful base does not enter into the rate-determining step, it is unlikely that the solvent does. An example of an E1 mechanism with a rate-determining second step (proton transfer) has been reported.<sup>39</sup>
2. If the reaction is performed on two molecules that differ only in the leaving group (e.g., *t*-BuCl and *t*-BuSMe<sub>2</sub><sup>+</sup>), the rates should obviously be different, since they depend on the ionizing ability of the molecule. However, once the carbocation is formed, if the solvent and the temperature are the same, it should suffer the same

<sup>36</sup> See Croft, A.P.; Bartsch, R.A. *Tetrahedron Lett.* **1983**, 24, 2737; Kwart, H.; Gaffney, A.H.; Wilk, K.A. *J. Chem. Soc., Perkin Trans. 2* **1984**, 565.

<sup>37</sup> Borchardt, J.K.; Saunders Jr., W.H. *J. Am. Chem. Soc.* **1974**, 96, 3912.

<sup>38</sup> Villano, S.M.; Eyet, N.; Lineberger, W.C.; Bierbaum, V.M. *J. Am. Chem. Soc.* **2009**, 131, 8227.

<sup>39</sup> Baciocchi, E.; Clementi, S.; Sebastiani, G.V.; Ruzziconi, R. *J. Org. Chem.* **1979**, 44, 32.

fate in both cases. This means that the nature of the leaving group does not affect the second step, and *the ratio of elimination to substitution should be the same*. The two compounds mentioned here were solvolized at 65.3 °C in 80% aqueous ethanol. *tert*-Butyl chloride gave 36.3% of 2-methylprop-1-ene and 63.7% of *tert*-butanol. *t*-BuSMe<sub>2</sub><sup>+</sup> gave 35.7% of 2-methylprop-1-ene and 64.3% of *tert*-butanol.<sup>40</sup> Although the rates were greatly different (as expected with such different leaving groups), the product ratios were the same, within 1%. If these reactions had taken place by a second-order mechanism, the nucleophile would not be expected to have the same ratio of preference for attack at the β hydrogen compared to attack at a *neutral* chloride as for attack at the β hydrogen compared to attack at a *positive* SMe<sub>2</sub> group.

3. Many reactions carried out under first-order conditions on systems where E2 elimination is *anti* proceed quite readily to give alkenes where a *cis* hydrogen must be removed, often in preference to the removal of a *trans* hydrogen. For example, menthyl chloride (**2**), which by the E2 mechanism gave only **5**, under E1 conditions gave 68% **6** and 32% **5**, since the steric nature of the hydrogen is no longer a factor here, and the more stable alkene (*Zaitsev's rule*, **12-2**) is predominantly formed.
4. If carbocations are intermediates, rearrangements should occur with suitable substrates. These have often been found in elimination reactions performed under E1 conditions.

E1 reactions can involve ion pairs, just as is true for S<sub>N</sub>1 reactions (Sec. 10A.iii).<sup>41</sup> This effect is naturally greatest for nondissociating solvents: It is least in water, greater in ethanol, and greater still in acetic acid. It has been proposed that the ion-pair mechanism (Sec. 10.A.iii, category 1) extends to elimination reactions too, and that the S<sub>N</sub>1, S<sub>N</sub>2, E1, and E2 mechanisms possess an ion-pair intermediate in common, at least occasionally.<sup>42</sup>

### 17A.iii. The E1cB Mechanism<sup>43</sup>

In the E1 mechanism, X leaves first and then H is removed. In the E2 mechanism, H is removed, which triggers the expulsion of X. However, there is a third possibility: the H is removed first to form a carbanion β to the leaving group (X), and then X is expelled. This is a two-step process, called the *E1cB mechanism*,<sup>44</sup> or the *carbanion mechanism*, since the intermediate is a carbanion that “kicks out” the leaving group. The name E1cB comes from the fact that it is the conjugate base of the substrate that is giving up the leaving group (see the S<sub>N</sub>1cB mechanism, Sec. 10.G.iii, category 1). The IUPAC designation is A<sub>n</sub>D<sub>E</sub> + D<sub>N</sub> or A<sub>xh</sub>D<sub>H</sub> + D<sub>N</sub> (Sec. 9.F).

<sup>44</sup> See Ryberg, P.; Matsson, O. *J. Org. Chem.* **2002**, *67*, 811.

Three limiting cases can be distinguished:

1. The carbanion returns to starting material faster than it forms product: formation of the carbanion is reversible; expulsion of the leaving group is slow.
2. Formation of the carbanion is the slow step, and formation of product is faster than return of the carbanion to starting material. In this case formation of the carbanion is essentially irreversible.
3. Formation of the carbanion is rapid, and the carbanion goes slowly to product. This case occurs only with the most stable carbanions. Here, too, formation of the carbanion is essentially irreversible.

These cases have been given the designations: 1 as (E1cB)<sub>R</sub>, 2 as (E1cB)<sub>I</sub> (or E1cB<sub>irr</sub>), and 3 as (E1)<sub>anion</sub>. Their characteristics are listed in Table 17.1.<sup>45</sup> Investigations of the reaction order are generally not very useful (except for case 3, which is first order), because cases 1 and 2 are second order and thus difficult or impossible to distinguish from the E2 mechanism by this procedure.<sup>46</sup> The greatest likelihood of finding the E1cB mechanism is expected in substrates that have (i) a poor nucleofuge and (ii) an acidic hydrogen. In addition, most investigations have concerned such substrates.

The following is some of the evidence in support of the E1cB mechanism.

1. The first step of the (E1cB)<sub>R</sub> mechanism involves a reversible exchange of protons between the substrate and the base. In that case, if deuterium is present in the base, recovered starting material should contain deuterium. This was found to be the case in the treatment of Cl<sub>2</sub>C=CHCl with NaOD to give ClC≡CCl. When the reaction was stopped before completion, there *was* deuterium in the recovered alkene.<sup>47</sup> A similar result was found for pentahaloethanes.<sup>48</sup> These substrates are relatively acidic. In both cases the electron-withdrawing halogens increase the acidity of the hydrogen, and in the case of trichloroethylene there is the additional factor that a hydrogen on an *sp*<sup>2</sup> carbon is more acidic than one on an *sp*<sup>3</sup> carbon (Sec. 8.F, category 7). Thus, the E1cB mechanism is more likely to be found in eliminations yielding triple bonds than in those giving double bonds. Another likely place for the E1cB mechanism should be in reaction of a substrate like PhCH<sub>2</sub>CH<sub>2</sub>Br, since the carbanion is stabilized by resonance with the phenyl group. Nevertheless, no deuterium exchange was found here.<sup>49</sup> If this type of evidence is a guide, then it may be inferred that the (E1cB)<sub>R</sub> mechanism is quite rare, at least for eliminations with common leaving groups such as Br, Cl, or OTs, which yield C=C double bonds.
2. When the elimination reaction was carried out in water containing acetohydroxamate buffers, a plot of the rate against the buffer concentration was curved and the

<sup>45</sup> This table, which appears in Cockerill, A.F.; Harrison, R.G. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 9, Elsevier, NY, 1973, p. 161, was adapted from a longer one in Bordwell, F.G. *Acc. Chem. Res.* 1972, 5, 374 (see p. 375).

<sup>46</sup> (E1cB)<sub>I</sub> cannot be distinguished from E2 by this means, because it has the identical rate law: rate = *k* [substrate] [B<sup>-</sup>]. The rate law for (E1cB)<sub>R</sub> is different: rate = *k* [substrate] [B<sup>-</sup>]/[BH], but this is often not useful because the only difference is that the rate is also dependent (inversely) on the concentration of the conjugate acid of the base, and this is usually the solvent, so that changes in its concentration cannot be measured.

rate leveled off at high buffer concentrations, indicating a change in rate-determining step.<sup>50</sup> This rules out an E2 mechanism, which has only one step.<sup>51</sup> When D<sub>2</sub>O was used instead of H<sub>2</sub>O as solvent, there was an initial inverse solvent isotope effect of 7.7 (the highest inverse solvent isotope effect yet reported). In other words, the reaction took place faster in D<sub>2</sub>O than in H<sub>2</sub>O. This result is compatible only with an E1cB mechanism in which the proton-transfer step is not entirely rate determining. The isotope effect arises from a partitioning of a carbanion intermediate. This intermediate either can go to product or it can revert to starting compound, which requires taking a proton from the solvent. In D<sub>2</sub>O the latter process is slower (because the O–D bond of D<sub>2</sub>O cleaves less easily than the O–H bond of H<sub>2</sub>O), reducing the rate at which a carbanion intermediate returns to starting compound. With the return reaction competing less effectively, the rate of conversion of a carbanion intermediate to product is increased.

3. Substrates containing acidic hydrogen atoms and poor leaving groups are most likely to proceed by the E1cB mechanism. Compounds of the type ZCH<sub>2</sub>CH<sub>2</sub>OPh, where Z is an electron-withdrawing group (e.g., NO<sub>2</sub>, SME<sub>2</sub><sup>+</sup>, ArSO<sub>2</sub>, CN, CO<sub>2</sub>R), belong to this category, because OPh is a very poor leaving group (Sec. 10.A.iii, category 1). There is much evidence to show that the mechanism here is indeed E1cB.<sup>52</sup> Isotope effects, measured for MeSOCD<sub>2</sub>CH<sub>2</sub>OPh and Me<sub>2</sub>S<sup>+</sup>CD<sub>2</sub>CH<sub>2</sub>OPh with NaOD in D<sub>2</sub>O, are ~0.7. This is compatible with an (E1cB)<sub>R</sub> mechanism, but not with an E2 mechanism for which an isotope effect of perhaps 5 might be expected (of course, an E1 mechanism is precluded by the extremely poor nucleofugal ability of OPh). The fact that  $k_H/k_D$  is less than the expected value of 1 is attributable to solvent and secondary isotope effects. Among other evidence for an E1cB mechanism in these systems is that changes in the identity of Z had a dramatic effect on the relative rates, with a span of 10<sup>11</sup> between NO<sub>2</sub> and COO<sup>-</sup>. Note that elimination from substrates of the type RCOCH<sub>2</sub>CH<sub>2</sub>Y is the reverse of *Michael-type addition* to C=C bonds. Such addition involves initial attack by a nucleophile Y and subsequent protonation (Sec. 15.A.ii). Thus the initial loss of a proton from substrates of this type (i.e., an E1cB mechanism) is in accord with the principle of microscopic reversibility.<sup>53</sup> It may also be recalled that the benzyne formation (Sec. 13.A.iii) can occur by such a process. It has been suggested that all base-initiated eliminations wherein the proton is activated by a strong electron-withdrawing group are E1cB reactions.<sup>54</sup> However, there is evidence that this is not the case when there is a good nucleofuge; the mechanism is E2 even when strong electron-withdrawing groups are present.<sup>55</sup> On the other hand, Cl<sup>-</sup> has been found to be a leaving group in an E1cB reaction.<sup>56</sup>

Of the three cases of the E1cB mechanism, the one most difficult to distinguish from E2 is (E1cB)<sub>1</sub>. One way to make this distinction is to study the effect of a change in leaving group. This was done in the case of the three acenaphthylenes **10**, where it was found that (i) the three rates were fairly similar, the largest being only about four times that of the smallest, and (ii) in compound c (X = Cl, Y = F), the only product contained Cl and no F, i.e., only the poorer nucleofuge F departed while Cl remained.<sup>57</sup>

Result (i) rules out all the E1cB mechanisms except (E1cB)<sub>1</sub>, because the others should all have considerable leaving group effects (Table 17.1). An ordinary E2 mechanism should also have a large leaving group effect, but an E2 mechanism with substantial carbanionic character (see the next section) might not. However, no E2 mechanism can explain result (ii), which can be explained by the fact that an  $\alpha$  Cl is more effective than an  $\alpha$  F in stabilizing the planar carbanion that remains when the proton is lost. Thus (as in the somewhat similar case of aromatic nucleophilic substitution, Sec. 13.B.ii), when X<sup>-</sup> leaves in the second step, the one that leaves is not determined by which is the better nucleofuge, but by which has had its  $\beta$  hydrogen removed.<sup>58</sup> Additional evidence for the existence of the (E1cB)<sub>1</sub> mechanism was the observation of a change in the rate-determining step in the elimination reaction of *N*-(2-cyanoethyl)pyridinium ion, treated with base, when X was changed to give acrylonitrile and a pyridine derivative.<sup>59</sup> Once again, the demonstration that two steps are involved precludes the one-step E2 mechanism. Note that pyridyl systems appear to be a borderline case, and it is not obvious if the reaction involves a carbanion intermediate (E1cb, A<sub>xh</sub>D<sub>H</sub> + D<sub>N</sub>) or if the reaction proceeds by concerted loss of a proton and the halide (E2, ANEDN) with attack by the base.<sup>60</sup>

- An example of an (E1)<sub>anion</sub> mechanism has been found with the substrate 1-methoxy-1-phenyl-2-nitrocyclopentane, which when treated with methoxide ion gives nitro enolate anion. This nitro enolate anion undergoes elimination to 1-phenyl-2-nitrocyclopent-1-ene, which is unstable under the reaction conditions and rearranges to 1-phenyl-5-nitrocyclopent-1-ene.<sup>61</sup> Among the evidence for the proposed mechanism in this case were kinetic and isotope effect results, as well as the spectral detection of the nitro enolate anion.<sup>62</sup>

5. In many eliminations to form C=O and C≡N bonds the initial step is loss of a positive group (normally a proton) from the oxygen or nitrogen. These may also be regarded as E1cB processes.

There is evidence that some E1cB mechanisms can involve ion pairs, as in the deprotonation of 1,2-dibromoethene with NEt<sub>3</sub> in DMF to give the anion with a triethylammonium counterion, which gives the 1-bromoalkyne.<sup>63</sup> This case is designated (E1cB)<sub>ip</sub>; its characteristics are shown in Table 17.1.

#### 17.A.iv. The E1-E2-E1cB Spectrum

In the three mechanisms so far considered, the similarities are greater than the differences. In each case, there is a leaving group that comes off with its pair of electrons and another group (usually hydrogen) that comes off without a pair of electrons. The only difference is in the order of the steps. It is now generally accepted that there is a spectrum of mechanisms ranging from one extreme, in which the leaving group departs well before the proton (pure E1), to the other extreme, in which the proton is removed first and then, after some time, the leaving group follows (pure E1cB). The *pure* E2 case would be somewhere in the middle, with both groups leaving simultaneously. However, most E2 reactions are not exactly in the middle, but somewhere to one side or the other. For example, the nucleofuge might depart just before the proton. This case may be described as an E2 reaction with a small amount of E1 character. The concept can be expressed by a question: "In the transition state, which bond (C–H or C–X) has undergone more cleavage?"<sup>64</sup>

Note that in both E1 and E2 reactions, removal of the hydrogen atom is an acid–base reaction, requiring a base. A stronger base is required for the E2 and a weaker base for E1. Further, the E1 reaction requires a solvent that facilitates ionization to a carbocation, such as aqueous media, whereas the E2 reaction is usually done in a protic solvent such as an alcohol.

One way to determine just where a given reaction stands on the E1-E2-E1cB spectrum is to study isotope effects, which ought to tell something about the behavior of bonds in the transition state.<sup>65</sup> For example, CH<sub>3</sub>CH<sub>2</sub>NMe<sub>3</sub><sup>+</sup> showed a nitrogen isotope effect ( $k^{14}/k^{15}$ ) of 1.017, while PhCH<sub>2</sub>CH<sub>2</sub>NMe<sub>3</sub><sup>+</sup> gave a corresponding value of 1.009.<sup>66</sup> It would be expected that the phenyl group would move the reaction toward the E1cB side of the line, which means that for this compound the C–N bond is not as greatly broken in the transition state as it is for the unsubstituted one. The isotope effect bears this out, for it shows that in the phenyl compound, the mass of the nitrogen has less effect on the reaction rate than it does in the unsubstituted compound. Similar results have been obtained with SR<sub>2</sub><sup>+</sup>

leaving groups by the use of  $^{32}\text{S}/^{34}\text{S}$  isotope effects<sup>67</sup> and with Cl ( $^{35}\text{Cl}/^{37}\text{Cl}$ ).<sup>68</sup> The position of reactions along the spectrum has also been studied from the other side of the newly forming double bond by the use of H/D and H/T isotope effects,<sup>69</sup> although interpretation of these results is clouded (i) by the fact that  $\beta$  hydrogen isotope effects are expected to change smoothly from small to large to small again as the degree of transfer of the  $\beta$  hydrogen from the  $\beta$  carbon to the base increases<sup>70</sup> (in Sec. 6.B, it was noted that isotope effects are greatest when the proton is half-transferred in the transition state), (ii) by the possibility of secondary isotope effects (e.g., the presence of a  $\beta$  deuterium or tritium may cause the leaving group to depart more slowly), and (iii) by the possibility of tunneling.<sup>71</sup> Other isotope-effect studies have involved labeled  $\alpha$  or  $\beta$  carbon, labeled  $\alpha$  hydrogen, or labeled base.<sup>61</sup>

Another way to study the position of a given reaction on the spectrum involves the use of  $\beta$ -aryl substitution. Since a positive *Hammett*  $\rho$  value is an indication of a negatively charged transition state, the  $\rho$  value for substituted  $\beta$ -aryl groups should increase as a reaction moves from E1-like to E1cB-like along the spectrum. This has been shown to be the case in a number of studies;<sup>72</sup> for example,  $\rho$  values of  $\text{ArCH}_2\text{CH}_2\text{X}$  increase as the leaving-group ability of X decreases. A typical set of  $\rho$  values was: X = I, 2.07; Br, 2.14; Cl, 2.61;  $\text{SMe}_2^+$ , 2.75; F, 3.12.<sup>73</sup> As seen previously, decreasing leaving-group ability correlates with increasing E1cB character.

Still another method measures volumes of activation.<sup>74</sup> These are negative for E2 and positive for E1cB mechanisms. Measurement of the activation volume therefore provides a continuous scale for deciding just where a reaction lies on the spectrum.

### 17.A.v. The E2C Mechanism<sup>75</sup>

Certain alkyl halides and tosylates undergo E2 eliminations faster when treated with weak bases such as  $\text{Cl}^-$  in polar aprotic solvents or  $\text{PhS}^-$  than with the usual E2 strong bases such as  $\text{RO}^-$  in ROH.<sup>76</sup> In order to explain these results, it was proposed<sup>77</sup> that there is a spectrum<sup>78</sup> of E2 transition states in which the base can interact in the transition state with the  $\alpha$  carbon, as well as with the  $\beta$  hydrogen. At one end of this spectrum is a mechanism (called E2C) in which, in the transition state, the base interacts mainly with the carbon. The E2C mechanism is characterized by strong nucleophiles that are weak bases. At the other extreme is the normal E2 mechanism, here called E2H to distinguish it from E2C, characterized by strong bases. Transition state **11** represents a transition state between these

<sup>78</sup> This is apart from the E1-E2-E1cB spectrum.

extremes. Additional evidence<sup>79</sup> for the E2C mechanism is derived from *Brønsted equation* considerations (Sec. 8.D), from substrate effects, from isotope effects, and from the effects of solvents on rates.

However, the E2C mechanism has been criticized, and it has been contended that all the experimental results can be explained by the normal E2 mechanism.<sup>80</sup> McLennan has suggested that the transition state is that shown as **12**.<sup>81</sup> An ion-pair mechanism has also been proposed.<sup>82</sup> Although the actual mechanisms involved may be a matter of controversy, there is no doubt that a class of elimination reactions exists that is characterized by second-order attack by weak bases.<sup>83</sup> These reactions also have the following general characteristics:<sup>84</sup> (i) they are favored by good leaving groups; (ii) they are favored by polar aprotic solvents; (iii) the reactivity order is tertiary > secondary > primary, which is the opposite of the normal E2 order (Sec. 17.D.i); (iv) the elimination is always *anti* (*syn* elimination is not found), but in cyclohexyl systems, a diequatorial *anti* elimination is about as favorable as a diaxial *anti* elimination (unlike the normal E2 reaction, Sec. 17.A.i, categories 2 and 3); and (v) they follow *Zaitsev's rule* (see Sec. 17.B below), where this does not conflict with the requirement for *anti* elimination.

## 17.B. REGIOCHEMISTRY OF THE DOUBLE BOND

With some substrates, a  $\beta$  hydrogen is present on only one carbon and (barring rearrangements) there is no doubt as to the identity of the product. For example,  $\text{PhCH}_2\text{CH}_2\text{Br}$  can give only  $\text{PhCH}=\text{CH}_2$ . However, in many other cases two or three alkenyl products are possible. In the simplest such case, a *sec*-butyl compound can give either but-1-ene or but-2-ene. There are a number of rules that, in many instances, enable a prediction of which product will predominantly form.<sup>85</sup>

1. No matter the mechanism, a double bond does not go to a bridgehead carbon unless the ring sizes are large enough (*Bredt's rule*, Sec. 4.P.iii). This means, for example, not only that **13** gives only **14** and not **15** (indeed **15** is not a known compound), but also that **16** does *not* undergo elimination.

<sup>79</sup> See Kwart, H.; Wilk, K.A. *J. Org. Chem.* **1985**, *50*, 3038.

<sup>82</sup> Ford, W.T. *Acc. Chem. Res.* **1973**, *6*, 410.

<sup>83</sup> For convenience, these are called E2C reactions, although the actual mechanism is in dispute.

<sup>84</sup> See Beltrame, P.; Ceccon, A.; Winstein, S. *J. Am. Chem. Soc.* **1972**, *94*, 2315.

<sup>85</sup> See Hüchel, W.; Hanack, M. *Angew. Chem. Int. Ed.* **1967**, *6*, 534.

2. No matter the mechanism, if there is a double bond (C=C or C=O) or an aromatic ring already in the molecule that can be in conjugation with the new double bond, the conjugated product usually predominates, sometimes even when the stereochemistry is unfavorable (for an exception, Sec. 17.C).
3. In the E1 mechanism the leaving group is gone before the choice is made as to which direction the new double bond takes. Therefore the direction is determined almost entirely by the relative stabilities of the two (or three) possible alkenes. In such cases *Zaitsev's rule*<sup>86</sup> operates. This rule states that *the double bond goes mainly toward the most highly substituted carbon*. That is, 3-bromo-2,3-dimethylpentane gives more 2,3-dimethylpent-2-ene than either 3,4-dimethylpent-2-ene or 2-ethyl-3-methylbut-1-ene. Thus Zaitsev's rule predicts that the alkene predominantly formed will be the one with the largest possible number of alkyl groups on the C=C carbons, and in most cases this is what is found. From heat of combustion data (Sec. 1.L), it is known that alkene stability increases with alkyl substitution, although just why this should be is a matter of conjecture. The most common explanation is hyperconjugation. For E1 eliminations, Zaitsev's rule governs the orientation whether the leaving group is neutral or positive, since, as already mentioned, the leaving group is not present when the choice of direction is made. This statement does not hold for E2 eliminations, and it may be mentioned here, for contrast with later results, that E1 elimination of  $\text{Me}_2\text{CHCHMeSMe}_2^+$  gave 91% of the Zaitsev product and 9% of the other.<sup>87</sup> However, there *are* cases in which the leaving group affects the direction of the double bond in E1 eliminations.<sup>88</sup> This may be attributed to ion pairs; that is, the leaving group is not completely gone when the hydrogen departs. Zaitsev's rule breaks down in cases where the non-Zaitsev product is more stable for steric reasons. For example, E1 or E1-like eliminations of 1,2-diphenyl-2-X-propanes ( $\text{PhMeCXCH}_2\text{Ph}$ ) were reported to give about 50%  $\text{CH}_2=\text{CPhCH}_2\text{Ph}$ , despite the fact that the double bond of the Zaitsev product ( $\text{PhMeC}=\text{CHPh}$ ) is conjugated with two benzene rings.<sup>89</sup>
4. For the *anti* E2 mechanism a *trans*  $\beta$  proton is necessary; if this is available in only one direction, that is the way the double bond will form. Because of the free rotation in acyclic systems (except where steric hindrance is great), this is a factor only in cyclic systems. Where *trans*  $\beta$  hydrogen atoms are available on two or three carbons, two types of behavior are found, depending on substrate structure and the nature of the leaving group. Compounds either follow Zaitsev's rule and give predominant formation of the most highly substituted alkene, or they follow *Hofmann's rule: the double bond goes mainly toward the least highly substituted carbon*.

<sup>86</sup> Often given the German spelling: Saytzeff, or Saytseff, or Saytzev.

<sup>87</sup> de la Mare, P.B.D. *Prog. Stereochem.* **1954**, *1*, 112.

<sup>88</sup> See Cram, D.J.; Sahyun, M.R.V. *J. Am. Chem. Soc.* **1963**, *85*, 1257.

<sup>89</sup> Ho, I.; Smith, J.G. *Tetrahedron* **1970**, *26*, 4277.

Since Zaitsev orientation almost always gives the thermodynamically more stable isomer, why in some cases the less stable Hofmann product predominates must be explained. *Hofmann orientation*<sup>90</sup> is caused by the fact that the acidity of the  $\beta$  hydrogen is decreased by the presence of the electron-donating alkyl groups. It is noted that in most cases, Hofmann elimination is an intramolecular acid–base reaction. Experiments showed that Hofmann elimination increases with the size of the leaving group.<sup>91</sup> Hofmann elimination was also shown to increase with increase in bulk of the substrate,<sup>92</sup> and steric factors operate in extreme cases.<sup>93</sup> In further experiments, a large series of bases of different kinds was shown to obey linear free-energy relationships between basicity and percentage of Hofmann elimination.<sup>94</sup>

5. Only a few investigations on the orientation of syn E2 eliminations have been carried out, but these show that Hofmann orientation is greatly favored over Zaitsev.<sup>95</sup>
6. In the E1cB mechanism, the question of orientation seldom arises because the mechanism is generally found only where there is an electron-withdrawing group in the  $\beta$  position, and that is where the double bond goes.
7. As already mentioned, E2C reactions show a strong preference for Zaitsev orientation.<sup>96</sup> The compound  $\text{PhCH}_2\text{CHOTsCHMe}_2$  gave  $\sim 98\%$   $\text{PhCH}=\text{CHCHMe}_2$  under the usual E2 reaction conditions (*t*-BuOK in *t*-BuOH). In this case the double bond goes to the side with more hydrogen atoms because on that side it will be able to conjugate with the benzene ring.

### 17.C. STEREOCHEMISTRY OF THE DOUBLE BOND

Several factors affect the stereochemistry of the product, including the nature of the leaving group, the base, the solvent, and the substrate. Not all these effects are completely understood.<sup>97</sup> If a chiral, nonracemic halide [e.g., (*2R*)-bromo-(*3R*)-methylpentane] is treated with KOH in ethanol then the more highly substituted product predicted by Zaitsev's rule is 3-methylpent-2-ene rather than 3-methylpent-1-ene, but there are *two* 3-methylpent-2-enes. Experimentally the E2 reaction is known to be *diastereospecific*. In other words, one diastereomeric alkyl halide will generate either the (*E*)-alkene or the (*Z*)-alkene and the other diastereomeric alkyl halide will give only the other alkene stereoisomer. The transition state for an E2 reaction of (*2R*)-bromo-(*3R*)-methylpentane is represented by **17**, where the bromine leaving group and the  $\beta$  hydrogen are anti-periplanar. This transition state can be formed only when one rotamer of (*2R*)-bromo-(*3R*)-methylpentane has the  $\beta$  hydrogen atom and the bromine leaving group *anti*. This *anti* rotamer leads to the requisite E2 transition state and the final product, 3-methylpent-(*2E*)-ene.

<sup>97</sup> Alunni, S.; Baciocchi, E. *J. Chem. Soc., Perkin Trans. 2* **1976**, 877; Saunders Jr., W.H.; Cockerill, A.F. *Mechanisms of Elimination Reactions*, Wiley, NY, **1973**, pp. 165–193.

Once the *anti* rotamer is achieved in the presence of the hydroxide, the bond making–breaking process begins, and the stereochemical positions of all groups are essentially “locked” in position in transition state **17**. The two methyl groups in (2*R*)-bromo-(3*R*)-methylpentane are “on the same side” in transition state **17** and they will be on the same side in the alkene product, 3-methylpent-(2*E*)-ene. The requisite *anti* transition state dictates that an enantiopure halide will yield one and only one stereoisomeric alkene. The E2 reaction of (2*R*)-bromo-(3*R*)-methylpentane is diastereospecific, which means that the identical reaction of KOH with (2*S*)-bromo-(3*R*)-methylpentane [the diastereomer of (2*R*)-bromo-(3*R*)-methylpentane] will lead to transition state **18** and 3-methylpent-(2*Z*)-ene, as shown.

For E1 eliminations, if there is a free carbocation and rotation can occur about the C–C bond, then no matter the geometry of the original compound, the more stable situation will give the (*E*)-alkene. If the carbocation is not completely free, then to that extent, E2-type products are formed. Similar considerations apply in E1cB eliminations.<sup>98</sup>

## 17.D. REACTIVITY

In this section, the effects of changes in the substrate, base, leaving group, and medium on (i) overall reactivity, (ii) E1 versus E2 versus E1cB,<sup>99</sup> and (iii) elimination versus substitution will be examined.

### 17.D.i. Effect of Substrate Structure

1. *Effect on reactivity.* The carbon containing the nucleofuge (X) is referred to as the  $\alpha$  carbon and the carbon that loses the positive species (usually a proton) is referred to as the  $\beta$  carbon. Groups attached to the  $\alpha$  or  $\beta$  carbons can exert at least four kinds of influence:
  - a. they can stabilize or destabilize the incipient double bond (both  $\alpha$  and  $\beta$  groups);
  - b. they can stabilize or destabilize an incipient negative charge, affecting the acidity of the proton ( $\beta$  groups only);
  - c. they can stabilize or destabilize an incipient positive charge ( $\alpha$  groups only);
  - d. they can exert steric effects (e.g., eclipsing effects) (both  $\alpha$  and  $\beta$  groups).

<sup>98</sup> See Redman, R.P.; Thomas, P.J.; Stirling, C.J.M. *J. Chem. Soc., Chem. Commun.* **1978**, 43.

<sup>99</sup> See Cockerill, A.F.; Harrison, R.G. in Patai, S. *The Chemistry of Functional Groups*, Supplement A, pt. 1, Wiley, NY, **1977**, pp. 178–189.

Effects a and d can apply in all three mechanisms, although steric effects are greatest for the E2 mechanism. Effect b does not apply in the E1 mechanism, and effect c does not apply in the E1cB mechanism. Groups such as Ar and C=C increase the rate by any mechanism, except perhaps when formation of the C=C bond is not the rate-determining step, whether they are  $\alpha$  or  $\beta$  (effect a). Electron-withdrawing groups increase the acidity when in the  $\beta$  position, but have little effect in the  $\alpha$  position unless they also conjugate with the double bond. Thus Br, Cl, CN, Ts, NO<sub>2</sub>, CN, and SR in the  $\beta$  position all increase the rate of E2 eliminations.

2. *Effect on E1 versus E2 versus E1cB.*  $\alpha$ -Alkyl and  $\alpha$ -aryl groups stabilize the carbocation character of the transition state, shifting the spectrum toward the E1 end.  $\beta$ -Alkyl groups also shift the mechanism toward E1, since they *decrease* the acidity of the hydrogen. However,  $\beta$ -aryl groups shift the mechanism the other way (toward E1cB) by stabilizing the carbanion. Indeed, as seen in Sec. 17.A.iii, all electron-withdrawing groups in the  $\beta$  position shift the mechanism toward E1cB.<sup>100</sup>  $\alpha$ -Alkyl groups also increase the extent of elimination with weak bases (E2C reactions).
3. *Effect on elimination versus substitution.* Under second-order conditions, increased branching increases elimination, to the point where tertiary substrates undergo few S<sub>N</sub>2 reactions, as seen in Chapter 10. For example, Table 17.2 shows results on some simple alkyl bromides. Similar results were obtained with <sup>+</sup>SMe<sub>2</sub> as the leaving group.<sup>101</sup> Two reasons can be presented for this trend. One is statistical: as  $\alpha$  branching increases, there are usually more hydrogen atoms for the base to attack. The other is that  $\alpha$  branching presents steric hindrance to attack of the base at the carbon. Under first-order conditions, increased  $\alpha$  branching also increases the amount of elimination (E1 versus S<sub>N</sub>1), although not so much, and usually the substitution product predominates.<sup>102</sup>  $\beta$ -Branching also increases the amount of E2 elimination with respect to S<sub>N</sub>2 substitution (Table 17.2), not because elimination is faster but because the S<sub>N</sub>2 mechanism is so greatly slowed (Sec. 10.G.i). Under first-order conditions too,  $\beta$  branching favors elimination over substitution, probably for steric reasons.<sup>103</sup> However, E2 eliminations from compounds with charged leaving groups are slowed by  $\beta$  branching, which is related to *Hofmann's rule* (Sec. 17.B, category 4). Electron-withdrawing groups in the  $\beta$  position not only increase the rate of E2 eliminations and shift the mechanisms toward the E1cB end of the spectrum but they also increase the extent of elimination as opposed to substitution.

Another method that compares E2 and S<sub>N</sub>2 reactions is called the *activation-strain model*. In this model, the activation energy = activation strain + transition state interaction, and corresponds directly to the strength of the Lewis acid or base. A more basic nucleophile or base, with a higher energy HOMO, and a more acidic substrate, with a lower energy LUMO, interact more strongly.<sup>104</sup> Activation strain is connected with the strength of the bonds broken: a strong C leaving group bond has a higher activation strain and a higher barrier. Using this model, the E2 reaction has a higher activation strain than S<sub>N</sub>2 because two bonds are broken, and with weak bases, S<sub>N</sub>2 dominates E2 because S<sub>N</sub>2 has less activation

<sup>102</sup> Dhar, M.L.; Hughes, E.D.; Ingold, C.K. *J. Chem. Soc.* **1948**, 2058.

<sup>103</sup> Hughes, M.L.; Ingold, C.K.; Maw, G.A. *J. Chem. Soc.* **1948**, 2065.

<sup>104</sup> See van Zeist, W.-J.; Bickelhaupt, F.M. *Org. Biomol. Chem.* **2010**, 8, 3118.

strain.<sup>105</sup> With strong bases, a favorable interaction of the more acidic transition state for the E2 reaction leads to a preference for E2.

**TABLE 17.2** The effect of  $\alpha$  and  $\beta$  branching on the rate of E2 elimination and the amount of alkene formed<sup>a</sup>

Substrate	Temperature, °C	Alkene, %	Rate of E2 reaction, $\times 10^5$	Reference
CH <sub>3</sub> CH <sub>2</sub> Br	55	0.9	1.6	106
(CH <sub>3</sub> ) <sub>2</sub> CHBr	24	80.3	0.237	107
(CH <sub>3</sub> ) <sub>3</sub> Br	25	97	4.17	101
CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> Br	55	8.9	5.3	107
(CH <sub>3</sub> ) <sub>2</sub> CHCH <sub>2</sub> Br	55	59.5	8.5	107

<sup>a</sup>The reactions were between the alkyl bromide and <sup>-</sup>OEt. The rate for isopropyl bromide was actually greater than that for ethyl bromide, if the temperature difference is considered. Neopentyl bromide, the next compound in the  $\beta$ -branching series, cannot be compared because it has no  $\beta$  hydrogen and cannot give an elimination product without rearrangement.

### 17.D.ii. Effect of the Attacking Base

1. *Effect on E1 versus E2 versus E1cB.* In the E1 mechanism, an external base is generally not required: The solvent acts as the base. Hence, when external bases are added, the mechanism is shifted toward E2. Stronger bases and higher base concentrations cause the mechanism to move toward the E1cB end of the E1-E2-E1cB spectrum.<sup>108</sup> However, weak bases in polar aprotic solvents can also be effective in elimination reactions with certain substrates (the E2C reaction). Normal E2 elimination has been accomplished with the following bases:<sup>109</sup> H<sub>2</sub>O, NR<sub>3</sub>, <sup>-</sup>OH, <sup>-</sup>OAc, <sup>-</sup>OR, <sup>-</sup>OAr, <sup>-</sup>NH<sub>2</sub>, CO<sub>3</sub><sup>2-</sup>, LiAlH<sub>4</sub>, I<sup>-</sup>, <sup>-</sup>CN, and organic bases. Weak bases effective in the E2C reaction are Cl<sup>-</sup>, Br<sup>-</sup>, F<sup>-</sup>, <sup>-</sup>OAc, and RS<sup>-</sup>. These bases are often used in the form of their R<sub>4</sub>N<sup>+</sup> salts.
2. *Effect on elimination versus substitution.* Strong bases not only facilitate E2 rather than E1, but also benefit elimination rather than substitution. With a high concentration of strong base in a non-ionizing solvent, bimolecular mechanisms are favored and E2 predominates over S<sub>N</sub>2. At low base concentrations, or in the absence of base altogether, in ionizing solvents, unimolecular mechanisms are favored, and the S<sub>N</sub>1 mechanism predominates over the E1. In Chapter 10, it was pointed out that some species are strong nucleophiles but weak bases (Sec. 10.G.ii). The use of these obviously favors substitution, except that, as seen, elimination can predominate if polar aprotic solvents are used. It has been shown for the base cyanide that in polar aprotic

solvents, the less the base is encumbered by its counterion in an ion pair (i.e., the freer the base), the more substitution is favored at the expense of elimination.<sup>110</sup>

### 17.D.iii. Effect of the Leaving Group

1. *Effect on reactivity.* The leaving groups in elimination reactions are similar to those in nucleophilic substitution. E2 eliminations have been performed with the following groups:  $^+\text{NR}_3$ ,  $^+\text{PR}_3$ ,  $^+\text{SR}_2$ ,  $^+\text{OHR}$ ,  $\text{SO}_2\text{R}$ ,  $\text{OSO}_2\text{R}$ ,  $\text{OCOR}$ ,  $\text{OOH}$ ,  $\text{OOR}$ ,  $\text{NO}_2$ ,<sup>111</sup> F, Cl, Br, I, and CN (but not  $^+\text{OH}_2$ ). E1 eliminations have been carried out with:  $^+\text{NR}_3$ ,  $^+\text{SR}_2$ ,  $^+\text{OH}_2$ ,  $^+\text{OHR}$ ,  $\text{OSO}_2\text{R}$ ,  $\text{OCOR}$ , Cl, Br, I, and  $^+\text{N}_2$ .<sup>112</sup> However, the major leaving groups for preparative purposes are  $^+\text{OH}_2$  (always by E1) and Cl, Br, I, and  $^+\text{NR}_3$  (usually by E2).
2. *Effect on E1 versus E2 versus E1cB.* Better leaving groups shift the mechanism toward the E1 end of the spectrum, *since they make ionization easier*. This effect has been studied in various ways. One way already mentioned was a study of  $\rho$  values (Sec. 17.A.iv). Poor leaving groups and positively charged leaving groups shift the mechanism toward the E1cB end of the spectrum because the strong electron-withdrawing field effects increase the acidity of the  $\beta$  hydrogen.<sup>113</sup> The E2C reaction is favored by good leaving groups.
3. *Effect on elimination versus substitution.* As seen previously (Sec. 17.A.ii), for first-order reactions the leaving group has nothing to do with the competition between elimination and substitution, since the leaving group is gone before the decision is made as to which path to take. However, this is not true where ion pairs are involved, and results have been found where the nature of the leaving group does affect the product.<sup>114</sup> In second-order reactions, the elimination/substitution ratio is not greatly dependent on a halide leaving group, although there is a slight increase in elimination in the order  $\text{I} > \text{Br} > \text{Cl}$ . When OTs is the leaving group, there is usually much more substitution. For example,  $n\text{-C}_{18}\text{H}_{37}\text{Br}$  treated with  $t\text{-BuOK}$  gave 85% elimination, while  $n\text{-C}_{18}\text{H}_{37}\text{OTs}$  gave, under the same conditions, 99% substitution.<sup>115</sup> On the other hand, positively charged leaving groups increase the amount of elimination.

### 17.D.iv. Effect of the Medium

1. *Effect of solvent on E1 versus E2 versus E1cB.* With any reaction a more polar environment enhances the rate of mechanisms that involve ionic intermediates. For neutral leaving groups, it is expected that E1 and E1cB mechanisms will be aided by

increasing the polarity of the solvent and by increasing ionic strength. With certain substrates, polar aprotic solvents promote elimination with weak bases (the E2C reaction).

2. *Effect of solvent on elimination versus substitution.* Increasing polarity of solvent favors  $S_N2$  reactions at the expense of E2. In the classical example, alcoholic KOH is used to effect elimination, while the more polar aqueous KOH is used for substitution. Charge-dispersal discussions, similar to those in Sec. 10.G.iv,<sup>116</sup> only partially explain this. In most solvents  $S_N1$  reactions are favored over E1. The E1 reactions compete best in polar solvents that are poor nucleophiles, especially dipolar aprotic solvents<sup>117</sup> A study made in the gas phase, where there is no solvent, has shown that when 1-bromopropane reacts with  $\text{MeO}^-$  only elimination takes place (no substitution) even with this primary substrate.<sup>118</sup>
3. *Effect of temperature.* Elimination is favored over substitution by increasing temperature, whether the mechanism is first order or second order.<sup>119</sup> The reason is that the activation energies of eliminations are higher than those of substitutions (because eliminations have greater changes in bonding).

## 17.E. MECHANISMS AND ORIENTATION IN PYROLYTIC ELIMINATIONS

### 17.E.i. Mechanisms<sup>120</sup>

Several types of compounds undergo elimination on heating, with no other reagent present. Reactions of this type are often run in the gas phase. The mechanisms are obviously different from those already discussed, since all those mechanisms require an external base (which may be the solvent) in one of the steps, and there is no external base or solvent present in pyrolytic elimination. Two mechanisms have been found to operate. One involves a cyclic transition state, which may be four, five, or six membered. In this mechanism the two groups leave at about the same time and bond to each other as they are doing so. The designation is  $E^i$  in the Ingold terminology and  $\text{cyclo-D}_E\text{D}_N\text{A}_n$  in the IUPAC system. The elimination must be *syn* and, for the four- and five-membered transition states, the four or five atoms making up the ring must be coplanar. Coplanarity is not required for the six-membered transition state, since there is room for the outside atoms when the leaving atoms are staggered.

As in the E2 mechanism, it is not necessary that the C—H and C—X bonds be broken simultaneously in the transition state. In fact, there is also a spectrum of mechanisms here, ranging from a mechanism in which C—X bond breaking is a good deal more advanced

Rev.* **1969**, *69*, 33.

than C—H bond breaking to one in which the extent of bond breaking is virtually identical for the two bonds. Evidence for the existence of the  $E^i$  mechanism includes the following:

1. The kinetics are first order, so only one molecule of the substrate is involved in the reaction (i.e., if one molecule attacked another, the kinetics would be second order in substrate).<sup>121</sup>
2. Free-radical inhibitors do not slow the reactions, so no free-radical mechanism is involved.<sup>122</sup>
3. The mechanism predicts exclusive *syn* elimination, and this behavior has been found in many cases.<sup>123</sup> The evidence is inverse to that for the *anti* E2 mechanism and generally involves the following facts: (i) an *erythro* isomer gives a *trans* alkene and a *threo* isomer gives a *cis* alkene; (ii) the reaction takes place only when a *cis*  $\beta$  hydrogen is available; (iii) if, in a cyclic compound, a *cis* hydrogen is available on only one side, the elimination goes in that direction.

Another piece of evidence involves a pair of steroid molecules. In  $3\beta$ -acetoxy-(*R*)- $5\alpha$ -methylsulfinylcholestane (structure **19** shows rings A and B of this compound) and in  $3\beta$ -acetoxy-(*S*)- $5\alpha$ -methylsulfinylcholestane (**20**; rings A and B), the *only* difference is the configuration of oxygen and methyl about the sulfur. Yet pyrolysis of **19** gave only elimination to the 4 side (86% 4-ene), while **20** gave predominant elimination to the 6 side (65% 5-ene and 20% 4-ene).<sup>124</sup> Models show that interference from the 1 and 9 hydrogen atoms causes the two groups on the sulfur to lie *in front of it* with respect to the rings, rather than behind it. Since the sulfur is a stereogenic center, this means that in **19** the oxygen is near the 4 hydrogen, while in **20** it is near the 6 hydrogen. This experiment is compatible only with *syn* elimination.<sup>125</sup>

4. The <sup>14</sup>C isotope effects for the Cope elimination (**17-7**) show that both the C—H bond and the C—N bond have been extensively broken in the transition state.<sup>126</sup>
5. Some of these reactions have been shown to exhibit negative entropies of activation, indicating that the molecules are more restricted in geometry in the transition state than they are in the starting compound.

Where a pyrolytic elimination lies on the mechanistic spectrum seems to depend mostly on the leaving group. When the leaving group is halogen, all available evidence suggests

<sup>125</sup> See Bailey, W.J.; Bird, C.N. *J. Org. Chem.* **1977**, *42*, 3895.

<sup>126</sup> Wright, D.R.; Sims, L.B.; Fry, A. *J. Am. Chem. Soc.* **1983**, *105*, 3714.

that in the transition state the C—X bond is cleaved to a much greater extent than the C—H bond, that is, there is a considerable amount of carbocation character in the transition state. This observation is in accord with the fact that a completely nonpolar four-membered cyclic transition state violates the *Woodward-Hoffmann rules* (see the similar case of **15-59**). Evidence for the carbocation-like character of the transition state when halide is the leaving group is that relative rates are in the order  $I > Br > Cl$ <sup>127</sup> (Sec. 10.G.iii), and that the effects of substituents on reaction rates are in accord with such a transition state.<sup>128</sup> Rate ratios for pyrolysis of some alkyl bromides at 320 °C were ethyl bromide, 1; isopropyl bromide, 280; *tert*-butyl bromide, 78 000. Also,  $\alpha$ -phenylethyl bromide had about the same rate as *tert*-butyl bromide. On the other hand,  $\beta$ -phenylethyl bromide was only slightly faster than ethyl bromide.<sup>129</sup> This result indicates that C—Br cleavage was much more important in the transition state than C—H cleavage, since the incipient carbocation was stabilized by  $\alpha$ -alkyl and  $\alpha$ -aryl substitution, while there was no incipient carbanion to be stabilized by  $\beta$ -aryl substitution. These substituent effects, as well as those for other groups, are very similar to the effects found for the  $S_N1$  mechanism and are thus in very good accord with a carbocation-like transition state.

For carboxylic esters, the rate ratios were much smaller,<sup>130</sup> although still in the same order, so that this reaction is closer to a pure  $E^i$  mechanism, although the transition state still has some carbocationic character. Other evidence for a greater initial C—O cleavage with carboxylic esters is that a series of 1-arylethyl acetates followed  $\sigma^+$  rather than  $\sigma$ , showing carbocationic character at the 1 position.<sup>131</sup> The extent of  $E1$  character in the transition state increases in the following order of ester types: acetate < phenylacetate < benzoate < carbamate < carbonate.<sup>132</sup> Cleavage of xanthates (**17-5**), cleavage of sulfoxides (**17-10**), the *Cope reaction* (**17-7**), and reaction **17-2** are probably very close to straight  $E^i$  mechanisms.<sup>133</sup>

The second type of pyrolysis mechanism is completely different and involves free radicals. Initiation occurs by pyrolytic homolytic cleavage to give the alkyl radical and  $X\bullet$ . The latter radical generates a new radical on the carbon  $\beta$  to the X group in a propagation step, and loss of  $X\bullet$  gives the alkene. Free-radical mechanisms are mostly found in pyrolyses of polyhalides and of primary monohalides,<sup>134</sup> although they also have been postulated in pyrolysis of certain carboxylic esters.<sup>135</sup>  $\beta$  Elimination of tosyl radicals is known.<sup>136</sup> Much less is known about these mechanisms and we will not consider them further. Free-radical eliminations in solution are also known, but are rare.<sup>137</sup>

### 17.E.ii. Orientation in Pyrolytic Eliminations

As in the E1-E2-E1cB mechanistic spectrum, *Bredt's rule* applies; and if a double bond is present, a conjugated system will be preferred, if sterically possible. Apart from these considerations, the following statements can be made for E<sup>i</sup> eliminations:

1. In the absence of considerations mentioned below, orientation is statistical and is determined by the number of  $\beta$  hydrogen atoms available (therefore *Hofmann's rule* is followed). For example, *sec*-butyl acetate gives 55–62% but-1-ene and 38–45% but-2-ene,<sup>138</sup> which is close to the 3:2 distribution predicted by the number of hydrogen atoms available.<sup>139</sup>
2. A *cis*  $\beta$  hydrogen is required. Therefore in cyclic systems, if there is a *cis* hydrogen on only one side, the double bond will go that way. However, when there is a six-membered transition state, this does not necessarily mean that the leaving groups must be *cis* to each other, since such transition states need not be completely coplanar. If the leaving group is axial, then the hydrogen obviously must be equatorial (and consequently *cis* to the leaving group), since the transition state cannot be realized when the groups are both axial. But if the leaving group is equatorial, it can form a transition state with a  $\beta$  hydrogen that is either axial (hence, *cis*) or equatorial (hence, *trans*). Thus ethyl (1*S*,2*R*)-2-acetoxycyclohexane-1-carboxylate, in which the leaving group is most likely axial, does not form a double bond in the direction of the carbethoxyl group, even although that would be conjugated, because there is no equatorial hydrogen on that side. Instead it gives 100% ethyl cyclohex-2-ene-1-carboxylate.<sup>140</sup> On the other hand, *S*-methyl *O*-((1*S*,2*R*)-2-methylcyclohexyl) carbonodithioate, with an equatorial leaving group, gave a 56:44 mixture of 3-methylcyclohex-1-ene and 1-methylcyclohex-1-ene but in only 31% yield, even though for elimination to 3-methylcyclohex-1-ene, the leaving group must depart with a *trans* hydrogen.<sup>141</sup>
3. In some cases, especially with cyclic compounds, the more stable alkene forms and *Zaitsev's rule* applies. For example, menthyl acetate gives 35% of the Hofmann product and 65% of the Zaitsev, even although a *cis*  $\beta$  hydrogen is present on both sides and the statistical distribution is the other way. A similar result was found for the pyrolysis of menthyl chloride.<sup>142</sup>
4. There are also steric effects. In some cases the direction of elimination is determined by the need to minimize steric interactions in the transition state or to relieve steric interactions in the ground state.

### 17.E.iii. 1,4 Conjugate Eliminations<sup>143</sup>

1,4 eliminations of the type  $\text{H}-\text{C}-\text{C}=\text{C}-\text{C}-\text{X} \rightarrow \text{C}=\text{C}-\text{C}=\text{C}$  are much rarer than conjugate additions (Chapter 15), but some examples are known.<sup>144</sup>

## 17.F. REACTIONS

### 17.F.i. Reactions in Which C=C and C≡C Bonds Are Formed

#### A. Reactions in Which Hydrogen Is Removed from One Side

In **17-1** to **17-5** the other leaving atom is oxygen. In **17-6** to **17-9**, it is nitrogen. For reactions in which hydrogen is removed from both sides, see **19-1** to **19-6**.

#### 17-1 Dehydration of Alcohols

Dehydration of alcohols can be accomplished in several ways.<sup>145</sup> Both  $\text{H}_2\text{SO}_4$  and  $\text{H}_3\text{PO}_4$  are common reagents, but formation of an intermediate carbocation can lead to rearrangement products and to ether formation (**10-12**). If the alcohol is volatile, vapor-phase elimination over  $\text{Al}_2\text{O}_3$  is an excellent method since side reactions are greatly reduced. This method has even been applied to such high molecular weight alcohols as dodecan-1-ol.<sup>146</sup> The presence of an electron-withdrawing group usually facilitates elimination of water, as in dehydration observed with the *aldol condensation* (**16-34**). Treating a 4-hydroxy lactam with DMAP and Boc anhydride leads to the conjugated lactam.<sup>147</sup> Elimination of serine derivatives to  $\alpha$ -alkylidene amino acid derivatives was accomplished with  $(\text{EtO})_2\text{POCl}$ .<sup>148</sup> The ease of dehydration increases with  $\alpha$  branching, and tertiary alcohols are dehydrated so easily with only a trace of acid that it sometimes happens spontaneously. Dehydration is almost always spontaneous when the new double bond can be in conjugation with one already there.

Many other dehydrating agents<sup>149</sup> have been used on occasion:  $\text{P}_2\text{O}_5$ ,  $\text{I}_2$ ,  $\text{PPh}_3/\text{I}_2$ ,<sup>150</sup>  $\text{BF}_3$ -etherate, DMSO,  $\text{KHSO}_4$ , anhydrous  $\text{CuSO}_4$ , and phthalic anhydride, among others. Secondary and tertiary alcohols can also be dehydrated, without rearrangement, simply by heating in HMPA at reflux,<sup>151</sup> or by mixing with Amberlyst-15.<sup>152</sup> With nearly all reagents, dehydration follows *Zaitsev's rule*. An exception involves the passage of hot alcohol vapors over thorium oxide at 350–450 °C, under which conditions *Hofmann's rule* is followed.<sup>153</sup>

Alcohols were converted to the alkene via a dehydration protocol in which the alcohol is first converted to the alkoxide with NaH, and subsequent reaction with phenyl isothiocyanate gave the sodium carboimidothioate salt, which was heated overnight at 200 °C to give the alkene.<sup>154</sup> The 1,2,3-triazole-promoted, iron-catalyzed dehydration of propargyl alcohols gave conjugated enynes.<sup>155</sup> Simple aliphatic alcohols were dehydrated to the corresponding alkene by heating on mesoporous silica MCM-41 catalyst, with high reaction rates.<sup>156</sup> Heating over Sc<sub>2</sub>O<sub>3</sub> has also been used for the dehydration of diols in the allylic alcohols.<sup>157</sup>

Transition metals can induce the dehydration of certain alcohols.  $\beta$ -Hydroxy ketones are converted to conjugated ketones by treatment with CeCl<sub>3</sub> and NaI.<sup>158</sup> A  $\delta$ -hydroxy- $\alpha,\beta$ -unsaturated aldehyde was converted to a dienyl aldehyde with a Hf catalyst.<sup>159</sup>  $\beta$ -Hydroxy esters are converted to conjugated esters when treated with 2 molar equivalents of SmI<sub>2</sub>.<sup>160</sup> In another variation of the dehydration reaction, vicinal bromohydrins are converted to alkenes upon treatment with In, InCl<sub>3</sub>, and a Pd catalyst.<sup>161</sup> Chlorohydrins react similarly when treated first with Sm and then diiodomethane.<sup>162</sup>

When proton acids catalyze alcohol dehydration, the mechanism is E1.<sup>163</sup> The principal process involves conversion of ROH to ROH<sub>2</sub><sup>+</sup> and cleavage of the latter to R<sup>+</sup> and H<sub>2</sub>O, although with some acids a secondary process probably involves conversion of the alcohol to an inorganic ester followed by ionization.

Note that these mechanisms are the reverse of those involved in the acid-catalyzed hydration of double bonds (**15-3**), in accord with the principle of microscopic reversibility. With anhydrides (e.g., P<sub>2</sub>O<sub>5</sub>, phthalic anhydride), as well as with some other reagents, such as HMPA,<sup>164</sup> it is likely that an ester is formed, and the leaving group is the conjugate base of the corresponding acid. In these cases, the mechanism can be E1 or E2. The mechanism with Al<sub>2</sub>O<sub>3</sub> and other solid catalysts has been studied extensively, but is poorly understood.<sup>165</sup>

The dehydration of *vic*-diols<sup>166</sup> gives either conjugated dienes or they lose only 1 equivalent of water to give an aldehyde or ketone. Dienes can be prepared, however, by heating alkynyl alcohols with triphenylphosphine.<sup>167</sup>

## 17-2 Cleavage of Ethers to Alkenes

Alkenes can be formed by the treatment of ethers with very strong bases, such as alkylsodium or alkyllithium<sup>168</sup> compounds, sodium amide,<sup>169</sup> or LDA,<sup>170</sup> although there are side reactions with many of these reagents. The reaction is aided by electron-withdrawing groups in the  $\beta$  position, and, for example,  $\text{EtOCH}_2\text{CH}(\text{COOEt})_2$  can be converted to  $\text{CH}_2=\text{C}(\text{COOEt})_2$  without any base at all, simply by heating.<sup>171</sup> *tert*-Butyl ethers are cleaved more easily than others. Several mechanisms are possible. In many cases, the mechanism is probably  $\text{E1cB}$  or on the  $\text{E1cB}$  side of the mechanistic spectrum,<sup>172</sup> since the base required is so strong, but it has been shown (by the use of  $\text{PhCD}_2\text{OEt}$ ) that  $\text{PhCH}_2\text{OEt}$  reacts by the five-membered  $\text{E}^i$  mechanism.<sup>173</sup> Propargylic benzyl ethers are converted to conjugated dienes by heating with a Ru catalyst.<sup>174</sup>

Cyclic ethers, such as THF, react slowly with organolithium reagents with cleavage that produces a  $\text{C}=\text{C}$  unit.<sup>175</sup> Fragmentation of 2,5-dihydrofuran with ethylmagnesium chloride and a chiral Zr catalyst leads to a chiral, homoallylic alcohol.<sup>176</sup> Acetals can be converted to enol ethers in this manner. When ketals react with 2 molar equivalents of triisobutylaluminum, the product is a vinyl ether.<sup>177</sup> This transformation can also be done at room temperature by treatment with trimethylsilyl triflate and a tertiary amine<sup>178</sup> or with  $\text{Me}_3\text{SiI}$  in the presence of hexamethyldisilazane.<sup>179</sup>

Conversion of a carbonyl compound to an enol phosphate<sup>180</sup> or triflate<sup>181</sup> allows a subsequent elimination reaction to give an alkyne. Conversion of an aldehyde to the vinyl nonaflate (nonafluorobutane-1-sulfonyl) was followed by reaction with a phosphazene base to give the alkyne.<sup>182</sup>

## 17-3 The Conversion of Epoxides and Episulfides to Alkenes

Epoxides can be converted to alkenes<sup>183</sup> by treatment with triphenylphosphine<sup>184</sup> or triethyl phosphite  $\text{P}(\text{OEt})_3$ .<sup>185</sup> The first step of the mechanism is nucleophilic substitution (**10-34**) to give a betaine, and a four-center elimination gives the alkene. Since inversion accompanies the substitution, the overall elimination is *anti*, that is, if two groups are *cis* in the epoxide, they will be *trans* in the alkene. Alternatively, the epoxide can be treated with lithium diphenylphosphide  $\text{Ph}_2\text{PLi}$ , and the product is quaternized with methyl iodide.<sup>186</sup> Alkenes have also been obtained from epoxides by reaction with a large number of reagents,<sup>187</sup> among them  $\text{Li}$  in  $\text{THF}$ ,<sup>188</sup> trimethylsilyl iodide,<sup>189</sup> and compounds of  $\text{Sm}$ ,<sup>190</sup>  $\text{Mo}$ ,  $\text{In}$ ,<sup>191</sup> and the  $\text{W}$  reagents mentioned in **17-16**. Some of these methods give *syn* elimination. Sodium amalgam with a  $\text{Co}$  salen complex converted epoxides to alkenes.<sup>192</sup>

Epoxides can be converted to allylic alcohols<sup>193</sup> by treatment with several reagents, including *sec*-butyllithium,<sup>194</sup> and *i*- $\text{Pr}_2\text{NLi}$ -*t*- $\text{BuOK}$  (the *LIDAKOR* reagent).<sup>195</sup> These bases remove the proton from the adjacent carbon, leading to formation of a  $\text{C}=\text{C}$  unit and opening of the epoxide to give an alkoxide. Phenyllithium reacts with epoxides in the presence of lithium 2,2,6,6-tetramethylpiperidide (LTMP) to give a *trans* alkene.<sup>196</sup> Sulfur ylids such as  $\text{Me}_2\text{S}=\text{CH}_2$  also convert epoxides to allylic alcohols.<sup>197</sup>  $\alpha,\beta$ -Epoxy ketones are converted to conjugated ketones by treatment with  $\text{NaI}$  in acetone in the presence of Amberlyst 15,<sup>198</sup> or with 2.5 molar equivalents of  $\text{SmI}_2$ .<sup>199</sup> The deoxygenation of epoxides to the alkene was catalyzed by oxo-rhenium(V) and (VII) complexes.<sup>200</sup> A mixture of  $\text{Sn}/\text{NaI}$  was used to deoxygenate epoxides to give the alkene.<sup>201</sup> Alkenes were prepared via electrolysis of epoxides with a pair of zinc electrodes, in a mixture of saturated aqueous

<sup>199</sup> Concellón, J.M.; Bardales, E. *J. Org. Chem.* **2003**, *68*, 9492. In a similar manner, epoxy amides are converted to conjugated amides, see Concellón, J.M.; Bardales, E. *Eur. J. Org. Chem.* **2004**, 1523.

<sup>200</sup> Sousa, S.C.A.; Fernandes, A.C. *Tetrahedron Lett.* **2011**, *52*, 6960.

<sup>201</sup> Pathe, G.K.; Ahmed, N. *Synthesis* **2015**, *47*, 3542.

$\text{NH}_4\text{Br}$  and tetrahydrofuran.<sup>202</sup> The reaction of aliphatic epoxides with a catalytic amount of  $\text{Re}_2\text{O}_7$  and triphenyl phosphite give the alkene with good stereoselectivity.<sup>203</sup> A 30 mol% solution of polyphosphoric acid (PPA) promoted the conversion of aliphatic and aromatic epoxides to alkenes.<sup>204</sup>

When an optically active reagent is used, optically active allylic alcohols can be produced from achiral epoxides.<sup>205</sup> Sparteine and *sec*-butyllithium generate a chiral base that leads to the formation of chiral allylic alcohols.<sup>206</sup> Chiral diamines react with organolithium reagents to produce chiral bases that convert epoxides to allylic alcohols with good enantioselectivity.<sup>207</sup> Chiral diamines with a mixture of LDA and DBU (**15-28**, **17-11**) give similar results.<sup>208</sup>

Episulfides<sup>209</sup> can be converted to alkenes.<sup>210</sup> However, in this case the elimination is *syn*, so the mechanism cannot be the same as that for conversion of epoxides. The phosphite attacks sulfur rather than carbon. Among other reagents that convert episulfides to alkenes are certain Rh complexes.<sup>211</sup> Episulfoxides can be converted to alkenes and sulfur monoxide simply by heating.<sup>212</sup>

#### 17-4 Pyrolysis of Carboxylic Acids and Esters of Carboxylic Acids To Form Alkenes

Functional groups can be incorporated into a molecule that will facilitate *syn* elimination via intramolecular removal of a  $\beta$  hydrogen.<sup>213</sup> A simple example is an acetoxy group ( $-\text{OCOMe}$ ), where the carbonyl oxygen of the ester functions as a tethered base.<sup>214</sup> The oxygen is a weak base and loss of the acetoxy group leads to loss of acetic acid. Such a *syn* elimination of acetic acid requires higher reaction temperatures, typically 300–550 °C. However, acetates are readily available by reaction of an alcohol with acetic anhydride or acetyl chloride and pyridine (or another base). The acetoxy unit at a tertiary carbon is usually eliminated in preference to an acetoxy at the secondary carbon. The reaction of  $\text{SmI}_2$

and aromatic allylic benzoates gave the alkene, with high selectivity for the nonconjugated alkene.<sup>215</sup>

No solvent is required for the decarboxylation. Since rearrangement and other side reactions are few, the reaction is synthetically very useful and is often carried out as an indirect method of accomplishing **17-1**. The yields are excellent and the workup is easy. Many alkenes have been prepared in this manner. For longer carbon chains (greater than around C<sub>10</sub>), pyrolysis of the alcohol in the presence of acetic anhydride is a better method.<sup>216</sup> Direct elimination of a carboxylic acid (decarboxylation) to an alkene has been accomplished by heating in the presence of Pd catalysts.<sup>217</sup> Allylic acetates give dienes when heated with certain Pd<sup>218</sup> or Mo<sup>219</sup> compounds.

The mechanism is E<sup>i</sup> (Sec. 17.E.i). Lactones can be pyrolyzed to give unsaturated acids, provided that the six-membered transition state required for E<sup>i</sup> reactions is available (it is not for five- and six-membered lactones, but it is for larger rings<sup>220</sup>). Amides give a similar reaction, but require higher temperatures.

Carboxylic acids can be dehydrated by pyrolysis to give a ketene: RCH<sub>2</sub>CO<sub>2</sub>H → RCH=C=O. Ketene itself is commercially prepared in this manner. Carboxylic acids have been converted to ketenes by treatment with certain reagents, including TsCl,<sup>221</sup> dicyclohexylcarbodiimide,<sup>222</sup> and 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).<sup>223</sup> Analogously, amides can be dehydrated with P<sub>2</sub>O<sub>5</sub>, pyridine, and Al<sub>2</sub>O<sub>3</sub> to give ketenimines.<sup>224</sup>

The dehydrosulfenylation of 2-arylsulfinyl esters to give the alkene followed a homolytic cleavage mechanism.<sup>225</sup>

xanthate occurs via a *syn* elimination to give the alkene and  $\text{RS}(\text{C}=\text{O})\text{SH}$ , which decomposes to  $\text{O}=\text{C}=\text{S}$  and the thiol. This reaction is called the *Chugaev reaction*.<sup>227</sup> The temperatures required with xanthates are lower than with ordinary esters, which is advantageous because possible isomerization of the resulting alkene is minimized. The mechanism is  $\text{E}^1$ , similar to that of **17-4**. For a time there was doubt as to which sulfur atom closed the ring, but now there is much evidence, including the study of  $^{34}\text{S}$  and  $^{13}\text{C}$  isotope effects, to show that it is the  $\text{C}=\text{S}$  sulfur.<sup>228</sup> In a structural variation of this reaction, heating a propargylic xanthate with 2,4,6-trimethylpyridinium trifluoromethyl sulfonate leads to formation of an alkene.<sup>229</sup>

OS VII, 139.

Several types of inorganic ester can be cleaved to alkenes by treatment with bases. Esters of sulfuric, sulfurous, and other acids undergo elimination in solution by  $\text{E}1$  or  $\text{E}2$  mechanisms, as do tosylates and other esters of sulfonic acids.<sup>230</sup> Esters of 2-pyridinesulfonic acid and 8-quinolinesulfonic acid gave alkenes in high yields simply on heating, without a solvent.<sup>231</sup> Phosphonate esters have been cleaved to alkenes by treatment with *Lawesson's reagent*<sup>232</sup> (see **16-10**).

OS, VI, 837; VII, 117.

## 17-6 Elimination of Quaternary Ammonium Hydroxides

Another example of *syn* elimination is the cleavage of quaternary ammonium hydroxides as the final step of the process known as *Hofmann exhaustive methylation* or *Hofmann degradation* or just *Hofmann elimination*.<sup>233</sup> In general, the less-substituted alkene is the major product. In the first step, a primary, secondary, or tertiary amine is treated with enough iodomethane to convert it to the quaternary ammonium iodide (**10-30**). In the second step, the iodide counterion is converted to the hydroxide counterion by treatment with silver oxide. In the cleavage step an aqueous or alcoholic solution of the ammonium hydroxide is distilled, often under reduced pressure. The decomposition generally takes place between 100 and 200 °C. Alternatively, the solution can be concentrated to a syrup by distillation or freeze-drying.<sup>234</sup> When the syrup is heated at low pressures, the cleavage reaction takes

React.* **1960**, *11*, 317.

<sup>234</sup> Archer, D.A. *J. Chem. Soc. C* **1971**, 1327.

place at lower temperatures than are required for the reaction in the ordinary solution, probably because the base ( $\text{HO}^-$  or  $\text{RO}^-$ ) is less solvated.<sup>235</sup>

A side reaction involving nucleophilic substitution to give an alcohol ( $\text{R}_4\text{N}^+ \text{OH}^- \rightarrow \text{ROH} + \text{R}_3\text{N}$ ) often accompanies the normal elimination reaction,<sup>236</sup> but seldom causes trouble. However, when none of the four groups on the nitrogen has a  $\beta$  hydrogen, substitution is the only reaction possible. On heating  $\text{Me}_4\text{N}^+ \text{OH}^-$  in water, methanol is obtained, although without a solvent the product is not methanol, but dimethyl ether.<sup>237</sup>

The mechanism of elimination is usually  $\text{E}2$  in protic solvents. *Hofmann's rule* is generally obeyed by acyclic substrates and *Zaitsev's rule* by cyclohexyl substrates (Sec. 17.B, category 4). In certain cases, where the molecule is highly hindered or if the ammonium hydroxide is heated without solvent (neat), a five-membered  $\text{E}^i$  mechanism, that is, the hydroxide in these cases, removes one of the methyl hydrogen atoms, which removes a proton from the less-substituted  $\beta$  carbon atom to give the less-substituted alkene with loss of the amine. It is also possible that the hydroxide (rather than the N-ylid) removes the  $\beta$  hydrogen atom via an eclipsed rotamer in which the hydroxide is tethered to the ammonium unit and a *syn* transition state is lower in energy.

The obvious way to distinguish between this mechanism and the ordinary  $\text{E}2$  mechanism is by the use of deuterium labeling. For example, if the reaction is carried out on a quaternary hydroxide deuterated on the  $\beta$  carbon ( $\text{R}_2\text{CDCH}_2\text{NMe}_3^+ \text{OH}^-$ ), the fate of the deuterium indicates the mechanism. If the  $\text{E}2$  mechanism were in operation, the trimethylamine produced would contain no deuterium (which would be found only in the water). But if the mechanism is  $\text{E}^i$ , the amine would contain deuterium. In the case of the highly hindered compound  $(\text{Me}_3\text{C})_2\text{CDCH}_2\text{NMe}_3^+ \text{OH}^-$ , the deuterium did appear in the amine, demonstrating an  $\text{E}^i$  mechanism for this case.<sup>238</sup> With simpler compounds, the mechanism is  $\text{E}2$ , since here the amine was deuterium free.<sup>239</sup>

When the nitrogen bears more than one group possessing a  $\beta$  hydrogen, which group cleaves? The *Hofmann rule* says that *within* a group the hydrogen on the least alkylated carbon cleaves. This tendency is also carried over to the choice of which group cleaves: thus ethyl with three  $\beta$  hydrogen atoms cleaves more readily than any longer *n*-alkyl group, all of which have two  $\beta$  hydrogen atoms. "The  $\beta$  hydrogen is removed most readily if it is located on a methyl group, next from  $\text{RCH}_2$ , and least readily from  $\text{R}_2\text{CH}$ ."<sup>240</sup> In fact, the *Hofmann rule* as first stated<sup>241</sup> in 1851 applied only to which group cleaved, not to the orientation within a group; the latter could not have been specified in 1851, since the structural theory of organic compounds was not formulated until 1857–1860. Of course, the *Hofmann rule* (applied to which group cleaves *or* to orientation within a group) is superseded by conjugation possibilities. Thus  $\text{PhCH}_2\text{CH}_2\text{N}^+\text{Me}_2\text{Et}^- \text{OH}^-$  gives mostly styrene instead of ethylene.

Triple bonds have been prepared by pyrolysis of 1,2-bis(ammonium) salts.<sup>242</sup>

When quaternary ammonium halides are treated with strong bases (e.g., PhLi, KNH<sub>2</sub> in liquid NH<sub>3</sub><sup>243</sup>), an elimination can occur that gives an alkene, although not by the mechanism discussed above. This reaction is done on the quaternary ammonium halide, so that it is not necessary to convert this to the hydroxide. The mechanism is E<sup>i</sup> via ylid formation and subsequent fragmentation.

An  $\alpha'$  hydrogen is obviously necessary in order for the ylid to be formed. This type of mechanism is called  $\alpha',\beta$  elimination, since a  $\beta$  hydrogen is removed by the  $\alpha'$  carbon of the ylid. The mechanism has been confirmed by labeling experiments similar to those described above,<sup>244</sup> and by isolation of the intermediate ylids.<sup>245</sup> An important synthetic difference between this base-induced elimination via an ylid and other base-induced eliminations is that *syn* elimination is observed here, so products of opposite configuration are formed when the alkene exhibits *cis-trans* isomerism.

### 17-7 Cleavage of Amine Oxides

Cleavage of amine oxides to produce an alkene and a hydroxylamine is called the *Cope reaction* or *Cope elimination*<sup>246</sup> (not to be confused with the *Cope rearrangement*, **18-32**).<sup>247</sup> The reaction is usually performed with a mixture of amine and oxidizing agent (see **19-28**) without isolation of the amine oxide. Side reactions are few because of the mild conditions, and the alkenes do not usually rearrange. The reaction is thus very useful for the preparation of many alkenes. A limitation is that it does not open six-membered rings containing nitrogen, although it does open rings of 5 and 7–10 members.<sup>248</sup> Rates of the reaction increase with increasing size of  $\alpha$  and  $\beta$  substituents.<sup>249</sup> The reaction can be carried out at room temperature in dry Me<sub>2</sub>SO or THF.<sup>250</sup> The influence of solvent effects has been examined.<sup>251</sup> The elimination is a stereoselective *syn* process,<sup>252</sup> and the five-membered E<sup>i</sup> mechanism operates. Almost all evidence indicates that the transition state must be planar. Deviations from planarity are not found here, and indeed this is why six-membered

heterocyclic nitrogen compounds do not react. Because of the stereoselectivity of this reaction and the lack of rearrangement of the products, it is useful for the formation of *trans* cycloalkenes (eight-membered and higher). A polymer-bound Cope elimination reaction has been reported.<sup>253</sup>

The Ir-catalyzed asymmetric allylation of imines gave 1,4-disubstituted homoallylic amines via an intermolecular regioselective allylation of 2-azaallyl anions and a subsequent 2-aza-Cope rearrangement.<sup>254</sup> The reaction of *N*-oxoammonium salts within the presence of DBU cycloalkenes followed by Cope elimination gave cycloalkadienes.<sup>255</sup> A reverse Cope elimination of hydroxylamines and alkenes or alkynes has been studied.<sup>256</sup>

OS IV, 612.

### 17-8 Pyrolysis of Keto Ylids

Phosphorus ylids are quite common (see 16-44) and keto-phosphorus ylids [RCOCH=PPh<sub>3</sub>] are also known. When these compounds are heated (flash vacuum pyrolysis, FVP) to > 500 °C, alkynes are formed. Simple alkynes<sup>257</sup> can be formed as well as keto-alkynes<sup>258</sup> and enynes.<sup>259</sup> Rearrangement from ylids derived from tertiary amines and α-diazo ketones is also known.<sup>260</sup>

### 17-9 Decomposition of Toluene-*p*-sulfonylhydrazones

Treatment of the tosylhydrazone of an aldehyde or a ketone with a strong base leads to the formation of an alkene, the reaction being formally an elimination accompanied by a hydrogen shift.<sup>261</sup> The reaction (called the *Shapiro reaction*) has been applied to tosylhydrazones<sup>262</sup> of many aldehydes and ketones. The most useful synthetic method involves

treatment of the substrate with at least 2 molar equivalents of an organolithium compound<sup>263</sup> (usually MeLi) in ether, hexane, or tetramethylenediamine.<sup>264</sup> This procedure gives good yields of alkenes without side reactions and, where a choice is possible, predominantly gives the less highly substituted alkene. Tosylhydrazones of  $\alpha,\beta$ -unsaturated ketones give conjugated dienes.<sup>265</sup> A modified Shapiro reaction was reported that used bis(mesityl)magnesium as the base.<sup>266</sup>

The mechanism<sup>267</sup> has been formulated as that shown.

Evidence for this mechanism is: (i) 2 molar equivalents of RLi are required; (ii) the hydrogen in the product comes from the water and not from the adjacent carbon, as shown by deuterium labeling;<sup>268</sup> and (iii) the intermediates **21** and **22** have been trapped, along with the vinyl lithium product.<sup>269</sup> This reaction, when performed in tetramethylenediamine, can be a synthetically useful method<sup>270</sup> of generating vinylic lithium compounds, which can be trapped by various electrophiles<sup>271</sup> such as D<sub>2</sub>O (to give deuterated alkenes), CO<sub>2</sub> (to give  $\alpha,\beta$ -unsaturated carboxylic acids, **16-30**), or DMF (to give  $\alpha,\beta$ -unsaturated aldehydes, **16-29**). Treatment of *N*-aziridino hydrazones with LDA leads to alkenes with high *cis* selectivity.<sup>272</sup>

The reaction also takes place with other bases (e.g., NaH, LiH,<sup>273</sup> Na in ethylene glycol, NaNH<sub>2</sub>) or with smaller amounts of RLi, but in these cases side reactions are common and the orientation of the double bond is in the other direction (to give the more highly substituted alkene). The reaction with Na in ethylene glycol is called the *Bamford-Stevens reaction*.<sup>274</sup> For these reactions two mechanisms are possible: a carbenoid mechanism and a carbocation mechanism.<sup>275</sup> The side reactions found are those expected of carbenes and carbocations. In general, the carbocation mechanism is chiefly found in protic solvents and the carbenoid mechanism in aprotic solvents. Both routes involve formation of a diazo compound (**23**), which is formed by base-induced deprotonation of the tosyl hydrazone to give an anion and loss of the tosyl group gives **23**. In fact, this reaction has been

used as a synthetic method for the preparation of diazo compounds.<sup>276</sup> In the absence of protic solvents, **23** loses N<sub>2</sub> and hydrogen migrates to give the alkene product. The migration of hydrogen may immediately follow, or be simultaneous with, the loss of N<sub>2</sub>. In a protic solvent, **23** becomes protonated to give the diazonium ion **24**, which loses N<sub>2</sub> to give the corresponding carbocation, that may then undergo elimination or give other reactions characteristic of carbocations.

A diazo compound is an intermediate in the formation of alkenes by treatment of *N*-nitrosoamides with a Rh catalyst.<sup>277</sup>

OS VI, 172; VII, 77; IX, 147. For the preparation of a diazo compound, see OS VII, 438.

### 17-10 Cleavage of Sulfoxides, Selenoxides, and Sulfones

Sulfonium compounds ( $-C^{+}SR_2$ ) undergo elimination similar to that of their ammonium counterparts (**17-6**) in scope and mechanism but this reaction is not of great synthetic importance and proceeds by *syn* elimination<sup>278</sup> to give the less-substituted alkene.

Sulfones and sulfoxides<sup>279</sup> with a  $\beta$  hydrogen, on the other hand, undergo elimination on treatment with an alkoxide or, for sulfones,<sup>280</sup> even with hydroxide.<sup>281</sup> Sulfones also eliminate in the presence of an organolithium reagent and a Pd catalyst.<sup>282</sup> Mechanistically, these reactions belong on the E1-E2-E1cB spectrum.<sup>283</sup> Although the leaving groups are uncharged, the orientation follows *Hofmann's rule*, not *Zaitsev's*. Sulfoxides (but not sulfones) also undergo elimination upon pyrolysis at  $\sim 80$  °C in a manner analogous to

<sup>276</sup> See Regitz, M.; Maas, G. *Diazo Compounds*, Academic Press, NY, **1986**, pp. 257–295. For an improved procedure, see Wulfman, D.S.; Yousefian, S.; White, J.M. *Synth. Commun.* **1988**, *18*, 2349.

<sup>283</sup> Hofmann, J.E.; Wallace, T.L.; Schriesheim, A. *J. Am. Chem. Soc.* **1964**, *86*, 1561.

**17-7.** The mechanism is also analogous, being the five-membered E<sup>i</sup> mechanism with *syn* elimination.<sup>284</sup>

Selenoxides<sup>285</sup> and sulfinates R<sub>2</sub>CH—CHR—SO—OMe<sup>286</sup> also undergo elimination by the E<sup>i</sup> mechanism, and the selenoxide reaction takes place at room temperature. The reaction with selenoxides has been extended to the formation of triple bonds.<sup>287</sup> Both α-keto selenoxides<sup>288</sup> and α-keto sulfoxides<sup>289</sup> have been used in a method for the conversion of ketones, aldehydes, and carboxylic esters to their α,β-unsaturated derivatives. Allylic sulfoxides undergo 1,4 elimination to give dienes.<sup>290</sup>

OS VI, 23, 737; VIII, 543; IX, 63.

### 17-11 Dehydrohalogenation of Alkyl Halides

The elimination of HX from an alkyl halide is a very general reaction and can be accomplished with chlorides, fluorides, bromides, and iodides, usually by an E<sub>2</sub> mechanism.<sup>291</sup> In other words, the more-substituted alkene is the major product. Hot alcoholic KOH is the most frequently used base, although stronger bases<sup>292</sup> (−OR, −NH<sub>2</sub>, etc.) or weaker ones (e.g., amines) are used when feasible.<sup>293</sup> The bicyclic amidines 1,5-diazabicyclo[3.4.0]non-5-ene (DBN)<sup>294</sup> and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)<sup>295</sup> are good reagents for difficult cases<sup>296</sup> and can convert primary halides to the corresponding alkene.

Solvation by HMPA promotes LDA-mediated dehydrobromination.<sup>297</sup> An ionic liquid-dependent mechanism has been examined.<sup>298</sup> The decomposition kinetics of ethyl halides, phenethyl halides, and methoxyphenethyl halides were investigated using high level computational chemistry methods.<sup>299</sup>

Dehydrohalogenation with the nonionic base  $(\text{Me}_2\text{N})_3\text{P}=\text{N}-\text{P}(\text{NMe}_3)_2=\text{NMe}$  is even faster.<sup>300</sup> A Co catalyst with dimethylphenylsilylmethylmagnesium chloride leads to the formation of terminal alkenes from secondary alkyl bromides.<sup>301</sup> Phase-transfer catalysis has been used with hydroxide as base.<sup>302</sup> As previously mentioned (Sec. 17.A.v), certain weak bases in dipolar aprotic solvents are effective reagents for dehydrohalogenation. Among those most often used for synthetic purposes are LiCl or LiBr/LiCO<sub>3</sub> in DMF.<sup>303</sup> Dehydrohalogenation occurs by simply heating the alkyl halide in HMPA with no other reagent present.<sup>304</sup> As in nucleophilic substitution (Sec. 10.G.iii), the order of leaving group reactivity is I > Br > Cl > F.<sup>305</sup> Tertiary halides undergo elimination most easily. Eliminations of chlorides, bromides, and iodides follow *Zaitsev's rule*, except for a few cases where steric effects are important (for an example, see Sec. 17.B, category 4). Elimination of fluorides follow *Hofmann's rule* (Sec. 17.B, category 4).

Mechanistic studies have been carried out for the Pd-catalyzed base-induced dehydrohalogenation of primary allyl bromides to terminal alkenes.<sup>306</sup> The In- and Zn-mediated dehalogenation reaction of 1-bromo-2-iodo alkenes in an aqueous solvent gave allenes.<sup>307</sup> The Cu-catalyzed enantioselective reaction of propargylic dichlorides in the presence of a Grignard reagent gave axially chiral chloroallenes.<sup>308</sup> The elimination rate of base-induced alkyl iodides, including primary, secondary, and tertiary iodides in water, was enhanced with irradiation by ultraviolet (UV) light.<sup>309</sup> The reaction of *vic*-dibromides containing  $\alpha$ -bromocarbonyl or  $\alpha$ -bromoaromatic moieties with *o*- and *m*-anisidines gave the (*E*) alkene.<sup>310</sup> Heating 1,1-dibromo-1-alkenes with Cs<sub>2</sub>CO<sub>3</sub> in DMSO gave the corresponding terminal alkyne.<sup>311</sup> The phase-transfer catalyzed synthesis of terminal alkynes from the corresponding vicinal dibromo compounds used anhydrous potassium phosphate as the base in aqueous PEG-900.<sup>312</sup>

This reaction is by far the most important way of introducing a triple bond into a molecule.<sup>313</sup> Alkyne formation can be accomplished with 1,1-dihalo, 1,2-dihalo, and vinyl halides.<sup>314</sup> When the base is  $\text{NaNH}_2$ , 1-alkynes predominate (where possible), because this base is strong enough to form the salt of the alkyne, shifting any equilibrium between 1-alkynes and 2-alkynes. When the base is  $^-\text{OH}$  or  $^-\text{OR}$ , the equilibrium tends to be shifted to the internal alkyne, which is thermodynamically more stable. If another hydrogen is suitably located (e.g.,  $-\text{CRH}-\text{CX}_2-\text{CH}_2-$ ), allene formation can compete, although alkynes are usually more stable. Tetrabutylammonium fluoride mediates the dehydrobromination of vinyl bromides to terminal alkynes.<sup>315</sup> Treatment of 1,1-dibromo-1-alkenes with a Pd catalyst, followed by reaction with tetrabutylammonium hydroxide, gives an internal alkyne.<sup>316</sup> 1,1-Dibromoalkenes are converted to alkynes when treated with *n*-butyllithium.<sup>317</sup> This transformation is a modification of the *Fritsch-Buttenberg-Wiechell rearrangement* in which a 1,1-diaryl vinyl bromide gives a diaryl alkyne upon treatment with base.<sup>318</sup> Vinyl sulfoxides that contain a leaving group such as chloride on the double bond react with *tert*-butyllithium to give a lithio alkyne, and hydrolysis leads to the final product, an alkyne.

Dehydrohalogenation is generally carried out in solution, with a base, and the mechanism is usually E2, although the E1 mechanism has been demonstrated in some cases. However, elimination of HX can be accomplished by pyrolysis of the halide, in which case the mechanism is E<sup>i</sup> (Sec. 17.E.i) or, in some instances, the free-radical mechanism (Sec. 17.E.i). Pyrolysis is normally performed without a catalyst at  $\sim 400^\circ\text{C}$ . The pyrolysis reaction is not generally useful synthetically, because of its reversibility. Less work has been done on pyrolysis with a catalyst<sup>319</sup> (usually a metallic oxide or salt), but the mechanisms here are probably E1 or E2.

give the reaction, but if at least one R is hydrogen, only the ketene dimer, not the ketene, is isolated. However, if a reactive ketene must be used in a reaction with a given compound, the ketene can be generated *in situ* in the presence of the given compound.<sup>322</sup>

Closely related is the reaction of tertiary amines with sulfonyl halides that contain an  $\alpha$  hydrogen. In this case the initial product is the highly reactive sulfene ( $\text{RCH}=\text{SO}_2$ ), which cannot be isolated but reacts further to give products, one of which may be the alkene that is the dimer of  $\text{RCH}$ .<sup>323</sup> Reactions of sulfenes *in situ* are also common (e.g., see **16-48**).

### 17-13 Elimination of Boranes

Trialkylboranes are formed from an alkene and  $\text{BH}_3$  (**15-11**). When the resulting borane is treated with another alkene, an exchange reaction occurs,<sup>324</sup> which is an equilibrium process. This equilibrium can be shifted by using a large excess of an unusually reactive alkene, or by using an alkene with a higher boiling point than the displaced alkene and removing the latter by distillation. The reaction is useful for shifting a double bond in the direction opposite to that resulting from normal isomerization methods (**12-2**). Therefore, heating borane **25** leads to **26** (**18-11**) and when **26** is heated with a higher boiling alkene (e.g., dec-1-ene), the exchange reaction gives 3-ethylpent-1-ene.

These isomerizations proceed essentially without rearrangement. The mechanism is probably the reverse of borane addition (**15-11**).

### 17-14 Conversion of Alkenes to Alkynes

Alkenes of the form shown lose the elements of methane when treated with sodium nitrite in acetic acid and water, to form alkynes in moderate to high yields.<sup>325</sup> The R may contain additional unsaturation, as well as OH, OR, OAc, C=O, and other groups, but the  $\text{Me}_2\text{C}=\text{CHCH}_2-$  portion of the substrate is necessary for the reaction to take place. The

<sup>322</sup> See Luknitskii, F.I.; Vovsi, B.A. *Russ. Chem. Rev.* **1969**, 38, 487.

<sup>323</sup> See King, J.F. *Acc. Chem. Res.* **1975**, 8, 10; Nagai, T.; Tokura, N. *Int. J. Sulfur Chem. Part B* **1972**, 207; Truce, W.E.; Liu, L.K. *Mech. React. Sulfur Compd.* **1969**, 4, 145.

<sup>325</sup> Abidi, S.L. *Tetrahedron Lett.* **1986**, 27, 267; *J. Org. Chem.* **1986**, 51, 2687.

mechanism is complex, beginning with a nitration that takes place with allylic rearrangement  $[\text{Me}_2\text{C}=\text{CHCH}_2\text{R} \rightarrow \text{H}_2\text{C}=\text{CMeCH}(\text{NO}_2)\text{CH}_2\text{R}]$ , and involving several additional intermediates.<sup>326</sup> The  $\text{CH}_3$  lost from the substrate appears as  $\text{CO}_2$ , as demonstrated by the trapping of this gas.<sup>326</sup>

### 17-15 Decarbonylation of Acyl Halides or Aldehydes

Acyl chlorides containing an  $\alpha$  hydrogen are smoothly converted to alkenes, with loss of  $\text{HCl}$  and  $\text{CO}$ , upon heating with chlorotris(triphenylphosphine)rhodium, with metallic  $\text{Pt}$ , or with certain other catalysts.<sup>327</sup> The mechanism probably involves conversion of  $\text{RCH}_2\text{CH}_2\text{COCl}$  to  $\text{RCH}_2\text{CH}_2-\text{RhCO}(\text{Ph}_3\text{P})_2\text{Cl}_2$  followed by a concerted *syn* elimination of  $\text{Rh}$  and  $\text{H}$ <sup>328</sup> (see also, **14-26** and **19-12**).

Aldehydes are decarbonylated to give the corresponding hydrocarbon in the presence of an  $\text{Ir}$  catalyst and triphenylphosphine.

## B. Reactions in Which Neither Leaving Atom is Hydrogen

### 17-16 Deoxygenation of Vicinal Diols

*vic*-Diols can be deoxygenated by treatment of the dilithium dialkoxide with a tungsten halide (e.g.,  $\text{K}_2\text{WCl}_6$ ), or with certain other tungsten reagents, in THF at reflux.<sup>329</sup> Tetra-substituted diols react most rapidly. The elimination is largely, but not entirely, *syn*. Several other methods have been reported,<sup>330</sup> in which the diol is deoxygenated directly, without conversion to the dialkoxide. These include treatment with  $\text{Ti}$  metal,<sup>331</sup> with  $\text{TsOH}/\text{NaI}$ ,<sup>332</sup> and by heating with  $\text{CpReO}_3$ ,<sup>333</sup> where  $\text{Cp}$  is cyclopentadienyl.

*vic*-Diols can also be deoxygenated indirectly, through sulfonate ester derivatives. For example, *vic*-dimesylates and *vic*-ditosylates have been converted to alkenes by treatment with naphthalene/sodium<sup>334</sup> and  $\text{NaI}$  in  $\text{DMF}$ ,<sup>335</sup> respectively. In another procedure, the

<sup>335</sup> Dafaye, J. *Bull. Soc. Chim. Fr.* **1968**, 2099.

diols are converted to bisdithiocarbonates (bis xanthates), which undergo elimination (probably by a free-radical mechanism) when treated with tri-*n*-butylstannane in toluene or benzene.<sup>336</sup> *vic*-Diols can also be deoxygenated through cyclic derivatives (**17-19**).

### 17-17 Cleavage of Cyclic Thionocarbonates

Cyclic thionocarbonates (**27**) can be cleaved to alkenes (the *Corey-Winter reaction*)<sup>337</sup> by heating with trimethyl phosphite<sup>338</sup> or other trivalent phosphorus compounds<sup>339</sup> or by treatment with bis(1,5-cyclooctadiene)nickel.<sup>340</sup> The thionocarbonates such as **27** can be prepared by treatment of 1,2-diols with thiophosgene and 4-dimethylaminopyridine (DMAP).<sup>341</sup> The elimination is of course *syn*, so the product is sterically controlled. Alkenes that are not sterically favored can be made this way in high yield (e.g., *cis*-PhCH<sub>2</sub>CH=CHCH<sub>2</sub>Ph).<sup>342</sup>

### 17-18 The Ramberg-Bäcklund Reaction

The reaction of an  $\alpha$ -halo sulfone with a base to give an alkene is called the *Ramberg-Bäcklund reaction*.<sup>343</sup> The reaction is quite general for  $\alpha$ -halo sulfones with an  $\alpha'$  hydrogen, despite the unreactive nature of  $\alpha$ -halo sulfones in normal S<sub>N</sub>2 reactions (Sec. 10.G.i, category 6). Halogen reactivity is in the order I > Br  $\gg$  Cl. Phase-transfer catalysis has been used.<sup>344</sup> In general, mixtures of *cis* and *trans* isomers are obtained, but usually the less stable *cis* isomer predominates. The mechanism involves formation of an episulfone, and then elimination of SO<sub>2</sub>. There is much evidence for this mechanism,<sup>345</sup> including the

isolation of the episulfone intermediate,<sup>346</sup> and also the preparation of episulfones in other ways and the demonstration that they give alkenes under the reaction conditions faster than the corresponding  $\alpha$ -halo sulfones.<sup>347</sup> Episulfones synthesized in other ways (e.g., **16-48**) are reasonably stable compounds, but eliminate  $\text{SO}_2$  to give alkenes when heated or treated with base.

If the reaction is run on the unsaturated bromosulfones  $\text{RCH}_2\text{CH}=\text{CHSO}_2\text{CH}_2\text{Br}$  (prepared by reaction of  $\text{BrCH}_2\text{SO}_2\text{Br}$  with  $\text{RCH}_2\text{CH}=\text{CH}_2$  followed by treatment with  $\text{Et}_3\text{N}$ ),  $\text{RCH}=\text{CHCH}=\text{CH}_2$  is produced in moderate to good yields.<sup>348</sup> The compound mesyltriflone  $\text{CF}_3\text{SO}_2\text{CH}_2\text{SO}_2\text{CH}_3$  can be used as a synthon for the tetra ion  $^{2-}\text{C}=\text{C}^{2-}$ .

2,5-Dihydrothiophene-1,1-dioxides (**28**) and 2,7-dihydrothiepin-1,1-dioxides (**29**) undergo analogous 1,4 and 1,6 eliminations, respectively (see also **17-34**). These are concerted reactions and, as predicted by the orbital-symmetry rules (**15-46.A**, and immediately preceding pages), the former<sup>349</sup> is a suprafacial process and the latter<sup>350</sup> an antarafacial process. The rules also predict that elimination of  $\text{SO}_2$  from episulfones cannot take place by a concerted mechanism (except antarafacially, which is unlikely for such a small ring), and the evidence shows that this reaction occurs by a nonconcerted pathway.<sup>351</sup> The eliminations of  $\text{SO}_2$  from **28** and **29** are examples of *cheletropic reactions*,<sup>352</sup> which are defined as reactions in which two  $\sigma$  bonds that terminate at a single atom (in this case the sulfur atom) are made or broken in concert.<sup>353</sup>

$\alpha,\alpha$ -Dichlorobenzyl sulfones react with an excess of the base triethylenediamine (TED) in DMSO at room temperature to give 2,3-diarylthiiren-1,1-dioxides, which can be isolated.<sup>354</sup> Thermal decomposition gives the alkyne.<sup>355</sup> A Ramberg-Bäcklund-type reaction has been carried out on the  $\alpha$ -halo sulfides ( $\text{ArCHClSCH}_2\text{Ar}$ ), which react with *t*-BuOK and  $\text{PPh}_3$  in refluxing THF to give the alkenes ( $\text{ArCH}=\text{CHAr}$ ).<sup>356</sup> Cyclic sulfides lead to

### 17-19 The Conversion of Aziridines to Alkenes

Aziridines not substituted on the nitrogen atom react with nitrous acid to produce alkenes.<sup>358</sup> An *N*-nitroso compound is an intermediate (**12-49**); other reagents that produce such intermediates also give alkenes. The reaction is stereospecific: *cis*-aziridines give *cis*-alkenes and *trans*-aziridines give *trans*-alkenes.<sup>359</sup> Aziridines carrying *N*-alkyl substituents can be converted to alkenes by treatment with ferrous iodide<sup>360</sup> or with *m*-chloroperoxybenzoic acid.<sup>361</sup> An *N*-oxide intermediate (**19-28**) is presumably involved in the latter case. *N*-Tosyl aziridines give allylic sulfonamides when treated with butyllithium.<sup>362</sup> *N*-Tosyl aziridines are converted to *N*-tosyl imines when treated with boron trifluoride.<sup>363</sup> 2-Tosylmethyl *N*-tosyl aziridines react with  $\text{Te}^{2-}$  in the presence of Adogen 464 to give allylic *N*-tosyl amines.<sup>364</sup> 2-Halomethyl *N*-tosyl aziridines also react with In metal in methanol to give *N*-tosyl allylic amines.<sup>365</sup>

### 17-20 Elimination of Vicinal Dihalides

Dehalogenation has been accomplished with many reagents, the most common being Zn, Mg, and iodide ion.<sup>366</sup> Heating in HMPA is often enough to convert a *vic*-dibromide to an alkene.<sup>367</sup> When the reagent is Zn, *anti* stereospecificity has been observed in some cases,<sup>368</sup> but not in others.<sup>369</sup> Electrochemical reduction has also been used,<sup>370</sup> as has treatment with

In<sup>371</sup> or Sm<sup>372</sup> metal in methanol, InCl<sub>3</sub>/NaBH<sub>4</sub>,<sup>373</sup> or heating with Zn in acetic acid.<sup>374</sup> Microwave irradiation of a *vic*-dibromide in an ionic liquid leads to the alkene.<sup>375</sup> The reaction of a vicinal dibromide with triethylamine and DMF with microwave irradiation leads to vinyl bromide.<sup>376</sup>  $\alpha,\beta$ -Dibromo amides are converted to conjugated amides upon photolysis in methanol.<sup>377</sup>

One useful feature of this reaction is that there is no doubt about the *position* of the new double bond, so that it can be used to give double bonds exactly where they are wanted. For example, allenes, which are not easily prepared by other methods, can be prepared from X—C—CX<sub>2</sub>—C—X or X—C—CX=C— systems.<sup>378</sup> Cumulenes have been obtained from 1,4 elimination, as in the reaction of Zn and 1,4-dibromobut-2-yne to give buta-1,2,3-triene. Cumulenes have also been prepared by treating alkynyl epoxides with boron trifluoride.<sup>379</sup>

Allylic rearrangements have also been demonstrated in propargyl systems, for example,<sup>380</sup> and the product in this case is an allene.<sup>381</sup> 1,4 elimination of BrC—C=C—CBr has been used to prepare conjugated dienes C=C—C=C.<sup>382</sup> Allenes are formed by heating propargylic alcohols with arylboronic acids (12-27) and a Pd catalyst.<sup>383</sup> Allenes are also formed from propargylic amines using CuI and a Pd catalyst.<sup>384</sup> In addition, allenes are formed from lithium bromocyclopropylidenoids.<sup>385</sup> Propargylic halides can be alkylated with essentially complete allylic rearrangement, to give allenes, by treatment with Grignard reagents and metallic salts,<sup>386</sup> or with dialkylcuprates R<sub>2</sub>Cu.<sup>387</sup> An enantioselective coupling of diazoalkanes with terminal alkynes to give allenes, using a Cu catalyst.<sup>388</sup> Allenes are formed by the coupling of alkylzinc halides and propargyl bromides using a Ni catalyst.<sup>389</sup> Allenes are obtained when propargyl acetates are treated with methylmagnesium iodide.<sup>390</sup> Propargylic ethers give allenes.<sup>391</sup> Propargylic tosylates couple with vinylic

cuprates to give vinylic allenes.<sup>392</sup> Racemic propargyl carbonates gave chiral allenes in the presence of LiF, CO, and a Pd catalyst.<sup>393</sup>

The reaction can be carried out for any combination of halogens, except where one is fluorine. Mechanisms are often complex and depend on the reagent and reaction conditions.<sup>394</sup> For different reagents, mechanisms involving carbocations, carbanions, and free-radical intermediates, as well as concerted mechanisms, have been proposed.

OS III, 526, 531; IV, 195, 268; V, 22, 255, 393, 901; VI, 310, VII, 241. Also see, OS IV, 877, 914, 964.

### 17-21 Dehalogenation of $\alpha$ -Halo Acyl Halides

Ketenes can be prepared by dehalogenation of  $\alpha$ -halo acyl halides with zinc or with triphenylphosphine.<sup>395</sup> The reaction generally gives good results when the two R groups are aryl or alkyl, but not when either one is hydrogen.<sup>396</sup>

OS IV, 348; VIII, 377.

### 17-22 Elimination of a Halogen and a Hetero Group

The elimination of OR and halogen from  $\beta$ -halo ethers is called the *Boord reaction*. It can be carried out with Zn, Mg, Na, or certain other reagents.<sup>397</sup> The yields are high and the reaction is of broad scope.  $\beta$ -Halo acetals readily yield vinylic ethers,  $\text{X}-\text{C}(\text{OR})_2 \rightarrow \text{C}=\text{C}-\text{OR}$  and 2 molar equivalents of  $\text{SmI}_2$  in HMPA is effective.<sup>398</sup> Besides  $\beta$ -halo ethers, the reaction can also be carried out on compounds of the formula  $\text{Z}-\text{C}-\text{C}-\text{Z}$  where X is halogen and Z is OCOR, OTs,<sup>399</sup>  $\text{NR}_2$ ,<sup>400</sup> or SR.<sup>401</sup> When  $\text{X} = \text{Cl}$  and  $\text{Z} = \text{OAc}$ , heating in THF with an excess of  $\text{SmI}_2$  followed by treatment with dilute aqueous HCl gives an

<sup>401</sup> Amstutz, E.D. *J. Org. Chem.* **1944**, *9*, 310.

alkene.<sup>402</sup> When  $Z = \text{I}$  and the other  $Z$  is an oxygen of an oxazolone (a carbamate unit), heating with  $\text{In}$  metal in methanol leads to an allylic amine.<sup>403</sup> The  $Z$  group may also be  $\text{OH}$ , but then  $X$  is limited to  $\text{Br}$  and  $\text{I}$ .<sup>404</sup> Like **17-20**, this method ensures that the new double bond will be in a specific position. The fact that  $\text{Mg}$  causes elimination in these cases limits the preparation of *Grignard reagents* from these compounds. It has been shown that treatment of  $\beta$ -halo ethers and esters with  $\text{Zn}$  gives nonstereospecific elimination,<sup>405</sup> so the mechanism cannot be  $\text{E2}$ . An  $\text{E1cB}$  mechanism was postulated because of the poor leaving group ability of  $\text{OR}$  and  $\text{OCOR}$ . Bromohydrins can be converted to alkenes (elimination of  $\text{Br, OH}$ ) in high yields by treatment with  $\text{LiAlH}_4/\text{TiCl}_3$ .<sup>406</sup>

OS **III**, 698, **IV**, 748; **VI**, 675.

## 17.F.ii. Fragmentations

When carbon is the positive leaving group (the electrofuge) in an elimination, the reaction is called *fragmentation*.<sup>407</sup> These processes occur on substrates of the form  $\text{W}-\text{C}-\text{C}-\text{X}$ , where  $X$  is a normal nucleofuge (e.g., halogen,  $^+\text{OH}_2$ ,  $\text{OTs}$ ,  $^+\text{NR}_3$ ) and  $\text{W}$  is a positive-carbon electrofuge. In most of the cases,  $\text{W}$  is  $\text{HO}-\text{C}-$  or  $\text{R}_2\text{N}-\text{C}-$ , so that the positive charge on the carbon atom is stabilized by the unshared pair of the oxygen or nitrogen. The following is an example:

The mechanisms are mostly  $\text{E1}$  or  $\text{E2}$ . We will discuss only a few fragmentations, since many are possible and not much work has been done on most of them. Reactions **17-23** to **17-26** and **17-28** may be considered fragmentations (see also **19-12** and **19-13**).

### 17-23 1,3-Fragmentation of $\gamma$ -Amino Halides, $\gamma$ -Hydroxy Halides, and 1,3-Diols

$\gamma$ -Dialkylamino halides undergo fragmentation when heated with water to give an alkene and an iminium salt, which under the reaction conditions is hydrolyzed to an aldehyde or ketone (**16-2**).<sup>408</sup>  $\gamma$ -Hydroxy halides and tosylates are fragmented with base. In this

<sup>408</sup> Grob, C.A.; Ostermayer, F.; Raudenbusch, W. *Helv. Chim. Acta* **1962**, 45, 1672.

instance, the base does not play its usual role in elimination reactions, but instead serves to remove a proton from the OH group, and electron transfer generates the carbonyl and an alkene with loss of the leaving group.

Prelog first observed this type of fragmentation in work that solved the structure of quinine and other *Cinchona* alkaloids in a 1,3-elimination ring-opening reaction.<sup>409</sup> Subsequent work by Grob elucidated the mechanism of the reaction,<sup>410</sup> and this 1,3 elimination is often referred to as *Grob fragmentation*.<sup>411</sup> The mechanism of these reactions is often E1, but an E2 mechanism also operates.<sup>412</sup> It has been shown that stereoisomers of cyclic  $\gamma$ -amino halides and tosylates in which the two leaving groups can assume an anti-periplanar conformation react by the E2 mechanism, while those isomers in which the groups cannot assume such a conformation either fragment by the E1 mechanism or do not undergo fragmentation at all, but in either case give rise to side products characteristic of carbocations.<sup>413</sup> An example of a Grob fragmentation is the conversion of **30** to **31** in a synthesis of vinigrol.<sup>414</sup>

Arynes have been prepared by application of the Grob fragmentation.<sup>415</sup> The conversion of 2-methylidimedone into the corresponding vinylogous acyl triflate and subsequent reduction of the ketone moiety to the alcohol allowed reaction with an ylid-forming reagent ( $\text{Et}_2\text{O}_3\text{PCH}_2\text{CO}_2\text{Et/LDA}$ ). Subsequent fragmentation/alkene-forming reaction gave the 1,6-enyne.  $\gamma$ -Dialkylamino alcohols do not give fragmentation, since ionization of the OH group requires protonation to give  $^+\text{OH}_2$ , which would convert  $\text{NR}_2$  to  $^+\text{NR}_2\text{H}$ . The ammonium salt does not have the unshared pair necessary to form the double bond with the carbon.<sup>416</sup>

The  $\text{C}_\beta\text{-C}_\gamma$  bond of bicyclic  $\gamma$ -silyloxy- $\beta$ -hydroxy- $\alpha$ -diazo ketones fragmented when treated with tin(IV) chloride to give 10-, 11-, and 12-membered alkynone cyclic 2-alkynones.<sup>417</sup>

1,3-Diols in which at least one OH group is tertiary or is located on a carbon with aryl substituents can be cleaved to a carbonyl and an alkene by acid treatment.<sup>418</sup> The reaction is most useful synthetically when at least one of the OH groups is on a ring.<sup>419</sup>

17-24 Decarboxylation of  $\beta$ -Hydroxy Carboxylic Acids and  $\beta$ -Lactones

An OH and a CO<sub>2</sub>H group can be eliminated from  $\beta$ -hydroxy carboxylic acids by heating with excess dimethylformamide dimethylacetal at reflux.<sup>420</sup> Mono-, di-, tri-, and tetrasubstituted alkenes have been prepared by this method in good yields.<sup>421</sup> There is evidence that the mechanism involves E1 or E2 elimination from the zwitterionic intermediate  $^{-}O_2C-C-C-O-C=N^+Me_2$ .<sup>422</sup> The reaction has also been accomplished<sup>423</sup> under extremely mild conditions (a few seconds at 0 °C) with PPh<sub>3</sub> and EtO<sub>2</sub>C-N=N-CO<sub>2</sub>Et (diethyl azodicarboxylate).<sup>424</sup> In a related procedure,  $\beta$ -lactones undergo thermal decarboxylation to give alkenes in high yields. The reaction has been shown to be stereospecific *syn* elimination.<sup>425</sup> There is evidence that this reaction also involves a zwitterionic intermediate.<sup>426</sup>

The microwave-assisted direct aerobic decarboxylative elimination of arylacetic acids gave the alkene using PIFA [bis(trifluoroacetoxy)iodobenzene] as an oxidant.<sup>427</sup> Heating carboxylic acids or dicarboxylic acids in the presence of a Pd catalyst 190 °C, neat, gave  $\alpha$ -olefins and  $\alpha,\omega$ -dienes.<sup>428</sup>

See OS VII, 172, for a related reaction.

17-25 Fragmentation of  $\alpha,\beta$ -Epoxy Hydrazones

Cyclic  $\alpha,\beta$ -unsaturated ketones<sup>429</sup> can be cleaved by treatment with base of their epoxy tosylhydrazone derivatives to give acetylenic ketones,<sup>430</sup> in what is known as the *Eschenmoser-Tanabe ring cleavage*. The reaction can be applied to the formation of

OS VI, 679.

### 17-26 Elimination of CO and CO<sub>2</sub> from Bridged Bicyclic Compounds

On heating, bicyclo[2.2.1]hept-2,3-en-7-ones usually lose CO to give cyclohexadienes,<sup>434</sup> in a type of *reverse Diels-Alder reaction* (**15-56**).

Bicyclo[2.2.1]heptadienones undergo the reaction so readily that they cannot generally be isolated, because of the stability of the benzene ring produced. The parent bicyclo[2.2.1]heptadienone has been obtained at 10–15 K in an Ar matrix, where its spectrum could be studied.<sup>435</sup> Such bicyclic systems can be prepared by a *Diels-Alder reaction* between a cyclopentadienone and an alkyne or alkene, so that this reaction is a useful method for the preparation of specifically substituted benzene rings and cyclohexadienes.<sup>436</sup> Unsaturated bicyclic lactones such as 2-oxabicyclo[2.2.2]oct-5-en-3-one can also undergo the reaction, losing CO<sub>2</sub> (see also, **17-33**).

OS III, 807; V, 604, 1037.

Reversal of the *Diels-Alder reaction* may be considered a fragmentation reaction (see **15-56**).

## 17.F.iii. Reactions in Which C≡N or C=N Bonds Are Formed

## 17-27 Dehydration of Oximes and Similar Compounds

Aldoximes can be dehydrated to nitriles<sup>437</sup> by many dehydrating agents, of which acetic anhydride is the most common. Among the reagents that are effective under mild conditions<sup>438</sup> are  $\text{Ph}_3\text{P}/\text{CCl}_4$ ,<sup>439</sup>  $\text{PPh}_3/\text{I}_2$ ,<sup>440</sup>  $\text{Pd}(\text{OAc})_2/\text{PPh}_3$  in  $\text{CH}_3\text{CN}$  at reflux,<sup>441</sup>  $\text{Cu}(\text{II})$  with ultrasound,<sup>442</sup> and  $\text{ZnO}/\text{CH}_3\text{COCl}$  under solvent-free conditions.<sup>443</sup> DMF catalyzes the thermal dehydration of aldoximes.<sup>444</sup> Heating an oxime with a Ru catalyst gives the nitrile.<sup>445</sup> Heating with the *Burgess reagent* [ $\text{Et}_3\text{N}^+ \text{SO}_2\text{N}-\text{CO}_2\text{Me}$ ] in polyethylene glycol is effective for this transformation.<sup>446</sup> Sulfuric acid-impregnated silica gel<sup>447</sup> gives the nitrile. Aldehydes can be converted to oximes *in situ* and microwave irradiation on alumina<sup>448</sup> or with ammonium acetate<sup>449</sup> gives the nitrile. Solvent-free reactions are known.<sup>450</sup> The reaction is most successful when the H and OH are *anti*. Hydroxylamines that have an  $\alpha$  proton are converted to nitrones when treated with a Mn/salen complex.<sup>451</sup> The Sn- or Ga-catalyzed conversion of oximes to nitriles has been reported,<sup>452</sup> and Ni catalysts have been used.<sup>453</sup> The dehydration of aldoximes used areneselenenic acids ( $\text{ArSeOH}$ ), which are readily generated from diaryl diselenides and  $\text{H}_2\text{O}_2$  by *in situ* oxidation, and gave the organonitrile.<sup>454</sup>

Quaternary hydrazone salts (from hydrazines derived from aldehydes) give nitriles when treated with  $^-\text{OEt}^{455}$  or DBU (see **17-11**),<sup>456</sup> as do dimethylhydrazones

(RCH=NNMe<sub>2</sub>) when treated with Et<sub>2</sub>NLi and HMPA.<sup>457</sup> All these are methods of converting aldehyde derivatives to nitriles. For the conversion of aldehydes directly to nitriles, without isolation of intermediates, see **16-14**.

Certain ketoximes can be converted to nitriles by the action of proton acids or Lewis acids.<sup>458</sup> Among these are the monooxime of  $\alpha$ -diketones, and the oximes of  $\alpha$ -keto acids,  $\alpha$ -dialkylamino ketones,  $\alpha$ -hydroxy ketones,  $\beta$ -keto ethers, and similar compounds.<sup>459</sup> These are fragmentation reactions, analogous to **17-23**. For example,  $\alpha$ -dialkylamino ketoximes also give amines and aldehydes or ketones besides nitriles.<sup>460</sup> The reaction that normally occurs on treatment of a ketoxime with a Lewis acid or proton acid is the *Beckmann rearrangement* (**18-17**); fragmentations are considered side reactions, often called "abnormal" or "second-order" *Beckmann rearrangements*.<sup>461</sup> Obviously, the substrates mentioned are much more susceptible to fragmentation than are ordinary ketoximes, since in each case an unshared pair of electrons is available to assist in removal of the group cleaving from the carbon. However, fragmentation is a side reaction even with ordinary ketoximes<sup>462</sup> and, in cases where a particularly stable carbocation can be cleaved, may be the main reaction.<sup>463</sup>

There are indications that the mechanism at least in some cases first involves a rearrangement and then cleavage. The ratio of fragmentation to Beckmann rearrangement of a series of oxime tosylates, RC(=NOTs)Me, was not related to the solvolysis rate but was related to the stability of R<sup>+</sup> (as determined by the solvolysis rate of the corresponding RCl), which showed that fragmentation did not take place in the rate-determining step.<sup>464</sup> It may be postulated then that the first step in the fragmentation and in the rearrangement is the same and that this is the rate-determining step. The product is determined in the second step. However, in other cases, the simple E1 or E2 mechanisms operate.<sup>465</sup>

## 17-28 Dehydration of Unsubstituted Amides

Unsubstituted amides can be dehydrated to nitriles.<sup>466</sup> Phosphorus pentoxide is the most common dehydrating agent for this reaction, but many others, including  $\text{POCl}_3$ ,  $\text{PCl}_5$ ,  $\text{CCl}_4/\text{Ph}_3\text{P}$ ,<sup>467</sup> HMPA,<sup>468</sup>  $\text{MeOOCNSO}_2\text{NEt}_3$  (the *Burgess reagent*),<sup>469</sup>  $\text{Me}_2\text{N}=\text{CHCl}^+ \text{Cl}^-$ ,<sup>470</sup>  $\text{PPh}_3/\text{NCS}$ ,<sup>471</sup> oxalyl chloride/DMSO/ $-78^\circ\text{C}$  (*Swern conditions*, see **19-3**),<sup>472</sup> *o*-iodoxybenzoic acid/ $\text{Et}_4\text{NBr}$ ,<sup>473</sup> TBAF and hydrosilanes,<sup>474</sup> and  $\text{SOCl}_2$ , have also been used.<sup>475</sup> Heating an amide with paraformaldehyde and formic acid gives the nitrile.<sup>476</sup> It is possible to convert an acid to the nitrile, without isolation of the amide, by heating its ammonium salt with the dehydrating agent,<sup>477</sup> or by other methods.<sup>478</sup> Treatment of an amide with aqueous NaOH and ultrasound leads to the nitrile.<sup>479</sup> *N*-Alkyl-substituted amides can be converted to nitriles and alkyl chlorides by treatment with  $\text{PCl}_5$ . This is called the *von Braun reaction* (not to be confused with the other von Braun reaction, **10-54**).

OS I, 428; II, 379; III, 493, 535, 584, 646, 768; IV, 62, 144, 166, 172, 436, 486, 706; VI, 304, 465.

17-29 Conversion of *N*-Alkylformamides to Isonitriles (Isocyanides)

Isonitriles (isonitriles) can be prepared by elimination of water from *N*-alkylformamides<sup>480</sup> with phosgene and a tertiary amine.<sup>481</sup> Other reagents, among

#### 17.F.iv. Reactions in Which C=O Bonds Are Formed

Many elimination-type reactions in which C=O bonds are formed were considered in Chapter 16, along with their more important reverse reactions (also see **12-39** and **12-40**).

#### 17-30 Pyrolysis of β-Hydroxy Alkenes

When pyrolyzed, β-hydroxy alkenes cleave to give alkenes and aldehydes or ketones.<sup>490</sup> Alkenes produced this way are quite pure, since there are no side reactions. The mechanism has been shown to be pericyclic, primarily by observations that the kinetics are first order<sup>491</sup> and that, for ROD, the deuterium appeared in the allylic position of the new alkene.<sup>492</sup> This mechanism is the reverse of that for the oxygen analog of the ene synthesis (**16-53**), as shown.

$\beta$ -Hydroxyacetylenes react similarly to give the corresponding allenes and carbonyl compounds.<sup>493</sup> The mechanism is the same despite the linear geometry of the triple bonds.

In a related reaction, pyrolysis of allylic ethers that contain at least one  $\alpha$  hydrogen gives alkenes and aldehydes or ketones. The mechanism is also pericyclic, analogous to homoallylic alcohols.<sup>494</sup>

## 17.F.v. Reactions in Which N=N Bonds Are Formed

### 17-31 Eliminations To Give Diazoalkanes

Various *N*-nitroso-*N*-alkyl compounds undergo elimination to give diazoalkanes.<sup>495</sup> One of the most convenient methods for the preparation of diazomethane involves base treatment of *N*-nitroso-*N*-methyl-*p*-toluenesulfonamide (illustrated above, with R = H).<sup>496</sup> Several other compounds are commonly used to prepare diazomethane and all require base treatment, although the sulfonamide shown, which is commercially available, is most satisfactory. *N*-Nitroso-*N*-methylcarbamate and *N*-nitroso-*N*-methylurea give good yields, but are highly irritating and carcinogenic.<sup>497</sup> For higher diazoalkanes the preferred substrates are nitrosoalkylcarbamates. Most of these reactions probably begin with a 1,3 nitrogen-to-oxygen rearrangement, followed by the actual elimination.

OS II, 165; III, 119, 244; IV, 225, 250; V, 351; VI, 981.

## 17.F.vi. Extrusion Reactions

An *extrusion reaction*<sup>498</sup> is one in which a molecule X–Y–Z has an atom or group Y that is initially connected to two other atoms X and Z and which is lost from the molecule, leading to a product in which X is bonded directly to Z. Reactions **14-26** and **17-18** also fit this definition. Reaction **17-26** does not fit the definition, but is often also classified as an extrusion reaction. A scale of extrusion facility has been developed, showing that the ease of extrusion of the common Y groups is in the order: –N=N– > –COO– > –SO<sub>2</sub>– > –CO–.<sup>499</sup>

17-32 Extrusion of N<sub>2</sub> from Pyrazolines, Pyrazoles, and Triazolines

1-Pyrazolines (**33**) can be converted to cyclopropane and N<sub>2</sub> on photolysis<sup>500</sup> or pyrolysis.<sup>501</sup> The tautomeric 2-pyrazolines (**34**), which are more stable than **33**, also give the reaction, but in this case an acidic or basic catalyst is required, the function of which is to convert **34** to **33**.<sup>502</sup> In the absence of such catalysts, **34** does not react.<sup>503</sup> In a similar manner, triazolines (**35**) are converted to aziridines.<sup>504</sup> Side reactions are frequent with both **33** and **35**, and some substrates do not give the reaction at all. However, the reaction has proved synthetically useful in many cases. In general, photolysis gives better yields and fewer side reactions than pyrolysis with both **33** and **35**. 3*H*-Pyrazoles<sup>505</sup> (**36**) are stable to heat, but in some cases can be converted to cyclopropenes on photolysis,<sup>506</sup> although in other cases other types of products are obtained.

The mechanism<sup>507</sup> of the 1-pyrazoline reactions generally involves extrusion of N<sub>2</sub> and formation of diradicals, although the mode of formation and detailed structure (e.g., singlet versus triplet) of these radicals may vary with the substrate and reaction conditions. The reactions of the 3*H*-pyrazoles (**36**) have been postulated to proceed through a diazo compound that loses N<sub>2</sub> to give a vinylic carbene.<sup>508</sup> It is noted that expulsion of N<sub>2</sub> from organic azides used a Au catalyst.<sup>509</sup>

17-33 Extrusion of CO or CO<sub>2</sub>

Although the reaction is not general, certain cyclic ketones can be photolyzed to give ring-contracted products.<sup>510</sup> An example is a *trans*-disubstituted cyclobutanone was photolyzed to give the cyclopropane derivative.<sup>511</sup> This reaction was used to synthesize tetra-*tert*-butyltetrahedrane, **37**.<sup>512</sup> The mechanism probably involves a Norrish type I cleavage (Sec. 7.A.vii), loss of CO from the resulting radical, and recombination of the radical fragments.

Certain lactones extrude CO<sub>2</sub> on heating or on irradiation.<sup>513</sup> Decarboxylation of  $\beta$ -lactones (see **17-24**) may be regarded as a degenerate example of this reaction. Unsymmetrical diacyl peroxides RCO—OO—COR' lose two molecules of CO<sub>2</sub> when photolyzed in the solid state to give the product RR'.<sup>514</sup> Electrolysis was also used, but yields were lower.

There are no OS references, but see OS VI, 418, for a related reaction.

17-34 Extrusion of SO<sub>2</sub>

In a reaction similar to **17-33**, certain sulfones, both cyclic and acyclic,<sup>515</sup> extrude SO<sub>2</sub> on heating or photolysis to give ring-contracted products.<sup>516</sup> An example is the preparation

of naphtho(*b*)cyclobutene shown above.<sup>517</sup> In a different kind of reaction, five-membered cyclic sulfones can be converted to cyclobutenes by treatment with butyllithium followed by  $\text{LiAlH}_4$ .<sup>518</sup> This method is most successful when both the  $\alpha$  and  $\alpha'$  position of the sulfone bear alkyl substituents (see also **17-18**). Treating four-membered ring sultams with  $\text{SnCl}_2$  led to aziridine products via loss of  $\text{SO}_2$ .<sup>519</sup>

OS VI, 482.

### 17-35 The Story Synthesis

When cycloalkylidene peroxides (e.g., **38**) are heated in an inert solvent (e.g., decane), extrusion of  $\text{CO}_2$  takes place; the products are the cycloalkane containing three carbon atoms less than the starting peroxide and the lactone containing two carbon atoms less<sup>520</sup> (the *Story synthesis*).<sup>521</sup> The two products are formed in comparable yields, usually  $\sim 15\text{--}25\%$  each. Although the yields are low, the reaction is useful because there are not many other ways to prepare large rings. The reaction is versatile, having been used to prepare rings of every size from 8 to 33 members.

Both dimeric and trimeric cycloalkylidene peroxides can be synthesized<sup>522</sup> by treatment of the corresponding cyclic ketones with  $\text{H}_2\text{O}_2$  in acid solution.<sup>523</sup> The trimeric peroxide is formed first and is subsequently converted to the dimeric compound.<sup>524</sup>

### 17-36 Alkene Synthesis by Two-fold Extrusion

4,4-Diphenyloxathiolan-5-ones (**39**) give good yields of the corresponding alkenes when heated with tris(diethylamino)phosphine.<sup>525</sup> This reaction is an example of a general

# Rearrangements

In a rearrangement reaction, a group moves from one atom to another in the same molecule.<sup>1</sup> Most are migrations from one atom to an adjacent one (called 1,2-shifts), but some are over longer distances (e.g., 1,3- or 1,4-shifts).

The group that migrates:

- may move with its electron pair; these can be called *nucleophilic* or *anionotropic* rearrangements and the migrating group can be regarded as a nucleophile
- may move without its electron pair; these are *electrophilic* or *cationotropic* rearrangements and, in the case of migrating hydrogen, *prototropic* rearrangements
- may move with just one electron; these are radical rearrangements.

The atom or atoms that move begin at the *migration origin* and the new attachment point is the *migration terminus*. However, there are some rearrangements that do not lend themselves to neat categorization in this manner. Among these are those with cyclic transition states (**18-27** to **18-36**). Molecular rearrangements are important components of organic synthesis.<sup>2</sup>

As will be seen, nucleophilic ( $X^-$ ) 1,2-shifts are much more common than electrophilic ( $X^+$ ) or free-radical ( $X^\bullet$ ) 1,2-shifts. The reason for this can be seen by a consideration of the transition states (or in some cases intermediates) involved. In the transition state or intermediate for all three cases, the orbital that connects X overlaps with the orbital on the migration terminus, and the overlap of these orbitals leads to a cyclic transition state that allows the migration.

In any rearrangement, two possible modes of reaction can, in principle, be distinguished. In one of these, the group X becomes completely detached and may end up on the atom of a different molecule (*intermolecular* rearrangement). In the other X migrates in the

<sup>1</sup> de Mayo, P. *Rearrangements in Ground and Excited States*, 3 Vols., Academic Press, NY, **1980**; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand-Reinhold, Princeton, **1973**; Collins, C.J.; Eastham, J.F. in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, **1966**, pp. 761–821. See also, the series *Mechanisms of Molecular Migrations*.

<sup>2</sup> *Molecular Rearrangements in Organic Synthesis*, Rojas, C.M. (Ed.), Wiley, Hoboken, **2015**.

same molecule, which is an *intramolecular* rearrangement. It is usually not difficult to tell whether a given rearrangement is intermolecular or intramolecular. The most common method involves the use of *crossover* experiments. In this type of experiment, rearrangement is carried out on a mixture of W—A—B and V—A—C, where V is closely related to W (say, methyl versus ethyl) and B is closely related to C. In an intramolecular process only A—B—W and A—C—V are recovered, but if the reaction is intermolecular, then not only will these two be found, but also A—B—V and A—C—W.

## 18.A. MECHANISMS

### 18.A.i. Nucleophilic Rearrangements<sup>3</sup>

This process of migration of one atom or group to the adjacent atom has been called the *Whitmore 1,2-shift*.<sup>4</sup> Since the migrating group carries the electron pair with it, the migration terminus must be an atom with only six electrons in its outer shell (an open sextet). Such a system can arise in various ways, but two of these are the most important:

1. *Formation of a carbocation.* Carbocations can be formed in a number of ways (Sec. 5.A.iii), but one of the most common methods is the acid treatment of an alcohol to give a carbocation from an intermediate oxonium ion. Once formed, such carbocations are subject to rearrangement to a more stable carbocation. These two steps are of course the same as the first two steps of the S<sub>N</sub>1cA or the E1 reactions of alcohols.
2. *Formation of a nitrene.* The decomposition of acyl azides is one of several ways in which acyl nitrenes are formed (Sec. 5.E). Once the nitrene is formed, the R migrates and an electron pair from the nitrogen moves into the C—N bond to give a stable isocyanate.

In both of these cases, after the migration has taken place, the atom at the migration origin must necessarily have an open sextet and in the final step this atom acquires an octet. In the case of carbocations, combinations with a nucleophile (rearrangement with substitution) or loss of H<sup>+</sup> (rearrangement with elimination) constitutes the final step.

In many reactions, the initial steps are simultaneous so there is no formal intermediate. Many investigations have been carried out in attempts to determine, in various reactions, whether intermediates actually form, or whether the steps are simultaneous (see, e.g., the discussions in 16-45 and Sec. 18.A.ii), but the difference between the two possibilities is often subtle, and the question is not always easily answered.<sup>5</sup>

Evidence for the formation of intermediates is that rearrangements occur under conditions where carbocations have previously been encountered: S<sub>N</sub>1 conditions, *Friedel-Crafts*

<sup>3</sup> Vogel, P. *Carbocation Chemistry*, Elsevier, NY, 1985, pp. 323–372; Shubin, V.G. *Top. Curr. Chem.* 1984, 116/117, 267; Saunders, M.; Chandrasekhar, J.; Schleyer, P.v.R. in de Mayo, P. *Rearrangements in Ground and Excited States*, Vol. 1, Academic Press, NY, 1980, pp. 1–53; Kirmse, W. *Top. Curr. Chem.* 1979, 80, 89. For reviews of rearrangements in vinylic cations, see Shchegolev, A.A.; Kanishchev, M.I. *Russ. Chem. Rev.* 1981, 50, 553; Lee, C.C. *Isot. Org. Chem.* 1980, 5, 1.

<sup>4</sup> It was first postulated by Whitmore, F.C. *J. Am. Chem. Soc.* 1932, 54, 3274.

<sup>5</sup> The IUPAC designations depend on the nature of the steps. For the rules, see Guthrie, R.D. *Pure Appl. Chem.* 1989, 61, 23 (pp. 44–45).

*alkylation*, and so on. Solvolysis of neopentyl bromide leads to rearrangement products, and the rate increases with increasing ionizing power of the solvent but is unaffected by concentration of base,<sup>6</sup> so that the first step is carbocation formation. The same compound under S<sub>N</sub>2 conditions gave no rearrangement, but slowly gave only ordinary substitution. Thus with neopentyl bromide, formation of a carbocation leads only to rearrangement.

Carbocations usually rearrange to more stable carbocations. Thus the direction of rearrangement is usually primary → secondary → tertiary, based on the relative stability of each carbocation.<sup>7</sup> Each migration is a formally a chemical reaction, and is exothermic by 12–15 kcal mol<sup>-1</sup> (50–63 kJ mol<sup>-1</sup>) when the migration generates a tertiary carbocation from a secondary carbocation or a secondary from a primary.<sup>8</sup> Neopentyl- (Me<sub>3</sub>CCH<sub>2</sub>), neophyl- (PhCMe<sub>2</sub>CH<sub>2</sub>), and norbornyl-type systems are especially prone to carbocation rearrangement reactions. It has been shown that the rate of migration increases with the degree of electron deficiency at the migration terminus.<sup>9</sup>

It was previously mentioned (Sec. 5.A.ii) that stable tertiary carbocations could be obtained, in solution, at very low temperatures. The NMR studies have shown that when these solutions are warmed, rapid migrations of hydride and of alkyl groups take place, resulting in an equilibrium mixture of structures.<sup>10</sup> For example, the *tert*-pentyl (2-methylbutyl) cation<sup>11</sup> equilibrates as shown.

Carbocations that rearrange to give products of identical structure are called *degenerate carbocations* and such rearrangements are *degenerate rearrangements*. Many examples are known.<sup>12</sup>

### 18.A.ii. The Actual Nature of the Migration

Most nucleophilic 1,2-shifts are intramolecular. The migrating group does not become free, but always remains connected in some way to the substrate. Apart from the evidence from crossover experiments, the strongest evidence is that when the migrating group is chiral, the configuration is *retained* in the product. For example, (+)-PhCHMeCO<sub>2</sub>H was converted to

(-)-PhCHMeNH<sub>2</sub> by the *Curtius* (**18-14**), *Hofmann* (**18-13**), *Lossen* (**18-15**), and *Schmidt* (**18-16**) reactions.<sup>13</sup> In these reactions, the extent of retention varied from 95.8% to 99.6%. Retention of configuration in the migrating group has been shown many times since.<sup>14</sup>

In cases where the steric nature of the migration origin atom or the migration terminus atom can be investigated, the results are mixed, and it has been shown that either inversion or racemization can occur.<sup>15</sup> One example is **1**, where the conversion proceeded with inversion (equivalent to inversion at B).<sup>16</sup>

Such inversion has been shown in other cases.<sup>17</sup> It is not always necessary for the product to have two steric possibilities in order to investigate the stereochemistry. Thus, in most *Beckmann rearrangements* (**18-17**), only the group *trans* (usually called *anti*) to the hydroxyl group migrates, as illustrated by formation of **2**, which shows inversion.

In certain cases of the S<sub>N</sub>1-type process, it is possible for migration to take place with net retention of configuration at the migrating terminus because of conformational effects in the carbocation.<sup>18</sup>

A few conclusions may be summarized:

1. The S<sub>N</sub>1-type process occurs mostly when the migrating group is a tertiary atom or has one aryl group and at least one other alkyl or aryl group. In other cases, the S<sub>N</sub>2-type process is more likely. Inversion of configuration (indicating an S<sub>N</sub>2-type process) has been shown for a neopentyl substrate by the use of the chiral neopentyl-1-*d* alcohol.<sup>19</sup> There is other evidence that neopentyl systems undergo rearrangement by a carbocation (S<sub>N</sub>1-type) mechanism.<sup>20</sup>
2. The question as to whether a cyclic, bridged cationic species is an intermediate or a transition state has been much debated. When R is aryl or vinyl, then a

bridged cationic species is probably an intermediate and the migrating group lends anchimeric assistance<sup>21</sup> (Sec. 10.C.i, category 3, preceding category 4 for resonance stabilization of this intermediate, when R is aryl). When R is alkyl, a bridged cationic species is a protonated cyclopropane (edge- or corner-protonated; Sec. 15.B.iv). There is much evidence that in simple migrations of a methyl group, the bulk of the products formed do not arise from protonated cyclopropane *intermediates*. Evidence for this statement has already been given (Sec. 10.C.i, category 4c). Further evidence was obtained from experiments involving labeling.

Rearrangement of the neopentyl cation labeled with deuterium in the 1 position gave only *tert*-pentyl products with the label in the 3 position, although if a cyclic, bridged intermediate were an intermediate, the cyclopropane ring could just as well cleave the other way to give *tert*-pentyl derivatives labeled in the 4 position.<sup>22</sup> Another experiment that led to the same conclusion was the generation, in several ways, of  $\text{Me}_3\text{C}^{13}\text{CH}_2^+$ . The only *tert*-pentyl products isolated were labeled in C-3, that is,  $\text{Me}_2\text{C}^+-^{13}\text{CH}_2\text{CH}_3$  derivatives; no derivatives of  $\text{Me}_2\text{C}^+-\text{CH}_2^{13}\text{CH}_3$  were found.<sup>23</sup>

Although the bulk of the products are not formed from protonated cyclopropane intermediates, there is considerable evidence that in 1-propyl systems at least, a small part of the product can in fact arise from such intermediates.<sup>24</sup> Among this evidence is the isolation of 10–15% cyclopropanes (mentioned in Sec. 10.C.i, category 4c). Additional evidence comes from propyl cations generated by diazotization of labeled amines ( $\text{CH}_3\text{CH}_2\text{CD}_2^+$ ,  $\text{CH}_3\text{CD}_2\text{CH}_2^+$ ,  $\text{CH}_3\text{CH}_2^{14}\text{CH}_2^+$ ), where isotopic distribution in the products indicated that a small amount (~5%) of the product had to be formed from protonated cyclopropane intermediates.<sup>25</sup> Even more scrambling was found in trifluoroacetylation of 1-propyl-1-<sup>14</sup>C-mercuric perchlorate.<sup>26</sup> However, protonated cyclopropane intermediates accounted for < 1% of the products from diazotization of labeled isobutylamine<sup>27</sup> and from formolysis of labeled 1-propyl tosylate.<sup>28</sup>

It is likely that protonated cyclopropane transition states or intermediates are also responsible for certain non-1,2-rearrangements.<sup>29</sup> For example, in superacid solution, the tertiary carbocation of 2,3-dimethylbutyl and the tertiary carbocation of 2-methylpentyl are in equilibrium. It is not possible for these to interconvert solely by 1,2-alkyl or 1,2-hydride shifts unless primary carbocations (which are highly

unlikely) are intermediates. However, the reaction can be explained<sup>30</sup> by postulating that (in the forward reaction) it is the 1,2-bond of the intermediate or transition state **3** that opens up rather than the 2,3-bond, which is the one that would open if the reaction were a normal 1,2-shift of a methyl group. In this case, opening of the 1,2-bond produces a tertiary cation, while opening of the 2,3-bond would give a secondary cation.

3. There has been much discussion of H as migrating group. There is no conclusive evidence that a bridged, cyclic intermediate is or is not a true intermediate, although arguments in favor of each position has been made (Sec. 10.C.i, category 4c).

The stereochemistry at the migration origin is less often involved, since in most cases migration origin does not end up as a tetrahedral atom; but when there is inversion here, there is an  $S_N2$ -type process at the beginning of the migration. This may or may not be accompanied by an  $S_N2$  process at the migration terminus. In some cases, it has been found that, when H is the migrating species, the configuration at A may be *retained*.<sup>31</sup>

There is evidence that the configuration of the molecule may be important even where the leaving group is gone long before migration takes place. For example, the 1-adamantyl cation (**4**) does not equilibrate intramolecularly, even at temperatures up to 130 °C,<sup>32</sup> though open-chain and cyclic tertiary carbocations undergo such equilibration at 0 °C or below. On the basis of this and other evidence it has been concluded that for a 1,2-shift of hydrogen or methyl to proceed as smoothly as possible, the vacant  $p$  orbital of the carbon bearing the positive charge and the  $sp^3$  orbital carrying the migrating group must be coplanar,<sup>32</sup> which is not possible for **4**.

### 18.A.iii. Migratory Aptitudes<sup>33</sup>

In many reactions, there is no question about which group migrates. For example, in the *Hofmann*, *Curtius*, and similar reactions there is only one possible migrating group in each molecule, and one can measure migratory aptitudes only by comparing the relative

<sup>30</sup> See Saunders, M.; Vogel, P. *J. Am. Chem. Soc.* **1971**, *93*, 2559, 2561; Kirmse, W.; Loosen, K.; Prolingheuer, E. *Chem. Ber.* **1980**, *113*, 129.

<sup>33</sup> See Koptug, V.A.; Shubin, V.G. *J. Org. Chem. USSR* **1980**, *16*, 1685; Wheland, G.W. *Advanced Organic Chemistry*, 3rd ed., Wiley, NY, **1960**, pp. 573–597.

rearrangement rates of different compounds. In other instances, there are two or more potential migrating groups, but which migrates is settled by the geometry of the molecule. The *Beckmann rearrangement* (**18-17**) provides an example. As seen in the formation of **2**, only the group *trans* to the OH migrates. In compounds whose geometry is not restricted in this manner, there still may be eclipsing effects (Sec. 17.C), so that the choice of migrating group is largely determined by which group is in the right place in the most stable conformation of the molecule.<sup>34</sup> However, in some reactions, especially the *Wagner-Meerwein* (**18-1**) and the *pinacol* (**18-2**) rearrangements, the molecule may contain several groups that, geometrically at least, have approximately equal chances of migrating, and these reactions have often been used for the direct study of relative migratory aptitudes. In the *pinacol rearrangement*, there is the additional question of which OH group leaves and which does not, since a group can migrate only if the OH group on the *other* carbon is lost.

The migration of several possible groups will be dealt with first. To study this question, the best type of substrate to use is one of the form  $R_2C(OH)-C(OH)R'_2$ , since the only thing that determines migratory aptitude is which OH group comes off. Once the OH group is gone, the migrating group is determined. As might be expected, the OH that leaves is the one whose loss gives rise to the more stable carbocation. Thus 1,1-diphenylethanediol (**5**) gives diphenylacetaldehyde, not phenylacetophenone. Obviously, it does not matter in this case whether phenyl has a greater inherent migratory aptitude than hydrogen or not. Only the hydrogen can migrate because **6** is *not* formed.

Remember that carbocation stability is enhanced by groups in the order aryl > alkyl > hydrogen, and this normally determines which side loses the OH group. However, exceptions are known, and which group is lost may depend on the reaction conditions.

In order to answer the question about inherent migratory aptitudes, the obvious type of substrate to use (in the pinacol rearrangement) is  $R'RC(OH)-C(OH)RR'$ , since the same carbocation is formed no matter which OH leaves, and it would seem that a direct comparison of the migratory tendencies of R and R' is possible. On closer inspection, however, it is clear that several factors are operating. Apart from the question of possible conformational effects, already mentioned, there is also the fact that whether the group R or R' migrates is determined not only by the relative inherent migrating abilities of R and R' but also by whether the group that does *not* migrate is better at stabilizing the positive charge that will now be found at the migration origin.<sup>35</sup> Thus, migration of R gives rise to the cation  $R'C^+(OH)CR_2R_2'$ , while migration of R' gives the cation  $R^+C(OH)CRR_2'$  and these cations have different stabilities. It is possible that in a given case R might be found to

<sup>34</sup> See Cram, D.J. in Newman, M.S. *Steric Effects in Organic Chemistry*, Wiley, NY, **1956**, pp. 270–276. For an interesting example, see Nickon, A.; Weglein, R.C. *J. Am. Chem. Soc.* **1975**, *97*, 1271.

<sup>35</sup> See McCall, M.J.; Townsend, J.M.; Bonner, W.A. *J. Am. Chem. Soc.* **1975**, *97*, 2743; Brownbridge, P.; Hodgson, P.K.G.; Shepherd, R.; Warren, S. *J. Chem. Soc., Perkin Trans. 1* **1976**, 2024.

migrate less than R' not because it actually has a lower inherent migrating tendency, but because it is much better at stabilizing the positive charge. In addition to this factor, the migrating ability of a group is also related to its capacity to render anchimeric assistance to the departure of the nucleofuge.

An example of this effect is the decomposition of tosylate **7**, where only the phenyl group migrates. However, in acid treatment of the corresponding alkene **8**, there is competitive migration of both methyl and phenyl (in these reactions  $^{14}\text{C}$  labeling is necessary to determine which group has migrated).<sup>36</sup> Both **7** and **8** give the same carbocation; the differing results must be caused by the fact that in **7** the phenyl group can assist the leaving group, while no such process is possible for **8**.

This example clearly illustrates the difference between migration to a relatively free terminus and one that proceeds with the migrating group lending anchimeric assistance.<sup>37</sup>

Therefore, it is not surprising that clear-cut answers as to relative migrating tendencies are not available. More often than not migratory aptitudes are in the order aryl > alkyl, but exceptions are known, and the position of hydrogen in this series is often unpredictable. In some cases, migration of hydrogen is preferred to aryl migration; in other cases, migration of alkyl is preferred to that of hydrogen. Mixtures are often found, and the isomer that predominates often depends on conditions. For example, the comparison between methyl and ethyl has been made many times in various systems, and in some cases methyl migration has been found to predominate and in others it is ethyl migration that does.<sup>38</sup> However, it can be said that among aryl migrating groups, electron-donating substituents in the *para* and *meta* positions increase the migratory aptitudes, while the same substituents in the *ortho* positions decrease them. Electron-withdrawing groups decrease migrating ability in all positions. The following are a few of the relative migratory aptitudes determined for aryl groups:<sup>39</sup> *p*-anisyl, 500; *p*-tolyl, 15.7; *m*-tolyl, 1.95; phenyl, 1.00; *p*-chlorophenyl, 0.7; *o*-anisyl, 0.3. For the *o*-anisyl group, the poor migrating ability probably has a steric cause, while for the others there is a fair correlation with activation or deactivation of electrophilic aromatic substitution, which is what the process is with respect to the benzene ring. It has been reported that at least in certain systems acyl groups have a greater migratory aptitude than alkyl groups.<sup>40</sup>

18.A.iv. Memory Effects<sup>41</sup>

Solvolysis of the *endo* bicyclic compound **9** (X = ONs, Sec. 10.G.iii, or Br) gave mostly the bicyclic allylic alcohol **12**, along with a smaller amount of the tricyclic alcohol **15**, while solvolysis of the *exo* isomers, **13**, gave mostly **15**, with smaller amounts of **12**.<sup>42</sup> Note that *endo* and *exo* here refers to the position of the XCH<sub>2</sub> group over the C=C unit or opposite the C=C unit, respectively.

The two isomers gave entirely different ratios of products, although the carbocation initially formed seems to be the same for each (marked **10** and **10'** for convenience). With **10**, a second rearrangement (a shift of the 1,7-bond) follows to give **11**, while with **10'** an intramolecular addition of the positive carbon to the double bond gives **14**. It seems as if **10** and **10'** “remember” how they were formed before they go on to give the second step. Such effects are called *memory effects* and other such cases are known.<sup>43</sup> The causes of these effects are not well understood, although there has been much discussion. One possible cause is differential solvation of the apparently identical ions **10** and **10'**. Other possibilities are: (i) that the ions have geometrical structures that are twisted in opposite senses (e.g., a twisted **10'** might have its positive carbon closer to the double bond than a twisted **10**); (ii) that ion pairing is responsible;<sup>44</sup> and (iii) that nonclassical carbocations are involved.<sup>45</sup>

One possibility that has been ruled out is that the steps **9** → **10** → **11** and **13** → **10'** → **14** are concerted, so that **10/10'** never exist at all. This possibility has been excluded by several kinds of evidence, including the fact that **9** gives not only **12**, but also some **15**; and **13** gives some **12** along with **15**. This means that some of the **10** and **10'** ions interconvert, a phenomenon known as *leakage*.

## 18.B. LONGER NUCLEOPHILIC REARRANGEMENTS

The question as to whether a group can migrate with its electron pair to an adjacent atom or over longer distances has been much debated. Although claims have been made that alkyl groups can migrate over distance, the evidence is that such migration is extremely rare, if it occurs at all. One experiment that demonstrated that such migrations are rare was the generation of the 3,3-dimethyl-1-butyl cation  $\text{Me}_3\text{CCH}_2\text{CH}_2^+$ . If 1,3-methyl migrations are possible, this cation would appear to be a favorable substrate, since such a migration would convert a primary cation into the tertiary 2-methyl-2-pentyl cation  $\text{Me}_2\text{C}^+\text{CH}_2\text{CH}_2\text{CH}_3$ , while the only possible 1,2-migration (of hydride) would give only a secondary cation. However, no products arising from the 2-methyl-2-pentyl cation were found, with the only rearranged products being those formed by the 1,2-hydride migration.<sup>46</sup> 1,3-Migration of bromine has been reported.<sup>47</sup>

Most of the debate over the possibility of 1,3-migrations has concerned not methyl or bromine but 1,3-hydride shifts.<sup>48</sup> Many instances have been found of *apparent* 1,3-hydride shifts, but the question is whether they are truly direct hydride shifts or whether they occur by another mechanism. There are at least two ways in which indirect 1,3-hydride shifts can take place: (i) by successive 1,2-shifts or (ii) through the intervention of protonated cyclopropanes (Sec. 18.A.ii, category 2). A direct 1,3-shift would have a four-centered transition state, while the transition state for a 1,3-shift involving a protonated cyclopropane intermediate would resemble a three-centered transition state. The evidence is that most reported 1,3-hydride shifts are actually the result of successive 1,2-migrations,<sup>49</sup> but in some cases small amounts of products cannot be accounted for in this way. The reaction of 2-methylbutan-1-ol with KOH and bromoform gave a mixture of alkenes, nearly all of which could have arisen from simple elimination or 1,2-shifts of hydride or alkyl. However, 1.2% of the product was 3-methylbut-1-ene.<sup>50</sup> Hypothetically, 3-methylbut-1-ene could have arisen from a 1,3-shift (direct or through a protonated cyclopropane) or from two successive 1,2-shifts:

However, the same reaction applied to 2-methylbutan-2-ol gave no 3-methylbut-1-ene., which demonstrated that **18** was not formed from **17**. The conclusion made was that **18** was formed directly from **16**. This experiment does not answer the question as to whether **18** was formed by a direct shift or through a protonated cyclopropane, but from other evidence<sup>51</sup>

<sup>50</sup> Skell, P.S.; Maxwell, R.J. *J. Am. Chem. Soc.* **1962**, *84*, 3963. See also, Skell, P.S.; Starer, I. *J. Am. Chem. Soc.* **1962**, *84*, 3962.

<sup>51</sup> Hudson, H.R.; Koplick, A.J.; Poulton, D.J. *Tetrahedron Lett.* **1975**, 1449; Fry, J.L.; Karabatsos, G.J. in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Vol. 2, Wiley, NY, **1970**, pp. 527.

it appears that 1,3-hydride shifts that do not result from successive 1,2-migrations usually take place through protonated cyclopropane intermediates, which (Sec. 18.A.ii, category 2) account for only a small percentage of the product in any case. However, there is evidence that direct 1,3-hydride shifts occur by way of a bridging hydrogen atom between C1 and C3, and may take place in superacid solutions.<sup>52</sup> Although direct nucleophilic rearrangements over distances greater than 1,2 are rare (or perhaps nonexistent) when the migrating atom or group must move *along* a chain, this is not so for a shift *across* a ring of 8–11 members. Many such transannular rearrangements are known<sup>53</sup> (Sec. 4.Q.ii): the mechanism for the conversion of **19** to **20** is shown.<sup>54</sup>

It is noteworthy that the *methyl* group does not migrate in this system. *It is generally true that alkyl groups do not undergo transannular migration.*<sup>55</sup> In most cases, it is hydride that undergoes this type of migration, though a small amount of phenyl migration has also been shown.<sup>56</sup>

### 18.C. FREE-RADICAL REARRANGEMENTS<sup>57</sup>

1,2-Free-radical rearrangements are much less common than the nucleophilic type previously considered, for the reasons mentioned in the introductory section to this chapter (preceding Sec. 18.A). Where 1,2-free-radical rearrangements do occur, the general pattern is similar.

1. There must first be generation of a free radical.
2. Then the actual migration occurs, in which the migrating group moves with one electron:

3. Finally, the new free radical will undergo a further reaction to generate a neutral molecule.

The order of radical stability leads to a prediction that here too, as with carbocation rearrangements, that migrations should be in the order primary  $\rightarrow$  secondary  $\rightarrow$  tertiary. The logical place to look for free-radical rearrangements should be in neopentyl and neophyl systems.

The most common way of generating free radicals for the purpose of detection of rearrangements is by decarbonylation of aldehydes (**14-26**). In this manner, it was found that neophyl radicals *do* undergo rearrangement.<sup>58</sup> Thus,  $\text{PhCMe}_2\text{CH}_2\text{CHO}$  treated with di-*tert*-butyl peroxide gave about equal amounts of the normal product  $\text{PhCMe}_2\text{CH}_3$  and of the product arising from migration of phenyl, as shown.<sup>59</sup>

Many other cases of free-radical migration of aryl groups have been found.<sup>60</sup> Intramolecular radical rearrangements are known.<sup>61</sup> The C4 radicals of  $\alpha$ - and  $\beta$ -thujone undergo two distinct rearrangement reactions, and it has been proposed that these could serve as simultaneous but independent radical clocks.<sup>62</sup>

A 1,2-shift has been observed in radicals bearing an OCOR group at the  $\beta$  carbon where the oxygen group migrates, as shown in the interconversion of **21** and **22**. This has been proven by  $^{18}\text{O}$  isotopic labeling experiments<sup>63</sup> and other mechanistic explorations.<sup>64</sup> A similar rearrangement was observed with phosphatoxy alkyl radicals such as **23**.<sup>65</sup>

A 1,2-shift of hydrogen atoms has been observed in aryl radicals.<sup>66</sup>

It is noteworthy that the extent of migration is much less than with corresponding carbocations: thus in the rearrangement of **21** there was only  $\sim 50\%$  migration, whereas the carbocation would have given much more. Also noteworthy is that there was no migration of the methyl group. In general, it may be said that free-radical migration of alkyl groups does not occur at ordinary temperatures. Many attempts have been made to detect such migration on the traditional neopentyl and bornyl types of substrates. However, alkyl migration is not observed, even in substrates where the corresponding carbocations undergo

facile rearrangement.<sup>67</sup> Another type of migration that is very common for carbocations, but not observed for free radicals, is 1,2-migration of hydrogen. Examples of the lack of migration of alkyl groups and hydrogen include the following:

1. 3,3-Dimethylpentanal (EtCMe<sub>2</sub>CH<sub>2</sub>CHO) gave no rearranged products on decarbonylation.<sup>68</sup>
2. Addition of RSH to norbornene gave only *exo*-norbornyl sulfides, and the secondary radical is an intermediate, but the corresponding carbocation cannot be formed without rearrangement.<sup>69</sup>

3. The cubylcarbinyl radical did not rearrange to the 1-homocubyl radical, although doing so would result in a considerable decrease in strain.<sup>70</sup>
4. It was shown<sup>71</sup> that no rearrangement of isobutyl radical to *tert*-butyl radical (which would involve the formation of a more stable radical by a hydrogen shift) took place during the chlorination of isobutane.

The 1,2-migration of alkyl groups has been shown to occur in certain *diradicals*.<sup>72</sup> For example, the following rearrangement has been established by tritium labeling.<sup>73</sup>

In this case, the fact that migration of the methyl group leads directly to a compound in which all electrons are paired undoubtedly contributes to the driving force of the reaction.

The fact that aryl groups migrate, but alkyl groups and hydrogen generally do not, leads to the proposition that **24**, in which the odd electron is not found in the three-membered ring, may be an intermediate.

<sup>67</sup> Several unsuccessful attempts: Slauch, L.H.; Magoon, E.F.; Guinn, V.P. *J. Org. Chem.* **1963**, 28, 2643.

<sup>68</sup> Seibold Jr., F.H. *J. Am. Chem. Soc.* **1954**, 76, 3732.

<sup>69</sup> Cristol, S.J.; Brindell, G.D. *J. Am. Chem. Soc.* **1954**, 76, 5699.

<sup>70</sup> Eaton, P.E.; Yip, Y. *J. Am. Chem. Soc.* **1991**, 113, 7692.

<sup>71</sup> Brown, H.C.; Russel, G.A. *J. Am. Chem. Soc.* **1952**, 74, 3995. See also, Desai, V.R.; Nechvatal, A.; Tedder, J.M. *J. Chem. Soc. B* **1970**, 386.

<sup>72</sup> See Freidlina, R.Kh.; Terent'ev, A.B. *Russ. Chem. Rev.* **1974**, 43, 129.

<sup>73</sup> McKnight, C.; Rowland, F.S. *J. Am. Chem. Soc.* **1966**, 88, 3179. See Gajewski, J.J.; Burka, L.T. *J. Am. Chem. Soc.* **1972**, 94, 8857, 8860, 8865.

There has been much controversy on this point, but the bulk of the evidence indicates that **24** is a transition state, not an intermediate.<sup>74</sup> Among the evidence is the failure to observe **24** either by ESR<sup>75</sup> or CIDNP.<sup>76</sup> Both of these techniques can detect free radicals with extremely short lifetimes (Sec. 5.C.i).<sup>77</sup>

Besides aryl, both vinylic<sup>78</sup> and acetoxy groups<sup>79</sup> also migrate. Vinylic groups migrate via a cyclopropylcarbinyl radical intermediate,<sup>80</sup> while the migration of acetoxy groups may involve the charge-separated structure shown in the figure (to the right).<sup>81</sup>

Thermal isomerization of 1-(3-butenyl)cyclopropane at 415 °C leads to bicyclo[2.2.1]heptane.<sup>82</sup>

Migration has been observed for chloro (and to a much lesser extent bromo) groups. For example, in the reaction of  $\text{Cl}_3\text{CCH}=\text{CH}_2$  with bromine under the influence of peroxides, the products were 47%  $\text{Cl}_3\text{CCHBrCH}_2\text{Br}$  (the normal addition product) and 53%  $\text{BrCCl}_2\text{CHClCH}_2\text{Br}$ , which arose by rearrangement. In this particular case the driving force for the rearrangement is the particular stability of dichloroalkyl free radicals.<sup>83</sup> It has been shown that the 1,2-migration of Cl readily occurs if the migration origin is tertiary and the migration terminus primary.<sup>84</sup> Migration of Cl and Br could take place by a transition state in which the odd electron is accommodated in a vacant *d* orbital of the halogen.

Migratory aptitudes have been measured for the phenyl and vinyl groups, and for three other groups, using the system  $\text{RCMe}_2\text{CH}_2\cdot \rightarrow \text{Me}_2\text{OC}\cdot\text{CH}_2\text{R}$ . Migratory aptitudes were found to be in the order  $\text{R} = \text{H}_2\text{C}=\text{CH}_2 > \text{Me}_3\text{CC}=\text{O} > \text{Ph} > \text{Me}_3\text{CC}\equiv\text{C} > \text{CN}$ .<sup>85</sup>

In summary, 1,2-free-radical migrations are much less prevalent than the analogous carbocation processes, and are important only for aryl, vinylic, acetoxy, and halogen migrating groups. The direction of migration is normally toward the more stable radical, but “wrong-way” rearrangements are also known.<sup>86</sup>

Despite the fact that hydrogen atoms do not migrate 1,2, longer free-radical migrations of hydrogen are known.<sup>87</sup> The most common are 1,5-shifts, but 1,6- and longer shifts have

also been found (see **18-29**). The possibility of 1,3-hydrogen shifts has been much investigated, but it is not certain if any actually occur. If they do they are rare, presumably because the most favorable geometry for  $C\cdots H\cdots C$  in the transition state is linear and this geometry cannot be achieved in a 1,3-shift. 1,4-Shifts are definitely known, but are still not very common. These long shifts are best regarded as internal abstractions of hydrogen. For reactions, see **14-5** and **18-40**. Transannular shifts of hydrogen atoms have also been observed.<sup>88</sup>

#### 18.D. CARBENE REARRANGEMENTS<sup>89</sup>

Carbenes can rearrange to alkenes in many cases.<sup>90</sup> A 1,2-hydrogen shift leads to an alkene, and this is often competitive with insertion reactions.<sup>91</sup> Benzylchlorocarbene (**25**) rearranges via a 1,2-hydrogen shift to give the alkene.<sup>92</sup> Similarly, carbene **26** rearranges to alkene **27**, and replacement of H on the  $\alpha$  carbon with D showed a deuterium isotope effect of  $\sim 5$ .<sup>93</sup> Vinylidene carbene ( $H_2C=C:$ ) rearranges to acetylene.<sup>94</sup> Rearrangement of alkylidene carbene **28** has been calculated to give the highly unstable cyclopentyne (**29**), which cannot be isolated, but can give a [2 + 2] cycloaddition product (**15-59**) when generated in the presence of a simple alkene.<sup>95</sup>

The spiro carbenes undergo rearrangement reactions.<sup>96</sup>

#### 18.E. ELECTROPHILIC REARRANGEMENTS<sup>97</sup>

Rearrangements in which a group migrates without its electrons are more rare than the two kinds previously considered, but the general principles are the same. A carbanion (or other negative ion) is created first, and the actual rearrangement step involves migration of a group without its electrons. The product of the rearrangement may be stable or may react further, depending on its nature (see also, **18-2**). An *ab initio* study predicts that a [1,2]-alkyl shift in alkyne anions should be facile.<sup>98</sup>

## 18.F. REACTIONS

The reactions in this chapter are classified into three main groups. 1,2-Shifts are considered first. Within this group, reactions are classified according to: (i) the identity of the substrate atoms and (ii) the nature of the migrating group. In the second group are the cyclic rearrangements. The third group consists of rearrangements that cannot be fitted into either of the first two categories.

Reactions in which the migration terminus is on an aromatic ring have been treated under aromatic substitution. These are reactions **11-27** to **11-32**, **11-36**, **13-30** to **13-32**, and, partially, **11-33**, **19-74**, and **19-58**. Double-bond shifts have also been treated in other chapters, although they may be considered to be rearrangements (Sec. 8.A, **12-4**, and **12-2**). Other reactions that may be regarded as rearrangements are the *Pummerer* (**19-87**) and *Willgerodt* (**19-8**) reactions.

## 18.F.i. 1,2-Rearrangements

## A. Carbon-to-Carbon Migrations of R, H, and Ar

## 18-1 Alkyl Shifts, Aryl Shifts: Wagner-Meerwein and Related Reactions

In the reaction shown, the reaction of an alkene with HBr gives the secondary carbocation, which rearranges to the more stable tertiary carbocation via a 1,2-hydride shift prior to reaction with the nucleophilic bromide ion to give the tertiary bromide product. Once formed, a carbocation rearranged via a 1,2-shift, with migration of a hydrogen atom (a 1,2-hydride shift), or of an alkyl group (a 1,2-alkyl shift), or of an aryl group (a 1,2-aryl shift),<sup>99</sup> to generate a more stable carbocation (Sec. 10.C). If the adjacent atoms have more than one proton, formation of the more stable carbocation governs the direction of atom or group migration, as expected. The more stable carbocation will react with a nucleophile (e.g., water, in which case the product is a rearranged alcohol) and this reaction generally occurs after the rearrangement. In other words, the rate of atom or group migration is faster than the rate of trapping the nucleophile by the carbocation. Such a rearrangement is an *exothermic* process by 12–15 kcal mol<sup>-1</sup> (50–63 kJ mol<sup>-1</sup>). The energy barrier to transfer a hydrogen atom is lower than that for alkyl or aryl shifts, although the energy barrier for a 1,2-methyl shift is estimated to be < 5 kcal mol<sup>-1</sup> (20.9 kJ mol<sup>-1</sup>).<sup>100</sup> For the degenerate rearrangement of 2,3-dimethylbutan-2-yl cation, the energy barrier for a 1,2-hydrogen shift was measured to be 3.4 kcal mol<sup>-1</sup> (14.2 kJ mol<sup>-1</sup>).<sup>101</sup> Although the difference in energy between a hydrogen shift and a methyl shift is small, hydrogen will migrate preferentially in virtually all cases. The cationic rearrangements mentioned (1,2-hydride shifts, 1,2-alkyl shifts, and 1,2-aryl shifts) all occur with great facility,<sup>102</sup> to form the more stable carbocation.

<sup>99</sup> See Beaulieu, A.; Canesi, S. *J. Org. Chem.* **2012**, *77*, 2121.

<sup>101</sup> Saunders, M.; Cline, G.W. *J. Am. Chem. Soc.* **1990**, *112*, 3955; Saunders, M.; Kates, M.R. *J. Am. Chem. Soc.* **1978**, *100*, 7082.

<sup>102</sup> Olah, G.A.; Olah, J.A. *Carbonium Ions*, Vol. 2, Olah, G.A.; Schleyer, P.v.R. (Ed.), Wiley, NY, **1969**, pp. 715–782; Richey, J.M. *The Chemistry of Alkenes*, Vol. 2, Zabicky, J. (Ed.), Interscience, NY, **1970**, p. 44.

As pointed out in Chapters 5 and 1, the carbocation intermediate that is a direct product of the rearrangement must lead to the more stable product, and loss of a hydrogen  $\beta$  to the positive center to give the more stable alkene, following *Zaitsev's rule* (Sec. 17.A.i, category 3).<sup>103</sup>

As just mentioned with rearrangements of alkyl carbocations, the direction of rearrangement is usually toward the most stable carbocation (the stability order is tertiary > secondary > primary), but rearrangements in the other direction have also been observed.<sup>104</sup> The product is sometimes a mixture corresponding to an equilibrium mixture of the possible carbocations. Aryl groups can migrate, generally via 1,2-aryl shifts, if the newly formed carbocation is more stable. The migration of aryl groups can involve a phenonium ion (Sec. 10.C.i, item 3).

Rearrangement is usually predominant in neopentyl and neophyl types of substrates, and with these types normal nucleophilic substitution is difficult and normal elimination is, of course, impossible. Under  $S_N2$  conditions, substitution is extremely slow;<sup>105</sup> and under  $S_N1$  conditions, carbocations are formed that rapidly rearrange. However, free-radical substitution, unaccompanied by rearrangement, can be carried out on neopentyl systems, although, as seen previously (Sec. 18.C), neophyl systems undergo rearrangement as well as substitution.

Examples of carbocation rearrangements are found in simpler systems, such as the reaction of 1-bromopropane with  $AlBr_3$  that gives 2-bromopropane.

1. Hydride ion can migrate. In the reaction with 1-bromopropane it was hydride that shifted, not bromine, in the conversion of the primary carbocation to a secondary carbocation.
2. The leaving group does not have to be  $H_2O$ , but can be any departing species whose loss creates a carbocation, including  $N_2$  from aliphatic diazonium ions<sup>106</sup> (see the section on leaving groups in nucleophilic substitution in Sec. 10.A.ii, category 1). Rearrangement may follow when the carbocation is created by addition of a proton or other positive species to a double bond.

*Wagner-Meerwein rearrangements* were first discovered in reactions of bicyclic terpenes, and most of the early development of this reaction was with these compounds.<sup>107</sup> An example is the conversion of isoborneol to camphene. It fundamentally involves a 1,2-alkyl shift of an intermediate carbocation, such as **30**  $\rightarrow$  **31**.

<sup>106</sup> In Patai, S. *The Chemistry of the Amino Group*, Wiley, NY, **1968**, see the articles by White, E.H.; Woodcock, D.J., pp. 407–497 (pp. 473–483) and by Banthorpe, D.V., pp. 585–667 (pp. 586–612).

<sup>107</sup> See Hogeveen, H.; van Kruchten, E.M.G.A. *Top. Curr. Chem.* **1979**, *80*, 89; Arbuzov, B.A.; Isaeva, Z.G. *Russ. Chem. Rev.* **1976**, *45*, 673; Banthorpe, D.V.; Whittaker, D. *Q. Rev. Chem. Soc.* **1966**, *20*, 373.

When alcohols are treated with acids, simple substitution (e.g., **10-47**) or elimination (**17-1**) usually accounts for most or all of the products. In many cases, however, especially where two or three alkyl or aryl groups are on the  $\beta$  carbon, some or all of the product is rearranged. These rearrangements have been called *Wagner-Meerwein rearrangements*, although this term is nowadays reserved for relatively specific transformations such as isborneol to camphene and related reactions.

2-Norbornyl cations (see **30**), besides displaying the 1,2-shifts of a  $\text{CH}_2$  group illustrated for the isborneol  $\rightarrow$  camphene conversion, are also prone to rapid hydride shifts from the 3 to the 2 position (known as 3,2-shifts). These 3,2-shifts usually take place from the *exo* side;<sup>108</sup> that is, the 3-*exo* hydrogen migrates to the 2-*exo* position.<sup>109</sup> This stereoselectivity is analogous to the behavior previously seen for norbornyl systems, namely, that nucleophiles attack norbornyl cations from the *exo* side (Sec. 10.C.i, category 4) and that addition to norbornenes is also usually from the *exo* direction (Sec. 15.B.iii).

The Wagner-Meerwein rearrangement has been observed for a secondary to a secondary carbocation rearrangement, leading to some controversy. Winstein<sup>110</sup> described norbornyl cations in terms of the resonance structures represented by the nonclassical ion **32**.<sup>111</sup> This view was questioned, primarily by Brown,<sup>112</sup> who suggested that the facile rearrangements could be explained by a series of fast 1,3-Wagner-Meerwein shifts.<sup>113</sup> There is considerable evidence, however, that *the norbornyl cation rearranges with  $\sigma$  participation*,<sup>114</sup> and there is strong NMR evidence for the nonclassical ion in superacids at low temperatures.<sup>115</sup>

As alluded to above, the term “Wagner-Meerwein rearrangement” is not precise. Some use it to refer to all the rearrangements in this section and in **18-2**. Others use it only when an alcohol is converted to a rearranged alkene. Many use the term only for rearrangements that involve a nonclassical carbocation intermediate. Terpene chemists call the migration of a methyl group the *Nametkin rearrangement*. The term *retropinacol rearrangement* is often applied to some or all of these. Fortunately, this disparity in nomenclature does not seem to cause much confusion.

Catalytic asymmetric Wagner-Meerwein shifts have been observed.<sup>116</sup> An asymmetric, Pd-catalyzed Wagner-Meerwein shift has been reported with allenic alcohols.<sup>117</sup>

Some alkanes undergo Wagner-Meerwein rearrangements if treated with Lewis acids and a small amount of initiator. An interesting application of this reaction is the conversion of tricyclic molecules to adamantane and its derivatives.<sup>118</sup> It has been found that *all* tricyclic alkanes containing 10 carbons are converted to adamantane by treatment with a Lewis acid, such as  $\text{AlCl}_3$ . If the substrate contains more than 10 carbons, alkyl-substituted adamantanes are produced. Such reactions are referred to as *Schleyer adamantization*. Two examples are the  $\text{AlCl}_3$ -mediated reactions of **33** and **34**.

If 14 or more carbons are present, the product may be diamantane or a substituted diamantane.<sup>119</sup> These reactions are successful because of the high thermodynamic stability of adamantane, diamantane, and similar diamond-like molecules. The most stable of a set of  $\text{C}_n\text{H}_m$  isomers (called the *stabilomer*) will be the end product if the reaction reaches equilibrium.<sup>120</sup> Best yields are obtained by the use of “sludge” catalysts<sup>121</sup> (i.e., a mixture of  $\text{AlX}_3$  and *tert*-butyl bromide or *sec*-butyl bromide).<sup>122</sup> Though it is certain that these adamantane-forming reactions take place by nucleophilic 1,2-shifts, the exact pathways are not easy to unravel because of their complexity.<sup>123</sup> Treatment of adamantane-2- $^{14}\text{C}$  with  $\text{AlCl}_3$  results in total carbon scrambling on a statistical basis.<sup>124</sup>

As already indicated, the mechanism of the Wagner-Meerwein rearrangement is usually nucleophilic. Carbanion mechanisms (electrophilic) have also been found.<sup>94</sup> Thus  $\text{Ph}_3\text{CCH}_2\text{Cl}$  treated with sodium gave  $\text{Ph}_2\text{CHCH}_2\text{Ph}$  along with unrearranged products.<sup>125</sup> This is called the *Grovenstein-Zimmerman rearrangement*. The intermediate is  $\text{Ph}_3\text{CCH}_2^-$ , and the phenyl moves without its electron pair. Only aryl and vinylic groups,<sup>126</sup> and not alkyl groups, migrate by the electrophilic mechanism (see the introduction preceding Sec. 18.A) and transition states or intermediates analogous to **21** and **22** are likely.<sup>127</sup>

## 18-2 The Pinacol Rearrangement

When 1,2-diols (*vic*-diols; glycols) are treated with acids,<sup>128</sup> they rearrange to give aldehydes or ketones, although elimination without rearrangement can also be accomplished. This reaction is called the *pinacol rearrangement*; the reaction gets its name from a prototype compound pinacol ( $\text{Me}_2\text{COHCOHMe}_2$ ), which is rearranged to pinacolone ( $\text{Me}_3\text{CCOCH}_3$ ).<sup>129</sup>

In this type of reaction, reduction can compete with rearrangement.<sup>130</sup> The reaction has been accomplished many times, with alkyl, aryl, hydrogen, and even ethoxycarbonyl ( $\text{CO}_2\text{Et}$ )<sup>131</sup> as migrating groups. In most cases, each carbon has at least one alkyl or aryl group, and the reaction is most often carried out with tri- and tetrasubstituted glycols. As mentioned earlier, glycols in which the four R groups are not identical can give rise to more than one product, depending on which group migrates (see Sec. 18.A.iii for a discussion of migratory aptitudes). A noncatalytic reaction is possible in supercritical water.<sup>132</sup>

Stereodifferentiation is possible in this reaction.<sup>133</sup> When TMSOTf was used to initiate the reaction, it was shown to be highly regioselective.<sup>134</sup> Mixtures are often produced, and which group preferentially migrates may depend on the reaction conditions as well as on the nature of the substrate. Thus the action of cold, concentrated sulfuric acid on 2-methyl-1,1-diphenylpropane-1,2-diol produces mainly 3,3-diphenylbutan-2-one (methyl migration), while treatment of 2-methyl-1,1-diphenylpropane-1,2-diol with acetic acid containing a trace of sulfuric acid gives mostly 2-methyl-1,2-diphenylpropan-1-one (phenyl migration).<sup>135</sup> If at least one R is hydrogen, aldehydes can be produced as well as ketones. Generally, aldehyde formation is favored by the use of mild conditions (lower temperatures, weaker acids), because under more drastic conditions the aldehydes may be converted to ketones (**18-4**). The reaction has been carried out in the solid state, by treating solid substrates with HCl gas or with a solid organic acid.<sup>136</sup> Organocatalysts have been used for an enantioselective vinylogous pinacol rearrangement.<sup>137</sup>

The mechanism involves a simple 1,2-shift. A carbocation where all four R groups are Me has been trapped by the addition of tetrahydrothiophene.<sup>138</sup> A migration takes place from the tertiary position because carbocations stabilized by an oxygen atom are even more

stable than tertiary alkyl cations (Sec. 5.A.ii). In addition, the new carbocation can immediately stabilize itself by losing a proton.

It is obvious that other compounds in which a positive charge can be placed on a carbon  $\alpha$  to one bearing an OH group can also give this rearrangement.  $\beta$ -Amino alcohols rearrange on treatment with nitrous acid in a reaction called the *semipinacol rearrangement*.<sup>139</sup> Allylic alcohols<sup>140</sup> can rearrange on treatment with a strong acid that protonates the double bond.<sup>141</sup> Catalytic asymmetric semipinacol rearrangements have been reported.<sup>142</sup> Electrophilic iodine compounds have been used to induce semipinacol rearrangements.<sup>143</sup> The aqueous media Zn/AlCl<sub>3</sub>-mediated pinacol coupling reactions have been reported.<sup>144</sup>

Epoxides are converted to aldehydes or ketones on treatment with certain metallic catalysts<sup>145</sup> including treatment with iron complexes,<sup>146</sup> IrCl<sub>3</sub>,<sup>147</sup> or with BiOClO<sub>4</sub>.<sup>148</sup> Acidic reagents such as BF<sub>3</sub>-etherate or MgBr<sub>2</sub>-etherate, 5 M LiClO<sub>4</sub> in ether,<sup>149</sup> In,<sup>150</sup> Sm,<sup>151</sup> Au/Ag,<sup>152</sup> Bi,<sup>153</sup> or sometimes by heat alone<sup>154</sup> can also be used.<sup>155</sup>

The *Meinwald rearrangement* converts epoxides to carbonyl compounds.<sup>156</sup> Several reagents mediate this transformation, including Cu compounds.<sup>157</sup> The mechanism of palladium hydride catalysis for the isomerization of epoxides to ketones has been examined.<sup>158</sup>

A closely related reaction of vinyl epoxides gives alkenyl ketones upon treatment with Ga compounds.<sup>159</sup> It has been shown that epoxides are intermediates in the pinacol rearrangements of certain glycols.<sup>160</sup> Among the evidence for the mechanism given is that

### 18-3 Modification of Ring Size

When a positive charge is placed on a carbon  $\alpha$  to an alicyclic ring, ring expansion can take place,<sup>171</sup> as in the interconversion of the cyclobutyl cation and the cyclopropylcarbinyl cation (**35**).

The new carbocation, and the old one, can then give products by combination with a nucleophile, or by elimination, so that this reaction is a special case of **18-1**. Often, both rearranged and unrearranged products are formed, so that, for example, cyclobutylamine and cyclopropylmethylamine give similar mixtures of the two alcohols shown at the

opening of this section on treatment with nitrous acid (a small amount of 3-buten-1-ol is also produced). When the carbocation is formed by diazotization of an amine, the reaction is called the *Demjanov rearrangement*,<sup>172</sup> but of course similar products are formed when the carbocation is generated in other ways.

The expansion reaction has been performed on rings of C<sub>3</sub>–C<sub>8</sub>,<sup>173</sup> but yields are best with the smaller rings, where relief of small-angle strain provides a driving force for the reaction. Strain is apparently much less of a factor in the cyclobutyl–cyclopropylmethyl interconversion (for a discussion of this interconversion, Sec. 10.C.i). The influence of substituents on this rearrangement has been examined.<sup>174</sup> It is noted that a hybrid of a [1,2]-sigmatropic hydrogen shift (also see **18-29**) and a two-electron electrocyclic ring opening has been discovered for cyclopropylcarbinyl cations that was labeled as a “hisotropic” rearrangement.<sup>175</sup>

A related rearrangement involves cyclopropyl propargylic alcohols, which gives an alkylidene cyclobutanone in the presence of Ag and Au catalysts,<sup>176</sup> or of Ru and In catalysts.<sup>177</sup> Cyclopropylcarbinyl rearrangements are catalyzed by ionic liquids under solvent-free conditions.<sup>178</sup> Methylenecyclopropanes rearrange to cyclobutenes in the presence of 1 atm of CO and Pt catalyst<sup>179</sup> or a Pd catalyst, mediated by a Cu catalyst.<sup>180</sup> Arylvinylidenecyclopropanes rearrange to bicyclic systems in the presence of a Lewis acid.<sup>181</sup>

Ring expansions of certain hydroxyamines such as **36** are analogous to the semipinacol rearrangement (**18-2**). This reaction is called the *Tiffeneau-Demjanov ring expansion*.

These expansions have been performed on rings of C<sub>4</sub>–C<sub>8</sub> and the yields are better than for the simple Demjanov ring expansion. A similar reaction has been used to expand rings of from five to eight members.<sup>182</sup> In this case, a cyclic alcohol with a pendant bromoalkyl group of the form **37** is treated with a Grignard reagent, which, acting as a base, removes the OH proton to give the alkoxide which, when heated to reflux, displaces the bromide to give ring enlargement.

<sup>182</sup> See Sisti, A.J.; Vitale, A.C. *J. Org. Chem.* **1972**, *37*, 4090.

The reaction has been done with **37** in which at least one R group is phenyl or methyl,<sup>183</sup> but fails when both R groups are hydrogen.<sup>184</sup> Medium-size ring ketones have been prepared using  $\alpha$ -chloro- $\alpha$ -diazooacetate.<sup>185</sup>

A positive charge generated on a three-membered ring gives ring opening to an allylic cation.<sup>186</sup> As seen in Sec. 10.G.i, category 7, this ring opening is the reason nucleophilic substitutions are not feasible at a cyclopropyl substrate. The reaction is often used to convert cyclopropyl halides and tosylates to allylic products, especially for the purpose of ring expansion.<sup>187</sup> The stereochemistry of such cyclopropyl cleavages is governed by the principle of orbital symmetry conservation (for a discussion, see **18-27**, the Möbius-Hückel method).

Three-membered rings can also be cleaved to unsaturated products in at least two other ways.

1. Upon pyrolysis, cyclopropanes open to propenes.<sup>188</sup> In the simplest case, cyclopropane gives propene when heated to 400 to 500 °C. The mechanism is generally regarded<sup>189</sup> as involving a diradical intermediate<sup>190</sup> (recall that free-radical 1,2-migration is possible for diradicals, Sec. 18.C).
2. The generation of a carbene or carbenoid carbon in a three-membered ring can lead to allenes, and allenes are often prepared in this way.<sup>191</sup> Flash vacuum pyrolysis of 1-chlorocyclopropene thermally rearranges to chloroallene.<sup>192</sup> One way to generate such a species is treatment of a 1,1-dihalocyclopropane with an alkylolithium compound (**12-38**).<sup>193</sup>

In contrast, the generation of a carbene or carbenoid at a cyclopropylmethyl carbon gives ring expansion to give cyclobutene.<sup>194</sup> The activation parameters for this ring expansion has been reported.<sup>195</sup>

Some free-radical ring enlargements are also known.<sup>196</sup> This reaction has been used to make rings of 6, 7, 8, and 13 members. This reaction has been extended to the expansion of rings by three or four carbons, by the use of a substrate containing  $(\text{CH}_2)_n\text{X}$  ( $n = 3$  or 4)

#### 18-4 Acid-Catalyzed Rearrangements of Aldehydes and Ketones

Rearrangements of this type, where a group  $\alpha$  to a carbonyl “changes places” with a group attached to the carbonyl carbon, occur when migratory aptitudes are favorable.<sup>208</sup> The  $\text{R}^2$ ,  $\text{R}^3$ , and  $\text{R}^4$  groups may be alkyl or hydrogen. Certain aldehydes have been converted to ketones, and ketones to other ketones (though more drastic conditions are required for the latter), but no rearrangement of a ketone to an aldehyde ( $\text{R}^1 = \text{H}$ ) has so far been reported.

There are two mechanisms,<sup>209</sup> each beginning with protonation of the oxygen and each involving two migrations. In either case, the rearrangement must produce a carbocation that is more stable than the initially formed oxocarbenium ion. In one pathway, the migrations are in opposite directions:<sup>210</sup>

In the other pathway, the migrations are in the same direction. The actual mechanism of this pathway is not certain, but a protonated epoxide intermediate<sup>211</sup> is one possibility.<sup>212</sup> If the reaction is carried out with ketone labeled in the C=O group with <sup>14</sup>C, the first pathway predicts that the product will contain all the <sup>14</sup>C in the C=O carbon, while in the second pathway the label will be in the  $\alpha$  carbon (demonstrating migration of oxygen). The results of such experiments<sup>213</sup> have shown that in some cases only the C=O carbon was labeled, in other cases only the  $\alpha$  carbon, while in still others both carbons bore the label, indicating that in these cases both pathways were in operation. With  $\alpha$ -hydroxy aldehydes and ketones, the process may stop after only one migration (this is called the  *$\alpha$ -ketol rearrangement*). The  *$\alpha$ -ketol rearrangement* can also be brought about by base catalysis, but only if the alcohol is tertiary, since if R<sup>1</sup> or R<sup>2</sup> = hydrogen, enolization of the substrate is more favored than rearrangement.

### 18-5 The Dienone-Phenol Rearrangement

Cyclohexadienone derivatives that have two alkyl groups in the 4 position undergo, on acid treatment,<sup>214</sup> 1,2-migration of one of these groups from the initially formed vinylogous oxocarbenium ion, followed by loss of a proton to give the phenol. Note that a photochemical version of this reaction has been observed.<sup>215</sup> The driving force in the overall reaction (the *dienone-phenol rearrangement*) is of course creation of an aromatic system.<sup>216</sup> Note that both intermediates shown are arenium ions (Sec. 5.A.ii), analogous to those generated by attack of a phenol on an electrophile.<sup>217</sup>

<sup>211</sup> Zook, H.D.; Smith, W.E.; Greene, J.L. *J. Am. Chem. Soc.* **1957**, 79, 4436.

<sup>212</sup> Some such pathway is necessary to account for the migration of oxygen that is found. It may involve a protonated epoxide, a 1,2-diol, or simply a 1,2-shift of an OH group.

Sometimes, in the reaction of a phenol with an electrophile, a kind of reverse rearrangement (called the *phenol-dienone rearrangement*) takes place, though without an actual migration.<sup>218</sup> An example is the reaction of 2,4,6-tribromophenol with bromine to give 2,4,4,6-tetrabromocyclohexa-2,5-dien-1-one.

### 18-6 The Benzil-Benzilic Acid Rearrangement

When treated with base,  $\alpha$ -diketones rearrange to give the salts of  $\alpha$ -hydroxy acids, a reaction known as the *benzil-benzilic acid rearrangement* (benzil is PhCOCOPh; benzilic acid is Ph<sub>2</sub>COHCO<sub>2</sub>H).<sup>219</sup> A Rh-catalyzed version of this reaction has also been reported.<sup>220</sup> Though the reaction is usually illustrated with aryl groups, it can also be applied to aliphatic diketones<sup>221</sup> and to  $\alpha$ -keto aldehydes. The use of an alkoxide instead of hydroxide gives the corresponding ester directly,<sup>222</sup> although alkoxide ions that are readily oxidized (e.g., <sup>-</sup>OEt or <sup>-</sup>OCHMe<sub>2</sub>) are not useful here, since they reduce the benzil to a benzoin. The mechanism is similar to the rearrangements in **18-1** to **18-4**, but there is a difference: The migrating group does not move to a carbocation. The first step is attack of the base at the carbonyl group, the same as the first step of the tetrahedral mechanism of nucleophilic substitution (Sec. 16.A.i) and of many additions to the C=O bond (Chapter 16). The mechanism has been intensely studied,<sup>210</sup> and there is much evidence for it.<sup>223</sup> The reaction is irreversible.

OS I, 89.

### 18-7 The Favorskii Rearrangement

The reaction of  $\alpha$ -halo ketones (chloro, bromo, or iodo) with alkoxide ions<sup>224</sup> to give rearranged esters is called the *Favorskii rearrangement*.<sup>225</sup> The use of hydroxide ions or amines as bases leads to the free carboxylic acid (salt) or amide, respectively, instead of the ester. Cyclic  $\alpha$ -halo ketones give ring contraction, as in the conversion of 2-chlorocyclohexan-1-one to alkyl cyclopentanecarboxylate. The reaction has also been carried out on  $\alpha$ -hydroxy

ketones<sup>226</sup> and on  $\alpha,\beta$ -epoxy ketones, which give  $\beta$ -hydroxy acids.<sup>227</sup> The fact that an epoxide gives a reaction analogous to a halide indicates that the oxygen and halogen are leaving groups in a nucleophilic substitution step.

Investigation of the mechanism<sup>228</sup> of the Favorskii rearrangement shows that initial deprotonation of an  $\alpha$ -hydrogen atom gives an enolate anion, **38**, which is followed by displacement to give a cyclopropanone, **39**. Attack by the alkoxide leads to a tetrahedral intermediate, which opens to a carbanion that is protonated.

The finding<sup>229</sup> that 1-chloro-3-phenylpropan-2-one and 1-chloro-1-phenylpropan-2-one *both* give 3-phenylpropanoic acid (this behavior is typical) shows that both reactions go through a common intermediate. Another important result was determined by radioactive labeling. 2-Chlorocyclohexan-1-one, in which C-1 and C-2 were equally labeled with <sup>14</sup>C, was converted to the alkyl cyclopentanecarboxylate. The product was found to contain 50% of the label on the carbonyl carbon, 25% on C-1, and 25% on C-2.<sup>230</sup> Now the carbonyl carbon, which originally carried half of the radioactivity, still had this much, so the rearrangement did not directly affect *it*. However, if the C-6 carbon had migrated to C-2, the other half of the radioactivity would be only on C-1 of the product. The effect of ring size on the photo-Favorskii ring contraction reaction has been discussed.<sup>231</sup>

If the C-2 carbon had migrated to C-6, then this half of the radioactivity would be found solely on C-2 of the product. The fact that C-1 and C-2 were equally labeled showed that *both migrations occurred*, with equal probability. Since C-2 and C-6 of 2-chlorocyclohexan-1-one are not equivalent, this means that there must be a symmetrical intermediate.<sup>232</sup> The type of intermediate that best fits the circumstances is a cyclopropanone, **39**,<sup>233</sup> and the mechanism (for the general case) is formulated (replacing R<sup>1</sup> of our former symbolism with CHR<sup>5</sup>R<sup>6</sup>, since it is obvious that for this mechanism an  $\alpha$ -hydrogen is required on the nonhalogenated side of the carbonyl).

The intermediate corresponding to the cyclopropanone (**39**) for the reaction of 2-chlorocyclohexan-1-one is a symmetrical compound, and the three-membered ring can be

<sup>232</sup> A preliminary migration of the chlorine from C-2 to C-6 was ruled out by the fact that recovered 2-chlorocyclohexan-1-one had the same isotopic distribution as the starting 2-chlorocyclohexan-1-one.

<sup>233</sup> See Wasserman, H.H.; Clark, G.M.; Turley, P.C. *Top. Curr. Chem.* **1974**, *47*, 73; Turro, N.J. *Acc. Chem. Res.* **1969**, *2*, 25.

opened with equal probability on either side of the carbonyl, accounting for the results with  $^{14}\text{C}$ . In the general case, the cyclopropanone is not symmetrical and should open on the side that gives the more stable carbanion.<sup>234</sup> When the cyclopropanone is unsymmetrical, the ring opens to give the more stabilized product. The cyclopropanone intermediate has been isolated for di-*tert*-butylmethyl ketones,<sup>235</sup> and it has also been trapped.<sup>236</sup> Also, cyclopropanones synthesized by other methods have been shown to give Favorskii products on treatment with NaOMe or other bases.<sup>237</sup>

The mechanism discussed is in accord with all the facts when the halo ketone contains an  $\alpha$  hydrogen on the other side of the carbonyl group. However, ketones that do not have an  $\alpha$  hydrogen also rearrange to give the same type of product in what is usually called the *quasi-Favorskii rearrangement*. The quasi-Favorskii rearrangement cannot take place by the cyclopropanone mechanism. The mechanism that is generally accepted (called the *semibenzilic mechanism*<sup>238</sup>) is a base-catalyzed pinacol rearrangement-type mechanism similar to that of **18-6**. This mechanism requires inversion at the migration terminus and this has been found.<sup>239</sup> It has been shown that even where there is an appropriately situated  $\alpha$  hydrogen, the semibenzilic mechanism may still operate.<sup>240</sup> An interesting analog of the Favorskii rearrangement treats a ketone, such as 4-*tert*-butylcyclohexanone, without an  $\alpha$  halogen with  $\text{Ti}(\text{NO}_3)_3$  to give 3-*tert*-butylcyclopentane-1-carboxylic acid.<sup>241</sup>

OS IV, 594; VI, 368, 711.

## 18-8 The Arndt-Eistert Synthesis

In the *Arndt-Eistert synthesis*, an acyl halide is converted to a carboxylic acid with one additional carbon.<sup>242</sup> This rearrangement is called the *Wolff rearrangement*.<sup>243</sup> It is the best method of increasing a carbon chain by one from a *carboxylic acid* (see **10-76** and **16-30**). The diazo ketone can exist in two conformations, called *s-(E)* and *s-(Z)*.

Studies have shown that the *Wolff rearrangement* takes place preferentially from the *s*-(*Z*) conformation.<sup>244</sup>

If an alcohol R'OH is used instead of water, the ester RCH<sub>2</sub>CO<sub>2</sub>R' is isolated.<sup>245</sup> In a similar manner, treatment with ammonia gives the amide. Other catalysts are sometimes used (e.g., colloidal Pt, Cu, etc.), but occasionally the diazo ketone is simply heated or photolyzed in the presence of water, an alcohol, or ammonia, with no catalyst at all but using ultrasound.<sup>246</sup> The photolysis method<sup>247</sup> often gives better results than the Ag catalysis method. Of course, diazo ketones prepared in any other way also give the rearrangement.<sup>248</sup> The reaction is of wide scope. The R group may be alkyl or aryl and may contain many functional groups including unsaturation, but not including groups acidic enough to react with CH<sub>2</sub>N<sub>2</sub> or diazo ketones (e.g., **10-5** and **10-19**). Sometimes the reaction is performed with other diazoalkanes (i.e., R'CHN<sub>2</sub>) to give RCHR'COOH. An asymmetric variation converted ketones to esters using an azaferrrocene catalyst.<sup>249</sup>

The mechanism is generally regarded as involving formation of a carbene.<sup>250</sup>

The first step of this process is reaction **12-10**. The actual rearrangement occurs in the second step after treatment of the diazo ketone with water and silver oxide or with silver benzoate and triethylamine. It is the divalent carbon that has the open sextet and to which the migrating group brings its electron pair. The actual product of the reaction is thus the ketene, which then reacts with water (**15-3**), an alcohol (**15-5**), or ammonia or an amine (**15-8**). Particularly stable ketenes<sup>251</sup> (e.g., Ph<sub>2</sub>C=C=O) have been isolated and others have been trapped in other ways (e.g., as β-lactams,<sup>252</sup> **16-90**). The purpose of the catalyst is not well understood, though many suggestions have been made. This mechanism is strictly analogous to that of the *Curtius rearrangement* (**18-14**). Although the mechanism as shown above involves a free carbene, and there is much evidence to support this,<sup>253</sup> it is also possible that at least in some cases the two steps are concerted and a free carbene is absent.

When the *Wolff rearrangement* is carried out photochemically, the mechanism is basically the same,<sup>247</sup> but another pathway can intervene. Some of the ketocarbene originally formed can undergo a carbene-carbene rearrangement, through an oxirene intermediate.<sup>254</sup>

This rearrangement was shown by  $^{14}\text{C}$  labeling experiments, where diazo ketones labeled in the carbonyl group gave rise to ketenes that bore the label at both  $\text{C}=\text{C}$  carbons.<sup>255</sup> In general, the smallest degree of scrambling (and thus of the oxirene pathway) was found when  $\text{R}' = \text{H}$ . An intermediate believed to be an oxirene has been detected by laser spectroscopy.<sup>256</sup> The oxirene pathway is not found in the thermal Wolff rearrangement. It is likely that an excited singlet state of the carbene is necessary for the oxirene pathway to intervene.<sup>257</sup> In the photochemical process, ketocarbene intermediates, in the triplet state, have been isolated in an Ar matrix at 10–15 K, where they have been identified by UV-visible, IR, and ESR spectra.<sup>258</sup> These intermediates went on to give the rearrangement via the normal pathway, with no evidence for oxirene intermediates. A photochemical Wolff rearrangement has been reported using flow conditions (Sec. 7.D).<sup>259</sup>

OS III, 356; VI, 613, 840.

### 18-9 Homologation of Aldehydes and Ketones

Aldehydes and ketones<sup>260</sup> can be converted to their homologs with diazomethane.<sup>261</sup> Several other reagents<sup>262</sup> are also effective, including  $\text{Me}_3\text{SiI}$ , and then silica gel.<sup>263</sup> With the diazomethane reaction, formation of an epoxide (**16-46**) is a side reaction. Superficially, this reaction appears to be similar to the insertion of carbenes into  $\text{C}-\text{H}$  bonds (which is **12-21**), and IUPAC names the reaction with diazomethane as an insertion, but the mechanism is quite different. However, this reaction is a true rearrangement and no free carbene is involved. The first step is an addition to the  $\text{C}=\text{O}$  bond to give betaine **40**, which can sometimes be isolated. As shown in **16-46**, intermediate **40** can also go to the epoxide. The evidence for this mechanism has been summarized in the review by Gutsche.<sup>261</sup> Note that this mechanism is essentially the same as in the apparent “insertions” of oxygen (**18-19**) and nitrogen (**18-16**) into ketones.

<sup>262</sup> See Aoyama, T.; Shioiri, T. *Synthesis* **1988**, 228.

<sup>263</sup> Lemini, C.; Ordoñez, M.; Pérez-Flores, J.; Cruz-Almanza, R. *Synth. Commun.* **1995**, *25*, 2695.

The difluorohomologation of ketones followed by halogenation was reported using first a silylation reaction, and second the addition of difluorocarbene using  $\text{Me}_3\text{SiCF}_2\text{Br}$  activated by a bromide ion, with the final reaction of the intermediate cyclopropanes with *N*-bromo- or *N*-iodosuccinimide to give  $\alpha,\alpha$ -difluoro- $\beta$ -halo-substituted ketones.<sup>264</sup>

Aldehydes give fairly good yields of methyl ketones; that is, hydrogen migrates in preference to alkyl. The most abundant side product is not the homologous aldehyde, but the epoxide. However, the yield of aldehyde at the expense of methyl ketone can be increased by the addition of methanol. If the aldehyde contains electron-withdrawing groups, the yield of epoxides is increased and the ketone is formed in smaller amounts, if at all. Ketones give poorer yields of homologous ketones. Epoxides are usually the predominant product here, especially when one or both R groups contain an electron-withdrawing group. The yield of ketones also decreases with increasing length of the chain. The use of a Lewis acid increases the yield of ketone.<sup>265</sup> Cyclic ketones,<sup>266</sup> three membered<sup>267</sup> and larger, behave particularly well and give good yields of ketones with the ring expanded by one.<sup>268</sup> Aliphatic diazo compounds ( $\text{RCHN}_2$  and  $\text{R}_2\text{CN}_2$ ) are sometimes used instead of diazomethane, with the expected results.<sup>269</sup> Ethyl diazoacetate can be used analogously, in the presence of a Lewis acid or of triethyloxonium fluoroborate,<sup>270</sup> to give a  $\beta$ -keto ester.

When unsymmetrical ketones were used in this reaction (with  $\text{BF}_3$  as catalyst), the less highly substituted carbon preferentially migrated.<sup>271</sup> The reaction can be made regioselective by applying this method to the  $\alpha$ -halo ketone, in which case only the other carbon migrates.<sup>272</sup> The ethyl diazoacetate procedure has also been applied to the acetals or ketals of  $\alpha,\beta$ -unsaturated aldehydes and ketones.<sup>273</sup>

1,3-Diketones are converted to 1,4-diketones upon treatment with  $\text{CF}_3\text{CO}_2\text{ZnCH}_2\text{I}$ .<sup>274</sup> In a related reaction, alkenes insert into aldehydes in the presence of a Rh catalyst to give the corresponding ketone.<sup>275</sup> Bicyclic ketones can be expanded to form monocyclic ketones in the presence of certain reagents. Treatment of a bicyclo[4.1.0]hexan-4-one derivative with  $\text{SmI}_2$  led to a cyclohexanone.<sup>276</sup> The  $\text{SmI}_2$  also converts  $\alpha$ -halomethyl cyclic ketones to the next larger ring ketone<sup>277</sup> and cyclic ketones to the next larger ring ketone in the presence of  $\text{CH}_2\text{I}_2$ .<sup>278</sup>

## B. Carbon-to-Carbon Migrations of Other Groups

### 18-10 Migrations of Halogen, Hydroxyl, Amino, and so on

When a nucleophilic substitution is carried out on a substrate that has a neighboring group (Sec. 10.C) on the adjacent carbon, a cyclic intermediate can be generated that is opened on the opposite side, resulting in migration of the neighboring group. In the example shown above ( $\text{NR}_2 = \text{morpholino}$ ),<sup>279</sup> the reaction took place via an aziridinium salt **41** to give an  $\alpha$ -amino- $\beta$ -hydroxy ketone. Sulfonate esters and halides can also migrate in this reaction.<sup>280</sup>

$\alpha$ -Halo and  $\alpha$ -acyloxy epoxides undergo ready rearrangement to  $\alpha$ -halo and  $\alpha$ -acyloxy ketones, respectively.<sup>281</sup> These substrates are prone to rearrange upon standing without a catalyst, although an acid catalyst is necessary in some cases. It is also possible for one of the R groups (alkyl, aryl, or hydrogen) to migrate instead. In a related reaction,  $\alpha$ -bromoaziridines undergo rearrangement to the isomerized  $\alpha$ -bromoaziridine in the presence of  $\text{MgBr}_2$ .<sup>282</sup>

Allylic alcohols migrate to give a new allylic alcohol in the presence of a Re catalyst. An example is the conversion of **42** to **43**.<sup>283</sup>

Variations using  $\text{Rh}$ <sup>284</sup> or  $\text{Ir}$ <sup>285</sup> catalysts are known, and methanesulfonic acid catalyzes the isomerization.<sup>286</sup> With a  $\text{Ru}$  catalyst, allylic alcohols isomerize to an aliphatic ketone.<sup>287</sup> There is a similar  $\text{Au}$ -catalyzed isomerization of allylic acetates.<sup>288</sup>

The *Meyer-Schuster rearrangement* is an acid-catalyzed rearrangement of a propargyl alcohol to a conjugated carbonyl compound.<sup>289</sup> A rearrangement was also catalyzed by a

cationic Rh-bisphosphane complex.<sup>290</sup> An Au-catalyzed rearrangement of ethoxyalkynyl carbinols gave  $\alpha,\beta$ -unsaturated esters,<sup>291</sup> and enones have been prepared from propargylic alcohols.<sup>292</sup> The base-induced isomerization of a propargylic alcohol gave a conjugated ketone,<sup>293</sup> and a combination of Mo/Au led to rapid 1,3-rearrangement of propargyl alcohols.<sup>294</sup> The perchlorate-catalyzed rearrangement of 1-silylalkyn-3-ols formed  $\alpha,\beta$ -unsaturated acylsilanes.<sup>295</sup> The Fe-catalyzed preparation of acyclic  $\beta$ -amino ketones by Meyer-Schuster rearrangement of 3-aryl propargyl alcohols was followed by reaction with amines.<sup>296</sup> A Cu-catalyzed arylation Meyer-Schuster rearrangement of substituted propargylic alcohols and diaryliodonium salts gave primarily (*E*) trisubstituted enones.<sup>297</sup> 2-Acylfurans were prepared by rearrangement of 6-hydroxyhex-2-en-4-ynals.<sup>298</sup> Methyl triflate has been used to catalyze the reaction.<sup>299</sup>

In the presence of a Cu catalyst, alkenyl epoxides (vinyl oxiranes) rearrange to a 2,5-dihydrofuran.<sup>300</sup> Alkenyl thiiranes are similarly converted to 2,5-dihydrothiophenes with a Cu catalyst.<sup>301</sup>

### 18-11 Migration of Boron

Boranes are prepared by the reaction of  $\text{BH}_3$  ( $\text{B}_2\text{H}_6$ ) or an alkylborane with an alkene (15-11). When a nonterminal borane is heated at temperatures ranging from 100 to 200 °C, the boron moves toward the end of the chain.<sup>302</sup> The reaction is catalyzed by small amounts of borane or other species containing B–H bonds. The boron can move past a branch [dimethyl(2-methylbutyl)borane to dimethyl(3-methylbutyl)borane], but not past a double branch. The reaction is an equilibrium mixture of organoboranes. The migration can go quite a long distance, including a migration of 11 positions.<sup>303</sup> If the boron is on a cycloalkyl ring, it can move around the ring; if any alkyl chain is also on the ring, the boron may move from the ring to the chain, ending up at the end of the chain.<sup>304</sup> The reaction is

useful for the migration of double bonds in a controlled way (see **12-2**). The mechanism may involve a  $\pi$  complex, at least partially.<sup>305</sup>

## 18-12 The Neber Rearrangement

$\alpha$ -Amino ketones can be prepared by treatment of ketoxime tosylates with a base such as ethoxide or pyridine.<sup>306</sup> This reaction is called the *Neber rearrangement*. The R group is usually aryl, although the reaction has been carried out with R = alkyl or hydrogen. The R' group may be alkyl or aryl, but not hydrogen. The *Beckmann rearrangement* (**18-17**) and the abnormal Beckmann reaction (elimination to the nitrile, **17-28**) may be side reactions, although these generally occur in acid media.

The mechanism of the Neber rearrangement involves an azirine intermediate **44**.<sup>307</sup>

The best evidence for this mechanism is that the azirine intermediate has been isolated.<sup>308</sup> In contrast to the *Beckmann rearrangement*, this reaction is sterically indiscriminate.<sup>309</sup> Both a *syn* and an *anti* ketoxime give the same product. The mechanism is shown as stepwise, but it is possible that the first two steps are concerted, and it is also possible that what is shown as the second step is actually two steps: loss of OTs to give a nitrene, and formation of the azirine.

*N*-Chloroimines prepared in other ways also give the reaction.<sup>310</sup> Indoles have been prepared via a Neber rearrangement.<sup>311</sup> Organocatalysts have been used for asymmetric Neber reactions.<sup>312</sup>

### C. Carbon-to-Nitrogen Migrations of R and Ar

The reactions in this group are nucleophilic migrations from a carbon atom to a nitrogen atom. In each case the nitrogen atom either has six electrons in its outer shell (and thus invites the migration of a group carrying an electron pair) or else loses a nucleofuge concurrently with the migration (Sec. 18.A.i).<sup>313</sup>

In many cases, it is not certain whether the nucleofuge X is lost first, creating an intermediate nitrene<sup>314</sup> or nitrenium ion, or whether migration and loss of the nucleofuge are simultaneous.<sup>315</sup> It is likely that both possibilities can exist, depending on the substrate and reaction conditions.

#### 18-13 The Hofmann Rearrangement

In the *Hofmann rearrangement*, an unsubstituted amide is treated with sodium hypobromite (or sodium hydroxide and bromine, which is essentially the same thing) to give an isocyanate, but this compound is seldom isolated<sup>316</sup> since it is usually hydrolyzed under the reaction conditions. The final isolated product is a primary amine that has *one carbon fewer than the starting amide*.<sup>317</sup> The R group may be alkyl or aryl, but if it is an alkyl group of more than about six or seven carbons, low yields are obtained unless Br<sub>2</sub> and NaOMe are used instead of Br<sub>2</sub> and NaOH.<sup>318</sup> Another modification uses NBS/NaOMe.<sup>319</sup> Under these conditions the product of addition to the isocyanate is the carbamate RNHCOOMe (**16-7**), which is easily isolated or can be hydrolyzed to the amine.<sup>320</sup> A mixture of NBS and DBU (see **17-11**) in methanol gives the carbamate,<sup>321</sup> as does electrolysis in methanol.<sup>322</sup> Hypervalent iodine reagents have been used for the preparation of carbamates.<sup>323</sup> Side reactions when NaOH is the base are formation of ureas RNHCONHR and acyl ureas RCONHCONHR by addition, respectively, of RNH<sub>2</sub> and RCONH<sub>2</sub> to RNCO (**16-18**). The microwave-assisted Hofmann rearrangement of aromatic benzamides was mediated by tri-bromoisocyanuric acid/KOH/MeOH.<sup>324</sup>

The mechanism shown follows the pattern outlined in the discussion preceding this reaction. The first step is an example of **12-51** and intermediate *N*-halo amides (**45**) have been isolated. Compound **45** is acidic because of the presence of two electron-withdrawing groups (acyl and halo) on the nitrogen, and in the second step, **45** loses a proton to the base.

It is possible that the third step is actually two steps: loss of bromide to form a nitrene, followed by the actual migration, but most of the available evidence favors the concerted reaction.<sup>325</sup>

A variation of the Hofmann rearrangement treated a  $\beta$ -hydroxy primary amide with  $\text{PhI}(\text{O}_2\text{CCF}_3)_3$  in aqueous acetonitrile, giving an isocyanate via  $-\text{CON}-\text{I}$ , which reacts with the hydroxyl group intramolecularly to give a cyclic carbamate.<sup>326</sup> Note that carbamates are converted to isocyanates by heating with Montmorillonite K-10.<sup>327</sup> Imides react to give amino acids; for example, phthalimide gives *o*-aminobenzoic acid.  $\alpha$ -Hydroxy and  $\alpha$ -halo amides give aldehydes and ketones by way of the unstable  $\alpha$ -hydroxy- or  $\alpha$ -haloamines. However, a side product with an  $\alpha$ -halo amide is a *gem*-dihalide. Ureas analogously give hydrazines.

OS II, 19, 44, 462; IV, 45; VIII, 26, 132.

### 18-14 The Curtius Rearrangement

The *Curtius rearrangement* involves heating acyl azides to yield isocyanates.<sup>328</sup> The reaction gives good yields of isocyanates, since no water is present to hydrolyze them to the amine. Of course, they can be subsequently hydrolyzed, and indeed the reaction *can* be carried out in water or alcohol, in which case the products are amines, carbamates, or acylureas, as in **18-13**.<sup>329</sup> This is a very general reaction and can be applied to almost any carboxylic acid: aliphatic, aromatic, alicyclic, heterocyclic, unsaturated, and containing many functional groups. Acyl azides can be prepared as in **10-42** or by treatment of acylhydrazines (hydrazides) with nitrous acid (analogous to **12-48**). The Curtius rearrangement is catalyzed by Lewis acids or protic acids, but these are usually not necessary.

The mechanism is similar to that in **18-13** to give an isocyanate. Also note the exact analogy between this reaction and **18-8**. However, in this case, there is no evidence for a free nitrene and it is probable that the conversion is concerted.<sup>330</sup>

<sup>330</sup> See, Smalley, R.K.; Bingham, T.E. *J. Chem. Soc. C* **1969**, 2481.

Alkyl azides can be similarly pyrolyzed to give imines, in an analogous reaction:<sup>331</sup> The R groups may be alkyl, aryl, or hydrogen, though if hydrogen migrates, the product is the unstable  $R_2C=NH$ . The mechanism is essentially the same as that of the Curtius rearrangement. However, in pyrolysis of tertiary alkyl azides, there is evidence that free alkyl nitrenes are intermediates.<sup>332</sup> The reaction can also be carried out with acid catalysis, in which case lower temperatures can be used, though the acid may hydrolyze the imine (**16-2**). Cycloalkyl azides give ring expansion, as in the conversion of 1-azido-1-alkylcyclohexane to 7-alkyl-3,4,5,6-tetrahydro-2*H*-azepine.<sup>333</sup> Aryl azides also give ring expansion on heating, as in the conversion of azidobenzene to *N*-phenyl-2*H*-azepin-7-amine by heating with aniline.<sup>334</sup>

### 18-15 The Lossen Rearrangement

The *O*-acyl derivatives of hydroxamic acids<sup>335</sup> give isocyanates when treated with bases or sometimes even just on heating, in a reaction known as the *Lossen rearrangement*.<sup>336</sup> The mechanism is similar to that of **18-13** and **18-14**:

In a similar reaction, aromatic acyl halides are converted to amines in one laboratory step by treatment with hydroxylamine-*O*-sulfonic acid.<sup>337</sup> Metal-assisted Lossen rearrangements are known.<sup>338</sup> Unsymmetrical ureas were prepared using bromodimethylsulfonium bromide as a mediator.<sup>339</sup> A chiral Lossen rearrangement is known.<sup>340</sup>

The *Tiemann rearrangement*<sup>341</sup> is an old reaction in which *N*-phenylurea was formed by tosylation of benzamidoxine. Various *N*-substituted cyanamides were prepared by the

### 18-16 The Schmidt Reaction

There are actually three reactions given the name *Schmidt reaction*, involving the addition of hydrazoic acid to carboxylic acids, aldehydes and ketones, and alcohols and alkenes.<sup>343</sup> The most common is the reaction with carboxylic acids, illustrated above.<sup>344</sup> Sulfuric acid is a common catalyst, but Lewis acids have also been used. Triflic acid has been used for chemoselective Schmidt reactions.<sup>345</sup> Good results are obtained for aliphatic R, especially for long chains. When R is aryl, the yields are variable, being best for sterically hindered compounds like mesitoic acid. This method has the advantage over **18-13** and **18-14** in that there is just one laboratory step from the acid to the amine, but conditions are more drastic.<sup>346</sup> Under the acid conditions employed, the isocyanate is virtually never isolated. The Schmidt reaction has been done in ionic liquids.<sup>347</sup> Interconverting isomeric allylic azides were treated with SnCl<sub>4</sub> to give an intramolecular Schmidt reaction that led to substituted lactams stereoselectively.<sup>348</sup> Hexafluoroisopropanol has been used as a solvent.<sup>349</sup>

The reaction between a ketone and hydrazoic acid is a method for “insertion” of NH between the carbonyl group and one R group, converting a ketone into an amide.<sup>350</sup> Either or both of the groups attached to the carbonyl carbon may be aryl. In general, dialkyl ketones and cyclic ketones react more rapidly than alkyl aryl ketones, and these more rapidly than diaryl ketones. Diaryl ketones require sulfuric acid and do not react in concentrated HCl, though HCl is strong enough for dialkyl ketones. Dialkyl and cyclic ketones react sufficiently faster than diaryl or aryl alkyl ketones or carboxylic acids or alcohols, so that these functions may be present in the same molecule without interference. Cyclic ketones give lactams.<sup>351</sup> With alkyl aryl ketones, it is the aryl group that generally migrates to the nitrogen, except when the alkyl group is bulky.<sup>352</sup> The reaction of acylsilanes and alkyl azides with triflic acid gave the amide.<sup>353</sup>

The reaction has been applied to a few aldehydes, but rarely. With aldehydes the product is usually the nitrile (**16-14**). Even with ketones, conversion to the nitrile is often a side reaction, especially with the type of ketone that gives **17-28**. A useful variation of the Schmidt reaction treats a cyclic ketone such as cyclohexanone with an alkyl azide (RN<sub>3</sub>)<sup>354</sup>

<sup>351</sup> See Krow, G.R. *Tetrahedron* **1981**, *37*, 1283.

<sup>352</sup> Exceptions to this statement: see Tomita, M.; Minami, S.; Uyeo, S. *J. Chem. Soc. C* **1969**, 183.

<sup>353</sup> Yu, C.-J.; Li, R.; Gu, P. *Tetrahedron Lett.* **2016**, *57*, 3568.

<sup>354</sup> See Furness, K.; Aubé, J. *Org. Lett.* **1999**, *1*, 495.

in the presence of  $\text{TiCl}_4$ , generating a lactam such as caprolactam (azepan-2-one).<sup>355</sup> An intramolecular Schmidt reaction gives bicyclic amines.<sup>356</sup> Another variation treats a silyl enol ether of a cyclic ketone with  $\text{TMSN}_3$  and photolyzes the product with UV light to give a lactam.<sup>357</sup> Nitrogen-containing heterocycles have been prepared via an intramolecular Schmidt reaction of acyl chlorides and alkyl azides.<sup>358</sup>

Alcohols and alkenes react with  $\text{HN}_3$  to give alkyl azides,<sup>359</sup> which in the course of reaction rearrange in the same way as discussed in reaction **18-14**.<sup>331</sup> The *Mitsunobu reaction* (**10-17**) can be used to convert alcohols to alkyl azides, and an alternative reagent for azides,  $(\text{PhO})_2\text{PON}_3$ , for use in the Mitsunobu reaction, is now available.<sup>360</sup> In the presence of an Au catalyst, an acetylenic azide was converted to a pyrrole derivative.<sup>361</sup>

There is evidence that the mechanism with carboxylic acids<sup>350</sup> is similar to that of **18-14**, except that it is the protonated azide that undergoes the rearrangement.<sup>362</sup>

The first step is the same as that of the  $\text{A}_{\text{AC}}1$  mechanism (**16-58**), which explains why good results are obtained with hindered substrates. The mechanism with ketones involves formation of **46**, which loses nitrogen to give a nitrilium ion **47**, which reacts with water.

Intermediates such as **46** have been independently generated in aqueous solution.<sup>363</sup> Note the similarity of this mechanism to those of “insertion” of  $\text{CH}_2$  (**18-9**) and of  $\text{O}$  (**18-19**). The three reactions are essentially analogous, both in products and in mechanism.<sup>350,364</sup>

### 18-17 The Beckmann Rearrangement

When oximes are treated with  $\text{PCl}_5$  or a number of other reagents, they rearrange to substituted amides in a reaction called the *Beckmann rearrangement*.<sup>365</sup> Reagents used include concentrated  $\text{H}_2\text{SO}_4$  acid, propylphosphonic anhydride,<sup>366</sup> formic acid, liquid  $\text{SO}_2$ , silica gel,<sup>367</sup> Ti,<sup>368</sup> Cu,<sup>369</sup> W,<sup>370</sup> Fe,<sup>371</sup> Ru,<sup>372</sup> Y,<sup>373</sup> I<sub>2</sub>,<sup>374</sup>  $\text{HgCl}_2$ ,<sup>375</sup> triphosphazene,<sup>376</sup> neat with  $\text{FeCl}_3$ ,<sup>377</sup> cyanuric acid,<sup>378</sup> and polyphosphoric acid.<sup>379</sup> Organocatalysts have been used.<sup>380</sup> Simply heating the oxime of benzophenone neat leads to *N*-phenyl benzamide.<sup>381</sup> The complex of pivaloyl chloride and DMF converted ketoximes to the amide or lactam via the Beckmann rearrangement.<sup>382</sup> The reaction has been done in supercritical water<sup>383</sup> and in ionic liquids.<sup>384</sup> A polymer-bound Beckman rearrangement has been reported.<sup>385</sup> Microwave-assisted Beckmann rearrangements are known.<sup>386</sup>

The oximes of cyclic ketones give ring enlargement to give the lactam,<sup>387</sup> as in the formation of caprolactam (see **18-16**) from the oxime of cyclohexanone. Solvent-free reactions are known.<sup>388</sup> Cyclic ketones can be converted directly to lactams in one laboratory step by treatment with  $\text{NH}_2\text{OSO}_2\text{OH}$  and formic acid (**16-13** takes place first, then the Beckmann rearrangement).<sup>389</sup>

Of the groups attached to the carbon of the  $\text{C}=\text{N}$  unit, the one that migrates in the Beckmann rearrangement is generally the one *anti* to the hydroxyl, which is often used as a method of determining the configuration of the oxime. However, it is not unequivocal. It is known that with some oximes the *syn* group migrates and that with others, especially where R and R' are both alkyl, mixtures of the two possible amides are obtained. However, in most cases, the oxime undergoes isomerization under the reaction conditions *before* migration takes place.<sup>390</sup> The scope of the reaction is quite broad and R and R' may be alkyl, aryl, or hydrogen. However, hydrogen very seldom migrates, so the reaction is not generally a means of converting aldoximes to unsubstituted amides ( $\text{RCONH}_2$ ). This latter conversion can be accomplished, however, by treatment of the aldoxime with nickel acetate under neutral conditions<sup>391</sup> or by heating the aldoxime for 60 hours at 100 °C after it has been adsorbed onto silica gel.<sup>392</sup> As in the case of the *Schmidt rearrangement* (**18-16**), when the oxime is derived from an alkyl aryl ketone, it is generally the aryl group that preferentially migrates.<sup>393</sup>

In the first step of the mechanism, the OH group is converted by the reagent to a better leaving group, for example, proton acids convert it to  $^+\text{OH}_2$ . After that, the mechanism<sup>394</sup> follows a course analogous to that for the *Schmidt reaction* of ketones (**18-16**) from the formation of nitrilium ion **48** onwards.<sup>395</sup>

Alternative modes of reaction are possible. For example, when  $\text{PCl}_5$  is used to induce the reaction, a  $\text{N}-\text{O}-\text{PCl}_4$  species is formed, which generates **48**. Nitrilium ion intermediates have been detected by NMR and UV spectroscopy.<sup>396</sup> The rearrangement has also

<sup>396</sup> Gregory, B.J.; Moodie, R.B.; Schofield, K. *J. Chem. Soc. B* **1970**, 338.

been found to take place by a different mechanism, involving formation of a nitrile by fragmentation, and then addition by a *Ritter reaction* (**16-85**).<sup>397</sup> Beckmann rearrangements have also been carried out photochemically.<sup>398</sup> A computational study compared concerted versus stepwise mechanisms for the Beckmann rearrangement, and found that proton relay between the substrate and the solvent molecules controls the reaction, and migration and N–O bond scission occur simultaneously.<sup>399</sup>

Not only do oximes undergo the Beckmann rearrangement, but so also do esters of oximes with many acids, both organic and inorganic. A side reaction with many substrates is the formation of nitriles (the “abnormal” Beckmann rearrangement, **17-28**). The *O*-carbonates of imines, such as  $\text{Ph}_2\text{C}=\text{N}-\text{OCO}_2\text{Et}$  react with  $\text{BF}_3 \cdot \text{OEt}_2$  to give the corresponding amide, in this case *N*-phenyl benzamide.<sup>400</sup>

If the rearrangement of oxime sulfonates is induced by organoaluminum reagents,<sup>401</sup> the nitrilium ion intermediate **48** is captured by the nucleophile originally attached to the Al. By this means an oxime can be converted to an imine, an imino thioether ( $\text{R}-\text{N}=\text{C}-\text{SR}$ ), or an imino nitrile ( $\text{R}-\text{N}=\text{C}-\text{CN}$ ).<sup>402</sup> In the last case, the nucleophile comes from added trimethylsilyl cyanide. In the presence of LiI, 2-benzyloxypyridine is converted to *N*-benzyl-2-pyridone.<sup>403</sup>

Thioamides were prepared from ketoximes via Beckmann rearrangement.<sup>404</sup>  
OS II, 76, 371; VIII, 568.

## 18-18 The Stieglitz and Related Rearrangements

In addition to the reactions discussed at **18-13** to **18-17**, other rearrangements are known in which an alkyl group migrates from C to N. Certain bicyclic *N*-haloamines, for example *N*-chloro-2-azabicyclo[2.2.2]octane (above), undergo rearrangement when solvolyzed in the presence of silver nitrate.<sup>405</sup> This reaction is similar to the *Wagner-Meerwein rearrangement* (**18-1**) and is initiated by the silver-catalyzed departure of the chloride ion.<sup>406</sup> Similar reactions have been used for ring expansions and contractions, analogous to those discussed for reaction **18-3**.<sup>407</sup> An example is the conversion of 1-(*N*-chloroamino)cyclopropanols to

$\beta$ -lactams.<sup>408</sup> Methyl prolinatate was converted to the 2-piperidone upon treatment with  $\text{SmI}_2$  and pivalic acid/THF.<sup>409</sup>

The name “*Stieglitz rearrangement*” is generally applied to the rearrangements of trityl *N*-haloamines or hydroxylamines to aryl imines via treatment with base or  $\text{PCl}_5$ , respectively. These reactions are similar to the rearrangements of alkyl azides (**18-14**), and the name Stieglitz rearrangement is also given to the rearrangement of trityl azides. Another similar reaction is the rearrangement undergone by tritylamines when treated with lead tetraacetate ( $\text{Ar}_3\text{CNH}_2 \rightarrow \text{Ar}_2\text{C}=\text{NAr}$ ).<sup>410</sup>

#### D. Carbon-to-Oxygen Migrations of R and Ar

##### 18-19 The Baeyer-Villiger Rearrangement<sup>411</sup>

The treatment of ketones with peroxy acids, such as peroxybenzoic or peroxyacetic acid, or with other peroxy compounds in the presence of acid catalysts,<sup>412</sup> gives carboxylic esters by migration of an alkyl group oxygen<sup>413</sup> and gives the carboxylic acid parent of the peroxy acid as a by-product. In other words, there is a C  $\rightarrow$  O rearrangement, and the reaction is called the *Baeyer-Villiger rearrangement*.<sup>414</sup> A particularly good reagent is peroxytrifluoroacetic acid. Reactions with this reagent are rapid and clean, giving high yields of product, although it is often necessary to add a buffer, such as  $\text{Na}_2\text{HPO}_4$ , to prevent transesterification of the product with trifluoroacetic acid that is also formed during the reaction. The reaction is often applied to cyclic ketones to give lactones.<sup>415</sup> Hydrogen peroxide has been used with a catalytic amount of  $\text{MeReO}_3$ ,<sup>416</sup> a W catalyst,<sup>417</sup> or a diselenide catalyst.<sup>418</sup> Heterogeneous catalysts are used for the Baeyer-Villiger reaction.<sup>419</sup>

Transition metal catalysts have been used with peroxy acids to facilitate the oxidation.<sup>420</sup> Polymer-supported peroxy acids have been used,<sup>421</sup> and solvent-free reactions are known.<sup>422</sup> Potassium peroxomonosulfate supported on acidic silica gel has been used.<sup>423</sup>

Enantioselective synthesis<sup>424</sup> of chiral lactones from achiral ketones has been achieved by the use of enzymes<sup>425</sup> and other asymmetric reactions are known.<sup>426</sup> Chiral Pd complexes have been used, with high enantioselectivity.<sup>427</sup> Bacteriogenic iron oxide has been used as a catalyst.<sup>428</sup> Other chiral catalysts are known,<sup>429</sup> including organocatalysts.<sup>430</sup> Baeyer-Villiger oxidation of chiral substrates with *m*-chloroperoxybenzoic acid (mcpba) also leads to chiral lactones.<sup>431</sup>

For acyclic compounds, R' must usually be secondary, tertiary, or vinylic, although primary R' has been rearranged with peroxytrifluoroacetic acid,<sup>432</sup> with I<sub>2</sub>/H<sub>2</sub>O<sub>2</sub>,<sup>433</sup> and BF<sub>3</sub>/H<sub>2</sub>O<sub>2</sub>.<sup>434</sup> For unsymmetrical ketones the approximate order of migration is tertiary alkyl > secondary alkyl, aryl > primary alkyl > methyl. Since the methyl group has a low migrating ability, the reaction provides a means of cleaving a methyl ketone (R'COMe) to produce an alcohol or phenol (R'OH) (by hydrolysis of the ester R'OCOME). The migrating ability of aryl groups is increased by electron-donating substituents and decreased by electron-withdrawing substituents.<sup>435</sup> There is a preference of *anti* over *gauche* migration.<sup>436</sup> Enolizable β-diketones do not react.

The mechanism<sup>437</sup> is similar to those of the analogous reactions with hydrazoic acid (**18-16** with ketones) and diazomethane (**18-8**). Evidence for this mechanism was that benzophenone-<sup>18</sup>O gave ester entirely labeled in the carbonyl oxygen, with none in the

alkoxy oxygen.<sup>438</sup> Carbon-14 isotope-effect studies on acetophenones have shown that migration of aryl groups takes place in the rate-determining step,<sup>439</sup> demonstrating that the migration is concerted with departure of OCOR<sup>2</sup>.<sup>440</sup>

It is unlikely that migration would be the slow step if the leaving group departed first to give an ion with a positive charge on an oxygen atom, which would be a highly unstable species.

The reaction of alkenes in aqueous hydrogen peroxide, in the presence of benzonitrile at pH 9.5–10, gave the epoxide, in what is known as *Payne epoxidation*.<sup>441</sup>

### 18-20 Rearrangement of Hydroperoxides

Hydroperoxides (R = alkyl, aryl, or hydrogen) can be cleaved by proton or Lewis acids in a reaction whose principal step is a rearrangement.<sup>442</sup> The reaction has also been applied to peroxy esters (R<sub>3</sub>COOCOR'), but less often. When aryl and alkyl groups are both present, migration of aryl dominates. It is not necessary actually to prepare and isolate hydroperoxides. The reaction takes place when the alcohols are treated with H<sub>2</sub>O<sub>2</sub> and acids. Migration of an alkyl group of a primary hydroperoxide provides a means for converting an alcohol to its next lower homolog:

The mechanism is as shown.<sup>443</sup> The last step is hydrolysis of the unstable hemiacetal. Alkoxy carbocation intermediates (an oxocarbenium ion, R = alkyl) have been isolated in

superacid solution<sup>444</sup> at low temperatures, and their structures proved by NMR.<sup>445</sup> The protonated hydroperoxides could not be observed in these solutions, evidently reacting immediately on formation.

OS V, 818.

## E. Nitrogen-to-Carbon, Oxygen-to-Carbon, and Sulfur-to-Carbon Migration

### 18-21 The Stevens Rearrangement

In the *Stevens rearrangement*,<sup>446</sup> a quaternary ammonium salt containing an electron-withdrawing group Z on one of the carbons attached to the nitrogen is treated with a strong base (e.g., NaOR or NaNH<sub>2</sub>) to give a rearranged tertiary amine. The Z group may be RCO, ROOC, or phenyl.<sup>447</sup> The most common migrating groups are allylic, benzylic, benzhydryl, 3-phenylpropargyl, and phenacyl, although even methyl migrates to a sufficiently negative center. Migration of aryl is rare, but has been reported.<sup>448</sup> When an allylic group migrates, it may or may not involve an allylic rearrangement within the migrating group (see **18-35**), depending on the substrate and reaction conditions. The reaction has been used for ring enlargement, illustrated by the rearrangement of **49** to give the ring-expanded product in 90% yield.<sup>449</sup>

The mechanism has been the subject of much study.<sup>450</sup> The rearrangement is intramolecular, as shown by crossover experiments, by <sup>14</sup>C labeling,<sup>451</sup> and by the fact that retention of configuration is found at R<sup>1</sup>.<sup>452</sup> The first step is loss of the acidic proton to give a

nitrogen ylid, which has been isolated.<sup>453</sup> The finding<sup>454</sup> that CIDNP is observed<sup>455</sup> in many instances shows that in these cases the product is formed directly from a free-radical precursor and a radical pair mechanism was proposed:<sup>456</sup>

The radicals do not drift apart because the solvent cage holds them together. According to this mechanism, the radicals must recombine rapidly in order to account for the fact that  $\text{R}^1$  does not racemize. Other evidence in favor of a radical pair mechanism is that in some cases small amounts of coupling products ( $\text{R}^1\text{—R}^1$ ) have been isolated,<sup>457</sup> which would be expected if some  $\bullet\text{R}^1$  leaked from the solvent cage. However, not all the evidence is easily compatible with the ylid mechanism.<sup>458</sup> It is possible that another mechanism, similar to the radical pair mechanism but involving ion pairs in a solvent cage, operates in some cases. A third possible mechanism would be a concerted 1,2-shift,<sup>459</sup> but the orbital symmetry principle requires that this take place with inversion at  $\text{R}^1$  (see **18-30** and [1,5]-migration).<sup>460</sup> Since the actual migration takes place with retention, it *cannot*, according to this argument, proceed by a concerted mechanism. However, in the case where the migrating group is allylic, a concerted mechanism can also operate (**18-35**). An interesting finding compatible with all three mechanisms is that optically active allylbenzylmethylphenylammonium iodide (asymmetric nitrogen, Sec. 4.C, category 3) gave an optically active product.<sup>461</sup> An arylne [2,3]-Stevens' rearrangement is known.<sup>462</sup>

The *Sommelet-Hauser rearrangement* competes when Z is an aryl group (see **13-32**). *Hofmann elimination* competes when one of the R groups contains a  $\beta$  hydrogen atom (**17-6** and **17-2**).

The formation of *o*-benzylbenzyltrimethylamine from benzhydryltrimethylammonium bromide, by heating to 180 °C with concentrated hydroxide, illustrates the *Sommelet rearrangement*.<sup>463</sup> Initial deprotonation probably occurred at the benzylic site, but under equilibrium conditions an ylid was generated. Nucleophilic attack at the proximal benzene ring gave led to cleavage of the C—N bond, and subsequent aromatization gave the final product 1-(2-benzylphenyl)-*N,N*-dimethylmethanamine. Evidence suggests the mechanism is a

[1,2]-shift of the ylid via a caged radical pair intermediate.<sup>464</sup> Steric effects appear to be less significant than electronic effects for ylid stability.<sup>465</sup> The so-called *ortho substitution rearrangement*<sup>466</sup> involves reaction of the benzyltrimethylammonium salt with  $\text{NaNH}_2$  to give 2-(dimethylaminomethyl)toluene. This rearrangement is either the same reaction as the Sommelet rearrangement, or it is closely related.<sup>466</sup>

Sulfur ylids containing a Z group give an analogous rearrangement to give the sulfide, as shown, and this has been referred to as a *Stevens rearrangement*.<sup>467</sup>

In this case too, there is much evidence (including CIDNP) that a radical-pair cage mechanism is operating,<sup>468</sup> except that when the migrating group is allylic, the mechanism may be different (see **18-35**).

Another reaction with a similar mechanism<sup>469</sup> is the *Meisenheimer rearrangement*,<sup>470</sup> in which certain tertiary amine oxides rearrange on heating to give substituted hydroxylamines.<sup>471</sup>

The migrating group  $\text{R}^1$  is almost always allylic or benzylic.<sup>472</sup> The  $\text{R}^2$  and  $\text{R}^3$  groups may be alkyl or aryl, but if one of the R groups contains a  $\beta$  hydrogen, *Cope elimination* (**17-7**) often competes. In a related reaction, when 2-methylpyridine *N*-oxides are treated with trifluoroacetic anhydride, the *Boekelheide reaction* occurs to give 2-hydroxymethylpyridines.<sup>473</sup>

Isocyanides, when heated in the gas phase or in nonpolar solvents, undergo a 1,2-intramolecular rearrangement to nitriles:  $\text{RNC} \rightarrow \text{RCN}$ .<sup>474</sup> In polar solvents the mechanism is different.<sup>475</sup>

### 18-22 The Wittig Rearrangement<sup>476</sup>

The rearrangement of ethers upon treatment with alkyllithium reagents is called the *Wittig rearrangement* (not to be confused with the *Wittig reaction*, **16-44**) and is similar to **18-21**.<sup>454</sup> However, a stronger base is required (e.g., phenyllithium or sodium amide). The R and R<sup>1</sup> groups may be alkyl,<sup>477</sup> aryl, or vinylic.<sup>478</sup> One of the hydrogen atoms may be replaced by an alkyl or aryl group, in which case the product is the salt of a tertiary alcohol. Migratory aptitudes here are allylic, benzylic > ethyl > methyl > phenyl.<sup>479</sup> The stereospecificity of the 1,2-Wittig rearrangement has been discussed.<sup>480</sup>

A radical-pair mechanism<sup>481</sup> (similar to ylid mechanism of **18-21**) is likely, after removal of the proton by the base. One of the radical pair is a ketyl. Evidence for this mechanism includes: (i) the rearrangement is largely intramolecular; (ii) migratory aptitudes are in the order of free-radical stabilities, not of carbanion stabilities<sup>482</sup> (which rules out an ion-pair mechanism); (iii) aldehydes are obtained as side products;<sup>483</sup> (iv) partial racemization of R<sup>1</sup> has been observed<sup>484</sup> (the remainder of the product retained its configuration); (v) crossover products have been detected,<sup>485</sup> and (vi) when ketyl radicals and R• radicals from different precursors were brought together, similar products resulted.<sup>486</sup> However, there is evidence that at least in some cases the radical-pair mechanism accounts for only a portion of the product, and some kind of concerted mechanism can also take place.<sup>487</sup> Most of the above investigations were carried out with systems where R<sup>1</sup> is alkyl, but a radical-pair mechanism has also been suggested for the case where R<sup>1</sup> is aryl.<sup>488</sup> When R<sup>1</sup> is allylic a concerted mechanism can operate (**18-35**).

When R is vinylic it is possible, by using a combination of an alkyllithium and *t*-BuOK, to get migration to the  $\gamma$  carbon (as well as to the  $\alpha$  carbon), producing an enolate that,

### 18-23 Conversion of Boranes to Alcohols

Hydroboration (**15-11**) of alkenes leads to organoboranes, which need not be isolated since subsequent reaction with basic hydrogen peroxide gives the anti-Markovnikov alcohol and boric acid. Oxidation of organoboranes (see **15-11**) uses NaOH and hydrogen peroxide, which react to give the hydroperoxide anion,  $\text{HOO}^-$ . Reaction of the organoborane with basic hydrogen peroxide (via  $\text{HOO}^-$ ) leads to an "ate" complex, and subsequent  $\text{B} \rightarrow \text{O}$  rearrangement of an alkyl group on boron to a peroxy oxygen, with expulsion of hydroxide, leads to a borate, and then an alcohol after hydrolysis. The proposed mechanism<sup>492</sup> is shown, in which a trialkylborane is converted to 3 molar equivalents of the alcohol, along with boric acid.

As mentioned, if the hydroboration reaction in **15-11** is used then this procedure converts alkenes to an *anti-Markovnikov* borane, and oxidation leads to the anti-Markovnikov alcohol. An example is the conversion of methylcyclopentene to *trans*-2-methylcyclopentanol.<sup>493</sup> Formation of the organoborane proceeds via a *cis* addition of  $\text{B-H}$ , placing the boron *trans* to the methyl group, and stereoselective oxidation and  $\text{B} \rightarrow \text{O}$  rearrangement leads to retention of configuration in the alcohol.

Chem.* **1983**, *112*, 67; Cragg, G.M.L. *Organoboranes in Organic Synthesis*, Marcel Dekker, NY, **1973**, pp. 249–300.

<sup>492</sup> Brown, H.C. *Hydroboration*, W.A. Benjamin, New York, **1962**. See Kuivila, H.G. *J. Am. Chem. Soc.* **1954**, *76*, 870; **1955**, *77*, 4014; See Kuivila, H.G.; Armour, A.G. *J. Am. Chem. Soc.* **1957**, *79*, 5659; Wechter, W.J. *Chem. & Ind. (London)* **1959**, 294.

<sup>493</sup> Zweifel, G.; Brown, H.C. *Org. React.* **1964**, *13*, 1.

Trialkylboranes can be prepared from alkenes by **15-11**, and they react with carbon monoxide<sup>494</sup> at 100–125 °C in the presence of ethylene glycol to give the 2-bora-1,3-dioxolanes (**50**), which are easily oxidized (**12-27**) to tertiary alcohols.<sup>495</sup>

The R groups may be primary, secondary, or tertiary, and may be the same or different.<sup>496</sup> Yields are high and the reaction is quite useful, especially for the preparation of sterically hindered alcohols, such as 9-decalol (**51**) and *cis,cis,trans*-perhydro-9b-phenalenol (**52**), which are difficult to prepare by **16-22**.

The overall conversion of a diene or triene to a cyclic alcohol was described by H.C. Brown as “stitching” with B and “riveting” with C.

The mechanism has been shown to be intramolecular by the failure to find crossover products when mixtures of boranes are used.<sup>497</sup> The mechanistic scheme to form **50** involves formation of a  $\text{B}^+-\text{C}=\text{O}$  intermediate and three boron-to-carbon migrations before reaction with the diol,<sup>497</sup> which otherwise forms polymers that are difficult to oxidize.

There are two other methods for achieving the conversion  $\text{R}_3\text{B} \rightarrow \text{R}_3\text{COH}$ , which often give better results: (i) treatment with  $\alpha,\alpha$ -dichloromethyl methyl ether and the base lithium triethylcarboxide<sup>498</sup> and (ii) treatment with a suspension of sodium cyanide in THF followed by reaction of the resulting trialkylcyanoborate with an excess (>2 equivalents) of trifluoroacetic anhydride.<sup>499</sup> All the above migrations take place with retention of configuration at the migrating carbon.<sup>500</sup> Several other methods for the conversion of boranes to tertiary alcohols are also known.<sup>501</sup>

If the reaction between trialkylboranes and carbon monoxide (**18-23**) is carried out in the presence of water followed by addition of NaOH, the product is a secondary alcohol. If  $\text{H}_2\text{O}_2$  is added along with the NaOH, the corresponding ketone is obtained instead.<sup>502</sup> Various functional groups (e.g., OAc, COOR, CN) may be present in R without being affected,<sup>503</sup> although if they are in the  $\alpha$  or  $\beta$  position relative to the boron atom, difficulties

may be encountered. The use of an equimolar amount of trifluoroacetic anhydride leads to the ketone rather than the tertiary alcohol.<sup>504</sup> By this procedure thexylboranes ( $RR^1R^2B$ , where  $R^2 = \text{thexyl}$ ) can be converted to unsymmetrical ketones ( $RCOR^1$ ).<sup>505</sup> Variations of this methodology have been used to prepare optically active alcohols.<sup>506</sup> See **18-26** for another conversion of trialkylboranes to ketones.<sup>507</sup> It is noted that Oxone was used to oxidize organotrifluoroborates to the corresponding alcohol.<sup>508</sup>

OS **VII**, 427. Also see, OS **VI**, 137.

### 18-24 Conversion of Boranes to Primary Alcohols, Aldehydes, or Carboxylic Acids

When the reaction between a trialkylborane and carbon monoxide (**18-23**) is carried out in the presence of a reducing agent such as lithium borohydride or potassium triisopropoxyborohydride, the reduction agent intercepts the intermediate so that only one  $B \rightarrow C$  migration takes place, and the product is hydrolyzed to a primary alcohol or oxidized to an aldehyde.<sup>509</sup> This procedure wastes two of the three R groups, but this problem can be avoided by the use of *B*-alkyl 9-BBN derivatives (see **15-11**). Since only the 9-alkyl group migrates, this method permits the conversion in high yield of an alkene to a primary alcohol or aldehyde containing one more carbon.<sup>510</sup> When *B*-alkyl 9-BBN derivatives are treated with CO and lithium tri-*tert*-butoxyaluminum hydride,<sup>511</sup> other functional groups (e.g., CN and ester) can be present in the alkyl group without being reduced.<sup>512</sup> Boranes can be directly converted to carboxylic acids by reaction with the dianion of phenoxyacetic acid.<sup>513</sup>

Boronic esters  $RB(OR')_2$  react with methoxy(phenylthio)methyl lithium,  $LiCH(OMe)SPh$ , to give salts, which, after treatment with  $HgCl_2$  and then  $H_2O_2$ , yields aldehydes.<sup>514</sup> This synthesis has been made enantioselective, with high ee values (>99%), by the use of an optically pure boronic ester.<sup>515</sup>

## 18-25 Conversion of Vinylic Boranes to Alkenes

The reaction between trialkylboranes and iodine to give alkyl iodides was mentioned at **12-31**. When the substrate contains a vinylic group, the reaction takes a different course,<sup>516</sup> with one of the  $R'$  groups migrating from the boron to the carbon, to give alkenes.<sup>517</sup> The reaction is stereospecific in two senses: (i) if the groups  $R$  and  $R^2$  are *cis* in the starting compound, they will be *trans* in the product; (ii) there is retention of configuration within the migrating group  $R'$ .<sup>518</sup> Since vinylic boranes can be prepared from alkynes (**15-11**), this is a method for the addition of  $R'$  and  $H$  to a triple bond. If  $R^2 = H$ , the product is a (*Z*)-alkene. The mechanism is believed to involve an iodonium intermediate, such as **53**, and attack by iodide on boron. When  $R'$  is vinylic, the product is a conjugated diene.<sup>519</sup>

In another procedure, the addition of a dialkylborane to a 1-haloalkyne produces an  $\alpha$ -halo vinylic borane.<sup>520</sup> Treatment of the 1-bromovinyl borane with  $\text{NaOMe}$  gives the rearrangement, and protonolysis of the product produces an (*E*)-alkene.<sup>518</sup> If one of the groups is hexyl, the other migrates.<sup>521</sup> A combination of both of the procedures described above results in the preparation of trisubstituted alkenes.<sup>522</sup>

## 18-26 Formation of Alkynes, Alkenes, and Ketones from Boranes and Acetylides

A hydrogen directly attached to a triple-bond carbon can be replaced in high yield by an alkyl or an aryl group, by treatment of the lithium acetylide with a trialkyl- or triarylborane, followed by reaction of the lithium alkynyltrialkylborate with iodine.<sup>523</sup> The  $R'$  group may be primary or secondary alkyl as well as aryl, so the reaction has a broader scope than the older reaction **10-74**.<sup>524</sup> The  $R$  group may be alkyl, aryl, or hydrogen, although in the last-mentioned case satisfactory yields are obtained only if lithium acetylide-ethylenediamine is used as the starting compound.<sup>525</sup> Optically active alkynes can be prepared by using optically active hexylborinates ( $\text{RR}^2\text{BOR}'$ ,  $R^2 = \text{hexyl}$ ), where  $R$  is

chiral, and  $\text{LiC}\equiv\text{CSiMe}_3$ .<sup>526</sup> The reaction can be adapted to the preparation of alkenes<sup>527</sup> by treatment of the lithium alkynyltrialkylborate with an electrophile such as propanoic acid<sup>528</sup> or tributyltin chloride.<sup>529</sup> The reaction with  $\text{Bu}_3\text{SnCl}$  produces the (*Z*)-alkene stereoselectively.

Treatment of the lithium alkynyltrialkylborate with electrophiles such as methyl sulfate, allyl bromide, or triethyloxonium tetrafluoroborate, followed by oxidation of the resulting vinylic borane, gives a ketone.<sup>530</sup> Note that there are reactions that involve  $\text{N} \rightarrow \text{O}$  rearrangements, including those mediated by silicon.<sup>531</sup>

## 18.F.ii. Non 1,2-Rearrangements

### A. Electrocyclic Rearrangements

#### 18-27 Electrocyclic Rearrangements of Cyclobutenes and 1,3-Cyclohexadienes

Cyclobutenes and 1,3-dienes can be interconverted by treatment with UV light or with heat.<sup>532</sup> These are  $4\pi$  electrocyclizations. The thermal reaction is generally not reversible (although exceptions<sup>533</sup> are known), and many cyclobutenes have been converted to 1,3-dienes by heating at temperatures between 100 and 200 °C.<sup>534</sup> Benzocyclobutenes also undergo electrocyclic ring opening,<sup>535</sup> as do benzocyclobutanones.<sup>536</sup> The photochemical conversion can in principle be carried out in either direction, but most often 1,3-dienes are converted to cyclobutenes rather than the reverse, because the dienes are stronger absorbers of light at the wavelengths used.<sup>537</sup> In a similar reaction, 1,3-cyclohexadienes interconvert with 1,3,5-trienes, but in this case the ring-closing process is generally favored thermally and the ring-opening process photochemically, but exceptions are known in both directions.<sup>538</sup> Substituent effects can lead to acceleration of the electrocyclization

process.<sup>539</sup> *Torquoselectivity* in cyclobutene ring-opening reactions<sup>540</sup> and the origins of 1,6-stereoselection in torquoselective  $6\pi$  electrocyclizations<sup>541</sup> has been examined.

Examples of these types of reactions include:

An interesting example of 1,3-cyclohexadiene  $\rightarrow$  1,3,5-triene interconversion is the reaction of norcaradienes to give cycloheptatrienes,<sup>543</sup> a  $6\pi$  electrocyclization that has been catalyzed by Lewis acids.<sup>544</sup> Norcaradienes<sup>545</sup> (e.g., bicyclo[4.1.0]hepta-2,4-diene to cyclohepta-1,3,5-triene) give this reaction so readily (because they are *cis*-1,2-divinylcyclopropanes, see **18-32**) that they cannot generally be isolated, though some exceptions are known<sup>546</sup> (see also, **15-61**).

These reactions, called *electrocyclic rearrangements*,<sup>547</sup> take place by pericyclic mechanisms and are important in natural product synthesis.<sup>548</sup> The evidence comes from stereochemical studies, which show a remarkable stereospecificity whose direction depends on whether the reaction is induced by heat or light. For example, it was found for the thermal reaction that *cis*-3,4-dimethylcyclobutene gave only *cis,trans*-hexa-2,4-diene, while the *trans* isomer gave only the *trans,trans* diene:<sup>549</sup>

This experiment is evidence for a four-membered cyclic transition state and arises from conrotatory motion about the C-3–C-4 bond.<sup>550</sup> It is called conrotatory because both

movements are clockwise (or both counterclockwise). Because both rotate in the same direction (conrotatory), the *cis* isomer gives the *cis,trans* diene.<sup>551</sup> The other possibility (*disrotatory* motion) would have one moving clockwise while the other moves counterclockwise (the groups move in opposite directions); the *cis* isomer would have given the *cis,cis* diene (shown) or the *trans,trans* diene. If the motion had been disrotatory, this would still have been evidence for a cyclic mechanism. If the mechanism were a diradical or some other kind of noncyclic process, it is likely that no stereospecificity of either kind would have been observed.

The reverse reaction is also conrotatory. In contrast, the photochemical cyclobutene to 1,3-diene interconversion is *disrotatory* in either direction.<sup>552</sup> Predictions of the stereochemistry are possible.<sup>553</sup> There is evidence, however, that steric effects<sup>554</sup> are an important factor, and that electronic effects also play a role, and their role may be even greater.<sup>555</sup> An electron-donating group stabilizes the transition state when it rotates *outward*, because it mixes with the LUMO; if it rotates *inward*, it mixes with the HOMO, destabilizing the transition state.<sup>556</sup>

The compound 3-formylcyclobutene provided a test. Steric factors would cause the CHO (an electron-withdrawing group) to rotate outward; electronic effects would cause it to rotate inward. The experiment showed inward rotation.<sup>557</sup>

Cyclohexadiene shows precisely the opposite behavior for 1,3,5-triene interconversion. The thermal process is *disrotatory*, while the photochemical process is *conrotatory* (in either direction). These startling results are a consequence of the symmetry rules mentioned in **15-56**, the *Frontier Orbital Method*.<sup>558</sup> As in the case of cycloaddition reactions, the frontier orbital and Möbius-Hückel approaches<sup>559</sup> will be used. Cyclohexadienes are of course 1,3-dienes, and in certain cases it is possible to convert them to cyclobutenes

FIGURE 18.1. Symmetries of the  $X_2$  and  $X_3^*$  orbitals of a conjugated diene.

instead of to 1,3,5-trienes.<sup>560</sup> An interesting example is found in the pyrocalciferols, where photolysis of the *syn* isomer leads to the corresponding cyclobutene,<sup>561</sup> while photolysis of the *anti* isomers gives the ring-opened 1,3,5-triene. These products are predictable based on a combination of orbital symmetry rules and steric influences.

Heating to  $>500$  °C induced the rearrangement of 6,6-dicyanopentafulvenes to 1,3- and 1,4-dicyanobenzenes in polar aprotic solvents, presumably via a polar “ring-walk” mechanism.<sup>562</sup> The Rh-catalyzed cycloisomerization of 1,6-enynes gave functionalized six-membered carbocyclic systems.<sup>563</sup> Substituents effects for  $8\pi/6\pi$  electrocyclization cascade reactions of 1,3,5,7-tetraenes have been studied.<sup>564</sup> A Cu-catalyzed  $6\pi$  photocyclization of dienynes has been reported.<sup>565</sup> The study of enhanced photochemical  $6\pi$  electrocyclization in lipophilic proteins has been reported.<sup>566</sup> Substituted naphthylamines were prepared by the  $6\pi/10\pi$  electrocyclization of ketene iminium salts.<sup>567</sup> Pyrroles have been prepared by a  $4\pi$  electrocyclic ring closure of 1-azapentadienyl cations.<sup>568</sup> Pyrrole-2-carboxylates and 2-carboxamides have been prepared via an electrocyclization–oxidation sequence.<sup>569</sup>

The Frontier Orbital Method<sup>570</sup> As applied to these reactions, the frontier orbital method may be expressed in this way: A  $\sigma$  bond will open in such a way that the resulting p orbitals will have the symmetry of the highest occupied  $\pi$  orbital of the product. In the case of cyclobutenes, the HOMO of the product in the thermal reaction is the  $X_2$  orbital (Figure 18.1). Therefore, in a thermal process, the cyclobutene must open so that on one side

**FIGURE 18.2.** Thermal opening of 1,2-diethylcyclobutene. The two hydrogens and two methyls are forced into conrotatory motion so that the resulting  $p$  orbitals have the symmetry of the HOMO of the diene.

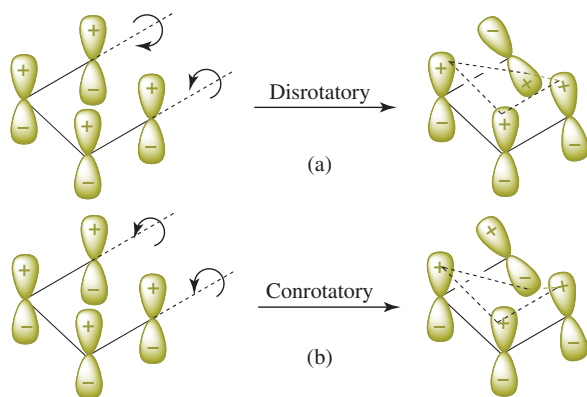

the positive lobe lies above the plane, and on the other side below it. Thus the substituents are forced into conrotatory motion (Figure 18.2). On the other hand, in the photochemical process, the HOMO of the product is now the  $X_3$  orbital (Figure 18.1), and in order for the  $p$  orbitals to achieve this symmetry (the two plus lobes on the same side of the plane), the substituents are forced into disrotatory motion.

This reaction may be considered from the opposite direction (ring closing). For this direction, the rule is that *those lobes of orbitals that overlap (in the HOMO) must be of the same sign*. For thermal cyclization of butadienes, this requires conrotatory motion (Figure 18.3). In the photochemical process the HOMO is the  $X_3$  orbital, so that disrotatory motion is required for lobes of the same sign to overlap.

**The Möbius-Hückel Method** As seen in **15-56** (the Möbius-Hückel method), a basis set of  $p$  orbitals is chosen and inspected for sign inversions in the transition state. Figure 18.4 shows a basis set for a 1,3-diene. It is seen that disrotatory ring closing (Figure 18.4a) results in overlap of plus lobes only, while in conrotatory closing (Figure 18.4b) there is one overlap of a plus with a minus lobe. In the first case, there are zero sign inversions, while in the second there is one sign inversion. With zero (or an even number of) sign inversions, the disrotatory transition state is a *Hückel system*, and so is allowed thermally only if the total number of electrons is  $4n + 2$  (**15-56**, the Möbius-Hückel Method). Since the total here is 4, the disrotatory process is not allowed. On the other hand, the conrotatory process, with one sign inversion, is a *Möbius system*, which is thermally allowed if the total number is  $4n$ . The conrotatory process is therefore allowed thermally. For the photochemical reactions, the rules are reversed: a reaction with  $4n$  electrons requires a Hückel system, so only the disrotatory process is allowed.

**FIGURE 18.3.** Thermal ring closing of a 1,3-diene. Conrotatory motion is required for two + lobes to overlap.

**FIGURE 18.4.** The 1,3-diene–cyclobutene interconversion. The orbitals shown are *not* molecular orbitals, but a basis set of *p* atomic orbitals. (a) Disrotatory ring closure gives zero sign inversion. (b) Conrotatory ring closure gives one sign inversion. We could have chosen to show any other basis set (e.g., another basis set would have two plus lobes above the plane and two below, etc.). This would change the number of sign inversion, but the disrotatory mode would still have an even number of sign inversions, and the conrotatory mode an odd number, whichever basis set was chosen.

Both the frontier orbital and the Möbius–Hückel methods can also be applied to the cyclohexadiene to 1,3,5-triene reaction;<sup>571</sup> in either case the predicted result is that for the thermal process, only the disrotatory pathway is allowed, and for the photochemical process, only the conrotatory. For example, for hexa-1,3,5-triene, the symmetry of the HOMO is:

In the thermal cleavage of cyclohexadienes, then, the positive lobes must lie on the same side of the plane, requiring disrotatory motion:

<sup>571</sup> For the transition structures and energy, see Zora, M. *J. Org. Chem.* **2004**, *69*, 1940.

Disrotatory motion is also necessary for the reverse reaction, in order that the orbitals that overlap may be of the same sign:

All these directions are reversed for photochemical processes, because in each case a higher orbital, with inverted symmetry, is occupied.

In the Möbius-Hückel approach, diagrams similar to Figure 18.4 can be drawn for this case. Here too, the disrotatory pathway is a Hückel system and the conrotatory pathway a Möbius system, but since six electrons are now involved, the thermal reaction follows the Hückel pathway and the photochemical reaction follows the Möbius pathway.

A related process is the *Bergmann cyclization*,<sup>572</sup> where an ene-diyne cyclizes to a biradical (**54**) and then aromatizes as shown.

Simply heating the ene-diyne will usually lead to aromatization via this pathway.<sup>573</sup> Ene-diyne dimerization versus Bergman cyclization has been discussed.<sup>574</sup> Quinones can be formed via Bergman cyclization<sup>575</sup> and there are other synthetic applications.<sup>576</sup> The role of vinyl substitution has been examined.<sup>577</sup> An *aza-Bergman cyclization* is known.<sup>578</sup>

The 1,3-diene-cyclobutene interconversion can even be applied to benzene rings.<sup>579</sup> Aromatic compound **55** is converted to **56** by heating to 120 °C,<sup>580</sup> and the Dewar benzene

(**56**) is actually more stable than the benzene. In this case thermolysis of the benzene gives the Dewar benzene (rather than the reverse), because of the strain of four adjacent *tert*-butyl groups on the ring.

Predictions of the reactions discussed in this section can be summarized according to whether the number of electrons involved in the cyclic process is of the form  $4n$  or  $4n + 2$  (where  $n$  is any integer including zero). Although the orbital symmetry rules predict the stereochemical results in almost all cases, it is necessary to recall (**15-56**, the Möbius-Hückel Method) that they only say what is allowed and what is forbidden, but *the fact that a reaction is allowed does not necessarily mean that the reaction takes place*, and if an allowed reaction does take place, it does not *necessarily* follow that a concerted pathway is involved, since other pathways of lower energy may be available.<sup>581</sup> Furthermore, a “forbidden” reaction might still be made to go, if a method of achieving its high activation energy can be found. This was, in fact, done for the cyclobutene–butadiene interconversion (*cis*-3,4-dichlorocyclobutene gave the forbidden *cis,cis*- and *trans,trans*-1,4-dichlorobuta-1,3-dienes, as well as the allowed *cis,trans* isomer) by the use of IR laser light.<sup>582</sup> This is a thermal reaction. The laser light excites the molecule to a higher vibrational level (Sec. 7.A.i), but not to a higher electronic state.

	Thermal reaction	Photochemical reaction
$4n$	Conrotatory	Disrotatory
$4n + 2$	Disrotatory	Conrotatory

As is the case for [2 + 2] cycloaddition reactions (**15-59**), certain forbidden electrocyclic reactions can be made to take place by the use of metallic catalysts.<sup>583</sup> An example is the silver ion-catalyzed conversion of tricyclo[4.2.0.0<sup>2,5</sup>]octa-3,7-diene to cyclooctatetraene.<sup>584</sup>

This conversion is very slow thermally (i.e., without the catalyst) because the reaction must take place by a disrotatory pathway, which is disallowed thermally.<sup>585</sup>

The ring opening of cyclopropyl cations (Sec. 10.G.i, category 7 and **18-3**) is an electrocyclic reaction and is governed by the orbital symmetry rules.<sup>586</sup> For this case, the rule is invoked that the  $\sigma$  bond opens in such a way that the resulting  $p$  orbitals have the symmetry of the highest occupied orbital of the product, in this case, an allylic cation. Recall that an allylic system has three molecular orbitals (Sec. 2.C, category 3). For the cation, with only two electrons, the highest occupied orbital is the one of the lowest energy (HOMO). Thus, the cyclopropyl cation must undergo a disrotatory ring opening in order to maintain the symmetry.

Note that, in contrast, ring opening of the cyclopropyl *anion* must be conrotatory,<sup>587</sup> since in this case it is the next orbital of the allylic system that is the highest occupied, and this has the opposite symmetry.<sup>588</sup> However, it is difficult to generate a free cyclopropyl cation (Sec. 10.G.i, category 7), and it is likely that in most cases, cleavage of the  $\sigma$  bond is concerted with departure of the leaving group in the original cyclopropyl substrate. This fact, of course, means that the  $\sigma$  bond provides anchimeric assistance to the removal of the leaving group (an  $S_N2$ -type process), and it is expected that such assistance should come from the back side, which has an important effect on the direction of ring opening. The orbital symmetry rules require that the ring opening is disrotatory, but as seen above, there are two disrotatory pathways and the rules do not indicate which is preferred. But the fact that the  $\sigma$  orbital provides assistance from the backside means that the two substituents that are *trans* to the leaving group must move *outward*, not inward.<sup>589</sup>

Thus, the disrotatory pathway that is followed is the one shown in **A**, not the one shown in **A'**, because the former puts the electrons of the  $\sigma$  bond on the side opposite that of the leaving group.<sup>590</sup> Strong confirmation of this picture<sup>591</sup> comes from acetolysis of *endo*- (**57**)

<sup>587</sup> See Boche, G. *Top. Curr. Chem.* **1988**, *146*, 1.

<sup>588</sup> See Coates, R.M.; Last, L.A. *J. Am. Chem. Soc.* **1983**, *105*, 7322. For a review of the analogous ring opening of epoxides, see Huisgen, R. *Angew. Chem. Int. Ed.* **1977**, *16*, 572.

<sup>589</sup> DePuy, C.H.; Schnack, L.G.; Hausser, J.W.; Wiedemann, W. *J. Am. Chem. Soc.* **1965**, *87*, 4006.

<sup>590</sup> It has been suggested that the pathway shown in **C** is possible in certain cases: Hausser, J.W.; Grubber, M.J. *J. Org. Chem.* **1972**, *37*, 2648; Hausser, J.W.; Uchic, J.T. *J. Org. Chem.* **1972**, *37*, 4087.

<sup>591</sup> Also see Reese, C.B.; Shaw, A. *J. Am. Chem. Soc.* **1970**, *92*, 2566; Dolbier Jr., W.R.; Phanstiel, O. *Tetrahedron Lett.* **1988**, *29*, 53, and references in these papers.

and *exo*-bicyclo[3,1,0]hexyl-6-tosylate (**58**). The groups *trans* to the tosylate must move outward. For **57** this means that the two hydrogen atoms can go outside the framework of the six-membered ring, but for **58** they are forced to go inside.

Consequently, it is not surprising that the rate ratio for solvolysis of **57/58** was found to be  $> 2.5 \times 10^6$  and that at  $150^\circ\text{C}$  **58** did not solvolyze at all.<sup>592</sup> This evidence is kinetic. Unlike the cases of the cyclobutene (1,3-diene and cyclohexadiene) 1,3,5-triene interconversions, the direct product here is a cation, which is not stable but reacts with a nucleophile and loses some of its steric integrity in the process, so that much of the evidence has been of the kinetic type rather than from studies of product stereochemistry. However, it has been shown by investigations in superacids (Sec. 5.A.ii), where it is possible to keep the cations intact and to study their structures by NMR, that in all cases studied the cation that is predicted by these rules is in fact formed.<sup>593</sup>

### 18-28 Conversion of One Aromatic Compound to Another

Stilbenes can be converted to phenanthrenes by irradiation with UV light<sup>594</sup> in the presence of an oxidizing agent, such as dissolved molecular oxygen,  $\text{FeCl}_3$ , or iodine.<sup>595</sup> The reaction is a photochemically allowed conrotatory<sup>596</sup> conversion of a 1,3,5-hexatriene to a cyclohexadiene, followed by removal of two hydrogen atoms by the oxidizing agent. The intermediate dihydrophenanthrene has been isolated.<sup>597</sup> The actual reacting species must be the *cis*-stilbene, but *trans*-stilbenes can often be used, because they are isomerized to the *cis* isomers under the reaction conditions. The reaction can be extended to the preparation of many fused aromatic systems, as in the conversion of 1,1':2',1'':2'',1''':-quaterphenyl to dibenzo[*fg,op*]tetracene.<sup>598</sup>

Not all such systems give this reaction.<sup>599</sup> The use of substrates containing heteroatoms (e.g., PhN=NPh) allows the formation of heterocyclic ring systems.

Isomerization of biphenylene to benzo[*a*]pentalene<sup>600</sup> is a well-known benzene ring contraction rearrangement,<sup>601</sup> driven by relief of strain in the four-membered ring. Related to this process is the flash vacuum pyrolysis (FVP) of the alternant polycyclic aromatic hydrocarbon benzo[*b*]biphenylene at 1100 °C, which gives fluoranthene, a nonalternant polycyclic aromatic hydrocarbon, as the major product at 1100 °C in the gas phase.<sup>602</sup> The mechanism used to explain this isomerization involves equilibrating diradicals of 2-phenylnaphthalene, which rearrange by the net migration of a phenyl group to give equilibrating diradicals of 1-phenylnaphthalene, one isomer of which then cyclizes to fluoranthene.

Another transformation of one aromatic compound to another is the *Stone-Wales rearrangement* of pyracyclene (**59**),<sup>603</sup> which is a bond-switching reaction. The rearrangement of bifluorenylidene (**60**) to dibenzo[*g,p*]chrysene (**61**) occurs at temperatures as low as 400 °C and is accelerated in the presence of decomposing iodomethane, a convenient source of methyl radicals.<sup>604</sup>

This result suggested a radical rearrangement. This rearrangement is believed to occur by a radical-promoted mechanism consisting of a sequence of homoallyl–cyclopropylcarbinyll rearrangement steps.<sup>605</sup>

## B. Sigmatropic Rearrangements

A sigmatropic rearrangement is defined<sup>606</sup> as migration, in an uncatalyzed intramolecular process, of a  $\sigma$  bond, adjacent to one or more  $\pi$  systems, to a new position in a molecule, with the  $\pi$  systems becoming reorganized in the process. Examples are shown here.

The *order* of a sigmatropic rearrangement is expressed by two numbers set in brackets:  $[i,j]$ . These numbers can be determined by counting the atoms over which each end of the  $\sigma$  bond has moved. Each of the original termini is given the number 1. Thus in the first example above, each terminus of the  $\sigma$  bond has migrated from C-1 to C-3, so the order is [3,3]. In the second example the carbon terminus has moved from C-1 to C-5, but the hydrogen terminus has not moved at all, so the order is [1,5].

### 18-29 [1,*j*]-Sigmatropic Migrations of Hydrogen

Many examples of thermal or photochemical rearrangements in which a hydrogen atom migrates from one end of a system of  $\pi$  bonds to the other have been reported,<sup>607</sup> although the reaction is subject to geometrical constraints. Isotope effects play a role in sigmatropic rearrangements, and there is evidence for a kinetic silicon isotope effect.<sup>608</sup> Pericyclic mechanisms are involved,<sup>609</sup> and the hydrogen must, in the transition state, be in contact with both ends of the chain at the same time. This means that for [1,5] and longer rearrangements, the molecule must be able to adopt the *s-cis* conformation. Furthermore, there are two geometrical pathways by which any sigmatropic rearrangement can take place, illustrated for the case of a [1,5]-sigmatropic rearrangement,<sup>610</sup> starting with a substrate of the form **62**, where the migration origin is an asymmetric carbon atom and  $U \neq V$ .

<sup>607</sup> Gajewski, J.J. *Hydrocarbon Thermal Isomerizations*, Academic Press, NY, **1981**; Mironov, V.A.; Fedorovich, A.D.; Akhrem, A.A. *Russ. Chem. Rev.* **1981**, *50*, 666; Spangler, C.W. *Chem. Rev.* **1976**, *76*, 187.

<sup>608</sup> Lin, Y.-L.; Turos, E. *J. Am. Chem. Soc.* **1999**, *121*, 856.

<sup>609</sup> Moss, S.; King, B.T.; de Meijere, A.; Kozhushkov, S.I.; Eaton, P.E.; Michl, J. *Org. Lett.* **2001**, *3*, 2375.

<sup>610</sup> Note that a [1,5] sigmatropic rearrangement of hydrogen is also an internal ene synthesis (15-15).

In one of the two pathways, the hydrogen moves along the top or bottom face of the  $\pi$  system. This is called *suprafacial migration*. In the other pathway, the hydrogen moves *across* the  $\pi$  system, from top to bottom, or vice versa. This is *antarafacial migration*. Altogether, a single isomer like **62** (different rotamers) can give four products. In a suprafacial migration, H can move across the top of the  $\pi$  system (as drawn above) to give the (*R,Z*) isomer, or it can rotate  $180^\circ$  and move across the bottom of the  $\pi$  system to give the (*S,E*) isomer.<sup>611</sup> The antarafacial migration can similarly lead to two diastereomers, in this case the (*S,Z*) and (*R,E*) isomers.

In any given sigmatropic rearrangement, only one of the two pathways is allowed by the orbital symmetry rules; the other is forbidden. To analyze this situation, first use a modified frontier orbital approach.<sup>612</sup> Imagine that, in the transition state, the migrating H atom breaks away from the rest of the system, which is treated as if it were a free radical. Note that this is not what actually takes place; it is *imagined* in order to analyze the process. In a [1,3]-sigmatropic rearrangement, the imaginary transition state consists of a hydrogen atom and an allyl radical. The latter species (Sec. 2.C, category 3) has three  $\pi$  orbitals, but the only one that is of concern, the HOMO, which, in a thermal rearrangement is **B**. The electron of the hydrogen atom is of course in a  $1s$  orbital, which has only one lobe. The rule governing sigmatropic migration of hydrogen is *the H must move from a plus to a plus or from a minus to a minus lobe, of the HOMO; it cannot move to a lobe of opposite sign*.<sup>613</sup> The only way this can happen in a thermal [1,3]-sigmatropic rearrangement is by an antarafacial migration. Consequently, the rule predicts that antarafacial thermal [1,3]-sigmatropic rearrangements are allowed, but the suprafacial pathway is forbidden. However, in a photochemical reaction, promotion of an electron means that **C** is now the HOMO; the suprafacial pathway is now allowed and the antarafacial pathway forbidden.

A similar analysis of [1,5]-sigmatropic rearrangements shows that in this case the thermal reaction must be suprafacial and the photochemical process antarafacial. For the general case, with odd-numbered  $j$ , [1, $j$ ]-suprafacial migrations are allowed thermally when  $j$  is of the form  $4n + 1$ , and photochemically when  $j$  has the form  $4n - 1$ ; the opposite is true for antarafacial migrations.

As expected, the Möbius-Hückel method leads to the same predictions. Here, examine the basis set of orbitals shown in **D** and **E** for [1,3]- and [1,5]-rearrangements, respectively. A [1,3]-shift involves four electrons, so an allowed thermal pericyclic reaction must be a

<sup>611</sup> The designations U, V, Y, and Z are arbitrary, so which isomer is (*R,Z*) and which is (*S,E*) is arbitrary.

<sup>612</sup> See Woodward, R.B.; Hoffmann, R. *The Conservation of Orbital Symmetry*, Academic Press, NY, 1970, pp. 114–140.

<sup>613</sup> This statement follows from the principle that bonds are formed only by overlap of orbitals of the same sign. Since this is a concerted reaction, the hydrogen orbital in the transition state must overlap simultaneously with one lobe from the migration origin and one from the terminus. It is obvious that both of these lobes must have the same sign.

Möbius system (**15-56**, the Möbius-Hückel Method) with one or an odd number of sign inversions. As can be seen in **D**, only an antarafacial migration can achieve this. A [1,5]-shift, with six electrons, is allowed thermally only when it is a Hückel system with zero or an even number of sign inversions; hence it requires a suprafacial migration.<sup>614</sup>

The actual reported results bear out this analysis. Thus a thermal [1,3]-migration is allowed to take place only antarafacially, but such a transition state would be extremely strained, and thermal [1,3]-sigmatropic migrations of hydrogen are unknown.<sup>615</sup> On the other hand, the photochemical pathway allows suprafacial [1,3]-shifts, and a few such reactions are known, an example being the photochemical rearrangement of **63** to **64**.<sup>616</sup>

Substituents influence the efficacy of the [1,3]-hydrogen shift.<sup>617</sup> Hot water was used as a mildly acidic catalyst that promoted 1,*n*-rearrangement ( $n = 3, 5, 7, 9$ ) of allylic alcohols to give a new allylic alcohol.<sup>618</sup> An Ir-catalyzed [1,3]-hydrogen shift involving allylic alcohols was reported.<sup>619</sup> The heterocyclization of sulfur and 1,3-migration of silicon has been reported.<sup>620</sup>

The situation is reversed for [1,5]-hydrogen shifts. In this case the thermal rearrangements, being suprafacial, are quite common, while photochemical rearrangements are rare.<sup>621</sup> Two examples of the thermal reaction are shown:

<sup>623</sup> See Klärner, F. *Top. Stereochem.* **1984**, *15*, 1; Hess Jr., B.A.; Baldwin, J.E. *J. Org. Chem.* **2002**, *67*, 6025.

Note that the first example bears out the stereochemical prediction made earlier. Only the two isomers shown were formed. In the second example, migration can continue around the ring, which is common for substituted cyclopentadiene derivatives. Migrations of this kind are called *circumambulatory rearrangements*,<sup>624</sup> and such migrations are known for cyclopentadiene,<sup>625</sup> pyrrole, and phosphole derivatives.<sup>626</sup> Geminal bond participation has been observed in pentadienes,<sup>627</sup> the effects of phenyl substituents have been studied,<sup>628</sup> and the kinetics and activation parameters of [1,5]-hydrogen shifts have been examined.<sup>629</sup> The [1,5]-hydrogen shifts are also known with vinyl aziridines.<sup>630</sup> A Ru-catalyzed cycloisomerization of en-1-yne leads to cyclic dienes.<sup>631</sup> Highly substituted naphthylamine derivatives were prepared via a Pd-catalyzed [1,5]-sigmatropic hydrogen shift and cyclization reaction of propargyl esters.<sup>632</sup> The Pt-catalyzed cycloisomerization involved the 1,5-acyl migration of benzoendiyne esters.<sup>633</sup> The competition between  $6\pi$  electrocyclization and [1,5]-H sigmatropic shifts in tetrahydro-1*H*-cyclobuta[*e*]indene derivatives has been studied.<sup>634</sup> The Co-catalyzed synthesis of tetrahydroquinolines involved 1,5-hydride transfer/cyclization.<sup>635</sup> The [1,5]-shift of aldehyde hydrogen in dienal compounds gave ketenes.<sup>636</sup> An azo-hydrazo conversion involved [1,5]-hydrogen shifts.<sup>637</sup>

The rare [1,4]-hydrogen transfer has been observed in radical cyclizations.<sup>638</sup> With respect to [1,7]-hydrogen shifts, the rules predict the thermal reaction to be antarafacial.<sup>639</sup> Unlike the case of [1,3]-shifts, the transition state is not too greatly strained.<sup>640</sup> Photochemical [1,7]-shifts are suprafacial and, not surprisingly, many of these have been observed.<sup>641</sup> The orbital symmetry rules also help to explain the unexpected stability of certain compounds (see **15-59**, the text immediately preceding **15-60**, and **18-27**, the Möbius-Hückel Method).

Analogs of sigmatropic rearrangements in which a cyclopropane ring replaces one of the double bonds are also known, as in the reaction shown.<sup>642</sup>

The reverse reaction has also been reported.<sup>643</sup> 2-Vinylcycloalkanoles<sup>644</sup> undergo an analogous reaction, as do cyclopropyl ketones (see **18-33**, the text immediately preceding **18-34**, for this reaction).

### 18-30 [1,*j*]-Sigmatropic Migrations of Carbon

Ref. 645

Ref. 646

Sigmatropic migrations of alkyl or aryl groups<sup>647</sup> are less common than the corresponding hydrogen migrations.<sup>648</sup> When they do take place, there is an important difference. Unlike a hydrogen atom, whose electron is in a *s* orbital with only one lobe, a carbon free radical has its odd electron in a *p* orbital that has *two lobes of opposite sign*. Therefore, if the imaginary transition states for this case are drawn, a thermal suprafacial [1,5]-process (Figure 18.5) is observed, and symmetry can be conserved only if the migrating carbon moves in such a way that the lobe which was originally attached to the  $\pi$  system remains attached to the  $\pi$  system.

This can happen only if configuration is *retained within the migrating group*. On the other hand, thermal suprafacial [1,3]-migration (Figure 18.6) *can* take place if the migrating carbon switches lobes. If the migrating carbon was originally bonded by its minus lobe, it

**FIGURE 18.5.** Hypothetical orbital movement for a thermal [1,5]-sigmatropic migration of carbon. To move from one negative lobe, the migrating carbon uses only its own negative lobe, retaining its configuration.

**FIGURE 18.6.** Hypothetical orbital movement for a thermal [1,3]-sigmatropic migration of carbon. The migrating carbon moves a negative to a positive lobe, requiring it to switch its own bonding lobe from negative to positive, inverting its configuration.

must now use its plus lobe to form the new C–C bond. Thus, configuration in the migrating group will be *inverted*.

From these considerations, suprafacial [1,*j*]-sigmatropic rearrangements in which carbon is the migrating group should always be allowed, both thermally and photochemically, but thermal [1,3]-migrations<sup>649</sup> will proceed with inversion, and thermal [1,5]-migrations will proceed with retention of configuration within the migrating group. More generally, suprafacial [1,*j*]-migrations of carbon in systems where  $j = 4n - 1$  proceed with inversion thermally and retention photochemically, while systems where  $j = 4n + 1$  show the opposite behavior. Where antarafacial migrations take place, all these predictions are of course reversed. A Au-catalyzed [1,3]-O → C rearrangement of allenyl ethers was reported.<sup>650</sup>

The first laboratory test of these predictions was the pyrolysis of deuterated *endo*-bicyclo[3.2.0]hept-2-en-6-yl acetate, which gave the *exo*-deuterio-*exo*-norbornyl acetate.<sup>651</sup> Thus, as predicted by the orbital symmetry rules, this thermal suprafacial [1,3]-sigmatropic reaction took place with complete inversion at C-7. Similar results have been obtained in a number of other cases.<sup>652</sup> Other cases of lack of complete inversion are also known.<sup>653</sup>

<sup>653</sup> See Pikulin, S.; Berson, J.A. *J. Am. Chem. Soc.* **1988**, *110*, 8500.

A diradical mechanism has been invoked to explain such cases.<sup>653,654</sup> There is strong evidence for a radical mechanism for some [1,3]-sigmatropic rearrangements.<sup>655</sup> Photochemical suprafacial [1,3]-migrations of carbon have been shown to proceed with retention, as predicted.<sup>656</sup> Although allylic vinylic ethers generally undergo [3,3]-sigmatropic rearrangements (**18-33**), they can be made to give the [1,3] kind, to give aldehydes. An example is the reaction of 1-(vinyloxy)-2,3,4,5,6,7-hexahydro-1*H*-indene with LiClO<sub>4</sub> in diethyl ether to give 2-(2,3,4,5,6,7-hexahydro-1*H*-inden-1-yl)acetaldehyde.<sup>657</sup> In this case, the C—O bond undergoes a 1,3-migration from the O to the end vinylic carbon. When the vinylic ether is of the type ROCR'=CH<sub>2</sub>, ketones RCH<sub>2</sub>COR' are formed. There is evidence that this [1,3]-sigmatropic rearrangement is not concerted, but involves dissociation of the substrate into ions.<sup>657</sup> Thermal suprafacial [1,5]-migrations of carbon have been found to take place with retention,<sup>658</sup> but also with inversion.<sup>659</sup> A diradical mechanism has been suggested for the latter case.<sup>659</sup> The effect of ring size and the nature of the migratory groups on [1,*n*]-suprafacial shifts were examined vis-à-vis aromatic and antiaromatic transition states via ring current analysis.

Simple nucleophilic, electrophilic, and free-radical 1,2-shifts can also be regarded as sigmatropic rearrangements (in this case, [1,2]-rearrangements). As previously discussed (see discussion preceding Sec. 18.A) similar principles applied to such rearrangements show that nucleophilic 1,2-shifts are allowed, but the other two types are forbidden unless the migrating group has some means of delocalizing the extra electron or electron pair. The mechanism of the forbidden [3*s*,5*s*]-sigmatropic shift has been examined.<sup>660</sup>

Substituted pyrroles were prepared via [3,3]- or [1,3]-rearrangements of *O*-vinyl oximes.<sup>661</sup>

### 18-31 Vinylcyclopropane Rearrangements

The thermal expansion of a vinylcyclopropane to a cyclopentene ring<sup>662</sup> is a special case of a [1,3]-sigmatropic migration of carbon, although it can also be considered an internal [ <sub>$\pi$</sub> 2 +  <sub>$\sigma$</sub> 2]-cycloaddition reaction (see **15-59**). It is known as a *vinylcyclopropane*

*rearrangement.*<sup>663</sup> The reaction has been carried out on many vinylcyclopropanes bearing various substituents in the ring<sup>664</sup> or on the vinyl group and has been extended to 1,1-dicyclopolyethylene<sup>665</sup> and (both thermally<sup>666</sup> and photochemically<sup>667</sup>) to vinylcyclopropenes.

This rearrangement can be catalyzed by Rh and Ag compounds, and has been used to form rings.<sup>668</sup> Two competing reactions are the homodienyl [1,5]-shift (if a suitable H is available, see **18-29**), and simple cleavage of the cyclopropane ring, leading in this case to a diene (see **18-3**).

Flash vacuum pyrolysis of the trimethylsilyl ether of cyclopropylcarbinyl alcohols gives ring-expanded ketones.<sup>669</sup> Various heterocyclic analogs<sup>670</sup> are also known, as in the rearrangement of aziridinyl amides [such as aziridin-1-yl(phenyl)methanone], which gave 2-phenyl-4,5-dihydrooxazole when heated.<sup>671</sup> Cyclopropyl ketones can be treated with tosylamine and a Zr catalyst, which converts the imine formed *in situ* to a pyrroline.<sup>672</sup> *N*-Cyclopropylimines undergo rearrangement to cyclic imines (pyrrolines) under photochemical conditions.<sup>673</sup> Vinylcyclobutanes can be converted to cyclohexenes,<sup>674</sup> but larger ring compounds do not generally give the reaction.<sup>675</sup>

The CuCN-mediated rearrangement reaction of allenylcyclopropanols gave 5-alkyl or 4-alkyl cyclopentenone regioisomers, depending reaction conditions.<sup>676</sup> Alkynylcyclopropanol derivatives were rearranged to cyclopentenones using a Ru catalyst.<sup>677</sup> The ring expansion of alkenyl cyclobutanols by reaction with ethynylbenziodoxolones gave  $\beta$ -alkynylated cyclopentanones.<sup>678</sup> The visible light-mediated, Ru-catalyzed photocatalytic reaction of alkenylcyclobutanols with aryldiazonium salts gave cyclopentanones.<sup>679</sup> The

Cu-catalyzed ring expansion of vinyl oxetanes gave 3,6-dihydro-2*H*-pyrans.<sup>680</sup> A ring expansion–oxidative arylation reaction via visible light photocatalysis and Au-catalyzed<sup>681</sup> coupling of alkenyl and allenyl cycloalkanols with aryl diazonium salts gave cyclobutanone derivatives.<sup>682</sup>

The reaction rate has also been greatly increased by the addition of a one-electron oxidant tris-(4-bromophenyl)aminium hexafluoroantimonate  $\text{Ar}_3\text{N}^+\text{SbF}_6^-$  (Ar = *p*-bromophenyl).<sup>683</sup> This reagent converts the substrate to a cation radical, which undergoes ring expansion much faster.<sup>684</sup> The mechanisms of these ring expansions are not certain. Both concerted<sup>685</sup> and diradical<sup>686</sup> pathways have been proposed,<sup>687</sup> and it is possible that both pathways operate, in different systems. Density functional theory computations were reported for the Cu-catalyzed ring expansion of vinyloxiranes to 2,5-dihydrothiophene derivatives via a Cu catalyst mechanism.<sup>688</sup>

The Cu-catalyzed reaction of chiral vinyl aziridines gave the chiral 2,5-*cis*- or 2,5-*trans*-3-pyrroline.<sup>689</sup> Vinylidenecyclopropanes gave the corresponding alkylidenecyclobutanone derivatives in the presence of an Au/Ag catalyst system and a substituted pyridine *N*-oxide.<sup>690</sup>

### 18-32 The Cope Rearrangement<sup>691</sup>

When 1,5-dienes are heated, a [3,3]-sigmatropic rearrangement, known as the *Cope rearrangement* (not to be confused with the *Cope elimination* reaction, **17-7**), occurs to generate an isomeric 1,5-diene.<sup>692</sup> When the diene is symmetrical about the 3,4-bond, the reaction gives a product identical with the starting material.<sup>693</sup> Therefore, a Cope rearrangement can be detected only when the diene is not symmetrical about this bond. The 1,5-diene 3-methylhexa-1,5-diene was heated to 300 °C and gave hepta-1,5-diene.<sup>694</sup> The

<sup>694</sup> Levy, H.; Cope, A.C. *J. Am. Chem. Soc.* **1944**, *66*, 1684.

reaction takes place more easily (lower temperature required) when there is a group on the 3- or 4-carbon (of the original diene) that leads to the new double bonds being more substituted. An organocatalytic Cope rearrangement has been reported.<sup>695</sup> A theoretical investigation of the thermal rearrangements of hex-1-en-5-yne, hexa-1,2,5-triene, and 2-methylenebicyclo[2.1.0]pentane used density functional theory (DFT) and high level *ab initio* methods.<sup>696</sup> Some concerted Cope rearrangements can be promoted by noncovalent association of their transition state structures with ammonium cations, according to a theoretical investigation of concerted and stepwise Cope rearrangements of natural products.<sup>697</sup>

The reaction is reversible<sup>698</sup> and produces an equilibrium mixture of the two 1,5-dienes that is *richer in the thermodynamically more stable isomer*. However, the equilibrium is shifted to the right for 3-hydroxy-1,5-dienes,<sup>699</sup> because the enol product tautomerizes to the ketone or aldehyde. The rearrangement of 3-hydroxy-1,5-dienes is called the *oxy-Cope rearrangement*,<sup>700</sup> and has proved highly useful in synthesis.<sup>701</sup>

An oxy-Cope rearrangement using microflow conditions (Sec. 7.D) gave cycloheptane derivatives.<sup>702</sup> The oxy-Cope rearrangement is greatly accelerated (by factors of  $10^{10}$ – $10^{17}$ ) if the alkoxide is used rather than the alcohol (the *anionic oxy-Cope rearrangement*),<sup>703</sup> where the direct product is the enolate ion, which is hydrolyzed to the ketone.

A metal-free reaction using a phosphazene base has been reported.<sup>704</sup>

*aza-Cope rearrangements* are also known,<sup>705</sup> and there is an enantioselective aza-Cope rearrangement.<sup>706</sup> In *amino-Cope rearrangements*, the solvent plays a role in the regioselectivity of the reaction.<sup>707</sup> It has been suggested that this latter reaction does not proceed

<sup>707</sup> Dobson, H.K.; LeBlanc, R.; Perrier, H.; Stephenson, C.; Welch, T.R.; Macdonald, D. *Tetrahedron Lett.* **1999**, *40*, 3119.

solely by a concerted [3,3]-sigmatropic rearrangement.<sup>708</sup> An asymmetric 2-aza-Cope rearrangement was used for the dynamic kinetic resolution of  $\alpha$ -stereogenic- $\beta$ -formyl amides using a chiral phosphoric acid catalyst to give  $\beta$ -imino amides.<sup>709</sup> There is also a 1,2-oxaza-Cope rearrangement that involves esters and alkyl nitrites.<sup>710</sup>

The 1,5-diene system may be inside a ring or part of an allenic system.<sup>711</sup> When the two double bonds are in vinylic groups attached to adjacent ring positions, the product is a ring four carbons larger. This fact has been applied to Cope rearrangement of divinylcyclopropanes and divinylcyclobutanes, as shown.<sup>712</sup>

Indeed, *cis*-1,2-divinylcyclopropanes rearrange so rapidly that they generally cannot be isolated at room temperature,<sup>713</sup> but exceptions are known.<sup>714</sup> It is noted that divinylloxiranes, divinylphosphiranes, and divinylthiiranes undergo similar rearrangements.<sup>715</sup> When heated, 1,5-dienes are converted to 3,4-dimethylenecyclobutenes.<sup>716</sup> A rate-determining Cope rearrangement is followed by a very rapid electrocyclic (**18-27**) reaction. Note that the reaction does not take place when one of the double bonds is part of an aromatic system (e.g., 4-phenylbut-1-ene).<sup>717</sup>

The interconversion of 1,3,5-trienes and cyclohexadienes (in **18-27**) is very similar to the Cope rearrangement, but in **18-27**, the 3,4-bond goes from a double bond to a single bond rather than from a single bond to no bond. Like [2 + 2] cycloadditions (**15-59**), Cope rearrangements of simple 1,5-dienes can be catalyzed by certain transition metal compounds. For example, the addition of a Pd catalyst causes the reaction to take place at room temperature.<sup>718</sup>

As indicated with the electron transfer arrows, the mechanism of the uncatalyzed Cope rearrangement is a simple six-centered pericyclic process.<sup>719</sup> Since the mechanism is so simple, it has been possible to study some rather subtle points, among them the question of whether the six-membered transition state is in the boat or the chair form.<sup>720</sup> For the case

of 3,4-dimethylhexa-1,5-diene, it was demonstrated conclusively that the transition state is in the chair form. This fact was shown by the stereospecific nature of the reaction: The *meso* isomer gave the *cis,trans* product, while the ( $\pm$ ) diastereomer gave the *trans,trans* diene.<sup>721</sup>

If the transition state is in the chair form (taking the *meso* isomer, for example), one methyl must be “axial” and the other “equatorial” and the product must be the *cis,trans* alkene. There are two possible boat forms for the transition state of the *meso* isomer. One leads to a *trans,trans* product; the other to a *cis,cis* alkene. For the ( $\pm$ ) pair the predictions are just the opposite. There is just one boat form, and it leads to the *cis,trans* alkene, while one chair form (“diaxial” methyls) leads to the *cis,cis* product and the other (“diequatorial” methyls) predicts the *trans,trans* product. Thus the nature of the products obtained demonstrates that the transition state is a chair and not a boat.<sup>722</sup> While 3,4-dimethylhexa-1,5-diene is free to assume either the chair or boat (it prefers the chair), other compounds are not so free. Thus 1,2-divinylcyclopropane (see above) can react *only* in the boat form, demonstrating that such reactions are possible.<sup>723</sup>

Because of the nature of the transition state<sup>724</sup> in the pericyclic mechanism, optically active substrates with a stereogenic carbon at C-3 or C-4 transfer the chirality to the product. (For an example in the mechanistically similar *Claisen rearrangement*, see **18-33**.)<sup>725</sup> There are many examples of asymmetric [3,3]-sigmatropic rearrangements.<sup>726</sup>

Not all Cope rearrangements proceed by the cyclic six-centered mechanism.<sup>727</sup> Thus *cis*-1,2-divinylcyclobutane rearranges smoothly to cycloocta-1,5-diene, since the geometry is favorable. The *trans* isomer also gives this product, but the main product is 4-vinylcyclohexene (resulting from **18-31**). This reaction can be rationalized as proceeding by a diradical mechanism,<sup>728</sup> although it is possible that at least part of the cyclooctadiene produced comes from a prior epimerization of the *trans*- to the *cis*-divinylcyclobutane followed by Cope rearrangement of the latter.<sup>729</sup>

It has been suggested that another type of diradical two-step mechanism may be preferred by some substrates.<sup>730</sup> Indeed, a nonconcerted Cope rearrangement has been reported.<sup>731</sup> In this pathway,<sup>732</sup> the 1,6-bond is formed before the 3,4-bond breaks:

This rearrangement is related to the *Bergman cyclization* that was introduced in **18-27**.

It was pointed out earlier that a Cope rearrangement is degenerate for the symmetrical hexa-1,5-diene that gives back hexa-1,5-diene (Sec. 18.A.ii). Bicyclo[5.1.0]octadiene (**65**) undergoes a similar rearrangement.<sup>733</sup> At room temperature, the NMR spectrum of **65** is in accord with the two structures shown.

At 180 °C, it is converted by a Cope reaction to a compound equivalent to itself. The interesting thing is that at 180 °C the NMR spectrum shows that what exists is an equilibrium mixture of the two structures. That is, at this temperature the molecule rapidly (faster than  $10^3$  times per second) changes back and forth between the two structures. This is called *valence tautomerism* and is quite distinct from resonance, even though only electrons shift<sup>734</sup> (Sec. 2.N for other types of tautomerism). The positions of the nuclei are not the same in the two structures.

The molecule could also have undergone rearrangements to put this ring at 1,2,8 or 1,2,7.

Any of these could then undergo several Cope rearrangements. In all, there are  $\frac{10!}{3}$  or more than 1.2 million tautomeric forms, and the cyclopropane ring can be at any three carbons that are adjacent. Since each of these tautomers is equivalent to all the others, this has been called an *infinitely degenerate Cope rearrangement*. Bullvalene (**66**) has been synthesized and its <sup>1</sup>H NMR spectrum determined.<sup>735,736</sup> At -25 °C, there are two peaks

with an area ratio of 6:4, in accord with a single nontautomeric structure. The six protons are the vinylic protons and the four protons are the allylic ones. But at 100 °C the compound shows only one NMR peak, indicating that the compound rapidly interchanges its structure among 1.2 million equivalent forms.<sup>737</sup> The <sup>13</sup>C NMR spectrum of bullvalene also shows only one peak at 100 °C.<sup>738</sup>

Another compound for which degenerate Cope rearrangements result in equivalence for all the carbons is *hypostrophene* (**67**).<sup>739</sup>

In the case of the compound *barbaralane* (**68**)<sup>740</sup> (bullvalene in which one CH=CH has been replaced by a CH<sub>2</sub>): there are only two equivalent tautomers.<sup>741</sup>

However, NMR spectra indicate that even at room temperature a rapid interchange of both tautomers is present, although by about –100 °C this has slowed to the point where the spectrum is in accord with a single structure.

In the case of *semibullvalene* (**69**) (barbaralane in which the CH<sub>2</sub> has been removed), not only is there a rapid interchange at room temperature, but even at –110 °C.<sup>742</sup>

Compound **69** has the lowest energy barrier of any known compound capable of undergoing the Cope rearrangement.<sup>743</sup> The role of strain in the homoaromatization of

semibullvalene has been discussed.<sup>744</sup> The molecules taking part in a valence tautomerization need not be equivalent. The interconversion benzene oxide<sup>745</sup> and oxepin, for example, exist in a tautomeric equilibrium at room temperature.<sup>746</sup>

Bullvalene and hypostrophene are members of a group of compounds all of whose formulas can be expressed by the symbol  $(\text{CH})_{10}$ .<sup>747</sup> Many other members of this group are known. Similar groups of  $(\text{CH})_n$  compounds exist for other even-numbered values of “ $n$ ”.<sup>747</sup> For example, there are 20 possible  $(\text{CH})_8$ <sup>748</sup> compounds,<sup>749</sup> and five possible  $(\text{CH})_6$  compounds,<sup>750</sup> all of which are known: benzene, prismane (Sec. 4.Q.i), Dewar benzene (see 18-27, the Möbius-Hückel Method), bicyclopropenyl,<sup>751</sup> and benzvalene.<sup>752</sup>

An interesting example of valence tautomerism is the case of 1,2,3-tri-*tert*-butylcyclobutadiene (Sec. 2.K.ii). There are two isomers, both rectangular, and <sup>13</sup>C NMR spectra show that they exist in a dynamic equilibrium, even at  $-185\text{ }^\circ\text{C}$ .<sup>753</sup>

### 18-33 The Claisen Rearrangement<sup>754</sup>

Allylic aryl ethers, when heated, rearrange to *o*-allylphenols in a reaction called the *Claisen rearrangement*.<sup>755</sup> If both *ortho* positions are filled, the allylic group migrates to the *para*

position (this has been called the *para*-Claisen rearrangement).<sup>756</sup> There is no reaction when the *para* and both *ortho* positions are filled. Migration to the *meta* position has not been observed. In the *ortho* migration, the allylic group always undergoes an allylic shift. As shown, a substituent  $\alpha$  to the oxygen is now  $\gamma$  to the ring (and vice versa). On the other hand, in the *para* migration there is never an allylic shift: e.g., the allylic group is found exactly as it was in the original ether. Compounds with propargylic groups (i.e., groups with a triple bond in the appropriate position) do not generally give the corresponding products. The Claisen rearrangement of benzyl vinyl ethers was reported.<sup>757</sup> The impact of Novel Process Windows (Sec. 7.D) on the Claisen rearrangement has been discussed.<sup>758</sup>

The mechanism is a concerted pericyclic [3,3]-sigmatropic rearrangement<sup>759</sup> and accounts for all these facts. For the *ortho* rearrangement there is a fast tautomerization of the initially formed cyclohexa-2,4-dien-1-one to the phenol. Evidence is the lack of a catalyst, the fact that the reaction is first order in the ether, the absence of crossover products when mixtures are heated, and the presence of the allylic shift, which is required by this mechanism. The allylic shift for the *ortho* rearrangement (and the absence of one for the *para*) has been demonstrated by <sup>14</sup>C labeling, even when no substituents are present. Studies of the transition-state geometry have shown that, like the *Cope rearrangement*, the Claisen rearrangement usually prefers a chair-like transition state.<sup>760</sup> A *retro*-Claisen rearrangement is known and its mechanism has been examined.<sup>761</sup>

When the *ortho* positions have no hydrogen, a second [3,3]-sigmatropic migration (a Cope reaction) follows to give the *para*-substituted product. Intermediates in such reactions have been trapped by means of a *Diels-Alder reaction* (**15-56**).<sup>762</sup> The rearrangement of aryl allyl ethers is facilitated by Ag/KI in hot acetic acid,<sup>763</sup> and by AlMe<sub>3</sub> in water.<sup>764</sup> A solid phase reaction of polymer-bound substrate undergoes the Claisen rearrangement with microwave irradiation.<sup>765</sup>

Allylic ethers of enols (allylic vinylic ethers, **70**) also undergo the Claisen rearrangement;<sup>766</sup> in fact, it was discovered with these compounds first.<sup>767</sup> In these cases, the final tautomerization does not take place even when R' = H, since *there is no aromaticity to restore, and ketones are more stable than enols*.<sup>768</sup>

Catalytic Claisen rearrangements of allyl vinyl ethers are well known.<sup>769</sup> The use of water as solvent accelerates the reaction.<sup>770</sup> Microwave-induced reactions on silica gel<sup>771</sup> and in ionic liquids<sup>772</sup> are known. The mechanism is similar to that with allylic aryl ethers.<sup>773</sup> In the presence of a chiral Cu complex, Claisen rearrangements proceed with good enantioselectivity.<sup>774</sup> *N*-Heterocyclic carbenes catalyzed an enantioselective Claisen rearrangement.<sup>775</sup> Using a Cu complex catalyst, a Claisen rearrangement of allyl vinyl ethers was reported.<sup>776</sup> A Rh-catalyzed rearrangement of propargyl vinyl ethers has been reported.<sup>777</sup> A Au-catalyzed Claisen rearrangement of allenyl vinyl ethers has been reported.<sup>778</sup> A chiral hydrogen bond donor has been used for enantioselective Claisen rearrangements.<sup>779</sup> A chiral allylic ether gave an enantioselective Claisen rearrangement with an Ir catalyst.<sup>780</sup>

Since the Claisen rearrangement mechanism does not involve ions, it should not be greatly dependent on the presence or absence of substituent groups on the ring,<sup>781</sup> and this is the case. Electron-donating groups increase the rate and electron-withdrawing groups decrease it, but the effect is small, with the *p*-amino compound reacting only ~10–20 times faster than the *p*-nitro compound.<sup>782</sup> However, solvent effects<sup>783</sup> are greater, and rates varied over a 300-fold range when the reaction was run in 17 different solvents.<sup>784</sup> An especially good solvent is trifluoroacetic acid, in which the reaction can be carried out at room temperature.<sup>785</sup> Most Claisen rearrangements are performed without a catalyst, but AlCl<sub>3</sub> or BF<sub>3</sub> are sometimes used.<sup>786</sup>

Allyl allene ethers undergo a Claisen rearrangement when heated in DMF to give the expected diene with a conjugated aldehyde unit.<sup>787</sup> Butenolides with a β-allylic ether unit undergo a *Claisen rearrangement-Conia reaction*<sup>788</sup> cascade to give an oxaspiroheptane

with  $\beta$ -keto lactone comprising the five-membered ring.<sup>789</sup> Allylic esters of  $\beta$ -keto acids undergo a Claisen rearrangement in what is known as the *Carroll rearrangement*<sup>790</sup> (also called the *Kimel-Cope rearrangement*<sup>791</sup>), and the reaction can be catalyzed by a Ru complex.<sup>792</sup> An asymmetric Carroll rearrangement was catalyzed by a chiral Pd complex.<sup>793</sup> The ketene-Claisen rearrangement has been reviewed.<sup>794</sup>

Heating an allylic alcohol with *N,N*-dimethylacetamide dimethyl acetal gave a transient intermediate, and subsequent Claisen rearrangement gave an amide in a sequence that is known as the *Eschenmoser variant* or the *Eschenmoser-Claisen rearrangement*.<sup>795</sup> This reaction has also been called the *Meerwein-Eschenmoser Claisen rearrangement*.<sup>796</sup> An enantioselective version has been reported using a chiral Pd complex.<sup>797</sup>

Allylic esters can be converted to their enolate anions (**71**) by treatment of the esters with LICA, and a Claisen rearrangement then leads to a  $\gamma,\delta$ -unsaturated acid.<sup>798</sup>

Alternatively, the silylketene acetal  $R^3R^2C=C(OSiR_3)OCH_2CH=CHR^1$  may be used instead of **71**.<sup>799</sup> This rearrangement also proceeds at room temperature. By either procedure, the reaction is called the *Ireland-Claisen rearrangement*.<sup>800</sup> Note the presence of the negative charge in **71**. As with the oxy-Cope rearrangement (in **18-34**), negative charges generally accelerate the Claisen reaction,<sup>801</sup> although the extent of the acceleration can depend on the identity of the positive counterion.<sup>802</sup> The reaction proceeds with good *syn* selectivity in many cases.<sup>803</sup> The Ireland-Claisen rearrangement has been made enantioselective by converting **71** to an enol borinate in which the boron is attached to a chiral group.<sup>804</sup> The Ireland-Claisen rearrangement can be done with amide derivatives also.<sup>805</sup> A spontaneous [3,3]-sigmatropic rearrangement for the enolate of

2-vinyl-6-acyldihydropyran gave a cyclooctadienone via an anionic oxy-Claisen rearrangement.<sup>806</sup>

As just mentioned, asymmetric Claisen rearrangement reactions are well known.<sup>807</sup> Chiral Lewis acids have been designed for this purpose.<sup>808</sup> In general, asymmetric [3,3]-sigmatropic rearrangements are well known.<sup>809</sup>

A number of analogs of the Claisen rearrangement are known, for example rearrangement of  $\text{ArNHCH}_2\text{CH}=\text{CH}_2$ <sup>810</sup> and of  $\text{RCH}=\text{NRCHRCH}_2\text{CH}=\text{CH}_2$ . These rearrangements of nitrogen-containing compounds can be called *aza-Claisen rearrangements*<sup>811</sup> but are sometimes called *aza-Cope rearrangements*.<sup>812</sup> There is a catalytic enantioselective aza-Cope rearrangement.<sup>813</sup> A Pd-catalyzed aza-Claisen has been reported.<sup>814</sup> The use of excess base was shown to promote an asymmetric aza-Claisen rearrangement.<sup>815</sup> An important contribution to this variation is the rearrangement of trichloroacetimidate derivatives of prochiral (*Z*)-2-alken-1-ols, usually with a Pd catalyst, to give chiral allylic esters.<sup>816</sup> The Claisen rearrangement of allylic alcohols that leads to allylic trichloroacetamides via an intermediate imidate is known as the *Overman rearrangement*.<sup>817</sup> A so-called amine-Claisen rearrangement was reported for *N*-allyl indoles, when heated in the presence of  $\text{BF}_3 \cdot \text{OEt}_2$ .<sup>818</sup> In a related reaction, allylic phosphorimidates undergo [3,3]-sigmatropic rearrangement.<sup>819</sup>

The conversion of allylic aryl thioethers,  $\text{ArSCH}_2\text{CH}=\text{CH}_2$ , to *o*-allylic thiophenols is not feasible, because the latter are not stable<sup>820</sup> but react to give bicyclic compounds.<sup>821</sup> However, many allylic vinylic sulfides do give the rearrangement (the *thio-Claisen rearrangement*).<sup>822</sup> Allylic vinylic sulfones such as  $\text{H}_2\text{C}=\text{CRCH}_2-\text{SO}_2-\text{CH}=\text{CH}_2$  rearrange, when heated in the presence of ethanol and pyridine, to unsaturated sulfonate salts  $\text{CH}_2=\text{CRCH}_2\text{CH}_2\text{CH}_2\text{SO}_3^-$ , produced by reaction of the reagents with the unstable sulfene intermediates  $\text{CH}_2=\text{CRCH}_2\text{CH}_2\text{CH}=\text{SO}_2$ .<sup>823</sup> Allylic vinylic sulfoxides rapidly rearrange

at room temperature or below.<sup>824</sup> Chiral vinyl sulfoxides undergo Claisen rearrangement with good enantioselectivity.<sup>825</sup>

Medium-ring cyclic amines were prepared by conjugate addition/[3,3]-sigmatropic shifts.<sup>826</sup> Butenolides were prepared from allylic cyclopropenecarboxylates via ring expansion [3,3]-sigmatropic rearrangement.<sup>827</sup> (*E*)-1*H*-Inden-1-one derivatives were prepared by Au-catalyzed [3,3]-propargyl ester rearrangement.<sup>828</sup>

Ethers with an alkyl group in the  $\gamma$  position (ArO—C—C=C—R systems) sometimes give abnormal products, with the  $\beta$  carbon becoming attached to the ring.<sup>829</sup> It has been established that these abnormal products do not arise directly from the starting ether but are formed by a further rearrangement of the normal product via a cyclopropyl intermediate.<sup>830</sup> This rearrangement, which has been called an *enolene rearrangement*, a *homodienyl [1,5]-sigmatropic hydrogen shift* (see **18-29**), and a [1,5]-*homosigmatropic rearrangement*, involves a shift of three electron pairs over seven atoms. It has been found that this “abnormal” Claisen rearrangement is general.

### 18-34 The Fischer Indole Synthesis

When arylhydrazones of aldehydes or ketones are treated with a catalyst, elimination of ammonia takes place and an indole is formed; this is the *Fischer indole synthesis*.<sup>831</sup> Zinc chloride is a commonly used catalyst, but dozens of others, including other metal halides, proton and Lewis acids, and certain transition metals, have also been used. Microwave irradiation has been used to facilitate this reaction.<sup>832</sup> The reaction has been done using an AlCl<sub>3</sub> complex as an ionic liquid,<sup>833</sup> and solid-phase Fischer indole syntheses are known.<sup>834</sup> Arylhydrazones are easily prepared by the treatment of aldehydes or ketones with phenylhydrazine (**16-2**) or by aliphatic diazonium coupling (**12-7**). However, it is not necessary to

isolate the arylhydrazone. The aldehyde or ketone can be treated with a mixture of phenylhydrazine and the catalyst; this is now common practice. In order to obtain an indole, the aldehyde or ketone must be of the form  $\text{RCOCH}_2\text{R}'$  ( $\text{R} = \text{alkyl, aryl, or hydrogen}$ ). Vinyl ethers, such as dihydrofuran, serve as an aldehyde surrogate when treated with phenylhydrazine and a catalytic amount of aqueous sulfuric acid to give a 3-substituted indole.<sup>835</sup> The benzyne Fisher indole reaction has been reported.<sup>836</sup> A microwave-assisted, propylphosphonic anhydride-mediated reaction has been reported.<sup>837</sup> The catalytic asymmetric Fisher indole synthesis has been discussed.<sup>838</sup> Rhodium catalysts have been used in this reaction.<sup>839</sup> Isothioureas catalyzed the asymmetric [2,3]-rearrangement of allylic ammonium ylids.<sup>840</sup>

At first glance, the reaction does not seem to be a rearrangement. However, the key step of the mechanism<sup>841</sup> is a [3,3]-sigmatropic rearrangement.<sup>842</sup>

There is much evidence for this mechanism. The main function of the catalyst seems to be to speed the conversion of the hydrazone: (i) the isolation of side products that could only have come from **73**,<sup>843</sup> (ii) the detection of **74** by <sup>13</sup>C and <sup>15</sup>N NMR,<sup>844</sup> (iii) the isolation of **75**,<sup>845</sup> and (iv) <sup>15</sup>N labeling experiments that showed that it was the nitrogen farther from the ring that is eliminated as ammonia.<sup>846</sup>

Sulfur ylids bearing an allylic group are converted to unsaturated sulfides on heating.<sup>847</sup> This is a concerted [2,3]-sigmatropic rearrangement<sup>848</sup> and has also been demonstrated for the analogous cases of nitrogen ylids<sup>849</sup> and the conjugate bases of allylic ethers. In this last case it is called a [2,3]-Wittig rearrangement (**18-22**).<sup>850</sup>

The reaction has been extended to certain other systems,<sup>851</sup> even to an all-carbon system.<sup>852</sup> A phase transfer-catalyzed [2,3]-rearrangement has been reported.<sup>853</sup>

Treatment of an  $\alpha$ -(*N*-allylic amino) ketone with NaH led to 2-allylic  $\alpha$ -amino ketones via a [2,3]-rearrangement.<sup>854</sup> In the presence of a chiral ligand on nitrogen,<sup>854</sup> or with a chiral additive,<sup>855</sup> good asymmetric induction is possible. Vinylaziridines undergo [2,3]-sigmatropic rearrangement.<sup>856</sup> The Pd-catalyzed, enantioselective [2,3]-rearrangement of amine *N*-oxides has been discussed.<sup>857</sup> Both H bond catalysis and Ca catalytic methods have been developed.<sup>858</sup> The biocatalyst cytochrome P411<sub>BM3</sub> variants promoted a sulfimination/[2,3]-rearrangement sequence in whole cells.<sup>859</sup> The [2,3]-Wittig rearrangement in particular has often been used as a means of transferring chirality.<sup>860</sup> If a suitable stereogenic center is present, then stereocontrol over three contiguous stereogenic centers can be achieved. Stereocontrol of the new double bond (*E* or *Z*) has also been accomplished.

Since the reactions involve migration of an allylic group from a sulfur, nitrogen, or oxygen atom to an adjacent negatively charged carbon atom, they are special cases of the *Stevens or Wittig rearrangements* (**18-21**, **18-22**). However, in this case the migrating group *must* be allylic while in **18-21** and **18-22** other groups can also migrate. Thus, when the migrating group is allylic, there are two possible pathways: (i) the radical-ion

or ion-pair mechanisms (**18-21**, **18-22**) and (ii) the concerted pericyclic [2,3]-sigmatropic rearrangement. These are easily distinguished since the latter always involves an allylic shift (as in the *Claisen rearrangement*), while the former pathway does not.

A [2,3]-sigmatropic rearrangement of allylic selenimides has been discussed.<sup>861</sup> The Rh-catalyzed [2,3]-sigmatropic rearrangement of sulfur ylids was reported,<sup>862</sup> as has the Cu-catalyzed rearrangement of propargylic sulfinates.<sup>863</sup> Another [2,3]-sigmatropic rearrangement, called the *Mislow-Evans rearrangement*,<sup>864</sup> converts allylic sulfoxides to **76**, and subsequently a rearranged allylic alcohol by treatment with a thiophilic reagent such as trimethyl phosphite.<sup>865</sup> In this case, the migration is from sulfur to oxygen.

[2,3]-Oxygen-to-sulfur migrations are also known.<sup>866</sup>  
OS VIII, 427.

### 18-36 The Benzidine Rearrangement

When hydrazobenzene is treated with acids, it rearranges to give ~70% 4,4'-diaminobiphenyl (benzidine) and ~30% 2,4'-diaminobiphenyl. This reaction is called the *benzidine rearrangement* and is general for *N,N'*-diarylhydrazines.<sup>867</sup> Usually, the major product is the 4,4'-diaminobiaryl, but four other products may also be produced: the 2,4'-diaminobiaryl (already referred to), the 2,2'-diaminobiaryl, and the *o*- and *p*-arylaminoanilines (called *semidines*). The 2,2'- and *p*-arylaminoaniline compounds are formed less often and in smaller amounts than the other two side products. Usually, the 4,4'-diaminobiaryl predominates, except when one or both *para* positions of the

diarylhydrazine are occupied. However, the 4,4'-diamine may still be produced even if the *para* positions are occupied. If  $\text{SO}_3\text{H}$ ,  $\text{CO}_2\text{H}$ , or  $\text{Cl}$  (but not  $\text{R}$ ,  $\text{Ar}$ , or  $\text{NR}_2$ ) is present in the *para* position, that group may be ejected. With dinaphthylhydrazines, the major products are not the 4,4'-diaminobinaphthyls, but the 2,2' isomers. Another side reaction is disproportionation to  $\text{ArNH}_2$  and  $\text{ArN}=\text{NAr}$ . For example, *p,p'*- $\text{PhC}_6\text{H}_4\text{NHNHC}_6\text{H}_4\text{Ph}$  gives 88% disproportionation products at 25 °C.<sup>868</sup>

The mechanism has been exhaustively studied and several mechanisms have been proposed.<sup>869</sup> At one time it was believed that  $\text{NHAr}$  broke away from  $\text{ArNHNHAr}$  and became attached to the *para* position to give the semidine, which then went on to product, but this theory was disproved. An important discovery was the fact that, although the reaction is always first order in substrate, it can be either first<sup>870</sup> or second<sup>871</sup> order in  $[\text{H}^+]$  but fractional orders can often be observed;<sup>872</sup> this is because at intermediate acidities, both first order and second order processes take place simultaneously. These kinetic results seem to indicate that the actual reacting species can be either the monoprotonated substrate  $\text{ArNHNH}_2\text{Ar}$  or the diprotonated  $\text{ArNH}_2\text{NH}_2\text{Ar}$ .

Most of the proposed mechanisms<sup>873</sup> attempted to show how all five products could be produced by variations of a single process. An important breakthrough was the discovery that the two main products are formed in entirely different ways, as shown by isotope effect studies.<sup>874</sup> When the reaction was run with hydrazobenzene labeled with  $^{15}\text{N}$  at both nitrogen atoms, the isotope effect was 1.022 for formation of benzidine, but 1.063 for formation of 2,4'-diaminobiphenyl. This showed that the  $\text{N}-\text{N}$  bond is broken in the rate-determining step in both cases, but the steps themselves are obviously different. When the reaction was run with hydrazobenzene labeled with  $^{14}\text{C}$  at a *para* position, there was an isotope effect of 1.028 for formation of benzidine, but essentially no isotope effect (1.001) for formation of 2,4'-diaminobiphenyl. This can only mean that for the formation of benzidine the new  $\text{C}-\text{C}$  bond and breaking of the  $\text{N}-\text{N}$  bond both take place in the rate-determining step; in other words, the mechanism is concerted. The [5,5]-sigmatropic rearrangement shown accounts for this.<sup>875</sup> The diion **77** was obtained as a stable species in superacid solution at  $-78\text{ }^\circ\text{C}$  by treatment of hydrazobenzene with  $\text{FSO}_3\text{H}/\text{SO}_2$  ( $\text{SO}_2\text{ClF}$ ).<sup>876</sup>

Although the results just given were obtained with hydrazobenzene, which reacts by the diprotonated pathway, monoprotonated substrates have been found to react by the same [5,5]-sigmatropic mechanism.<sup>877</sup> Some of the other rearrangements in this section are also sigmatropic. Thus, formation of the *p*-semidine takes place by a [1,5]-sigmatropic rearrangement,<sup>878</sup> and the conversion of 2,2'-hydrazonaphthalene to 2,2'-diamino-1,1'-binaphthyl takes place by a [3,3]-sigmatropic rearrangement.<sup>879</sup>

2,4'-Diaminobiphenyl is formed by a completely different mechanism, although the details are not known. There is rate-determining breaking of the N–N bond, but the C–C bond is not formed during this step.<sup>880</sup> The formation of the *o*-semidine also takes place by a nonconcerted pathway.<sup>881</sup> Under certain conditions, benzidine rearrangements have been found to go through radical cations.<sup>882</sup>

### C. Other Cyclic Rearrangements

#### 18-37 Metathesis of Alkenes (Alkene or Olefin Metathesis)<sup>883</sup>

When alkenes are treated with certain catalysts they are converted to other alkenes in an equilibrium reaction in which one set of alkylidene groups ( $\text{R}^1\text{R}^2\text{C}=\text{C}$ ) have become interchanged with other alkylidene groups ( $\text{R}^3\text{R}^4\text{C}=\text{C}$ ) by a process schematically illustrated by the equilibrium reaction shown. In the early example shown, pent-2-ene (either *cis*, *trans*, or a *cis-trans* mixture) is converted to a mixture of ~50% pent-2-ene, 25% but-2-ene, and 25% hex-3-ene. Nowadays, superior catalysts and experimental procedures have made this reaction synthetically useful (see below). The reaction is reversible,<sup>884</sup> so the alkene starting material and products exist in equilibrium.<sup>885</sup> In the example cited, the same mixture can be obtained by starting with equimolar quantities of but-2-ene and hex-3-ene. The reaction is called *metathesis* of alkenes or *alkene metathesis* (*olefin metathesis*).<sup>886</sup>

In an example, a mixture of  $R^1R^2C=CR^1R^2$  and  $R^3R^4C=CR^3R^4$  gives rise to only one new alkene ( $R^1R^2C=CR^3R^4$ ), while in the most general case, the reaction of two alkenes  $R^1R^2C=CR^3R^4$  and  $R^5R^6C=CR^7R^8$  can give a mixture of 10 alkenes: the original 2 + 8 new ones.

In early work, W, Mo,<sup>887</sup> or Re complexes were used. With simple alkenes the proportions of products are generally statistical,<sup>888</sup> which limited the synthetic utility of the reaction since the yield of any one product is low. In some cases one alkene may be more or less thermodynamically stable than the rest, so that the proportions are not statistical in all cases. Work has been done toward a model for alkene ring-closing metathesis.<sup>889</sup>

It is possible to shift the equilibrium to favor certain products. For example, 2-methylbut-1-ene gives rise to ethylene and 3,4-dimethylhex-3-ene. By allowing the gaseous ethylene to escape, the yield of 3,4-dimethylhex-3-ene can be raised to 95%.<sup>890</sup> This example shows that it is possible to tailor the substrate to include two terminal alkenes that then lead to ethylene as a product, whose escape from the reaction drives the equilibrium to product. Copper iodide is an effective co-catalyst for alkene cross metathesis.<sup>891</sup>

The generally accepted mechanism is a chain mechanism,<sup>892</sup> involving the intervention of a metal-carbene complex (**78** and **79**)<sup>893</sup> and a four-membered ring containing a metal<sup>894</sup> (**80–83**).<sup>895</sup>

In the cross-metathesis reaction shown as an example,  $R_2C=CR_2$  reacts with  $R^1_2C=CR^1_2$  in the presence of a metal catalyst,  $M$ . Initial reaction with the catalyst leads to the two expected metal carbenes, **78** and **79**. Metal carbene **79** can react with both alkenes to form metallocyclobutanes **80** and **81**. Each of these intermediates loses the metal to form alkenes, either the product of metathesis  $R_2C=CR^1_2$  or one of the original alkenes. In a likewise manner, **78** reacts with each alkene to form metallocyclobutanes **82** and **83**, which decompose to  $R_2C=CR_2$  (one of the original alkenes) and the metathesis product. It has been shown that the phosphine-containing methylidene complexes decompose to methylphosphonium salts.<sup>896</sup>

The development of better catalysts has revolutionized this reaction,<sup>897</sup> making it one of the most important methods available for modern synthesis. Both homogeneous<sup>898</sup> and heterogeneous<sup>899</sup> catalysts have been used for this reaction. Of the many homogeneous catalysts, Ru complexes are the most important,<sup>900</sup> and important heterogeneous catalysts include oxides of Mo, W, and Re deposited on alumina or silica gel.<sup>901</sup> The major

breakthrough in these catalysts was the development of catalysts that are relatively air stable. Three important catalysts are metal carbene complexes **84**<sup>902</sup> and **85**<sup>903</sup> (*Grubbs catalyst I and II*, respectively; Mes = mesityl), and **86** (the *Shrock catalyst*).<sup>904</sup> Catalyst **85** can be generated *in situ* from air-stable precursors.<sup>905</sup>

The exploration of Ru catalysts continues to be an important area of research. The synthetic importance<sup>906</sup> of ring-closing and ring-opening<sup>907</sup> metathesis reactions has, in part, led to the ongoing development of new catalysts.<sup>908</sup> A metal-free ring-opening metathesis polymerization has been developed.<sup>909</sup> Catalysts have been developed that are compatible with both water and methanol.<sup>910</sup> The reaction is compatible with the presence of other functional groups,<sup>911</sup> such as other alkene units,<sup>912</sup> carbonyl units,<sup>913</sup> allyl alcohols,<sup>914</sup>

two cyclopropyl substituents.<sup>970</sup> Vinylcyclopropane-alkyne metathesis reactions have been reported.<sup>971</sup>

Dienes can react intermolecularly or intramolecularly.<sup>972</sup> Intramolecular reactions generate rings, including small rings,<sup>973</sup> usually alkenes or dienes. Alkene metathesis can be used to form very large rings, including 21-membered lactone rings.<sup>974</sup> Diynes undergo both cross metathesis and ring-closing metathesis.<sup>975</sup> Diynes can also react intramolecularly to give large-ring alkynes.<sup>976</sup> Metathesis with vinyl cyclopropyl alkynes is also known, producing a ring-expanded product.<sup>977</sup> Vinyl halides undergo metathesis reactions.<sup>978</sup> Two cyclic alkenes react to give dimeric dienes in the metathesis reaction of cyclopentene to give cyclodeca-1,6-diene.<sup>979</sup> With many catalysts, the products can then react with additional monomers and with each other, so that polymers are produced, and the cyclic dienes are obtained only in low yield. The reaction between a cyclic and a linear alkene can give a ring-opened diene.<sup>980</sup> The reaction has also been applied to internal alkynes,<sup>981</sup> and some success has been reported for terminal triple bonds.<sup>982</sup> As noted above, molecules with a terminal alkene and a terminal alkyne react quite well (ene-yne metathesis).<sup>983</sup> Intramolecular reactions of a double bond with a triple bond are known<sup>984</sup> and a tetracyclic tetraene has been prepared from a poly-yne-diene.<sup>985</sup> Cross metathesis of terminal alkynes and terminal alkenes (en-yne)<sup>986</sup> to give a diene has also been reported.<sup>987</sup> En-yne metathesis generates 1,3-dienes.<sup>988</sup>

Ring-opening metathesis generates dienes from cyclic alkenes.<sup>989</sup> Allenes undergo a metathesis reaction to give symmetrical allenes.<sup>990</sup> An interesting variation reacts an  $\alpha,\omega$ -diene with a cyclic alkene. The combination of ring-opening metathesis and ring-closing cross metathesis leads to ring expansion to give a macrocyclic nonconjugated diene.<sup>991</sup>

OS 80, 85; 81, 1.

### 18-38 Metal Ion-Catalyzed $\sigma$ -Bond Rearrangements

Many highly strained cage molecules undergo rearrangement when treated with metallic ions, such as  $\text{Ag}^+$ ,  $\text{Rh(I)}$ , or  $\text{Pd(II)}$ .<sup>992</sup> The bond rearrangements observed are formally classified into two main types: type 1 are [2 + 2] ring openings of cyclobutanes and type 2 are conversions of a bicyclo[2.2.0] system to a bicyclopropyl system. The molecule cubane supplies an example of each type. Treatment with Rh complexes converts cubane to tricyclo[4.2.0.0<sup>2,5</sup>]octa-3,7-diene (**87**),<sup>993</sup> an example of type 1, while  $\text{Ag}^+$  or  $\text{Pd(II)}$  causes the second type of reaction, producing cuneane.<sup>994</sup>

The mechanisms of these reactions are not completely understood, although relief of strain undoubtedly supplies the driving force. The reactions are thermally forbidden by the orbital symmetry rules, and the role of the catalyst is to provide low-energy pathways so that the reactions can take place. The type 1 reactions are the reverse of the catalyzed [2 + 2] ring closures discussed at **15-59**.

Simple bicyclobutanes can also be converted to dienes, but in this case the products usually result from cleavage of the central bond and one of the edge bonds.<sup>995</sup> For example, treatment of **88** with  $\text{AgBF}_4$ <sup>996</sup> or  $[(\pi\text{-allyl})\text{PdCl}]_2$ <sup>997</sup> gives a mixture of the two dienes shown, resulting from a formal cleavage of the C-1–C-3 and C-1–C-2 bonds (note that a hydride shift has taken place).

Dienes can also be converted to bicyclobutanes under photochemical conditions.<sup>998</sup>

18-39 The Di- $\pi$ -Methane and Related Rearrangements

1,4-Dienes carrying alkyl or aryl substituents on C-3<sup>999</sup> can be photochemically rearranged to vinylcyclopropanes in a reaction called the *di- $\pi$ -methane rearrangement*.<sup>1000</sup> An example is conversion of **89** to **90**.<sup>1001</sup> For most 1,4-dienes it is only the singlet excited state that gives the reaction; triplet states generally take other pathways.<sup>1002</sup> For unsymmetrical dienes, the reaction is regioselective. For example, **91** gave **92**, not **93**.<sup>1003</sup>

The mechanism can be described by the diradical pathway given<sup>1004</sup> (the C-3 substituents act to stabilize the radical), although the species shown are not necessarily intermediates, but may represent transition states. It has been shown, for the case of certain substituted substrates, that configuration is retained at C-1 and C-5 and inverted at C-3.<sup>1005</sup>

The reaction has been extended to allylic benzenes, which give cyclopropylbenzenes,<sup>1006</sup> to  $\beta,\gamma$ -unsaturated ketones, which give cyclopropyl ketones<sup>1007</sup> (this reaction, called the

*oxa-di- $\pi$ -methane rearrangement*,<sup>1008</sup> generally occurs only from the triplet state), to  $\beta,\gamma$ -unsaturated imines,<sup>1009</sup> and to triple bond systems.<sup>1010</sup> 2,4-Cyclohexadienones also undergo photochemical rearrangements, but the products are different, generally involving ring opening.<sup>1011</sup>

### 18-40 The Hofmann-Löffler and Related Reactions

A common feature of the reactions in this section<sup>1012</sup> is that they serve to introduce functionality at a position remote from functional groups already present. As such, they have proved very useful in synthesizing many compounds, especially in the steroid field (see also **19-2** and **19-18**). When *N*-haloamines in which one alkyl group has a hydrogen in the 4 or 5 position are heated with sulfuric acid, then pyrrolidines or piperidines are formed, in a reaction known as the *Hofmann-Löffler reaction* (also called the *Hofmann-Löffler-Freytag reaction*).<sup>1013</sup> The R' group is normally alkyl, but the reaction has been extended to R' = H by the use of concentrated sulfuric acid solution and ferrous salts.<sup>1014</sup> An iodine-catalyzed reaction has been reported.<sup>1015</sup>

As illustrated by the reaction of 1-bromo-2-propylpiperidine,<sup>1016</sup> a radical anion is formed (**94**) and hydrogen transfer leads to a distal radical (**95**).

Reaction with protonated 1-bromo-2-propylpiperidine occurs *in situ* to give the distal bromide, which reacts via internal substitution to give octahydroindolizine. The reaction is most often induced by heat, but this is not necessary, and irradiation and chemical initiators (e.g., peroxides) have been used instead. The mechanism is of a free-radical type, with

the main step involving an internal hydrogen abstraction.<sup>1017</sup> A similar reaction has been carried out on *N*-halo amides, which give  $\gamma$ -lactones.<sup>1018</sup>

Another related reaction is the *Barton reaction*,<sup>1019</sup> by which a methyl group in a unique position relative to an OH group can be oxidized to a CHO group. The alcohol is first converted to the nitrite ester. Photolysis of the nitrite results in conversion of the nitrite group to the OH group and nitrosation of the methyl group. Formation of a radical and with the methyl group in the appropriate position, hydrogen atom transfer via a six-center transition state leads to a nitrite. Hydrolysis of the oxime tautomer gives the aldehyde, for example.<sup>1020</sup>

This reaction takes place only when the methyl group is in a favorable steric position.<sup>1021</sup> The mechanism is similar to that of the *Hofmann-Löffler reaction*.<sup>1022</sup> This is one of the few known methods for effecting substitution at an angular methyl group. Not only CH<sub>3</sub> groups but also alkyl groups of the form RCH<sub>2</sub> and R<sub>2</sub>CH can give the Barton reaction if the geometry of the system is favorable. An RCH<sub>2</sub> group is converted to the oxime R(C=NOH) (which is hydrolyzable to a ketone) or to a nitroso dimer, while an R<sub>2</sub>CH group gives a nitroso compound R<sub>2</sub>C(NO). With very few exceptions, the only carbons that become nitrosated are those in the position  $\delta$  to the original OH group, indicating that a six-membered transition state is necessary for the hydrogen abstraction.<sup>1023</sup>

### 18-42 The Chapman Rearrangement

In the *Chapman rearrangement*, *N,N*-diaryl amides are formed when aryl imino esters are heated.<sup>1027</sup> Best yields are obtained in refluxing tetraethylene glycol dimethyl ether (tetraglyme),<sup>1028</sup> although the reaction can also be carried out without any solvent at all. Many groups may be present in the rings, for example, alkyl, halo, OR, CN, and CO<sub>2</sub>R. Aryl migrates best when it contains electron-withdrawing groups. On the other hand, electron-withdrawing groups in Ar<sup>2</sup> or Ar<sup>3</sup> decrease the reactivity. The products can be hydrolyzed to diarylamines, and this is a method for preparing these compounds. The mechanism probably involves an intramolecular<sup>1029</sup> aromatic nucleophilic substitution, resulting in a 1,3 oxygen-to-nitrogen shift via a species such as **94**.

Aryl imino esters can be prepared from *N*-aryl amides by reaction with PCl<sub>5</sub>, followed by treatment of the resulting imino chloride with an aroxide ion.<sup>1030</sup> Imino esters with any or all of the three groups being alkyl also rearrange, but they require catalysis by H<sub>2</sub>SO<sub>4</sub> or a trace of methyl iodide or methyl sulfate.<sup>1031</sup> The mechanism is different, involving an intermolecular process.<sup>1032</sup> This is also true for derivatives for formamide (Ar<sup>2</sup> = H).

## 18-43 The Wallach Rearrangement

The conversion of azoxy compounds such as **95**, upon acid treatment, to *p*-hydroxy azo compounds such as **96** (or sometimes the *o*-hydroxy isomers<sup>1033</sup>) is called the *Wallach rearrangement*.<sup>1034</sup> When both *para* positions are occupied, the *o*-hydroxy product may be obtained, but *ipso* substitution at one of the *para* positions is also possible.<sup>1035</sup> The following facts are known for the proposed mechanism.<sup>1036</sup> (i) The *para* rearrangement is intermolecular.<sup>1037</sup> (ii) When the reaction was carried out with an azoxy compound in which the N—O nitrogen was labeled with <sup>15</sup>N, *both* nitrogens of the product carried the label equally,<sup>1038</sup> demonstrating that the oxygen did not have a preference for migration to either the near or the far ring. This shows that there is a symmetrical intermediate. (iii) Kinetic studies show that two protons are normally required for the reaction.<sup>1039</sup> The mechanism<sup>1040</sup> involves the symmetrical intermediate, Ar—<sup>+</sup>N≡N<sup>+</sup>—Ar, which has been proposed to explain the facts.<sup>1041</sup> It has proved possible to obtain intermediates as stable species in superacid solutions.<sup>876</sup> Another mechanism, involving an intermediate with only one positive charge, has been proposed for certain substrates at low acidities.<sup>1042</sup>

A photochemical Wallach rearrangement<sup>1043</sup> is also known. The product is the *o*-hydroxy azo compound, the OH group is found in the farther ring, and the rearrangement is intramolecular.<sup>1044</sup>

A *dyotropic rearrangement*<sup>1046</sup> is an uncatalyzed process in which two  $\sigma$  bonds simultaneously migrate intramolecularly.<sup>1047</sup> There are two types. The above is an example of type 1, which consists of reactions in which the two  $\sigma$  bonds interchange positions. In type 2, the two  $\sigma$  bonds do not interchange positions. An example is:

Some other examples are:

Type 1

Type 1

Type 2

A useful type 1 example is the *Brook rearrangement*,<sup>1051</sup> a stereospecific intramolecular migration of silicon from carbon to oxygen that occurs for ( $\alpha$ -hydroxybenzyl)trialkylsilanes in the presence of a catalytic amount of base.<sup>1052</sup> Formation of a Si–O bond rather than the Si–C bond drives the rearrangement, which is believed to proceed via formation of a –C–O–Si– three-membered ring intermediate, and proceeds with inversion of configuration at carbon and retention of configuration at silicon.<sup>1053</sup> A *reverse Brook rearrangement* is also known.<sup>1054</sup> The reaction has been extended to other systems. A *homo-Brook rearrangement* has also been reported.<sup>1055</sup> Another variation is the *aza-Brook rearrangement* of

## Oxidations and Reductions

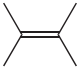

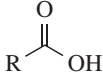

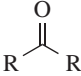

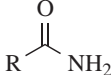

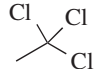

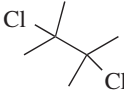

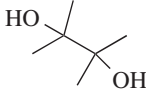

Before there can be a discussion of oxidation and reduction, the terms “oxidation” and “reduction” must be clarified. Inorganic chemists define oxidation in two ways: (i) loss of electrons and (ii) an increase in oxidation number. In organic chemistry, these definitions, while still correct, are not easy to apply. While electrons are directly transferred in some organic oxidations and reductions, and electrons are certainly transferred by making and breaking bonds, the mechanisms of most of these reactions do not involve a direct electron transfer. As for oxidation number, while this is easy to apply in some cases (e.g., the oxidation number of carbon in  $\text{CH}_4$  is  $-4$ ), in most cases attempts to apply the concept lead to fractional values or to apparent absurdities. The carbon atoms in propane have an oxidation number of  $-2.67$  and those in butane are  $-2.5$ , although organic chemists seldom think of these two compounds as having different oxidation states. An improvement could be made by assigning different oxidation states to different carbon atoms in a molecule, depending on what is bonded to them (e.g., the two carbons in acetic acid are obviously in different oxidation states), but for this a whole set of arbitrary assumptions would be required, since the oxidation number of an atom in a molecule is assigned on the basis of the oxidation numbers of the atoms attached to it. There would seem little to be gained by such a procedure.

The practice in organic chemistry has been to set up a series of functional groups, in a qualitative way, arranged in order of increasing oxidation state, and then to define oxidation as *the conversion of a functional group in a molecule from one category to a higher one*. Reduction is the opposite. This series is shown in Table 19.1 for the simple functional groups.<sup>1</sup> Note that this classification applies only to a single carbon atom or to two adjacent carbon atoms. Thus 1,3-dichloropropane is in the same oxidation state as chloromethane, but 1,2-dichloropropane is in a higher one. Obviously, such distinctions are somewhat arbitrary; if we attempt to carry them too far we will find ourselves painted into a corner. Nevertheless, the basic idea has served organic chemistry well. Note that conversion of any compound to another in the same category is not an oxidation or a reduction. Most oxidations in organic chemistry involve a gain of oxygen and/or a loss of hydrogen (Lavoisier’s original definition of oxidation). The reverse is true for reductions.

Of course, there is no oxidation without a concomitant reduction. However, reactions are classified as oxidations or reductions depending on whether the *organic compound* is

<sup>1</sup> For more extensive tables, see Soloveichik, S.; Krakauer, H. *J. Chem. Educ.* **1966**, *43*, 532.

-4	-2	0	+2	+4

<sup>a</sup>Oxidation is the conversion of a functional group in a molecule to a higher category; reduction is conversion to a lower one. Conversions within a category are neither oxidations nor reductions. The numbers given at the bottom are only approximations.

oxidized or reduced. In some cases both the oxidant and reductant are organic; those reactions are treated separately at the end of the chapter.

## 19.A. MECHANISMS

Note that the stated definition of oxidation has nothing to do with mechanism. Thus the conversion of bromomethane to methanol with KOH (**10-1**) is a substitution and the reaction methane of bromomethane with LiAlH<sub>4</sub> (**19-57**) is a reduction. It is impractical to consider the mechanisms of oxidation and reduction reactions in broad categories in this chapter as has been done for the reactions considered in Chapters 10–18.<sup>2</sup> The main reason is that the mechanisms are too diverse, and this in turn is because the bond changes are too different. Another reason is that the mechanism of a given oxidation or reduction reaction can vary

<sup>2</sup> See Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 16, Elsevier, NY, **1980**; *Oxidation in Organic Chemistry*, Academic Press, NY, pt. A [Wiberg, K.B.], **1965**, pts. B, C, and D [Trahanovsky, W.S.], **1973**, **1978**, **1982**; Waters, W.A. *Mechanisms of Oxidation of Organic Compounds*, Wiley, NY, **1964**; Stewart, R. *Oxidation Mechanisms*, W.A. Benjamin, NY, **1964**. For a review, see Stewart, R. *Isot. Org. Chem.* **1976**, *2*, 271.

greatly with the oxidizing or reducing agent employed. Very often the mechanism has been studied intensively for only one or a few of many possible agents. Although oxidation and reduction mechanisms are not covered in the same way as other mechanisms, it is still possible to list a few broad mechanistic categories. The scheme of Wiberg is followed.<sup>3</sup>

1. *Direct electron transfer.*<sup>4</sup> Several reactions have been encountered in which the reduction is a direct gain of electrons or the oxidation a direct loss of them. An example is the *Birch reduction* (**19-36**), where sodium directly transfers an electron to an aromatic ring. An example from this chapter is found in the bimolecular reduction of ketones with a metal (**19-80**), where again it is a metal that supplies the electrons. This kind of mechanism is found largely in three types of reaction:<sup>5</sup>
  - a. the oxidation or reduction of a free radical (oxidation to a positive ion or reduction to a negative ion)
  - b. the oxidation of a negative ion or the reduction of a positive ion to a comparatively stable free radical
  - c. electrolytic oxidations or reductions (an example is the Kolbe reaction, **14-23**).

An important example of point b is oxidation of phenolate ions to phenoxide radicals. These reactions occur easily because of the relative stability of the radicals involved.<sup>6</sup> The single electron-transfer mechanism (SET), which has been seen several times (Sec. 10.B) is an important case.
2. *Hydride transfer.*<sup>7</sup> In some reactions, a hydride ion is transferred to or from the substrate.<sup>8</sup> The reduction of epoxides with  $\text{LiAlH}_4$  is an example (**19-39**). Another is the *Cannizzaro reaction* (**19-85**). Reactions in which a hydride ion is transferred to a carbocation belong in this category.
3. *Hydrogen-atom transfer.* Many oxidation and reduction reactions are free-radical substitutions and involve the transfer of a hydrogen atom. For example, one of the two main propagation steps of **14-1** involves abstraction of hydrogen:

This is the case for many of the reactions of Chapter 14.

4. *Displacement mechanisms.* In these reactions, the organic substrate uses its electrons to cause displacement on an electrophilic oxidizing agent. One example is the addition of bromine to an alkene (**15-35**), which gives a bromonium ion as an intermediate. An example from this chapter is found in **19-28**.
5. *Addition-elimination mechanisms.* In the reaction between  $\alpha,\beta$ -unsaturated ketones and alkaline peroxide (**15-46**), the oxidizing agent adds to the substrate and then part of it is lost. In this case, the oxygen of the oxidizing agent is in oxidation state  $-1$  and the hydroxide ion departs with its oxygen in the  $-2$  state; the oxidizing agent is

reduced and so the substrate is oxidized. There are several reactions that follow this pattern of addition of an oxidizing agent and the loss of part of the agent, usually in a different oxidation state. Another example is the oxidation of ketones with  $\text{SeO}_2$  (19-15). This reaction is also an example of category 4, since it involves formation and E2 cleavage of an ester. This example shows that these five categories are not mutually exclusive.

## 19.B. REACTIONS

In this chapter, the reactions are classified by the type of bond change occurring to the organic substrate, in conformity with other chapters.<sup>9</sup> This classification means that there is no discussion in any one place of the use of a particular oxidizing or reducing agent, for example, acid dichromate or  $\text{LiAlH}_4$  (except for a discussion of selectivity of reducing agents, for which see 19.B.ii, part A). Some oxidizing or reducing agents are fairly specific in their action, attacking only one or a few types of substrate. Others, like acid dichromate, permanganate,  $\text{LiAlH}_4$ , and catalytic hydrogenation, are much more versatile.<sup>10</sup>

### 19.B.i. Oxidations<sup>11</sup>

#### A. Eliminations Of Hydrogen

##### 19-1 Aromatization of Six-Membered Rings

Six-membered alicyclic rings can be aromatized in a number of ways.<sup>12</sup> Aromatization is accomplished most easily if there are already one or two double bonds in the ring or if the ring is fused to an aromatic ring. The reaction can also be applied to heterocyclic five- and six-membered rings. Many groups may be present on the ring without interference, and even *gem*-dialkyl substitution does not always prevent the reaction. In such cases one alkyl group often migrates or is eliminated, but more drastic conditions are usually required for this. In some cases OH and COOH groups are lost from the ring. Cyclic ketones are converted to phenols. Seven-membered and larger rings are often isomerized to six-membered aromatic

rings, although this is not the case for partially hydrogenated azulene systems (which are frequently found in nature); these are converted to azulenes.

There are three types of reagents most frequently used to effect aromatization.

1. Hydrogenation catalysts,<sup>13</sup> such as Pt, Pd,<sup>14</sup> and Ni.<sup>15</sup> Palladium trifluoroacetate also facilitates oxidative aromatization of cyclohexene.<sup>16</sup> In this case, the reaction is the *reverse* of double-bond hydrogenation (**19-34** and **19-38**), and presumably the mechanism is also the reverse, although not much is known.<sup>17</sup> Cyclohexene has been detected as an intermediate in the conversion of cyclohexane to benzene, using Pt.<sup>18</sup> The substrate is heated with the catalyst at  $\sim 300\text{--}350\text{ }^\circ\text{C}$ . The reactions can often be carried out under milder conditions if a hydrogen acceptor, such as maleic acid, cyclohexene, or benzene, is present to remove hydrogen as it is formed. The acceptor is reduced to the saturated compound. Other transition metals can be used.<sup>19</sup> It has been reported that dehydrogenation of 1-methylcyclohexene-1-<sup>13</sup>C over an alumina catalyst gave toluene with the label partially scrambled throughout the aromatic ring.<sup>20</sup> For polycyclic systems, heating with oxygen on activated carbon generates the aromatic compound, as in the conversion of dihydroanthracene to anthracene.<sup>21</sup>
2. The elements sulfur and selenium, which combine with the hydrogen evolved to give, respectively, H<sub>2</sub>S and H<sub>2</sub>Se. Little is known about this mechanism either.<sup>22</sup>
3. Quinones<sup>23</sup> become reduced to the corresponding hydroquinones. Two important quinones often used for aromatizations are chloranil (2,3,5,6-tetrachloro-1,4-benzoquinone) and DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone).<sup>24</sup> The latter is more reactive and can be used in cases where the substrate is difficult to dehydrogenate. It is likely that the mechanism involves a transfer of hydride to the quinone oxygen, followed by the transfer of a proton to the phenolate ion.<sup>25</sup>

Other reagents<sup>26</sup> have been used for aromatization of six-membered rings, including atmospheric oxygen, MnO<sub>2</sub>,<sup>27</sup> SeO<sub>2</sub>, H<sub>2</sub>SO<sub>4</sub>, and a Ru catalyst.<sup>28</sup> The last-mentioned reagent also dehydrogenates cyclopentanes to cyclopentadienes. In some instances, the hydrogen is not released as H<sub>2</sub> or transferred to an external oxidizing agent, but instead serves to reduce another molecule of substrate. This is a disproportionation reaction, as illustrated by the conversion of cyclohexene to cyclohexane and benzene.

A Pd-catalyzed aerobic dehydrogenation of substituted cyclohexenes gave the corresponding arene derivatives using sodium anthraquinone-2-sulfonate as a co-catalyst.<sup>29</sup> The cycloaromatization of dienyl propargylic ethers used Triton B in DMSO to give highly substituted phenol derivatives via an electrocyclization followed by 1,3-proton transfer.<sup>30</sup> The Pd-catalyzed aerobic bimolecular carbocyclization of (*Z*)-hexa-1,5-dien-3-ene derivatives, in the presence of a Cu salt, gave 2,6-diacynaphthalenes.<sup>31</sup> A Pd-catalyzed tandem Sonogashira coupling (**13-13**)/cyclization/aromatization sequence of β-halo vinyl sulfones/ketones with terminal alkynes gave benzene derivatives.<sup>32</sup>

The Pd-catalyzed aerobic dehydrogenative aromatization of cyclohexanone imines, generated by *in situ* reaction of cyclohexanone derivatives and amines, gave arylamines.<sup>33</sup> Heating benzoin and deoxybenzoin with acetic acid and ammonium acetate led to tetraaryl-substituted pyrroles via cross-dehydrative aromatization.<sup>34</sup> Heating the Nd-catalyzed reaction of 2-alkynylbiphenyl derivatives gave phenanthrene derivatives.<sup>35</sup> Phenols were prepared from cyclohexenones via the reaction with a copper acetate catalyst, in the presence of LiBr and CF<sub>3</sub>COOH under oxygen.<sup>36</sup> Note that hydrogenolysis of cyclohexane leads to *n*-hexane with hydrogen and an Ir catalyst.<sup>37</sup> It is noted that hydrogenolysis of alkanes in general has been examined.<sup>38</sup>

Heteroatom rings, as found in quinoline derivatives, for example, can be generated from amino ketones with [hydroxy(tosyloxy)iodo]benzene and perchloric acid<sup>39</sup> or with NaHSO<sub>4</sub>/Na<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> on wet silica.<sup>40</sup> Dihydropyridines are converted to pyridines with NaNO<sub>2</sub>/oxalic acid and wet silica,<sup>41</sup> BaMnO<sub>4</sub>,<sup>42</sup> FeCl<sub>3</sub>/acetic acid,<sup>43</sup> or SeO<sub>2</sub>.<sup>44</sup> *Hantzsch*

## 19-2 Dehydrogenations Yielding Carbon-Carbon Double Bonds

Dehydrogenation of an aliphatic compound to give a double bond in a specific location is not usually a feasible process, although industrially mixtures of alkenes are obtained in this way from mixtures of alkanes (generally by heating with chromia/alumina catalysts). There are, however, some notable exceptions. Heating cyclooctane with an Ir catalyst leads to cyclooctene.<sup>54</sup> Treating alkenes that have an allylic hydrogen with CrCl<sub>2</sub> converts them to allenes.<sup>55</sup> It is not surprising, however, that most of the exceptions generally involve cases where the new double bond can be in conjugation with a double bond or with an unshared pair of electrons already present.<sup>56</sup> One example is the synthesis developed by Leonard and co-workers,<sup>57</sup> in which tertiary amines give enamines (**10-69**) when treated with mercuric

acetate.<sup>58</sup> In one example, the initial product is the iminium ion **1**, which loses a proton to give the enamine. Other transition metal catalysts convert amines to enamines, including Co compounds.<sup>59</sup>

The oxidizing agent SeO<sub>2</sub> can in certain cases convert a carbonyl compound to an  $\alpha,\beta$ -unsaturated carbonyl compound by removing H<sub>2</sub><sup>60</sup> (note that this reagent more often gives **19-18**). Similarly, SeO<sub>2</sub> has been used to dehydrogenate 1,4-diketones<sup>61</sup> and 1,2-diaryllkanes. These conversions can also be carried out by certain quinones, most notably DDQ (see **19-1**).<sup>25</sup>

Simple aldehydes and ketones have been dehydrogenated (e.g., cyclopentanone  $\rightarrow$  cyclopentenone) by PdCl<sub>2</sub><sup>62</sup> and by FeCl<sub>3</sub>,<sup>63</sup> among other reagents. In an indirect method of achieving this conversion, the silyl enol ether of a simple ketone is treated with DDQ<sup>64</sup> or with triphenylmethyl cation.<sup>65</sup> For another indirect method, see **17-10**.

The Ru-catalyzed reaction with a cobalt(salophen) co-catalyst lead to oxidative dehydrogenation of tetrahydroquinolines to give the corresponding quinoline.<sup>66</sup> The Pd-catalyzed dehydrogenation of cyclic ketones to the corresponding enones used O<sub>2</sub> as the oxidant.<sup>67</sup> Formation of a zinc enolate followed by the addition of allyl pivalate and a Pd catalyst gave the  $\alpha,\beta$ -unsaturated ester, lactone, or nitrile.<sup>68</sup> Using a Au nanoparticle catalyst, the dehydrogenative oxidation reaction of 2-substituted indoline and dihydropyridine under molecular oxygen was accomplished in aqueous solution.<sup>69</sup> The DMF-promoted dehydrogenation of 1-substituted 1,2,3,4-tetrahydroisoquinolines gave cyclic imines.<sup>70</sup> 2-Arylpyrroles were prepared from 1-aryl-1-pyrrolines using a Pd catalyst on alumina.<sup>71</sup>

Simple linear alkanes have been converted to alkenes by treatment with certain transition metal compounds.<sup>72</sup> A transient Ti alkylidyne facilitated the dehydrogenation conversion of ethane to ethene.<sup>73</sup> The Ru-catalyzed dehydrogenation of alkanes to alkenes<sup>74</sup> was

accomplished using photoirradiation.<sup>75</sup> An entirely different approach (remote functionalization) allows specific dehydrogenation, as reported by R. Breslow<sup>76</sup> and by J.E. Baldwin.<sup>77</sup> 3 $\alpha$ -Cholesterol was converted to 5 $\alpha$ -cholest-14-en-3 $\alpha$ -ol, for example, thus introducing a double bond at a specific site remote from any functional group.<sup>78</sup> A different kind of dehydrogenation was used in the final step of Paquette's synthesis of dodecahedrane.<sup>79</sup>

OS V, 428, VII, 4, 473.

### 19-3 Oxidation of Alcohols to Aldehydes and Ketones<sup>80</sup>

Primary alcohols can be converted to aldehydes and secondary alcohols converted to ketones via a dehydrogenation reaction that constitutes an oxidation.<sup>81</sup> There are myriad oxidizing agents, categorized by reagent type where possible.

1. *With chromium reagents.*<sup>82</sup> Secondary alcohols are easily oxidized to ketones by dichromate in acidic media<sup>83</sup> at room temperature or slightly above. A solution of chromic acid and sulfuric acid in water is known as the *Jones reagent*.<sup>84</sup> Secondary alcohols are oxidized to ketones rapidly and in high yield without disturbing any double or triple bonds that may be present (see **19-10**) and without epimerizing an adjacent stereogenic center.<sup>85</sup> Mixing sodium dichromate with an alcohol, without solvent, provides a method for oxidation when the mixture is shaken.<sup>86</sup> CrO<sub>3</sub><sup>87</sup>

has been used to oxidize primary alcohols under solvent-free conditions. Chromium trioxide on silica gel, in supercritical CO<sub>2</sub>, oxidizes alcohols to the corresponding carbonyl.<sup>88</sup> For acid-sensitive compounds, trimethylsilyl chromates<sup>89</sup> can be used. Phase-transfer catalysis is particularly useful,<sup>90</sup> especially when the substrates are generally insoluble in water (Sec. 10.G.v).

The Jones reagent can also oxidize primary allylic alcohols to the corresponding aldehydes,<sup>91</sup> although over-oxidation to the carboxylic acid is a problem.<sup>92</sup> Oxidative cleavage of primary alcohols has been observed in the presence of molecular sieves 3 Å.<sup>93</sup> One way to mitigate over-oxidation is to distil the aldehyde as it is formed, but this is not always possible. Due to these problems, other oxidizing conditions or modified chromium reagents have been used to convert at least some primary alcohols to aldehydes.<sup>94</sup> Perhaps the three most commonly used Cr(VI) reagents used for the oxidation of allylic alcohols include<sup>95</sup> dipyridine Cr(VI) oxide (*Collins' reagent*),<sup>96</sup> pyridinium chlorochromate (PCC),<sup>97</sup> and pyridinium dichromate (PDC).<sup>98</sup> PCC is somewhat acidic, and acid-catalyzed rearrangements have been observed.<sup>99</sup> For allylic alcohols and alkenyl alcohols, (*Z*)/(*E*) isomerization has been observed.<sup>100</sup> The Ru-catalyzed, asymmetric isomerization of allylic alcohols to chiral aliphatic ketones has been reviewed.<sup>101</sup> Platinum metals have also been used.<sup>102</sup> An Ir-catalyzed isomerization is selective for primary alcohols.<sup>103</sup>

Analogous to the use of pyridine for PCC and PDC, a variety of amines and diamines have been converted to tetraalkylammonium halochromates or dichromates, including *N*-benzyl 1,4-diazabicyclo[2.2.2]octane ammonium dichromate

with microwave irradiation,<sup>104</sup> guanidinium chlorochromate,<sup>105</sup>  $\gamma$ -picolinium chlorochromate,<sup>106</sup> and quinolinium fluorochromate.<sup>107</sup> Benzyltriphenylphosphonium chlorochromate has been used in a similar manner.<sup>108</sup> Triphenylmethylphosphonium dichromate is effective for selective oxidation of benzylic alcohols.<sup>109</sup>

Studies on the mechanism of oxidation with acid dichromate<sup>110</sup> led to the currently accepted mechanism as proposed by Westheimer.<sup>111</sup> The base in the second step may be water, although it is also possible<sup>112</sup> that in some cases no external base is involved and that the proton is transferred directly to one of the  $\text{CrO}_3\text{H}$  oxygen atoms, in which case the  $\text{Cr(IV)}$  species produced would be  $\text{H}_2\text{CrO}_3$ . Part of the evidence for this mechanism was the isotope effect of  $\sim 6$  found on use of  $\text{MeCDOHMe}$ , showing that the  $\alpha$  hydrogen is removed in the rate-determining step.<sup>113</sup> Note that the substrate is oxidized by three different oxidation states of chromium.<sup>114</sup>

Mechanisms are less clear for the other oxidizing agents discussed below.<sup>115</sup> A summary of many proposed mechanisms is given by Littler.<sup>116</sup>

2. *With manganese oxidizing agents.* Potassium permanganate ( $\text{KMnO}_4$ ) has been used for the oxidation of alcohols.<sup>117</sup> Benzylic and allylic alcohols have been selectively oxidized to the aldehyde in the presence of saturated alcohols by the use of potassium manganate(VI) ( $\text{K}_2\text{MnO}_4$ ) under phase-transfer conditions.<sup>118</sup> Phase-transfer catalysis has also been used with chromic acid,<sup>119</sup> ruthenium tetroxide,<sup>120</sup> and Lewis acid-activated potassium permanganate.<sup>121</sup> Ultrasound has been used for  $\text{KMnO}_4$  oxidations.<sup>122</sup> Potassium permanganate has been supported on Kieselgühr,<sup>123</sup> and manganese dioxide supported on aluminum silica has been used.<sup>124</sup>

The oxidizing reagent  $\text{MnO}_2$ <sup>125</sup> is an important reagent for the selective oxidation of benzylic alcohols, in preference to aliphatic substrates.<sup>126</sup> Benzylic and allylic alcohols were oxidized using  $\text{Mn}(\text{OAc})_3$  and a 2,3-dichloro-5,6-dicyano-1,4-benzoquinone catalyst.<sup>127</sup> Manganese(VI) oxidizing agents that are soluble in organic solvents have been developed.<sup>128</sup> Manganese complexes of  $\text{N}_4$  ligands have been used for the oxidation of secondary alcohols to ketones.<sup>129</sup>

3. *The Oppenauer oxidation.* When a ketone in the presence of an aluminum alkoxide is used as the oxidizing agent (it is reduced to a secondary alcohol), the reaction is known as the *Oppenauer oxidation*.<sup>130</sup> Triorganoaluminum reagents have been used.<sup>131</sup> This oxidation is the reverse of the *Meerwein-Ponndorf-Verley reduction* (19-40) and the mechanism is also the reverse. The ketones most commonly used are acetone, butanone, and cyclohexanone. A common base is aluminum *tert*-butoxide. The chief advantage of the method is its high selectivity. Although the method is most often used for the preparation of ketones, it has also been used for aldehydes. An In catalyst<sup>132</sup> and an Ir catalyst<sup>133</sup> have been developed for the Oppenauer oxidation, as has a water-soluble Ir catalyst.<sup>134</sup> Homogeneous water-soluble complexes

catalyze the reaction.<sup>135</sup> An uncatalyzed reaction under supercritical conditions was reported.<sup>136</sup> A heterogeneous zirconia catalyst was used in a flow system (Sec. 7.D).<sup>137</sup> A Ru-NNN complex was used to catalyze Oppenauer oxidation of secondary alcohols.<sup>138</sup>

4. *DMSO-based reagents*. The use of oxalyl chloride and DMSO at low temperature is called the *Swern oxidation*<sup>139</sup> and is widely used. A sulfonium salt is produced *in situ*, which reacts with the alcohol to generate the key intermediate required for oxidation.<sup>140</sup> Maintaining the low reaction temperature is essential in this reaction, however, since the reagent generated *in situ* decomposes at temperatures significantly below ambient. Note that Swern oxidation of molecules having alcohol moieties, as well as a disulfide, leads to the carbonyl compound without oxidation of the sulfur.<sup>141</sup> Sulfoxides other than DMSO can be used in conjunction with oxalyl chloride for the oxidation of alcohols,<sup>142</sup> including fluorinated sulfoxides<sup>143</sup> and a polymer-bound sulfoxide.<sup>144</sup>

Similar oxidation of alcohols has been carried out with DMSO and other reagents<sup>145</sup> in place of DCC: acetic anhydride,<sup>146</sup> SO<sub>3</sub>/pyridine/triethylamine,<sup>147</sup> trifluoroacetic anhydride,<sup>148</sup> trimethylamine *N*-oxide,<sup>149</sup> and a Mo catalyst and O<sub>2</sub>.<sup>150</sup> Iodine has been used in conjunction with DMSO and hydrazine.<sup>151</sup> DMSO and polymer bromide has been used for the oxidation of alcohols.<sup>152</sup> An alcohol is treated with DMSO, DCC, and anhydrous phosphoric acid<sup>153</sup> in what is called *Moffatt oxidation*. In this way a primary alcohol can be converted to the aldehyde with no carboxylic acid being produced. The strong acid conditions are sometimes a problem, and complete removal of the dicyclohexylurea by-product can be difficult.<sup>154</sup> Oxidation of alcohols was reported using [methoxycarbonylsulfamoyl]triethylammonium hydroxide (*Burgess reagent*) in DMSO.<sup>155</sup>

<sup>155</sup> Sultane, P.R.; Bielawski, C.W. *J. Org. Chem.* **2017**, *82*, 1046.

5. *TEMPO and related reagents.* The nitroxyl radical TEMPO (**2**) has been used in conjunction with co-reagents, including mcpba,<sup>156</sup> O<sub>2</sub> with transition metal catalysts,<sup>157</sup> Cu/air,<sup>158</sup> CuBr•SMe<sub>2</sub> in perfluorinated solvents,<sup>159</sup> enzymes,<sup>160</sup> carbenes,<sup>161</sup> NaOCl,<sup>162</sup> Fe,<sup>163</sup> NaIO<sub>4</sub>,<sup>164</sup> periodic acid,<sup>165</sup> and H<sub>3</sub>IO<sub>6</sub>.<sup>166</sup>

Silica-supported TEMPO,<sup>167</sup> polymer-bound TEMPO,<sup>168</sup> and PEG-TEMPO<sup>169</sup> (where PEG is polyethylene glycol) have been used. TEMPO-derived ionic liquids,<sup>170</sup> or ionic liquid-supported TEMPO,<sup>171</sup> have been used for the oxidation of alcohols. An ionic liquid immobilized TEMPO reagent was developed for oxidation under solvent-free conditions<sup>172</sup> and a TEMPO-based ionic liquid has been developed.<sup>173</sup> A Cu/TEMPO catalyst system has been used for the aerobic oxidation of primary alcohols.<sup>174</sup> A catalytic reaction using 5% TEMPO and 5% CuCl with O<sub>2</sub> in an ionic liquid oxidizes benzylic alcohols to the corresponding aldehyde.<sup>175</sup> The Fe/9-azabicyclo[3.3.1]nonan-*N*-oxyl (ABNO)-catalyzed aerobic oxidation of alcohols gave aldehydes or ketones.<sup>176</sup>

Other nitroxyl radical oxidizing agents are known.<sup>177</sup> A related oxidizing agent is oxoammonium salt **3** (*Bobbitt's reagent*), a stable and nonhygroscopic salt that

oxidizes primary and secondary alcohols in dichloromethane.<sup>178</sup> The mechanism of oxidation for **3** has been examined.<sup>179</sup>

The chemoselective oxidation of benzylic alcohols was reported in the presence of aliphatic alcohols by reaction with a nitroxyl radical, and proceeded via an oxoammonium species.<sup>180</sup> The oxidative cleavage of allylic ethers by an oxoammonium salt was reported.<sup>181</sup> The oxidation of primary and secondary benzyl and alkyl alcohols to the carbonyl compound by the metal-free reaction with air, catalytic amounts of  $\text{NH}_4\text{NO}_3$ , 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO), and HCl or  $\text{H}_2\text{SO}_4$  has been reported.<sup>182</sup>

6. *With hypervalent iodine reagents.*<sup>183</sup> Treatment of 2-iodobenzoic acid with  $\text{KBrO}_3$  in sulfuric acid and heating the resulting product to  $100\text{ }^\circ\text{C}$  with acetic anhydride and acetic acid<sup>184</sup> gives hypervalent iodine reagent **4**, the so-called *Dess-Martin periodinane*.<sup>185</sup> This reagent reacts with alcohols at ambient temperature to give the corresponding aldehyde or ketone.<sup>186</sup> The reaction is accelerated by water<sup>187</sup> and a water-soluble periodinane (*o*-iodoxybenzoic acid, **5**, IBX)<sup>188</sup> has been prepared that oxidized allylic alcohols to conjugated aldehydes.<sup>189</sup>

<sup>189</sup> Thottumkara, A.P.; Vinod, T.K. *Tetrahedron Lett* **2001**, *43*, 569.

An ionic liquid-supported IBX reagent has been used,<sup>190</sup> as has a graphene oxide-supported reagent.<sup>191</sup> 2-Methylpropan-2-ol has been used as a solvent.<sup>192</sup> The reagent has an indefinite shelf life in a sealed container but hydrolysis occurs upon long-term exposure to atmospheric moisture. A note of CAUTION! The Dess-Martin reagent can be shock sensitive under some conditions and can explode at temperatures above 200 °C.<sup>193</sup>

Iodine has been used as a co-catalyst.<sup>194</sup> Other hypervalent iodine oxidizing reagents are known,<sup>195</sup> including PhI(OAc)<sub>2</sub>/TEMPO,<sup>196</sup> and PhI(OAc)<sub>2</sub>-chromium salen.<sup>197</sup> Microwave irradiation of benzylic alcohols with PhI(OH)OTs gave the corresponding aldehyde.<sup>198</sup> Hypervalent iodine compounds have been used in ionic liquids.<sup>199</sup> A recyclable, soluble polyisobutylene-bound oxidizing agent has been reported.<sup>200</sup> Heating benzylic alcohols with *o*-iodoxybenzoic acid under solvent-free conditions gave the aldehyde.<sup>201</sup> 2-Iodobenzenesulfonic acid is a very active catalyst for oxidation of alcohols using Oxone.<sup>202</sup>

7. *Tetrapropylammonium perruthenate* (Pr<sub>4</sub>N<sup>+</sup> RuO<sub>4</sub><sup>-</sup>; also called TPAP; the *Ley reagent*).<sup>203</sup> This is an important oxidizing agent that is compatible with the presence of other functionality in the molecule.<sup>204</sup> In the presence of molecular oxygen, oxidation of alcohols is catalytic in TPAP.<sup>205</sup> This reagent has been bound to a polymer.<sup>206</sup> Methods have been developed for recovery of the catalyst and reuse of TPAP.<sup>207</sup>
8. *By catalytic dehydrogenation*. For the conversion of primary alcohols to aldehydes, dehydrogenation catalysts have the advantage over strong oxidizing agents that further oxidation to the carboxylic acid is prevented. Copper chromite is often used, but other catalysts (e.g., Ag and Cu) have also been employed. Many ketones were prepared in this manner. Catalytic dehydrogenation is more often used industrially than as a laboratory method. However, procedures using Cu,<sup>208</sup> Rh,<sup>209</sup>

Ru,<sup>210</sup> Raney nickel,<sup>211</sup> and Pd complexes<sup>212</sup> (under phase-transfer conditions)<sup>213</sup> have been reported. Allylic alcohols<sup>214</sup> are oxidized to the corresponding saturated aldehyde or ketone by heating with a Rh catalyst, and benzylic alcohols are converted to the aldehyde with a Rh catalyst.<sup>215</sup> Propargylic alcohols are oxidized by heating with a V catalyst.<sup>216</sup> Secondary alcohols are oxidized with Bi(NO<sub>3</sub>)<sub>3</sub> on Montmorillonite.<sup>217</sup> Biooxidation is possible as well via hydrogen transfer.<sup>218</sup>

9. *Miscellaneous reagents.*<sup>219</sup> Enzymatic oxidations have been reported.<sup>220</sup> Dimethyl dioxirane<sup>221</sup> oxidizes benzylic alcohols to the corresponding aldehyde,<sup>222</sup> and dioxirane reagents are sufficiently mild that an  $\alpha,\beta$ -epoxy alcohol was oxidized to the corresponding ketone, without disturbing the epoxide, using methyl trifluoromethyl dioxirane.<sup>223</sup>

The oxidation of benzylic alcohols to aldehydes or ketones used H<sub>2</sub>O<sub>2</sub> with a catalytic amount of Br<sup>-</sup> and acid in a continuous-flow system (Sec. 7.D).<sup>224</sup> Nitric acid in dichloromethane oxidizes benzylic alcohols to the corresponding ketone.<sup>225</sup> Bromine is an effective oxidant, and iodine under photochemical conditions has been used.<sup>226</sup> Heating a 1,2-diol with NBS in CCl<sub>4</sub> gave the 1,2-diketone,<sup>227</sup> as did an iron nitrite oxidant with microwave irradiation.<sup>228</sup> The Pd/Cu-catalyzed oxidation of alkynes to 1,2-diketones used DMSO as a solvent.<sup>229</sup> A V/air catalyst was used for the oxidation of benzyl alcohols.<sup>230</sup> Oxidation of alcohols in water is

#### 19-4 Oxidation of Phenols and Aromatic Amines to Quinones

Ortho and para diols are easily oxidized to ortho- and para-quinones, respectively.<sup>302</sup> Either or both OH groups can be replaced by NH<sub>2</sub> groups to give the same products, although for the preparation of ortho-quinones, the presence of only OH groups is usually satisfactory. The reaction has been successfully carried out with other groups para to OH or NH<sub>2</sub>: halogen, OR, Me, *t*-Bu, and even H, although yields are poor with the latter. Many oxidizing agents have been used: acid dichromate,<sup>303</sup> silver oxide, silver carbonate, lead tetraacetate, HIO<sub>4</sub>, NBS/H<sub>2</sub>O/H<sub>2</sub>SO<sub>4</sub>,<sup>304</sup> dimethyl dioxirane,<sup>305</sup> and atmospheric oxygen.<sup>306</sup> Oxidation has been done photochemically with O<sub>2</sub> and tetraphenylporphine.<sup>307</sup> The oxidation of hydroquinones to quinones has been reported via reaction with a silica gel-supported Ce(NH<sub>4</sub>)<sub>2</sub>(NO<sub>3</sub>)<sub>6</sub>/NaBrO<sub>3</sub> reagent.<sup>308</sup> Chlorine dioxide has been used for the oxidation of phenols.<sup>309</sup>

A particularly effective reagent for rings with only one OH or NH<sub>2</sub> group is (KSO<sub>3</sub>)<sub>2</sub>N—O• (dipotassium nitrosodisulfonate; *Fremy's salt*), which is a stable free radical.<sup>310</sup> A mixture of 4-iodophenoxyacetic acid and Oxone is an effective catalyst for the oxidation of *p*-alkoxyphenols to *p*-quinones.<sup>311</sup> A supported iron phthalocyanine facilitates the aromatic oxidation of phenols.<sup>312</sup>

Less is known about the mechanism than is the case for oxidizing simple alcohols in **19-3**, and it seems to vary with the oxidizing agent. For oxidation of catechol with  $\text{NaIO}_4$ , it was found that the reaction conducted in  $\text{H}_2^{18}\text{O}$  gave unlabeled quinone,<sup>313</sup> possibly via an  $\text{IO}_3$  coordination complex with one OH group of the catechol (category 4, Sec. 19.A). When catechol was oxidized with  $\text{MnO}_4^-$  under aprotic conditions, a semiquinone radical ion intermediate was involved.<sup>314</sup> For autoxidations<sup>315</sup> (i.e., with atmospheric  $\text{O}_2$ ) a free-radical mechanism is known to operate.<sup>316</sup>

### 19-5 Dehydrogenation of Amines or Amides to Nitriles or Imines

Primary amines on a primary carbon can be dehydrogenated to nitriles. The reaction has been carried out with a variety of reagents, among others,  $\text{I}_2$  in aqueous  $\text{NH}_3$ ,<sup>317</sup> iodoxybenzoic acid (IBX, see **19-3**),<sup>318</sup>  $\text{NaOCl}$ ,<sup>319</sup>  $\text{TiCl}_4$ ,<sup>320</sup>  $\text{Co}_3\text{O}_4$ ,<sup>321</sup> nicotinium dichromate,<sup>322</sup> and  $\text{Ru}/\text{Al}_2\text{O}_3/\text{O}_2$ .<sup>323</sup> Iodine and 1,3-diiodo-5,5-dimethylhydantoin in aqueous ammonia converted both amines and alcohols to nitriles.<sup>324</sup> Dehydrogenation of amines has been done in aqueous micelles.<sup>325</sup>

The  $\text{NNN}/\text{Ru}(\text{II})$  hydride-catalyzed dehydrogenation of primary and secondary amines to give the corresponding nitriles and imines liberates dihydrogen.<sup>326</sup> An oxoammonium salt was used to oxidize primary amines to nitriles.<sup>327</sup> The reaction of DL-threonine with salicylaldehyde to give corresponding Schiff base and subsequent complexation with Fe provided an ionic liquid that functioned as a green catalyst for solvent-free aerobic oxidation of amines to nitriles.<sup>328</sup> The use of a V complex catalyst in an ionic liquid converted an amine to a nitrile, as did a Cu catalyst with hydrogen peroxide in water, or a photoinduced oxidation using oxygen in the presence of a zinc/chlorine complex catalyst.<sup>329</sup> Methyl arenes were converted to aryl nitriles by reaction with a Pd/*N*-hydroxyphthalimide catalyst and *tert*-butyl nitrite.<sup>330</sup> The U-<sup>331</sup> or Zn<sup>332</sup>-catalyzed dehydration of primary

amides gave nitriles. Aldoximes and primary amides were converted to nitriles by reaction with oxalyl chloride, using cyclopropanone as an organocatalyst.<sup>333</sup> The *in situ*-generated Burgess-type reagent was used to convert amides or oximes to the nitrile.<sup>334</sup> Oximes were converted to nitriles by reaction with a phosphonium salt catalyst.<sup>335</sup> A Lewis acid ionic liquid was also used to convert aldoximes to nitriles.<sup>336</sup> An Fe-catalyzed dehydration has also been reported,<sup>337</sup> and PCC has been used to prepare nitriles.<sup>338</sup> A Ru(OH)<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst converted primary azides, including benzylic, allylic, and aliphatic, to the corresponding nitriles.<sup>339</sup> Primary azides were oxidized to nitriles and secondary azides were oxidized to ketones with bis(*tert*-butylperoxy)iodobenzene, generated *in situ* by the reaction of diacetoxyl iodobenzene (DIB) with *tert*-butyl hydroperoxide.<sup>340</sup> Aldoximes and primary amides were converted to nitriles by reaction with XtalFluor-E.<sup>341</sup> Oximes of aromatic aldehydes are converted to aryl nitriles with InCl<sub>3</sub>.<sup>342</sup> Note that ketoximes give a *Beckmann rearrangement*, 18-17.

Several methods have been reported for the dehydrogenation of secondary amines to imines.<sup>343</sup> Among them<sup>344</sup> are (i) treatment with iodobenzene (PhIO) alone or in the presence of a Ru complex,<sup>345</sup> (ii) treatment with DMSO and oxalyl chloride,<sup>346</sup> and (iii) treatment with *t*-BuOOH and a Rh catalyst.<sup>347</sup> *N*-Tosyl aziridines are converted to *N*-tosyl imines when heated with a Pd catalyst.<sup>348</sup> Benzyl amines were oxidized to the imine by heating with H<sub>2</sub>O<sub>2</sub>.<sup>349</sup> A Cu-catalyzed oxidation of amines to imines used H<sub>2</sub>O<sub>2</sub> in water,<sup>350</sup> and a Cu/TEMPO aerobic oxidation was reported.<sup>351</sup> The reaction of 4-*tert*-butyl-2-hydroxybenzoquinone and O<sub>2</sub> selectively oxidized primary benzylic amines to the corresponding imine.<sup>352</sup> The aerobic photocatalytic reaction of amines on TiO<sub>2</sub> gives the corresponding imine.<sup>353</sup>

*N,N'*-Diarylhydrazines (hydrazo compounds) are oxidized to azo compounds by several oxidizing agents, including NaOBr,  $K_3Fe(CN)_6$  under phase-transfer conditions,<sup>354</sup>  $FeCl_3$ ,<sup>355</sup>  $MnO_2$  (this reagent yields *cis*-azobenzenes),<sup>356</sup>  $CuCl_2$ , and air and NaOH.<sup>357</sup> The reaction is also applicable to *N,N'*-dialkyl- and *N,N'*-diacylhydrazines. Hydrazines (both alkyl and aryl) substituted on only one side also give azo compounds,  $Ar-N=NH$ ,<sup>358</sup> but these are unstable and decompose to nitrogen and the hydrocarbon,  $ArH$ . Aniline derivatives are converted to azo compounds by heating with cetyltrimethylammonium dichromate in chloroform.<sup>359</sup> When hydrazones are oxidized with  $HgO$ ,  $Ag_2O$ ,  $MnO_2$ ,  $PbO_4$ , or certain other oxidizing agents, diazo compounds are obtained ( $R_2C=N-NH_2 \rightarrow R_2C=N^+=N^-$ ).<sup>360</sup>

Hydrazones of the form  $ArCH=NNH_2$  react with  $HgO$  in solvents, such as diglyme or ethanol, to give nitriles  $ArCN$ .<sup>361</sup> It is possible to oxidize dimethylhydrazones ( $R-C=N-NMe_2$ ) to the corresponding nitrile ( $R-C\equiv N$ ) with magnesium monoperoxyphthalate (MMPP),<sup>362</sup> or with dimethyl dioxirane.<sup>363</sup> Oxone on wet alumina also converts hydrazones to nitriles with microwave irradiation.<sup>364</sup>

The reaction of  $\alpha,\beta$ -unsaturated oximes and diaryliodonium salts with KOH gave  $\alpha,\beta$ -unsaturated *N*-aryl ketonitrone.<sup>365</sup> A nanoporous Au catalyst was used for the aerobic oxidation of hydroxylamines to nitrones.<sup>366</sup> Hypervalent iodine compounds oxidized *N,N*-disubstituted hydroxylamines to the corresponding nitrone.<sup>367</sup>

In a related reaction, primary aromatic amines have been oxidized to azo compounds by a variety of oxidizing agents, among them  $BaMnO_4$ ,<sup>368</sup>  $MnO_2$ , lead tetraacetate,  $O_2$  and a base, and sodium perborate in acetic acid. *tert*-Butyl hydroperoxide has been used to oxidize certain primary amines to azoxy compounds.<sup>369</sup>

Nitrones,  $C=N^+(R)-O^-$ , are generated by the oxidation of *N*-hydroxyl secondary amines with 5% aqueous NaOCl.<sup>370</sup> Secondary amines, such as dibenzylamine, can be converted to the corresponding nitrone by heating with cumyl hydroperoxide in the presence of a titanium catalyst.<sup>371</sup>

## B. Oxidations Involving Cleavage of Carbon-Carbon Bonds<sup>372</sup>

### 19-7 Oxidative Cleavage of Glycols and Related Compounds

1,2-Diols (glycols) are easily cleaved under mild conditions and in good yield with periodic acid or lead tetraacetate.<sup>373</sup> The reaction generates 2 molar equivalents of aldehyde, or 2 molar equivalents of ketone, or 1 molar equivalent of each, depending on the groups attached to the two carbons. The yields are so good that alkenes are often converted to diols (**15-44**) and then cleaved with  $\text{HIO}_4$  or  $\text{Pb(OAc)}_4$ , rather than being cleaved directly with ozone (**19-9**), dichromate, or permanganate (**19-10**). The diol can be generated from an alkene and cleaved *in situ* to give the carbonyl compounds.<sup>374</sup> A number of other oxidizing agents also give the same products, among them<sup>375</sup> aqueous sodium hypochlorite ( $\text{NaOCl}$ ),<sup>376</sup> activated  $\text{MnO}_2$ ,<sup>377</sup>  $\text{O}_2$  and a Ru catalyst,<sup>378</sup> and pyridinium chlorochromate (PCC).<sup>379</sup> Permanganate, dichromate, and several other oxidizing agents<sup>380</sup> also cleave glycols, giving carboxylic acids rather than aldehydes, but these reagents are seldom used synthetically. The two reagents (periodic acid and lead tetraacetate) are complementary, since periodic acid is best used in water and lead tetraacetate in organic solvents.

The use of a catalytic amount of 1-Me-nitroxyl radical 2-azaadamantane *N*-oxyls with  $\text{NaOCl}$  and  $\text{NaClO}_2$  gave the oxidative cleavage of terminal 1,2-diols to carboxylic acids that are one carbon unit shorter.<sup>381</sup> Nitroxyl radical and  $\text{PhI(OAc)}_2$  has also been used for the cleavage of vicinal diols to give carboxylic acids.<sup>382</sup> The  $\text{NaO-}t\text{-Bu/O}_2$  oxidative cleavage of 1,2-diols to carboxylic acids has been reported.<sup>383</sup> The aerobic cleavage of vicinal diols to carboxylic acids used photoirradiation with a high-pressure mercury lamp and 2-chloroanthraquinone as an additive.<sup>384</sup>

Other compounds that contain oxygen atoms or nitrogen atoms on adjacent carbons undergo similar cleavage, including  $\beta$ -amino alcohols, 1,2-diamines,  $\alpha$ -hydroxy aldehydes,

$\alpha$ -hydroxy ketones,  $\alpha$ -diketones,  $\alpha$ -keto aldehydes, and glyoxals. Cyclic 1,2-diamines are cleaved to diketones with dimethyl dioxirane.<sup>385</sup>  $\alpha$ -Diketones and  $\alpha$ -hydroxy ketones are also cleaved by alkaline  $\text{H}_2\text{O}_2$ .<sup>386</sup>  $\text{HIO}_4$  has been used to cleave epoxides to aldehydes.<sup>387</sup>

$\alpha$ -Hydroxy acids and  $\alpha$ -keto acids are not cleaved by  $\text{HIO}_4$  but are cleaved by  $\text{NaIO}_4$  in methanol in the presence of a crown ether,<sup>388</sup>  $\text{Pb}(\text{OAc})_4$ , alkaline  $\text{H}_2\text{O}_2$ , and other reagents. These are oxidative decarboxylations.  $\alpha$ -Hydroxy acids give aldehydes or ketones, and  $\alpha$ -keto acids give carboxylic acids. Also see, **19-12** and **19-13**.

The mechanism of glycol oxidation with  $\text{Pb}(\text{OAc})_4$  was proposed by Criegee:<sup>389</sup>

This mechanism is supported by: (i) the kinetics are second order (first order in each reactant); (ii) added acetic acid retards the reaction (drives the equilibrium to the left); and (iii) *cis*-glycols react much more rapidly than *trans*-glycols.<sup>390</sup> The mechanism is similar for periodic acid, with a 1,1-dioxo-1 $\lambda^7$ ,2,5-iodadioxolan-1-ol intermediate.<sup>391</sup> However, the cyclic-intermediate mechanism cannot account for all glycol oxidations, since some glycols such as (4*a*,8*a*)-octahydronaphthalene-4*a*,8*a*-diol, with *trans*-OH units, cannot form such an ester but are nevertheless cleaved by lead tetraacetate to give cyclodecane-1,6-dione (although other glycols that cannot form cyclic esters are *not* cleaved, by either reagent<sup>392</sup>). To account for such cases, a cyclic transition state has been proposed.<sup>390</sup>

Chiral lead carboxylates have been prepared for the oxidative cleavage of 1,2-diols.<sup>393</sup> When three or more OH groups are located on adjacent carbons, the middle one (or ones) is converted to formic acid.

OS IV, 124; VII, 185; VIII, 396.

Oxidative cleavage of open-chain ketones or alcohols<sup>394</sup> is seldom useful, not because these compounds do not undergo oxidation (they do, except for diaryl ketones), but because the result is generally a hopeless mixture. Aryl methyl ketones, such as acetophenone, however, are readily oxidized to aryl carboxylic acids with  $\text{Re}_2\text{O}_7$  and 70% aqueous *tert*-butyl hydroperoxide.<sup>395</sup> Oxygen with a mixture of Mn and Co catalysts give similar oxidative cleavage,<sup>396</sup> as do hypervalent iodine compounds.<sup>397</sup> Aldehydes, such as  $\text{PhCH}_2\text{CHO}$ , are cleaved to benzaldehyde with phosphonium dichromate in refluxing acetonitrile.<sup>398</sup> 1,3-Diketones, such as 1,3-diphenyl-1,3-propanedione, are oxidatively cleaved with aqueous Oxone to give benzoic acid.<sup>399</sup> Cyclic  $\alpha$ -chloro ketones are cleaved to give an  $\alpha,\omega$ -functionalized compound (acetal ester) when treated with cerium(IV) sulfate tetrahydrate and  $\text{O}_2$ ,<sup>400</sup> and the corresponding secondary alcohols to the dicarboxylic acid in good yield. The formation of adipic acid from cyclohexanone (shown above) is an important industrial procedure. Dichromate in acidic media and permanganate are the most common oxidizing agents, although autoxidation (oxidation with atmospheric oxygen) in alkaline solution<sup>401</sup> and potassium superoxide under phase-transfer conditions<sup>402</sup> have also been used. *O* Silyl ketones have been cleaved to esters using electrolysis in alcohol solvents.<sup>403</sup>

Ynones were prepared by  $\text{O}=\text{C}-\text{C}$  cleavage of an aldehyde by reaction with hypervalent alkynyl iodides, a Au catalyst, and pyrrolidine.<sup>404</sup> The reaction of PCC with 4-keto-2-hydroxy esters gave 1,2-diketones via  $\text{C}-\text{C}$  bond cleavage.<sup>405</sup>  $\alpha$ -Keto esters and 1,2-diketones were prepared by oxidative cleavage of  $\beta$ -keto esters and 1,3-diketones, mediated by Oxone/aluminum trichloride.<sup>406</sup> Benzoines were oxidatively cleaved to benzoic acids using sodium hydride under an oxygen atmosphere.<sup>407</sup> Heating aromatic and heteroaromatic methyl ketones with  $\text{S}_2\text{Cl}_2$ ,  $\text{SO}_2\text{Cl}_2$ , and catalytic amounts of pyridine gave acyl chlorides.<sup>408</sup> The reaction of iodosylbenzene complexes with  $\text{HBF}_4$  led to oxidative cleavage of  $\alpha$ -aryl aldehydes to give chain-shortened carbonyl compounds and formaldehyde.<sup>409</sup> The oxidative  $\text{C}-\text{C}$  bond cleavage of aldehydes to give ketones used a ruthenium photoredox catalyst.<sup>410</sup>

Cyclic 1,3-diketones, which exist mainly in the mono-enolic form, can be cleaved with sodium periodate with loss of one carbon as  $\text{CO}_2$ , as in the oxidative cleavage of

### 19-9 Ozonolysis

When compounds containing double bonds are treated with ozone, usually at low temperatures, initial formation of a 1,2,3-trioxolane is followed by formation of compounds called 1,2,4-trioxolanes (*ozonides*, **6**). Ozonodides can be isolated but, because some of them are explosive, they are decomposed with Zn and acetic acid or catalytic hydrogenation, but more commonly with dimethyl sulfide,<sup>414</sup> to give 2 molar equivalents of aldehyde, or 2 molar equivalents of ketone, or 1 molar equivalent of each, depending on the groups attached to the original alkene.<sup>415</sup> The decomposition of **6** has also been carried out with triethylamine<sup>416</sup> and with reducing agents such as trimethyl phosphite<sup>417</sup> or thiourea.<sup>418</sup> However, ozonides can also be *oxidized* with oxygen, peroxyacids, or  $\text{H}_2\text{O}_2$  to give ketones and/or carboxylic acids. Note that the presence of a hydrogen atom on the  $\text{C}=\text{C}$  unit ( $\text{C}=\text{C}-\text{H}$ ) leads to differences in oxidation or reduction of **6**. In such a system, oxidation leads to the acid whereas reduction leads to the aldehyde. It is also possible to reduce **6** with  $\text{LiAlH}_4$ ,  $\text{NaBH}_4$ ,  $\text{BH}_3$ , or catalytic hydrogenation with excess  $\text{H}_2$  to give 2 molar equivalents of alcohol.<sup>419</sup> Ozonides can be treated with ammonia, hydrogen, and a catalyst to give the corresponding amines,<sup>420</sup> or with an alcohol and anhydrous HCl to give the corresponding carboxylic esters.<sup>421</sup> Ozonolysis is therefore an important synthetic reaction.<sup>422</sup>

Ozonolysis can be done in solvent/water mixtures.<sup>423</sup> A biphasic ozonolysis of alkenes has been reported using film shear flow reactor technology (Sec. 7.D).<sup>424</sup>

Many alkenes undergo ozonolysis, including cyclic alkenes. Alkenes in which the double bond is connected to electron-donating groups react many times faster than those in which the double bond is connected to electron-withdrawing groups.<sup>425</sup> Ozonolysis of compounds containing more than one double bond generally leads to cleavage of all the bonds. In some cases, especially when bulky groups are present, conversion of the substrate to an epoxide (15-46) becomes an important side reaction and can be the main reaction.<sup>426</sup> Rearrangement is possible in some cases.<sup>427</sup> Ozonolysis of triple bonds<sup>428</sup> is less common and the reaction proceeds less easily, since ozone is an electrophilic agent<sup>429</sup> and prefers double to triple bonds (Sec. 15.B.i). Compounds that contain triple bonds generally give carboxylic acids, although sometimes ozone oxidizes them to  $\alpha$ -diketones (19-26).

Aromatic compounds are attacked less readily than alkenes, but cleavage is known. Ozonolysis of benzene gives 3 molar equivalents of glyoxal (HCOCHO), and *o*-xylene gives a glyoxal/MeCOCHO/MeCOCOME ratio of 3:2:1, which shows that in this case cleavage is statistical. With polycyclic aromatic compounds the site of attack depends on the structure of the molecule and on the solvent.<sup>430</sup>

Although a large amount of work has been done on the mechanism of ozonolysis (formation of 6), not all the details are known. Note that a primary ozonide has been trapped.<sup>431</sup> Criegee formulated the basic mechanism.<sup>432</sup> The first step of the *Criegee mechanism*<sup>433</sup> is a 1,3-dipolar addition (15-54) of ozone to the substrate to give a 1,2,3-trioxolane 7, identified by microwave and other spectral methods.<sup>434</sup> However, 7 is highly unstable and cleaves to an aldehyde or ketone and an intermediate<sup>435</sup> that Criegee showed as a zwitterion (8)<sup>436</sup> but which may be a diradical (9).<sup>437</sup>

This intermediate is usually referred to as a carbonyl oxide.<sup>438</sup> The carbonyl oxide (**8**) can then undergo various reactions, three of which lead to normal products. One is a recombination with the aldehyde or ketone, which leads to the ozonide. The second is a dimerization to the bis(peroxide) **10**, and the third a kind of dimerization to **11**.<sup>439</sup>

If the first path is taken (this is normally possible only if an aldehyde is formed; most ketones do not do this)<sup>440</sup> the product is an ozonide (see 1,2,4-trioxolane **6**),<sup>441</sup> and hydrolysis of the ozonide gives the normal products. If **10** is formed, hydrolysis of it gives one of the products, and, of course, the carbonyl compound (which then does not undergo further reaction), is the other. If intermediate **11** is formed, direct decomposition is possible, as shown, to give the normal products and oxygen. In protic solvents, **8** is converted to a hydroperoxide, and these have been isolated; for example,  $\text{Me}_2\text{C}(\text{OMe})\text{OOH}$  from  $\text{Me}_2\text{C}=\text{CMe}_2$  in methanol. Further evidence for the mechanism is that **10** can be isolated in some cases; for example, from  $\text{Me}_2\text{C}=\text{CMe}_2$ . But perhaps the most impressive evidence comes from the detection of cross products. In the Criegee mechanism, the two parts of the original alkene break apart and then recombine to form the ozonide. In the case of an unsymmetrical alkene  $\text{RCH}=\text{CHR}'$  there should be three ozonides since there are two different aldehydes and two different species **8**, and these can recombine in three ways:  $\text{R}-\text{R}$ ,  $\text{R}-\text{R}'$ , and  $\text{R}'-\text{R}$ . Actually *six* ozonides, corresponding to the *cis* and *trans* forms, were isolated and characterized for methyl oleate.<sup>442</sup> Similar results have been reported for smaller alkenes, for example, pent-2-ene, non-4-ene, and even 2-methylpent-2-ene.<sup>443</sup> The last-mentioned case is especially interesting, since it is quite plausible that this compound would cleave in only one way, so that only one ozonide (in *cis* and *trans* versions) would be found; but this is not so, and three were found for this case too. However, terminal alkenes give little or no cross ozonide formation.<sup>444</sup> In general, the less alkylated end of the alkene tends to go to the carbonyl and the other to **8**. Still other evidence<sup>445</sup> for the Criegee mechanism is: (i) when  $\text{Me}_2\text{C}=\text{CMe}_2$  was ozonized in the presence of  $\text{HCHO}$ ,

<sup>444</sup> Murray, R.W.; Williams, G.J. *J. Org. Chem.* **1969**, 34, 1891.

<sup>445</sup> See Wojciechowski, B.J.; Chiang, C.; Kuczowski, R.L. *J. Org. Chem.* **1990**, 55, 1120; Murray, R.W.; Morgan, M.M. *J. Org. Chem.* **1991**, 56, 684, 6123.

the ozonide could be isolated;<sup>446</sup> (ii) **8** prepared in an entirely different manner (photooxidation of diazo compounds), reacted with aldehydes to give ozonides;<sup>447</sup> and (iii) *cis* and *trans* alkenes generally give the same ozonide, which would be expected if they cleave first.<sup>448</sup> However, this was not true for Me<sub>3</sub>CCH=CHCMe<sub>3</sub>, where the *cis* alkene gave the *cis* ozonide (chiefly), and the *trans* alkene gave the *trans* ozonide.<sup>449</sup> The latter result is not compatible with the Criegee mechanism. Also incompatible with the Criegee mechanism was the finding that the *cis/trans* ratios of symmetrical (cross) ozonides obtained from *cis*- and *trans*-4-methylpent-2-ene were not the same.<sup>450</sup> If the Criegee mechanism operated as shown above, the *cis/trans* ratio for each of the two cross ozonides would have to be identical for the *cis* and *trans* alkenes, since in this mechanism they are completely cleaved. A discussion of highly oxidized multifunctional products for the ozonolysis of cyclohexene has been reported.<sup>451</sup>

The above stereochemical results have been explained<sup>452</sup> on the basis of the Criegee mechanism with the following refinements: (i) The formation of **7** is stereospecific, as expected from a 1,3-dipolar cycloaddition. (ii) Once formed, **8** and the aldehyde or ketone remain attracted to each other, much like an ion pair. (iii) Intermediate **8** exists in *syn* and *anti* forms, which are produced in different amounts and can hold their shapes, at least for a time. This is plausible if we remember that a C=O canonical form contributes to the structure. (iv) The combination of **8** and the aldehyde or ketone is also a 1,3-dipolar cycloaddition, so configuration is retained in this step too.<sup>453</sup>

Evidence that the basic Criegee mechanism operates even in these cases comes from <sup>18</sup>O labeling experiments, making use of the fact, mentioned above, that mixed ozonides (e.g., **8**) can be isolated when an external aldehyde is added. Both the normal and modified Criegee mechanisms predict that if <sup>18</sup>O-labeled aldehyde is added to the ozonolysis mixture, the label will appear in the ether oxygen, and this is what is found.<sup>454</sup> There is evidence that the *anti*-**8** (−O is *anti* to R') couples much more readily than the *syn*-**8** (−O is *syn* to R').<sup>455</sup>

The ozonolysis of ethylene<sup>456</sup> in the liquid phase (without a solvent) was shown to take place by the Criegee mechanism.<sup>457</sup> This reaction has been used to study the structure of

the dioxirane intermediate or a biradical ( $\bullet\text{CH}_2\text{—O—O}\bullet$ ). The dioxirane was identified in the reaction mixture<sup>458</sup> at low temperatures and is probably in equilibrium with the biradical. Dioxirane has been produced in solution but it oxidatively cleaves dialkyl ethers (e.g., Et—O—Et) via a chain radical process,<sup>459</sup> so the choice of solvent is important.

Ozonolysis in the gas phase is not generally carried out in the laboratory. However, the reaction is important because it takes place in the atmosphere and contributes to air pollution.<sup>460</sup> There is much evidence that the Criegee mechanism operates in the gas phase too, although the products are more complex because of other reactions that also take place.<sup>461</sup>

### 19-10 Oxidative Cleavage of Double Bonds and Aromatic Rings

Carbon-carbon double bonds can be cleaved by many oxidizing agents,<sup>462</sup> the most common of which are permanganate in neutral or acid media and dichromate in acid media. The products are generally 2 molar equivalents of ketone, 2 molar equivalents of carboxylic acid, or 1 molar equivalent of each, depending on what groups are attached to the alkene. With ordinary solutions of permanganate or dichromate yields are generally low, and the reaction is seldom a useful synthetic method; but high yields can be obtained by oxidizing with  $\text{KMnO}_4$  dissolved in benzene containing the crown ether dicyclohexano-18-crown-6 (Sec. 3.C.ii).<sup>463</sup> The crown ether coordinates with  $\text{K}^+$ , permitting the  $\text{KMnO}_4$  to dissolve in benzene. Another reagent frequently used for synthetic purposes is the *Lemieux-von Rudloff reagent*, which is  $\text{HIO}_4$  containing a trace of  $\text{MnO}_4^-$ .<sup>464</sup> The  $\text{MnO}_4^-$  is the actual oxidizing agent, being reduced to the manganate stage ( $\text{MnO}_4^{2-}$ ), and the purpose of the  $\text{HIO}_4$  is to reoxidize the manganate(VI) back to  $\text{MnO}_4^-$ . Another reagent that behaves similarly is  $\text{NaIO}_4$ /ruthenium tetroxide.<sup>465</sup> Oxidative cleavage of alkenes is catalyzed by Ru with  $\text{IO}(\text{OH})_5$ .<sup>466</sup> Cyclic alkenes are cleaved to dialdehydes with  $\text{KMnO}_4 \cdot \text{CuSO}_4$  in dichloromethane.<sup>467</sup>

<sup>467</sup> Göksu, S.; Altundaş, R.; Sütbeyaz, Y. *Synth. Commun.* **2000**, *30*, 1615.

The *Barbier-Wieland procedure* for decreasing the length of a chain by one carbon involves oxidative cleavage by acid dichromate ( $\text{NaIO}_4/\text{RuO}_4$  has also been used), but this is cleavage of a 1,1-diphenyl alkene, which generally gives good yields.

Addition of a catalytic amount of  $\text{OsO}_4$  to *Jones reagent* (**19-3**) leads to good yields of the carboxylic acid from simple alkenes.<sup>468</sup> A combination of Oxone<sup>®</sup> and  $\text{OsO}_4$  in DMF cleaves alkenes to carboxylic acids.<sup>469</sup> Cleavage of alkynes is generally rather difficult, but treatment of internal alkynes with an excess of Oxone with a Ru catalyst leads to aliphatic carboxylic acids.<sup>470</sup>

With certain reagents, the oxidation of double bonds can be stopped at the aldehyde stage, and in these cases the products are the same as in the ozonolysis procedure. Among these reagents are *tert*-butyl iodoxybenzene<sup>471</sup> and  $\text{NaIO}_4/\text{OsO}_4$ .<sup>472</sup> Enol ethers,  $\text{RC}(\text{OR}')=\text{CH}_2$ , have been cleaved to carboxylic esters  $\text{RC}(\text{OR}')=\text{O}$  by atmospheric oxygen.<sup>473</sup> Oxidative cleavage of alkenes is catalyzed by a Mn/porphyrin complex.<sup>474</sup>

The mechanism of oxidation in most cases probably involves the initial formation of a glycol (**15-25**) or cyclic ester,<sup>475</sup> and then further oxidation as in **19-7**.<sup>476</sup> In line with the electrophilic attack on the alkene, triple bonds are more resistant to oxidation than double bonds. Terminal triple-bond compounds can be cleaved to carboxylic acids with  $\text{Ti}(\text{III})\text{NO}_3$ <sup>477</sup> or with [bis(trifluoroacetoxy)iodo]pentafluorobenzene [i.e.,  $\text{C}_6\text{F}_5\text{I}(\text{OCOCF}_3)_2$ ].<sup>478</sup>

Other methods have been developed for the oxidative cleavage of alkenes to give carbonyl derivatives. The *N*-hydroxyphthalimide-catalyzed oxidative cleavage of alkenes using  $\text{O}_2$  as an oxidant gave the carbonyl derivatives.<sup>479</sup> Oxidative cleavage of  $\text{C}=\text{C}$  double bonds with a phenyl substituent by reaction with iodosylbenzene gave carbonyl compounds via a radical pathway.<sup>480</sup> When heating an alkene with Oxone in an acetonitrile/water mixture, the alkenes underwent oxidative cleavage to the corresponding acids.<sup>481</sup> Heating alkenes with an organoselenium catalyst alkene in ethanol with hydrogen peroxide gave

carbonyl compounds.<sup>482</sup> A Ru catalyst with an *N*-heterocyclic carbene ligand oxidatively cleaved C=C bonds to aldehydes and C≡C bonds to α-diketones.<sup>483</sup> The oxidative cleavage of alkenes with PhI(OAc)<sub>2</sub> and ammonium hydrogen carbonate gave the nitrile.<sup>484</sup>

Aromatic rings can be cleaved with sufficiently strong oxidizing agents. An important laboratory reagent for this purpose is RuO<sub>4</sub>, along with a co-oxidant such as NaIO<sub>4</sub> or NaOCl (household bleach can be used). Ruthenium tetroxide is an expensive reagent, but the cost can be greatly reduced by the use of an inexpensive co-oxidant such as NaOCl, the function of which is to oxidize RuO<sub>2</sub> back to ruthenium tetroxide. Examples<sup>485</sup> are the oxidation of naphthalene to phthalic acid<sup>486</sup> and, even more remarkably, of cyclohexylbenzene to cyclohexanecarboxylic acid.<sup>487</sup> The latter conversion was also accomplished with ozone.<sup>488</sup> Another reagent that oxidizes aromatic rings is air catalyzed by V<sub>2</sub>O<sub>5</sub>. The oxidations of naphthalene to phthalic anhydride and of benzene to maleic anhydride by this reagent are important industrial procedures.<sup>489</sup> *o*-Diamines have been oxidized to hexa-2,4-dienedinitrile with nickel peroxide, with lead tetraacetate,<sup>490</sup> and with O<sub>2</sub> catalyzed by CuCl.<sup>491</sup> The latter reagent also cleaves *o*-dihydroxybenzenes (catechols) to give, in the presence of MeOH, the mono-methylated dicarboxylic acids HO<sub>2</sub>C–C=C–C=C–CO<sub>2</sub>Me.<sup>492</sup>

### 19-11 Oxidation of Aromatic Side Chains

Alkyl chains on aromatic rings can be oxidized to CO<sub>2</sub>H groups by many oxidizing agents, including permanganate, nitric acid, and acid dichromate.<sup>493</sup> The method is most often applied to the methyl group (CH<sub>3</sub> → CO<sub>2</sub>H), although longer side chains can also be cleaved. Tertiary alkyl groups are resistant to oxidation, and when they *are* oxidized, ring cleavage usually occurs too.<sup>494</sup> It is usually difficult to oxidize an R group on a fused aromatic system without cleaving the ring or oxidizing it to a quinone (**19-19**). However, such oxidation has been done (e.g., 2-methylnaphthalene was converted to 2-naphthoic acid)

with aqueous  $\text{Na}_2\text{Cr}_2\text{O}_7$ .<sup>495</sup> Aryl methyl groups are oxidized to aryl  $\text{CO}_2\text{H}$  with  $\text{NaOCl}$  in acetonitrile,<sup>496</sup> or with  $\text{NBS}$  in aqueous  $\text{NaOH}$  under photochemical conditions.<sup>497</sup> Functional groups can be present anywhere on the side chain and, if in the  $\alpha$  position, greatly increase the ease of oxidation. An exception is an  $\alpha$ -phenyl group. In such cases, the reaction stops at the diaryl ketone stage. Molecules containing aryl groups on different carbons cleave so that each ring gets one carbon atom, as in the cleavage of the 9,10 bond of dihydrophenanthrene to the diacid.

It is possible to oxidize only one alkyl group of a ring that contains more than one. The order of reactivity<sup>498</sup> toward most reagents is  $\text{CH}_2\text{Ar} > \text{CHR}_2 > \text{CH}_2\text{R} > \text{CH}_3$ .<sup>499</sup> Groups on the ring susceptible to oxidation ( $\text{OH}$ ,  $\text{NHR}$ ,  $\text{NH}_2$ , etc.) must be protected. The oxidation can be performed with oxygen, in which case it is autoxidation, and the mechanism is like that in **14-6**, with a hydroperoxide intermediate.<sup>500</sup> With this procedure it is possible to isolate ketones from  $\text{ArCH}_2\text{R}$ .<sup>501</sup>

The mechanism has been studied for the closely related reaction:<sup>502</sup>

A deuterium isotope effect of 6.4 was found, indicating that the rate-determining step is either  $\text{Ar}_2\text{CH}_2 \rightarrow \text{Ar}_2\text{CH}\cdot$  or  $\text{Ar}_2\text{CH}_2 \rightarrow \text{Ar}_2\text{CH}^+$ . Either way this explains why tertiary groups are not converted to  $\text{CO}_2\text{H}$  and why the reactivity order is  $\text{CHR}_2 > \text{CH}_2\text{R} > \text{CH}_3$ , as mentioned above. Both free radicals and carbocations exhibit this order of stability (Chapter 5). Just how the radical or the cation goes on to the product is not known.

When the alkyl group is oxidizable to  $\text{CO}_2\text{H}$  (**19-11**), cupric salts are oxidizing agents, and the  $\text{OH}$  group is found in a position *ortho* to that occupied by the alkyl group.<sup>503</sup> This reaction is used industrially to convert toluene to phenol.

In another kind of reaction, an aromatic aldehyde  $\text{ArCHO}$  or ketone  $\text{ArCOR}'$  is converted to a phenol  $\text{ArOH}$  on treatment with alkaline  $\text{H}_2\text{O}_2$ ,<sup>504</sup> but there must be an  $\text{OH}$  or  $\text{NH}_2$  group in the *ortho* or *para* position. This is called the *Dakin reaction*.<sup>505</sup> The mechanism may be similar to that of the *Baeyer-Villiger reaction* (**18-19**),<sup>506</sup> and an acetate intermediate has been isolated.<sup>507</sup> The reaction has been performed on aromatic aldehydes with an alkoxy group in the ring, and no  $\text{OH}$  or  $\text{NH}_2$ . In this case, acidic  $\text{H}_2\text{O}_2$  was used.<sup>508</sup> The Dakin

## 19-12 Oxidative Decarboxylation

Carboxylic acids can be decarboxylated<sup>511</sup> with lead tetraacetate to give a variety of products: an ester ROAc, the alkane RH (see **12-39**), an alkene if  $\alpha,\beta$  hydrogens are present, as well as numerous other products arising from rearrangements, internal cyclizations,<sup>512</sup> and reactions with solvent molecules. When R is tertiary, the chief product is usually the alkene. High yields of alkenes can also be obtained when R is primary or secondary using  $\text{Cu(OAc)}_2$  along with the  $\text{Pb(OAc)}_4$ .<sup>513</sup> In the absence of  $\text{Cu(OAc)}_2$ , primary acids give mostly alkanes (though yields are generally low) and secondary acids may give carboxylic esters or alkenes. Other oxidizing agents,<sup>514</sup> including Co(III), Ag(II), Mn(III), and Ce(IV), have also been used to effect oxidative decarboxylation.<sup>515</sup>

The mechanism with lead tetraacetate is generally accepted to be of the free-radical type.<sup>516</sup> First, there is an interchange of ester groups. A free-radical chain mechanism follows. (Other lead esters can behave similarly.) Products can then be formed either from  $\text{R}\cdot$  or  $\text{R}^+$ . Primary  $\text{R}\cdot$  abstract H from solvent molecules to give RH. The  $\text{R}^+$  can lose  $\text{H}^+$  to give an alkene, react with HOAc to give the carboxylic ester, react with solvent molecules or with another functional group in the same molecule, or rearrange, thus accounting for the large number of possible products. The radical  $\text{R}\cdot$  can also dimerize to give RR. The effect of  $\text{Cu}^{2+}$  ions<sup>517</sup> is to oxidize the radicals to alkenes, thus producing good yields of alkenes from primary and secondary substrates. The  $\text{Cu}^{2+}$  ion has no effect on tertiary radicals, which are efficiently oxidized to alkenes by lead tetraacetate.

In another type of oxidative decarboxylation, aryl acetic acids can be oxidized to aldehydes with one less carbon ( $\text{ArCH}_2\text{COOH} \rightarrow \text{ArCHO}$ ) by tetrabutylammonium

periodate.<sup>518</sup> Simple aliphatic carboxylic acids were converted to nitriles with one less carbon ( $\text{RCH}_2\text{COOH} \rightarrow \text{RC}\equiv\text{N}$ ) by treatment with trifluoroacetic anhydride and  $\text{NaNO}_2$  in  $\text{F}_3\text{CCO}_2\text{H}$ .<sup>519</sup>

### 19-13 Bis(decarboxylation)

Compounds containing carboxyl groups on adjacent carbons (succinic acid derivatives) can be bis(decarboxylated) with lead tetraacetate in the presence of  $\text{O}_2$ .<sup>509</sup> The reaction is of wide scope. The elimination is stereoselective, but not stereospecific (both *meso*- and *dl*-2,3-diphenylsuccinic acid gave *trans*-stilbene);<sup>520</sup> a concerted mechanism is thus unlikely. Replacement of OAc of lead tetraacetate with a  $\text{O}_2\text{CR}$  unit of the diacid, followed by loss of the lead moiety to give a carbocation, and decarboxylation to give the alkene is compatible with the data. A free-radical mechanism seems to hold in some cases. Bis(decarboxylation) of succinic acid derivatives give alkenes.<sup>521</sup> Compounds containing geminal carboxyl groups (disubstituted malonic acid derivatives) can be bis(decarboxylated) with lead tetraacetate<sup>522</sup> and *gem*-diacetates (acylals) are produced, which are easily hydrolyzable to ketones.<sup>523</sup>

A related reaction involves  $\alpha$ -substituted aryl nitriles having a sufficiently acidic  $\alpha$  hydrogen, which can be converted to ketones by oxidation with air under phase-transfer conditions.<sup>524</sup> The nitrile is added to  $\text{NaOH}$  in benzene or DMSO containing a catalytic amount of triethylbenzylammonium chloride (TEBA).<sup>525</sup> This reaction could not be applied to aliphatic nitriles, but an indirect method for achieving this conversion is given in 19-65.

## C. Reactions Involving Replacement of Hydrogen by Heteroatoms

### 19-14 Hydroxylation at an Aliphatic Carbon

Compounds containing susceptible C–H bonds can be oxidized to alcohols (C–OH).<sup>526</sup> Nearly always, the C–H bond involved is tertiary, so the product is a tertiary alcohol. This is

<sup>518</sup> Santaniello, E.; Ponti, F.; Manzocchi, A. *Tetrahedron Lett.* **1980**, 21, 2655. Also see Doleschall, G.; Tóth, G. *Tetrahedron* **1980**, 36, 1649.

partly because tertiary C–H bonds are more susceptible to free-radical attack than primary and secondary bonds and partly because the reagents involved would oxidize primary and secondary alcohols further. An arcane method is the reaction with ozone and the substrate is absorbed on silica gel.<sup>527</sup> Yields as high as 99% have been obtained by this method. Other reagents are chromic acid,<sup>528</sup> RuO<sub>4</sub>,<sup>529</sup> thallium acetate,<sup>530</sup> sodium chlorite (NaClO<sub>2</sub>) with a metalloporphyrin catalyst,<sup>531</sup> and OsO<sub>4</sub>.<sup>532</sup> Alkanes and cycloalkanes have been oxidized at secondary positions, to a mixture of alcohols and trifluoroacetates, by 30% aqueous H<sub>2</sub>O<sub>2</sub> in trifluoroacetic acid.<sup>533</sup> This reagent does not oxidize the alcohols further and ketones are not found. The ω – 1 position is the most favored. Use of an optically active Fe(III)/porphyrin gave modest enantioselective hydroxylation.<sup>534</sup>

When chromic acid is the reagent, the mechanism is probably as follows: a Cr<sup>6+</sup> species abstracts a hydrogen to give R<sub>3</sub>C•, which is held in a solvent cage near the resulting Cr<sup>5+</sup> species. The two species then combine to give R<sub>3</sub>COCr<sup>4+</sup>, which is hydrolyzed to the alcohol. This mechanism predicts retention of configuration; this is largely observed.<sup>535</sup> The oxidation by permanganate also involves predominant retention of configuration, and a similar mechanism has been proposed.<sup>536</sup>

Hydroxylation can be accomplished using enzymatic systems. In the presence of *Bacillus megaterium* and oxygen, cyclohexane is converted to cyclohexanol.<sup>537</sup> Allylic oxidation to an allylic alcohol was accomplished with cultured cells of *Gossypium hirsutum*.<sup>538</sup> The reaction of tetradecanoic acid with the α-oxidase from *Pisum sativum*, in the presence of molecular oxygen, gives (2*R*)-hydroxytetradecanoic acid with high asymmetric induction.<sup>539</sup> Cyclodecane was oxidized to cyclodecanone by reaction with P450 monooxygenase BM-3 19A12 and then alcohol dehydrogenase from *L. kefir*., with 10% NADP<sup>+</sup> and oxygen.<sup>540</sup> The highly regio- and diastereoselective enzymatic hydroxylation of nonactivated disubstituted cyclohexane derivatives was catalyzed using wild-type P450-BM3.<sup>541</sup> The highly selective terminal hydroxylation of *gem*-difluorinated octanes by whole-cell catalysis using alkane hydroxylase derived from *Pseudomonas putida* Gpo1 gave *gem*-difluorinated octan-1-ols.<sup>542</sup> The fatty acid hydroxylase wild-type

P450BM3 is unable to oxidize gaseous alkanes unless a perfluorocarboxylic acid is added, in which case the P450BM3 catalytic cycle gave hydroxylation of butane and propane.<sup>543</sup> The terminal-selective cytochrome P450pyr has been successfully engineered through directed evolution for the hydroxylation of *n*-octane to (*S*)-octan-2-ol with excellent regio- and enantioselectivity.<sup>544</sup>

Hydroxylation of unactivated  $sp^3$ -hybridized bonds is possible using an oxaziridine-mediated, organocatalyzed reaction.<sup>545</sup> Hydrogen peroxide and trifluoroacetic acid has also been used for oxidation of alkanes.<sup>546</sup> The same type of conversion, with lower yields (20–30%), has been achieved with the *Gif system*.<sup>547</sup> One variation consists of pyridine/acetic acid, with  $H_2O_2$  as oxidizing agent and tris(picolinato)iron(III) as catalyst.<sup>548</sup> Other *Gif* systems use  $O_2$ <sup>549</sup> as oxidizing agent and Zn as a reductant.<sup>550</sup> The mechanism of oxygen insertion into alkanes has been examined.<sup>551</sup> The selectivity of the *Gif* systems toward alkyl carbons is  $CH_2 > CH \geq CH_3$ , which is unusual, and shows that a simple free-radical mechanism (Sec. 14.A.iv) is not involved.<sup>552</sup> Another reagent that can oxidize the  $CH_2$  of an alkane is methyl(trifluoromethyl)dioxirane, but this produces  $CH-OH$  more often than  $C-O$  (see **19-14**; **19-16**).<sup>553</sup> Cyclic alkanes are oxidized to a mixture of the alcohol and the ketone with  $Ph(OAc)_2$  and a manganese complex in an ionic liquid.<sup>554</sup> Oxidation of cyclic alkanes to cyclic ketones was accomplished using a Ru catalyst.<sup>555</sup> The iron/thymine-1-acetate system catalyzed conversion of alkanes to ketones.<sup>556</sup>

Oxidation of  $CH_2$  to  $C=O$  groups is possible indirectly, even if they are not near any functional groups, by the remote oxidation method of Breslow<sup>76</sup> (see **19-2**). Remote oxidations<sup>557</sup> have also been reported. Octan-2-ol was oxidized to give 2-propyl-5-methyl  $\gamma$ -butyrolactone with lead tetraacetate in a CO atmosphere.<sup>558</sup> Chloramine-T (see **15-50**),  $O_2$ , and an Fe catalyst give selective oxidation of hydrocarbons to ketones.<sup>559</sup>

Nanocrystalline cobalt oxide is another catalyst for alkane oxidation.<sup>560</sup> A tandem biocatalyst system of a monooxygenase-containing microorganism and an alcohol

### 19-15 Oxidation of Benzylic or Allylic Positions

Benzylic and allylic methylene groups are more readily oxidized to benzylic alcohols when compared to simple alkanes. Methyl groups on an aromatic ring can be oxidized to an aldehyde by several oxidizing agents.

When the reagent is chromyl chloride (CrO<sub>2</sub>Cl<sub>2</sub>), the reaction is called the *Étard reaction*<sup>572</sup> and the yields are high.<sup>573</sup> The mechanism of the *Étard reaction* is not completely

<sup>572</sup> The name *Étard reaction* is often applied to any oxidation with chromyl chloride, for example, oxidation of glycols (**19-7**), alkenes (**19-10**), etc.

<sup>573</sup> See Hartford, W.H.; Darrin, M. *Chem. Rev.* **1958**, 58, 1 (see pp. 25–53).

known.<sup>574</sup> An insoluble complex is formed on addition of the reagents, which is hydrolyzed to the aldehyde. The complex is probably a kind of acylal, but the identity of the structure is not fully settled, although many proposals have been made as to its structure and as to how it is hydrolyzed. It is known that  $\text{ArCH}_2\text{Cl}$  is not an intermediate (see **19-20**), since it reacts only very slowly with chromyl chloride. Magnetic susceptibility measurements<sup>575</sup> indicate that the complex from toluene is  $\text{PhCH}(\text{O}-\text{CrCl}_2\text{OH})_2$ , a structure first proposed by Étard. According to this proposal, the reaction stops after only two hydrogen atoms have been replaced because of the insolubility of the Cr complex. There is a disagreement on how the Cr complex is formed, assuming that the complex has this structure. Both ionic<sup>576</sup> and free-radical<sup>577</sup> processes have been proposed. An entirely different structure for the complex was proposed by Nenitzescu and co-workers.<sup>578</sup> On the basis of ESR studies they proposed that the complex is  $\text{PhCH}_2\text{OCrCl}_2\text{OCrCl}_2\text{OH}$ , which is isomeric with the other Cr complex. However, this view has been challenged by Wiberg and Eisenthal,<sup>577</sup> who interpret the ESR result as being in accord with  $\text{PhCH}(\text{O}-\text{CrCl}_2\text{OH})_2$ . Still another proposal is that the complex is composed of benzaldehyde coordinated with reduced chromyl chloride.<sup>579</sup>

Another oxidizing agent is a mixture of  $\text{CrO}_3$  and  $\text{Ac}_2\text{O}$ , where the reaction stops at the aldehyde stage because the initial product is  $\text{ArCH}(\text{OAc})_2$  (an acylal), which is resistant to further oxidation. Hydrolysis of the acylal gives the aldehyde. Many oxidizing agents<sup>580</sup> have been used to accomplish the conversion of  $\text{ArCH}_3$  to  $\text{ArCHO}$ , including ceric ammonium nitrate,<sup>581</sup> *N*-hydroxyphthalimide/Co,<sup>582</sup> hypervalent iodoso compounds,<sup>583</sup> *Bi*/*t*-BuOOH,<sup>584</sup> and urea/ $\text{H}_2\text{O}_2$  with microwave irradiation.<sup>585</sup> Other oxidizing agents include the Jones reagent,<sup>586</sup> DDQ,<sup>587</sup>  $\text{KMnO}_4$  supported on  $\text{MnO}_2$ ,<sup>588</sup>  $\text{KMnO}_4/\text{CuSO}_4$  neat<sup>589</sup> or with ultrasound,<sup>590</sup> *tert*-butylhydroperoxide and a Ru catalyst,<sup>591</sup> or hydrogen peroxide with a Cu catalyst.<sup>592</sup> The reaction of ethylarenes with *N*-bromosuccinimide and a catalytic amount of AIBN in aqueous solvents, followed by reaction with molecular iodine and aqueous  $\text{NH}_3$  gave primary aromatic amides.<sup>593</sup> Oxidation of benzylic positions to the

corresponding carbonyl has been reported using two heterogeneous catalysts.<sup>594</sup> Oxidation of ArCH<sub>3</sub> to carboxylic acids is considered at **19-11**. Typical reagents include manganese salen and PhIO<sup>595</sup> or peroxides.<sup>596</sup> With minimal water, cerium(IV) triflate converts benzylic arenes to benzylic alcohols, although the major product is the ketone when >15% of water is present.<sup>597</sup> Benzylic arenes are converted to the corresponding  $\alpha$ -hydroxy compounds by treatment with the enzymes of *Bacillus megaterium*, with modest enantioselectivity.<sup>598</sup> Benzylic and allylic C–H have been oxidized in aqueous media.<sup>599</sup>

Much research continues in this area. An aerobic photooxidation of methylarenes to benzoic acid derivatives in a continuous-flow microreactor (Sec. 7.D) utilized a reaction with oxygen and 2-*tert*-butylanthraquinone as a photosensitizer.<sup>600</sup> The aerobic benzylic oxidation with air and tetrabutylammonium hydrogensulfate gave  $\alpha$ -keto amides.<sup>601</sup> The Rh/AgSbF<sub>6</sub> system catalyzed the reaction of the methyl group of 8-methylquinoline with 3-phenyl-1,4,2-dioxazol-5-one to give the corresponding amide.<sup>602</sup> Oxidation of the methyl group of 2-methylquinolines in the presence of phenyliodine diacetate (PIDA), under microwave irradiation, gave 2-quinolinecarboxaldehydes.<sup>603</sup> The benzylic CH<sub>2</sub> units of heteroaryl compounds were oxidized to the corresponding ketone with O<sub>2</sub> mediated by ethyl chloroacetate and a Cu catalyst.<sup>604</sup> The (hetero)benzylic *sp*<sup>3</sup> C–H oxidation to the corresponding ketone used KO*t*-Bu as a promoter and oxygen in the presence of 18-crown-6.<sup>605</sup> (Hetero)aryl acetimidates were oxidized to aryl  $\alpha$ -keto esters using molecular oxygen with a Cu catalyst, followed by hydrolysis.<sup>606</sup>

The benzylic oxidation of alkylarenes to aryl ketones used alkali metal bromides and Oxone via thermal oxidation or photooxidation.<sup>607</sup> The reaction of methyl arenes and *N*-chloroamines in the presence of MnO<sub>2</sub> and TBHP gave the corresponding amide.<sup>608</sup> Heating benzylic compounds with CO and an alcohol with a Pd catalyst and di-*tert*-butylperoxide gave the corresponding benzylic ester.<sup>609</sup> Benzylic compounds were oxidized to the corresponding aryl ketone using a zinc catalyst with H<sub>2</sub>O<sub>2</sub> in the presence of TFA.<sup>610</sup> The oxidation of ethylbenzene to acetophenone used (diacetoxyiodo)benzene, mcpba, and TBHP.<sup>611</sup> Benzylic bromides reacted with tertiary amine *N*-oxides to give aryl aldehydes.<sup>612</sup> Diarylmethanes were converted to diaryl ketones using O<sub>2</sub>, mediated by

*t*-BuONa.<sup>613</sup> 2-Methylbenzoic acid derivatives were converted to benzolactones by the Pd-catalyzed, intramolecular insertion of the carboxyl oxygen to the methyl C–H.<sup>614</sup> An Fe-catalyzed oxidation of allyl arenes with DDQ in the presence of water gave alkenyl aldehydes.<sup>615</sup> Diarylmethanes reacted with a catalytic amount of DDQ/*tert*-butyl nitrite with O<sub>2</sub> in acetic acid to give the diaryl ketone.<sup>616</sup> Alkyl aromatics were oxidized to diaryl ketones using nanoamorphous MnO<sub>2</sub> as a catalyst and *t*-BuOOH as the oxidant.<sup>617</sup> Benzylic oxidation to the ketone used a Co catalyst in the presence of Oxone.<sup>618</sup>

Alkenes of the form C=C–CH<sub>2</sub> (an allylic position) have been oxidized to α,β-unsaturated ketones<sup>619</sup> by sodium dichromate in HOAc/Ac<sub>2</sub>O, by *t*-BuOOH and Cr compounds,<sup>620</sup> and by *t*-BuOOH and a Pd<sup>621</sup> or Rh<sup>622</sup> catalyst. Thallium(III) nitrate in aqueous acetic acid converts allylic alkenes to the corresponding saturated ketone, even in the presence of a primary alcohol elsewhere in the molecule.<sup>623</sup> The propargylic position of internal alkynes are oxidized to give propargylic ketones with an Fe catalyst,<sup>624</sup> with a dirhodium catalyst in water,<sup>625</sup> or with O<sub>2</sub>/*t*-BuOOH in the presence of a Cu catalyst.<sup>626</sup> Treatment of double-bond compounds with selenium dioxide introduces an OH group into the allylic position.<sup>627</sup> This reaction also produces conjugated aldehydes in some cases.<sup>628</sup> Allylic rearrangements are common. There is evidence that the mechanism does not involve free radicals, but includes two pericyclic steps (A and B).<sup>629</sup> The step marked A to give **12** is similar to the ene synthesis (**15-23**). Subsequent reaction with water gives **13**, and a rearrangement gives **14**. The step marked B to give **14** is a [2,3]-sigmatropic rearrangement (see **18-35**).

<sup>629</sup> Arigoni, D.; Vasella, A.; Sharpless, K.B.; Jensen, H.P. *J. Am. Chem. Soc.* **1973**, 95, 7917; Woggon, W.; Ruther, F.; Egli, H. *J. Chem. Soc., Chem. Commun.* **1980**, 706. Also see Stephenson, L.M.; Speth, D.R. *J. Org. Chem.* **1979**, 44, 4683.

The reaction can also be accomplished with *tert*-butyl hydroperoxide, if SeO<sub>2</sub> is present in catalytic amounts (the *Sharpless method*).<sup>630</sup> The SeO<sub>2</sub> is the actual reagent; the peroxide reoxidizes the Se(OH)<sub>2</sub>.<sup>631</sup> This method makes workup easier, but gives significant amounts of side products when the double bond is in a ring.<sup>632</sup>

Alkynes generally give  $\alpha,\alpha'$ -dihydroxylation.<sup>633</sup> Allylic hydroxylation<sup>634</sup> with selenium dioxide often gives aldehydes. Allylic benzyloxylation occurs when an alkene is treated with *t*-BuOOCOPh and a Cu/Na zeolite<sup>635</sup> or a Cu catalyst.<sup>636</sup> A chiral Lewis acid has been used for an enantioselective allylic CH oxidation to an allylic acyl derivative.<sup>637</sup>  $\alpha$ -Acetoxylation of allylic alkenes can proceed with allylic rearrangement.<sup>638</sup>

Allylic oxidation is an active area of research. Allylic alcohols have been oxidized to enones.<sup>639</sup> Electrolysis was used to oxidize allylic hydrocarbons to the corresponding enone.<sup>640</sup> The Ir-catalyzed reaction of aryl cycloalkenes with 2.2 equivalents of *N*-propylthiosuccinimide and alcohols gave the corresponding allylic ether.<sup>641</sup> The reaction of cyclic alkenes with *tert*-butyl perbenzoate to give allylic esters was catalyzed by self-assembly of a coordination polymer. With a coordinating solvent, such as acetone or acetonitrile, the coordination polymer disassembles, allowing catalysis to take place in homogeneous phase, but after the reaction is complete, the catalyst reassembles upon evaporation of the solvent and addition of hexane, and the catalyst is recovered as an insoluble solid.<sup>642</sup>

The Co-catalyzed oxidative reaction of allylic/benzylic bonds with carboxylic acids gave the ester.<sup>643</sup> The Cu-catalyzed asymmetric allylic oxidation of cyclohexene with *t*-butyl *p*-nitroperbenzoate gave the allylic 4-nitrobenzoate with good enantioselectivity.<sup>644</sup> The Cu-catalyzed allylic oxidation of alkenes with PhCO<sub>3</sub>*t*-Bu gave the allylic benzoate with good enantioselectivity.<sup>645</sup> Cyclohexene was oxidized to give the allylic benzoate by reaction with CuCl, DBU, and *tert*-butyl peroxybenzoate.<sup>646</sup>

19-16 Oxidation of Activated Methylene to OH, O<sub>2</sub>CR, or OR

Methyl or methylene groups  $\alpha$  to a carbonyl can be oxidized to give  $\alpha$ -hydroxy ketones,<sup>647</sup> aldehydes, or carboxylic acid derivatives. Ketones can be  $\alpha$ -hydroxylated in good yields, without conversion to the enolates, by treatment with the hypervalent iodine reagents<sup>648</sup> *o*-iodosobenzoic acid.<sup>649</sup> Dioxygen (O<sub>2</sub>) and a chiral phase-transfer catalyst gave enantioselective  $\alpha$ -hydroxylation of ketones, if the  $\alpha$  position was tertiary.<sup>650</sup> Dimethyl dioxirane is quite effective for hydroxylation of 1,3-dicarbonyl compounds,<sup>651</sup> and O<sub>2</sub> with a Mn or Ce catalyst also gives hydroxylation.<sup>652</sup> The hydroxylation of the more substituted position  $\alpha$  to a carbonyl group used a dinuclear Pd(II) complex in the presence of bimolecular oxygen.<sup>653</sup> The Pd/C-catalyzed<sup>654</sup> and the Au-catalyzed<sup>655</sup>  $\alpha$ -oxygenation of 1,3-dicarbonyl compounds can be accomplished using O<sub>2</sub>. An engineered cytochrome P450 BM-3 is effective for the enantioselective  $\alpha$ -hydroxylation of esters of benzylic acids.<sup>656</sup> Hypervalent iodine(III) sulfonate has been used for the  $\alpha$ -hydroxylation of aryl ketones.<sup>657</sup>

Ketones and carboxylic esters can be  $\alpha$ -hydroxylated by treatment of their enolate anions (prepared by adding the ketone or ester to LDA) with MoO<sub>5</sub>/pyridine/HMPA (called MoOPH) in THF/hexane at -70 °C.<sup>658</sup> The enolate forms of amides and esters<sup>659</sup> and the enamine derivatives of ketones<sup>660</sup> can similarly be converted to their  $\alpha$ -hydroxy derivatives by reaction with molecular oxygen. The MoO<sub>5</sub> method can also be applied to certain nitriles.<sup>661</sup>

Ketones are converted to  $\alpha$ -hydroxy ketones by reaction of the enolate anion with a 2-sulfonyloxaziridine (e.g., **15**).<sup>662</sup> The mechanism shown is likely.

<sup>647</sup> For strategies for the synthesis of  $\alpha$ -hydroxy ketones, see Streuff, J. *Synlett* **2013**, 24, 276.

<sup>662</sup> Davis, F.A.; Vishwakarma, L.C.; Billmers, J.M.; Finn, J. *J. Org. Chem.* **1984**, 49, 3241.

The method is also successful for carboxylic esters<sup>663</sup> and *N,N*-disubstituted amides,<sup>664</sup> and can be made enantioselective by the use of a chiral oxaziridine.<sup>665</sup> Dimethyldioxirane also oxidizes the enolate anions of ketones to  $\alpha$ -hydroxy ketones.<sup>666</sup> Titanium enolates are oxidized with *tert*-butyl hydroperoxide<sup>667</sup> or with dimethyl dioxirane<sup>668</sup> and hydrolyzed with aqueous ammonium fluoride to give the  $\alpha$ -hydroxy ketone.  $\alpha$ -Lithio sulfones have been hydroxylated with  $\text{Me}_3\text{SiOO}t\text{-Bu}$ .<sup>669</sup>

Ketones have been  $\alpha$ -hydroxylated by conversion to the silyl enol ether, followed by treatment with *m*-chloroperoxybenzoic acid,<sup>156</sup> or with certain other oxidizing agents.<sup>670</sup>  $\alpha$ -Hydroxy ketones can be prepared from silyl enol ethers with a catalytic amount of  $\text{MeReO}_3$  and  $\text{H}_2\text{O}_2$ .<sup>671</sup> When the silyl enol ethers are treated with iodobenzene in the presence of trimethylsilyl trifluoromethyl sulfonate, the product is the  $\alpha$ -keto triflate.<sup>672</sup> Silyl ketene ethers are converted to  $\alpha$ -hydroxy esters with  $\text{H}_2\text{O}_2$  and  $\text{MeReO}_3$ .<sup>673</sup> The  $\alpha'$  position of  $\alpha,\beta$ -unsaturated ketones can be selectively oxidized.<sup>674</sup>

$\alpha$ -Acetoxylation of ketones with concurrent  $\alpha$ -arylation occurs when ketones react with  $\text{Mn}(\text{OAc})_3$  in benzene.<sup>675</sup> Iodobenzene with 30% aqueous hydrogen peroxide and acetic anhydride generates  $\alpha$ -acetoxy ketones.<sup>676</sup> Thallium(III) triflate converts acetophenone to  $\alpha$ -formyloxy acetophenone.<sup>677</sup> The reaction of  $\text{PhI}(\text{OH})\text{OTs}$  and ketones gave  $\alpha$ -tosyloxy (OTs) ketones.<sup>678</sup> *N*-Methyl-*O*-tosylhydroxylamine is another reagent that effects direct  $\alpha$ -oxytosylation of ketones and aldehydes.<sup>679</sup>  $\alpha$ -Acetoxylation of ketones results from *in situ* generation of hypervalent iodine species in the presence of acetic acid.<sup>680</sup>

Tetrahydrofuran was converted to the hemiacetal 2-hydroxytetrahydrofuran (which was relatively stable under the conditions used) by electrolysis in water.<sup>681</sup>  $\alpha$ -Hydroxy ethers are generated by reaction of  $\text{SO}_2/\text{O}_2$  and a V catalyst with ethers.<sup>682</sup>

This type of oxidation is an active area of research. The 2-hydroxylation of 1,3-diketones was reported by heating with atmospheric oxygen in the presence of CsF, CaF<sub>2</sub>, KF, or TBAF and NaOH.<sup>683</sup> The iodine-catalyzed  $\alpha$ -hydroxylation using air has also been reported.<sup>684</sup> A transition metal-free Cs<sub>2</sub>CO<sub>3</sub>-catalyzed  $\alpha$ -hydroxylation of carbonyl compounds with O<sub>2</sub>, and triethylphosphine as an additive, gave tertiary  $\alpha$ -hydroxycarbonyl compounds.<sup>685</sup> The reaction of ketones and DMSO was catalyzed by I<sub>2</sub> or NBS to give the  $\alpha$ -hydroxy carbonyl, where DMSO is the oxidant, oxygen source, and solvent.<sup>686</sup>

The  $\alpha$ -hydroxylation of  $\beta$ -oxo esters and  $\beta$ -oxo amides used *m*-chloroperbenzoic acid as the oxidant and the hydroxylated products were converted into vicinal tricarbonyl compounds by reaction with cupric acetate.<sup>687</sup> *Cinchona* alkaloid-derived organocatalysts were used for the enantioselective  $\alpha$ -hydroxylation of  $\beta$ -oxo esters with hydroperoxides to give  $\alpha$ -hydroxy- $\beta$ -oxo esters.<sup>688</sup> A mixture of Pr(O*i*Pr)<sub>3</sub> and a fluoro-substituted amide-based ligand was used to catalyze the asymmetric hydroxylation of  $\alpha$ -alkoxycarbonyl primary amides using oxaziridine as the oxidizing reagent to give the  $\alpha$ -hydroxy compound.<sup>689</sup> The base-free  $\alpha$ -hydroxylation of  $\beta$ -keto esters and amides used air as the oxygen source and catalytic amounts of SmI<sub>3</sub> and I<sub>2</sub> to give  $\alpha$ -hydroxylated 1,3-dicarbonyl products.<sup>690</sup> In a related reaction, the reaction of phenylglyoxylic acids with amides or cyclic ethers, TBHP and TBAI gave decarboxylative acyloxylation and formation of *N*-acyloxymethylamides and  $\alpha$ -acyloxy ethers.<sup>691</sup> Note that homoallylic-type oxidation occurs when an  $\alpha,\alpha$ -dimethyl oxime ether is treated with PhI(OAc)<sub>2</sub> and a Pd catalyst in acetic acid/acetic anhydride, converting one of the methyl groups to an acetoxymethyl.<sup>692</sup> The  $\alpha$ -hydroxylation of ketones was catalyzed by CuBr<sub>2</sub> or HBr in DMSO to give secondary/tertiary  $\alpha$ -hydroxy carbonyl compounds.<sup>693</sup>

The terminal-selective, Pt-catalyzed oxidation of methyl units of a long-chain aliphatic amine proceeds without using CuCl<sub>2</sub>.<sup>694</sup> A primary amine catalyst for the asymmetric  $\alpha$ -hydroxylation by reaction with an oxaziridine and  $\alpha$ -fluorination has been developed for the reaction of *N*-fluorobenzenesulfonimide with  $\alpha$ -branched aldehydes.<sup>695</sup> Heating a series of phthaloyl-protected primary amines and amino acid derivatives that have a CH<sub>3</sub>CH<sub>2</sub>— unit oxidized this unit to a methyl ketone moiety by reaction with Na<sub>2</sub>S<sub>2</sub>O<sub>8</sub> in aqueous methanol.<sup>696</sup> A distal —CH<sub>2</sub>— unit of the ammonium salt of aliphatic amines was selectively oxidized to an alcohol (—CHOH—) by reaction with K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> in water.<sup>697</sup> The Cu-catalyzed reaction of *N*-alkyl-3-aryl-3-(4-pentenyl)oxaziridine derivatives gave the

rearrangement product, 1-aryl-4-hydroxyhex-1-one-5-ene derivatives.<sup>698</sup> 1-Iodopropane was oxidized to iodosylpropane, which decomposed to form hypoiodous acid as a catalyst; reaction with mcpba and tosic acid gave  $\alpha$ -tosyloxy ketones.<sup>699</sup> In a Pd-catalyzed annulation of an oxime-masked alcohols with internal alcohol nucleophiles, annulation occurred at the  $\beta$  position to give aliphatic cyclic ethers.<sup>700</sup>

*N*-Acyl amines are converted to  $\alpha$ -hydroxy derivatives with PhIO and a Mn salen catalyst.<sup>701</sup> Cyclic amines react with *Pseudomonas oleovorans* GPol to give hydroxy amines; *N*-benzylpyrrolidine is converted to 3-hydroxy *N*-benzylpyrrolidine.<sup>702</sup> *Sphingomonas* sp. HXN-200 gives similar results,<sup>703</sup> and lactams are converted to the corresponding 3-hydroxy lactam with *sphingomonas* sp. HXN-200.<sup>704</sup> *N*-Benzyl piperidine is converted to the 4-hydroxy derivative under the same conditions.<sup>705</sup> *N*-Benzylphthalimide reacts with NBS, NaOAc, and acetic acid to give *N*-( $\alpha$ -acetoxybenzyl)phthalimide.<sup>706</sup>

In some cases, similar reactions are possible, producing sulfur-containing compounds. Longifolene, as well as other hydrocarbons, reacted with a *N*-xanthylamide derivative in the presence of a blue LED to give the xanthate derivative.<sup>707</sup> Cyclic alkanes are converted to the corresponding alkylsulfonic acid with SO<sub>2</sub>/O<sub>2</sub> and a V catalyst.<sup>708</sup> A Pd-catalyzed intermolecular reaction of the methyl group 8-methylquinoline with *N*-fluorobis(phenylsulfonyl)imide gave the corresponding (bis)sulfonimide.<sup>709</sup>

The Cu-catalyzed hydroxylation of phosphonate compounds by reaction with *N*-hydroxyphthalimide, O<sub>2</sub>, and PPh<sub>3</sub>, gave quaternary  $\alpha$ -hydroxy phosphonates.<sup>710</sup> Quaternary  $\alpha$ -hydroxy phosphonates were prepared by the [bmIm]OH-catalyzed  $\alpha$ -hydroxylation of phosphonates using O<sub>2</sub>.<sup>711</sup>

as in ethylbenzene, is oxidized with  $\text{PhI}(\text{OAc})_2$  in the presence of  $\text{TsNH}_2$  and a fluorinated manganese porphyrin to give the corresponding *N*-tosylamine,  $\text{PhCHMe}(\text{NHTs})$ .<sup>713</sup> Alkenes with an allylic CH react with  $\text{PhI}=\text{NTs}$  and a Ru catalysts to give an allylic *N*-tosylamine.<sup>714</sup> When an  $\alpha$ -keto ester reacts with DEAD (diethyl azodicarboxylate) and a chiral Cu complex, an  $\alpha$ -carbamate is formed,  $\text{RCH}(\text{NHCO}_2\text{Et})\text{C}(=\text{O})\text{CO}_2\text{Et}$ , with modest enantioselectivity.<sup>715</sup> The oxidation of amides to imides has been reviewed.<sup>716</sup>

### 19-18 Oxidation of Methylene to Carbonyl

Methyl or methylene groups  $\alpha$  to a carbonyl can be oxidized with selenium dioxide to give, respectively,  $\alpha$ -keto aldehydes (see **19-15**) and  $\alpha$ -diketones.<sup>717</sup> The reaction can also be carried out  $\alpha$  to an aromatic ring or to a double bond, although in the latter case, hydroxylation (see **19-14**) is the more common result. Selenium dioxide,  $\text{SeO}_2$  is often used, but the reaction has also been carried out with other oxidizing agents,<sup>718</sup> including hypervalent iodine compounds.<sup>719</sup>

Two mechanisms have been suggested for the reaction with  $\text{SeO}_2$ . One of these involves a selenate ester of the enol, **16**.<sup>720</sup>

In the other proposed mechanism,<sup>721</sup> the principal intermediate is  $\alpha,\beta$ -ketoseleninic acid  $\text{O}=\text{C}-\text{CH}-\text{SeO}_2\text{H}$ , and a selenate ester is not involved.

Sodium nitrite/HCl oxidizes cyclic ketones to the diketone.<sup>722</sup> Substrates most easily oxidized contain two aryl groups on  $\text{CH}_2$ , and these substrates can be oxidized with many oxidizing agents (see **19-11**). Methyl ketones are oxidized to the  $\alpha$ -keto ester in a two-step procedure using a fluorous selenic acid with an iodoxy benzene, followed by treatment with sodium metabisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ ).<sup>723</sup> The distal oxidation of a methylene unit in alkyl

Primary alkyl halides (chlorides, bromides, and iodides) can be oxidized to aldehydes easily and in good yields with dimethyl sulfoxide,<sup>755</sup> in what has been called the *Kornblum reaction*. In Kornblum's original work, the reaction of  $\alpha$ -halo ketones with DMSO at elevated temperatures gave good yields of the corresponding glyoxal (an  $\alpha$ -keto aldehyde).<sup>756</sup> If the glyoxal could be removed from the reaction medium by distillation as it was formed, the reaction was very efficient. In many cases it was difficult to isolate high boiling glyoxals from DMSO. Primary and secondary<sup>757</sup> alkyl iodides or tosylates<sup>758</sup> can be converted to aldehydes or ketones, although they are much less reactive than  $\alpha$ -halo ketones. Primary chlorides reacted with DMSO, NaBr, and ZnO give the corresponding aldehyde when heated to 140 °C.<sup>759</sup> Benzylic halides are oxidized to aryl aldehydes with  $\text{MnO}_2$ <sup>760</sup> or with  $\text{NaIO}_4/\text{LiBr}$ .<sup>761</sup> Hydrogen peroxide in ethanol oxidizes organic halides to carbonyl compounds.<sup>762</sup> Pyridine *N*-oxide in the presence of silver oxide oxidizes benzylic and allylic halides.<sup>763</sup>

The mechanism of these DMSO oxidations is probably that shown, with **17** and **18** as intermediates<sup>764</sup> although in some cases the base abstracts a proton directly from the carbon being oxidized, in which case the ylid **18** is not an intermediate.

Alkoxysulfonium salts (**17**) have been isolated.<sup>765</sup> This mechanism predicts that secondary compounds should be oxidizable to ketones, and this is the case. In a related procedure for the oxidation of alcohols, the intermediate **17**<sup>766</sup> is formed without the use of DMSO by treating the substrate with a complex generated from chlorine or NCS and dimethyl sulfide.<sup>767</sup> Also see the *Swern oxidation* in **19-3**.

Another way to oxidize primary alkyl halides to aldehydes is by the use of hexamethylenetetramine followed by water. However, this reaction, called the *Sommelet reaction*,<sup>768</sup> is limited to benzylic halides. The reaction is seldom useful when the R in RCH<sub>2</sub>Cl

is alkyl. The first part of the reaction is conversion to the amine,  $\text{ArCH}_2\text{NH}_2$ , which can be isolated. Reaction of the amine with excess hexamethylenetetramine gives the aldehyde. It is this last step that is the actual Sommelet reaction, although the entire process can be conducted without isolation of intermediates. Once the amine is formed, it is converted to an imine ( $\text{ArCH}_2\text{N}=\text{CH}_2$ ) with formaldehyde liberated from the reagent. The key step then follows: transfer of hydrogen from another mole of the arylamine to the imine. This last imine is then hydrolyzed by water to the aldehyde. Alternatively, the benzylamine may transfer hydrogen directly to hexamethylenetetramine.

Organic halides were converted into carbonyl derivatives via microwave-assisted oxidation with *N*-methylmorpholine *N*-oxide in an ionic liquid.<sup>769</sup> Benzylic halides were oxidized to aryl aldehydes via reaction with trimethylamine/ $\text{H}_2\text{O}_2$  in aqueous media.<sup>770</sup> Use of pyridine followed by *p*-nitrosodimethylaniline and then water converts benzylic halides to aldehydes, and is called the *Kröhnke reaction*. Primary halides and tosylates have been oxidized to aldehydes by trimethylamine *N*-oxide,<sup>771</sup> and by pyridine *N*-oxide with microwave irradiation.<sup>772</sup>

### 19-21 Oxidation of Amines or Nitro Compounds to Aldehydes, Ketones, or Dihalides

Primary aliphatic amines can be oxidized to aldehydes or ketones, using silver compounds as shown.<sup>773</sup> Other reagents have been used,<sup>774</sup> including *N*-bromoacetamide<sup>775</sup> (for benzylic amines) or aqueous NaOCl with phase-transfer catalysts.<sup>776</sup> Several indirect methods for achieving the conversion  $\text{RR}'\text{CHNH}_2 \rightarrow \text{RR}'\text{C}=\text{O}$  ( $\text{R}' = \text{alkyl, aryl, or H}$ ) have been reported.<sup>777</sup>

Primary, secondary, and tertiary aliphatic amines have been cleaved to give aldehydes, ketones, or carboxylic acids with aqueous bromine<sup>778</sup> and with neutral permanganate.<sup>779</sup> The other product of this reaction is the amine with one less alkyl group. Reaction of a

quite common<sup>831</sup> and has been carried out with many oxidizing agents, including permanganate in acid, basic, or neutral solution,<sup>832</sup> chromic acid,<sup>833</sup> and bromine. Silver oxide is a fairly specific oxidizing agent for aldehydes and does not readily attack other groups. *Benedict's solution* and *Fehling's solution* oxidize aldehydes<sup>834</sup> (there is a test for aldehydes that depends on this reaction), but the method is seldom used for preparative purposes and gives very poor results with aromatic aldehydes.  $\alpha,\beta$ -Unsaturated aldehydes can be oxidized by sodium chlorite without disturbing the double bond.<sup>835</sup>

Mechanisms of aldehyde oxidation<sup>836</sup> are not firmly established, but there are at least two main types: a free-radical mechanism and an ionic one. In the free-radical process, the aldehyde hydrogen is abstracted to leave an acyl radical, which obtains OH from the oxidizing agent. In the ionic process, the first step is addition of an alkoxide tetrahedral intermediate in alkaline solution, or a hydroxyl-containing tetrahedral intermediate in acid or neutral solution. For oxidation with acid dichromate the picture seems to be quite complex.<sup>837</sup> Still another possible process has been proposed, in which the chromic acid ester decomposes.<sup>838</sup> The mechanism with permanganate is less well known, but an ionic mechanism has been proposed<sup>839</sup> for neutral and acid permanganate. For alkaline permanganate, a tetrahedral mechanism has been proposed.<sup>840</sup>

Aldehydes are also oxidized to carboxylic acids by atmospheric oxygen, but the actual direct oxidation product in this case is the peroxyacid  $\text{RCO}_3\text{H}$ ,<sup>841</sup> which then disproportionates with another molecule of aldehyde to give two molecules of acid (see **14-6**).<sup>842</sup> The air oxidation of aldehydes to carboxylic acids is mediated by a mixture of  $\text{Pd/C}/\text{NaBH}_4$  and  $\text{KOH}$ .<sup>843</sup> An aldehyde can be converted to the carboxylic acid by treatment with 30% hydrogen peroxide and methyl(trioctyl)ammonium hydrogen sulfate at 90 °C.<sup>844</sup> Aryl aldehydes are similarly oxidized by a mixture of hydrogen peroxide and selenium dioxide ( $\text{SeO}_2$ ).<sup>845</sup>

aldehydes via oxidation by NCS.<sup>864</sup> The Cu-catalyzed reaction of aldehydes with hydroxylamine hydrochloride gave the acid upon heating,<sup>865</sup> and a bioglycerol-based carbon catalyst has been used.<sup>866</sup>

The NHC-catalyzed reaction of aldehydes with thiols used phenazine as an oxidant to give the thioester.<sup>867</sup> Photocatalysis using an Fe catalyst converted aldehydes to esters.<sup>868</sup> Organocatalysts were used to convert aldehydes to amides or esters.<sup>869</sup>

Aldehydes reacted with ammonium chloride or amine hydrochloride salts using Cu catalysts and aqueous *tert*-butyl hydroperoxide.<sup>870</sup> Aromatic and aliphatic aldehydes that reacted with trichloroisocyanuric acid were first converted to the corresponding acyl chloride, and subsequent reaction with a variety of alcohols or phenols then gave the corresponding esters.<sup>871</sup> Aldehydes reacted with TsNBr<sub>2</sub> and methanol to give the methyl ester.<sup>872</sup> Heating aromatic aldehydes with ammonium<sup>+</sup> or pyridinium<sup>+</sup> S<sub>2</sub>O<sub>8</sub><sup>-</sup> salts and alcohols gave aromatic esters.<sup>873</sup>  $\alpha,\beta$ -Unsaturated or aromatic aldehydes reacted with reactive cinnamyl bromides with a *N*-heterocyclic carbene catalyst in the presence of air oxygen or MnO<sub>2</sub> to give the ester.<sup>874</sup> Heating aldehydes with phenols in the presence of air gave the phenyl ester via Pd-catalyzed esterification.<sup>875</sup> Heating aryl aldehydes with benzyl bromide with a Pd catalyst in ethanol gave the corresponding ethyl ester.<sup>876</sup> 1-Butyl-3-methylimidazolium tetrafluoroborate (BmimBF<sub>4</sub>) has been used in the NHC-catalyzed oxidation with MnO<sub>2</sub> and DBU or CsCO<sub>3</sub> to give the corresponding ester.<sup>877</sup> The reaction of aryl aldehydes with methanol and H<sub>2</sub>O<sub>2</sub> in the presence of CaCl<sub>2</sub> or MgCl<sub>2</sub> gave the corresponding methyl benzoate.<sup>878</sup> A nitrile intermediate was formed by reaction of an aldehyde with hydroxylamine hydrochloride in dimethyl sulfoxide (DMSO) at 100 °C, and subsequent reaction with ethanol and sulfuric acid at 130 °C gave the ethyl ester.<sup>879</sup> Aldehydes were converted to thioesters by reaction with thiols, 4-methyl-3-(2,4,6-trimethylphenyl)thiazolium tetrafluoroborate, 4-methyl-3-(2,6-diisopropylphenyl)thiazolium tetrafluoroborate, or DMAP, and by using a graphite anode and a Pt cathode.<sup>880</sup> The iron-catalyzed reaction is also known.<sup>881</sup>

Nitriles were prepared by the reaction of aldehydes with acyl hydroxylamine, with a Bi catalyst, that converted an intermediate aldoxime to the nitriles.<sup>882</sup> Aldehydes reacted

### 19-24 Oxidation of Carboxylic Acids to Peroxyacids

The oxidation of carboxylic acids with H<sub>2</sub>O<sub>2</sub> and an acid catalyst is the best general method for the preparation of peroxyacids.<sup>893</sup> A mixture of Me<sub>2</sub>C(OMe)OOH and DCC has also been used.<sup>894</sup> Concentrated sulfuric acid is a common catalyst for aliphatic R. The reaction is in an equilibrium and is driven to the right by removal of water or by the use of excess reagents. For aromatic R, the best catalyst is methanesulfonic acid, which is also used as the solvent.

Monosubstituted and 1,2-disubstituted alkenes can be oxidized to aldehydes and ketones by PdCl<sub>2</sub>, where the PdCl<sub>2</sub> is reduced to Pd.<sup>895</sup> Internal alkenes have been oxidized using a Pd catalyst and TBHP.<sup>896</sup> Similar salts of noble metals also work, but 1,1-disubstituted alkenes generally give poor results. The reaction is used industrially to prepare acetaldehyde from ethylene (the *Wacker process*),<sup>897</sup> but it is also suitable for laboratory preparations. The reagent is expensive, so the reaction is usually carried out with a co-oxidant, often CuCl<sub>2</sub>, whose function is to reoxidize the Pd to Pd(II). The CuCl<sub>2</sub> is reduced to Cu(I), which itself is reoxidized to Cu(II) by air, so that atmospheric oxygen is the only oxidizing agent actually used up. Many other co-oxidants have been tried, among them O<sub>3</sub>, O<sub>2</sub>,<sup>898</sup> Fe<sup>3+</sup>, and PbO<sub>2</sub>. Terminal alkenes are oxidized to methyl ketones with O<sub>2</sub> and a Pd catalyst<sup>899</sup> and hypervalent iodine has been used.<sup>900</sup> An aldehyde is the principal product only from ethylene, while with other alkenes *Markovnikov's rule* is followed, and ketones are formed predominantly, although anti-Markovnikov reactions have been reported.<sup>901</sup> A catalyst-controlled Wacker-type oxidation, using Pd/Cu catalysts, gave functionalized aldehydes.<sup>902</sup> Palladium and hypervalent iodine co-catalysis allowed the tandem Wacker oxidation–dehydrogenation of terminal alkenes to give linear aryl and alkyl α,β-unsaturated ketones.<sup>903</sup> The Wacker oxidation of homoallylic alcohols has been reported.<sup>904</sup> An aldehyde-selective Wacker oxidation of aryl-substituted alkenes used a palladium catalyst, 1,4-benzoquinone, and *t*-BuOH in air.<sup>905</sup> An Oxone-mediated oxidation of benzo-fused alkenes has been reported.<sup>906</sup> The Ru-catalyzed oxidation of alkenes with TBHP gave the α-diketone.<sup>907</sup> Alkynes were converted to 1,2-diketones using RuO<sub>4</sub>, generated *in situ* from RuCl<sub>3</sub>·xH<sub>2</sub>O, and NaOCl.<sup>908</sup>

<sup>908</sup> Miao, Y.; Dupé, A.; Bruneau, C.; Fischmeister, C. *Eur. J. Org. Chem.* **2014**, 5071.

The generally accepted mechanism shown below involves  $\pi$  complexes of Pd.<sup>909</sup> This mechanism accounts for the fact, established by deuterium labeling, that the four hydrogen atoms of the acetaldehyde all come from the original ethylene and none from the solvent.

Similar reactions have been carried out with other oxidizing agents. An example involving migration of an alkyl group instead of hydrogen is oxidation of  $\text{Me}_2\text{C}=\text{CMe}_2$  with peroxytrifluoroacetic acid/boron trifluoride to give  $\text{Me}_3\text{COME}$  (pinacolone).<sup>910</sup> This reaction consists of epoxidation (**15-50**) followed by pinacol rearrangement of the epoxide (**18-2**). A migration is also involved in the conversion of  $\text{ArCH}=\text{CHCH}_3$  to  $\text{ArCH}(\text{CH}_3)\text{CHO}$  by treatment with  $\text{I}_2/\text{Ag}_2\text{O}$  in aqueous dioxane.<sup>911</sup> Other reagents have been used, for example  $\text{Pb}(\text{OAc})_4/\text{F}_3\text{CCO}_2\text{H}$ ,<sup>912</sup> or  $\text{H}_2\text{O}_2$  and a Pd catalyst for the conversion  $\text{PhCH}=\text{CH}_2 \rightarrow \text{PhCH}_2\text{CHO}$ .<sup>913</sup> Terminal alkenes react with ceric ammonium nitrate in methanol to give  $\alpha$ -methoxy ketones.<sup>914</sup>

Alkenes have also been converted to more highly oxidized products. Examples of these reactions are: (i) treatment with  $\text{KMnO}_4$  in aqueous acetone containing acetic acid gives  $\alpha$ -hydroxy ketones;<sup>915</sup> (ii) 1,2-disubstituted and trisubstituted alkenes give  $\alpha$ -chloro ketones when oxidized with chromyl chloride in acetone ( $\text{RCH}=\text{CR}^1\text{R}^2 \rightarrow \text{RCOCClR}^1\text{R}^2$ );<sup>916</sup> (iii)  $\alpha$ -iodo ketones can be prepared by treating alkenes with bis(*sym*-collidine)iodine(I) tetrafluoroborate;<sup>917</sup> and (iv) potassium permanganate in acetic anhydride oxidizes large-ring cycloalkenes to 1,2-diketones.<sup>918</sup>

Enol ethers are oxidized to carboxylic esters ( $\text{RCH}=\text{CHOR}' \rightarrow \text{RCH}_2\text{COOR}'$ ) with pyridinium chlorochromate (PCC)<sup>919</sup> and enamines are oxidized to  $\alpha$ -amino ketones with

*N*-sulfonyloxaziridines.<sup>920</sup> Polysubstituted enamines ( $R^1R^4C=CR^2NR_2^3$ ,  $R^4 \neq H$ ) do not give these products, but lose the amino group to give  $\alpha$ -hydroxy ketones,  $R^1R^4C(OH)COR^2$ .<sup>920</sup> Carboxylic acids can be prepared from terminal alkynes by conversion of the alkyne to its phenylthio ether ( $RC\equiv CPh$ ) and treatment of this with  $HgSO_4$  in  $HOAc/H_2SO_4$ .<sup>921</sup> Aza-Wacker reactions are known.<sup>922</sup>

OS VI, 1028; VII, 137; VIII, 208.

## 19-26 The Oxidation of Alkynes to $\alpha$ -Diketones

Internal alkynes have been oxidized<sup>923</sup> to  $\alpha$ -diketones<sup>924</sup> by several oxidizing agents,<sup>925</sup> including neutral  $KMnO_4$ ,<sup>926</sup> bis(trifluoroacetoxy)iodobenzene,<sup>927</sup>  $NaIO_4/RuO_2$ ,<sup>928</sup>  $MeReO_3/H_2O_2$ ,<sup>929</sup> or oxygen and a mixture of Pd and Cu catalysts.<sup>930</sup> A Ru complex with a small amount of trifluoroacetic acid converts internal alkynes to the  $\alpha$ -diketone.<sup>931</sup> The Ru-catalyzed oxidation of alkynes using Oxone and a catalytic amount of TEMPO gave 1,2-diketones.<sup>932</sup> The Pd/C-catalyzed and pyridine *N*-oxide-mediated oxidation of diarylalkynes gave the 1,2-diketone derivative.<sup>933</sup> Ozone generally oxidizes triple-bond compounds to carboxylic acids (**19-9**), but  $\alpha$ -diketones are sometimes obtained.<sup>934</sup> Selenium dioxide ( $SeO_2$ ) with a small amount of  $H_2SO_4$  oxidizes alkynes to  $\alpha$ -diketones as well as arylacetylenes to  $\alpha$ -keto acids ( $ArC\equiv CH \rightarrow ArCOCO_2H$ ).<sup>935</sup> A mixture of formic acid, methanesulfonic acid, and DMSO with an HBr catalyst converts alkynes to  $\alpha$ -diketones.<sup>936</sup>

## 19-27 Oxidation of Amines and Other Nitrogen Compounds

Primary aromatic amines can be oxidized<sup>937</sup> to nitroso compounds. Most often the conversion is accomplished by *Caro's acid* ( $\text{H}_2\text{SO}_5$ ) or with  $\text{H}_2\text{O}_2$  in HOAc.<sup>938</sup> The mechanism with  $\text{H}_2\text{SO}_5$  has been postulated to involve attack of the amine on the electrophilic oxygen of  $^-\text{O}_3\text{S}-\text{O}-\text{OH}$  (the OH unit).<sup>939</sup> Other reagents used for this oxidation are  $\text{H}_2\text{O}_2$  with a Ti complex,<sup>940</sup> HOF generated *in situ*,<sup>941</sup> and  $\text{Na}_2\text{WO}_4/\text{H}_2\text{O}_2$ .<sup>942</sup> Hydroxylamines have been oxidized to oximes, using Cu/air,<sup>943</sup> In/TEMPO,<sup>944</sup> or TEMPO.<sup>945</sup> Hydroxylamines, which are probably intermediates in most cases, can sometimes be isolated, but under the reaction conditions they are generally oxidized to the nitroso compounds. Primary aliphatic amines can be oxidized in this manner, but the nitroso compound is stable only if there is no  $\alpha$  hydrogen. If there is an  $\alpha$  hydrogen, the compound tautomerizes to the oxime.<sup>946</sup> *N*-Nitroso compounds, known as nitrosamines, have also been prepared. The reaction of secondary or tertiary amines with *o*-iodoxybenzoic acid, a catalytic amount of TBAF, and nitromethane gave aliphatic or aromatic *N,N*-disubstituted nitrosamines.<sup>947</sup>

Secondary amines ( $\text{R}_2\text{NH}$ ) are oxidized to hydroxylamines ( $\text{R}_2\text{NHOH}$ ), which are resistant to further oxidation by reaction with dimethyldioxirane<sup>948</sup> or by reaction with benzoyl peroxide and  $\text{Na}_2\text{HPO}_4$ .<sup>949</sup> Oxone on silica also oxidizes secondary alcohols to the hydroxylamine.<sup>950</sup> Hydroxylamines are formed when secondary amines react with the enzyme cyclohexanone monooxygenase.<sup>951</sup> Carbamates, such as *N*-Boc amines, are converted to the *N*-hydroxy compound with *bis*(trifluoromethyl)dioxirane.<sup>952</sup> Dialkylamines are oxidized to the *N*-nitroso compound with  $\text{N}_2\text{O}_2$  on poly(vinylpyrrolidone).<sup>953</sup>

Tertiary alkyl primary amines can be oxidized to nitro compounds in excellent yields with  $\text{KMnO}_4$ .<sup>954</sup> All classes of primary amine (including primary, secondary, and tertiary alkyl as well as aryl) are oxidized to nitro compounds in high yields with dimethyldioxirane.<sup>955</sup> Other reagents that oxidize various types of primary amines to nitro compounds are dry ozone,<sup>956</sup> peroxyacids,<sup>957</sup>  $\text{MeReO}_3/\text{H}_2\text{O}_2$ ,<sup>958</sup> Oxone,<sup>959</sup> and sodium perborate.<sup>960</sup> An aqueous solution of fluorine oxidizes amino esters to  $\alpha$ -nitro esters.<sup>961</sup>

Dimethyldioxirane in wet acetone oxidizes isocyanates to nitro compounds ( $\text{RNCO} \rightarrow \text{RNO}_2$ ).<sup>962</sup> Oximes can be oxidized to nitro compounds with peroxytrifluoroacetic acid, or with sodium perborate,<sup>963</sup> among other ways.<sup>954</sup> Secondary hydroxylamines are also oxidized to nitrones with  $\text{MnO}_2$  in dichloromethane.<sup>964</sup> Primary and secondary alkyl azides have been converted to nitro compounds by treatment with  $\text{Ph}_3\text{P}$  followed by ozone.<sup>965</sup> Aromatic nitroso compounds are easily oxidized to nitro compounds by many oxidizing agents.<sup>966</sup>

Secondary amines were oxidized to nitrones using a Mo catalyst.<sup>967</sup> Tertiary and secondary amines were oxidized to their corresponding *N*-oxides and nitrones, respectively, by reaction with trichloroacetonitrile–hydrogen peroxide.<sup>968</sup> An Ir-catalyzed reaction of *N*-hydroxyamides with  $(\text{Me}_2\text{HSi})_2\text{O}$  gave functionalized nitrones.<sup>969</sup> Magnetically separable tungstophosphoric acid-supported silica-encapsulated  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles have been used for the oxidation of amines to nitrones.<sup>970</sup> Primary amines were oxidized to oximes using  $\text{O}_2$  and 1,1-diphenyl-2-picrylhydrazyl, with  $\text{WO}_3/\text{Al}_2\text{O}_3$  as catalysts.<sup>971</sup> The mcpba-mediated conversion of aliphatic amines to oximes was reported.<sup>972</sup>

Primary azides were oxidized to nitriles using aqueous TBHP and a catalytic amount of KI.<sup>973</sup>

## 19-28 Oxidation of Tertiary Amines to Amine Oxides

Tertiary amines can be converted to amine oxides by oxidation. Hydrogen peroxide is often used, but peroxyacids are also important reagents for this purpose. Pyridine and its derivatives are oxidized by peroxyacids<sup>974</sup> rather than hydrogen peroxide. Note, however, that urea/H<sub>2</sub>O<sub>2</sub> in formic acid does indeed oxidize pyridine.<sup>975</sup> Oxidation with *Caro's acid* has been shown to proceed via attack of the amine on the electrophilic oxygen of <sup>-</sup>O<sub>3</sub>S—O—OH (the OH unit).<sup>976</sup> This mechanism is the same as that in the previous section; the products differ only because tertiary amine oxides cannot be further oxidized. The mechanism with other peroxyacids is probably the same. A green procedure for oxidation of tertiary amines has been developed, using a Mg/Al complex with aqueous hydrogen peroxide.<sup>977</sup> Nitrones can be prepared using a ball-mill.<sup>978</sup>

An alternative oxidation using O<sub>2</sub> and a RuCl<sub>3</sub> catalyst converted pyridine to pyridine *N*-oxide.<sup>979</sup> Bromamine-T and RuCl<sub>3</sub> in aqueous acetonitrile also oxidizes pyridine to the *N*-oxide.<sup>980</sup> Tertiary amines are oxidized to the *N*-oxide with O<sub>2</sub> and Fe<sub>2</sub>O<sub>3</sub> in the presence of an aliphatic aldehyde.<sup>981</sup> Oxygen and a Co/Schiff base complex also oxidizes tertiary amines, including pyridine.<sup>982</sup> Bifunctional organocatalysts have been used for the enantioselective synthesis of axially chiral isoquinoline *N*-oxides.<sup>983</sup> Isoxazoline *N*-oxides have been prepared by reaction with hypervalent iodine compounds.<sup>984</sup>

Analogous to the oxidation of tertiary amines, tertiary phosphines are oxidized to phosphine oxides (R<sub>3</sub>P=O). Triphenylphosphine is converted to triphenylphosphine oxide with N<sub>2</sub>O at 100 °C, for example. Triphenylphosphine is also oxidized with PhIO on Montmorillonite K-10.<sup>985</sup> *tert*-Butylhydroperoxide oxidizes Ph<sub>3</sub>P→BH<sub>3</sub> to Ph<sub>3</sub>P=O.<sup>986</sup> *P*-Stereogenic phosphine oxides have been prepared.<sup>987</sup> 1,1-Diethoxyalkylphosphinates reacted with bromine and an alcohol or an amine to give phosphonates or phosphonamides.<sup>988</sup> Tertiary phosphines reacted with Selectfluor in aqueous acetonitrile to give tertiary phosphine oxides, phosphinates, and phosphonates.<sup>989</sup>

### 19-29 Oxidation of Thiols and Other Sulfur Compounds to Sulfonic Acid Derivatives

Thiols, sulfoxides, sulfones, disulfides,<sup>990</sup> and other sulfur compounds can be oxidized to sulfonic acids with various oxidizing agents, but for synthetic purposes the reaction is most important for thiols.<sup>991</sup> Among oxidizing agents used are boiling nitric acid, barium permanganate, and dimethyl dioxirane.<sup>992</sup> Autoxidation (oxidation by atmospheric oxygen) can be accomplished in basic solution.<sup>993</sup> Oxidation of thiols with chlorine and water gives sulfonyl chlorides directly.<sup>994</sup> Thiols can also be oxidized to disulfides (19-33).

In another oxidation reaction, primary alkyl aryl sulfones were oxidized to the corresponding carboxylic acids via double deprotonation by reaction with a base, followed by subsequent exposure to atmospheric oxygen.<sup>995</sup>

OS II, 471; III, 226. Also see, OS V, 1070.

### 19-30 Oxidation of Thioethers to Sulfoxides and Sulfones

Thioethers can be oxidized to sulfoxides<sup>996</sup> by 1 equivalent of 30% H<sub>2</sub>O<sub>2</sub> or by many other oxidizing agents,<sup>997</sup> including H<sub>2</sub>O<sub>2</sub> and Sc,<sup>998</sup> MeReO<sub>3</sub>,<sup>999</sup> Ti,<sup>1000</sup> Cu,<sup>1001</sup> Zn,<sup>1002</sup> sulfamic acids,<sup>1003</sup> 2,2,2-trifluoroacetophenone,<sup>1004</sup> cyanuric chloride/urea,<sup>1005</sup> diselenide/

urea,<sup>1006</sup> Cr,<sup>1007</sup> or V as catalyst.<sup>1008</sup> Other catalysts include NaIO<sub>4</sub>,<sup>1009</sup> HIO<sub>3</sub>/wet SiO<sub>2</sub>,<sup>1010</sup> dioxiranes,<sup>1011</sup> graphite oxide,<sup>1012</sup> O<sub>2</sub> and a ceric ammonium nitrate catalyst,<sup>1013</sup> H<sub>5</sub>IO<sub>6</sub>/FeCl<sub>3</sub>,<sup>1014</sup> Au/Mn,<sup>1015</sup> thiourea dioxide,<sup>1016</sup> Ag/*t*-BuOOH,<sup>1017</sup> aminotetrazoles/H<sub>2</sub>O,<sup>1018</sup> Bi/*t*-BuOOH,<sup>1019</sup> calcium hypobromite,<sup>1020</sup> flavin/O<sub>2</sub>,<sup>1021</sup> polymer-anchored Cu,<sup>1022</sup> pyridinium bromide perbromide/*tert*-butyl nitrite/air,<sup>1023</sup> peroxotungsten complex,<sup>1024</sup> hypervalent iodine compounds,<sup>1025</sup> cetyltrimethylammonium periodate,<sup>1026</sup> and peroxyacids.<sup>1027</sup> Sulfides were oxidized to sulfoxides using a bifunctional ionic liquid, [pmim] IO<sub>4</sub>.<sup>1028</sup> Immobilized taurine and homotaurine in aqueous media were used to oxidize sulfides to sulfoxides.<sup>1029</sup> A vitamin B2 organocatalyst has been used.<sup>1030</sup> Sulfides reacted with 1.1 equivalents of PhI(OAc)<sub>2</sub> and a TsOH catalyst to give the sulfoxide in aqueous solution, whereas sulfones were formed by treatment with 2.1 equivalents of PhI(OAc)<sub>2</sub>.<sup>1031</sup>

When the oxidizing agent is a peroxide, the mechanism<sup>1032</sup> of oxidation to the sulfoxide is similar to that of **19-28**, and the sulfide sulfur attacks the electrophilic O of R'OOH to give R<sub>2</sub>S<sup>+</sup>—OH, which loses R'OH to give the sulfoxide.<sup>1033</sup> The second oxidation to the sulfone, which is normally slower than the first (which is why sulfoxides are so easily isolable), has the same mechanism in neutral or acid solution, but in basic solution it has been shown that the conjugate base of the peroxy compound (R'OO<sup>-</sup>) also attacks the SO group as a nucleophile, and loss of R'O<sup>-</sup> leads to the sulfone.<sup>1034</sup> It is possible to oxidize

a thioether to a sulfoxide in the presence of an alcohol moiety using  $\text{MnO}_2/\text{HCl}$ .<sup>1035</sup> *N*-Sulfonyloxaziridines can be used to oxidize sulfides to sulfoxides.<sup>1036</sup>

Selenides ( $\text{R}_2\text{Se}$ ) can be oxidized to selenoxides and selenones.<sup>1037</sup>

Sulfoxides can be further oxidized to sulfones by another equivalent of  $\text{H}_2\text{O}_2$ ,  $\text{KMnO}_4$ , sodium perborate, or a number of other agents. If enough oxidizing agent is present, thioethers can be directly converted to sulfones without isolation of the sulfoxides.<sup>1038</sup> Thioethers can be oxidized directly to the sulfone by treatment with  $\text{H}_2\text{O}_2$ <sup>1039</sup> and a Fe,<sup>1040</sup> Zr,<sup>1041</sup> Ta,<sup>1042</sup> V,<sup>1043</sup> Au,<sup>1044</sup> Mo,<sup>1045</sup> or urea catalyst.<sup>1046</sup> In addition, TPAP,<sup>1047</sup> a flavin/ionic liquid catalyst,<sup>1048</sup> or peroxy monosulfate and a Mn catalyst<sup>1049</sup> can be used. These reactions give high yields, and many functional groups do not interfere.<sup>1050</sup> There are some reagents that oxidize sulfoxides in preference to sulfides, for example,  $\text{NaMnO}_4$ .<sup>1051</sup>

As with tertiary amines (19-28), racemic thioethers can be kinetically resolved by oxidation to sulfoxides with an optically active reagent, and this has often been done.<sup>1052</sup> In addition, the use of chiral additives in conjunction with various oxidizing agents leads to chiral nonracemic sulfoxides with good-to-excellent enantioselectivity.<sup>1053</sup> Asymmetric oxidation using bacterial monooxygenases is known,<sup>1054</sup> and horseradish peroxidase gives modest enantioselectivity.<sup>1055</sup> Chiral sulfur reagents are also known.<sup>1056</sup> Oxidation to give chiral sulfoxides with good enantioselectivity has been reported using confined chiral Brønsted acids,<sup>1057</sup> Mn,<sup>1058</sup> Ti,<sup>1059</sup> Ru/mcpba,<sup>1060</sup> Fe/porphyrin/

## E. Oxidative Coupling

### 19-31 Coupling Involving Carbanions

Alkyl halides with an electron-withdrawing group on the halogen-bearing carbon can be dimerized to alkenes by treatment with bases. The Z group may be nitro, aryl, and so on. It is likely that in most cases the mechanism<sup>1068</sup> involves nucleophilic substitution followed by elimination.<sup>1069</sup>  $\alpha,\alpha$ -Dibromotoluenes ( $\text{ArCHBr}_2$ ) give tolanes  $\text{ArC}\equiv\text{CAr}$  by debromination of the intermediates  $\text{ArCBr}=\text{CBrAr}$ .<sup>1070</sup> In a related reaction, diarylmethane dihalides ( $\text{Ar}_2\text{CX}_2$ ) have been dimerized to tetraaryl alkenes ( $\text{Ar}_2\text{C}=\text{CAr}_2$ ) with Cu,<sup>1071</sup> and with iron(II) oxalate dihydrate.<sup>1072</sup>

A somewhat different type of coupling is observed when salts of  $\beta$ -keto esters, ary-lacetonitriles ( $\text{ArCH}_2\text{CN}$ ), and other compounds of the form  $\text{ZCH}_2\text{Z}'$  are treated with an oxidizing agent, such as iodine<sup>1073</sup> or Cu(II) salts.<sup>1074</sup> Arylmethanesulfonyl chlorides ( $\text{ArCH}_2\text{SO}_2\text{Cl}$ ) couple to give  $\text{ArCH}=\text{CHAr}$  when treated with  $\text{Et}_3\text{N}$ .<sup>1075</sup>

## 19-32 Dimerization of Silyl Enol Ethers or of Lithium Enolates

Silyl enol ethers can be dimerized to symmetrical 1,4-diketones by treatment with  $\text{Ag}_2\text{O}$  in DMSO or certain other polar aprotic solvents.<sup>1076</sup> The reaction has been performed with  $\text{R}^2, \text{R}^3 = \text{hydrogen or alkyl}$ , although best yields are obtained when  $\text{R}^2 = \text{R}^3 = \text{H}$ . In certain cases, unsymmetrical 1,4-diketones have been prepared by using a mixture of two silyl enol ethers. Other reagents that have been used to achieve either symmetrical or cross-coupled products are iodobenzene/ $\text{BF}_3\text{-OEt}_2$ ,<sup>1077</sup> ceric ammonium nitrate,<sup>1078</sup> and lead tetraacetate.<sup>1079</sup> If  $\text{R}^1 = \text{OR}$  (in which case the substrate is a ketene silyl acetal), dimerization with  $\text{TiCl}_4$  leads to a dialkyl succinate ( $\text{R}^1 = \text{OR}$ ; above).<sup>1080</sup>

In a similar reaction, lithium enolates,  $\text{RC}(\text{OLi})=\text{CH}_2$ , were dimerized to 1,4-diketones ( $\text{RCOCH}_2\text{CH}_2\text{COR}$ ) with  $\text{CuCl}_2$ ,  $\text{FeCl}_3$ , or copper(II) triflate, in a nonprotic solvent.<sup>1081</sup> The V-induced intermolecular cross-coupling of boron enolates and silyl enolates gave unsymmetrical 1,4-diones via an electrophilic carbonyl  $\alpha$ -radical species.<sup>1082</sup>

OS VIII, 467.

## 19-33 Oxidation of Thiols to Disulfides

Thiols are easily oxidized to disulfides.<sup>1083</sup> Hydrogen peroxide is the most common reagent,<sup>1084</sup> but many oxidizing agents give the reaction, among them  $\text{Br}_2$  on hydrated silica,<sup>1085</sup>  $\text{SmI}_2$ ,<sup>1086</sup>  $\text{PPh}_3/\text{Rh}$ ,<sup>1087</sup> a Pd catalyst,<sup>1088</sup> cupric nitrate,<sup>1089</sup>  $\text{I}_2/\text{DMSO}$ ,<sup>1090</sup> diaryl tellurides,<sup>1091</sup>  $\text{O}_2$  with nanoporous Co,<sup>1092</sup> Se/ionic liquid,<sup>1093</sup> cetyltrimethylammonium

dichromate,<sup>1094</sup> and NO. Hydrogen peroxide (30%) in hexafluoropropan-2-ol converts thiols to disulfides,<sup>1095</sup> and solvent-free reactions on MnO<sub>2</sub>,<sup>1096</sup> PCC,<sup>1097</sup> or SO<sub>2</sub>Cl<sub>2</sub><sup>1098</sup> are also effective. Even oxygen in the air oxidizes thiols on standing, if a small amount of base is present. The reaction is reversible, and the interconversion between cysteine and cystine is an important one in biochemistry. The mechanism has been studied for several oxidizing agents and varies with the agent.<sup>1099</sup>

Unsymmetrical disulfides can be prepared<sup>1100</sup> by treatment of a thiol RSH with diethyl azodicarboxylate (EtOOCN=NCOOEt) to give an adduct, to which another thiol R'SH is then added, producing the disulfide RSSR'.<sup>1101</sup>

The oxidation of thiols to the corresponding disulfide used HBr or HI with dimethyl sulfoxide.<sup>1102</sup> The oxidative coupling of two different thiols with trichloroisocyanuric acid gave the unsymmetrical disulfide.<sup>1103</sup> Thiols were converted to the corresponding homodisulfides by reaction with O<sub>2</sub> and H<sub>2</sub>O/Et<sub>2</sub>NH.<sup>1104</sup> Unsymmetrical sulfides were prepared by the cross-coupling reaction of aryl/het-aryl/benzyl halides with sulfonyl hydrazides as thiol surrogates by reaction with [DBU][HOAc] and CuI with microwave irradiation.<sup>1105</sup> A mixture of thiols reacted with DDQ to give the corresponding unsymmetrical disulfide.<sup>1106</sup> Aryl iodides reacted with elemental tellurium in the presence of KOH to give the diaryl telluride.<sup>1107</sup> Aryl or alkyl halides reacted with potassium 5-methyl-1,3,4-oxadiazole-2-thiolate in the presence of a Ni catalyst to give symmetrical aryl or alkyl disulfides.<sup>1108</sup> Symmetrical dibenzyl diselenides or disulfides were prepared by reaction of a benzyl alcohol with NaBH<sub>2</sub>Se<sub>3</sub> or NaBH<sub>2</sub>S<sub>3</sub> as the selenium-transfer or the sulfur-transfer reagent.<sup>1109</sup>

OS III, 86, 116.

### 19.B.ii. Reductions<sup>1110</sup>

The reactions in this section are classified into groups depending on the type of bond change involved. These groups are (i) attack at carbon (C=C, C≡C, C—O, and C=O), (ii) attack at noncarbonyl multiple bonds to heteroatoms, (iii) reactions in which a heteroatom is removed from the substrate, (iv) reduction with cleavage, (v) reductive coupling, and (vi) reactions in which an organic substrate is both oxidized and reduced. Most of the reagents in this section are metal hydrides, metals with an acid or a protic solvent, hydrogen gas with

a catalyst, etc. Other reducing agents are available, and will be introduced in the appropriate section. It is noted that plants can be used as reducing agents.<sup>1111</sup>

## A. Selectivity<sup>1112</sup>

It is often necessary to reduce one group in a molecule without affecting another reducible group (this is called chemoselectivity), and reducing agents are available that will do this. The most common broad-spectrum reducing agents are the metal hydrides<sup>1113</sup> or hydrogen (with a catalyst).<sup>1114</sup> Many different metal hydride systems and hydrogenation catalysts have been investigated in order to find conditions under which a given group will be reduced chemoselectively. The ease of reduction for various functional groups towards catalytic hydrogenation is acyl halides > alkyl nitro compounds > alkynes > aldehydes > alkenes > ketones > benzylic ethers > nitriles > esters > amides.<sup>1115</sup> A list of the reactivity of various functional groups with  $\text{LiAlH}_4$  or with  $\text{BH}_3$  has been reported.<sup>1115</sup> Table 19.2 shows which groups can be reduced by catalytic hydrogenation or by various metal hydrides.<sup>1116</sup> Of course, the tables cannot be exact, because the nature of R and the reaction conditions obviously affect reactivity. Nevertheless, the tables do give a fairly good indication of which reagents reduce which groups.<sup>1117</sup>  $\text{LiAlH}_4$  is very powerful and unselective reagent.<sup>1118</sup> Other metal hydrides are generally used when chemoselectivity is required. As will be seen in **19-40**, less reactive (and more selective) reagents have been prepared by replacing some of the hydrogen atoms of  $\text{LiAlH}_4$  with alkoxy groups.<sup>1119</sup> Most of the metal hydrides are nucleophilic reagents and attack the carbon atom of a carbon-hetero single or multiple bond. However,  $\text{BH}_3$ <sup>1120,1121</sup> and  $\text{AlH}_3$ <sup>1122</sup> are electrophiles (Lewis acids) and attack the heteroatom. This accounts for the different patterns of selectivity.

<sup>1128</sup> Reduced to a hydroxylamine (19-46).

## B. Attack at Carbon (C=C, C≡C, C–O, and C=O)

### 19-34 Hydrogenation of Double and Triple Bonds<sup>1129</sup>

Most carbon-carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.<sup>1130</sup> However, a transition metal catalyst is required to break apart H<sub>2</sub> into metal-bound hydrogen atoms before reaction can occur with the alkene. Almost all known alkenes added hydrogen at temperatures between 0 and 275 °C.<sup>1131</sup> Hydrogenation is generally under thermodynamic control and steric effects play an important role.<sup>1132</sup> The catalysts used can be divided into two broad classes:

1. Catalysts insoluble in the reaction medium (*heterogeneous catalysts*). Among the most effective are Raney nickel,<sup>1133</sup> Pd-on-charcoal,<sup>1134</sup> Co,<sup>1135</sup> Pt metal<sup>1136</sup> or its oxide, Rh, and Ru. The facet-dependent catalysis in the hydrogenation of alkenes was examined using shape-controlled Pd nanocrystals.<sup>1137</sup> It is noted that heterogeneous catalysts are usually poisoned by small amounts of sulfur, which is often found in rubber stoppers, or by thiols and sulfides.<sup>1138</sup>
2. Catalysts soluble in the reaction medium (*homogeneous catalysts*).<sup>1139</sup> Heterocycles such as pyrroles were hydrogenated to chiral 1-pyrrolines using a Pd catalyst and EtSO<sub>3</sub>H.<sup>1140</sup> An important example is *Wilkinson's*

*catalyst*<sup>1141</sup> [chlorotris(triphenylphosphine)rhodium,  $\text{RhCl}(\text{Ph}_3\text{P})_3$ ],<sup>1142</sup> which is tolerant of many functional groups in the same molecule.<sup>1143</sup> Even unsaturated aldehydes can be reduced to saturated aldehydes,<sup>1144</sup> although in this case decarbonylation (**14-26**) is sometimes a side reaction. While homogenous catalysts are generally tolerant of many functional groups, some are susceptible to catalytic reduction. However, it is usually possible to find conditions under which double bonds can be reduced selectively.<sup>1145</sup> Using soluble homogeneous catalysts,<sup>1146</sup> unfunctionalized alkenes are hydrogenated with good selectivity using various metal catalysts. Modification of the catalyst includes a polymer-bound Ru catalyst<sup>1147</sup> and a polymer-incarcerated Pd catalyst.<sup>1148</sup> A nanoparticulate Pd catalyst in an ionic liquid has been used for the hydrogenation of alkenes.<sup>1149</sup>

Homogeneous catalysts<sup>1150</sup> have the advantages of better catalyst reproducibility and better selectivity. Homogeneous catalysts are also less susceptible to catalyst poisoning.<sup>1151</sup> It is noted that heterogeneous catalysts are usually easier to separate from a reaction mixture. Apart from Wilkinson's catalyst, chlorotris(triphenylphosphine)hydridoruthenium(II),  $(\text{Ph}_3\text{P})_3\text{RuClH}$ ,<sup>1152</sup> is an important homogeneous catalyst that is specific for terminal double bonds. Other double bonds are hydrogenated slowly or not at all.

Hydrogenations are carried out at room temperature and just above atmospheric pressure, in most cases, but some double bonds are more resistant and require higher temperatures and pressures. The poor reactivity is usually a function of increasing substitution and is presumably caused by steric factors since both alkene and hydrogen gas must bind to the catalyst (see below). Trisubstituted double bonds require, say, 25 °C and 100 atm, while tetrasubstituted double bonds may require 275 °C and 1000 atm. Among the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings. Hydrogenations, even at about atmospheric pressure, are often performed in a special hydrogenator, but this is not always necessary. Indeed, placing a hydrogen-filled balloon over the reaction flask is common for small-scale hydrogenations that do not require heat or pressure. It has been shown that the pressure of the reaction can influence enantioselectivity in asymmetric catalytic hydrogenations.<sup>1153</sup>

Ligand development<sup>1154</sup> has been an important area of research that impacts homogeneous catalysts, especially enantioselective reactions,<sup>1155</sup> and ligands are used with many transition metals, including Ir,<sup>1156</sup> Co,<sup>1157</sup> Ni,<sup>1158</sup> Rh,<sup>1159</sup> Ru,<sup>1160</sup> Os,<sup>1161</sup> Au,<sup>1162</sup> Pd,<sup>1163</sup> or Zr.<sup>1164</sup> The chiral transition metal catalyst (Rh and Ru are probably the most common) is usually prepared with suitable chiral ligands<sup>1165</sup> prior to addition to the reaction. Alternatively, an achiral catalyst such as *Wilkinson's catalyst* is simply added along with a chiral ligand. With monophosphine chiral ligands,<sup>1166</sup> the phosphorus may be chiral but pyramidal inversion at elevated temperatures (Sec. 4.C) limits the utility of such ligands. Examples are R-camp, which is cyclohexyl(2-methoxyphenyl)(methyl)phosphane,<sup>1167</sup> and dipamp, which is 1,2-bis((2-methoxyphenyl)(phenyl)phosphane)ethane.<sup>1168</sup> The alternative is to prepare phosphines that contain a chiral carbon, as in ((2*S*,3*S*)-butane-2,3-diyl)bis(diphenylphosphane) (known as Chiraphos),<sup>1169</sup> but there are many variations of chiral bis(phosphine) ligands.<sup>1170</sup> Chiral poisoning has been used as a strategy for asymmetric catalysis.<sup>1171</sup> Ionic liquids have been used for catalytic hydrogenation.<sup>1172</sup>

The influence of organic solvents on the bioreduction of alkenes was studied using ene-reductases.<sup>1173</sup> A biocatalytic hydrogenation has been reported using continuous flow conditions (Sec. 7.D).<sup>1174</sup> There is a biocompatible alkene hydrogenation which uses hydrogen gas produced directly by microbial metabolism for the hydrogen of alkenes as well as other substrates.<sup>1175</sup> The frustrated Lewis acid-catalyzed hydrogenation of alkenes has been reported.<sup>1176</sup>

Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned in the following two sections. The comparative reactivity of triple and double bonds depends on the catalyst. *With most catalysts (e.g., Pd), triple bonds are hydrogenated more easily*, and therefore it is usually possible to add just 1 equivalent of hydrogen and reduce a triple bond to a double bond or to reduce a triple bond without affecting a double bond present in the same molecule.<sup>1177</sup> A particularly good catalyst for this purpose is the *Lindlar catalyst* (Pd/CaCO<sub>2</sub>/PbO),<sup>1178</sup> which gives rather clean *syn* addition, and a (*Z*)-alkene. An alternative catalyst used for selective hydrogenation to (*Z*)-alkenes is Pd on barium sulfate (BaSO<sub>4</sub>), poisoned with quinoline<sup>1179</sup> (sometimes called the *Rosenmund catalyst*). Palladium-on-calcium carbonate in polyethylene glycol (PEG) has also been used as a recyclable catalyst system.<sup>1180</sup> Other (*Z*)-selective hydrogenation catalysts have been developed,<sup>1181</sup> including those based on Au,<sup>1182</sup> Ni,<sup>1183</sup> Ru,<sup>1184</sup> Co,<sup>1185</sup> Pd,<sup>1186</sup> Cu,<sup>1187</sup> or Nb,<sup>1188</sup> although transition metal catalysis of the semihydrogenation of terminal alkynes is known, including using an Au<sup>1189</sup> or a Pd<sup>1190</sup> catalyst. Semihydrogenation with (*E*)-selectivity is known using heterobimetallic

catalysts,<sup>1191</sup> Fe,<sup>1192</sup> or Ru/AgOTf.<sup>1193</sup> The transition metal-free (*E*)-selective semihydrogenation has been reported using Na<sub>2</sub>S•9H<sub>2</sub>O.

Conjugated dienes can add hydrogen by 1,2 or 1,4 addition. Selective 1,4 addition can be achieved by hydrogenation in the presence of CO, with bis(cyclopentadienyl)chromium as catalyst.<sup>1194</sup> With allenes<sup>1195</sup> catalytic hydrogenation usually reduces both double bonds.

The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly understood.<sup>1196</sup> Because the metal catalyst is insoluble in the reaction medium, kinetic data, although easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret and there are the difficulties caused by hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.<sup>1197</sup> According to this proposal, the alkene is adsorbed onto the surface of the metal. The nature of the actual bonding is unknown,<sup>1198</sup> despite many attempts to elucidate it.<sup>1199</sup> In the 1934 work, the metallic site was indicated by an asterisk, but here  is used. For steric reasons it is apparent that adsorption of the alkene takes place with its less-hindered side attached to the catalyst surface, probably as an η<sup>2</sup> complex (Sec. 3.C.i). The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before hydrogen reacts with the alkene. It has been shown that Pt catalyzes homolytic cleavage of hydrogen molecules,<sup>1200</sup> and cleavage of H–H is likely common to the other metal catalysts. The H<sub>2</sub> molecule is probably adsorbed on (coordinated to) the metal catalyst, and then cleavage occurs to give η<sup>1</sup>-coordinated hydrogen atoms (Sec. 3.C.i).

Note that this model suggests a single metal particle for coordination of the alkene and the hydrogen atoms, but the hydrogen atoms and the alkene could be coordinated to different metal particles.<sup>1201</sup> In the second step, one of the adsorbed (η<sup>1</sup>-coordinated) hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical (which is still bound to the catalyst although only by one bond, probably η<sup>1</sup> coordination). Transfer of a hydrogen atom to carbon opens a site on the metal catalyst for coordination to additional

hydrogen atoms. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and the metal catalyst is now available for coordination of additional hydrogen atoms and/or alkenes. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process.<sup>1202</sup>

It is noted that a different mechanism has been proposed,<sup>1203</sup> and there are questions that the mechanistic cartoon shown does not answer,<sup>1204</sup> among them the nature of the  $\sigma$  bond, the nature of the bonding, and the differences caused by the differing nature of each catalyst.<sup>1204</sup> An important problem with any study of heterogeneous catalysis is that it occurs at the surface, and there are different exposures of the metal to the medium and reactants. Maier suggested the presence of *terrace*-, *step*-, and *kink*-type atoms on the surface of a heterogeneous catalyst. These terms refer to different atom types, characterized by the number of nearest neighbors,<sup>1204</sup> which effectively correspond to different coordination states of that metal.<sup>1205</sup> A terrace-type atom typically has eight or nine neighbors and corresponds to a geometry for a  $ML_5$  particle. The step-type of atom usually has seven neighbors and can be correlated with the geometry for a  $ML_4$  particle. Finally, the kink-type atom has six neighbors and corresponds to geometry for the  $ML_3$  particle. Depending on how much of the metal is "buried" in the heterogeneous metal particle, only one, two or three sites are available for binding to the alkene and  $H_2$ .<sup>1206</sup> In general, as the particle size increases, the relative concentration of terrace atoms will increase, whereas small particle size favors the kink-type of surface atoms.

The mechanism of homogeneous hydrogenation varies with the metal<sup>1207</sup> but can be illustrated by the reaction of  $RhCl(Ph_3P)_3$  (Wilkinson's catalyst)<sup>1208</sup> with hydrogen to form a metal hydride  $(PPh_3)_2RhH_2Cl$  (**19**).<sup>1209</sup>

Replacement of a triphenylphosphine ligand with two atoms of hydrogen constitutes an oxidative addition. After coordination of the alkene to form **20**, transfer of hydrogen to carbon is an insertion process, presumably generating **21**, and a second insertion liberates the hydrogenated compound, and Rh species **22**, which adds hydrogen by oxidative addition to give **19**. In a different study of Pd-catalyzed hydrogenations, a palladium hydride species was detected.<sup>1210</sup> Alternatively, replacement of triphenylphosphine can lead to **20**, with two hydrogen atoms and a  $\eta^2$  alkene complex. If a mixture of H<sub>2</sub> and D<sub>2</sub> is used, the product contains only dideuterated and nondeuterated compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H<sub>2</sub> or D<sub>2</sub> has been added to one alkene molecule and that no exchange takes place.<sup>1208</sup> Although conversion of **20** to the products takes place in two steps,<sup>1211</sup> the addition of H<sub>2</sub> to the double bond is *syn*, although bond rotation in **21** can lead to stereochemical mixtures.

Catalytic hydrogenation of double or triple bonds (involve binding of both a  $\pi$  bond and hydrogen to the metal, whether heterogeneous or homogeneous) has been shown to be mostly *syn*, with the hydrogen atoms incorporated from the less-hindered side of the molecule.<sup>1212</sup> The *selectivity depends in large part of how well the reactive intermediates are bound to the metal, and isomerization of the double bond is possible*. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the *cis*-alkene (usually at least 80%), even when it is thermodynamically less stable, but this observation depends on the metal catalyst used. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogen atoms takes place, as can be shown by hydrogenation with deuterium.<sup>1213</sup> Thus deuterogenation of ethylene produced all the possible deuterated ethenes and ethanes (even C<sub>2</sub>H<sub>6</sub>), as well as HD.<sup>1214</sup> With but-2-ene, it was found that double-bond migration, *cis/trans* isomerization, and even exchange of hydrogen with groups not on the double bond, could occur. For example, C<sub>4</sub>H<sub>2</sub>D<sub>8</sub> and C<sub>4</sub>HD<sub>9</sub> were detected on treatment of *cis*-but-2-ene with deuterium and a catalyst.<sup>1215</sup> Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,<sup>1216</sup> for example, CH<sub>4</sub> + CD<sub>4</sub> → CHD<sub>3</sub> + CH<sub>3</sub>D in the gas phase, with a catalyst. These problems make it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.

Reductions of double and triple bonds are found at OS **I**, 101, 311; **II**, 191, 491; **III**, 385, 794; **IV**, 298, 304, 408; **V**, 16, 96, 277; **VI**, 68, 459; **VII**, 226, 287; **VIII**, 420, 609; **IX**, 169, 533.

Catalysts and apparatus for hydrogenation are found at OS **I**, 61, 463; **II**, 142; **III**, 176, 181, 685; **V**, 880; **VI**, 1007.

### 19-35 Other Reductions of Double and Triple Bonds

<sup>1216</sup> See Gudkov, B.S.; Balandin, A.A. *Russ. Chem. Rev.* **1966**, *35*, 756. For an intramolecular exchange, see Lebrilla, C.B.; Maier, W.F. *Tetrahedron Lett.* **1983**, *24*, 1119. See also, Poretti, M.; Gäumann, T. *Helv. Chim. Acta* **1985**, *68*, 1160.

Although catalytic hydrogenation is the method most often used, double or triple bonds can also be reduced by other reagents. These reagents include sodium in ethanol, sodium and *tert*-butyl alcohol in HMPA,<sup>1217</sup> lithium in aliphatic amines<sup>1218</sup> (see also, **19-36**), zinc and acids, and (EtO)<sub>3</sub>SiH/Pd(OAc)<sub>2</sub>.<sup>1219</sup> When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the *Birch reduction* (**19-36**).<sup>1220</sup> Note that sodium in liquid ammonia does not reduce ordinary double bonds,<sup>1221</sup> although it does reduce alkynes, allenes, conjugated dienes,<sup>1222</sup> and aromatic rings (**19-36**). Zinc metal catalyzes the reduction of alkenes in water in the presence of a Rh complex.<sup>1223</sup> Trialkylsilanes (R<sub>3</sub>SiH) in conjunction with an acid will reduce double bonds.<sup>1224</sup> The reduction with trifluoroacetic acid and Et<sub>3</sub>SiH has an ionic mechanism, with H<sup>+</sup> coming in from the acid and “H<sup>-</sup>” from the silane,<sup>1225</sup> so the reaction can be applied only to those alkenes which when protonated can form a tertiary carbocation or one stabilized in some other way, for example, by a OR substitution.<sup>1226</sup>

Reduction of an alkyne to an alkene can be done by heating with In metal in aqueous ethanol.<sup>1227</sup> Alkynes are reduced with palladium acetate and sodium ethoxide. In methanol the product is the alkane, whereas in THF the product is the *cis*-alkene.<sup>1228</sup> Triethylamine reduces alkynes in the presence of a Pd catalyst.<sup>1229</sup> Samarium iodide in water and a triamine additive led to reduction of alkenes.<sup>1230</sup>

Another hydrogenation method is called *transfer hydrogenation*.<sup>1231</sup> In this method the hydrogen atom comes from another organic molecule, which is oxidized. A transition metal catalyst, heterogeneous or homogeneous, is frequently employed. Nickel nanoparticles reduce alkenes by transfer hydrogenation using propan-2-ol.<sup>1232</sup> Transfer hydrogenation of alkenes with strongly electron-withdrawing groups on one side of the double bond occurs by reaction with ammonia borane under mild conditions without using a catalyst.<sup>1233</sup> The Ru-catalyzed transfer hydrogenation of 1,6-diyne occurs via alcohol activation.<sup>1234</sup> The Fe-catalyzed transfer hydrogenation of terminal alkynes has been reported.<sup>1235</sup>

Asymmetric transfer hydrogenation in propan-2-ol with 2 equivalents of KOH per Ru atom by using a Ru catalyst is reported for the hydrogenation of alkene moieties.<sup>1236</sup>

Diimide NH=NH is a reducing agent for simple alkenes, and is formed *in situ* from N<sub>2</sub>H<sub>4</sub> from the reaction of a mixture of hydrazine and hydroxylamine.<sup>1237</sup> The rate of this reaction has been studied.<sup>1238</sup> Diimide has been generated from hydrazine with synthetic flavin catalysts.<sup>1239</sup> Diimide has been generated using flow techniques (Sec. 7.D).<sup>1240</sup> Although both the *syn* and *anti* forms of diimide are produced, only the *syn* form reduces the double bond,<sup>1241</sup> at least in part by a cyclic mechanism shown.<sup>1242</sup>

The addition is stereospecifically *syn*<sup>1243</sup> and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, although not much discrimination in this respect is observed where the difference in bulk effects is small.<sup>1244</sup> Diimide reductions are most successful with symmetrical multiple bonds (C=C, C≡C, N=N) and are not useful for those that are inherently polar (C≡N, C=N, C=O, etc.). Diimide is not stable enough for isolation at ordinary temperatures, although it has been prepared<sup>1245</sup> as a yellow solid at  $-196\text{ }^{\circ}\text{C}$ .

Hydrazine has been used for the hydrogenation of alkenes.<sup>1246</sup> The hydrogenation of alkenes using aqueous hydrazine and quinidine nitrate has been reported.<sup>1247</sup> The reaction of alkenes and hydrazine under photolytic conditions and air gave the hydrogenation product.<sup>1248</sup> Enantioselective reduction of certain alkenes has also been achieved by reduction with baker's yeast.<sup>1249</sup> A complex of lumiflavin with 2,6-bis(acylamino)pyridine that bears a 3,4,5-trialkoxybenzyl ether dendron unit was an efficient organocatalyst for the aerobic reduction of styrene to ethylbenzene.<sup>1250</sup>

An indirect method<sup>1251</sup> of double-bond reduction involves formation of an alkylborane from an alkene, followed by hydrolysis of the borane (**15-11**). Trialkylboranes can

be hydrolyzed by heating to reflux with carboxylic acids,<sup>1252</sup> while monoalkylboranes (RBH<sub>2</sub>) can be hydrolyzed with base.<sup>1253</sup> Triple bonds can be similarly reduced to *cis*-alkenes.<sup>1254</sup> Further reduction is also possible.<sup>1255</sup> Reduction of alkenes occurs with *tert*-butylamine•borane complex in methanol with 10% Pd/C.<sup>1256</sup>

Metallic hydrides, such as lithium aluminum hydride and sodium borohydride, without additives, do not typically reduce carbon-carbon double bonds. There are special cases where the double bond is polar, as in 1,1-diarylethenes<sup>1257</sup> and in enamines,<sup>1258</sup> where reduction can occur. Note that both LiAlH<sub>4</sub> and NaBH<sub>4</sub>, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts such as FeCl<sub>2</sub> or CoBr<sub>2</sub>.<sup>1259</sup> Transition metals such as Pd<sup>1260</sup> and Ru<sup>1261</sup> catalyze the reduction of alkenes using NaBH<sub>4</sub>. The Ni-catalyzed semihydrogenation of alkynes in the presence of NaBH<sub>4</sub> showed good selectivity for the (*Z*)-alkene.<sup>1262</sup>

Triple bonds can also be selectively reduced to double bonds with diisobutylaluminum hydride (Dibal-H),<sup>1263</sup> with activated zinc (see **12-37**),<sup>1264</sup> or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low molecular weight amine.<sup>1265</sup> Terminal alkynes are not reduced by the Na/NH<sub>3</sub> procedure because they are converted to acetylide ions under these conditions. A terminal alkyne was reduced with lithium naphthalenide and NiCl<sub>2</sub>.<sup>1266</sup> and simple alkenes could be reduced.<sup>1267</sup> It is noted that the reaction with Dibal-H usually gives the *cis* alkene (**19-34**). Most of the other methods of triple-bond reduction lead to the more thermodynamically stable *trans* alkene. However, hydrolysis of boranes or reductions with activated zinc, hydrazine, or NH<sub>2</sub>OSO<sub>3</sub>H give the *cis* products.

Reduction of just one double bond of an allene, to give an alkene, has been accomplished by treatment with Na/NH<sub>3</sub><sup>1268</sup> or with Dibal-H,<sup>1269</sup> and by hydrogenation with RhCl(PPh<sub>3</sub>)<sub>3</sub> as catalyst.<sup>1270</sup>

Reductions of double and triple bonds are found at OS **III**, 586, 742; **IV**, 136, 302, 887; **V**, 281, 993; **VII**, 524; **80**, 120.

## 19-36 Reduction of Aromatic Rings

Aromatic rings can be reduced by catalytic hydrogenation,<sup>1271</sup> but higher temperatures (100–200 °C) are required than for double bonds in alkenes.<sup>1272</sup> Although the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.<sup>1273</sup> Hydrogenations using phase-transfer catalysts often proceed under mild conditions.<sup>1274</sup> Hydrogenation in ionic liquids is known,<sup>1275</sup> as is hydrogenation in supercritical ethane containing water.<sup>1276</sup> Phenols may be reduced to cyclohexanones, presumably through the enol. A computational study of the mechanism of hydrogenation of aromatic compounds has been reported, and it was shown that the barrier for uncatalyzed 1,4-hydrogenation is substantially lower than that for 1,2-hydrogenation, despite similar reaction enthalpies.<sup>1277</sup>

It is usually impossible to stop the reduction of benzene rings after only one or two bonds have been reduced, since alkenes are more easily reduced than aromatic rings.<sup>1278</sup> Thus, 1 molar equivalent of benzene, treated with 1 molar equivalent of hydrogen, gives no cyclohexadiene or cyclohexene, but one-third equivalent of cyclohexane and two-thirds equivalent of recovered benzene.<sup>1279</sup> This mixture is not true for all aromatic systems. With anthracene, for example, it is easy to stop after only the 9,10-bond has been reduced (Sec. 2.I.i). The catalytic asymmetric hydrogenation of naphthalenes<sup>1280</sup> and other polycyclic aromatic hydrocarbons has been reported.<sup>1281</sup> Hydrogenation of phenol derivatives can lead to conjugated cyclohexenones.<sup>1282</sup> Hydrogenation of toluene in an ionic liquid using a Ru catalyst gave methylcyclohexane.<sup>1283</sup>

Heterocyclic compounds are often reduced by hydrogenation.<sup>1284</sup> The catalytic asymmetric hydrogenation of several heterocycles<sup>1285</sup> has been reported, including *N*-Boc-imidazoles and oxazoles,<sup>1286</sup> thiophenes and benzothiophenes,<sup>1287</sup> furans,<sup>1288</sup> benzofurans,<sup>1289</sup> pyridines,<sup>1290</sup> pyrimidines,<sup>1291</sup> indoles,<sup>1292</sup> isoquinolines,<sup>1293</sup> and quinolines.<sup>1294</sup> Furan gives THF, pyrroles<sup>1295</sup> give pyrrolidines, and pyridines<sup>1296</sup> give piperidines. The nitrogen-containing ring of quinolines is reduced by hydrogenation using iodine and an Ir catalyst.<sup>1297</sup> Catalytic hydrogenation of the five-membered ring in indole derivatives using a chiral Rh catalyst gave hydroindoles with excellent enantioselectivity.<sup>1298</sup>

When aromatic rings are reduced by Li (or K or Na) in liquid ammonia (such reductions are known as *dissolving metal reductions*), it is usually in the presence of an alcohol (often ethyl, isopropyl, or *tert*-butyl alcohol), 1,4-Addition of hydrogen takes place and nonconjugated cyclohexadienes are produced.<sup>1299</sup> This reaction is called the *Birch reduction*.<sup>1300</sup> Heterocycles, such as pyrroles,<sup>1301</sup> furans,<sup>1302</sup> pyridines,<sup>1303</sup> and indolones<sup>1304</sup> can be reduced using Birch reduction. Ammonia obtained commercially often has iron salts as impurities that lower the yield in the Birch reduction. Therefore it is often necessary to distill the ammonia.

When substituted aromatic compounds are subjected to the Birch reduction, electron-donating groups such as alkyl or alkoxy decrease the rate of the reaction and are

generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups, such as COOH or CONH<sub>2</sub>, increase the reaction rate and are found on the reduced positions of the product.<sup>1305</sup> The regioselectivity of the reaction has been examined.<sup>1306</sup> The mechanism involves solvated electrons,<sup>1307</sup> which are transferred from the metal to the solvent, and hence to the ring.<sup>1308</sup>

The sodium becomes oxidized to Na<sup>+</sup> and creates a radical ion (**23**).<sup>1309</sup> There is a great deal of evidence from esr spectra for these species.<sup>1310</sup> The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **24** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **23** are frequently obtained. There is evidence,<sup>1311</sup> at least with some substrates such as biphenyl, that the radical ion corresponding to **23** is converted to the carbanion corresponding to **24** by a different pathway, in which the order of the steps is reversed: first a second electron is gained to give a dianion,<sup>1308</sup> which then acquires a proton, producing the intermediate such as **24**. Ordinary alkenes are usually unaffected by Birch reduction conditions, so double bonds may be present in the molecule if they are not conjugated with the ring. However, phenylated alkenes, internal alkynes (**15-12**),<sup>1312</sup> and conjugated alkenes (with C=C or C=O) are reduced under these conditions.

Note that **23** is a resonance hybrid; that is, two additional canonical forms can be written. The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?<sup>1313</sup> An answer to this question has been proposed by Hine, who suggested that this case is an illustration of the operation of the *principle of least motion*.<sup>1314</sup> According to this principle, “those elementary reactions will be favored that involve the least

change in atomic position and electronic configuration.”<sup>1313</sup> Note that the <sup>13</sup>C NMR spectrum of **24** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.<sup>1315</sup>

Reduction of aromatic rings with Li<sup>1316</sup> or Ca<sup>1317</sup> in amines (instead of ammonia: called *Benkeser reduction*) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.<sup>1318</sup>

Transition metals and metal compounds can reduce aromatic rings in the proper medium. Indium metal reduces the pyridine ring in quinoline in aqueous ethanol solution<sup>1319</sup> as well as the C=C unit in the five-membered ring of indole derivatives.<sup>1320</sup> Samarium iodide (SmI<sub>2</sub>) reduces pyridine in aqueous THF<sup>1321</sup> and phenol in MeOH/KOH.<sup>1322</sup> Ammonium formate and a Pd/C catalyst reduces pyridine *N*-oxide to piperidine in methanol.<sup>1323</sup> The nitrogen-containing ring of quinolines is reduced with an Ir catalyst in isopropyl alcohol.<sup>1324</sup> The reduction of phenol to cyclohexanone over a Pd/C catalyst and HCOONa/H<sub>2</sub>O has been reported.<sup>1325</sup>

a Rh,<sup>1329</sup> Ru,<sup>1330</sup> Pd,<sup>1331</sup> Au,<sup>1332</sup> Ni,<sup>1333</sup> or Ir<sup>1334</sup> catalyst, and with Raney nickel alone.<sup>1335</sup> Reagents such as SmI<sub>2</sub><sup>1336</sup> and catecholborane<sup>1337</sup> are effective. Formic acid with a Pd catalyst reduced conjugated carboxylic acids.<sup>1338</sup> A zinc/titanocene protocol has been developed for conjugate reductions.<sup>1339</sup> Both NaBH<sub>4</sub> in MeOH/THF<sup>1340</sup> and NaCNBH<sub>3</sub> on a zeolite<sup>1341</sup> reduce  $\alpha,\beta$ -unsaturated nitro compounds to nitroalkanes.

In certain cases<sup>1342</sup> metallic hydride reagents may selectively reduce double bonds that are in conjugation with C=O bonds,<sup>1343</sup> although the C=O bonds are also reduced in many cases, as in the conversion of cyclopentenone to cyclopentanol.<sup>1344</sup> The reagent NaBH<sub>4</sub> has a greater tendency than LiAlH<sub>4</sub> to effect this double reduction, although even with NaBH<sub>4</sub> the product of 1,2-reduction (of the C=O bond) is usually formed in larger amount than the doubly reduced product. The NaBH<sub>4</sub>/acetic acid and Pd-catalyzed conditions gave selective 1,4-conjugate reduction of conjugated compounds.<sup>1345</sup> Mixed hydride reducing agents such as NaBH<sub>4</sub>/BiCl<sub>3</sub>,<sup>1346</sup> NaBH<sub>4</sub>/InCl<sub>3</sub>,<sup>1347</sup> and NaBH<sub>4</sub>/Er(OTf)<sub>3</sub><sup>1348</sup> have been used. The InCl<sub>3</sub>/NaBH<sub>4</sub> reagent was used to convert conjugated diene ketones (C=C–C=C–C=O) selectively to the nonconjugated alkenyl ketone (C=C–CH<sub>2</sub>CH<sub>2</sub>–C=O).<sup>1349</sup>

Transfer hydrogenation can be applied to the reduction of conjugated alkenes, including conjugated nitroalkenes.<sup>1350</sup> Reduction of the C=C unit of conjugated aldehydes is

conjugated carboxylic acids with a Rh catalyst used base-free conditions,<sup>1372</sup> and an Ir catalyst has also been used with tetrasubstituted alkene units of conjugated acids.<sup>1373</sup> The enantioselective hydrogenation of  $\alpha,\beta$ -disubstituted nitroalkenes using a Rh catalyst has been reported.<sup>1374</sup>

Optically active homogeneous hydrogenation catalysts have been used to achieve the enantioselective hydrogenation<sup>1375</sup> of many prochiral conjugated substrates.<sup>1376</sup> For example,<sup>1377</sup> hydrogenation of (*Z*)-2-acetamido-3-phenylacrylic acid with a suitable catalyst gives (+)- or (-)-acetylphenylalanine (depending on which enantiomer of the catalyst is used) with an enantiomeric excess as high as 96%.<sup>1378</sup> Prochiral substrates that give such high optical yields generally contain functional groups such as a carbonyl group,<sup>1379</sup> amide groups, cyano groups, or combinations of such groups.<sup>1380</sup> The catalyst in such cases<sup>1381</sup> is usually a Ru<sup>1382</sup> or Rh complex<sup>1383</sup> with chiral phosphine ligands.<sup>1384</sup> Good asymmetric induction<sup>1385</sup> has been achieved using chiral Rh complexes with other chiral additives.<sup>1386</sup> Iridium complexes have been used with excellent enantioselectivity.<sup>1387</sup> The role of solvent has been examined.<sup>1388</sup> Asymmetric hydrogenation of conjugated carboxylic acids in an ionic liquid is known using a chiral Ru complex.<sup>1389</sup>

The C=C unit of conjugated aldehydes has been reduced using AlMe<sub>3</sub> with a catalytic amount of CuBr<sup>1390</sup> and with ammonium formate/Pd/C.<sup>1391</sup> Polymer-supported formate

has been used for the 1,4-reduction of conjugated ketones<sup>1392</sup> and conjugated acids using a Rh catalyst and microwave irradiation.<sup>1393</sup> Isopropanol and an Ir catalyst give conjugate reduction of conjugated ketones.<sup>1394</sup> The reaction of conjugated ketones with aluminum chlorides, followed by treatment with water, generates the saturated ketone.<sup>1395</sup>

The use of frustrated Lewis pair dihydrogen activation gave selective hydrogenation of the carbon–carbon triple bond of conjugated ynones.<sup>1396</sup> The Rh-catalyzed enantioselective hydrogenation of unsaturated phosphonates has been reported.<sup>1397</sup>

Enzymatic reduction of conjugated systems requires reaction with certain purified or whole cell enzymes. Baker's yeast reduces conjugated nitro compounds to nitroalkanes<sup>1398</sup> and also reduces the C=C unit of conjugated ketones.<sup>1399</sup> Other enzymatic reductions are possible. A reductase from *Nicotiana tabacum* reduced a conjugated ketone to the saturated ketone, with excellent enantioselectivity.<sup>1400</sup> Enzyme YNAR-I and NADP-H reduces conjugated nitro compounds to nitroalkanes.<sup>1401</sup> Conjugated nitro compounds are reduced in the presence of *Clostridium sporogenes*.<sup>1402</sup>

### 19-38 Reductive Cleavage of Cyclopropanes

Cyclopropanes can be cleaved by catalytic hydrogenolysis.<sup>1403</sup> Among the catalysts used have been Ni, Pd, Rh,<sup>1404</sup> and Pt. The reaction can often be run under mild conditions.<sup>1405</sup> Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,<sup>1406</sup> can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.<sup>1407</sup> Similar reductions have been accomplished photochemically in the presence of LiClO<sub>4</sub>.<sup>1408</sup> This reaction is an excellent way to introduce a *gem*-dimethyl

unit into a molecule. Hydrogenation of a cyclopropane ring, for example, gave the *gem*-dimethyl unit.

### 19-39 Reduction of Epoxides

Reduction of epoxides is a special case of **19-61** and is easily carried out.<sup>1409</sup> A common reagent is LiAlH<sub>4</sub>,<sup>1410</sup> which reacts by the S<sub>N</sub>2-type mechanism, giving inversion of configuration. An epoxide on a substituted cyclohexane ring cleaves in such a direction as to give an axial alcohol. As expected for an S<sub>N</sub>2 mechanism, the hydrogen atom is usually delivered to the less-substituted carbon. The reaction has also been carried out with other reagents, for example, sodium amalgam in EtOH, Li in ethylenediamine,<sup>1411</sup> and by catalytic hydrogenolysis.<sup>1412</sup> Chemoselective and regioselective ring opening of allylic epoxides and of epoxy ketones and esters has been achieved with SmI<sub>2</sub>,<sup>1413</sup> with HCOOH/NEt<sub>3</sub> and a Pd catalyst,<sup>1414</sup> and with sodium bis(2-methoxyethoxy)aluminum hydride (Red-Al; also known as Vitride).<sup>1415</sup> Highly hindered epoxides can be conveniently reduced, without rearrangement, with lithium triethylborohydride (called Super Hydride).<sup>1416</sup> For certain substrates, the epoxide ring can be opened the other way by reduction with Pd/C and HCOONH<sub>4</sub>,<sup>1417</sup> or with BH<sub>3</sub> in THF.<sup>1418</sup> The usual product of epoxide reductions is the alcohol, but epoxides are reduced all the way to the alkane by titanocene dichloride<sup>1419</sup> and by Et<sub>3</sub>SiH/BH<sub>3</sub>.<sup>1420</sup>

Epoxy ketones are selectively reduced with lithium naphthalenide,<sup>1421</sup> or a Ca-mediated NaBH<sub>4</sub> reduction<sup>1422</sup> to the β-hydroxy ketone. Other reduction methods can lead to the epoxy alcohol. Reduction of epoxy amides with SmI<sub>2</sub> in methanol gave the α-hydroxy amide.<sup>1423</sup> Silica-coated magnetic nanoparticles, organic hydride, and 1-benzyl-1,4-dihydronicotinamide showed efficient activity in the catalytic reduction of α,β-epoxy ketones to β-hydroxy ketones.<sup>1424</sup> The reduction of α,β-epoxy ketones or 1,2-diketones to the corresponding β-hydroxy ketones or α-hydroxy ketones used a catalytic amount of BNAH (1-benzyl-1,4-dihydronicotinamide) or BNA<sup>+</sup>Br<sup>-</sup> in the presence of HCOOH/Et<sub>3</sub>N.<sup>1425</sup>

Epi-sulfides can be reduced to give the alkene using Bu<sub>3</sub>SnH in the presence of BEt<sub>3</sub>.<sup>1426</sup>

### 19-40 Reduction of Aldehydes and Ketones to Alcohols<sup>1427</sup>

Aldehydes can be reduced to primary alcohols, and ketones to secondary alcohols, by a number of reducing agents.<sup>1428</sup> Among the most used are metal hydrides such as LiAlH<sub>4</sub>, NaBH<sub>4</sub>, and related compounds.<sup>1429</sup> The hydride affinity of various aldehydes and ketones<sup>1430</sup> and their thermodynamic hydricity<sup>1431</sup> have been determined. Hydride reagents have two main advantages over many other reducing agents: They do not reduce unactivated carbon-carbon double or triple bonds (with the exception of propargylic alcohols),<sup>1432</sup> and with LiAlH<sub>4</sub> all four hydrogen atoms are theoretically usable for reduction. Methods are available for titrating hydride reagents.<sup>1433</sup> The scope of these reagents with ketones is similar to that with aldehydes.

The reaction is broad and general. Lithium aluminum hydride easily reduces aliphatic, aromatic, alicyclic, and heterocyclic aldehydes or ketones, containing double or triple bonds and/or nonreducible groups such as NR<sub>3</sub>, OH, OR, and F. If the molecule contains a group reducible by LiAlH<sub>4</sub> (e.g., NO<sub>2</sub>, CN, COOR), then that group is usually reduced. Since

$\text{LiAlH}_4$  reacts readily with water and alcohols, protic solvents must be excluded. Despite limited solubility, common solvents are ether and THF. Lithium aluminum hydride reduces even sterically hindered ketones.

The compound  $\text{NaBH}_4$  (sodium borohydride) has a similar scope, but is less reactive so it is more selective and so may be used in molecules that also contain  $\text{NO}_2$ , Cl, COOR, CN, and so on. Another advantage of  $\text{NaBH}_4$  is that it can be used in water or alcoholic solvents, and so is available to reduce compounds, such as sugars, that are not soluble in ethers.<sup>1434</sup> Other solvents can be used with some modification of the borohydride. For example, butyl-triphenylphosphonium borohydride reduces aldehydes to alcohols in dichloromethane.<sup>1435</sup> Reduction with  $\text{NaBH}_4$  activated by solid acid has been reported.<sup>1436</sup> A polymer-bound phase-transfer material that uses  $\text{NaBH}_4$  in wet THF has also been reported.<sup>1437</sup> Sodium borohydride on alumina, under microwave irradiation, is an effective reagent.<sup>1438</sup> Sodium borohydride has been used on silica gel.<sup>1439</sup> The aqueous borohydride reduction of carbonyls used sealed tube microwave conditions.<sup>1440</sup>

Addition of cerium salts to sodium borohydride leads to a reagent, presumably cerium borohydride (known as the *Luche reagent*),<sup>1441</sup> that gives very selective 1,2-reduction of conjugated aldehydes and ketones.<sup>1442</sup> The carbonyl of a conjugated ketone is reduced faster than that of a normal ketone. A cerium-free *Luche reduction* (1,2-reduction) on rehydrated alumina has been reported.<sup>1443</sup>

When a functional group is selectively attacked in the presence of a different functional group, the reaction is said to be *chemoselective*.<sup>1444</sup> A number of reagents have been found to reduce aldehydes much faster than they reduce ketones. Among these reagents<sup>1445</sup> are sodium triacetoxyborohydride,<sup>1446</sup>  $\text{NaBH}_4/\text{HCO}_2\text{H}$ ,<sup>1447</sup> and zinc borohydride in THF.<sup>1448</sup> Ketones can be chemoselectively reduced in the presence of aldehydes with  $\text{NaBH}_4$  in aqueous EtOH at  $-15^\circ\text{C}$  in the presence of cerium trichloride ( $\text{CeCl}_3$ ).<sup>1449</sup> The reagent lithium *n*-dihydropyridylaluminum hydride reduces diaryl ketones much better than dialkyl or alkyl aryl ketones.<sup>1450</sup> Most other hydrides reduce diaryl ketones more slowly than other types of ketones. Saturated ketones can be reduced in the presence of  $\alpha,\beta$ -unsaturated ketones with zinc borohydride.<sup>1451</sup>

<sup>1451</sup> Sarkar, D.C.; Das, A.R.; Ranu, B.C. *J. Org. Chem.* **1990**, 55, 5799.

In general,  $\text{NaBH}_4$  reduces carbonyl compounds in the order aldehydes >  $\alpha,\beta$ -unsaturated aldehydes > ketones >  $\alpha,\beta$ -unsaturated ketones, and a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type.<sup>1452</sup> A number of reagents will preferentially reduce the less sterically hindered of two carbonyl compounds, but by the use of diisobutylaluminum hydride (DIBALH, *i*- $\text{Bu}_2\text{AlH}$ ) in the presence of the Lewis acid methylaluminum bis(2,6-di-*tert*-butyl-4-methylphenoxide), it was possible selectively to reduce the *more hindered* of a mixture of two ketones.<sup>1453</sup> Diisobutylaluminum hydride is a strong reducing reagent, reducing most functional groups, and is most commonly used for the reduction of functional groups other than aldehydes or ketones. It is obvious that reagents can often be found to reduce one kind of carbonyl function in the presence of another.<sup>1454</sup> Quinones are reduced to hydroquinones by  $\text{LiAlH}_4$ ,  $\text{SnCl}_2/\text{HCl}$ , or sodium hydrosulfite  $\text{Na}_2\text{S}_2\text{O}_4$ , as well as by other reducing agents.

Sodium bis(2-methoxyethoxy)aluminum hydride ( $\text{NaAlH}_2(\text{OC}_2\text{H}_4\text{OMe})_2$ ; Red-Al) was prepared by Vit in 1967,<sup>1455</sup> and its reducing power is close to that of lithium aluminum hydride. In addition, it is stable to dry air (it does not ignite in even moist air or oxygen) and is thermally stable up to 200 °C. The greatest practical utility of Red-Al is its solubility in aromatic hydrocarbon and ether solvents, which allows it to be conveniently used for applications that require inverse addition of hydrides. Red-Al essentially reacts in the same way as  $\text{LiAlH}_4$ , reducing aldehydes, ketones<sup>1456</sup> and acid derivatives to alcohols.<sup>1457</sup> Reduction of conjugated carbonyls gives primarily 1,2-reduction to an allylic alcohol.<sup>1458</sup> Other functional groups can be reduced.<sup>1459</sup>

The  $\text{C}=\text{C}$  units in compounds that contain  $\text{C}=\text{O}$  double bonds are generally not affected by metallic hydrides. The  $\text{C}=\text{C}$  unit may be isolated or conjugated, but double bonds that are conjugated with the  $\text{C}=\text{O}$  group may or may not be reduced, depending on the substrate, reagent, and reaction conditions.<sup>1460</sup> Some reagents that reduce only the  $\text{C}=\text{O}$  bonds of  $\alpha,\beta$ -unsaturated aldehydes and ketones are  $\text{AlH}_3$ ,<sup>1461</sup>  $\text{NaBH}_4$ , or  $\text{LiAlH}_4$  in the presence of lanthanide salts,<sup>1462</sup> Co complexes,<sup>1463</sup>  $\text{NaBH}_4/\text{LiClO}_4$ ,<sup>1464</sup>  $\text{NaBH}_3(\text{OAc})$ ,<sup>1465</sup> and

Zn(BH<sub>4</sub>)<sub>2</sub><sup>1466</sup> on Y zeolite.<sup>1467</sup> Also, both LiAlH<sub>4</sub><sup>1468</sup> and NaBH<sub>4</sub><sup>1469</sup> predominantly reduce only the C=O bonds of C=C–C=O systems in most cases, although substantial amounts of fully saturated alcohols have been found in some cases.<sup>1468</sup> A mixture of InCl<sub>3</sub> and NaBH<sub>4</sub> reduced both the C=C and C=O units of conjugated ketones.<sup>1470</sup>

The reagent lithium tri-*sec*-butylborohydride LiBH(*sec*-Bu)<sub>3</sub> (L-Selectride) reduces cyclic and bicyclic ketones in a highly stereoselective manner.<sup>1471</sup> For example, 2-methylcyclohexanone gave *cis*-2-methylcyclohexanol with an isomeric purity greater than 99%. Both L-Selectride and the potassium salt (K-Selectride) reduce carbonyls in cyclic and acyclic molecules with high diastereoselectivity.<sup>1472</sup> The more usual reagents, for example, LiAlH<sub>4</sub> and NaBH<sub>4</sub>, reduce relatively unhindered cyclic ketones either with little or no stereoselectivity<sup>1473</sup> or give predominant formation of the more stable isomer (axial attack).<sup>1474</sup> Cyclohexanones that have a large degree of steric hindrance near the carbonyl group usually give predominant formation of the less stable alcohol, even with LiAlH<sub>4</sub> and NaBH<sub>4</sub>.

With most hydride reagents there is an initial attack on the carbon of the carbonyl group by a hydride equivalent (H<sup>-</sup>), but with BH<sub>3</sub><sup>1475</sup> the initial attack is on the oxygen. Detailed mechanisms are not known in most cases.<sup>1476</sup> With LiAlH<sub>4</sub> or NaBH<sub>4</sub>, the attacking species is the AlH<sub>4</sub><sup>-</sup> (or BH<sub>4</sub><sup>-</sup>) ion, which, in effect, transfers H<sup>-</sup> to the acyl carbon via a four-center transition state (**26**) to give the alkoxyaluminate.<sup>1477</sup> Hydrolysis in a second step gives the alcohol.

The mechanism is probably the same for NaBH<sub>4</sub>, except that B replaces Al in the sequence shown. Evidence that the cation plays an essential role, at least in some cases, is that when the Li<sup>+</sup> was effectively removed from LiAlH<sub>4</sub> (by the addition of a crown ether), the reaction did not take place.<sup>1478</sup> For NaBH<sub>4</sub>, the Na<sup>+</sup> does not seem to participate

<sup>1466</sup> For a review of the reactivity of this reagent, see Ranu, B. *Synlett* **1993**, 885.

in the transition state, but kinetic evidence shows that an OR group from the solvent does participate and remains attached to B.<sup>1479</sup>

The question of whether the initial complex in the  $\text{LiAlH}_4$  reduction can reduce another carbonyl to give  $(\text{H}-\text{C}-\text{O})_2\text{Al}^-\text{H}_4$  and so on has been controversial. It has been shown<sup>1480</sup> that this is probably not the case but that, more likely, the initially formed alkoxyaluminate disproportionates to  $(\text{H}-\text{C}-\text{O})_4\text{Al}^-$  and  $\text{AlH}_4^-$ , which is the only attacking species. Disproportionation has also been reported in the  $\text{NaBH}_4$  reaction.<sup>1481</sup>

An alkoxyaluminate is essentially  $\text{LiAlH}_4$  with one of the hydrogen atoms replaced by an alkoxy group, that is,  $\text{LiAlH}_3\text{OR}$ . The fact that alkoxyaluminates and other alkoxy derivatives of  $\text{LiAlH}_4$  are less reactive than  $\text{LiAlH}_4$  itself has led to the use of such compounds as reducing agents that are less reactive and more selective than  $\text{LiAlH}_4$ .<sup>1482</sup> An example is  $\text{LiAlH}(\text{O}-t\text{-Bu})_3$ . As an example of chemoselectivity in this reaction it may be mentioned that  $\text{LiAlH}(\text{O}-t\text{-Bu})_3$  has been used to reduce only the keto group in a molecule containing both keto and carboxylic ester groups.<sup>1483</sup> However, the use of such reagents is sometimes complicated by the disproportionation mentioned above, which may cause  $\text{LiAlH}_4$  to be the active species, even if the reagent is an alkoxy derivative. Another highly selective reagent (reducing aldehydes and ketones, but not other functional groups), which does not disproportionate, is potassium triisopropoxyborohydride.<sup>1484</sup>

Other reagents reduce aldehydes and ketones to alcohols.<sup>1485</sup>

1. *Hydrogen and a catalyst*.<sup>1486</sup> Catalytic hydrogenation of alkenes and alkynes is discussed in **19-34**. Aldehydes and ketones are readily reduced to alcohols. Common heterogeneous catalysts for carbonyls are Pt and Ru,<sup>1487</sup> Au,<sup>1488</sup> Ag,<sup>1489</sup> Mn,<sup>1490</sup> Pd,<sup>1491</sup> and homogeneous catalysts are commonly used,<sup>1492</sup> especially for

asymmetric hydrogenation. Frustrated Lewis pairs have been used to enable catalytic hydrogenation.<sup>1493</sup> Before the discovery of the metal hydrides, hydrogenation was one of the most common ways of effecting this reduction, but it suffers from the fact that C=C, C≡C, C=N, and C≡N bonds are also susceptible to reduction and there is often little or no selectivity for the C=O group.<sup>1494</sup> For aromatic aldehydes and ketones, reduction to the hydrocarbon (**19-66**) is a side reaction via hydrogenolysis of the initially produced alcohol (**19-59**). The mechanism of catalytic hydrogenation of aldehydes and ketones is probably similar to that of reaction **19-34**.<sup>1495</sup> A Pt/Co catalyst has been developed for the 1,2-reduction of conjugated aldehydes.<sup>1496</sup> Iron catalysts<sup>1497</sup> have been reported to show high chemoselectivity for the reduction of aldehydes with an isolated C=C bond.<sup>1498</sup>

2. *Sodium in ethanol*.<sup>1499</sup> This procedure is called the *Bouveault-Blanc procedure* and was more popular for the reduction of carboxylic esters (**19-42**) than of aldehydes or ketones before the discovery of LiAlH<sub>4</sub>.

Formation of a ketyl intermediate that is converted to a radical and then a carbanion prior to protonation<sup>1500</sup> has been suggested for the reaction with sodium in ethanol.<sup>1501</sup> The ketyl intermediate can be isolated.<sup>1502</sup>

Lithium is often a superior metal for alkali metal reductions.<sup>1503</sup>

3. *Other metal reductions*. A single carbonyl group of an  $\alpha$ -diketone can be reduced to give an  $\alpha$ -hydroxy ketone by heating with Zn powder in aqueous DMF<sup>1504</sup> or by heating with Zn in methanol in the presence of benzyltriethylammonium chloride.<sup>1505</sup> Aluminum and NaOH in aqueous methanol reduces ketones.<sup>1506</sup>  $\beta$ -Hydroxy ketones are reduced with good *anti* selectivity using an excess of SmI<sub>2</sub> in water,<sup>1507</sup> and other ketones or aldehydes are reduced with SmI<sub>2</sub><sup>1508</sup> in aqueous THF<sup>1509</sup> or with SmI<sub>2</sub>

in alcohols.<sup>1510</sup> Other metals can be used, including Mg in alcohols.<sup>1511</sup> Titanocene and Mn in water reduced acetophenone to the benzylic alcohol.<sup>1512</sup> 1,2-Diketones were reduced to the  $\alpha$ -hydroxy ketone with  $\text{TiI}_4$  in acetonitrile, followed by hydrolysis.<sup>1513</sup> Ammonia and aqueous  $\text{TiCl}_3$  in methanol reduces ketones.<sup>1514</sup> Ketones were reduced to the alcohol by treatment with a lithium•water dispersion and either  $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$  or  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  in THF.<sup>1515</sup> Ketones were reduced to alcohols using a Ni/Al alloy and 2.8 kbar pressure in an aqueous medium.<sup>1516</sup> Aromatic ketones have been reduced using a Rh complex.<sup>1517</sup> Functionalized acetylenic ketones have been reduced.<sup>1518</sup>

4. *Isopropyl alcohol and aluminum isopropoxide.*<sup>1519</sup> This is called the *Meerwein-Ponndorf-Verley reduction*.<sup>1520</sup> It is reversible, and the reverse reaction is known as the *Oppenauer oxidation* (see **19-3**):

The equilibrium is shifted by removal of the acetone by distillation. There is a report of the reduction of benzaldehyde to benzyl alcohol by heating with propan-2-ol at 225 °C for 1 day.<sup>1521</sup> The reaction usually takes place under very mild conditions and is highly specific for aldehydes and ketones, so that C=C bonds (including those conjugated with the C=O bonds) and many other functional groups can be present without themselves being reduced.<sup>1522</sup> This high specificity includes acetals, so that one of two carbonyl groups in a molecule can be specifically reduced if the other is first converted to an acetal.  $\beta$ -Keto esters,  $\beta$ -diketones, and other ketones and aldehydes with a relatively high enol content do not give this reaction. Zeolites have been used as a medium for this reduction.<sup>1523</sup> Indium tri(isopropoxide)<sup>1524</sup> and ytterbium triflate<sup>1525</sup> have been used as catalysts.

This reduction can be done catalytically<sup>1526</sup> and an aluminum-free, Zr/zeolite catalyst has been developed.<sup>1527</sup> Microwave irradiation of a ketone with propan-2-ol, KOH, and activated alumina gives good yields of the alcohol.<sup>1528</sup> When the carbonyl substrate has a stereogenic center, the reaction proceeds with good diastereoselectivity.<sup>1529</sup> A combination of propan-2-ol with BINOL and AlMe<sub>3</sub> leads to reduction of  $\alpha$ -chloro ketones to the chlorohydrin with good enantioselectivity.<sup>1530</sup>

The Meerwein-Ponndorf-Verley reaction usually<sup>1531</sup> involves a cyclic transition state, as shown:<sup>1532</sup>

but in some cases 2 molar equivalents of aluminum alkoxide are involved: one attacking the carbon and the other the oxygen, a conclusion that stems from the finding that in these cases the reaction was 1.5 order in alkoxide.<sup>1533</sup> *The alcohol solvent acts as a hydrogen donor in this reaction.*<sup>1534</sup> Although, for simplicity, the alkoxide is shown as a monomer, it actually exists as trimers and tetramers, which are the actual reactive species.<sup>1535</sup> It is noted that supercritical propan-2-ol has been used for reduction of ketones, without the need for a catalyst.<sup>1536</sup>

5. **Boranes.** Borane (BH<sub>3</sub>) and substituted boranes reduce aldehydes and ketones in a manner similar to their addition to C=C bonds (**15-11**).<sup>1537</sup> That is, the boron adds to the oxygen and the hydrogen to the carbon.<sup>1538</sup> The resulting borate is then hydrolyzed to the alcohol. A variety of alkylboranes can be used for reduction.<sup>1539</sup> Both 9-BBN<sup>1540</sup> (**15-11**) and BH<sub>3</sub>/Me<sub>2</sub>S<sup>1541</sup> reduce only the C=O group of conjugated aldehydes and ketones.<sup>1542</sup> Tributylborane in ionic solvents reduces aldehydes to alcohols.<sup>1543</sup> Enantioselective borane reductions lead to chiral alcohols.<sup>1544</sup> Spiroborate esters have been used for enantioselective

- the reduction of aldehydes in the presence of ketones.<sup>1568</sup> Thiol-capped Au nanoparticles were used in a flow system (Sec. 7.D) using an organosilane as a reducing agent.<sup>1569</sup> Controlling temperature and solvent leads to different ratios of *syn* and *anti* products.<sup>1570</sup> Silanes reduce ketones in the presence of  $\text{BF}_3 \cdot \text{OEt}_2$ .<sup>1571</sup> Piers and Parks discovered that  $\text{B}(\text{C}_6\text{F}_5)_3$  catalyzed carbonyl hydrosilation,<sup>1572</sup> and this reaction is now referred to as the *Piers hydrosilation*. *N*-Heterocyclic carbenes have used to catalyze the hydrosilation of carbonyl compounds.<sup>1573</sup>
9. *Ammonium formates*. Sodium formate and trialkylammonium formates can be used to reduce aldehydes and ketones to the corresponding alcohol. Decanal was reduced to decan-1-ol, for example, using sodium formate in *N*-methyl-2-pyrrolidinone as a solvent.<sup>1574</sup> A mixture of formic acid and ethyl magnesium bromide was used to reduce decanal to decan-1-ol in 70% yield.<sup>1575</sup> Transfer hydrogenation also occurs with formic acid/triethylamine and a Ru catalyst,<sup>1576</sup> in water<sup>1577</sup> or with a Pd catalyst.<sup>1578</sup> Transfer hydrogenation<sup>1579</sup> is the addition of hydrogen to a molecule from a source other than gaseous  $\text{H}_2$ . The reduction of aryl ketones by hydrogen transfer has been reported using *sec*-BuOH as the hydrogen donor in the presence of KOH.<sup>1580</sup> The transfer hydrogenation of aldehydes and ketones has been reported using flow conditions (Sec. 7.D) and hydrous zirconia<sup>1581</sup> or immobilized iridium.<sup>1582</sup>
10. *Enzymatic reductions*. Successful asymmetric reductions (see section A<sup>1112</sup>) have been achieved with biologically derived reducing agents,<sup>1583</sup> such as baker's yeast,<sup>1584</sup> enzymes from other organisms,<sup>1585</sup> or with other biocatalysts.<sup>1586</sup> Biocatalytic reduction of cyclic ketones using an alcohol dehydrogenase gave the axially chiral (*R*)-alcohol.<sup>1587</sup> Ionic liquids have been used in conjunction with enzymatic

reduction,<sup>1588</sup> and enzymatic reduction has been done in supercritical CO<sub>2</sub>.<sup>1589</sup> The chemoenzymatic reduction of 2-oxoacids has been reported, with good enantioselectivity.<sup>1590</sup> The bioreduction of ethyl 3-oxohexanoate has been reported.<sup>1591</sup> New biocatalysts have been used or developed.<sup>1592</sup> The bioreduction of acetophenone derivatives used red marine algae bacteria.<sup>1593</sup>

For other reduction reactions of aldehydes and ketones see **19-66**, **19-80**, and **19-85**.

### Asymmetric Reduction<sup>1594</sup>

Unsymmetrical ketones are prochiral (Sec. 4.M); that is, reduction creates a new stereogenic center. The relative effectiveness of various reagents for reduction of eight other types of ketone was determined, using several different reducing agents.<sup>1595</sup> The ketones examined included heterocyclic, aralkyl,  $\beta$ -keto esters,  $\beta$ -keto acids,<sup>1596</sup> and so on.<sup>1583</sup> Much effort has been put into finding optically active reducing agents that will produce one enantiomer of the alcohol enantioselectively.<sup>1597</sup> Each reagent tends to show a specificity for certain types of ketones.<sup>1598</sup> Good enantioselectivity is usually obtained with the proper reagent.<sup>1599</sup> Substituents that are remote to the carbonyl group can play a role in facial selectivity of the reduction.<sup>1600</sup> Asymmetric reduction has been accomplished using bioreagents such as enzymes: see item 10 in the list above.
